Conjugation and the periodic system of the elements

P P Shorygin, K Ya Burshtein
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The knowledge of the characteristics and mechanisms of the interaction of the active centres of complex molecules is of primary importance for the development of theoretical and applied organic chemistry, promotes a more productive utilisation of the enormous amount of experimental data available, facilitates predictions and the search for new routes to and new varieties of the synthesis, industrial technology, and applications of organic compounds, and leads to more complete ideas about their functions in chemical, physical, and physiological processes. The studies in this field have been subjected to a critical survey and attention has been drawn to the possibility of distinguishing different forms of the mutual influence of atomic groups, the establishment of correlations between different parameters of conjugation and of the role of relativistic effects, the characteristics of conjugation systems incorporating heteroatoms from different groups in the Periodic System, and the study of the evolution of excited molecules.

The bibliography includes 188 references.

I. Introduction

The properties and parameters of complex molecules made up of isotypical atomic groups are largely associated with the entire set of these groups; in the presence of heterogeneous fragments, a more or less marked relationship with individual fragments can be noted (examples: the colour of compounds with some kind of chromophoric centre; quasi-local vibration modes of the atoms; the dipole moment of a molecule containing a highly polar group). The application of mathematical methods makes it possible to obtain more detailed information (for example, the conversion of normal vibration frequencies of atoms into the force constants of individual chemical bonds) and leads to data for the distribution of electron density among the atoms, the interatomic distances, the structures of individual molecular orbitals having a bearing on the physical or chemical processes investigated, etc.

The more or less "local" characteristics of atomic groups or bonds obtained directly from experiment or by calculation make it possible to compare isotypical groups in various molecules. Slight variations in the corresponding parameters are usually attributed to the influence of adjacent and non-adjacent molecular fragments. Knowledge of the characteristic features of the mutual influence of atomic groups, to which the specific features of the physical and chemical properties of polyatomic (complex) molecules are in some way related, greatly expands the information afforded by the usual structural formulae and constitutes the most important problem in theoretical organic chemistry. However, one should note that the idea of mutual influence is based on comparisons with a selected initial basis, usually with a set of simpler molecules, simulating the fragments of a complex molecule, or with the classical structural formula. When there is an appreciable discrepancy between the real structures and such formulae, the choice of what one could describe as the "origin of coordinates" proves ambiguous and arbitrary. Difficulties of a similar kind and arbitrary features can arise also in other problems, for example, in the selection of a system of independent natural coordinates in the description of the force field (especially in cyclic molecules).

In order to expand and deepen our knowledge in the field under consideration, the constants and functions characterising reactivity (the Hammett, Taft, etc. constants), thermochemical properties, geometrical and electronic structures, the systems of electronic excitation levels, the force field in deformed molecules, optical and magnetic properties, various forms of relaxation, and biological activity have been resorted to. Computational quantum-chemical methods are being employed to an increasing extent. With their aid, it is possible to characterise the coordinates of chemical reactions and the transition states, to construct three-demensional electron density diagrams, to calculate (or if necessary to predict) the spectra of compounds of light and heavy elements, including electronic absorption spectra with identification of valence and Rydberg transitions, to assign the lines (bands) in the spectra and thus impart to them a much greater information content,[1–4] and to estimate the contribution of relativistic effects.[5,6] The latter are important for the chemical and phyiscal properties of molecules incorporating the atoms of heavy elements; it is sufficient to say that their contribution to the energy of the chemical bond reaches 50% in some cases.

Procedures for the productive employment of new physical methods for the investigation of molecular structures have been developed in the recent period. The electron-transmission spectroscopic technique[7,8] has been improved,[7–8] the use of

synchrotron emission has made absorption spectra in the range 1000–2000 Å accessible, and the technical possibilities of resonance Raman spectroscopy have been greatly expanded (the method has been extended to virtually all classes of organic compounds by employing excitations up to 1400 Å, the employment of recording times approaching the femtosecond range, and the measurement of spectra of microobjects, for example a *single* bacterium; the recording of the transformation of light by a single atom of molecule has been an outstanding achievement). Nuclear quadrupole resonance and binary (e, $2e$) spectroscopic data as well as non-linear optical methods have attracted attention. The formation of images of individual molecules with the aid of a scanning tunnel microscope has become realistic. The employment of light pulses with femtosecond durations (10^{-14}–10^{-15} s) has opened up new horizons; the determination of the characteristics of a chemical reaction of a molecule in a detailed time scan, eventually reflecting the evolution of the transition state and the possible rapid oscillations of the system within the limits of the coherence time ("femtochemistry",[9] reaction "vector dynamics",[10] attempts to analyse the photodissociation of a molecule by examining the dynamics of wave packets[11]) has become feasible.

Experimental and theoretical studies on numerous organic compounds have demonstrated the complexity of the entire pattern of intramolecular interactions. Here it is sufficient to draw attention to the multiplicity of (1) types of alternation of chemical bonds and heteroatoms in the chain, (2) three-dimensional forms of conjugated π-systems (quasi-linear systems—poly-ynes; two-dimensional systems—polyacenes, polyenes; three-dimensional, including spherical, systems—footballene), (3) couplings between different degrees of freedom, (4) degrees of stability (stable, and bistable, multistable, dynamic, unstable, non-rigid, and hypothetical systems), and (5) different versions of quantum states of the molecule.

The endeavour to make the enormous virtually non-encompassable accumulated data more readily available for practical use has led to numerous attempts to establish some kind of simple correlations between different properties of the molecule, on the one hand, and in series of structurally similar compounds, on the other (see, for example, Chau and McDowell[12] and Sacher[13]). The proposed relations with empirically selected constants are far from universal and have limited cognitive value; nevertheless many of them are extremely useful in practice.

The interaction between the active centres of a complex molecule† is reflected in one way or another in the energy and structure of the molecular orbitals, favouring their delocalisation, in the orders of chemical bonds and in the interatomic distances (promoting in most cases a certain degree of smoothing of the alternation), in the distribution of electron density, in the electronic and vibrational excitation energies, and in the possibilities of the evolution of the state of the system. These features can be greatly modified following the application of an external field as a result of association and solvation.

Henceforth, certain problems of conjugation and, in a broader sense, of the coupling between the active centres will be described in the text (see Sections II–IV and also Maier et al.[14] and Cook et al.[15]). Controversial problems, the limitations of the models employed, and contradictions in the estimates of the mutual influence of atomic groups will not be ignored.

II. Coupling between the active centres of a complex molecule

The distribution of electron density (the distribution of excitation energy in other problems) in a polyatomic molecule, for example, in a molecule involving a simple π–π conjugation system, can be in principle determined as a characteristic of the "stationary state". However, in the case of molecules, complexes, or ions incorporating weakly bound active centres, for example, a conjugation system of the π–σ–π type, one cannot rule out the practical possibility of recording the evolution of the state of individual centres, for example, oscillations in electron density or beats in the populations of the orbitals of fragments, provided that the vibration period is greater than 10^{-14} s [9,16] (see Section III). Whether or not a weak or strong coupling is produced between the subsystems depends on the molecular structure; the principal trend is towards a weakening of the interaction with increase in the distance between the centres R and in the number of intermediate units.

Compounds with a very *weak* but stable coupling between the active centres, including conjugation systems of the π–σ–π type or others, are of exceptional interest in connection with problems of biophysics and of the functions of biological systems. On the other hand, fundamentally new possibilities arise here for the use of molecules as systems susceptible to reproduction, regulation, and control by changes in the state of atomic groups as a function of time. Nowadays the study of these problems has been acquiring increasing importance. An active search is being prosecuted for new molecular structures which enable one molecule to perform the functions of a specific element or block in microprocessor ("submicroprocessor") technology—memory, logic, signal amplification, etc. functions;[17–19] an exceptionally high "packing density" and a greatly increased speed of operation can be achieved, in principle, in this way.

Polyconjugated π–π systems with a very strong coupling between the subsystems are closer to the other limiting case and have aroused special interest as a possible basis for the preparation of organic semiconductors, superconductors, and materials in which migrating excitation zones of various types, described as wave packets, can be created. They are suitable for the solution of certain technical problems, including the creation of systems for the transformation of information.

It would perhaps not be an exaggeration to say that the majority of other organic compounds belong to systems of an intermediate type. The entire wide variety of different kinds of coupling between the active centres can be seen in such compounds and the mechanisms of their functioning can be investigated.

The coupling between the electron clouds of adjacent or close atomic groups can be characterised in a fairly convenient form within the framework of ideas about stationary states: in asymmetric molecules, in terms of the degree of delocalisation of the molecular orbitals formed from the orbitals of the fragments and in terms of their displacements on the energy scale; in symmetrical molecules, in terms of the splitting of the molecular orbitals, reaching frequently 2–4 eV. In any case, it is useful to determine the matrix elements of the operator V of the excitation energy associated with the interaction between the orbitals a and b, i.e. $V_{ab} = \langle \varphi_a | V | \varphi_b \rangle$, where φ are electronic wave functions.

† Depending on the way in which the molecule is acted upon, different fragments can become the active zone or the reaction centre. The term "active centre" has the designation of a more or less local subsystem and therefore a conventional significance; in optical studies, the chromophoric group is usually implied.

However, these matrix elements cannot alone serve as a characteristic of the degree of mixing of the orbitals of the fragments (cf. Traven' and Stepanov[20]) or of the displacement of the molecular orbitals on the energy scale (ΔE), because data for the energy gap ΔE_0 between the initial orbitals are also necessary. We do not refer to the fact that in most cases one cannot make do with the "two level" approximations and data for only one element of the matrix $||V_{ab}||$; however, fairly simple relation (see Baidin et al.,[21] etc.)

$$\Delta E = 0.5\left[\sqrt{4V_{ab}^2 + \Delta E_0^2} - \Delta E_0\right],$$

should be used whenever possible. It is represented graphically in Fig. 1.

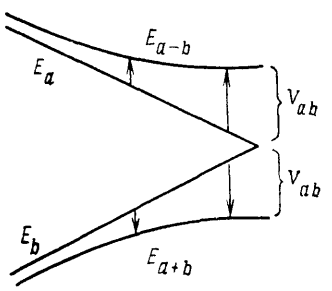

Figure 1. The shifts of the orbitals *a* and *b* on the energy scale induced by their interaction and the formation of orbitals of a mixed type with different initial splittings ($E_a - E_b$) but with a constant value of V_{ab}; the vertical arrows denote the shifts for two arbitrarily selected values of $E_a - E_b$.

Together with the molecular orbital energies, one can use also the set of ionisation potentials. The difference between these two variants is in most cases small and is determined by the contribution arising from the adaptation of the molecule to new conditions created as a result of the abstraction of an electron. The latter takes place very rapidly, approximately in 10^{-15} s, while the subsequent rearrangement of the molecule is slower and in principle one cannot rule out macroscopic time scales (the complete relaxation after a chemical reaction has taken place also requires a fairly appreciable time). In describing complex systems and processes to which correspond slight changes in electron density, it is more convenient to begin with molecular orbital energy data; otherwise, for example in the study of ionisation, it is best to resort to ionisation potentials and electron affinities (or to data derived from molecular orbital calculations with a parametrisation selected on the basis of photoelectron spectra[20]). There is no point in treating these variants as opposed procedures, since they are more likely to supplement one another.

If one is dealing with a coupling between remote active centres of the molecule, it is no longer possible to use the above criteria; in fact a splitting of the molecular orbital in terms of energy less than 0.1 eV is hardly susceptible to observation. However, under these conditions one still cannot rule out the possibility of the complete delocalisation of the molecular orbitals. On the other hand, among the manifestations of conjugation in different molecular properties, including reactivity, there may be some more sensitive to the interaction and even small differences in the structure of the interface can then prove of practical importance. As an example, one may refer to experiments[22] in which it has been shown that an increase in the number of units in the intervening polymethylene chain from 6 to 8 altered sharply the direction of a chemical reaction.

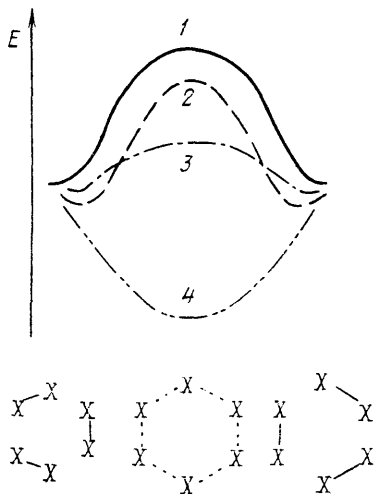
As regards the coupling between the vibrations of *atoms* in the subsystems under consideration, it is manifested by the establishment of delocalised modes and in the absence of interference can be readily observed in symmetrical molecules from the splitting of frequencies, which is associated, roughly speaking, with the rigidity of the entire intervening subsystem. The delocalisation of the vibrational modes has no direct bearing on the delocalisation of molecular orbitals and conjugation, which is unfortunately not always recognised (see, for example, Randhawa and Suri[23]); however, the contribution of non-diagonal force coeffcients has a bearing on the electronic interactions between different chemical bonds, manifested in the atomic vibration process.[24]

III. Comments on the mechanism of intramolecular interaction. What is the inductive effect?

The desirability of distinguishing different types of "electronic effects" (conjugation, the inductive effect, steric hindrance, etc.) and of the representation of their essential features has on the whole been evaluated in different ways in the literature; it has been noted that one is dealing not with physical phenomena but with a transition in describing the electronic structure of a molecule from the zeroth approximation to higher approximations. However, one should not go to extremes; the change in conditions in an intramolecular interaction and the appearance of definite specific features in properties, for example as a result of a transition from non-planar to planar diene systems, is entirely real. Avoiding the rather inappropriate but frequently resorted to references to "the delocalisation of electrons",[25–28] one can nevertheless speak of delocalisation of the molecular orbitals of conjugated systems. The presence of such molecular orbitals affects in one way or another the experimental data (see, however, the comments by Streitweiser and Vorpagel[29] and also Dewar[30] and Shaik et al.[31]). Speaking of conjugation, we have in mind the set of its manifestations in different properties of molecules, based on the overlap and mixing of the orbitals of the interacting fragments with a concomitant change in the orbital energies.[32] Deviations from a simple additive scheme, in which the property of a complex molecule is defined as the sum of the contributions of its fragments, are to some extent associated with conjugation. However, the specific features of the property or parameter investigated are then of primary importance and questions concerning "non-additivity" and its origin must be resolved separately for each property (see Section IV).

Among the possible manifestations of conjugation in chains with an alternation of chemical bond orders, for example, in polyenes and poly-ynes, one should mention the more or less pronounced smoothing of the differences in the alternating bond orders, lengths, and rigidities (it is frequently referred to as "delocalisation of bonds", which is in essence equivalent to "delocalisation of valence characteristics"). The set of distibine, diarsine, and certain others can serve as new interesting examples.[33,34] In such cases the

disposition of the Z–Z σ-bonds of a certain number of identical molecules on a single straight line favours the formation of delocalised orbitals, incorporating the entire chain of heteroatoms, or one may say the "conjugation of the σ-bonds of adjacent molecules". The molecules of diphosphine H_2P-PH_2 hardly interact with one another under such conditions (this is indicated by the symbol P–P P–P P–P). A very weak interaction with an insignificant smoothing of the bond alternation has been noted in diarsine (...As–As...As–As...); the molecules virtually retain their individuality, although, strictly speaking, delocalised orbitals must be used to describe the entire chain. The bonds between distibine molecules are more distinct; the large bathochromic shift of the absorption bands, which vanishes when the ordered arrangement of the molecules is lost, i.e. on breakdown of the conjugation chain, is striking.



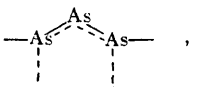


Figure 2. The energy of cyclic systems X_6. The extreme points of the curves on the right and on the left correspond to sets of three molecules X_2 (D_{3h} symmetry). Those in the middle correspond to systems in which all six X–X bonds are the same (D_{6h} symmetry). The H_6 system corresponds to curve *1*,[31] the benzene molecule corresponds to curve *4*,[31] molecules with only slight smoothing of bond alternation correspond to curve *2*, and the example of a structurally modulated (dynamic) system corresponds to curve *3*.

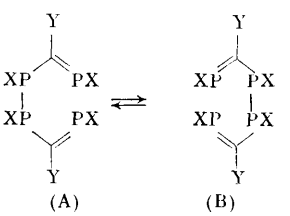
While there is an appreciable similarity in the manifestation of conjugation in distibines and poly-ynes, the forms of the bonds *between the fragments* of these structures differ greatly: in the former case, the overlap of the p_x orbitals of Sb, oriented along the chain, plays the main role, while in the latter case the main role is assumed by the overlap of the p_y and p_z orbitals oriented at right angles to the chain. In the first case, there is no rigid σ-skeleton ensuring the stability of the geometry and integrity of the system.

An almost complete equalisation of the bonds between the heteroatoms has been noted in dibismuthines (...Bi...Bi...Bi...Bi...).[34]

A symmetrical system, resembling the π-allyl system, i.e.



has been described.[35]

It is believed[31] that the equalisation of the carbon–carbon bonds in benzene is due to the σ-skeleton and that the π-subsystem is more likely to counteract this, the π-delocalisation being regarded merely as a concomitant factor. This interpretation is not convincing, but comparison of the six-membered C_6H_6 and X_6 systems is very appropriate. According to calculations,[31] the resonance energy in the H_6 system is insufficient to compensate for the energy expended on the deformation of the bonds and for the conversion of three H_2 molecules into the delocalised form H_6. However, in the Li_6 and C_6H_6 systems the energy is entirely sufficient (Fig. 2, curves *1* and *4*).

The smoothing of the bond alternation in the chain and certain other aspects of conjugation are frequently described[36] with the aid of a combination of resonance structures (to each of which the significance of a solution of the Schrödinger equation is attributed without due justification[37]); the use for this purpose of the symbolism of valence characteristics is unjustified, since one is dealing with the representation of wave functions and not their squares. The resonance structures do not by themselves provide an idea about the conjugation energy (and in general whether or not the proposed structures are suitable), the properties of molecules associated with the delocalisation of molecular orbitals, and the principal features of conjugation in chains of σ-bonds, for which intraatomic exchange integrals, etc. are important; the traditional description of the electronic structure of conjugated systems, for example, amides is not very satisfactory (see Sections VI, IX, and X), while in a more complete description one loses compactness (thus the description of one of the compounds mentioned in Section I requires the representation of more than 12000 (Kekulé structures). In any case, the data on the set of molecular orbitals provide much greater possibilities.

Among molecular systems with different forms of the potential, including those with two or several potential energy minima, it is easy to find examples of a high stability of *one* form, systems which readily isomerise (rearrange), structurally modulated (dynamic) rapidly oscillating systems, and, finally, "mesomeric" systems, where there is no justification for attributing their principal features to "oscillations". An interesting example[38] of a structurally modulated (dynamic) system can be represented by the following scheme:

On rapid oscillation (A)⇌(B) and for a relatively long recording time (τ_{rec}), we are able to observe a six-membered ring which is to a large extent equalised and in the absence of other information we can describe the system in terms of two resonance structures of types (A) and (B), which in a certain sense resemble Kekulé structures.

However, for a short τ_{rec} either structure (A) or (B) might be observed, which implies some similarity with the systems represented by curve *3* in Fig. 2.

The separation of the different forms of intramolecular interaction mentioned at the beginning of the Section is fairly problematical. These forms and simple summation of their contributions correspond to a fairly rough approximation. Thus the differentiation of the contribution by the inductive effect to the experimentally determined Hammett constants implies in essence a transition from reality to some kind of convention. Such a transition is justified if it facilitates to some extent the prediction of quantities (which are in principle observable); however, successes of this kind are fairly modest. The situation is complicated by the multiplicity of different versions of the interpretation of the very concept of the "inductive effect". This effect has been considered[39] as competition between acceptor ligands adjoining the atom, while in other studies[15,40–44] it has been regarded as the influence of a polar group on the σ-skeleton of the molecule, as a result of a change in the hybridisation of the atomic orbitals or of the involvement of unoccupied orbitals, etc. Some workers have calculated separately the contributions of the effects of the field of the polar group and of the inductive effect, while others assume that the latter in fact consists in the effect of the field; the use of this concept to account for the polarity of diatomic molecules has also not been ruled out. Such large discrepancies have created disadvantages but they can also have a humorous aspect.

In most studies the term "inductive effect" is understood as the polarisation of a molecular fragment induced by the static field of excess charges (+) or (–) on the atoms of other fragments, such polarisation not involving a redistribution of electron density between bonds[45] (cf. Cook et al.[15]); the latter is usually attributed to the donor–acceptor interaction as one of the aspects of conjugation with participation of unoccupied orbitals of the acceptor. Since in fact electron systems assigned to individual chemical bonds are not autonomous, the distinction between ideas concerning the distribution of electron density within the limits of bonds and between bonds can have no physical justification (see Section XI). The very differentiation of fragments and the corresponding part of the electron cloud (as well as the "electro-optical parameters" of chemical bonds) is fairly arbitrary. Thus the demarcation of conjugation and of the inductive effect is ambiguous and its possibilities should not be overestimated. It is not fortuitous that estimates of their relative roles based on the use of different criteria or schemes diverge appreciably. Thus the contribution of the inductive effect for nitrobenzene varies from zero to 100% according to the conclusions reached by different workers:[21,46–48]

The differentiation of the inductive effect has been of some interest as a route to the estimation of electron density from the form of the structural formula. Such estimates correspond to reality to some extent in certain simple molecules including a highly polar bond such as AlkF and AlkLi, but here too the involvement of hydrogen atoms and specific features of the cartesian component of the polarisability complicates the picture. In any case, the model with point charges on atoms and charge redistribution "along chemical bonds"[49] is clearly inadequate. As regards quantum-chemical calculations (see, for example, Topsom[50] and Shatkovskaya and Gineitite,[51] the latter yield more complete information but this is also by no means free of the influence of subjective factors associated with the choice of the method of separation. Under these conditions, the calculation of the resultant electron density on atoms without separating the contributions of the inductive effect on conjugation is entirely appropriate for the solution of the majority of problems without attributing great importance to the numerical estimates of these contributions obtained in different ways[21,44,52] (they have been frequently quoted with four significant figures), one can nevertheless assume that their qualitative comparisons are useful, particularly since they can differ sharply in terms of their conformational dependence (the orientation of specific orbitals is important for conjugation, while the orientation of the dipole is important for the inductive effect). However, judging from estimates,[52] the non-additivity of the influence of the effects considered can play a dominant role; if this is so, then the entire separation scheme is unjustified.

According to certain experimental and computational quantum-chemical data,[45,50–52] the influence of the inductive effect should diminish rapidly along the chain of C–C σ-bonds and more slowly along the chain of π-bonds. It is believed that the influence of conjugation diminishes more slowly (see the examples in Section X). However, one should not speak of conjugation "in general"—its different aspects (different manifestations) respond in different ways; thus one of the principal aspects is that the delocalisation of the molecular orbitals describing two identical active centres in a symmetrical molecule does not weaken at all with increase in the number of intermediate units, but its sensitivity to disturbances in molecular symmetry increases, while the conjugation energy actually diminishes rapidly. Examples of large differences between the coefficients of the transmission of influences on different parameters referring to the CHO group can be found in the paper of Yanovskaya et al.[52]

As the mechanism of the mutual influence of atomic groups was specified in further detail, the contributions of different channels leading to the interaction—through the intervening atoms or chemical bonds and through space—were considered.[53] The mixing of the electron wave functions of the above groups and the formation of delocalised molecular orbitals is possible as a result of the participation of the orbitals of the intervening bonds (an example is provided by the *n*,*n*-conjugation due to the slight involvement of the N–N σ orbital in the *trans*-conformer of hydrazine) or certain atomic orbitals of the intervening atoms (not necessarily the atomic orbitals which form the chemical bonds linking the active centres). Another channel is determined by the direct overlap of the orbitals of the active centres through space (for example, the overlap of two π orbitals in norbornadiene or the *n* orbitals in *cis*-hydrazine[54–56]). It is self-evident that the different forms of combination of these channels (leading to their enhancement or, on the contrary, to their weakening and even the disappearance of the observed signs of interaction) can be by no means ruled out (see Section XI).

The interaction between atoms or atomic groups of a complex molecule *through space* (TS) can be regarded, depending on how strong it is and what are the overlap populations of their orbitals, as an insignificant addition to the information yielded by classical structural formula, as a very weak chemical bond, or as a more important aspect of electronic structure which merits being reflected in the structural formula. Interaction through space is favoured by the diffuseness of atomic orbitals;[57] with increase in the distance between the centres, it diminishes faster than the interaction through the intervening subsystem. We have encountered this in the study of suitable conformers of non-rigid molecules as well as cyclic rigid structures in which the active centres approach one another in space (see Sections VII, VIII, X, and XI).

In this connection, the problem of the coupling between the active centres of molecules in close proximity has acquired great interest.[50,58] According to calculations,[59] the introduction of

extraneous molecules into the intervening region of space between two initial molecules (for a fixed distance R between them) promotes mixing, i.e. the delocalisation of orbitals within the limits of the entire system. One may add that the rate of electron transfer between the active centres of the molecule diminishes with increase in R, while the length of the intervening chain increases more slowly than the rate of transfer between two individual molecules.[60–62]

The question of the channel through which the influence of the inductive effect is transmitted[45] has been considered as a dilemma in which two variants are set in opposition (deliberate paraphrasing—the influence "through chemical bonds formed by intervening atoms" or "through space in which these atoms are located"). However, in reality, the atoms of a bridging group, side chains, the solvation shell, etc. are not always located in the particular part of the intervening space or near it. They influence in one way or another the strength of the field acting on the given object. Under these conditions, the presence of a continuous chain of intervening chemical bonds affects the "packing density", which is not by itself a decisive or essential apsect of the situation; among other things, one may mention that the polarisability of the butane molecule differs little from the polarisability of two ethane molecules and is described satisfactorily by the sum of atomic increments or, just as well, by the sum of bond increments. Under these conditions, the second variant (of the two quoted above in brackets) is less specific but more correct. It is not associated with limitations characteristic of the simple form of the LCBO (linear combination of bond orders) and the limitations in the multiplicity of the structures (cases) which actually exist.

In the estimation of the active field in practical studies, the intervening subsystem ("black box") was characterised by dielectric constants ε_{eff}; the values of ε_{eff} in the range from 1 to ∞(!) have been selected in different studies.[41,43,45,63] The arbitrary nature of the estimates of ε_{eff} naturally made the results worthless and made it evidently desirable to go over from macroscopic to "microscopic" characteristics and calculations at the LCAO level. We no longer speak of the inadmissibility (see Houk et al.[41] and many other studies) of the usual formula defining the Coulombic interaction between charges immersed in a medium for a model with an "intervening" medium (when the possibility of the intensification of the active field is not ruled out!).

A bridging group determines to some extent the distribution in space of the active centres and together with the latter can participate in the formation of delocalised molecular orbitals; the extent to which the subsystems are linked to one another and the possibility of the evolution of their state (the rate of energy or electron density transfer‡, the rate of even the direction of the chemical reaction) depend on its structure.

The possibility of an intramolecular energy transfer is associated with the overlap of parts of the emission spectrum of the emitter (excited chromophoric group) and the absorption spectrum of the receptor. The contribution of Forster's dipole mechanism then diminishes in proportion to R^{-6} and can be manifested for fairly long distances R between the π-subsystems (10–50 Å and more). The rate of energy transfer via Dexter's exchange mechanism, involving the overlap of the wave functions of the subsystem, diminshes exponentially and becomes insignificant for $R > 6$ Å; however, the participation of the σ-bonds of the intervening chain (for example, a polymethylene chain) in the $\pi-\sigma-\pi$ system can, according to some investigators,[59,60,62] alter the situation and enhance the role of the exchange mechanism. The rate of energy transfer $K_{en}(R)$ then diminishes with increase in R faster than the rate of electron transfer§ $K_{el}(R)$; in a series of studies[60–62] on compounds with $\pi_1-\sigma-\pi_2$ systems having different numbers of intervening units, $K_{en}(R)$ was found to be proportional to $K^2_{el}(R)$ and $K_{el} = 2.5 \times 10^{15}\ e^{-m}$, where m is the number of C–C σ-bonds in the intervening chain. Energy transfer along the receptor–polyene subsystem–emitter system has been considered by Maier et al.,[14] while the mechanism of the energy transfer as a result of the exchange of virtual photons (which is described by the non-diagonal elements of the decay matrix) has been examined by Morozov and Shorygin.[64]

We confined ourselves to brief remarks about the principal types of intramolecular interaction of atomic groups. Since even these principal forms are not clearly differentiated, it did not appear necessary (despite the inspiring terminology) to consider the numerous existing variants—homohyperconjugation and supra-annular, inductoelectromeric, and other effects.[56]

IV. Are correlations between different conjugation parameters possible?

The set of manifestations of conjugation in different properties of molecules includes numerous and varied parameters and naturally cannot be characterised by any one figure (provided that one does not postulate, contrary to facts, the existence of unambiguous correlations between all the properties investigated). The above parameters are by no means determined by identical factors. For example, the delocalisation of orbitals and the accompanying phenomena are favoured by the *similarity* in the disposition of the orbitals of the fragments on the energy scale, while the redistribution of electron density is favoured by *differences* between the latter.

One may refer to examples of complex molecules in which the deviations from additivity in some properties are clearly pronounced, while in others they are absent and also to systems in which the opposite picture is observed. Examples of compounds, similar to benzamide, in which an anomalously large dipole moment is associated with the preferential conjugation of the carbonyl group with one subsystem (NH_2) while the long-wavelength UV absorption is associated with its conjugation with another system (Ph), are no less instructive. Furthermore, it is seen from experimental data that the π-donors and π-acceptors in aromatic compounds influence the electron density in the benzene ring, the reactivity characterised by the Hammett constants σ_{para}, and also the ionisation potentials P_1 in opposite directions, but their influence on a number of optical properties[65] (the positions of the benzene UV absorption bands, the electron polarisability, the intensities of many Raman lines) and certain geometrical parameters of the molecule is in the same direction. Yet another aspect may be noted by referring to the compound $I-\Phi-NO_2$, where iodine is a π-donor and influences the optical properties like other π-donors, but its influence on the

‡ We have in mind the rate of change of the probability of recording the transfer and not the characteristic of the time scan of the process.

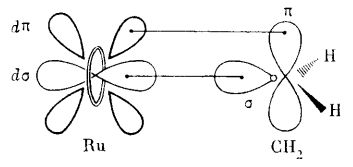
§ The energy and electron density transfer processes, which can be regarded as transitions between quasi-degenerate states of the entire system should not generally speaking, be contrasted. Depending on the structure of the orbitals of the subsystems and their initial state, these processes can differ sharply or can be of a mixed character; here it is appropriate to mention the electronic transitions with "charge transfer" or with "elements of charge transfer".

frequency of the nitro-group $\omega(NO_2)$ (on the dissociation constant in *p*-iodobenzoic acid) is more like that of an acceptor¶ (see also Sections VII, IX, and X).

In practice we have an exceptionally wide range of variants and a complex picture of interactions between subsystems and relations between different manifestations of non-additivity. However, these relationships are susceptible to analysis and can be adequately explained by studying the modification of molecular orbitals induced by the influence of substituents, in particular, their delocalisation and the changes in their energy and involvement in the redistribution of electron density.

The differences between the influences of intramolecular interaction on different properties of molecules have frequently led to contradictory conclusions and in some studies have served as a basis for conclusions concerning the suitability or unsuitability of particular parameters for the quantitative estimations of conjugation; such conclusions are based on a subjective choice of the criterion used as a reference standard or as a "measure of the conjugation effect" (according to Randhawa and Suri[23] as the "percentage resonance"!). In this connection, one may say that the majority of parameters are associated with the response of the molecule to external influences and characterise the possibility or probability of a particular transformation or transition to a new state, which occurs, for example, as a result of a chemical reaction or as a result of the application of the measuring procedure itself. The final state of the molecule is then specific to the observed process and possibly the conditions under which it takes place. The correlations between the parameters characterising the transitions to different final states would imply also correlations between the latter, which is fortuitous rather than the rule.

Nevertheless, it is possible to identify certain groups of parameters which are related to a greater or lesser extent. For example, the relation between certain optical properties of molecules can be established on the basis of known physical laws and is entirely explicable. However, even in this case the picture is not simple. It is determined by the involvement of a large number of electronic excitation levels of the molecule. Both low-lying and high-lying excitation levels, including those which determine the absorption spectrum in the range 500–1000 Å, then contribute to the static polarisability of the molecule. The long-wavelength part of the absorption spectrum, including the near UV region (2000–4000 Å) is somewhat more important for the refractive index of visible light; the longest-wavelength intense absorption zone or band has a major or even decisive importance for the dispersion of the refractive index and even more so for the intensity of Raman lines (especially for overtones).[66]



There is some chance of success in the search for correlations when different properties are considered in some specific electronic state of the molecule, for example, in the ground (unexcited) state. However, correlations with reactivity, which depends significantly on the presence of conjugation and its influence on the energy of the system in the transition and final states, are of greatest interest. The question what are the interrelations between the set of σ_{para} constants of the substituents X and the physicochemical characteristics of the compounds Y–Φ–X, for example R_2N–Φ–X, has been frequently dealt with in the literature. However, it is incorrect to formulate the question in this way. It is more logical to ask what are the correlations between the, by no means identical, sets of constants obtained from the corresponding types of initial data; it is even more appropriate to elucidate what relations exist between different kinds of initial data themselves (for example, between the basicity constants and the spectra). The establishment of certain relations of this kind would be extremely useful, but we are nevertheless faced by a complex set of conjugation parameters. Which of them will be usefully considered or adopted as the cornerstone depends on the aims of the investigator and perhaps on the ways in which he thinks.

¶ Here and henceforth the following notation is used: R = methyl group, Vy = vinyl group, All = allyl group, Φ = *para*-phenylene fragment, Π = π-bond system, and M = bridging group.

V. Chemical bonds and atomic groups incorporating heteroatoms

Before turning to complex systems, we shall note certain characteristic features of chemical bonds and atomic groups incorporating a heteroatom Z, which may constitute in certain combinations complex structures and conjugation systems. Comparison of the dissociation energies of the Z–Z and also Z–C, Z=C, and Z=Z chemical bonds formed by different atoms Z shows that the energy as a rule decreases on passing to bonds with heavier elements (as a result of the decrease in the overlap integrals of the more diffuse atomic orbitals) and in most cases with decrease in the atomic number of the element Z within the limits of the Period. This applies particularly to the π-component of double bonds. Thus, according to calculations,[67] the C=Al bond energy is smaller by a factor of 2 than the C=B bond energy, while the energy of the π-component (E_π) is correspondingly lower by a factor of 5; in the author's words, E_π for C=Z bonds decreases rapidly with decrease in the electronegativity of Z. According to calculations,[68] it amounts to 65, 35, 31, and 20 kcal mol^{-1} in the series C=C, C=Si, C=Ge, and C=Sn; estimates for the carbon–chromium bond yield a value less than 5 kcal mol^{-1}, so that the use of the double bond symbol is no longer necessary. The total energy ($E_\pi + E_\sigma$) of the C=Z double bond diminishes as Z varies in the sequence $0 \gg N > C > B \gg S > P \gg Ru, Al$.[67–70]

It is significant that the double bonds formed with participation of the atoms Z of different elements are by no means uniform in their nature. For example, whereas the C=Ti bond is described satisfactorily by two localised equivalent orbitals (with an appreciable participation of the 3*d* atomic orbital of titanium), the C=Mn bond represents a set of very different contributions of the σ- and π-components and involves a π-component which is very weak and markedly asymmetric as regards the contributions of the atomic orbitals of the manganese and carbon atoms.[69] According to calculations,[70] the $\rangle Ru=C\langle$ bond is covalent and is formed from 4*d* atomic orbitals of ruthenium:

The fragments must be arranged not as in ethylene but in mutually perpendicular planes. Judging from the arguments put forward by Zilm et al.,[71] the Sn=Sn bond can be regarded preferably as a mutually-dative linkage; the unoccupied *p* orbital of the adjoining atom participates in each of the two contributions to this bond.

In general, double bonds with participation of a heteroatom Z in most cases bear little resemblance to the C=C bond; in conformity with their specific features, the manifestations of conjugation with adjoining fragments can differ greatly (see Section VI).

The available data suitable for a comprehensive characterisation of simple compounds ZR_m and their Z–C bonds are compiled in Table 1. These compounds imitate in a certain sense the fragments of complex conjugate systems incorporating groups of the type ZR_n. Each box in Table 1 indicates the heteroatom Z and its valence state if it is not the usual one; the following data are presented in the form of a column or two columns: (1) the vertical ionisation potential (eV) (the first of those corresponding to the Z–C bonds);[39,72–77] (2) the force constant of the Z–C bond (mdyn $Å^{-1}$) (indicated in bold type);[78–84] (3) the electronegativity of the $-ZR_n$ group;[85,86] (4) the *average* Z–R bond dissociation energy (kcal mol^{-1}).[87–89] In the second column we have (1) the electron affinity of the ZR_m molecule (eV) [90–92] and (2) the intense long-wavelength UV absorption band (in most cases the $\sigma \rightarrow \sigma^*$ band; gas phase, nm).[73,93–100] Approximate estimates based on analogies and comparisons with molecules having similar structures are indicated in brackets. The arrangement of the data in Table 1 was dictated by the need for compactness.

The principal trends noted when compounds ZR_m are compared are as follows: as Z varies across the Periodic System from right to left and from above downwards, the force constant K(Z–C) and the ionisation potential decrease; the electronic polarisability per Z–C bond increases; there is a sharp increase in the intensity of the Raman lines[32,66] and the Z → C electron density shift becomes more pronounced (in LiR, it corresponds to a transfer of a charge amounting to ~0.6 e); the electronic excitation energy decreases, at least within the limits of a particular Group in the Periodic System (comparisons along Periods are difficult because of the lack of uniformity as regards symmetry types and the unreliability of the assignments of the absorption bands). Similar trends have been noted also on comparing data for Z–Z bonds as well as Z=C and Z=Z bonds. However, all the foregoing features cannot be fully extended to compounds of the heaviest elements such as Au, Pt, and Hg, which is associated to a large extent with the contribution of relativistic effects and the corresponding contraction of the valence shells.

We have presented data for molecules with fairly simple structures. One may note that *almost any increase in the complexity* of the molecule (attachment of additional atomic groups) *reduces* the electronic excitation energy and in many cases (excluding the addition of active acceptors) also the ionisation potential. Naturally, in individual instances the appearance of steric hindrance can lead to the breakdown of conjugation as a result of a change in conformation, but one cannot rule out also the converse possibility where the real conformation which is relatively unfavourable for conjugation (say in hydrazine) is converted into a more favourable conformation as the structure becomes more complex or when the bond angles are greatly distorted (for example, in cubene compared with alkenes).

The assignment of molecules of the type ZR_m to the class of comparatively simple ones does not imply that they do not exhibit the non-additivity and mutual influence of fragments. In relation to the $H_3C-Zn-CH_3$ molecule, one may note an appreciable splitting (~2.2 eV) of the delocalised σ molecular orbitals of the Zn–C bonds, the non-zero value of the non-diagonal Zn–C/Zn–C force coefficient, etc. However, these aspects will not be considered here.

VI. π−π conjugation

The principal types of conjugated systems (π−π, σ−π, *n*−*n*, etc.) and the characteristics of their reactivity were at one time examined in detail.[101] At the present time compounds with conjugated π-bonds have been most thoroughly investigated by physical and chemical methods. Almost all the most important features of the physical, chemical, and technical properties of polyenes, poly-ynes, polyphenylenes, and other similar systems are related directly or indirectly to π−π conjugation; the functions of polyconjugated systems constitute the basis of many most important physiological processes; the photochemical reactions of π-conjugated systems can be seen among chemical processes which occur in the interstellar space, for example, on dust particles.[102,103]

It is know that the C−C central bond in the molecules of butadiene, diacetylene, and dicyanogen is shortened and its rigidity has increased more than might have been expected judging from the C−C bonds in propene, propyne, and acetonitrile; the specific features of the π-bonds are much less marked. According to new data,[104] the alternation of bonds in *trans*-polyenes is slightly smoothed out and to a greater extent in the centre of the chain where the rigidity of the double bonds (compared with the terminal ones) is reduced by 5−10% and the bond lengths are greater by approximately 1%. The changes in interatomic distances as the conformations are varied can be demonstrated in relation to glyoxal, whose conjugation energy (~3 kcal mol^{-1}) is close to that of butadiene. According to calculated data,[105] presented in Fig. 3, in the planar conformers there is a small amount of double bond character in the region of the central C−C bond (which according to R Bader's calculations should be accompanied by the breakdown of axial symmetry, i.e. by some ellipticity of the distribution of electron density). In *gauche*-conformers, all the manifestations of π−π conjugation, including effects in the bond lengths, are reduced to a minimum.

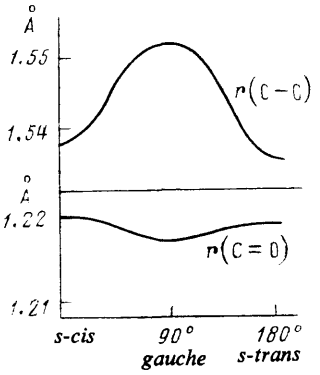

Figure 3. The C−C and C=O bond lengths in the OHC−CHO molecule in different conformations (θ = 180° for the *s-trans*-conformer).[105]

The conditions governing the conjugation of the C=C double bonds with the C=Z and Z=Z bonds can vary within wide limits. The transition for systems incorporating heavy atoms Z should be accompanied by the mutual approach of the frontier orbitals (which in general favours an increase in conjugation energy) and by a tendency towards an increase in the contribution of the C=Z fragment to the long-wavelength region of the electronic absorption spectrum. According to calculations,[106] the conjugation energy in the C=C−C=Ti system should be somewhat greater than in butadiene; in other cases, there is a possibility of its decrease and of the weakening of other manifestations of conjugation, which is partly associated with the contribution of relativistic effects.[57,107]

VII. Does the methylene bridge break the conjugation chain?

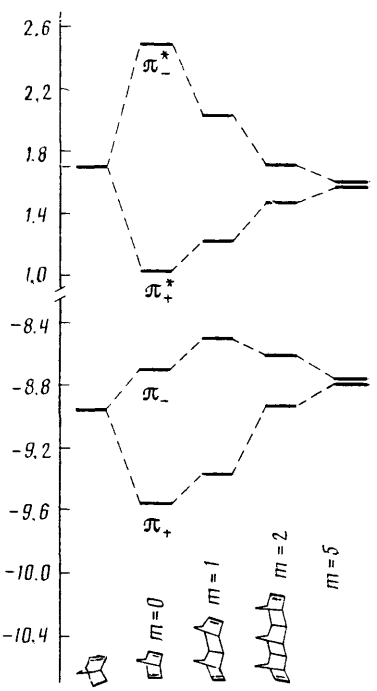
This question has been discussed for a long time in the literature but hitherto contradictory views have been expressed; the interest in this question has increased in connection with new problems, in particular the search for the possibility of creating organic conductors on the basis of polyconjugated systems, for example, polyacetylenes (see Section II). In a recently published study,[108] the authors confirmed the version stating that conjugation and π-electron delocalisation are retained in the presence of a methylene bridge but in another study[109] this version was rejected; semiempirical calculations of the interatomic distances and carbon−carbon bond orders led to the conclusion that in polyacetylenes there is no conjugation of the π-subsystems through the methylene group. A more complete idea about this problem is provided by calculations of the energies and structures of molecular orbitals.[110,111] The reasons for the contradictions are associated partly with the choice of different criteria (see Section IV) and with the differences in terminology. By invoking the delocalisation of π orbitals as the criterion, one must bear in mind that, when the π-subsystems are identical, such delocalisation should, generally speaking, be complete not only in molecules such as those of butadiene but even in the presence of a very weak bond between the subsystems (say between two ethylene molecules separated by a distance of 5−10 Å). However, under the conditions of a weak bond, a slight difference between the structures of the π-subsystems is sufficient to cause a breakdown in delocalisation; furthermore, the defects in the π−π conjugation chain in real polyacetylene specimens are not arranged regularly, the defect-free conjugation zones are not identical and, furthermore, they are not uniform as regards conformations at the locations of bridging groups. The question stated in the heading can therefore be answered in the given instance only by taking into account statistics and, naturally, the specific features of the criteria employed.

We shall consider in greater detail the simplest dienes with a symmetrical structure. Here the π orbitals of two vinyl groups, π_1 and π_2, can be mixed and can form two delocalised molecular orbitals, in one of which π_1 and π_2 are incorporated with the same signs (π_+) while in the other they have different signs (π_-). The energies of the new orbitals differ by Δπ. In the case where the interaction of the π-bonds through space predominates, π_- lies higher on the energy scale than π_+ and, when interactions through a bridge predominate, the opposite arrangement is possible.[54–56] The mixing of the unoccupied π* orbitals leads to a splitting Δπ*, which frequently differs greatly from Δπ. The mechanisms of the mixing (see Section III) of the occupied and unoccupied orbitals may not in fact be the same.

Henceforth in the text the deviations from the Koopmans theorem, the allowance for which in many problems is absolutely essential[56] and merits consideration in a special review, will not be discussed; we shall therefore retain the conventional designations of

the type $\Delta\pi$ and $\Delta\pi^*$ in the analysis of experimental ionisation potentials, etc.

According to experimental data, $\Delta\pi$ = 2.4 eV and $\Delta\pi^*$ = 2.2 eV in the planar *s-trans*-butadiene molecule. The values of $\Delta\pi$ and $\Delta\pi^*$ diminish rapidly in the series of compounds butadiene, penta-1,4-diene, hexa-1,5-diene, etc.; this can also be said about diynes, dinitriles, and diketones. However, in compounds containing a chain of methylene groups $-(CH_2)_n$ there are too many conformational possibilities† and this makes a simple comparison of experimental data relatively unproductive—the conformation is in this instance one of the decisive factors on which depend the degree of overlap of the orbitals of the fragments and the values of $\Delta\pi$ and $\Delta\pi^*$. One can also mention that, for a large chain length, one cannot rule out the possibility of the mutual approach the appreciable interaction of the terminal C=C bonds through space, i.e. the occurrence of a conformation resembling a ring.[112]



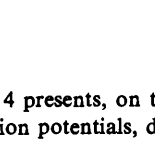


Figure 4. The energies of the π orbitals of type I diene hydrocarbons with an increasing number of intervening C–C σ-bonds.[55]

Fig. 4 presents, on the basis of the data of Balaji et al.,[55] the first ionisation potentials, designated by the indices π_+ and π_-, as well as the electron affinities (indices π_+^* and p_-^*) of symmetrical dienes (I) with a fixed relative orientation of the C=C bonds.

(I)

† The relative distribution of the double bonds in space can be described taking into account six degrees of freedom.

Fig. 4 presents experimental data for compounds with m = 0, 1, and 2, and the results of an approximate extrapolation for compounds with $m > 2$; the extrapolation for m = 7 (16 intervening C–C σ-bonds) yields $\Delta\pi \simeq 0.003$ eV.[55] Such a low value of $\Delta\pi$ is naturally not susceptible to detection by photoelectron spectroscopy, but, under suitable conditions, the possibility of investigating the interaction by other methods is not as yet ruled out. In particular, the study may be based on the rate of the photoinduced electron transfer, which was found to be in the subnano-second range in experiments[113] in the presence of ten intervening C–C bonds and was an order of magnitude lower in the presence of twelve C–C bonds. If the "conductivity" of the interface is still smaller, the transition time may run to seconds, i.e. may correspond to the possibility of clear representations.

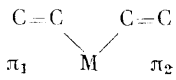
With increase in m and hence in the distance R between the double bonds in dienes (I), the direct overlap of the π orbitals through space (TS) diminishes rapidly. Whereas in norbornadiene (m = 0, R = 2.4 Å) such overlap largely determines the real splitting ($\Delta\pi$ and $\Delta\pi^*$), for m = 1 and R = 4.8 Å it becomes very small and less significant than the interaction through the intervening C–C bonds (TB), which weakens much more slowly—by a factor of 2–3 when m increases by unity.[55]

In connection with these comparisons, one may mention that the influence of the inductive effect of the polar groups on the dissociation constants of carboxylic acids weakens by a factor of 2–3 with increase in the length of the intervening chain by one additional C–C bond,[45] while the induced charges on the C atoms of the alkyl group should diminish along the chain even faster according to calculations.[50,51]

Quantum-chemical studies of $\pi-\sigma-\pi$ systems have shown that the weakening of the interaction with increase in the number of intervening σ-bonds is not an immutable rule; under suitable conditions, one cannot exclude the possibility of the introduction of an additional unit such that the bond between the terminal active centres would be enhanced.

In norbornadiene, the dihedral angle θ between the planes of the two "ethylene" fragments is 116°. In other dienes with a similar structure but with a larger angle θ, the direct overlap of the π orbitals is less marked; in the almost planar cyclohexa-1,4-diene it becomes very small whereas the interaction through bridging groups (TB) is to a large extent retained and thus comes to the fore; accordingly, the π_+ orbital is located higher on the energy scale than the π_- orbital. Signs of non-additivity in the UV and Raman spectra of norbornadiene have been noted.[114]

If the two π-subsystems are arranged at right angles to one another, then, without the involvement of suitable intervening units, we have $\Delta\pi$ = 0; this is the case with the spiropentadiene



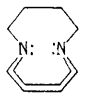
We shall designate such a system by the symbol ||=. Without going into specific structural details, one can say, in principle, that the introduction of an intervening double bond, oriented at a certain angle in such a way that there is a possibility of its interaction with each of the initial bonds (symbol ||⁄=), gives rise to the possibility of the formation of delocalised molecular orbitals with an appreciable energy splitting. A structurally suitable combination of σ-bonds can also serve as an active intervening unit; thus the

involvement of the orbitals of the intervening ring in the tricyclododecatetraene molecule

promotes the mixing of the highest occupied orbitals of the two diene fragments and the splitting of the HOMO reaches 1.5 eV.[115]

The question arises how the bond between the π-subsystems depends on the nature of the bridging group. Some information about this can be drawn from the results of studies on divinyl compounds.[116]

The coupling between the orbitals π_1 and π_2 is determined by the fact that they both overlap simultaneously with a suitable orbital of the bridging group M and thus (even for a very small contribution of the latter) form a conjugation system with delocalised orbitals of the type π_+ and π_- (see above).



The difference between the energies $\Delta\pi$ of the new molecular orbitals is greater the closer is the energy of the orbital of M to that of the $\pi_{1,2}$ orbitals and the greater the overlap population in the M–C bonds. The difference $\Delta\pi$ is a maximum for planar conformers and reaches 3.5 eV for M = C=C, i.e. in the case of hexatriene. In the series of dienes with M=NH, O, CH_2, SiH_2, SnH_2, and $-CH_2-CH_2-$ the quantity $\Delta\pi$ diminishes and approaches zero but the orbital π_+ nevertheless lies higher than π_-, which is consistent with the conditions under which the bond through the bridge predominates (TB > TS). However, when M = CF_2 or CCl_2, the energy of the atomic orbitals of the bridging carbon atom is reduced under the influence of the electronegative ligands and the overlap population in the C–C bond of the C–$CHal_2$–C fragment diminishes appreciably; the conjugation of the π-bonds through the bridge is therefore weakened so much that even their slight interaction through space predominates and the delocalised orbitals π_+ and π_- are arranged on the energy scale in the opposite order characteristic of this type of interaction.[116]

VIII. *n*–*n* and σ–σ conjugation

Turning now to examples of *n*–*n* conjugation, we may note that the interaction of the *n* orbitals of adjoining atoms is unimportant for the formation of a chemical bond between fragments; however, the wave functions of the lone pairs (LP) in the Z–Z systems are mixed and their (+) and (–) combinations are split as regards energy for suitable molecular conformations with the accompanying destabilisation of the highest occupied molecular orbital (HOMO).

The difference (Δn) between the first two ionisation potentials, which corresponds approximately to the splitting of the above combinations of the atomic orbitals forming the two highest occupied orbitals, is illustrated by several examples in Table 2. The data for the first two compounds refer to the *s-trans*-conformations (the angle of rotation θ about the central σ-bond is 180°) corresponding to the maximum splitting; they were obtained on the basis of calculations and using analogies. The table also includes experimental data for the *n* orbitals of the oxygen atoms and certain dicarbonyl compounds, more precisely for those where the maximum splitting has been noted owing to a more favourable conformation (by no means in all cases optimal) for conjugation.[117]

Table 2. The gap between the first and second ionisation potentials corresponding to the delocalised n_+ and n_- orbitals.[54,72,77,117,118]

No.	Compound	Δn, eV	No.	Compound	Δn, eV
1	R_2N-NR_2	2.5	9		2.1
2	$R_2As-AsR_2$	1.6			
3	Cl–Cl	2.5			
4	I–I	1.8			
5	Diketones: α	2.6			
6	β	0.9	10		1.1
7	γ	0.5			
8	δ	0.3			

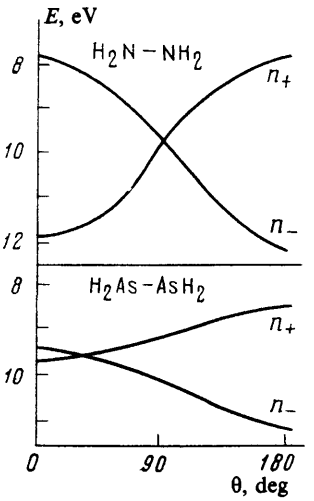


Figure 5. The energies of the delocalised *n* orbitals of N_2H_4 and As_2H_4, designated by the symbols n^+ and n^-, for different conformations including the *s-cis*-conformation (θ = 0°) and the *s-trans*-conformation (θ = 180°) (data obtained in Galasso's non-empirical calculations[54]).

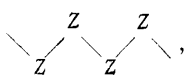
Fig. 5 shows how the energies of the n_+ and n_- orbitals of H_2N-NH_2 and $H_2As-AsH_2$ should change as the conformations are varied according to calculations.[54] The splitting Δn in the *cis*-conformers is determined by the direct overlap of the *n* atomic orbitals of the heteroatom "through space". In the *trans*-conformers, it takes place as a result of the mixing of the low-lying σ orbitals of the central Z–Z bonds; despite the fact that the energies of these σ orbitals in the compounds of heavier atoms approach those of the *n* orbitals of the heteroatoms, the splitting diminishes, which is apparently associated with the change in the

nature of the lone pair and the decrease in their overlap with the molecular orbital σ_{Z-Z}. The lengthening of the Z–Z bond also has an effect in the *cis*-conformer.



The principal conclusions drawn from ionisation potential data are as follows: (1) the manifestations of $n-n$ conjugation are associated with the interaction both through the intervening chemical bonds and through space; the relative roles of these channels depend on the molecular conformation; (2) with increase in the atomic weight of the heteroatom, Δn diminishes, which can be assessed as the weakening of conjugation as a result of the decrease in the contributions of both channels; (3) the difference Δn diminishes with increase in the distance R between the active centres; (4) in the molecules of compound (IX), which appears in Table 2 ($R \simeq 2.5$ Å), the interaction through the C–C σ-bond predominates, while in compound (X) ($R = 2.6$ Å) the interaction through space is dominant, which is favoured by the orientation of the n orbitals of the two nitrogen atoms "towards one another".[118] If the orientation and the distance R are kept constant, then in the bimolecular system $R_3N...NR_3$ one may expect approximately the same value of Δn.

The molecular orbitals of σ–σ conjugation systems, consisting of isotypical units, are delocalised. With increase in chain length, the number of occupied molecular orbitals and their maximum splitting on the energy scale increase, while the energy gap between the frontier orbitals, the first ionisation potential, and the electronic excitation energy diminish.[77,119,120] In this respect, there is no fundamental difference between the σ–σ conjugation chains (including those in *n*-paraffins) and polyenes, but the linkage between the electron clouds of the fragments and the features of non-additivity enumerated above depend on the nature of the atoms Z and become more explicit[119] in the series of chains formed by the following groups:

$$CR_2 < SiR_2 < SnR_2 < CH=CH.$$

The coupling between the orbitals of the atoms in a chain of σ-bonds was described on the basis of estimated intraatomic [interatomic? (Ed. of Translation)] exchange integrals $\langle\varphi_1|V|\varphi_2\rangle$ and also the weak overlap of the atomic orbitals of non-adjacent atoms;[42] the overlap and order of the bonds between non-adjacent atoms cannot, however, be regarded (contrary to what has been stated by Gineityte and Shatkovskaya[121]) as "criteria of the delocalisation of electrons".

We may note that, in systems involving "conjugation of the σ-bonds of adjacent molecules" ···Z–Z···Z–Z··· (Section III), the optimum geometry is attained more readily than in the chains

noted above, where the α-skeleton imposes certain limitations. Accordingly, among the entire wide variety of systems (chemical compounds), we have in the first case a wider range of possible interaction conditions.

IX. The donor–acceptor interaction of atomic groups

Considering a wide range of X–Y and X–M–Y systems in their *stationary* states, one may say that conjugation or, more precisely, the mixing of the orbitals of molecular fragments may not be accompanied (as happens, for example, in the C=C–C=C–C=C system) or may be accompanied (for X ≠ Y) by a redistribution of electron density between the groups X and Y– which is slight or appreciable depending on the structure of these groups. If it is appreciable and can be described as the electron transfer X → Y, then in the majority of problems it is more practical to employ another terminology and to begin with another procedure for the differentiation of the initial "fragments" with the corresponding excess charges; in this case, it may not be necessary to introduce the terms "redistribution", "interaction", etc. in describing the system.

In any case, the contribution of the donor–acceptor interaction can be estimated approximately *a priori* on the basis of empirical rules and approaches and can be determined from experimental data (from the molecular dipole moment μ, from IR absorption band intensities, etc.) or from information about the systems of unoccupied and occupied molecular orbitals, whose analysis provides a more detailed picture and fairly understandable explanations.

The electronegativities of the atomic groups χ tabulated in the literature are attractive because of the possibility of inferring directly the donor–acceptor capacities of the substituents in which we are interested. However, in fact we have a set of extremely heterogeneous data obtained in different ways, frequently without information about the type of atomic partner-groups and about the molecular conformations, although such information is of primary importance (as well as the information about the influence of the medium and especially the solvation of the active centres, which may greatly modify the donor–acceptor properties and the conditions governing the mutual influence of the atomic groups). For this reason, the values of χ quoted in the text below can be used only for qualitative comparisons.

In view of the multiplicity of methods proposed for the determination of χ, this constant has come to be adopted as an independent property inherent in the atomic group; there is no need for comments and it is sufficient to quote some of the large number (more than 30) of the published values of χ for the amino-group: 1.361, 2.992, and 3.63 (quoted after Vereshchagin[86]).

A step towards a more correct analysis consisted in the differentiation of two types of donor–acceptor interaction—with increase or decrease in the order of the bond connecting the molecular fragments under consideration.[122] Thus combinations of atomic groups favouring a redistribution of electron density between them and accompanied by manifestations of non-additivity in other properties have been noted. The designations "π-donor + π-acceptor" and "σ-donor + σ-acceptor" began to be used widely subsequently for the designation of such combinations. This problem was reflected indirectly much earlier by the introduction of the Hammett constants σ^+ and σ^-.

Even after the more concrete specification indicated, the designations "donor" (D) and "acceptor" (A) should not be treated as a classification of the atomic groups. Depending on the "partners" and the molecular conformation, the latter can behave differently. Thus the systems of carbon–carbon π-bonds (Π) can be π-acceptors in Π–D molecules, for example in aniline, and π-donors in Π–A molecules, for example in nitrobenzene.

The dipole moment of nitrobenzene is known to be greater than that of nitromethane by 0.8 D, which corresponds by convention to a Ph → NO_2 charge transfer of the order of (1/20)e. When the nitro-group is displaced from the plane of the benzene ring up to an angle of rotation of approximately 90°, the contribution of the π–π conjugation is virtually ruled out and the difference from nitromethane diminishes by a factor greater than 4 and, according

to quantum-chemical calculations,[46] by a factor of 1.5 (see also Baidin et al.[21]); according to the generally accepted view, only the contribution of the inductive effect then remains and the nitro-group becomes a σ-acceptor. The appreciable $H_2N \rightarrow Ph$ charge transfer in aniline molecules justifies the usual classification of NH_2 as a π-donor, but in an unfavourable conformation the amino-group (as well as the SR group) becomes a σ-acceptor.

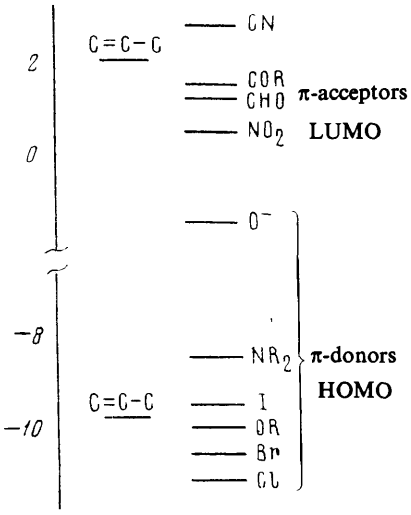


Figure 6. The positions on the energy scale of the HOMO of the π-donors and LUMO of the π-acceptors (simulated by the D−R and A−R molecules);[123] the possibility of the involvement of the groups D and A in the donor−acceptor interaction is related to them (however, cf. the data for PR_2 and AsR_2!).

The π-donor → π-acceptor redistribution of electron density depends significantly on the energy gap between the occupied orbital of the donor and the unoccupied π-orbital of the acceptor (Fig. 6) and also on the structure of the interface. It is self-evident that the electronic excitation of the molecule can alter radically the donor−acceptor properties of the substituents.

Table 3 provides data on the first vertical ionisation potentials (P_1) corresponding to molecular orbitals with an appreciable contribution of the *n* orbital (the lone electron pair) of the amino-nitrogen for compounds containing an active π-donor (amino-group) and intervening units of various types.[72,77,124] The values of ΔP_1 quoted denote the changes in P_1 on passing from simpler amines (X = H) to derivatives incorporating other groups X. Thus, whereas P_1 = 8.95 eV and ΔP_1 = 0 for R_2NH, the corresponding values for R_2N-NO_2 are P_1 = 9.75 eV and ΔP_1 = 0.8 eV. The influence of substituents on the amino-group can be inferred also from other data.[125–128] These include the experimental and calculated relative proton affinities (PA) of the amino-group in the compounds H_2N-CH_2-X (seventh column in Table 1—PA, kcal mol^{-1} [125]); the results of the calculation of the changes, induced by the influence of the group X, in the extremum of the electrostatic potential (EPE) generated by the lone pair,[128] which indicates the degree of involvement of the lone pair in conjugation (the fourth, eight, and twelfth columns—EPE, kcal mol^{-1}; the values for X = H were adopted as zero). The tenth column lists the Hammett constants σ_{para} [127] which are suitable for the investigation of the influence of X on reactions in electron-donating groups.

Some idea about the way that the amino-group influences in its turn the group X is provided by the changes induced by it in the stretching vibration frequency of the π-bond in the group X ($\Delta\omega_X$, cm^{-1}) (the fifth, ninth, and fifteenth columns).[32] For comparison, Table 3 includes electronegativity (χ) data for all the substituents X [85,86] in the form of the difference $\chi - 2.3 = \Delta\chi$.

Table 3. Signs of the mutual influence of the substituents in the D−A and D−M−A* systems.

* Approximate estimates are indicated in brackets.

The values of $\Delta\mu$ characterised the redistribution of electron density in the direction $R_2N \rightarrow X$, or, more precisely, the deviations of the dipole moment of $R_2N-\Phi-X$ from the vector sum of the moments of PhX and $PhNR_2$.[65] In the fourteenth column, $\Delta\lambda$ denotes the bathochromic shifts of the intense absorption band, which is in the region of 250 nm for $PhNR_2$ and corresponds to an element of charge transfer.

All the figures in brackets in Table 3 were obtained by quantum-chemical calculations or are approximate estimates based on analogies.

We shall consider in greater detail compounds of the type H_2N-A with $n-\pi$ conjugation systems in which the $D \rightarrow A$ shift of electron density has been noted. The formamide molecule can serve as the simplest example. In order to describe its large dipole moment, one usually refers[128] to the contribution of the structure $H_2N^+=CH-\overline{O}$, which reflects qualitatively also the shortening of the N–C bond, the coplanarity of the molecule, and the large energy barrier (18 kcal mol^{-1}), which prevents the rotation of the amino-group. According to calculations,[129] on rotation about the C–N bond with transition from a non-planar to a planar conformation, favouring $n-\pi$ conjugation, the electron density on the O atom increases slightly (cf. Refs. 49 and 130), while the C–N bond is shortened by 0.1 Å and its rigidity increases significantly.[131] However, certain other data do not correspond to the above methods of describing the structure of amides. Thus the length and force constant of the carbonyl bond, $R(C=O)$ and $K(C=O)$, differ little from those of simple aldehydes and the redistribution of electron density concerns, according to Wiberg and Laidig,[129] mainly the C–N region. One may add that the available data for the R_2N-NO_2 [132,133] and R_2N-CN molecules (but not for the just as polar R_2N-SO_2R group in which many features of conjugation are manifested weakly or are absent[134,135]) are in broad outline of the same kind.

The manifestations of $n-\pi$ conjugation in $PhNR_2$ molecules are well known. The energies of the p orbital in the PR_2, AsR_2, SbR_2, and BiR_2 groups differ little from that of the orbital in NR_2 (± 0.1 eV), but, as shown by the dipole moments of the compounds $PhZR_2$ and the Hammett constants σ_{para} which are close to zero,[127] are not active π-donors. The neutral character of the AsR_2 group ($\sigma \simeq 0$) has been treated[136] as a result of the annihilation of the contributions of the inductive effect (+0.28) and conjugation (–0.28), but in all the ZR_n substituents investigated, NR_2 and OR, the constants σ_{para} are close to zero despite the large differences between polarities! At the same time, the characteristic features of conformational equilibria were not considered by Gel'fond et al.[136]

Studies on specific $PhZR_2$ conformers yielded more information. According to calculations,[137] in the $PhPR_2$ conformer, where the two groups R are located on one side of the plane of the benzene ring, the PR_2 group behaves as a weak π-donor, while in the conformer with the symmetrical disposition of the methyl groups on either side of the plane of the benzene ring, the above group behaves more as a weak acceptor; a more significant bathochromic shift of the UV bands and appreciable intensification of the 1600 cm^{-1} Raman line of the benzene ring—almost the same as in $PhNR_2$—are characteristic of the first conformer. In $PhAsR_2$, which consists mainly of the conformer of the second type, the substituent exhibits stronger electron-accepting properties, which are usually attributed to the participation of the unoccupied d orbital of the As atom. The energy of the $n-\pi$ conjugation in the $PhNR_2$ molecule reaches 8 kcal mol^{-1}; for comparable conformations, it should be smaller by a factor of 1.5–2 in the $PhPR_2$ molecules.[138]

Judging from the data presented and also from the results of calculations,[20] NMR spectra,[139] and other data,[39,140,141] one can assume that the features of $n-\pi$ conjugation weaken in the series of compounds $PhZR_2$, where Z = N, P, As, Sb, and Bi, and in the PhZR series, where Z = O, S, Se, or Te. This applies particularly to the π-overlap and the $C_{arom}-Z$ bond length,[142] to the mixing of the n and π orbitals,[20] to the deviations from additivity in the dipole moments,[140] to the electron density on the carbon atoms of the benzene ring and the σ_{para} constants, to the conjugation energy[141] and the tendency by the molecule to assume the planar conformation favouring conjugation, and to the HOMO energy and the sensitivity of all the above parameters to changes in the angle of rotation θ of the ZR_n group about the $C_{arom}-Z$ bond. However, the above principal trends do not occur in the compounds PhX (X = halogen) and also in the compounds $O_2N-\Phi-ZR$,[65,140] where transition to heavier atoms Z entails the intensification of many manifestations of non-additivity; one of the causes is associated with the absence of the "problem of conformations" in the compounds PhX (X = halogen).

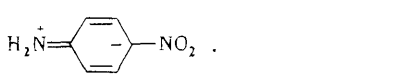
Allowance for the difference between the width of the energy gap ΔE between the n and π orbitals (which is smallest for PhI) is clearly insufficient to account for the entire observed picture; thus, one may turn ones attention to the appreciable decrease in the degree of $n-\pi$ mixing for almost identical values of ΔE in the series of compounds N ··· Bi. The latter is usually explained by the enhancement of the s character of the n orbitals, although this is not easy to test because of the lack of experimental data for the conformations being compared.

The sequences of Z based on the changes in the UV spectra of PhZr ($\Delta\lambda$) differ appreciably from those presented above. Within the limits of Group V elements, only nitrogen is outstanding. In the PhOR ··· PhTeR series and also in VyOR ··· VyTeR, a gradual shift of the region of intense absorption towards longer wavelengths is observed[143,144] (in conformity with this, a tendency towards an increase in the intensity of the Raman lines can be seen[143,145]); these data do not constitute an incontrovertible sign of the enhancement of any particular aspects of conjugation but it appears that the orbitals of heavy atoms are much more involved in the long-wavelength absorption (here one can turn ones attention to the energy of the n, σ, σ^*, and Rydberg orbitals and the UV spectra of the SR_2 and SeR_2 molecules and even more so TeR_2 molecules (see Table 1 and Refs. 73, 146, 147). Unfortunately, the interpretation of the PhX absorption bands is unreliable and incomplete, which applies particularly to the Rydberg transitions.

The overall pattern appears fairly complex and does not fit within the framework of a simple scheme; however, quantum-chemical calculations make it entirely possible to achieve qualitative explanations.

X. Donor–acceptor interaction in systems with a D–M–A bridging group

The question arises how the conditions governing the donor–acceptor interaction change on passing from D–A systems to D–M–A systems, where M is a bridging group. We shall consider initially the special case where the intervening unit is a system of carbon–carbon π-bonds. The degree of charge transfer in the $D-\Phi-NO_2$ molecules is smaller by a factor of $\sim 2-3$ than in $D-NO_2$. However, in the presence of the most active π-donors



($-CH_2^-$, $-O^-$, $-NH^-$, $-S^-$), it is nevertheless extremely pronounced‡ and reaches 0.1 ... 0.2 e within the framework of the conventional D → A scheme according to calculations.[148]

The charge transfer in the *p*-nitroaniline molecule can be estimated as approximately 0.03 e; here the interatomic distances[149] correspond to an approximation to the quinonoid structure

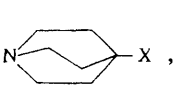
and the C–NO_2 bond is shorter than in nitrobenzene by 0.03 Å. This led to the conclusion that conjugation involves the participation of both substituents; according to Furukawa et al.,[150] the conjugation energy, the amount in excess of the energy yielded by the interaction with each substituent separately (this is ~5 kcal mol^{-1} for $PhNO_2$ and ~8 kcal mol^{-1} for $PhNH_2$), is approximately 2 kcal mol^{-1}.

This interpretation has been rejected in a number of investigations;[46,151,152] it is believed[151] that the nitro-group is subjected to the inductive influence by the excess negative charge (about 0.06) generated on an adjacent carbon atom as a result of the influence of the amino-group, i. e. as a result of $n-\pi$ conjugation:

In certain other studies, the decrease in the basicity of the amino-group was considered and it was attributed to the interaction of the substituents in the cation, and not in the initial nitroaniline molecule, or to the influence of solvation.

The set of experimental data is not fully consistent with these conclusions. It is sufficient to state that the displacement of the nitro-group (as well as R_2N-) from the molecular plane weakens the signs of the interaction of the substituents.[32] These signs include the high intensity of the long-wavelength and charge-transfer absorption bands (~3000 Å), the shortening of the $C_{arom}-N$ bonds,[149,152] the fairly appreciable energy barrier hindering the free rotation of the nitro-group, the predominant influence of the amino-group on the frequencies ω_{as} of the antisymmetric vibration of the nitro-group (more local, with small involvement of the C–NO_2 bond), the influence of the latter on the NH_2 frequencies, the anomalously large molecular dipole moment, the high intensity of the IR bands due to the symmetrical vibrations of NO_2 and NH_2 (much greater than for the monosubstituted benzene derivatives), which can be interpreted as an indication of the migration of electron density during the atomic vibrations to the region of the conjugation system, and the fairly high absorption intensity due to the antisymmetric vibration, indicating an appreciably greater polarity of the N–O bonds[153] (whereas in the $H_2N-\Phi-CH=CH_2$ and similar molecules the substituents hardly influence one another). As regards solvation, its influence on different signs of conjugation and on the electron-donating capacity of the amino-group is very appreciable (for example, see Refs. 154 and 155), but is nevertheless of secondary importance; the clear non-additivity of the influence of the substituents on the spectra of isolated molecules has been established experimentally (see Table 3 and also Refs. 154, 156, and many others).

‡The symbol D → A should not be accepted literally; the redistribution of electron density involves to some extent also the atoms of the intervening chain.



Whereas in the case of *p*-nitroaniline there are still some grounds for considering the structure of the quinonoid type (see above), in the presence of a longer intervening chain of π-bonds this becomes completely unjustified; the smoothing of the bond alternation induced by the substituents in the intervening poly-yne or polyene system is known to be observed only in the vicinity of substituents.

As the intervening subsystem lengthens, the D → A transfer of electron density diminishes, but, despite this the deviations from additivity in the dipole moments ($\Delta\mu$) increase owing to the increase in the effective length of the dipole. Thus $\Delta\mu$ = 0.6 D for R_2N-CHO, while in $R_2N-(CH=CH)_4CHO$ $\Delta\mu$ reaches 5 D.[52]

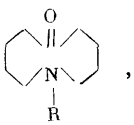
The changes in the force constant *K* (rigidity) of the π-bond in the group A can be traced in relation to nitro-compounds. According to experimental data, *K*(N–O) is reduced owing to the influence of the amino-group by more than 8% in the R_2N-NO_2 molecule, by approximately 3% in the $R_2N-\Phi-NO_2$ molecule, and by less than 0.5% in a system of the type $R_2N-\Phi-C\equiv C-\Phi-NO_2$.

In the presence of even longer chains of carbon–carbon π-bonds, the influence on the rigidity of the N–O bonds (and also the changes in the basicity of the amino-group itself under the influence of the nitro-group) are no longer susceptible to observation, but the non-additivity of the influence of substituents on certain optical properties actually becomes even more explicit. This is apparently associated with the fact that the absorption bands (electronic transitions) appear in the long-wavelength region, which is readily accessible to observation; they affect the colour and make a particularly large contribution to the electronic polarisability of the molecule (and also to the intensity of the Raman lines—some of them are more intense by a factor of 100–1000 than for nitrobenzene). However, the additional bathochromic shifts of the UV absorption bands following the increase in the length of the intervening chain by one unit gradually diminish. Thus the different properties respond in different ways to the lengthening of the chain, but these differences have a completely definite physical basis.

We shall now turn our attention to compounds of the type $D-CH_2-A$ and the entire set of data in Table 3. Despite the heterogeneity of the parameters listed there, which in general bear little relation to one another, one may note certain features common to them. Thus, the non-additivity in the influence of heterotypical atomic groups, where the electron-donating amino-group is coupled to the electron-accepting group X in one way or another, is most marked in almost all cases. Among electron-accepting groups, the nitro-group is outstanding, which can be accounted for by the lower position of its π* orbital (Fig. 6). On the other hand, a qualitative similarity may be seen in many aspects of the influence of the substituent X in the series of compounds R_2NX, R_2N-CH_2X, $R_2N-\Phi-X$, and 4-X-quinuclidine. Such similarity apparently extends to a significant degree also to systems consisting of D–Y and A–Y molecules in close proximity. Contrary to expectation, some of these parameters differ little in the above series (ΔP_1), others are weakened (EPE, PA, $\Delta\omega_X$), while some parameters are actually strengthened ($\Delta\mu$). Furthermore, in compounds of types *a*, *b*, and *c* the π-acceptor and π-donor substituents X influence the parameters associated with the amino-group—P_1 and the rigidity of the N–H bonds[126]—(as well as the dissociation constants of the acids $X-\Phi-COOH$) in opposite directions, while in the quinuclidine derivatives

they exert their influence in the same direction; this agrees with the fact that the values of $\Delta\chi$, which are very close to the characteristics of the σ-donor–acceptor capacities of the substituents, have the same sign for all the groups X considered (cf. the values of σ_{para}).

The similarity in the manifestations of the intramolecular interaction in the R_2N-CH_2-A and $R_2N-\Phi-A$ molecules does not imply identity of the mechanisms; one may say that the group A = CN, NO_2, Cl, or F (but not COR [157,158]) in the compounds R_2N-CH_2-A acts as a σ-acceptor, while in aromatic nitriles and nitro-compounds it acts as a π-acceptor:



The influence of the σ-acceptor properties of the above groups has been described as a tendency to assume an electronic structure of the type $R_2\overset{+}{N}=CH_2A^-$.[128,157] The shortening of the bond with the amino-group and the lengthening of the $C-NO_2$ bond, which follows from non-empirical calculations[159] for $H_2N-CH_2-NO_2$, is consistent with this; similar results have been obtained for H_2N-CH_2-Cl.[128]

The similarity noted above does not extend to UV spectra. The point is that in aromatic compounds the combination of the groups D and A promotes an intense absorption in the long-wavelength region where the band involving an element of the D → A charge transfer but also with an appreciable participation of the benzene ring is located (see the molecular orbital in Fig. 6 of Ref. 160). In the observed long-wavelength part of the absorption spectrum of R_2N-CH_2-CN, the contribution of the amino-group predominates; the electron-acceptor group promotes the stabilisation of the lone pair orbital and the zone of intense absorption moves away into the region of 1800 Å (see Figs. 1 and 2 in Ref.157). This example indicates the necessity to study and to interpret fully the bands over a wider region in the spectrum.

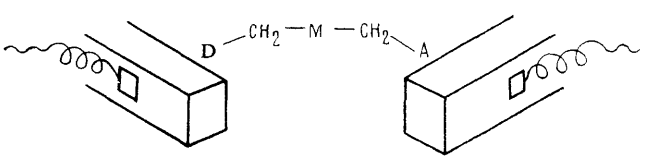
The quantitative conclusions which might be drawn from the entire data obtained require more detailed calculations. One has to bear in mind that in reality the structures of the molecular orbitals, for brevity referred to as lone pair orbitals, differ greatly in the compounds being compared; the description of the principal trends depends to a considerable extent on the choice of the reference standard (in Table 3, this is X = H); there is no certainty that the dominant conformations in compounds R_2N-CH_2-X are isotypical. Finally, the data for diamines, and in the first place for hydrazines, are not treated unambiguously. The question arises how the group $X=NR_2$ in these compounds influences the other amino-group. Here $\Delta P_1 = -0.65$ eV, while $\Delta P_2 = -0.15$ eV, but both P_1 and P_2 characterise not one amino-group but the set of two such groups and, in considering the processes involving one-amino-group, it is therefore better to employ the average (−0.4 eV). In this case, both variants yield a negative sign but in diazaadamantane with the N–C–N system analogous variants give rise to different signs; thus, in describing different processes, even qualitative differences may appear in estimates of the influence of intramolecular interaction.

Table 3 may be supplemented by data for molecules in which the groups A and D are located in such a way that they can interact appreciably through the intervening free space; the transannular interaction in atranes and in various cyclic and polycyclic bifunctional compounds in which the active centres are fixed at a comparatively short distance from one another by a rigid skeleton of chemical bonds which does not itself participate in the conjugation has long been known. The aminoketone

may serve as an example.

Despite its unusual structure, in terms of the value of ΔP_1 it differs little from other ketones included in Table 3, while in terms of $\Delta\omega_{C-O}$ it is actually superior to some of them.

It is even more useful to compare a molecule of the type D–M–A with a set of two molecules one of which includes the group A and the other the group D. In an experiment, it is possible to immobilise an AX + DY pair of this kind by a solid inert matrix (for example, argon). It is easy to imagine that, after the formation of the AX + DY system, there is a possibility of its further evolution involving several stages with the modification of the wave functions and hence of the electronic structure. Under suitable conditions, one of the stages may be the electron transfer D → A. The knowledge of the characteristic features of the generation of the potential within the limits of the entire system (AX + DY or D–M–A) and of the parameters of all types of relaxation facilitates the selection of the molecular structure of a compound or complex to be used in "submicroelectronic" devices. The symbolic representation of one of the simplest elements of such a device, incorporating one molecule of the type D–M–A, is presented in Fig. 7; the possibility of creating controllable elements has been described.[17,18,161]



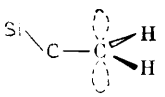


Figure 7. Model of an element in the microprocessor technique incorporating one molecule of the D–M–A type.

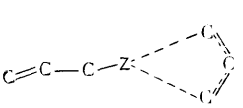
The study of the functions of D–M–A systems is of fundamental importance for the understanding of the mechanisms of many most important chemical, physical, and physiological processes.

XI. Conjugation in molecules of allylic compounds

The bond systems separated by the methylene bridge have been attracting increasing attention recently. It has become evident that the usual ideas about the weakness of the interaction between the subsystems cannot be extended to all molecules with a methylene

bridge; the manifestations of non-additivity are much more striking in certain cases than, say, in butadiene. We may refer to the examples of the solvolysis of derivatives of pentacyclononyl nitrobenzoate: under the influence of certain hydrocarbon substituents of low polarity, extending through two–three C–C σ-bonds, the rate of reaction increases by a factor of $10^{12}-10^{14}$.[162] Even more interesting examples may be quoted if one turns to ions, radicals, and electronically excited molecules, while the conjugation energy may prove to be an order of magnitude higher than in dienes. Thus such energy in the 3-silapropyl cation in the optimum conformation



exceeds 25 kcal mol^{-1}.[163]

Allylic, benzyl, and similar compounds of heavy elements have attracted attention.[53,101,107,164–169] It was necessary to establish the principal features of their structure and, as far as possible, to find answers to the following questions:

1. What determines the tendency towards the formation of π-complexes or σ-structures?
2. How do the manifestations of conjugation in σ-structures depend on the nature of the heteroatom and of its valence state and also on the conformation of the molecule?
3. What is the mechanism of this interaction?
4. How are relativistic effects reflected in the signs of conjugation?
5. Do the unshared electron pairs of the heteroatom contribute to conjugation?
6. How are the manifestations of conjugation in the electronic and vibrational spectra and the redistribution of electron density between the fragments of the molecule interrelated?

As regards the first question, one should note in the first place that in allylic compounds different structural variants may occur depending on the nature of the heteroatom and the types and positions of the substituents. These variants include symmetrical π-complexes (characteristic of transition metal and alkali metal compounds), slightly or appreciably asymmetric systems, and, finally, typical σ-allylic structures which will in fact be the subject of our attention.

In contrast to π-complexes, in the σ-allylic structures there is a fairly strong σ-bond between the heteroatom and one of the terminal carbon atoms and only weak or negligible overlap of the atomic orbitals of the heteroatom and other carbon atoms. In individual instances, it has been suggested that there is an equilibrium between the σ-allylic form and the π-complex.[170–172] In complex molecules, one cannot rule out the participation of one heteroatom simultaneously in bonds of two types—characteristic of π- and σ-structures:

The study of the reactivity of a series of σ-allylic systems led to the concept of σ–π conjugation,[101] which can be described, in terms of LCBO, as the mixing of orbitals localised on bonds—the C–Z σ orbitals and the C=C π orbitals. Subsequently spectroscopic studies on the compounds $\Pi-CH_2-ZY_n$ with the atoms Z belonging to different Groups in the Periodic System led to the conclusion that compounds of heavy elements and the elements in the first Groups have specific features.[53,107,164] Manifestations of conjugation clearly occur in these compounds. These include, in particular, the deepening of the colour,[160,164] an increase in electronic polarisability, a sharp increase in the intensity of the Raman lines of the π-bonds,[32,53,165] and specific changes in reactivity;[21,101,173,174] a decrease in the heat of hydrogenation of the double bond (by 1–10 kcal mol^{-1}), a decrease in the vibration frequency and rigidity of the C=C bond, and, in certain cases, a slight smoothing of the differences between the C–C and C=C bond lengths (complete equalisation occurs in symmetrical π-complexes).

The mixing of the above π and σ orbitals (with the corresponding delocalisation) leads to the expansion of the energy gap between them and to the destabilisation of the highest occupied molecular orbital (HOMO). These features are more marked the closer are the energies of the initial orbitals and the greater their overlap or, more aptly, the greater the integral $<\sigma|V|\pi>$ (see the formula in Section II). The overlap depends comparatively little (±30%) on the type of heteroatom Z, but depends greatly on the conformation, being a maximum for the *gauche*-conformers. In planar forms, the mixing is minimal and the sets of frontier molecular orbitals of the compounds $AllZR_n$ can be regarded, without stretching things too much, as a set of several modified molecular orbitals of propene (π and π*) and the compounds ZR_m (σ orbitals, including the C–Z bond, the *n* orbitals of the Z atom, etc.).

Several examples in Fig. 8 provide a qualitative idea about the possibilities in the mixing of the orbitals of fragments adjoining the methylene bridge and combination of various substituent groups ZR_n and the simplest π-subsystems. Each column indicates the corresponding Z atom. The continuous sections of the horizontal straight lines represent the position on the energy scale of the π molecular orbitals of propene and $R_3C-CO-R$ and the σ molecular orbitals of the ZR_m molecules, which simulate the molecular fragments of $All-ZR_n$ and $R_3C-CO-CH_2-ZR_n$ in the absence of conjugation. The divided sections correspond to the orbitals of some of the compounds $R-ZH_3$; their positions explain the causes of the possible differences between the conjugation conditions in the $AllZR_n$ and $AllZH_n$ molecules. The divided sections of the horizontal straight lines correspond to tentative estimates. The dotted lines join isotypical molecular orbitals. The wavy lines correspond to orbitals of the model in which the contribution of the relativistic effects is not included.[57]

In setting up a molecular orbital scheme, photoelectron and electron-transmission spectroscopic data[72,77,90–92] as well as the results of MNDO calculations[57,175,176] were resorted to. Unfortunately, this method does not take into account the Rydberg atomic orbitals and yields incomplete and insufficiently reliable data for the unoccupied orbitals. Nevertheless the major role of Rydberg transitions has been noted in the UV spectra of many organic compounds;[73,98,100,147] thus the long-wavelength electronic transition in SnR_4 is associated with the involvement of the 6*s* and 6*p* atomic orbitals of tin.

The vertical arrows in Fig. 8 show in relation to Si, Sn, P, and As compounds how the positions of the molecular orbitals change on passing from non-interacting fragments to the *gauche*-conformers of C=C–C–Z and O=C–C–Z. To a first approximation, these changes can be identified with the shift in the *trans* → *gauche* transition induced mainly by conjugation (although delocalisation of the orbitals and small shifts on the energy scale occur also in planar

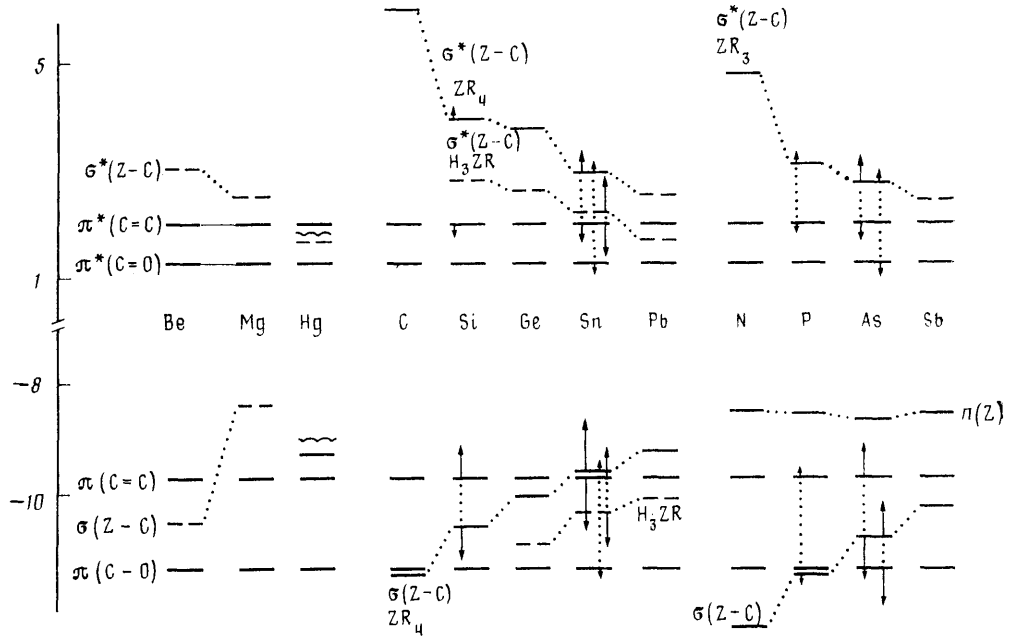


Figure 8. Schematic arrangement of the C=C and C=O π orbitals as well as orbitals associated primarily with the Z−C bonds in the ZR_m molecules; the proximity of the σ and π orbitals favours their mixing in the *gauche*-conformers of the $\Pi-CH_2-ZR_n$ molecules.

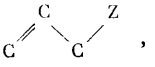

conformers). Changes of this kind in the B, C, N, and O compounds are slight but in allylic compounds of heavy elements, where the $E_\pi - E_\sigma$ energy gap is smaller, they become more significant.[57,107,175] They are accompanied by explicit changes in the UV absorption spectra;[160,164] the delocalisation of the occupied molecular orbitals in the non-planar conformers is then responsible for the intensification and the mutual approach of the frontier orbitals gives rise to the bathochromic shift of the absorption bands conventionally designated as $\pi \rightarrow \sigma^*$ bands, which can thus come to the fore.

More comprehensive information about allylic compounds is provided by Table 4. The figures quoted there show how much the following quantities *diminish* on passing from propene and ZR_m to the compounds $All-ZR_n$: (1) the first ionisation potential P_1 (which refers in addition to the lone pair of the Z atom):[39,72,77] (2) the wavelength λ of the first intense UV absorption band of the solutions in heptane (bold type):[32,73,92,164] (3) the stretching vibration frequency $\omega_{C=C}$.[32,78,160] The initial data for propene are as follows: $P_1 = 9.8$ eV, $\Delta P_1 = 0$, $\lambda = 180$ nm, $\Delta\lambda = 0$, $\omega = 1645$ cm^{-1}, and $\Delta\omega = 0$. Under the experimental conditions, the *gauche*-conformer predominated in most cases, which intensified the signs of conjugation. Approximate estimates based on analogies or on approximate quantum-chemical calculations, which are suitable only for qualitative inferences, are given in Table 4 in brackets; they correspond to the *gauche*-conformations.

The decrease in the ionisation potential (ΔP_1) characterises the destabilisation of the HOMO on passing from non-interacting fragments (simulated by the ZR_m and propene molecules) to the real $C=C-C-ZR_n$ system with orbitals of the mixed π/σ type. In those cases where the σ molecular orbital of ZR_m lies above the π molecular orbital of propene and makes a dominant contribution to the HOMO of $AllZR_n$, the ΔP_1 readings are begun from this orbital; the corresponding numbers in Table 4 are designated by the letter σ. In one way or another, the quantity ΔP_1 reflects the dominant influence of conjugation; in the majority of compounds, it is very close to the value which would have been observed in the conformational *trans* → *gauche* transition. The latter has been confirmed indirectly by the approximate constancy of E_π for the *trans*-conformer. However, among the compounds of certain elements (especially Li, F, and Cl), there is no such constancy; here the influence of the differences between the potential fields in the region of the heteroatom, which is usually regarded as the inductive effect, operates.

The shift of the UV band ($\Delta\lambda$) is in all cases determined relative to propene. In compounds of the Second Period *p* elements, this is a $\pi \rightarrow \pi^*$ transition, while in compounds of heavy elements it is a transition with participation of a molecular orbital to which the atomic orbitals of the heteroatom make an appreciable contribution; the involvement of the Rydberg states is then entirely probable (see above).

In interpreting the values of $\Delta\omega$ quoted above, one should bear in mind that in other structures, where the subsystem

is coplanar and there is no conjugation-induced decrease in the rigidity of the double bond but the influence of the greater mass of the heteroatom remains, the difference $\Delta\omega$ proved to be smaller by a factor of 2−3,[165] i.e. is relatively insignificant.

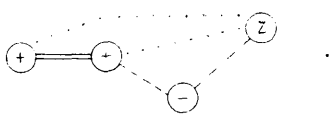

Table 4. The decrease in the first ionisation potential (ΔP_1, eV), the wavelength of the UV absorption band ($\Delta\lambda$, nm), and the C=C stretching vibration frequency ($\Delta\omega_{C=C}$, cm^{-1}) on transition from C=C−C to C=C−C−ZR_n.*

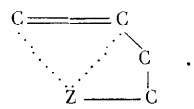
* Under the symbol of each element, the first, second, and third rows indicate ΔP_1, $\Delta\lambda$, and $\Delta\omega_{C=C}$ respectively.

It is seen from Tables 1 and 4 and Fig. 8 that there is some correspondence between the spectra of the compounds ZR_m and $AllZR_n$; when Z is varied along the Periodic System from above downwards and from right to left, the above signs of conjugation in allylic compounds in general become more marked (cf. the data in Section V). In compounds of the heaviest elements, this tendency becomes less marked partly owing to the contribution of the relativistic effects.[57,177] The energy of the σ orbitals is then very important. Fig. 8 shows that, when Z varies within one subgroup of the elements from above downwards, the σ molecular orbitals of the compounds ZR_m are located in an increasingly higher position and thus the energy gap $E_\pi - E_\sigma$ narrows (which favours the π/σ mixing), but subsequently, when the σ molecular orbital lies above the π molecular orbital and the gap actually begins to widen, the π/σ mixing should weaken (but with a further increase in the bathochromic shift of the UV absorption band). Such changes in the occupied and unoccupied molecular orbitals are by no means "synchronous". The mixing of the *n* and π orbitals is in this case very slight (in contrast to the $\Pi-ZR_n$ system where there is no bridging group).

The mechanism of conjugation in σ-allylic compounds can be elucidated by using a scheme simplified to the maximum extent:



Here the four carbon atoms of the main chain $C_\gamma=C_\beta-C_\alpha-Z$ are represented by circles; the lines between the circles symbolise the interaction of the atomic orbitals in pairs. The symbols (+) and (−) denote the signs of the contribution of the $2p_x$ atomic orbitals of the three carbon atoms to the HOMO, whose structure is close to the π orbital of ethylene§ but which includes in addition a small contribution by the $2p_x$ atomic orbital of the bridging C_α atom. If this atomic orbital has in addition a non-zero population of the overlap with the orbitals of the heteroatom Z (which happens in non-planar conformers), then conditions are created for the formation of delocalised molecular orbitals incorporating the entire C=C−C−Z system. One may say that the conformation of the system determines the overlap population mentioned above and transition to compounds of heavy elements implies a higher (and close to the π orbital) position on the energy scale of the σ orbital of the C−Z type, which favours the π/σ mixing. In conformity with the above (by no means complete) scheme, the atomic orbitals of the heteroatom Z can, at least in non-planar conformers, become mixed with the π molecular orbital as a result of overlap (1) with the $2p_x$ atomic orbitals of C_β and C_γ (interaction through space denoted by dotted lines) and (2) with the $2p_x$ atomic orbital of C_α (interaction through a bridge or, in other words, there is a bond between the fragments formed as a result of the simultaneous overlap of the $2p_x$ atomic orbitals of the bridging C_α atom with the orbitals of X and C=C). Generally speaking, each of these two channels separately might promote the destabilisation of the HOMO and a decrease in the first ionisation potential; in the case considered, the contributions of these channels have different signs and one cannot therefore rule out the possibility of their "annihilation" (as in certain dienes[178]). Which of these two channels predominates depends, generally speaking, on the nature of the heteroatom, the bridging group, and the π- bond and also on the molecular conformation and on the structure of specific orbitals. The mixing of different orbitals of the two active centres can be determined by different channels; thus one cannot rule out the possibility that the highest occupied orbitals of the fragments are mixed via one channel, while the unoccupied one are mixed via another.

According to calculations,[57,107,176] the interaction through a bridge predominates markedly in the majority of σ-allylic compounds of *p* elements; it in fact determines the destabilisation of the HOMO (by as much as 1−1.5 eV). The specific features of the conformation then have an effect mainly through the overlap population of the $2p_x$ atomic orbital of the C_α atom and the orbitals of the Z atom (although the latter makes only a small contribution to the formation of the C−Z chemical bond). The interaction through space in such molecules is altogether insignificant. However, the more diffuse atomic orbitals of the heteroatom, for example, the *s* atomic orbitals of the alkali metals can, like the *d* orbitals of transition metals, overlap effectively with the atomic orbitals of all three carbon atoms; under these conditions, π complexes are formed readily and in relation to such complexes it is more appropriate to speak not of interaction through space but of chemical bonds with the heteroatom. The involvement of the $d-\pi$ overlap the σ-allylic compound of rhenium is represented in Fig. 9 after Bodner et al.[179] In any case, the presence of two−three methylene groups instead of one weakens the interaction through the bridge system and facilitates the mutual approach of the heteroatom

§ The cartesian *x* axis is perpendicular to the  plane; the Z atom lies outside this plane.

and the double bond in space, creating additional possibilities for interaction through space:

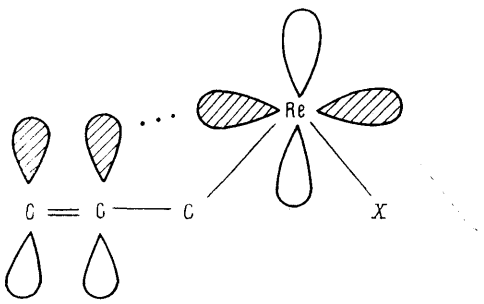


Figure 9. Involvement of the *d* atomic orbitals of rhenium in conjugation.[179]

The question arises of the correspondence between the above conclusions concerning the conjugation mechanism, based on the consideration of delocalised molecular orbitals, and the known ideas about $\sigma-\pi$ conjugation as a consequence of the overlap of the C=C π orbital and the C–Z σ orbital constructed from hybridised atomic orbitals and located in bonds. The electron density on the localised σ orbital is generated by several delocalised σ molecular orbitals, but in our case only one of them (the highest occupied σ molecular orbital) interacts with the π orbital, since the energies of the remaining orbitals differ markedly from that of the π orbital. Thus "conjugation with the σ-bond" can be interpreted as the participation of this particular "component" (by no means localised in the one σ-bond considered and not playing the principal role in the formation of the $C_\alpha-Z$ chemical bond). On the other hand, one may say that, for the description of the influence of conjugation on the parameters of an individual chemical bond (for example, on the force constant), the system of localised orbitals is more or less suitable but for the description of the electronic absorption spectra and various "one-electron" properties it is more convenient to resort to delocalised molecular orbitals.

By virtue of the influence of steric factors and conjugation, the *gauche*-conformation is more favourable on energy grounds for the majority of σ-allylic compounds (in contrast to $\pi-\pi$ conjugation systems). The conjugation energy, which is related to the weak interaction of the frontier orbitals having markedly different energies, is then low in the electronic ground state (<3 kcal mol^{-1}).[166,180] It proves to be somewhat greater for compounds of heavy elements, although the changes in the energy of the electrons occupying the π and σ molecular orbitals occurring under these conditions in the *s-trans* → *gauche* transition to some extent cancel out; however, after the transition of the molecule to the first electronically excited ($\pi \rightarrow \sigma^*$) or ionised state, such cancelling does not occur and the dependence of the energy of the molecule on the conformation should be appreciable[174] (see Fig. 10 and also Fig. 3 in the paper of Shorygin et al.[164]). The results of changes in the energies of the HOMO and LUMO not only do not cancel out but are actually added together if one considers the shift of the long-wavelength absorption band. Thus conjugation has little effect on the energy of an unexcited neutral molecule, has a greater effect on the ionisation potentials and electron affinities, and has a strong effect on the UV absorption spectrum.

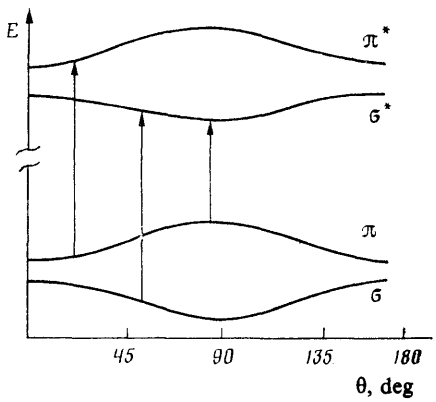

Figure 10. The energies of the σ and π orbitals of $XHg-CH_2-CH=CH_2$ for different conformations;[175] the arrows denote the types of allowed electronic transitions.

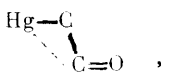
According to calculations,[166,167,175,176] the redistribution of electron density between the heteroatom and the vinyl group in the allylic compounds of the majority of *p* elements is insignificant and is almost independent of the conformations; the influence of the heteroatom on the charge of the C_γ atom, which varies within the range ± 0.03 e, is more instructive in this instance.

The redistribution of electron density on the atoms of the main chain in allyl fluoride and the hypothetical model of σ-allyl-lithium is more appreciable and can be represented by the following symbolic scheme for the *gauche*-conformers:[57,176]



$$\overset{0.05}{C}=\overset{0.25}{C}-C-F, \quad \overset{0.1}{C}=\overset{0.4}{C}-C-Li \;(0.1), \quad \overset{0.2}{C}=\overset{0.1}{C}-\overset{0.5}{C}-Li.$$

In precisely these two extreme cases, the results resemble the situation which may be expected on the basis of ideas concerning the inductive influence of strongly polar C–Z bonds. However, the inclusion in the scheme of two equally important variants (out of the multiplicity of the possible ones) for allyl-lithium is sufficient to draw ones attention to the ambiguity of the treatment. The latter appears even less satisfactory in view of the considerable decrease in the redistribution of charges in the planar conformers of both compounds. In any case, the estimation of the involvement of individual molecular orbitals and of the distribution of electron density in space in different conformers leads to a completely valid description of the entire picture.

On considering a wider range of allylic compounds, one may say that the low electronegativity of the $-ZR_n$ group in general favours the transfer of electron density—predominantly to the bridging carbon atom in the σ-allylic forms and to the terminal carbon atoms in π-complexes. If such a group is called a σ-donor, then the $-CH_2-ZR_n$ group can be regarded as a π-donor. Accordingly, the σ_{para} Hammett constant, for example of the $-CH_2-SnR_3$ group, is −0.35 whereas that for the $-SnR_3$ group is close to zero;[127] the data are even more striking for the mercury and lead compounds.

Most of the conclusions about allylic compounds can be extended by benzyl, indenyl, and other systems of a similar type. The question arises whether they can be extended also to the compounds R_nZ-CH_2-A incorporating a π-acceptor A, for example, CN, COR, and NO_2. The data for the amines R_2N-CH_2-A have already been considered in Section X. Heavy atoms Z with a low electronegativity promote in this instance to a somewhat greater extent than in allylic compounds a decrease in the rigidity of the π-bond, the enhancement of other signs of σ−π conjugation, and the "metal atom → terminal atom of the π-bond" charge transfer (see the spectra of carbonyl compounds[44,124,158,160,164,165,181] and nitriles[124,157,182]).

We shall consider as an example the XHg−C−C=O bond system. According to approximate quantum-chemical calculations,[183] the Hg → O charge transfer in the planar conformer should be approximately 0.02; when coplanarity breaks down, an additional conjugation-related change in the atomic charges (up to 0.02) and bond orders (up to 1−2%) and very weak bonding

(designated by dashed lines) are observed. However, the description of these small changes as a certain trend towards the structure $X-\overset{+}{H}gC=C-\overline{O}$ (similar to that in the paper of Guerrero et al.[44]) can be resorted to only in a qualitative consideration. Conjugation favours in this instance the predominance of the *gauche*-conformers and accordingly a more explicit non-additivity in the generation of the UV absorption spectrum (Fig. 11) and a decrease in the C=O frequency.[181]

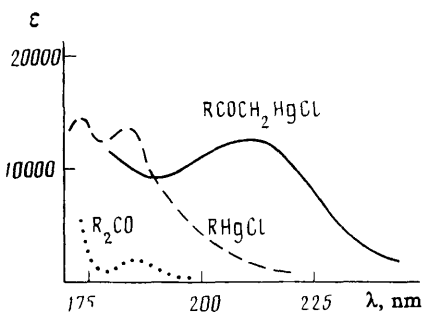


Figure 11. Signs of non-additivity in the UV absorption spectrum of $RCOCH_2HgCl$; the absorption band type is close to $\pi \rightarrow \sigma^*$.[180]

In compounds with the oxygen bridge, X−O−COR, the C=O frequency is much more sensitive to changes in the structure of X than in compounds with the CH_2, NH, S, and Φ bridges. Thus in the series of compounds $R_nZ-O-COR$ it varies within the range from 1785 cm^{-1} for Z = O to 1645 for Z = Sb^{III}, 1620 cm^{-1} for Z = Pb, and 1560 cm^{-1} for the anion $(OCOR)^-$.[181] Here we have a combination of $n-\pi$ conjugation in the O−COR subsystem, which is promoted by coplanarity, and σ−π conjugation, which is promoted by the breakdown of coplanarity. The correspondence between the electronegativity of the group ZR_n and the influence of the latter on ω_{C-O} is by no means always complete under these conditions.[184] It has also not been noted on comparing the A−M−Sb^{III} and A−M−Sb^V subsystems: judging from the data of Epstein et al.,[185] the M−Sb^V fragment is much more active as part of the conjugation system and a π-donor (while the −M−Au subsystem is more active than −M−Hg [186]). Interesting data for aromatic compounds with −O− and −NH− bridges can also be found in the communications of Chuvashev et al.[187] and Pozdnyakov et al.[188]

As already noted in Sections X and XI, the entire set of data obtained creates a basis for the interpretation of the characteristic features and the mechanism of the mutual influence of atomic groups separated by a bridging group (X−M−Y); it gives rise to additional possibilities for inferences about conjugation in electronically excited ionised states and the relative stabilities of σ-structures and π-complexes. The influence of substituents through a bridging group is of primary importance for the physical and chemical properties of many organic compounds; in many cases, it proves to be even greater than in the X−Y systems.

XII. Conclusion

The determination of the mechanism and of the characteristic features of the mutual influence of atomic groups forms part of the range of fundamental problems of organic chemistry. It leads ultimately to a more compact description of the enormous, almost unencompassable experimental data and hence to an improvement of its employment and to an increase in the productivity of the work of investigators endeavouring to obtain compounds with the required properties.

The mutual influence of functional groups is manifested by a complex set of heterogeneous signs of non-additivity; these signs are not linked by simple and universal correlations; it is sufficient to say that a change in the structure of the interface sometimes enhances and sometimes weakens other signs of conjugation. Under these conditions, the determination of at least the general trends, wherever this is possible, is already a useful step and facilitates further research.

The schemes for the differentiation of different forms of intramolecular interaction, including conjugation and the inductive effect, used in the literature are conventional in character and at the same time far from uniform, which very greatly complicates comparison of the conclusions of different workers. Calculations of the contribution by the inductive effect in the study of the interaction of the active centres of molecules is frequently based on estimates of the dielectric constant ε of the intervening medium, which is regarded as a kind of "black box". The adjustment or selection of ε in the range from 1 to ∞ and the use of the simple Coulomb law reveal the lack of validity of the method.

Almost all the most important features of the physical, chemical, and technical properties of organic compounds, including the possibility of the evolution of the state of the molecule in time (migration of the excitation energy or of the electron along the chain of chemical bonds) are associated directly or indirectly with conjugation and other forms of the mutual influence of atomic groups.

All forms of conjugation merit constant attention. The signs of the conjugation of σ-bonds are not an exception in this respect. They are significant even in the molecules of n-alkanes and in certain systems they actually prove more appreciable than in molecules with conjugated π-bonds. However, in view of the exceptionally great variety of the practical applications of organic compounds, it is not surprising that in some cases a strong interaction between the active centres plays an important or decisive role, while in others a weak interaction between such centres assumes this role. The latter factor has come to attract increasing attention in connection with the development of certain new types of study, including the study of the possibilities of using "submicroelectronic" systems for the transformation of information with an exceptionally high packing density, because in this instance one molecule with several active centres can in principle perform the function of a whole unit.

Advances in the experimental technique and in quantum-chemical calculations, the synthesis and study of new previously inaccessible model compounds, and the experience gained in logical analysis and generalisations, have made possible an appreciable advance in the understanding of the most important problems of theoretical organic chemistry, in particular, they have made it possible to characterise the principal aspects of conjugation with participation of heteroatoms from all the Groups of the Periodic System and to estimate at the same time the role of relativistic effects. Despite certain disappointments and a series of difficulties which have arisen at this new level of research, one can undoubtedly count on further rapid progress and the transformation of the science of molecular structure into an active research instrument designed to solve problems in practical chemistry.

Thermochemistry of the solvation of organic non-electrolytes

B N Solomonov, A I Konovalov
Kazan State University

ABSTRACT. This review surveys experimental data on the thermochemistry of the solvation of organic non-electrolytes. An analysis of the enthalpy of solvation as the sum of the enthalpies of non-specific solvation and of specific interaction is presented. The various methods for isolating the contribution of the enthalpies of the complex formation reactions between the solute and the solvent are examined. The role of the dipole moment of the solute molecule in solvation is analysed in detail.

The bibliography includes 104 references.

I. Introduction

The problem of the thermodynamics of the dissolution and solvation of organic compounds has always aroused the interest of investigators working in various fields of science where the problems of the behaviour of species in a liquid medium were raised. At the present time, the study of this problem is prosecuted in two directions. On the one hand, the "purely solution" problems are solved—for example liquid–vapour and extraction equilibria have been investigated, which is a subject of classical physical chemistry. Extensive experimental and theoretical data have accumulated in this field and generalisations have been made. These have already been reflected in the monographs of Morachevskii and co-workers.[1,2]

The quantitative features relating the thermodynamic parameters of the dissolution and solvation of organic compounds to their structural characteristics as well as the macroscopic properties of the solvents have been studied within the framework of the second aspect of the chemistry of solutions. Studies on these lines have been associated as a rule with the solution of the problem of the influence of the medium on various physicochemical processes.

Abraham and co-workers[3] have worked fruitfully on the analysis of the activity coefficients within the framework of multiparameter correlations with the properties of the medium. As a result of the efforts by Fuchs, Arnett, Krestov, the authors of the present review, as well as other investigators, extensive data have accumulated during the last two decades on the enthalpies of solution and solvation of organic non-electrolytes. It is therefore necessary to survey the existing data and to examine them from a single standpoint. In the present review, this has been done within the framework of the empirical approach developed previously.[4,5]

Problems of the solvation of compounds in binary solvents as well as problems of the thermochemistry of the hydration of organic non-electrolytes are not discussed in the present review. They have been dealt with in the monographs of Krestov and co-workers[6] and Belorusov and Panov.[7] Nor does the present review deal with the theoretical approaches to the analysis of the thermodynamic parameters of solvation, because these problems have already been described in monographs.[8,9]

II. Phenomenological description

The stability of a solute molecule A_i depends on its interaction with the molecules of the surrounding medium, i.e. with solvent molecules and with other solute molecules. Henceforth, we shall discuss only the situation where the interactions between the molecules of the solute A_i in solution have been ruled out. The thermodynamic transfer functions are used to characterise such infinitely dilute solutions. Thus the enthalpy of the transfer of the substance A_i to an infinitely dilute solution ($\Delta H_t^{A_i}$) is equal to the difference between the partial molar enthalpy of the solute A_i in the infinitely dilute solution ($\overline{H}^{A_i}$) and the partial molar enthalpy of A_i in the standard state ($\overline{H}_{st}^{A_i}$):

$$\Delta H_t^{A_i} = \overline{H}_{\infty}^{A_i} - \overline{H}_{st}^{A_i}. \quad (1)$$

If one uses the pure substance (p.s.) A_i at a temperature T and a pressure of 1 atm as the standard state [$H_{st}^{A_i}$ (p.s.)], then the enthalpy of the transfer of A_i to the infinitely dilute solution from this state represents the enthalpy of solution of compound A_i in the solvent S ($\Delta H_s^{A_i/S}$):

$$\Delta H_s^{A_i/S} = \overline{H}_{\infty}^{A_i} - \overline{H}_{st}^{A_i}\,(\text{p.s.}). \quad (2)$$

When the vapour of the pure non-electrolyte, which has the properties of an ideal gas and is at a temperature T and a pressure of 1 atm, is adopted as the standard state [$\overline{H}_{st}^{A_i}$(G)], the enthalpy of transfer represents the enthalpy of solvation of compound A_i in the solvent S ($\Delta H_{solv}^{A_i/S}$) and can be defined as follows:

$$\Delta H_{solv}^{A_i/S} = \overline{H}_{\infty}^{A_i} - \overline{H}_{st}^{A_i}\,(\text{G}). \quad (3)$$

According to Eqns. (2) and (3), the difference between the enthalpies of solution and solvation of compound A_i in the two standard states is in its turn equal to the enthalpy of evaporation of A_i ($\Delta H_{vap}^{A_i}$):

$$\Delta H_s^{A_i/S} - \Delta H_{solv}^{A_i/S} = \overline{H}_{st}^{A_i}(G) - \overline{H}_{st}^{A_i}(p.s.) = \Delta H_{vap}^{A_i}. \quad (4)$$

The enthalpy of transfer from one solvent to another $\{\delta H_s^{A_i}\}_{S_0}^{S}$, with the enthalpy of solution of A_i in the solvent S_0 adopted as the standard state, is also used in studies on the thermochemistry of dissolution and solvation:

$$\{\delta H_s^{A_i}\}_{S_0}^{S} = \Delta H_s^{A_i/S} - \Delta H_s^{A_i/S_0} = \Delta H_{solv}^{A_i/S} - \Delta H_{solv}^{A_i/S_0}. \quad (5)$$

In most cases the enthalpies of solvation of substances are determined from the differences between two experimentally measured quantities: the enthalpy of solution and the enthalpy of evaporation. Recommendations concerning the determination of the enthalpies of solution may be found in original communications, for example that of Izaat et al.[10] The methods used for the measurement, the estimation of errors, and the analysis of the enthalpy of evaporation data have been described in the monograph of Lebedev and Miroshnichenko.[11]

III. Enthalpies of solvation of alkanes in various media

Systems where the solute is an alkane (Y) are relatively simple from the standpoint of the study of the nature of the forces of the intermolecular interaction which determines the solvation of alkanes. Frequent attempts have been made to calculate the enthalpies of solvation of alkanes in different, media representing it in the form of dispersion and induction interactions.[12]

The problem of the study of the thermodynamics of the solvation of alkanes usually reduces in essence to seeking the increment per $-CH_2-$ group.[12–14] This increment is found by determining the slope of the linear relation between the enthalpies of solvation of alkanes in a solvent S and the number of carbon atoms n_C in the molecule of the dissolved alkane.

The influence of the branching of the alkane on the enthalpy of its solvation has been investigated[15] and it has been shown that the enthalpy of solvation of a normal hydrocarbon is greater in absolute magnitude than that of a branched hydrocarbon with the same number of carbon atoms in the molecule. The authors[15] explained this effect by the fact that steric hindrance arises in the interaction of the quaternary carbon atom with solvent molecules.

The dependence of the enthalpies of solution and evaporation of alkanes on their molar volumes [$V_M^{Y_i}$] and molecular refractions

$$[MR^{Y_i} = V_M^{Y}(n^2-1)/(n^2+2)],$$

has been investigated[4,5] and correlations have been established for the enthalpies of solution:

$$\Delta H_s^{Y_i/S} = k_S^{V_M} V_M^{Y_i}, \quad (6)$$

$$\Delta H_s^{Y_i/S} = k^{MR} MR^{Y_i}. \quad (7)$$

The proportionality coefficients $k_S^{V_M}$ and k^{MR} in Eqns. (6) and (7) represent individual characteristics of the solvent and their significance will be revealed below. It is noteworthy that Eqns. (6) and (7) are applicable to liquid alkanes. If the enthalpies of solution of solid alkanes are analysed, then, according to Eqns. (6) and (7), the ratio of the enthalpies of transfer of alkanes is equal to the ratio of their molar volumes and molecular refractions, because the contribution of the enthalpy of fusion of the same substance to the enthalpy of its solution in a series of solvents is constant.

In contrast to the enthalpies of solution, the enthalpies of evaporation of alkanes $\Delta H_{vap}^{Y_i}$ depend significantly on the degree of branching of the carbon skeleton, groups of hydrocarbons with the same degree of branching giving rise to several almost parallel lines on the plot of $\Delta H_{vap}^{Y_i}$ against MR^{Y_i}:[4]

$$\Delta H_{vap}^{Y_i} = a_Y + bMR^{Y_i}, \quad (8)$$

where a_Y is a constant term which depends on the structure of the alkane (kJ mol^{-1}) and b = 1.05 kJ cm^{-3}. For linear alkanes, a_Y = 0.91 ± 0.94 kJ mol^{-1} and for monocyclic hydrocarbons, a_Y = 4.39 ± 0.62 kJ mol^{-1}. the appearance in the alkane molecule of one tertiary or one quaternary carbon atom leads to a decrease in the enthalpy of evaporation by 1.31 ± 0.41 or 4.60 ± 0.93 kJ mol^{-1} respectively compared with the value for the unbranched hydrocarbon with the same number of carbon atoms. Here one should bear in mind that the degree of branching of hydrocarbons hardly alters their molecular refraction.

If Eqns. (4) and (8) are valid, then the enthalpy of solvation of an alkane Y_i in a solvent S is linearly related to the molar refraction of the dissolved hydrocarbon:

$$-\Delta H_{solv}^{Y_i/S} = a_Y + k_S^i MR^{Y_i}. \quad (9)$$

An example of such relations is presented in Fig. 1. The constant term a_Y in Eqn. (9) is almost independent of the type of solvent and is determined solely by the structural characteristics of the dissolved hydrocarbon. The coefficient k_S^i depends on the properties of the solvent and can be estimated from the equation

$$k_S^i = b - k_S^{MR(V_M)}. \quad (10)$$

Fuchs and Stephenson[14] found an empirical relation between the enthalpies of solvation of the methylene group in various solvents and solvent parameters such as the Taft–Kamlert π^* constant and a polarisability [function] $(n^2-1)/(2n^2+1)$:

$$\Delta H_{solv}^{-CH_2-} = -3.68 + 1.61(\pi^*)^2 - 5.99(n^2-1)/(2n^2+1). \quad (11)$$

By adding together several empirical correlations,[7,9,11] it is possible to obtain an expression which permits the estimation of the enthalpy of solvation of any alkane from its molar refraction, structural characteristics (A_Y), and the empirical parameters of the solvents:

$$\Delta H_{solv}^{Y_i/S} = a_Y + \left\{0.79 + 0.347(\pi^*)^2 + 1.29\frac{(n^2-1)}{(2n^2+1)}\right\} MR^{Y_i}. \quad (12)$$

The results presented in Table 1 show that there is agreement between the enthalpies of solvation calculated by Eqn. (12) and the experimental values.

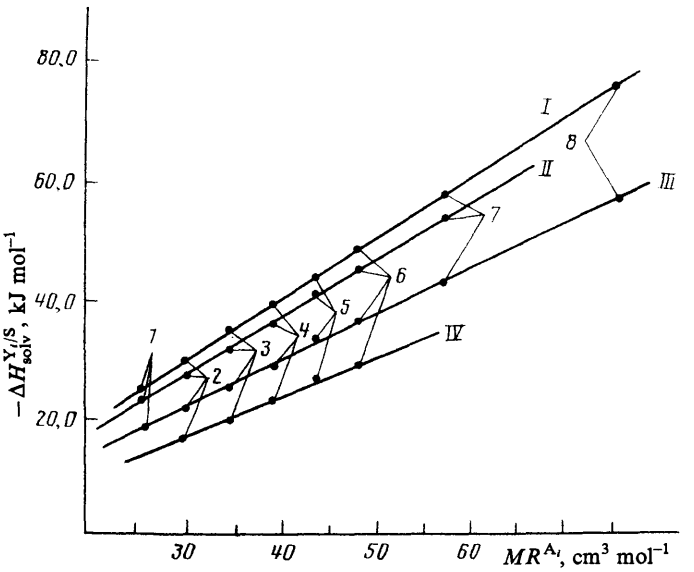

Figure 1. Relation between the enthalpies of solvation of alkanes and their molecular refractions in various solvents; (I) n-heptane; (II) n-butyl chloride; (III) dimethylformamide (DMF); (IV) dimethyl sulphoxide (DMSO). The numbers of the points correspond to the following compounds: *1*, n-pentane; *2*, n-hexane; *3*, n-heptane; *4*, n-octane; *5*, n-nonane; *6*, n-decane; *7*, n-dodecane; *8*, n-hexadecane. The enthalpies of solvation were taken from Fuchs and Stephenson.[14]

The relation obtained by Fuchs and Stephenson[14] is important also for the development of ideas about the solvation of organic compounds of different classes, because many organic compounds contain alkyl groups, the enthalpies of solvation of which enter additively into the enthalpy of solvation of the entire molecule.

The alkane solvation process can be subdivided arbitrarily into two stages:

(1) the creation in the solvent of a cavity whose size corresponds to the dimensions of the dissolved alkane molecule;

(2) the accommodation in this cavity of a molecule of the dissolved alkane and its interaction with solvent molecules.

Hence the enthalpy of solvation of an alkane can be represented by the sum of the enthalpies of formation of the cavity ($\Delta H_{cav}^{Y_i/S}$) and the enthalpy of the interaction of the alkane with the solvent ($\Delta H_{int}^{Y_i/S}$);

$$\Delta H_{solv}^{Y_i/S} = \Delta H_{cav}^{Y_i/S} + \Delta H_{int}^{Y_i/S}. \quad (13)$$

The problem of the subdivision of the solvation energy into the energy of formation of the cavity in the solvent and the energy of the interaction of the solute with the solvent has begun to be studied particularly vigorously during the last decade,[16–23] although this question had been raised already in the 1930's.[24,25] At the present time, there are two methods for calculating the energy of formation of the cavity. One of them is associated with the use of the theory of scaled particles (SPT) developed by Riess et al.[26] Another method for the calculation of the energy of formation of the cavity, based on the use of the concept of surface tension, was proposed by Sinanoglu.[27] It is noteworthy that the application of these methods to the calculation of the energy of the cavity leads to markedly divergent results.[18,19]

Table 1. Experimental enthalpies of solvation (kJ mol^{-1}) of cyclohexane and n-hexane in a series of solvents (298 K) and their values calculated by Eqn. (12).

Note. The enthalpies of solvation of the alkanes were taken from Refs.14, 15, and 29.

Attempts have been made to estimate experimentally the energy of formation of the cavity.[15,28–30] This was done most logically in the studies of the present authors and their co-workers.[28,29] The method proposed[28,29] was based on the following assertions: (1) the energy of formation of the cavity depends only on the energy of the solvent–solvent interaction and on the size of the solute molecules; (2) the energy of the interaction of the alkane with the solvent per unit volume of the latter is constant. The validity of the second postulate has been demonstrated in a series of studies.[31–34]

The enthalpy of solution of an alkane Y_i in a solvent S is described by the expression

$$\Delta H_s^{Y_i/S} = \Delta H_{vap}^{Y_i} + \Delta H_{cav}^{Y_i/S} + \Delta H_{int}^{Y_i/S}. \quad (14)$$

Taking into account the postulate that the energy of the interaction of the alkane with different organic non-electrolytic solvents is

constant, the differences between the enthalpies of solution of alkanes in a series of solvents are then determined by the differences between the enthalpies of formation of the cavity in these solvents:

$$(\delta H_s^{Y_i})_{S_h}^{S} = (\delta H_{cav}^{Y_i})_{S_h}^{S}, \quad (15)$$

where S_h is a hypothetical solvent in which the heats of solution of all saturated hydrocarbons are zero. It has been suggested[28,29] that each solvent be characterised by the specific relative enthalpy of formation of the cavity (δh_{cav}^{S}), which is equal to the proportionality coefficient k_S in Eqns. (6) and (7). Knowing k_S and the molecular refraction or molar volume of the substance A_i, it is possible to calculate the relative enthalpy of formation of the cavity generated by A_i in the solvent and to determine the enthalpy of the interaction of the solute with the solvent by an equation analogous to Eqn. (15).

The solvation energy has been represented[35] by three terms; the energy of formation of the cavity, the energy of the interaction of the solute with the solvent, and the energy of the reorganisation of the solvent molecules around the cavity in the solvent. The last term can be regarded as the "response" of the solvent to the replacement in the latter of a hypothetical molecule, not interacting with the solvent, by the real molecule which is capable of entering into various intermolecular interactions of the solvent–solute type.

Kiselev et al.[36] proposed a rigorous axiomatic approach to the consideration of the solvation process, which make it possible to justify theoretically the existing ideas in the literature concerning solvation as a multistage process and to estimate the limits of its applicability.

IV. Enthalpies of solvation of various compounds in alkanes

The thermochemistry of solvation of various compounds in alkanes has been studied in a number of investigations.[31,32,37–49] A universal relation between the enthalpies of solvation of compounds in cyclohexane and their molecular refractions was obtained on the basis of the results. It holds for most varied classes of compounds (Fig. 2). It is noteworthy that Fig. 2 presents data for compounds whose molecules contain an unbranched hydrocarbon skeleton. For cases where the solute molecule has a branched hydrocarbon skeleton, regularities have been found in the deviations from the linear relation between $\Delta H_{solv}^{A_i/S}$ and MR^{A_i}. An attempt has been made[5] to explain the universal relation between the enthalpies of solvation of compounds in cyclohexane and their molecular refractions on the basis of existing ideas about intermolecular interaction. It was verified if the molecular refraction is the only parameter of a substance to which its enthalpy of solvation in an alkane is linked by such a simple relation. For this purpose, correlations were drawn between $\Delta H_{solv}^{A_i/C_6H_{12}}$ and the molar volume ($V_M^{A_i}$), the molar magnetic susceptibility ($\chi_M^{A_i}$), and the surface area (A_W) calculated by Bondi's method:[50]

$$-\Delta H_{solv}^{A_i/C_6H_{12}} = 13.13 + 0.207 V_M^{A_i},$$
$$n = 72,\ r = 0.92,\ S_0 = 26.6;$$

$$-\Delta H_{solv}^{A_i/C_6H_{12}} = 15.21 + 1.995 \chi_M^{A_i},$$
$$n = 41,\ r = 0.95,\ S_0 = 16.4;$$

$$-\Delta H_{solv}^{A_i/C_6H_{12}} = 6.4 + 3.51 A_W,$$
$$n = 74,\ r = 0.80,\ S_0 = 7.99.$$

Comparison of the correlation parameters of the equation shows that the best description of the enthalpies of solvation in an alkane can be obtained with the aid of molecular refraction:

$$-\Delta H_{solv}^{A_i/C_6H_{12}} = 5.09 + 1.03 MR^{A_i}, \quad (16)$$
$$n = 102,\ r = 0.994,\ S_0 = 1.56.$$

Molecular refraction is known to be a thermodynamically invariant quantity.[51] Furthermore, the solvent exerts only a weak influence on it.[52] Molecular refraction and polarisability are sometimes regarded as measures of the "intrinsic volume" of molecules[53] or as the factors responsible for dispersion interactions. In the thermodynamics of solutions, the volume properties of the solute molecules are expressed in terms of the limiting values of the partial molar volumes ($\overline{V}_M^{A_i}$). It is believed that $\overline{V}_M^{A_i}$ is mainly made up of two quantities: the intrinsic volume of the molecule and the change in the volume of the solution as a result of the influence of the dissolved molecule on the packing of the solvent molecules in the perturbed part of the solution.[54]

The concept of the "intrinsic volume" of the molecule in a liquid is highly indefinite. The molecular size is sometimes expressed in terms of the molar volume, the van der Waals volume, the parachor, or the molar refraction. The interpretation of the observed relation between $\Delta H_{solv}^{A_i/C_6H_{12}}$ and MR^{A_i} would be greatly simplified if there were a relation between MR^{A_i} and $\overline{V}_M^{A_i}$. However, there are too few data for the partial molar volumes of different compounds in alkanes to reach any serious conclusions and the small amount of information available indicates the absence of a general relation between MR^{A_i} and $\overline{V}_M^{A_i}$.[5]

The interaction of alkanes with organic compounds has been discussed[12,38] within the framework of not only dispersion but also induction interactions. The existence of a relation between $\Delta H_{solv}^{A_i/C_6H_{12}}$ and MR^{A_i} in cyclohexane shows that, when solvation phenomena involving alkanes are considered, the induction interactions can be neglected, since, if it were the case that the contribution of these interactions plays a significant role, then for compounds having the same MR^{A_i} but different dipole moments, for example, for cyclooctane (μ = 0 D, MR^{A_i} = 36.5 cm^3 mol^{-1}) and acetophenone (μ = 3 D, MR^{A_i} = 36.5 cm^3 mol^{-1}), the enthalpies of solvation would not be the same, as indicated by experimental data. The molecular dipole moments of compounds dissolved in cyclohexane (Fig. 2) differ by several units. Since there is no general relation between molecular refraction and the dipole moment, the linear relation between $\Delta H_{solv}^{A_i/C_6H_{12}}$ and MR^{A_i} implies that, within the limits of experimental error, the enthalpies of solvation of compounds in alkanes are determined by forces related to the polarisability of molecules. It is believed that these forces are induced by dispersion interactions. Experimental enthalpies of solvation of compounds in cyclohexane have been compared[5] with the energies of dispersion interactions calculated in different ways. It has been shown that only the Kirkwood–Muller equation[16] reproduces the observed relation between $\Delta H_{solv}^{A_i/C_6H_{12}}$ and MR^{A_i} to an adequate degree of approximation.

The universal relation discovered[31,32] between the enthalpies of solvation of compounds in cyclohexane and their refractions created new possibilities for the determination of the enthalpies of solvation of compounds in other solvents. The point is that, in the present stage of the experimental determination of enthalpies of solvation, this is primarily the problem of measuring the enthalpy of evaporation of the solute. The problem consists not only in the fact that it is extremely difficult to measure $\Delta H_{vap}^{A_i}$ but also in the

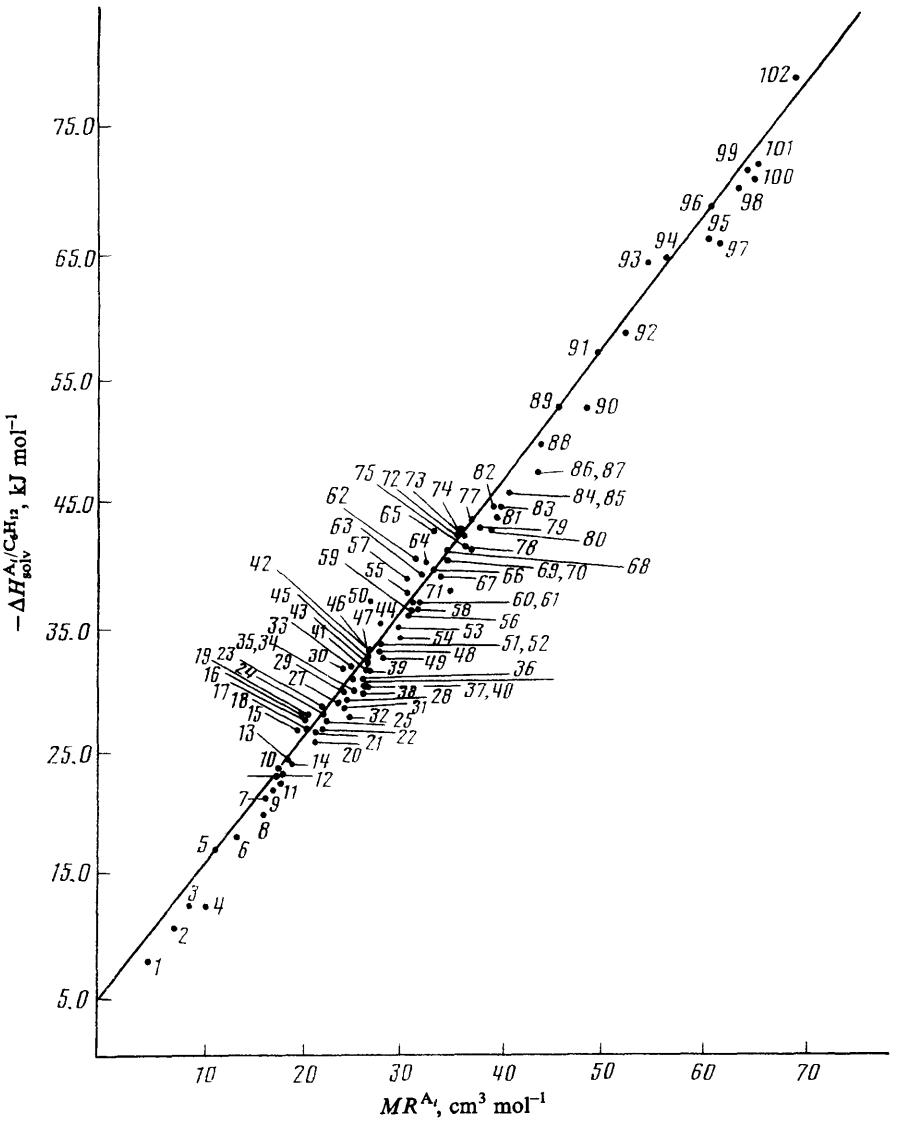

Figure 2. Relation between the enthalpies of solvation of compounds in cyclohexane and their molar refractions. The numbers of the points correspond to the following compounds: *1*, water; *2*, hydrogen chloride; *3*, methanol; *4*, hydrogen bromide; *5*, propionitrile; *6*, ethanol; *7*, propanal; *8*, propanone; *9*, 1-cyano-2-propene; *10*, 2-propen-1-ol; *11*, 1-propanol; *12*, methyl acetate; 13, 1-amino-2-propene; *14*, iodomethane; *15*, ethyl nitrate; *16*, tetrahydrofuran; *17*, chloroform; *18*, *cis*-1,2-dichloroethylene; *19*, *trans*-1,2-dichloroethylene; *20*, butanone; *21*, carbon disulphide; *22*, 1-butanol; *23*, methyl propionate; *24*, ethyl acetate; *25*, dimethyl sulphite; *26*, 1,4-dioxane; *27*, propane-1-thiol; *28*, 1-aminobutane; *29*, 1,2-dimethoxyethane; *30*, pyridine; *31*, thiophen; *32*, hexafluorobenzene; *33*, cyclopropyl methyl ketone; *34*, 2-pentanone; *35*, 3-pentanone; *36*, trichloroethylene; *37*, 1-chlorobutane; *38*, 1,4-difluorobenzene; *39*, fluorobenzene; *40*, benzene; *41*, carbon tetrachloride; *42*, piperidine; *43*, 1-pentanol; *44*, ethyl chloroacetate; *45*, methyl butyrate; *46*, n-propyl acetate; *47*, cyclohexane; *48*, 1-bromobutane; *49*, iodine; *50*, phenol; *51*, butane-1-thiol; *52*, 1-iodopropane; *53*, 2-hexanone; *54*, 3-hexanone; *55*, aniline; *56*, 1,1-dichlorobutane; *57*, 1,1,2,2-tetrachloroethane; *58*, 1-hexanol; *59*, chlorobenzene; *60*, n-butyl acetate; *61*, methyl valerate; *62*, benzonitrile; *63*, benzaldehyde; *64*, methyl trichloroacetate; *65*, nitrobenzene; *66*, methyl phenyl ether; *67*, bromobenzene; *68*, thiophenol; *69*, 2-heptanone; *70*, 4-heptanone; *71*, phenylacetylene; *72*, 1,4-dichlorobenzene; *73*, 1,2-dichlorobenzene; *74*, heptanol; *75*, vinylbenzene; *76*, acetophenone; *77*, ethyl trichloroacetate; *78*, phenyl acetate; *79*, methyl benzoate; *80*, 2-octanone; *81*, iodobenzene; *82*, 1,3-dinitrobenzene; *83*, methyl phenyl sulphide; *84*, 1-octanol; *85*, *N*,*N*-di-methylaniline; *86*, 2-nonanone; *87*, 5-nonanone; *88*, naphthalene; *89*, 1,2,4,5-tetrachlorobenzene; *90*, 2-decanone; *91*, 1-decanol; *92*, biphenyl; *93*, hexachlorobenzene; *94*, benzophenone; *95*, *cis*-azobenzene; *96*, phenanthrene; *97*, benzil; *98*, *trans*-azobenzene; *99*, anthracene; *100*, 1-bromodecane; *101*, 1,2-diphenylethylene; *102*, diphenylmercury. The enthalpies of solution and solvation were taken from Refs. 5, 31, 32, and 37–49.

fact that traditionally this problem is dealt with by specialists who use the values of $\Delta H_{vap}^{A_i}$ to determine the enthalpy of formation of a substance in the gas phase. It is quite natural that the set of experimental enthalpies of evaporation produced by them is suitable in the first place for the solution of problems in this field. Among the investigators known to us only Fuchs[47] and Suvorov and Kondrat'ev[55] measured enthalpies of evaporation in order to study solvation phenomena.

We proposed[4,31,32] a version of what is in our view an extremely convenient method for the determination of $\Delta H_{vap}^{A_i}$, which for many compounds is not inferior to dissolution calorimetry as regards its productivity and simplicity of its application. It is based on the use of the observed relation between the enthalpies of solvation of compounds in cyclohexane and their molar refractions. The determination of the enthalpy of evaporation in this method reduces to measurements of the enthalpy of solution of the given compound in cyclohexane and of its molecular refraction:

$$\Delta H_{vap}^{A_i} = \Delta H_s^{A_i/C_6H_{12}} + 4.39 + 1.05MR^{A_i}. \quad (17)$$

For compounds with a branched hydrocarbon skeleton, it is necessary to introduce the appropriate corrections.[32] Unfortunately, it is difficult to determine the error of the measurement of $\Delta H_{vap}^{A_i}$ by the method described,[31,32] because the existing significant discrepancies with literature data may be caused either by the limited applicability of Eqn. (17) or by the not always correct measurement of $\Delta H_{vap}^{A_i}$ by direct methods (the errors in the measurement of the enthalpies of solution of compounds in cyclohexane are not so great).

We shall now discuss the advantages of the method based on Eqn. (17). Firstly, in this method the molecular weight and the state of aggregation of the substance do not have such a significant influence on the accuracy of the measurement of $\Delta H_{vap}^{A_i}$ because the enthalpy of solution in alkane does not depend greatly on these parameters. An increase in the molecular weight of the substance leads in essence to a decrease in the relative error in the determination of the enthalpy of evaporation. Secondly, the determination of $\Delta H_{vap}^{A_i}$ for involatile compounds by classical methods requires fairly high temperatures. Many organic and organoelement compounds tend to decompose at these temperatures. Therefore, for compounds of this kind our method[31,32] may prove to be virtually the only one suitable at the present time.

There is no doubt that the direct experimental measurement of the enthalpy of evaporation is more promising from the standpoint of the accuracy of its determination. However, bearing in mind the difficulties in the determination of the enthalpy of formation at the present stage, the method based on the use of Eqn. (17) is, in our view, an essential instrument for the investigation of the thermochemistry of solvation over a wide range of organic compounds. Fuchs et al.[56] recently improved the equation relating the enthalpy of solvation and the molar refraction and put forward the following two parameter equation:

$$-\Delta H_{solv}^{A_i/S} = a + bMMR^{A_i} + cV_M^{A_i}, \quad (18)$$

where

$$MMR^{A_i} = V_M^{A_i} \quad (n^2-1)/(n^2+2),$$

is a function of polarisability. It was shown[56] that, for the range of compounds investigated (carbon tetrachloride, perfluoroheptane, diiodomethane, benzene, hexane, decane, hexadecane, cyclohexane, toluene, and mesitylene), Eqn. (18) describes the enthalpy of solvation better than Eqn. (17).

V. The influence of the polarity of the medium on the enthalpy of the non-specific solvation of organic non-electrolytes

Before proceeding to the description of this problem, it appears to be necessary to discuss the concept of the polarity of a non-electrolyte. The dipole moment of a molecule is the most widely used measure of the polarity of a non-electrolyte when solvation phenomena are considered. However, there exists also another viewpoint on the determination of the polarity of solute molecules which has been most fully formulated by Claessens et al.[57] These authors believe that the postulate that any polar molecule should possess a dipole moment is incorrect. Thus a molecule may have no dipole moment owing to the complete compensation of two systems of the distribution of charge density in the molecule, each of which is characterised by a dipole moment. The molecules having such a charge distribution have a quadrupole moment and are polar. The same considerations can be applied when oppositely directed quadrupoles are considered, etc. The authors[57] therefore suggest that the expression "polar molecule" be replaced by the expressions "dipolar molecule", "quadrupolar molecule", etc. The energies of electrostatic interactions for such molecules can be calculated by the equation[57]

$$\Delta G_{int} = -N_{A_i}\left[\frac{1}{2}\frac{2(\varepsilon_S-1)}{2\varepsilon_S+1}\frac{\mu_\alpha^2}{a^3} + \frac{1}{6}\frac{6(\varepsilon_S+1)}{3\varepsilon_S+2}\frac{\theta_{\alpha\beta}}{a^5} + \frac{1}{30}\frac{24(\varepsilon_S-1)}{4\varepsilon_S+3}\frac{\Omega_{\alpha\beta\gamma}}{a^7} + \ldots\right], \quad (19)$$

where ε_S is the dielectric constant of the solvent, μ_α a component of the dipole moment, a the radius of the cavity in which the molecule has been placed, $\theta_{\alpha\beta}$ a component of the quadrupole moment, and $\Omega_{\alpha\beta\gamma}$ a component of the octupole moment.

The idea of the polarity of the substance as a combination of the properties of dipolarity and polarisability appears less definite.[58] We adopt the dipole moment of the solute molecule as a measure of its polarity. The dielectric constant is adopted as a measure of the solvent polarity. Hence the problem of polarity reduces to the elucidation of the influence of these parameters on the energy of non-specific solvation.

The contribution of polar interaction is usually estimated by applying the homomorph principle, according to which the enthalpy of non-specific solvation, determined by dispersion forces for a compound capable of specific $[\Delta H_{int}^{A_i/S}(sp)]$ or polar $[\Delta H_{int}^{A_i/S}(or)]$ interactions is set equal to the enthalpy of solvation of a compound incapable of such interactions. An alkane Y_i with a molar volume equal to that of the solute A_i is usually selected as the homomorph:

$$\Delta H_{solv}^{A_i/S} - \Delta H_{solv}^{Y_i/S} = \Delta H_{int}^{A_i/S}(sp) + \Delta H_{int}^{A_i/S}(or). \quad (20)$$

If the polar molecule does not enter into a complex formation reaction with the solvent, the difference on the left-hand side of Eqn. (20) represents in this case the enthalpy of orientation interaction.

As can be seen from Eqn. (20), the homomorph method is based on the hypothesis that the dispersion interactions are determined

solely by the size of the solute molecules. However, it has been shown[4,59] that this hypothesis is incorrect, and the contributions of orientation interaction to the enthalpy of solvation, calculated by Eqn. (20), therefore represent overall quantities.

In this section, we shall attempt to show, using both our own and literature data, that the molecular dipole moment of the solute does not exert a significant influence on the enthalpy of solvation. The existence of a relation between the enthalpies of solvation of compounds of different polarity in cyclohexane (Fig. 2) and their molar refraction shows that the dipole–induction interactions do not make a significant contribution to the enthalpy of solvation.

The enthalpies of solvation of benzene and its halo-derivatives in cyclohexane and dimethyl sulphoxide are compared in Table 2. As can be seen from the results presented in Table 2, the difference between the enthalpies of solvation of chlorobenzene and benzene in cyclohexane and dimethyl sulphoxide ($\varepsilon_{C_6H_{12}}$ = 2.02, $\varepsilon_{(CH_3)_2SO}$ = 46.6) is approximately the same despite the fact that the polarities of the two solutes differ ($\mu_{C_6H_5Cl}$ = 1.7 D, $\mu_{C_6H_6}$ = 0 D). The enthalpies of solvation of these compounds are determined by dispersion forces. Relatively small differences between the $\Delta H_{solv}^{A_i/S}$ for halobenzenes in the two solvents can therefore be attributed, in principle, to their orientation interaction with dimethyl sulphoxide. However, the small size of the postulated orientation interaction of halobenzenes with the polar dimethyl sulphoxide is a major embarrassment. The results of Krichnan and Friedman[35] and Fuchs et al.[45] therefore stimulated our interest in the problem of solvation of aromatic hydrocarbons and their halo-derivatives.[59–61] It was found that, despite the difference between the polarities ($\Delta\mu$ = 2.5 D) of the solutes and solvents ($\Delta\varepsilon_S$ = 59), in all the cases investigated there is an excellent linear relation between $\Delta H_{solv}^{A_i/S}$ and the molar refraction of the solute:

$$-\Delta H_{solv}^{A_i/S} = a_S + b_S MR^{A_i}. \qquad (21)$$

Table 2. Enthalpies of solvation (kJ mol^{-1}) of benzene and fluoro-, chloro-, and bromo-benzenes in dimethyl sulphoxide and cyclohexane (298 K).

Solvent	$-\Delta H_{solv}^{C_6H_5X/S}$				Refs.
	X=H	X=F	X=Cl	X=Br	
Dimethyl sulphoxide	31.1	34.2	38.1	41.6	[35]
Cyclohexane	29.9	30.9	36.5	39.3	[45]

These results imply that the contribution of orientation interactions to the enthalpies of solvation of the test compounds is insignificant.

Another method of estimating the contribution of orientation interactions to the enthalpy of solvation has also been used[59–61] — comparison of the enthalpies of solution and solvation of compounds differing only in dipole moment. Such compounds are, in particular, the *o*-, *m*-, and *p*-isomers of disubstituted benzenes and the *cis*- and *trans*-isomers of disubstituted ethylenes. Pairwise comparison of the enthalpies of solution of these compounds in a series of solvents yielded a straight line with a slope close to unity.[59–61] The solvent polarity was varied within wide limits (from carbon tetrachloride to dimethyl sulphoxide). According to Eqn. (5), the difference between the enthalpies of solvation of compounds is equal to the difference between their enthalpies of solution. Hence it follows that the relative enthalpy of solvation is independent of the dipole moment ($\Delta\mu$ = 6.0 D) of the solute molecule.

The absence of an influence of the molecular dipole moment of the solute on the enthalpies of solvation of the organic non-electrolytes investigated may be due to several causes. Firstly, it is possible that not the dipole moment of the molecule as a whole but the dipole moments of individual groups or bonds in the molecule are important for solvation. This hypothesis makes it possible to explain the identical enthalpies of solvation of isomers. Secondly, the molecules investigated in the studies mentioned above [35,45,59–61] are fairly large and the continuous theory with the aid of which the contribution of electrostatic interactions to the solvation energy is estimated requires allowance not only for the dipole moment of the molecule but also for the size of the latter,[62] which was not done. Thirdly, it is possible that the contributions of polar interactions to the enthalpy of solvation are compensated by the energy of reorganisation of the solvent.[4,59] A detailed analysis of the causes which induced such an unusual phenomenon is therefore necessary.

The version which states that, for the analysis of the factors determining the solvation energy one must take into account not the dipole moment of the molecule as a whole but the dipole moments of its individual groups, appeared many years ago and was based on the study of different physicochemical characteristics of halobenzenes.[63]

The influence of the dipole moment of the $C_{Ar}-Hal$ bond on the enthalpies of solvation of halobenzenes was tested.[4,59] Since the dipole moment of the $H-C_{Ar}$ bond (0.7 D [64]) is approximately equal in absolute magnitude to the dipole moment of the $C_{Ar}-Hal$ bond (1.0 D [65]), the substitution of hydrogen atoms by halogen atoms in the molecule should not alter significantly the "polarity" of the latter. From this standpoint, the "polarities" of halobenzenes and benzene are the same. On the other hand, naphthalene, diphenyl, and anthracene are more "polar" than benzene, because they contain a larger number of polar bonds. If there is a linear relation between $\Delta H_{solv}^{A_i/S}$ for aromatic hydrocarbons and polyhalobenzenes and their MR^{A_i} while the dipole moments of individual bonds in the solute molecule influence its enthalpy of solvation, then at least a parallel variation should be observed between the characteristic of the "polarity" of the solute

$$n\sum_{i=1}^{n}\mu_i(C_{Ar}-H) \quad \text{or} \quad n\sum_{i=1}^{n}\mu_i(C_{Ar}-Hal),$$

and its molecular refraction. However, it has been shown[4,59] that such parallel variation is not observed. This means that the dipole moment of the $C_{Ar}-H$ or $C_{Ar}-Hal$ bond does not influence significantly the enthalpies of solvation of halobenzenes.

VI. Enthalpy of complex formation as a component of the enthalpy of solvation

The enthalpy of solvation of a substance can be represented by the sum of the enthalpies of non-specific solvation $\Delta H_{solv}^{A_i/S}$ and specific interaction $\Delta H_{int}^{A_i/S}$ (sp):

$$\Delta H_{solv}^{A_i/S} = \Delta H_{solv}^{A_i/S}(\text{non-sp}) + \Delta H_{int}^{A_i/S}(\text{sp}). \qquad (22)$$

The enthalpy of the specific interaction of the solute with the solvent represents the enthalpy of the complex formation reaction ($\Delta H_c^{A_i/S}$) (of the type of reaction involving the formation of hydrogen or donor–acceptor bonds between the solute and solvent molecules) per mole of the solute.

There are conflicting points of view in the literature on the relative contributions of the enthalpies of non-specific solvation and specific interaction to the enthalpy of solvation. Before proceeding to the discussion of the question of the subdivision of the enthalpy of solvation into components [Eqn. (22)], we shall demonstrate that these relative contributions may be different (Table 3).

Table 3. Relation between the enthalpies of non-specific solvation and the enthalpies of specific solvation (kJ mol^{-1}) for a series of compounds (at 298 K).[66]

Solute A_i in a solvent S	$-\Delta H_{solv}^{A_i/S}$(non-sp)	$-\Delta H_{int}^{A_i/S}$(sp)
Phenol in benzene	44.3	4.6
Iodine in chlorobenzene	37.7	4.6
Pyrrole in dimethylformamide	37.2	13.4
Phenol in pyridine	44.1	30.4
Water in tetrahydrofuran*	18.3	20.2
Water in dimethyl sulphoxide*	16.4	32.6

*Data taken from Somonov et al.[67] are quoted.

The development of a method for the subdivision of $\Delta H_{solv}^{A_i/S}$ into components consists in finding general principles of some kind which govern the determination of the enthalpy of non-specific solvation. Thus, from the difference between the enthalpies of solvation and non-specific solvation, we obtain the enthalpy of specific interaction, which may be compared with the enthalpy of complex formation, determined, for example, by spectroscopic methods. The agreement between the latter quantities may be a test of the validity of the method of subdivision of the enthalpy of solvation. Naturally, the most general principles governing the determination of the enthalpy of non-specific solvation can be deduced only when the principal quantitative relations involving the variation of the enthalpy as a function of the structural characteristics of the solute have become clear. Apparently the above problem cannot be fully solved at the present time but the search for ways of solving the problem of the subdivision of $\Delta H_{solv}^{A_i/S}$ into components by deducing the general principles governing the determination of the enthalpy of non-specific solvation nevertheless appears more progressive than the search for partial solutions.[44,68,69]

The simplest method of estimating the enthalpy of specific interaction consists in determining the difference between the enthalpies of solution in a solvent S and in a solvent I (usually carbon tetrachloride or an alkane) which is inert from the standpoint of the possibility of the formation of specific bonds with the solute:

$$\Delta H_{int}^{A_i/S}(sp) = \Delta H_s^{A_i/S} - \Delta H_s^{A_i/I} = \Delta H_{solv}^{A_i/S} - \Delta H_{solv}^{A_i/I}. \quad (23)$$

The disadvantages of this method as well as its modified version[70] have been discussed.[66] The method for the determination of $\Delta H_{int}^{A_i/S}$ (sp) according to which the enthalpy of specific interaction is determined from the difference between the enthalpies of solvation in a solvent S of the test compound A_i and of a compound M_i, which resembles A_i as regards molecular size, structure, and the parameters responsible for the non-specific interaction but is incapable of entering into specific interactions with the solvent S is free from fundamental disadvantages:

$$\Delta H_{int}^{A_i/S}(sp) = \Delta H_{solv}^{A_i/S} - \Delta H_{solv}^{M_i/S}. \quad (24)$$

Since the enthalpy of solvation of the compound M_i models the enthalpy of the non-specific solvation of compound A_i, M_i is referred to as a model compound.

The method based on Eqn. (24) has been used to determine the enthalpies of formation of hydrogen bonds between the molecules of pyridine, water, and methanol,[71] diazines, water, and methanol,[72] and oct-1-yne and a series of proton-accepting solvents.[73]

In order to obviate the difficulty involving the determination of $\Delta H_{vap}^{A_i}$, Arnett and co-workers[44,68,69] suggested that the enthalpy of specific interaction be determined from the equation

$$\Delta H_{int}^{A_i/S}(sp) = [\Delta H_s^{A_i/S} - \Delta H_s^{A_i/CCl_4}] - [\Delta H_s^{M_i/S} - \Delta H_s^{M_i/CCl_4}]. \quad (25)$$

This method, known as the "pure base method", has been used in numerous investigations.[74–80]

Spencer et al.[78] proposed an equation which makes it possible to calculate the enthalpy of specific interaction from the enthalpies of the transfer of compounds from one solvent to another.

Two further new methods for isolating the contribution of the enthalpy of specific interaction have been developed recently.[4,66,67,81–85] One of them[4,66,67,81] is based on the study of the dependence of the enthalpies of solvation of compounds in carbon tetrachloride on the molecular refraction, which makes it possible to classify the solutes in terms of the type of non-specific solvation: for example, aromatic hydrocarbons and their halo-derivatives; monofunctional aromatic compounds containing the nitrile, carbonyl, nitro-, amino-, and hydroxy-groups. This classification makes it possible to find the enthalpies of non-specific solvation of various compounds from the relation between $\Delta H_{solv}^{A_i/S}$ and MR^{A_i} established for compounds of the same type but incapable of specific interaction with the solvent.

Fig. 3 presents the relation between the enthalpies of solvation of some of the compounds investigated in the above studies[4,66,67,81] and their molecular refractions in carbon tetrachloride and in acetonitrile. The enthalpies of solvation of compounds in carbon tetrachloride are non-specific. In acetonitrile the picture is somewhat different: the points corresponding to compounds capable of specific interaction with the solvent deviate from the general relation. The magnitudes of the deviation of these points, determined from the plot of $\Delta H_{solv}^{A_i/S}$ and MR^{A_i} (Fig. 3*a*), is virtually equal to the enthalpy of complex formation between the solute† and the solvent determined in an inert solvent.

†The data for water are an exception, because the water molecule contains two hydrogen atoms capable of complex formation with the solvent.[67]

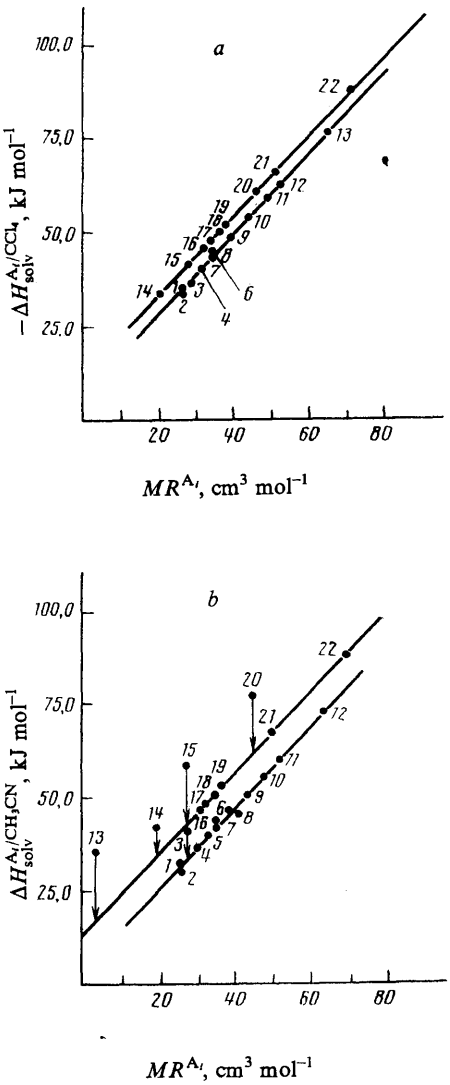

Figure 3. Relation between the enthalpies of solvation of compounds in carbon tetrachloride (*a*) and acetonitrile (*b*) and their molar refractions. The numbers of the points correspond to the following compounds: *1*, fluorobenzene; *2*, benzene; *3*, iodine; *4*, chlorobenzene; *5*, bromobenzene; *6*, *o*-dichlorobenzene; *7*, *p*-dichlorobenzene; *8*, iodobenzene; *9*, naphthalene; 10, 1-chloronaphthalene; *11*, biphenyl; *12*, anthracene; *13*, water; *14*, pyrrole; *15*, phenol; *16*, benzaldehyde; *17*, nitrobenzene; *18*, *p*-chlorobenzaldehyde; *19*, *p*-chloronitrobenzene; *20*, 1-naphthol; *21*, 1-nitronaphthalene; *22*, 9-anthraldehyde. The enthalpies of solvation were taken from Refs. 59, 66, and 67.

Fuchs and Stephenson[82–85] suggested that the "base line" method be used for the determination of the energies of hydrogen bonds. Its essential feature involves the comparison of the difference between the enthalpies of solvation of compounds A_i and M_i in a series of solvents with the Taft–Kamlert π^* constants. A "base line" is drawn through the points corresponding to inert solvents (n-heptane, cyclohexane, carbon tetrachloride, α,α,α-trifluorotoluene, and 1,2-dichloroethane). It takes into account the discrepancy between the enthalpies of solvation of the solute A_i and the model compound M_i, which models the non-specific solvation of A_i on passing from one solvent to another:

$$\Delta H_{solv}^{A_i/S} - \Delta H_{solv}^{M_i/S} = m\pi^* + d, \qquad (26)$$

where m and d are the parameters of the correlation. If the complex formation reaction takes place between the solute and the solvent, then the plot of the relation between the relative enthalpy of solvation $\Delta H_{solv}^{A_i/S} - \Delta H_{solv}^{M_i/S}$ and the π^* constant shows deviations of the points for the corresponding solvents which are equal to the enthalpies of specific interaction.

It is noteworthy that the methods for the determination of $\Delta H_{int}^{A_i/S}$ (sp) described in the studies quoted[4,66,67,81–85] reflect, in essence, two approaches to the study of the thermochemistry of solvation of organic non-electrolytes. In one of them,[4] emphasis is laid on the study of the solvation of structurally different solutes in one solvent of some kind. In the other approach,[82–85] the structure of the solutes is fixed and the properties of the solvent are varied. In contrast to the method based on the study of the relation between $\Delta H_{solv}^{A_i/S}$ and MR^{A_i}, the "base line" method reproduces the variation of the difference $\Delta H_{solv}^{A_i/S}$ (non-sp) – $\Delta H_{solv}^{M_i/S}$ in a series of solvents. In this case, it is necessary to solve a further two problems; to plot a reliable "base line" and to select the model compound.

In order to plot the "base line", it is essential to have data for several inert solvents which have different π^* constants, and this is not always possible. For example, it is difficult to determine the enthalpies of solution of carboxylic acids in cyclohexane, carbon tetrachloride, or benzene. One must be sure that the solvents employed are indeed inert. Since usually few such solvents are available, even a weak complex formation reaction with the solute can greatly distort the calculated results. If only two inert solvents are suitable for the test system, for example, cyclohexane and carbon tetrachloride, the probability of error increases.

The disadvantages of the existing methods for the determination of the enthalpy of specific interaction have been subjected to a thorough analysis.[66,86] This made it possible to formulate a series of measures whose application would permit the optimum determination of $\Delta H_{int}^{A_i/S}$ (sp). The essential features of these measures reduce to the following. In the initial stage, it is necessary to determine the enthalpy of the transfer of a molecule of compound A_i from an inert solvent to a solvent S [see Eqn (22)]. This permits a rough estimate of $\Delta H_{int}^{A_i/S}$ (sp). Here one must bear in mind that carbon tetrachloride and not an alkane must be used as the inert solvent.

In the case where the solute A_i contains an alkyl group the enthalpy of solvation of which varies significantly from solvent to solvent, the following equation has been proposed:

$$\Delta H_{int}^{A_i/S}(sp) = [\Delta H_s^{A_i/S} - \Delta H_s^{A_i/Y}] - [\Delta H_s^{M_i/S} - \Delta H_s^{M_i/S}] + \\ + MR^Y(\delta h_{cav}^S - \delta h_{cav}^Y). \qquad (27)$$

$\Delta H_{int}^{A_i/S}$ (sp) for proton donors not containing alkyl substituents can be determined by the "pure base" method having replaced the active hydrogen atom by the methyl group. It has been shown[74] that carbon tetrachloride, chloroform, or 1,2-dichloroethane can be used as the inert solvent. If none of the inert solvents can be used

but there is a possibility of determining the enthalpies of solvation of the proton donor and a model compound in which the active hydrogen can be replaced by the methyl group, then the enthalpy of specific interaction can be determined from the equation

$$\Delta H_{int}^{A_i/S}(sp) = \Delta H_{solv}^{A_i/S} - \Delta H_{solv}^{M_i/S} + 4.65k'_S, \quad (28)$$

where k'_S is the slope of the relation between the enthalpies of solvation of alkanes and their molecular refractions in the solvent S.

If there is a possibility of determining the enthalpies of solvation of compounds in several inert solvents, then one may resort to the "base line" method. If the number of inert solvents is small, it is necessary in this case to select model compounds whose employment leads to a slope of the "base line" close to zero. This can be achieved by applying the method based on the study of the relation between $\Delta H_{solv}^{A_i/S}$ and MR^{A_i}.[4,86]

When the enthalpies of specific interaction of proton acceptors are determined, the choice of the inert solvent necessary for the construction of the "base line" is very wide and the requirements as regards the choice of the model compound are less stringent. This factor is important in the determination of $\Delta H_{int}^{A_i/S}$ (sp) in solvents associated via hydrogen bonds.[86]

It is noteworthy that the determination of the enthalpy of specific interaction in associated solvents occupies a special place in the thermochemistry of solvation of organic compounds, since in a solvent of this kind there are equilibria between different types of associated species and in the course of the solvation of the solute A_i there is therefore the possibility of forming complexes consisting of the molecules of A_i and of the associated species. This complex formation process may be accompanied by a shift of the association equilibria in the solvent, which influences the enthalpy of the specific interaction of the solute with the solvent and the enthalpy of solvation in conformity with Eqn. (22).

An approach to the estimation of the influence of the shift of association equilibria in solution on the enthalpy of solvation has been developed.[87–89] Comparison of the enthalpies of the specific interaction of compounds such as phenols, alcohols, acids, ketones, aromatic and aliphatic amines, and pyridines with solvents associated via hydrogen bonding with the enthalpies of formation of complexes $\Delta H_c^{A_i/S}$ between A_i and S, measured in the absence of association of the molecules of the solvent S, showed that the relation between $\Delta H_{int}^{A_i/S}$ (sp) and $\Delta H_c^{A_i/S}$ depends on whether the solute is an "acid" (proton donor or electron acceptor) or a "base" (proton acceptor or electron donor). There is a possibility of two situations (1) $\Delta H_{int}^{A_i/S}$ (sp) is almost identical with $\Delta H_c^{A_i/S}$ ("acids" in aliphatic alcohols and acetic acids); (2) $\Delta H_{int}^{A_i/S}$ (sp) is appreciably smaller in absolute magnitude than $\Delta H_c^{A_i/S}$ and may be zero or positive ("bases" in aliphatic alcohols, acetic acids, formamide, and water; "acids" in water and formamide).

The results led to the development of ideas according to which the appearance of the reorganisation effect may be predicted from the nature of the solute—"acid" or "base"—and the ratio of the numbers of lone pairs and active hydrogen atoms in the solvent molecule.

VII. The dipole moment and the enthalpy of solvation. Additional arguments

If the reduced dipole moment of the molecule (the ratio of the square of the dipole moment of the molecule to the cube of its radius is adopted as a measure of the polarity of the solute, then one of the most polar non-electrolytes is water.

Fig. 4 presents the relation between the enthalpies of non-specific solvation in a series of compounds (including water) and the molecular refractions in a polar solvent—acetonitrile. Similar relations can be obtained for the entire set of solvents used by Solomonov et al.[67] The enthalpy of non-specific solvation is determined from the difference between the enthalpy of solvation of the given compound and the enthalpy of its complex formation reaction with the solvent molecule.‡

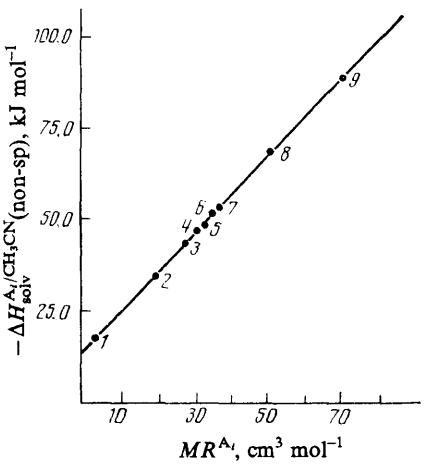

Figure 4. Relation between the enthalpies of non-specific solvation of a series of compounds in acetonitrile and their molar refractions. The numbers of the points correspond to the following compounds: *1*, water; *2*, pyrrole; *3*, phenol; *4*, benzaldehyde; *5*, nitrobenzene; *6*, *p*-chlorobenzaldehyde; *7*, *p*-chloronitrobenzene; *8*, 1-nitronaphthalene; *9*, 9-anthraldehyde.

Since the reduced dipole moments§ of molecules, presented in Fig. 4, differ significantly from one another, the existence of a relation between $\Delta H_{solv}^{A_i/S}$ and MR^{A_i} shows that this factor does not exert a significant influence on the enthalpy of non-specific solvation.

If benzaldehyde (μ = 2.6 D) or nitrobenzene (μ = 4.0 D) is adopted as the compound modelling the non-specific solvation of phenol (μ = 1.6 D) in the "pure base" method [Eqn. (25)], then, as shown by Solomonov and Konovalov[4] a correspondence is observed between the enthalpies of specific interaction and the enthalpies of complex formation determined in carbon tetrachloride for all the solvents investigated—proton acceptors, including highly polar ones (dimethyl formamide, dimethyl sulphoxide). This result also implies that the dipole moment of the solute molecule does not play a significant role.

Extensive experimental data on the thermochemistry of solvation of organic non-electrolytes show that the dipole moment of the

‡ In the case of water, twice the enthalpy of complex formation was adopted.

§ The ratio of the square of the dipole moment of the molecule to the electronic polarisability, which is proportional to the cube of the radius of the molecule, may be adopted as a measure of the reduced dipole moment.[90]

solute molecule does not influence significantly the enthalpy of solvation (at least for the compounds investigated).

Certain considerations have been put forward[4,59] concerning the possible compensation of the orientation interaction between solute and solvent molecules by the reorganisation of solvent molecules. However, if we accept that the energy of orientation interaction is compensated by the energy of the reorganisation of the solvent, then the next step must be taken — the recognition of the fact that in a physicochemical process occurring in solution, where the solvation shell "follows" reversibly (equilibrium process) the changes in the solute (for example, a chemical reaction), the contribution of the orientation interaction may not be observed because the experimental quantities reflect the overall solvent–solvent and solvent–solute interactions.

This view conflicts strongly with the existing ideas about the influence of the medium on various phyisochemical processes. Indeed, there exist a multiplicity of well established facts showing that the fraction of the more polar form of the solute increases in more polar solvents (for example, by virtue of tautomeric or conformational equilibria). Polar interactions are of decisive importance in the influence of the medium on the kinetics of reactions[91] and spectroscopic transitions.[92] The generally accepted Onsager–Böttcher model is in essence the only general physical model of the "test molecule–medium" system on the basis of which a large set of a wide variety of experimental data are analysed to this day.

Nevertheless, only the fact that, on passing from a less polar to a more polar solvent, certain parameters of the physicochemical process (reaction rate constants, activation energies, electronic transition energies, etc.) change has been reliably established experimentally. However, in the study of the influence of the medium on the thermodynamics of a process, the structure of the molecules of its final and initial states can be established and their dipole moments measured only in some cases. In the remaining instances, and these are in the vast majority, the polarity of the species (transition or excited state, non-isolatable complex) is unknown and is inferred from the influence of the solvent on the physicochemical process as a whole. It is therefore hardly possible to speak of the influence of the dipole moment on the solvation energy on the basis of "such" experimental data.

We shall now turn to the term "polarity of the medium". We shall not analyse the problem of which of the existing solvent polarity scales is best and shall only note that, on any of the solvent polarity scales known to us, acetonitrile, dimethyl formamide, and nitromethane are more polar than cyclohexane or carbon tetrachloride. It is also known that dimethyl formamide and dimethyl sulphoxide actually form the strongest hydrogen bonds with the solute, while acetonitrile and nitromethane are simultaneously proton donors and proton acceptors. These properties are absent from cyclohexane and carbon tetrachloride. The capacity of cyclohexane for dispersion interactions is also a minimum. Therefore an increase in the degree of interaction between the solvent and the solute may take place as a result of the increase in solvent "polarity". The parallel variation of the properties of the solvent has been frequently noted in the literature.[58,93] Hence it is entirely understandable that the observed changes in certain parameters of a physicochemical process on passing from a less polar to a more polar solvent are bound to be related to the change in the dipole moment of the species involved in this process.

The relative free energies of solvation of cryptate ion pairs have been investigated[94,95] in a series of solvents. Despite the large dipole moments of the solute molecules, the relative free energies of solvation of these compounds are comparable to the free energy of the transfer of polar neutral molecules in isodielectric solvents. Nevertheless, it has been shown[94,95] that the influence of the medium on the constants of the dissociation of the cryptate ion pairs into solvated ions and the absence of specific interactions with the solvent are due to polar forces. It may be that in this case the polar interaction plays a significant role only because the physicochemical processes are accompanied by the formation of ions.

The idea that the analysis of the solvation energy requires that account be taken of the contribution of quadrupole interactions together with that of dipole interactions has been developed in a number of studies.[57,96,97] This makes it possible to account for the enthalpies of solvation and solution of *cis*- and *trans*-dichloroethylenes,[96] dicyanoethylenes,[59] 1,3- and 1,4-dioxanes,[97] and *o*-, *m*-, and *p*-dinitrobenzenes.[59] Indeed, the absence of an effect of the dipole moment on the enthalpies of solvation of these compounds can be explained by approximately equal contributions of the dipole and quadrupole interactions to the enthalpy of solvation. The quadrupole moment is greater in the *trans*- and *para*-isomers, whereas the dipole moment is greater in the *cis*-, *meta*-, and *ortho*-isomers.

The importance of allowing for multipole interactions has been pointed out.[98] However, it has been shown[99] that the contribution of quadrupole and octupole interactions is negligible compared with the contribution of dipole interactions and the former should be regarded as corrections.

The experimental study of the influence of multipoles of a higher order than the dipole on the solvation energy is at present difficult, since the quadrupole and octupole moments are determined only with a very low accuracy.[57] Some doubts concerning a significant contribution of quadrupole interactions to the solvation energy have arisen from the relations obtained between $\Delta H_{solv}^{A_i/S}$ and MR^{A_i} for aromatic hydrocarbons and their halo-derivatives.[5]

VIII. Additivity in the enthalpies of the transfer and solvation of organic non-electrolytes

The question of the additivity of the solvation energies of organic compounds appears to be extremely important because, firstly, there is a prospect that the study of the solvation of complex organic compounds can be reduced to the study of simpler objects. Secondly, the possible deviations from the additivity of solvation energies may be caused by the mutual influence of atoms and groups in the solute molecule. The study of this question will help to improve our understanding of the inter-relation between the structure of the solute and its solvation energy.

The most significant argument in support of the additivity of the enthalpy of solvation of an alkyl group is the equality of the slopes of the relation between $\Delta H_{solv}^{A_i/S}$ and MR^{A_i} found for alkanes, ketones, and aliphatic alcohols. This equality implies identical solvation of the alkyl substituent at the carbonyl, hydroxy-, and aliphatic groups.[4]

An interesting observation was made by Fuchs and co-workers,[15] who showed that the enthalpy of solvation of benzene is approximately additive, corresponding to the enthalpies of solvation of the three double bonds. Unfortunately, no numerical data were

quoted in their communication. Apparently Fuchs based his treatment on the equation

$$\Delta H_{solv}^{C_6H_6/S} = 3\Delta H_{solv}^{C_6H_{10}/S} - 2\Delta H_{solv}^{C_6H_{12}/S}. \quad (29)$$

Table 4 lists the experimental enthalpies of solvation of benzene in various solvents and their values calculated by Eqn. (29). The enthalpies of solvation of benzene, cyclohexane, and cyclohexene were taken from Solomonov.[5]

Table 4. Experimental enthalpies of solvation (kJ mol^{-1}) of benzene in a series of solvents (298 K) and their values calculated by Eqn. (29).

Solvent	$-\Delta H_{solv}^{C_6H_6/S}$	
	experiment	calculation
Dimethylformamide	33.6	33.8
1,2-Dichloroethane	32.7	33.3
Methanol	32.4	32.5
Benzene	33.9	34.0
Carbon tetrachloride	32.7	33.0

Fuchs and Rodewald[100] determined the enthalpies of solution of 95 aromatic compounds in methanol and dimethyl formamide and showed that in the vast majority of cases the enthalpies of transfer of aromatic compounds are additive relative to the group composition regardless of the positions of the substituents in the aromatic ring. These findings were explained by the fact that not the dipole moment of the molecule as a whole but the dipole moments of its individual groups are important for solvation.

When there is a specific interaction between the molecule of an aromatic compound and the solvent, additivity is not observed in the enthalpies of transfer.[101]

— o0o —

During the last 15 years, an enormous amount of experimental data have been obtained on the thermochemistry of the dissolution and solvation of organic or non-electrolytes. These can be analysed within the framework of simple empirical relations between the enthalpies of solvation of compounds and their polarisabilities. These relations made it possible to develop an approach to the estimation of the enthalpies of non-specific solvation of organic non-electrolytes in various media.

Methods for the thermochemical determination of the energies of hydrogen and donor–acceptor bonds have been developed on the basis of the enthalpies of solution and solvation.

However, the question of the applicability of general ideas must be considered in each specific case and the simplified approaches are not always correct in the interpretation of thermochemical solvation data.

The extensive experimental data and the empirical relations found in the thermochemistry of solvation undoubtedly require a theoretical interpretation. Studies on these lines have already begun.[9,102–104]

1,3-Alkadienes and their derivatives in reactions with electrophilic reagents

V Kh Khristov, Kh M Angelov, A A Petrov
The Higher Pedogogical Institute, Shumen, Bulgaria
The Lensovet Technological Institute, Leningrad

ABSTRACT. **Literature data on the addition of electrophiles to 1,3-alkadienes and their derivatives have been reviewed. The chemo-, regio-, and stereo-selectivity of these reactions, mechanistic details, and their synthetic applications, are discussed.**

The bibliography contains 308 references.

I. Introduction

The chemistry of 1,3-alkadienes has been a subject of close scrutiny during the last hundred years.[1–3] Work in this area has been stimulated in two ways: firstly by theoretical developments in organic chemistry, largely in connection with the ability of 1,3-alkadienes to participate in 1,4-conjugate addition; and, secondly, by the utilization of these compounds as monomers for the preparation of various forms of rubber and other synthetic materials.

The majority of the fundamental questions relating to the chemistry of 1,3-alkadienes were addressed within the first fifty years of this century. Experimentally, this has been achieved without the use of physical separation techniques or structure determination, and without attempting to gather authentic quantitative data. Therefore, in recent years, many reactions of 1,3-dienes, even well established ones, have been studied anew with the aid of chromatography, and IR- and NMR-spectroscopy. As a result, new data have been obtained for theoretical analysis.

Certain aspects of the chemistry of 1,3-alkadienes, for example halogenation, have been developed during the last ten years, notably for potential industrial application. The chlorination of 1,3-butadiene, and the subsequent dehydrochlorination of the resulting dichloride, has been known since the 1930's, and provides the basis of a new commercial route to chloroprene.[4]

As a result, a large amount of data on the chemistry of 1,3-alkadienes has been published, particularly in the last twenty years, and has not yet been reviewed in the literature or surveyed in monographs.

Reactions of 1,3-alkadienes with electrophiles are characteristic of this class of compound, which also undergo radical addition and participate in pericyclic processes, such as heterocyclisation (4+1), dimerisation and diene synthesis (4+2), and catalytic dimerisation (4+4).

Electrophilic addition to unsaturated compounds is a widely studied aspect of organic chemistry.[1–3] The majority of these reactions proceed by a two-step A_E2 mechanism. A carbenium or an onium ion is intermediate in the reaction depending on the nature of the substrate and electrophile. There is also reference in the literature to the possibility of there being other intermediates, notable uncharged species.[2,3] An alternative A_E3 mechanism has sometimes been invoked for this electrophilic addition.[1]

Electrophilic addition to 1,3-alkadienes follows the rules established for reactions of other alkenes. However, the presence of a further conjugated double bond has an effect on chemo-, regio- and stereo-selectivity.[5–9]

According to the general theory of electrophilic addition, the orientation of attack of the electrophile at the double bond should be such that the most stable intermediate is formed with delocalisation of the positive charge within an allylic system. The second stage, i.e. the addition of the nucleophilic residue, may proceed at one or other of the electrophilic centres depending on the electronic and steric environment of the conjugated system (inclusive of solvent and catalyst).

Electrophilic addition can be accompanied by substitution of hydrogen, usually at an unsaturated carbon atom, and in the case of 1,3-butadiene homologues there may be allylic substitution with rearrangement (Lvov–Tishchenko reaction). Although a detailed study of the mechanism of these reactions has not been undertaken, there is no doubt that an electrophilic mechanism is involved: the first stage is akin to aromatic substitution, and the second is a deprotonation characteristic of carbenium ions.

The information gathered and examined in earlier reviews and monographs has only been touched upon in this review. The bibliography contains references up to 1989. The chemistry of cycloalkadienes and carbon-functionalised alkadienes has not been included.

II. The addition of compounds with an electrophilic halogen atom

The following compounds contain an electrophilic halogen atom: halogens themselves, hypohalites (acids, esters and mixed anhydrides) and *N*-halides. All of these compounds can react with unsaturated compounds by a radical or electrophilic mechanism depending on their structure and the reaction conditions. In all cases, a direct indication of the mechanism of the reaction can be obtained from the chemo-, regio- and stereo-selectivity of the addition. All reported reactions of 1,3-dienes with *N*-halides proceed under conditions for radical addition,[10] and therefore have not been examined in this review.

1. Halogenation

Of all the electrophilic additions to 1,3-alkadienes, halogenation has been the most widely studied. It is normally carried out with free halogen (except fluorine) in an inert solvent (CH_2Cl_2, CCl_4 at -20 to 0 °C. Studies have been made of the interaction of 1,3-alkadienes with fluorine, chlorine, bromine and iodine, as well as with mixed halogens: FCl, FBr, ClBr and ClI. Detailed studies in this area have been carried out by V L Heasley et al. between 1970 and 1980.

The reaction of 1,3-butadiene with fluorine was reported for the first time in 1984.[11] The regioselectivity of the reaction depends on the nature of the fluorinating agent: with XeF_2 the 1,2-adduct predominates (87%), whereas with $PhIF_2$ the 1,4-adduct is favoured (64%). It is thought that reaction proceeds via a carbenium intermediate. Replacement of hydrogen by fluorine takes place as a side-reaction.

The interaction of 1,3-butadiene with chlorine was studied as long ago as 1886.[12] However, detailed information on the regioselectivity of the reaction was not available until 1930,[13] after which the reaction became the focus of numerous researchers.[14–27] Normally, 1,3-butadiene yields *trans*-1,4-dichloro-2-butene as the major product in preference to 3,4-dichloro-1-butene. However, if chlorination is conducted under non-radical conditions, the ratio of 3,4-dichloride to 1,4-dichloride is 2 : 1.[21] Both dichlorides undergo isomerisation on heating in the presence of $ZnCl_2$. At equilibrium, the mixture contains ~70%, 1,4-dichloro-2-butene.[18] In the presence of complex metal catalysts, e.g. copper naphthylate, the 1,4-dichloride isomerises to 3,4-dichloro-1-butene.[20]

By conventional chlorination of 1,3-butadiene the yield of dichlorides does not exceed 40% since significant amounts of tetrachloride are formed together with higher telomers. By adjusting the conditions of chlorination and using specific additives, in particular metal chlorides or various amines and phosphines, the yield of dichlorides can be raised to 97%.[23,24]

Several studies have been devoted to the kinetics of chlorination of 1,3-butadiene.[19,25–27] It has been shown that the formation of isomeric dichlorides follows a complex kinetic profile: 1,4-dichloro-2-butene by a second order process, and 3,4-dichloro-1-butene by a third order process. The activation parameters in the latter case would not suggest the formation of an ionic intermediate. From this it follows that the mechanism of addition of chlorine to 1,3-dienes is more complex than thought hitherto. It is possible that 1,4-addition proceeds to some extent by a radical pathway.[19,21]

Bromination of 1,3-butadiene is one of the most studied reactions of this compound.[14,28–41] The mechanism of addition of bromine depends on the dilution: at low concentrations (0.02 to 0.04 mol/l) it is electrophilic, while at high concentration a radical mechanism is involved.[36] Under conditions of electrophilic addition, 1,2-addition is observed to the extent of 57% in CCl_4 and 24% in CH_2Cl_2. *trans*-1,4-Dibromo-2-butene is formed predominantly (60%) under normal conditions. *cis*-1,4-Dibromo-2-butene has not been detected. 3,4-Dibromo-1-butene is converted slowly at room temperature, or rapidly on heating, to an equilibrium mixture containing ~80% *trans*-1,4-dibromo-2-butene. Thus, in contrast to the corresponding chlorides, the ratio of isomeric dibromides markedly depends on the conditions of bromination, notably the nature of the solvent.

In recent years, reference has been made to bromination of 1,3-butadiene with bromine complexes, e.g. dioxane dibromide,[39] pyridine dibromide, pyridinium tribromide,[40] and tetrabutylammonium tribromide.[41] In the first case, the ratio of addition products is approximately the same as that with molecular bromine. 3,4-Dibromo-1-butene is formed predominantly on bromination with pyridine dibromide, pyridinium tribromide and tetrabutylammonium tribromide. This indicates that the amine is involved in the transition state and/or the formation of an intermediate. The kinetics of bromination with Br_3^- has been studied in detail, and the distribution of electron density in the intermediate has been considered.[41]

Treatment of 1,3-butadiene with methyl hypochlorite and BF_3 in methylene chloride proceeds by 1,2- and 1,4-addition of FCl and methyl hypochlorite. The amounts of both types of adduct are approximately the same. In CCl_4 the yield of fluorochlorides, relative to methoxychlorides, rises significantly. The addition of FCl at the 1,2-position is strictly in accord with the Markovnikov rule, and is noticeably more dominant than 1,4-addition (with formation of *trans*-1-fluoro-4-chloro-2-butene). In CH_2Cl_2, the ratio of 1,2- to 1,4-addition is ~2 : 1, and in CCl_4 it is 3 : 1.[42]

Similarly, treatment of 1,3-butadiene with methyl hypobromite and BF_3 results in addition of FBr. The yield of fluorobromides in this case is less than that of bromoethers. The ratio of 1,2- and 1,4-adducts is 4 : 1.[42] It is thought that a complex, $BF_3Hal^+OR^-$, is formed during the reaction; this complexes with 1,3-butadiene to give an onium intermediate which then undergoes attack by both fluoride ion and methoxide.

The reaction of 1,3-butadiene with ClBr gives a mixture of 4-bromo-1-chlorobut-2-ene and 4-bromo-3-chloro-1-butene in 73 : 27 proportion.[43] With $Bu_4N^+BrCl_2^-$, only 1,2-addition of ClBr takes place; here, 84% of the product is formed according to the Markovnikov rule, and 16% contrary to this rule.[43,44] It is suggested that in this case reaction proceeds with formation of a three-centred intermediate with a delocalised positive charge; this is then attacked by chloride ion.

ICl adds to 1,3-butadiene with the formation of 1,4- and 1,2-adducts in 4 : 1 ratio. This is probably very close to the equilibrium product ratio.[45,46]

Iodination of 1,3-butadiene proceeds regioselectively with formation of *trans*-1,4-diiodo-2-butene.[47] Anionotropic systems with allylic iodine are extremely labile, and here reaction is clearly under thermodynamic control.

As a consequence, on passing from fluorine to iodine the amount of 1,4-adduct increases. Evidently, the determining factor here is the status of the system relative to that at equilibrium, i.e. the extent to which reaction is favoured by kinetic or thermodynamic control.[5]

The stereochemistry of addition of halogens to 1,3-alkadienes has been investigated with a view to assessing potential re-orientation and rotation in the transition state.[48] There is a possibility that addition of halogen results in formation of a non-ionic cyclic intermediate not requiring a significant degree of solvation. This accords with information gathered on the stereospecificity of this reaction.[35]

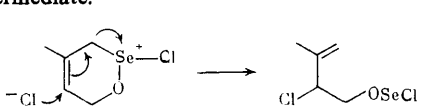
The regioselectivity of electrophilic chlorination of piperylene is markedly dependent on the geometry of the system and the polarity of the solvent. In CCl_4 *cis*-piperylene forms dichlorides (A), (B) and (C) in 29:20:46 proportion; in CH_2Cl_2 the proportion is 10:47:43. In CCl_4 *trans*-piperylene gives the same mixture of dichlorides in 4:47:49 proportion, while in CH_2Cl_2 the proportion is 2:66:32. Addition at the 3,4-position is stereospecific (89–95% *anti*).[48,49]

$$\underset{(A)}{MeCHCl{-}CHCl{-}CH{=}CH_2},$$

$$\underset{(B)}{MeCH{=}CH{-}CHCl{-}CH_2Cl},$$

$$\underset{(C)}{MeCHCl{-}CH{=}CH{-}CH_2Cl}.$$

Electrophilic bromination of piperylene proceeds predominantly with the formation of *trans*-1,4-dibromo-2-pentene.[50] 1,2-Addition at the disubstituted double bond (in the *anti*-mode) is much less, and minimal in the case of *trans*-piperylene. Thus, the halogen-onium complex at the terminal double bond, both on chlorination and bromination, is significantly more stable than the complex formed at the internal double bond.



Chlorination of isoprene proceeds to a large extent by replacement of hydrogen by chlorine (Lvov–Tishchenko reaction) with the formation of 2-chloromethyl-1,3-butadiene.[21,51–55] Amongst the adducts which are also formed, 1,4-dichloro-2-methyl-2-butene (C) predominates.

$$\underset{\text{(A), 7\%}}{CH_2Cl{-}\overset{\overset{Me}{|}}{C}Cl{-}CH{=}CH_2}, \qquad \underset{\text{(B), 3\%}}{CH_2{=}\overset{\overset{Me}{|}}{C}{-}CHCl{-}CH_2Cl},$$

$$\underset{\text{(C), 49\%}}{CH_2Cl{-}\overset{\overset{Me}{|}}{C}{=}CH{-}CH_2Cl}, \qquad \underset{\text{(D), 49\%}}{CH_2{=}\overset{\overset{CH_2Cl}{|}}{C}{-}CH{=}CH_2}.$$

Other mono-chlorides are also reported to be formed on chlorination of isoprene. These may arise by dehydrochlorination of the dichloride adducts or may be products derived by 'aromatic' chlorination.[54] It is interesting to note that heating 1,4-dichloro-2-methyl-2-butene in the presence of a catalytic amount of copper(I) chloride and copper powder at 140 °C affords a mixture of comprising ~45% dichloride (B) and only ~3% dichloride (C).[53]

Chlorination of isoprene with $SeOCl_2$ in CH_2Cl_2 yields 1,4-dichloro-2-methyl-2-butene (in 39% yield) as a 2:1 mixture of *E*-and *Z*-isomers and 3-chloro-2-methyl-1-buten-4-ol (in 28% yield). The authors consider that the latter is formed by rearrangement of an intermediate:[55]

Bromination of isoprene has been reported extensively, as far back as 1898.[40,50,56–59] *trans*-1,4-Dibromo-2-methyl-2-butene is the major product, formed in 71% yield. The amount of 3,4-dibromo-3-methyl-1-butene in the mixture of dibromides is ~21%. *cis*-1,4-Dibromo-2-methyl-2-butene and 3,4-dibromo-2-methyl-1-butene are present in the mixture in small amounts (5 and 3%, respectively).

Bromination of isoprene with $SeOBr_2$ affords 1,4-dibromo-2-methyl-2-butene as a 2:1 mixture of *E*- and *Z*-isomers.[55]

ClBr adds to isoprene on treatment with $Bu_4N^+BrCl_2^-$ predominantly at the 1,2-position according to the Markovnikov rule.

$$\underset{78.6\%}{CH_2Br{-}\overset{\overset{Me}{|}}{C}Cl{-}CH{=}CH_2}; \qquad \underset{11\%}{CH_2{=}\overset{\overset{Me}{|}}{C}{-}CHCl{-}CH_2Br};$$

$$\underset{9.2\%}{CH_2Br{-}\overset{\overset{Me}{|}}{C}{=}CH{-}CH_2Cl}.$$

The addition of halogens to 2,4-hexadiene is of particular interest in relation to the stereochemistry of the reaction since this alkadiene exists as three geometric isomers. Their chlorination and bromination in a variety of solvents yields: *erythro*-4,5-dihalogeno-*cis*-2-hexenes, *threo*-4,5-dihalogeno-*cis*-2-hexenes, *dl*-2,5-dihalogeno-*trans*-3-hexenes, *meso*-2,5-dihalogeno-*trans*-3-hexenes, *threo*-4,5-dihalogeno-*trans*-2-hexenes and *erythro*-4,5-dihalogeno-*trans*-2-hexenes. The determination of the amount of each of these dihalides provides evidence in favour of the *syn*- or *anti*-character of the addition.[49,59]

In all cases, 1,4-addition is noticeably less on chlorination than on bromination. There is little information on solvent effects. These results are in accord with the findings of Farmer et al. more than 50 years ago,[31] and disprove a more recent report that the proportion of 1,2- and 1,4-adducts is independent of the polarity of the solvent.[35]

Chlorination and bromination of 2,3-dimethyl-1,3-butadiene[60–65] and 3-methyl-1,3-pentadiene[66] proceeds predominantly with the formation of *trans*-1,4-dihalides, and is associated with a significant degree of allylic substitution.

3,4-Addition takes place on chlorination and bromination of 1-aryl- and 1,4-diaryl-1,3-butadienes, while 1,4-addition is favoured on chlorination and bromination of 2-aryl-1,3-butadienes.[67,69]

Molecular-orbital calculations (LCAO approximation and others) have been carried out on several occasions with a view to examining the regioselectivity of addition to 1,3-butadiene and derivatives.[70,71]

All mono- and dichloro-1,3-butadienes, and notably polychloro-1,3-butadienes, undergo chlorination. Mkryan et al. have contributed most to this aspect. Data on reactions with other halogens is very limited.

Chlorination of 1-chloro-1,3-butadiene affords predominantly 3,4- and 1,4-adducts in addition to three of the possible substitution products:[72–74]

$$\underset{50.7\%}{CHCl{=}CH{-}CHCl{-}CH_2Cl}; \qquad \underset{5.9\%}{CHCl_2{-}CHCl{-}CH{=}CH_2};$$

$$\underset{12.1\%}{CHCl_2{-}CH{=}CH{-}CH_2Cl}; \qquad \underset{5.4\%}{CCl_2{=}CH{-}CH{=}CH_2};$$

$$\underset{1\%}{CHCl{=}CCl{-}CH{=}CH_2}; \qquad \underset{21.8\%}{CHCl{=}CH{-}CH{=}CHCl}.$$

According to another report, the proportion of 3,4- and 1,4-adducts is 1:1, which changes to 2:1 on addition of DMF to the solvent. In each case, 5–6% of the mixture comprises 3,4,4-trichloro-1-butene.[20]

A mixture of 3,4- and 1,4-adducts is formed on bromination of 1-chloro-1,3-butadiene.[73]

There are conflicting reports on the structure of the main product obtained by bromination of 1-bromo-1,3-butadiene. According to one reference the main product is 1,3,4-tribromo-1-butene,[45] and according to another it is 1,1,4-tribromo-2-butene.[75] In each case the structure of the product was assigned on the basis of ozonolytic data.

There are several publications on the chlorination of chloroprene.[76–81] All three of the possible trichlorobutenes are formed, but the 1,2- and 3,4-adducts are always in small amount:[79]

$$\underset{2.6\%}{CH_2Cl{-}CCl_2{-}CH{=}CH_2};\quad \underset{3.4\%}{CH_2{=}CCl{-}CHCl{-}CH_2Cl};$$
$$\underset{69.5\%}{CH_2Cl{-}CCl{=}CH{-}CH_2Cl};\quad \underset{20\%}{CHCl{=}CCl{-}CH{=}CH_2}.$$

The proportion of 1,2- and 3,4-adducts noticeably increases on addition of DMF to the solvent.[20] On chlorination in DMF the ratio of the three dichloride adducts shown above is 3 : 1 : 10.[80]

Bromination of chloroprene leads almost exclusively to 1,4-dibromo-2-chloro-2-butene. A trace of 3,4-dibromo-2-chloro-1-butene is also formed.[78]

ICl adds to chloroprene in an entirely different way: the 4,3-adduct, 2,3-dichloro-4-iodo-1-butene, is formed predominantly together with a trace of 4,1-adduct, 1,2-dichloro-4-iodo-2-butene:[78,81]

$$CH_2{=}CCl{-}CHCl{-}CH_2I;\quad CH_2Cl{-}CCl{=}CH{-}CH_2I.$$

Thus initial attack in this case is at the terminal C-atom of the non-chlorinated double bond. Below, it will be seen that bromination also takes place initially at the same carbon atom, while chlorination of chloroprene proceeds predominantly by attack at the terminal carbon atom of the chloro-substituted double bond.

Bromination of bromoprene takes place almost exclusively by 1,4-addition to give 1,2,4-tribromo-2-butene.[82]

Tables 1 and 2 summarise the results obtained by chlorination of all five dichloro-1,3-butadienes, two trichloro-1,3-butadienes, two tetrachloro-1,3-butadienes and one pentachloro-1,3-butadiene,[79–90] as well as a number of chloro-substituted isoprenes.[91–96] The preferential chlorination of the terminal, non-chlorinated, double bond is evident. Replacement of hydrogen by chlorine at the terminal methylene or methyl group takes place to a significant extent. There is no such substitution in the absence of terminal methyl or methylene groups.

3,4-Addition takes place on chlorination of 1-phenyl-4-chloro-1,3-butadiene, i.e. addition to the chlorine-substituted double bond.[96]

There is also reference in the literature to halogenation of certain halogeno-substituted 1,3-alkadienes, but without reliable information on the structure of the adducts (e.g. references[97,98]); these have been excluded from this review.

Halogenation of nitro-substituted 1,3-alkadienes has been rarely studied.[99] It is reported that bromine adds to 1-nitro-1,3-butadiene at the unfunctionalised double bond.[100] However, in more recent work it has been shown that 1-nitro- and 2,3-dimethyl-1-nitro-1,3-butadiene form 1,4-adducts with bromine.[101] Evidently, the latter can isomerise with rearrangement of the halogen to give the 3,4-adducts.

Dinitroalkadienes add bromine far more slowly than mono-nitro derivatives. 1,4-Dibromo-2,3-dimethyl-1,4-dinitro-2-butene is obtained by bromination of 2,3-dimethyl-1,4-dinitro-1,3-butadiene.[102]

Electrophilic halogenation is noticeably inhibited by phenyl substitution in the dinitroalkadienes. 1,4-Dinitro-1,4-diphenyl-1,3-butadiene does not give an adduct.

Bromination of 1-trimethylsilyl-1,3-butadiene gives a mixture of 3,4- and 1,4-adducts in equal amount.[103] The regioselectivity is the same as that observed on bromination of the all-carbon analogue, 4,4-dimethyl-1,3-pentadiene.

1,4-Dibromo-1-trimethylsilylbut-2-ene readily isomerises on heating with migration of bromine from the 1-position to the 3-position and from the 4-position to the 2-position. As a result, 3,4-dibromo-4-trimethylsilylbut-1-ene and 3,4-dibromo-1-trimethylsilylbut-1-ene are obtained.

Table 1. Chlorination of di- and poly-chlorobutadienes.

Chloro-substituted 1,3-butadiene	Products of chlorination	Content, %	Refs.

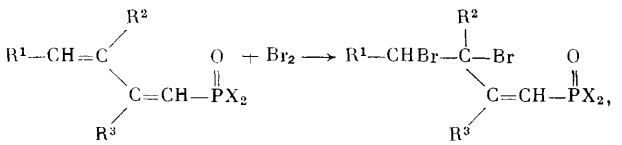
*One product isolated; **for *Z*- and *E*-isomers (given as a fraction); *** mainly the *cis*-isomer.

Thus, isomerisation leads in part to the formation of a dibromide which cannot be obtained by direct addition of bromine.



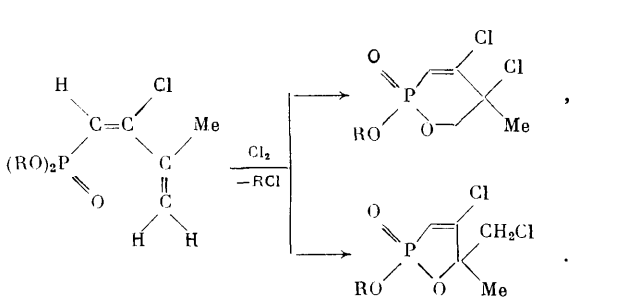
The isomeric ratio depends on the nature of the solvent and temperature: an increase in the solvent polarity and temperature favours the formation of the isomer having a silylated double bond.

The difference in the rate of bromination of 1-trimethylsilyl-1,3-butadiene and the all-carbon analogue suggests that the trimethylsilyl group exerts an electron-accepting activity relative to the tert-butyl group.[104]

Pudovik et al. established that chlorination of diethyl 1,3-butadiene-1-phosphonate takes place by attack at the non-phosphonated double bond.[105] More recently,[106] it was shown that bromination of both dialkyl 1,3-butadiene-1-phosphonates and the corresponding phosphonic acid chlorides also leads to the formation of the 3,4-adduct having the (*E*)-configuration.

Further studies on the interaction of 1,3-alkadiene-1-phosphonates with halogens has shown that various products result, depending on the preferred conformation of the 1,3-diene system. Thus, bromination of 1,3-alkadienephosphonates, prepared from PCl_5 and

the corresponding 1,3-alkadienes[107–109] and having, predominantly, the *S-trans*-conformation, proceeds with formation of 3,4-adducts:[110]



$R^1 = R^2 = R^3 = H$, Me; X = Cl, OMe, OEt.

Dehydrobromination with triethylamine leads to the corresponding 3-bromo-1,3-alkadienephosphonates.

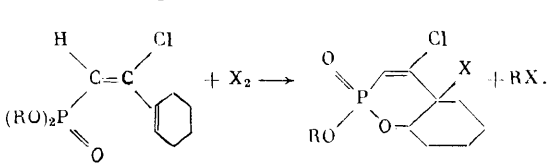
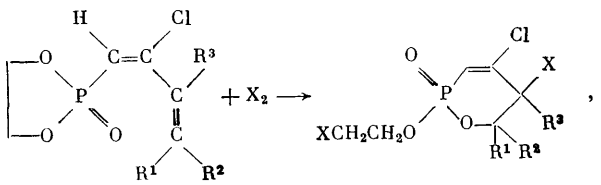
A mixture of 6- and 5-membered phosphorus-containing heterocyclics was obtained by chlorination of dialkyl 2-chloro-3-methyl-1,3-butadienephosphonates having predominantly the *S-cis*-conformation:[111–112]

The conversion to cyclic compounds is a consequence of a) the low energy of formation of such ring systems and b) the favourable transformation of the starting phosphonates into intermediates having a geometry which facilitates intramolecular nucleophilic attack by the phosphonyl group.[112,113] Chlorination of the corresponding 1,3-alkadienephosphonic dichloride does not effect cyclisation. Instead a complex mixture is obtained as a result of addition and dehydrochlorination of the adducts.[112]



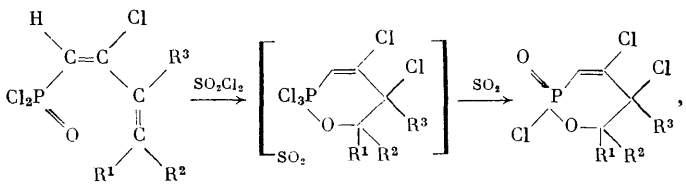
Halogenation of 2-chloro-3-alkyl-1,3-alkadienephosphonic acid esters having one or two substituents on the C_4 atom of the 1,3-diene system (which are obtainable via chlorination of the corresponding allenephosphonic acid dichlorides[114]) proceeds by heterocyclisation to yield 5,6-dihydro-2*H*-1,2-oxaphosphorins exclusively.[115,116] The highly selective interaction is due to the presence of an internal nucleophile (the phosphonyl group). This is attacked more readily by the electrophilic centre of the intermediate than by the anionic part of the reagent, thereby shifting the equilibrium towards formation of a stable six-membered phosphonium ion.[115]



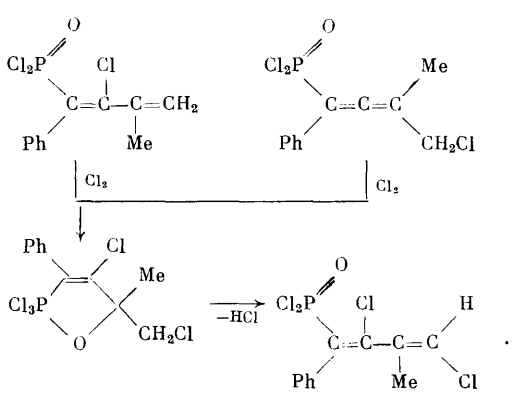
$R = Me, Et, Pr, Pr^i, Bu$; $R^1 = H, Me4$; $R^2 = Me, Et$; $R^3 = Me, Et, Pr, Pr^i$; $X = Cl, Br$.

Clearly, the preferential *S-cis*-conformation of the 1,3-diene system is particularly favourable for cyclisation.[117]

Halogenation[118,119] of dialkyl 2-chloro-2-(1-cyclohexenyl)-vinylphosphonates affords bicyclic *P,O*-containing heterocycles in which the C_3-C_4 double bond of the 1,3-diene system is incorporated in the ring.[118–120]

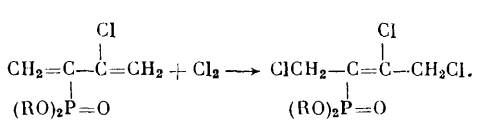


Halogenation of 2-(2-chloro-1,3-alkadienyl)-2-oxo-1,3,2-dioxaphospholanes proceeds in a similar way with associated cleavage of the dioxaphospholane ring and addition of halogen across the carbon-oxygen bond.[121]

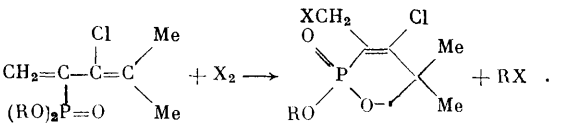


$R^1 = H$, Me; $R^2 = Me$; $R^3 = Me$, Et; X = Cl, Br.

Chlorination of 2-chloro-3-methyl-1,3-butadienylphosphonic acid dichloride with sulphuryl chloride yields a 3:1 mixture of the corresponding 5,6-dihydro-2*H*-1,2-oxaphosphorin and 2,5-dihydro-1,2-oxaphosphole.[122] However, 2-chloro-1,3-alkadienylphosphonic acid dichlorides with one or two substituents at the C_3 and C_4 positions give only a six-membered heterocycle under these conditions.[122]



$R^1 = H$ or Me; $R^2 = H$ or Me, Et; $R^3 = CH_3$ or C_2H_5, C_3H_7.



The interaction of 3-methyl-1-phenyl-2-chloro-1,3- and 3-methyl-1-phenyl-4-chloro-1,2-butadienylphosphonic acid dichloride with chlorine gives the same heterocycle, which eliminates HCl to give a dichloro-1,3-butadienylphosphonic acid dichloride.[123]

Halogenation of 3-chloro-1,3-alkadien-2-ylphosphonates gives a variety of products depending on the nature of the substituent at C_4 of the 1,3-diene system. Thus, interaction of dialkyl 3-chloro-1,3-butadien-2-ylphosphonates with chlorine leads to a 1,4-adduct.[124]

However, halogenation of 4-methyl-3-chloro-1,3-pentadien-2-ylphosphonic acid esters with two methyl groups at the 4-position yields 2,5-dihydro-1,2-oxophosphole derivatives.[124,125]

The geometry of the intermediate carbenium ion facilitates overlap of the unfilled orbital at the C_3-atom with the non-bonded orbitals of the phosphonyl group, leading to stabilisation of the entire system by ring closure.[124]

2. Addition of hypohalites

Hypohalites — hypohalous acids, their esters and mixed anhydrides — undergo addition to unsaturated compounds by a radical or ionic mechanism. In the latter case, reaction is conducted in dilute solution in the presence of radical inhibitors or in the presence of catalysts, such as BF_3, which facilitate electrophilic processes.

There is also the possibility of conjugate addition of hypochlorites to unsaturated compounds in hydroxylic solvents by using halogens, *N*-halogenamines and similar compounds with a positively polarised halogen atom. Under such conditions, the product obtained by addition of hypohalite contains a solvent molecule as well as halogen (solvo-adducts). Since the first step of the reaction (attack of the electrophile) is the same for both halogenation and conjugate hypohalogenation, the position of the halogen atom in the hypohalite adducts determines the direction of the initial attack in the first stage of halogenation. This reaction is important theoretically.

This reaction is also of significant synthetic value because it opens up a route to unsaturated epoxides, esters, carbonyl compounds, etc. The electrophilic addition of pre-formed hypohalites has only been studied in the hydrocarbon field. However, the products obtained by addition to 1,3-alkadienes are the same, irrespective of whether the hypohalite is pre-formed or formed *in situ*.

Conjugate addition of hypohalites to 1,3-alkadienes was studied systematically by A A Petrov et al. during the period 1935–1950.[126–129] 1,3-Butadiene, piperylene, isoprene and 2,4-hexadiene all undergo hypohalogenation. Various *N*-halogenamines and free halogen have been used as the halogenating agent. As a result of these studies, it has been established that hypohalites add predominantly at the 1,2-position, contrasting with addition of halogen and hydrogen halides. The proportion of 1,2- and 1,4-isomers is dependent on the method and the reaction conditions, as well as on the nature of the halogen.

Hydroxychlorination of 1,3-butadiene leads to the formation of the 1,2-adduct in 60–80% yield under various conditions.[126–131]

Alkoxyhalogenation of 1,3-butadiene also proceeds predominantly at the 1,2-position. As in the previously mentioned reaction, the regioselectivity depends on the method and temperature, the yield of 1,2-adduct being in the 80–90% range.[131–135] A 1,2-adduct is obtained in 62% yield by interaction of chlorine with a mixture of 1,3-butadiene and its mono-epoxide.[136]

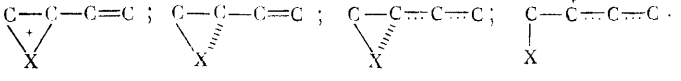
Electrophilic addition of methyl hypochlorite to 1,3-butadiene in methanol affords 3-methoxy-4-chloro-1-butene in 70% yield. Approximately the same yield was obtained by treatment of methanolic 1,3-butadiene with chlorine, while radical addition of

methyl hypochlorite gives 4-methoxy-1-chloro-2-butene in 80% yield and the 1,2-adduct in 14% yield (contrary to the Markovnikov rule).[137]

Electrophilic addition of methyl hypochlorite to 1,3-butadiene in the presence of BF_3 gives a 37 : 17.5 mixture of chloroethers in CH_2Cl_2 and a 25 : 5.5 mixture in CCl_4. Fluorochlorobutenes are also formed, as has already been mentioned.[42]

Acoxychlorination of 1,3-butadiene with *N*-halogenamines in carboxylic acids gives a very small amount of ester, and the reaction has not been studied in detail.[126] Recently it was shown that the yield of acoxychlorides is significantly improved in the presence of $LiClO_4$; however, under these conditions the proportion of 1,4-adduct is increased markedly.[138]

Pre-formed acyl hypochlorites also add predominantly at the 1,2-position under electrophilic conditions.[21] The ratio of 1,2- and 1,4-adducts depends on the nature of the solvent: 2.8 : 1 in pentane, 2 : 1 in acetic acid, and 1.3 : 1 in acetonitrile.



On hydroxy-, alkoxy- and acoxy-bromination of 1,3-butadiene with *N*-bromoamides, methyl hypobromite in the presence of BF_3, or with Br_2 in the appropriate hydroxylic solvent, the 1,4-adducts, if formed at all, are only obtained in small amounts; the corresponding bromoesters have not been isolated.[42,137,139,140]

The yield of 1,4-adduct is noticeably increased on acoxybromination with *N,N*-dibromobenzenesulfonamide in the presence of $LiClO_4$.[138] In contrast, alkyl hypobromites add exclusively at the 1,2-position in the presence of trimethyl borate.[141]

Only 1,2-adducts are obtained by hydroxy-, alkoxy- and acoxy-iodination of 1,3-butadiene with I_2/HgO in water or alcoholic media, or with iodoamides, e. g. NI_3, in acidic media.[142,143] The addition of pre-formed hypoiodites to alkadienes has not been studied.

The direction of the initial attack of halogen or hypohalite depends on the nature of the halogen atom; it is now thought that this directing influence is associated with the structure and stability of the intermediate onium ion.

It is conventional to represent the distribution of electron density in the intermediate by the following structures.[37]

The more the carbenium structure contributes to the intermediate ion, the more likely will reaction terminate by 1,4-addition. Kinetic and thermodynamic factors clearly play a leading role, being associated with the particular status of the system relative to that at equilibrium: on hypohalogenation under kinetic control, the less thermodynamically favourable 1,2-adduct is formed with a lower activation energy.[5]

Electrophilic addition of hypochlorous acid to piperylene leads to the formation of a mixture of 1,2-, 3,4- and 1,4-adducts in 47.1%, 39.7% and 13.2% yield respectively. The formation of the 3,4-adduct, which is contrary to the Markovnikov rule, requires further investigation.[144]

The interaction of piperylene with *N,N*-dichlorobenzenesulfonamide in methanol or ethanol proceeds by initial attack at the C_1-C_2 double bond to give, predominantly, a 5.6 : 4 mixture of 2-alkoxy-1-chloro-3-pentene and 4-alkoxy-1-chloro-2-pentene.[145]

The electrophilic interaction of piperylene with pre-formed hypochlorites (MeOCl) also provides a significant amount of 1,4-adduct. The yield of 1,2-, 1,4-, 4,1- and 4,3-adducts was 37–43%, 45–55%, 4–7% and 14–27%, respectively.[137]

It should be noted that the 3,4-adduct is formed in accordance with the Markovnikov rule, which is not the case for the addition of HOCl.[144]

2-Alkoxy-1-bromo-3-pentene and 4-alkoxy-1-bromo-2-pentene were obtained predominantly, in 5.6 : 4 proportion, by interaction of *N,N*-dibromobenzenesulfonamide with piperylene in alcoholic media (MeOH, EtOH).[146] Thus, as a general rule, alkyl hypobromites add to the 1,2-position to a greater extent than alkyl hypochlorites. However, in all cases piperylene forms much more of the 1,4-adduct. The reason for this is probably its rather high polarity.

Hypohalogenation of isoprene was first studied at the end of the last century.[56] More recently, reference has been made to the electrophilic addition of methyl and ethyl hypochlorite to isoprene in methanol and to the addition of tert-butyl hypochlorite in ethanol. A 3 : 2 mixture of 2-alkoxy-2-methyl-1-chloro-3-butene and 4-alkoxy-2-methyl-1-chloro-2-butene is formed in each case.[147] Other authors have reported slightly different ratios for these two products: 2 : 1 [148] and 3 : 1 [138] (with MeOCl), and 2.4 : 1 with EtOCl.[148] Small amounts of 3,4-adduct have also been reported.[148]

The interaction of isoprene with tert-butyl hypochlorite in acetic acid also leads primarily to the 1,2-adduct, which isomerises to the 1,4-adduct on treatment with acid.[147,149,150]

The 4,1-adduct is formed mainly if reaction is carried out in tert-butanol. This arises by radical addition of BuOCl to isoprene.

The addition of HOBr, alkyl hypobromites and alkyl hypoiodites to isoprene proceeds exclusively, or almost exclusively, at the 1,2-position.[148, 151, 152] This confirms that electrophilic bromination of isoprene is also initiated by attack at the C_1 atom.

The interaction of 1-tert-alkyl-substituted 1,3-butadienes with methyl hypoiodite (I_2, MeOH and HgO) leads to addition at the C_1-C_2 bond.[153]

Treatment of 1-phenyl-1,3-butadiene with dilute HOCl [154] and with HOBr [45] leads primarily to the 4,3-adduct. Later, the 1,2-adduct was also detected as one of the products.[155]

The study of reactions with halogeno-substituted alkadienes has revealed important mechanistic information on the addition of hypohalites to 1,3-dienes.

Hypohalites (HOBr, ROBr, ROI) add to 1-chloro- and 1-bromo-1,3-butadienes in the 4,3-mode.[14,156,157] Recently, an interesting reference was made to the conjugate chlorination of 1-chloro-1,3-butadiene in the presence of H_2O_2.[158] The reaction product is the hydroperoxide, $CHCl=CH-CH(OOH)CH_2Cl$.

Chloroprene and bromoprene add hypohalites in different ways depending on the nature of the halogen.

Contrasting with 1,3-butadiene, halogeno-1,3-alkadienes add HOCl and its esters predominantly at the 1,4-position; however 1,2-addition also takes place by attack at C_1 where the electron density is highest by virtue of the mesomeric effect of the halogen atom.[159] At the same time, reaction with HOBr or its esters and with HOI or its esters gives the 4,3-adduct almost exclusively with initial attack at C_4.[160–162] Clearly, these data would suggest that in the reactions of chloroprene and bromoprene with chlorine and iodine the direction of the initial attack is different.

Evidently, in both halogenation and hypohalogenation, the formation of an onium intermediate with participation of bromine and iodine is less facile in the presence of an electron-accepting C_1-C_2 bond. The intermediate is more stable if there is no halogen substitution of the double bond.

The recently reported conjugate addition of bromine and ethylene oxide to bromoprene is not in accord with the above. According to

the authors, reaction leads primarily to the formation of both types of 1,4-adduct as well as 3-bromethoxy-4-bromo-1-butene.[163]

1,2-Dichloro-1,3-butadiene adds methyl hypohalites at the unsubstituted double bond,[164] while 2,3-dichloro-1,3-butadiene gives both 1,2- and 1,4-adducts, the former predominating.[165]

1-Trialkylsilyl-1,3-alkadienes, just as the analogous all-carbon 1,3-alkadienes, add alkyl hypohalites only at the unsubstituted double bond (i.e. the non-silylated unsaturation) to give the 4,3-adduct.[166] The fact that the ratio of *cis*- and *trans*-isomers in the starting silyl-1,3-dienes and in the resulting 4,3-adducts is the same would suggest that an allyl-type carbenium ion is not formed in an intermediate step.

There is also reference in the literature to the formation of other solvo-adducts on halogenation of 1,3-butadiene. Thus, chlorination of 1,3-butadiene in DMF at −50 °C affords up to 70% of solvo-adducts as a mixture of two isomers which decompose at −10 °C:[167]

$$CH_2Cl{-}CH(OCH{=}N^+Me_2Cl^-){-}CH{=}CH_2;\quad CH_2Cl{-}CH{=}CH{-}CH_2OCH{=}N^+Me_2Cl^-.$$

III. The addition of compounds with an electrophilic hydrogen atom

Reagents in this category include hydrogen halides, hydroxylic compounds (water, alcohols, carboxylic acids) and mercapto compounds (hydrogen sulphide, thioalcohols, thioacids). Most of the data covering this aspect relates to the addition of hydrogen halides. Only the latter add to 1,3-dienes in the absence of catalyst, although in certain cases the use of a catalyst is necessary. An electrophilic mechanism is involved in the majority of reactions. Hydroxylic compounds add to 1,3-alkadienes only by an electrophilic mechanism in the presence of acid.

1. Hydrohalogenation

The hydrohalogenation of both 1,3-dienes and halogeno-1,3-dienes has been reported. There is reference to the addition of all four hydrogen halides to 1,3-alkadienes, but most of the data pertains to the reactions with HCl and HBr. A catalyst is required for the addition of HCl in non-aqueous media.

Table 3. Hydrochlorination of some chloro-substituted 1,3-alkadienes.

* Only one product isolated.

1,3-Butadienes polymerise in the presence of HF.[168] Treatment with HCl in the presence of a catalyst (Cu_2Cl_2, $FeCl_2$, $FeCl_3$, $ZnCl_2$, $HgCl_2$) at room temperature in acetic acid, or without solvent at −80 °C, leads to a mixture of products containing 75−80% 3-chloro-1-butene and 20−25% 1-chloro-2-butene. The addition of peroxide has no effect on the course of the reaction. There is no interconversion of the two isomeric chlorides in the absence of catalyst, but on prolonged treatment with HCl or in the presence of catalyst (Cu_2Cl_2, $FeCl_3$) the mixture equilibrates to give ~25% 1,2-adduct.[169–171] Thus, on hydrochlorination the thermodynamically less stable isomer is present in far greater amount than in the equilibrated mixture. It is also reported that more than 96% of the 1,2-adduct is formed at low temperatures.[172]

The kinetics of the addition of HCl to 1,3-butadiene has been studied.[173] Electrophilic addition of HBr to 1,3-butadiene leads to the preferential formation of 1-bromo-2-butene. At equilibrium the mixture contains ~80% 1,2-adduct at −80 °C, and 80% 1-bromo-2-butene at 40 °C.[174,175] 1,2-Addition takes place to the extent of 65−90% in the absence of peroxide and at low temperatures.[175]

1-Iodo-2-butene is obtained by passing 1,3-butadiene through 57% HI at 20 °C.[169]

For the interaction of hydrogen halides with homologues of 1,3-butadiene, the direction of the initial electrophilic attack is in accord with the Markovnikov rule: the proton always adds to the terminal atom of the conjugated system since in this way the most stable (conjugated) carbenium ion is formed. For halogenation, there are a few exceptions to this rule. As seen in the tabulation above, small amounts of regioisomer may also be formed as a result of the two possible modes of cleavage of the halonium intermediate.

Because of the symmetry of the intermediate carbenium ion, hydrochlorination and hydrobromination of piperylene leads to the formation of only one halogenopentene isomer: 4-chloro- or 4-bromo-2-pentene. These may arise either by 1,2- or 1,4-addition of the hydrogen halide.[48,176,177] But, in fact, the 1,2-pathway is preferred. This is evident from a study of the interaction of *trans*-piperylene with DCl in a variety of solvents in the temperature range −78 to 25 °C. In all cases the 1,2-adduct is formed preferentially, i.e. 4-chloro-5-deuterio-2-pentene (62−78% of the mixture).[178]

The addition of HCl and HBr to isoprene has been studied by many authors.[179–183] Preferential 1,4-addition is reported, except in one instance[183] where 76−85% of the 1,2-adduct was isolated on hydrochlorination of isoprene at low temperatures under kinetic control.

Treatment of 2,4-hexadiene with HBr affords 90% of the 2,3-adduct,[179,184] while HCl and HBr react with 2,3-dimethyl-1,3-butadiene primarily by 1,4-addition.[46,179]

A special note should be made of the addition of HCl to the third isomer of dimethylbutadiene, namely 4-methyl-1,3-pentadiene.[88] Here, the product is reported to be 4-chloro-4-methyl-1-butene. Thus, if this information is correct, then it is the only example which is not in accord with the general rule mentioned above: that the proton adds only to the terminal carbon atom of the conjugated system. With 4-methyl-1,3-pentadiene, the intermediate carbenium atom is evidently stabilised by hyperconjugation with the C−H bonds of the two methyl groups.

Hydrochlorination and hydrobromination of 1-phenyl-1,3-butadiene leads to the 4,3-adducts, i.e. 1-phenyl-3-halogeno-2-butenes.[185,186]

1-Chloro-1,3-butadiene adds HCl at −10 to −15 °C in the presence of Cu_2Cl_2 to give primarily 1,3-dichloro-1-butene (73%

4,3-adduct) together with a mixture of 1,1-dichloro-2-butene and 1,4-dichloro-2-butene (in 15% yield).[187] A catalyst, e.g. $AlCl_3$ or $FeCl_3$, is necessary for this reaction in non-aqueous media.[188]

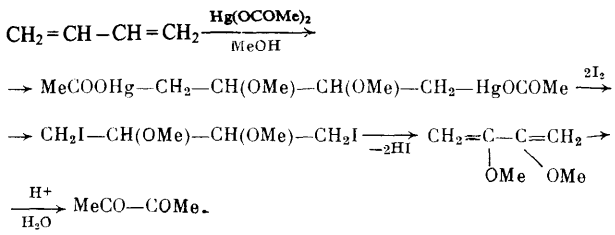
1,3-Dihalogeno-2-butenes are formed predominantly by interaction of chloroprene or bromoprene with HCl or HBr in the presence of copper halides.[189–194] The reaction of bromoprene with HCl, either in the presence or absence of Cu_2Cl_2, is accompanied by isomerisation and halogen exchange to give 3% of the 2,1-adduct.[195] The formation of a small amount of primary carbenium ion is possibly associated with the participation of the halogen atom in the conjugated system.

The hydrochlorination of a numbr of dichlorobutadienes and mono- and dichloro-isoprenes is summarised in Table 3.

It is clear from the tabulation that addition of HCl takes place preferentially at the unfunctionalised double bond.

The replacement of the hydrogen atoms of the methyl group by chlorine lowers its electron-donating properties in relation to the conjugated double bond system, and the mesomeric effect of a chlorine atom at the other double bond has a clear effect on the orientation of attack by the proton.

1,2-Dichloro-1,3-butadiene adds HBr at the unchlorinated double bond in accordance with the Markovnikov rule,[198] and 2,3-dichloro-1,3-butadiene affords the 1,4-adduct.[85]



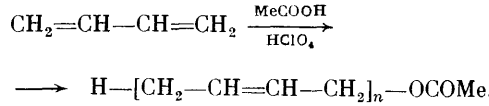
Hydrobromination of 1-phenyl-4-chloro-1,3-butadiene takes place at the 4,3-position, i.e. by attack of proton at the terminal carbon atom of the chlorinated double bond.[45]

2. Addition of water, alcohols and organic acids

The reactions of 1,3-alkadienes with hydroxyl-containing compounds have not been extensively studied, although they are of significant interest as methods of preparing unsaturated alcohols and ethers. Certain of the latter may serve as suitable synthons in, for example, the synthesis of natural products and their analogues.

Diacetyl has been obtained by addition of water to 1,3-butadiene in the presence of Hg^{2+} and acid.[199,200]

The initial stage of formation of diacetyl involves addition of methanolic mercuric acetate to 1,3-butadiene according to the following scheme.[201]

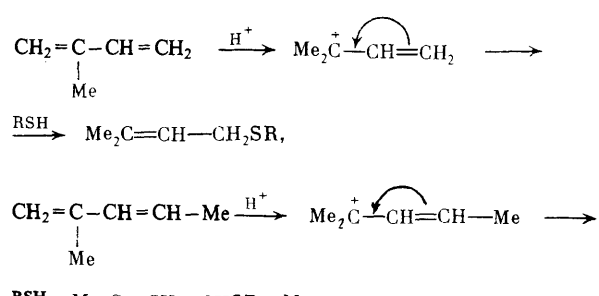


A mixture of 1,2- and 1,4-adducts was obtained by hydration of 2-alkyl-1,3-butadienes in the presence of mineral acid. Hydration of isoprene gives primarily 3-methyl-1-buten-3-ol.[202]

The addition of water to 1-phenyl-1,3-butadiene in the presence of acid, under kinetic control, proceeds with initial protonation of the C_4 atom and formation of a mixture of isomeric alcohols (4,3- and 4,1-adducts).[203]

A kinetic study has been made of acid-catalysed hydration of 1,3-butadiene, chloroprene, bromoprene, and 2-phenyl-1,3-butadiene.[202]

Addition of acetic and propionic acid to 1,3-butadiene in the presence of perchloric acid affords mainly the 1,4-adduct. Telomerisation takes place simultaneously with the formation of esters having two or more linearly bonded butene residues.[204]



In the case of acetic acid, the yield of 1,4-adduct (n = 1) is ~15% and that of the telomer (n = 2) is ~35%. Isomeric esters were also isolated in trace amounts as a result of telomerisation of the corresponding isomeric carbenium ions. Several patents have been published on this process, e.g. Ref. 205.

The addition of acetic acid to isoprene in the presence of $HClO_4$ proceeds mainly by 1,4-addition and is accompanied by telomerisation.[206] This reaction has been applied to the synthesis of prenyl acetate, aliphatic terpenes, sesquiterpenes, etc., notably geranyl acetate and farnesyl acetate.

Hydration of chloroprene in the presence of acid proceeds predominantly by 1,4-addition with the formation of 3-chloro-2-buten-1-ol.[192] More recently, it has been shown that methyl vinyl ketone is formed as a by-product in small amounts, i.e. 1,2-addition also takes place.[202]

3. Addition of thiols

Thiols and mercapto-containing compounds in general add to unsaturated hydrocarbons and their derivatives primarily by radical and nucleophilic mechanisms. Electrophilic addition does not normally take place. However, reference has been made to the electrophilic addition of thiols to 1,3-dienes in the presence of catalytic amounts of $HClO_4$.[207] In this way, 1,4-adducts are formed preferentially (> 80% yield). With unsymmetrical alkadienes proton attack takes place at the terminus having the most nucleophilic carbon atom to give the corresponding carbenium ion.

Reaction with 2-methyl-1,3-pentadiene is more facile than with isoprene, as would be anticipated for electrophilic addition.

IV. Addition of compounds with an electrophilic carbon atom

Organic halides add to a multiple bond only in the presence of a Friedel-Crafts-type catalyst. Acyl halides and α-halogenoethers are the most reactive.

1. Addition of alkyl and alkenyl halides

The first reference to the addition of alkyl and alkenyl halides to 1,3-alkadienes was made in a French patent in 1938.[208] This reaction was studied in detail by Leets and A A Petrov et al., commencing in 1954.[209–213,215–223] In the addition to unsaturated halogeno derivatives, satisfactory yields were only obtained by reaction with tertiary alkyl halides. The latter add in the 1,4-position, reaction being accompanied by telomerisation, i.e. 1:1 adducts are formed together with 2:1, 3:1, etc. adducts. Most reactions have been carried out in the presence of $SnCl_4$ as catalyst, although improved yields may be obtained with $BiCl_3$.[214] The regioselectivity of addition to unsymmetrical alkadienes is the same as that with hydrogen halides. The products of these reactions have been widely used in the synthesis of unsaturated hydrocarbons, carbonyl compounds, carboxylic acids, and various heterocyclics.[211]

The reaction between 1,3-alkadienes and allylic halides is synthetically the most interesting, notably the reaction of isoprene with isoprene-HCl adducts.[215,216] In this case, a mixture of 1:1 adducts is obtained, comprising geranyl chloride (52–56%), linalyl chloride (7–8%), lavandulyl chloride (9–10%), α-terpenyl chloride (18–20%) and prenyl chloride dimers (9–10%).[217] Farnesyl chloride is one of the components of the fraction containing a 2:1 mixture of telomers.[218–200] This compound can also be obtained by reaction of isoprene with geranyl chloride.[221,222]

The above-mentioned reaction has been applied in recent years to the synthesis of various natural compounds and their analogues, including vitamins, hormones and insecticides.

Studies have also been made of the products formed by telomerisation of other alkadienes with various allylic chlorides. Thus, a number of homologues, isomers and analogues of natural terpenes have been obtained.

2-Chloro-1,3-butadiene adds alkyl and alkenyl halides in the 1,4-position, the regioselectivity being the same as with HCl.[223]

2. Addition of halogenoethers

The study of the reaction between 1,3-dienes and α-halogenoethers in the presence of Friedel–Crafts catalysts was undertaken much earlier than that with other organic halides.[224] This reaction was investigated in detail by Pudovik between 1945 and 1949.[225–227] Catalytic activity decreases in the following order: $ZnI_2 > ZnBr_2 > ZnCl_2 > HgCl_2 > Cu_2Br_2 > PdCl_2 > CoCl_2$. Ethers of the type ArCH(Hal)OMe react with alkadienes without a catalyst. A mixture of 1,2- and 1,4-adducts is obtained from 1,3-butadiene, the former comprising 75–80% if isomerisation is prevented. At equilibrium the mixture contains 75% of 1-methoxy-3-pentene.

Isoprene affords 1,4-adducts predominantly, i.e. 4-alkoxy-1-chloro-2-methyl-2-butenes.[227] The reaction of 1,3-alkadienes with α-chloroalkyl acetates leads to alcohols following 1,4-addition.[228] The reaction of alkadienes with cyclic α-chloroethers proceeded in the same manner.[229–231] 4-Alkoxy-1,3-dichloro-2-butenes were chiefly obtained by treatment of chloroprene with α-chloroethers, i.e. the regioselectivity of the reaction is the same as that with hydrogen halides.[232,233] Tetrahydropyran derivatives were mainly formed by reaction of alkadienes with α,α-dichloroalkyl ethers.[234] The products obtained by reaction with α-halogenoethers have been used synthetically in a variety of ways, e.g. in the synthesis of juvenile hormones and insecticides.[211,234–236]

3. Addition of acyl halides

The reactions of unsaturated compounds with acyl halides with Friedel–Crafts catalysts were first studied in the 1960s.[211,237,238]

It was not until several years later that Badanyan et al. reported the successful chloracylation of alkadienes, e.g. isoprene, chloroprene, isomeric dichlorobutadienes and other alkadienes.[239–243] Acyl halides add to alkadienes in the presence of $AlCl_3$ at −78 °C to give ethylenic ketones of the type $RCOCH_2CX=CHCH_2Cl$, which readily dehydrochlorinate with triethylamine to give primarily *cis*-2,4-dienones of the type (*E*)-$RCOCH=CX-CH=CH_2$.[240,241] Dehydrochlorination can take place during the reaction.

Unsaturated aromatic ketones are obtained by chloroacylation of 1,3-alkadienes and their halogen-containing derivatives in the presence of aromatic compounds:[243]

$$CH_2=CX-CX=CH_2 \xrightarrow[AlCl_3]{MeCOCl,\ PhR} Me-CO-CH_2-CX=CX-CH_2-C_6H_4R.$$

Dibasic dicarboxylic acid chlorides (derived from suberic, azelaic and sebacic acids) react similarly with 1,3-butadiene and chloroprene under the same conditions. The products formed by double addition readily dehydrohalogenate with triethylamine to give (*E,E*)-diketotetraenes of the type $[CH_2=CH-CX=CHCO(CH_2)_n]_2$.[242]

Acylation of 1,3-butadiene with acetyl fluoroborate in the presence of acetic anhydride (in 1:1 proportion) leads to the formation of 1,2- and 1,4-solvo-adducts, namely (*E*)-3-acetoxy-1-hexen-5-one (by 1,2-addition) and 1-acetoxy-2-hexen-5-one (by 1,4-addition), respectively, in 1:8 proportion.[244,245]

$$CH_2=CH-CH=CH_2 \xrightarrow[(MeCO)_2O]{MeCO^+,\ BF_4^-} \begin{cases} \rightarrow Me-CO-CH_2-CH(OCOMe)-CH=CH_2, \\ \rightarrow Me-CO-CH_2-CH=CH-CH_2OCOMe. \end{cases}$$

The addition of acetyl fluorosulfonate to alkadienes provides a potential synthetic route to acyl-1,3-alkadienes.[246] The latter are obtained by treatment of the adducts with triethylamine. If the dehydrohalogenation is carried out in methanol, the corresponding solvo-adducts are formed, i.e. β-alkoxy-γ,δ-ethyleneketones.

$$CH_2=CH-CH=CH_2 \xrightarrow{Me-CO-OSO_2F} Me-CO-CH_2-CH(OSO_2F)-CH=CH_2$$

$$\xrightarrow{Et_3N} Me-CO-CH=CH-CH=CH_2, \qquad \xrightarrow{Et_3N,\ MeOH} Me-CO-CH_2-CH(OMe)-CH=CH_2.$$

V. The addition of compounds with an electrophilic atom of sulphur or its analogues

Organosulphur compounds with the sulphur atom in all three valence states may participate in electrophilic addition or substitution of 1,3-alkadienes. Most of the data in this area relates to the reactions of 1,3-alkadienes with sulphenyl chlorides, RSCl. However, reactions with sulphinyl chlorides, sulphonyl chlorides and SO_3 are also known.

1. Addition of sulphenyl halides and their analogues

Reactions of unsaturated compounds with sulphenyl halides and their analogues have already been the subject of a review.[247] They all proceed by electrophilic attack with the intermediate formation of an episulphonium ion.[248,249] With unsymmetrical olefins, adducts may arise in accordance with, and contrary to, the Markovnikov rule, the Markovnikov products predominating under kinetic control. These reactions are more facile in polar media, and are characterised by *trans*-addition.

Studies have been made of the reactions of sulphenyl chlorides with 1,3-alkadienes, their halogeno- and trialkylsilyl-derivatives, and with 1,3-alkadienylphosphonates. 1,2-Addition or 3,4-addition takes place in all cases, either exclusively or predominantly.[250–257] As is evident from Table 4, sulphenyl ion initially attacks 1-alkyl- or 1-aryl-derivatives at the 4-position, 2-methyl-derivatives at the 1-position, and 2-phenyl-derivatives at the 4-position. The rate of addition can vary by factors of ten.[252]

The nature of the solvent has a pronounced effect on the regioselectivity of addition. Thus, in acetic acid, isoprene and *p*-chlorobenzenesulphenyl chloride give 1,2-, 4,3- and 4,1-adducts in 20:20:60 proportion, while in nitromethane the ratio is 61:18:21, in THF it is 33:27:40, and in CCl_4 it is 63:22:15.[253]

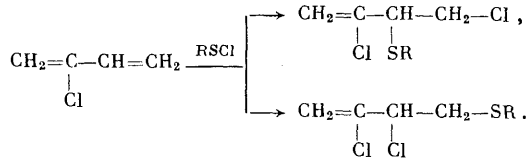
The 1,2-adducts readily isomerise, even at room temperature, to give the thermodynamically more stable 1,4-adducts. At equilibrium the mixture contains more than 90% of the 1,4-isomer. The rate of isomerisation increases on heating in the presence of sulphuric acid as catalyst. The nature of the substituent on the sulphur atom influences the rate of isomerisation. Thus, the products obtained by addition of PhSCl isomerise less than those obtained with MeSCl.[251]

Acetylthiosulphenyl chloride (MeCOSSCl) adds to 1,3-butadiene in the same manner at −20 °C in CH_2Cl_2. With piperylene, addition takes place preferentially (82%) at the mono-substituted double bond.[255]

Dimethyl and diphenyl disulphide undergo 1,4-addition with 1,3-butadiene in the presence of boron fluoride. Reaction also proceeds via an episulphonium intermediate, although in the presence of a catalyst rearrangement takes place.[256]

Diethoxyphosphorylsulphenyl chloride adds to 1,3-butadiene to give the 1,2-adduct in accordance with the Markovnikov rule.[257]

p-Chlorobenzenesulphenyl chloride adds to 1-chloro-1,3-butadiene at the unfunctionalised double bond.[253]



The reaction of methyl- and *p*-chlorobenzene-sulphenyl chloride with chloroprene proceeds chemo- and regio-selectively. Attack takes place at the more nucleophilic C_3-C_4 double bond with the

Table 4. Addition of *p*-chlorobenzenesulfenyl chloride to 1,3-alkadienes.

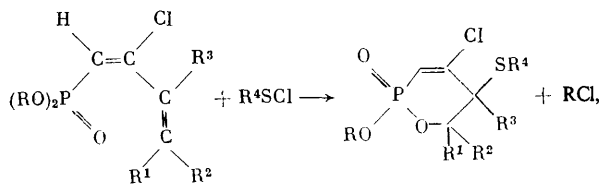
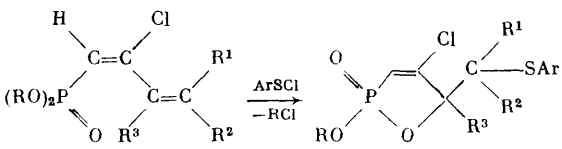
* The first number refers to the yield from the *Z*-isomer, and the second number from the *E*-isomer; 2* only one isomer isolated; 3* the yield was almost the same from either *E*- or *Z*-isomer; 4* the *Z*-adduct was formed from the *Z,Z*-isomer; the *Z*/*E* proportion was ≃28:67 from the *Z,E*-isomer, and ≃22:73 from the *E,E*-isomer.

predominant formation of the Markovnikov adduct (74–94%) and 6–26% of the anti-Markovnikov adduct.[255]



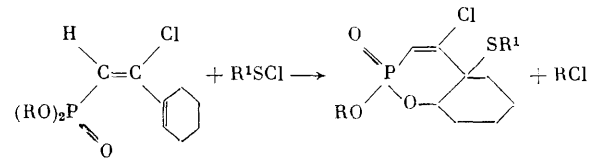
The addition of alkylsulphenyl halides (chlorides and bromides) to 1-trialkylsilyl-1,3-dienes takes place at the non-silyated double bond in accordance with the Markovnikov rule, i.e. formation of 4,3-adducts.[258]

The high regioselectivity is evidently a consequence of increased steric hindrance at the silylated double bond. It is also probable that the addition at the 4,3-position is facilitated by the increased stability of the episulphonium ion at the unfunctionalised double bond relative to that at the C_1-C_2 double bond due to $d_\pi-p_\pi$ interaction. The resulting 4,3-adducts undergo allyl rearrangement on heating (distillation) with migration of halogen from tertiary to primary carbon atom.[258]



R = Me, Et; R^1 = H; Me; R^2 = Me, Et; X = Cl.

Sulphenyl chlorides react with phosphorylated 1,3-alkadienes at the C_3-C_4 double bond, as is the case with addition of halogens (as mentioned earlier). A 5- or 6-membered heterocycle is then formed depending on the nature of the sulphenyl chloride. This interaction is not regioselective since a number of conformers are involved in the reaction.[259] With alkylsulphenyl chlorides, the *cis*-conformer of the alkadienylphosphonate is involved.



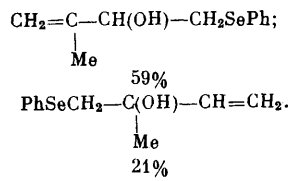
R^4 = Me, Pr^i.

Because of steric hindrance by substituents, the interaction with arylsulphenyl chlorides involves the *S-trans*-conformer, which leads to 2,5-dihydro-1,2-oxaphospholes:[259]

Ar = Ph, *p*-MeC_6H_4.

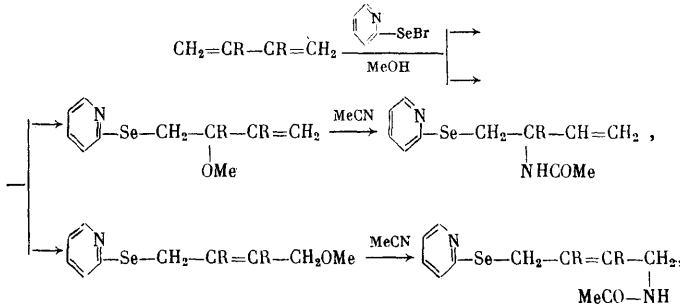
The interaction of 2-chloro-2-(1-cyclohexenyl)vinylphosphonates with sulphenyl chlorides affords hexahydrobenz-2*H*-1,2-oxaphosphorines, irrespective of the nature of the substituent on the sulphur atom.[260]

R^1 = Me, Pr^i, Ph, *p*-MeC_6H_4.



The fact that 6-membered bicyclic *P,O*-heterocyclics are formed predominantly, irrespective of the nature of the organic residue (on sulphur), can be explained, in part, by the stability of the *S-cis*-conformer of the starting dienephosphonate and, in part, by the probable increased stability of the intermediate involved in formation of the bicyclic compound relative to that of the spirocyclic intermediate which would arise if a 5-membered *P,O*-heterocycle were formed.

Phenylselenenyl chloride adds to isoprene both at the 1,2- and 4,3-positions. The ratio of the adducts is 1:1 at 0 °C and 5:2 at 60 °C.[261]

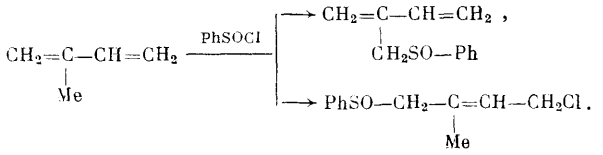


Alkylselenenyl chlorides add to *Si*-containing 1,3-alkadienes only at the unfunctionalised double bond, in the same manner as alkylsulphenyl chlorides. Here, the electrophile (RSe^+) attacks C_4 of the conjugated system to give the corresponding 4,3-adducts.[262]

The interaction of 1,3-alkadienes with selenenyl chlorides may also lead to solvo-adducts,[263] as is the case with halogenation (see earlier). Hydroxyl-containing selenoethers are obtained by reaction of PhSeCl with 1,3-butadiene, isoprene, and 2,3-dimethyl-1,3-butadiene in acetonitrile-THF in the presence of water.

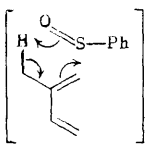
With isoprene, addition takes place predominantly at the monosubstituted double bond. 1,4-Adducts are not formed.

The interaction of 1,3-butadiene and 2,3-dimethyl-1,3-butadiene with 2-pyridylselenenyl bromide in methanol and acetonitrile proceeds in a similar way in the presence of CF_3SO_3H, although here solvo-adducts of a different type are formed.[264] With 1,3-butadiene, the ratio of 1,2- and 1,4-adduct was 67:33, while 2,3-dimethyl-1,3-butadiene gave only the 1,4-adduct.



R = H or Me.

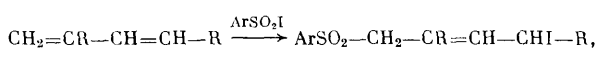
As 1,2-adducts readily isomerise into 1,4-adducts, the latter may arise via isomerisation of initially-formed 1,2-adducts.



The interaction of 1,3-alkadienes with $PhSeCl_3$ has also been studied.[265] 1,3-Butadiene affords 2-chloro-3-butenyl(phenyl)selenide dichloride, which can be converted to chloroprene on hydrolytic removal of the selenium function. Isoprene gives a mixture of 1,2- and 4,3-adducts in 1 : 1 proportion.

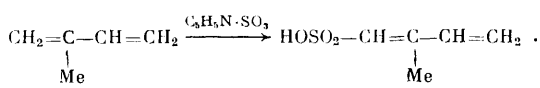
2. Reactions with oxygen-containing sulphur compounds

The interaction of 1,3-alkadienes with benzenesulphinyl chloride has only been studied in the case of isoprene.[266,267] Reaction proceeds predominantly by sulphinylation, but the mechanism of the conversion has not yet been established with certainty.



It is thought that sulphinylation takes place by an ene-type reaction through the following transition state:

Reactions of 1,3-alkadienes with aromatic sulphonyl halides has been studied widely. In the majority of cases, reaction proceeds in the presence of a catalyst, notably copper halides, by a radical-ion mechanism (Ascher–Vofsi reaction).[268,269] The same is true for the related sulphonylhalogenation based on the reaction between diazo compounds and SO_2.[270]



Sulfonylhalogenation by electrophilic addition in the absence of catalyst is rare. However, 1,4-addition does take place in the absence of catalyst by reaction of 1,3-butadiene, *trans*-piperylene, isoprene, and 2,3-dimethyl-1,3-butadiene with arenesulfonyl iodides.[271] The regioselectivity of the reaction with piperylene and isoprene is in accord with a mechanism involving electrophilic addition.

R = H, Me.

The amount of the lesser regioisomer, i.e. the 1,4-adduct, depends on the reaction conditions, but never exceeds 17%.

Direct sulfonylation of alkadienes with pyridine.SO_3 complex is of potential synthetic interest, but has not been greatly studied.[272] In all examples, replacement of hydrogen proceeds at the most nucleophilic carbon atom, being C_1 in the case of isoprene.

The mechanism of this reaction has not been studied. However, in all probability it is similar to aromatic electrophilic substitution. The authors of these investigations consider that reaction involves the intermediate formation of a 1 : 2 complex between the alkadiene and pyridine.SO_3.

VI. The addition of compounds with an electrophilic nitrogen atom

The addition of compounds with an electrophilic nitrogen atom to unsaturated compounds has not been studied extensively. The mechanism of such reactions has only been established in certain instances, but even here there is uncertainty in some respects. There is evidence to support electrophilic attack at the double bond by such reagents as nitrosyl chloride ($NO^{\delta+}Cl^{\delta-}$), N_2O_3, N_2O_4, nitryl halides ($NO_2^{\delta+}Hal^{\delta-}$), etc. However, one cannot exclude the possibility of addition of the reagents via a four-centred transition state, or by a free radical mechanism as a result of the weak polarisation.[2,273]

1. Addition of nitrogen oxides

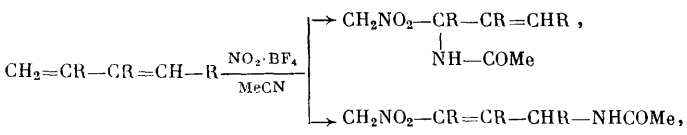
NOCl adds to 1,3-butadiene at the 1,2-position in accordance with the Markovnikov rule, followed oxidation of the resulting nitroso compounds to nitro derivatives.[274] It is likely that this reaction proceeds through a four-centred transition state.[5]

Dinitro compounds and nitro(nitroso)alkenes are obtained by interaction of conjugated dienes with N_2O_3. Thus, 2,3-dimethyl-1,3-butadiene affords 2,3-dimethyl-1,4-dinitro-2-butene and 2,3-dimethyl-4-nitro-1-nitroso-2-butene dimer.[275,276]

1,3-Butadiene,[277,278] 2,3-dimethyl-1,3-butadiene,[279] 2,3-di-tert-butyl-1,3-butadiene[280] and 1,4-diphenyl-1,3-butadiene[281,282] yield 1,4-adducts with N_2O_4, while 2,3-diphenyl-1,3-butadiene[283] affords a mixture of 1,2- and 1,4-adducts.

The interaction of nitryl chloride with 1,3-butadiene, isoprene and piperylene in methylene chloride leads to a mixture of 1,4-adducts and products derived by isomerisation of the latter wherein the double bond migrates towards the nitro group.[284,285] Such isomerisation of unsaturated nitro compounds has been reported elsewhere in the literature.[286]

The addition of nitryl iodide (N_2O_4 + I_2) to 1,3-alkadienes leads to the formation of only 1,4-adducts.[287–289]



It is possible to nitrate 1,3-butadiene with concentrated nitric acid.[290,291] However, there are no details on this reaction, and it cannot be excluded that it proceeds with the participation of nitrogen oxides by a radical mechanism.

Recently, the reaction of 1,3-alkadienes with nitronium acetate [HNO_3 + $(MeCO)_2O$] was studied.[292] Thus, the reagent adds to isoprene to give a 3 : 7 mixture of 1,2- and 1,4-adducts, the latter containing 85% of the *trans*-isomer. In contrast to nitronium acetate, the corresponding trifluoroacetate (trifluoroacetic anhydride with added NH_4NO_3) adds to 1,3-alkadienes at the 1,2-position according to the Markovnikov rule.[293]

The adducts formed in the two reactions mentioned above readily eliminate acetic or trifluoroacetic acid to yield 1-nitro-1,3-alkadienes.

Nitronium fluoroborate has been used to prepare solvo-adducts.[294,295] In acetonitrile reaction with 1,3-alkadienes affords acetylaminonitro compounds. The ratio of 1,2- to 1,4-adducts is as follows: 48 : 51 for 1,3-butadiene, 39 : 50 for isoprene, 35 : 35 for

2,3-dimethyl-1,3-butadiene, 26:64 for piperylene, and 6:78 for 2,4-hexadiene.

R = H, Me.

Treatment of chloroprene with N_2O_4 leads to both 1,4- and 1,2-adduct, the former predominating.[296,297] The addition of NO_2Cl affords 1,4-adducts and products derived by their subsequent isomerisation (the double bond shifting towards the nitro group).

There are many reports on the nitration of polyhalogenated 1,3-alkadienes. Thus, nitration of 1,4-dichloro-1,3-butadiene with HNO_3 at 0–70 °C leads to *trans,trans*-1,4-dinitro-1,4-dichloro-1,3-butadiene, while treatment with $Cu(NO_3)_2$ at 20 °C leads to the formation of 1,4-dinitro-1-chloro-1,3-butadiene.[298]

The addition of N_2O_4 to polyhalogenated 1,3-butadienes proceeds mainly at the 1,4-position. Thus, a mixture of fluorinated 1,4-dinitro-2-butenes and 4-nitro-2-buten-1-ol nitrites was obtained on nitration of 1,1,4,4-tetrafluoro- and perfluoro-1,3-butadiene,[299] while the interaction of 1,2,3,4-tetrachloro-1,3-butadiene[89,300] and 1,1,2,4,4-pentachloro-1,3-butadiene[301] with N_2O_4 gives only 1,4-dinitro-adducts.

2. Reactions with aromatic diazo compounds

The reactions of 1,3-dienes with diazonium salts represent a special area of study. Recently, 1,4-halogenoarylation of 1,3-dienes in the presence of copper salts has been widely applied. Normally, reaction proceeds by a radical-ion mechanism,[302–305] but in certain cases an electrophilic mechanism is possible in the absence of copper ion.

1,3-Alkadienes participate in azo coupling with active diazonium salts in the same manner as aromatic compounds. The mechanism of this azo coupling has not been studied. However, one could invoke a mechanism similar to electrophilic aromatic azo coupling.

This reaction was discovered in 1919 by Meyer.[306] Terent'ev proposed an application of the method for the assay of 1,3-dienes in hydrocarbon mixtures.[307] It was studied more recently by Arbuzov and Rafikov, as exemplified by reactions with 1,3-butadiene and 2,4-hexadiene.[308] Brightly coloured crystalline azo compounds were isolated, and converted to the corresponding pyrazolines on reduction.

VII. Conclusion

From the data set out in this review, certain general conclusions can be drawn on electrophilic addition to 1,3-dienes.

The regioselectivity of electrophilic addition to 1,3-dienes is dependent on the nature of the electrophile, the structure and configuration of the 1,3-alkadiene, the nature of the solvent, the concentration of the reactants, and the temperature.

The reactions with hydrogen-containing electrophiles proceed with formation of carbenium ions, stabilised by allylic conjugation; in general, electrophilic attack takes place at the most nucleophilic atom of the conjugated system in accordance with the Markovnikov rule. The addition of HCl to 2-methyl-2,4-pentadiene is an exception: a tertiary carbenium ion, stabilised by hyperconjugation, is predominantly formed in this case.

Dilution favours electrophilic addition of halogens. Normally, the latter attack the terminal carbon atom of the conjugated system, but the nature of the halogen is an important factor. The position of attack by chlorine is determined by the electron density in the system, and evidently leads to that carbenium or ionium ion which is energetically most favoured. Attack by bromine and iodine need not take place at the most nucleophilic atom of the conjugated system since, being associated with formation of a cyclic onium salt, may be subject to steric factors.

The proportion of 1,2- and 1,4-adducts is determined first and foremost by the structure of the intermediate. The closer the intermediate is, in structure, to a carbenium ion, the more likely is 1,4-addition. Sulphenyl chlorides, which form stable episulphonium ions, add almost exclusively at the 1,2-position, in spite of the fact that such adducts tend to rearrange, even at room temperature, into the thermodynamically more stable 1,4-adducts.

The solvent has an effect on the regioselectivity of addition, either by virtue of its higher or lower polarity, or by its involvement in formation of the intermediate.

Both addition and replacement of hydrogen by halogen take place on treatment of 1,3-alkadienes with fluorine or chlorine.

1,3-Alkadienes participate in electrophilic substitution with nitronium salts, diazonium salts and pyridine.SO_3 complex, in the same manner as aromatic substrates.

Solvo-adducts may be formed on reaction of 1,3-alkadienes with halogens and with compounds containing electrophilic sulphur or nitrogen atoms; in the second stage of the addition process, a hydroxyl-containing nucleophile (e.g. water, alcohols, carboxylic acids, H_2O_2) or a nitrogen-containing nucleophile, such as a nitrile or a carboxylic acid amide, may participate.

The electrophilic addition to 1,3-alkadienylphosphonates is particularly interesting since, here, phosphorus-containing heterocyclics are formed as a result of intramolecular trapping of a nucleophilic centre.

All of these chemical properties of 1,3-alkadienes and their derivatives have been applied in organic synthesis, and the possibilities of broadening their synthetic value are by no means exhausted.

Synthetic aspects of the chemistry of *p*,π-unsaturated amines

I A Maretina
The Lensovet Technological Institute, Leningrad

ABSTRACT. The review covers the electrophilic and nucleophilic addition of mono- and bi-functionalised reagents to ynaminocarbonyl compounds to 1,3-enynes possessing an enamine or ynamine group. Amines of this type are synthons for preparing five-, six-, seven- and eight-membered rings with two heteroatoms as well as condensed ring systems. The effect of the structure of the acetylenic compound on the mode of interaction has been analysed. Special features of the intra- and inter-molecularity of the reactions were discussed. Data are presented in 1,3-dipolar cycloaddition with all three types of amine.

The bibliography contains 108 references.

IV. 1,3-Dipolar cycloaddition 68

I. Introduction

Acetylenes and their nitogen-containing derivatives play an important role in modern organic chemistry, as indicated in a number of reviews[1–3] and monographs.[4–7]

Over the last ten years, acetylene chemistry has developed along non-classical lines, and there has been particular emphasis on the study of 1,3-enynes possessing an ynamine (I) or enamine groups (II) and of ynaminocarbonyl compounds of type (III).

$$\underset{(I)}{R_2NC{\equiv}CCH{=}CR_2'}, \quad \underset{(II)}{R_2NCH{=}CHC{\equiv}CR'}, \quad \underset{(III)}{R_2NC{\equiv}CCOX},$$

where X = H, R′, OR′.

The reactivity of such compounds is different from that of the corresponding 1,3-enynes and acetylenecarbonyl compounds, and the amino group reactivity differs from that of simple tertiary amines. Unsaturated nitrogen-containing systems of this type, which are obtainable from the commercially available diacetylene[1], vinylacetylene and propargyl alcohol, are valuable synthons for the preparation of five-, six-, seven- and eight-membered heterocyclics with two heteroatoms, as well as condensed systems. In addition, alkenylynamines and ynaminocarbonyl compounds are synthetically useful starting materials for the synthesis of novel types of polyfunctionalised compound.

The study of reactions of *p*,π-conjugated unsaturated amines with bifunctional compounds, and research into structural effects, the nature of the reagent and the factors affecting the course of the reaction, have provided the basis for new routes to synthetically important compounds. The chemistry of ynamines has particularly developed in this direction during recent years, and their participation in multi-step syntheses of terpenes, steroids[8], vitamin D_3 [9] and peptides[5] has been noted. Conjugated ynamines with acceptor groups are especially valuable in this respect. They are considerably more active than simple and vinylacetylenic ynamines; furthermore, they possess reaction centres which offer wider scope for synthetic applications.

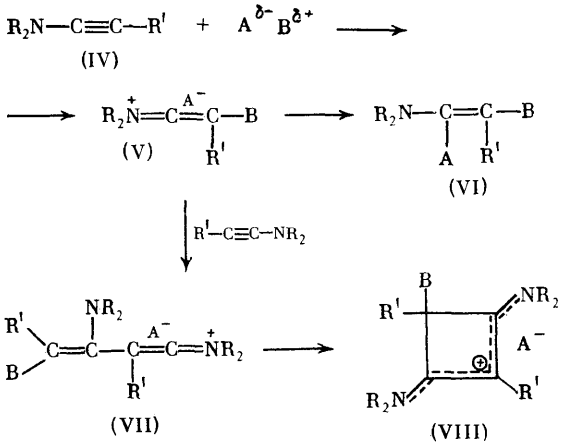
In one of the recent reviews, Shrot[2] states that "in the synthesis of heterocycles the triple bond serves as a latent carbonyl function, participating in the usual carbonyl condensations as well as in heteronucleophilic addition, being equivalent to vinylation at a heteronucleophilic centre". Developing the concept of "alkynes as pseudo-carbonyl compounds", the author formulated an orientation principle which is governed largely by electronic effects; other factors are not considered.

In heterocyclic syntheses from *p*,π-unsaturated amines (I–III), the pattern of behaviour is more complex.

II. The interaction of *p*,π-unsaturated amines with mono-functionalised electrophiles and nucleophiles

1. Reactions of alkenylynamines

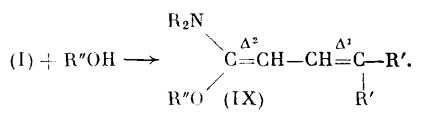
The first compounds with an ynamine structure (in the phenothiazine series) were obtained by chance in 1958. In 1961, while studying the nucleophilic replacement of halogen at sp^2- and *sp*-carbon atoms, Belgian chemists developed a number of methods of preparing this class of compound. Around the same time, further syntheses of ynamines were carried out by Viehe et al. (FRG), Ficini et al. (France), Arens et al. (Holland), A A Petrov et al. (USSR) and by a number of chemists in the United States.[5]



Contrasting with acetylenic hydrocarbons, conjugated *p*,π-unsaturated ynamines are strong nucleophiles.

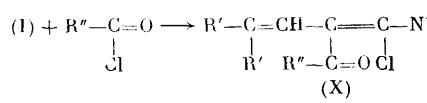
By interaction of ynamines (IV) with a polar molecule, $A^{\delta-}B^{\delta+}$, reaction proceeds at the C_2-atom with formation of a ketenimminium salt (V) (Scheme 1).

It is quite probable that the mechanism involves addition of B^+ at the nitrogen atom. Such an interaction would not be unlike that of the corresponding enamines,[6] but in the case of ynamines no stable salts have been formed. In the meantime, Drenth[10] reported a kinetic study of the acid-catalysed hydration of ynamines by stopped flow technique, which confirmed the formation of N-protonated intermediates with subsequent charge transfer to the C_2-atom of the acetylene group. The rate constant for the hydration of ynamines is 2000 times greater than that for the hydration of enamines. This is because the process of transferring a proton from the nitrogen atom

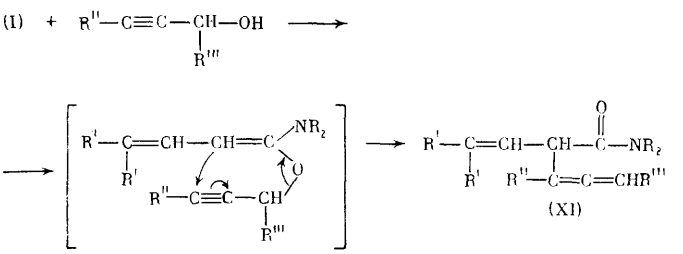


to the β-carbon of the ynamine is concerted, the separation and addition of the proton being accomplished in one step.

Scheme 1

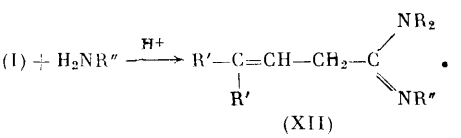


The pathway by which the ketenimminium salt is transformed is dependent on the reagent. Thus, on treatment with electrophilic reagents having a weakly nucleophilic anion, the salt (V) undergoes subsequent reaction with a second ynamine molecule rather than with the anion; in this way, an enamine-ketenimminium intermediate (VII) is formed, which subsequently undergoes intramolecular C-alkylation to form a π-cyclobutenyl cation (VIII) via addition of B^+ to the corresponding cyclobutadiene.[11]

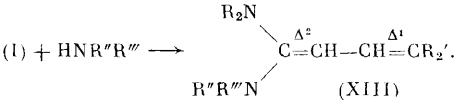


The reactivity of 1-dialkylaminoalk-3-en-1-ynes is noticeably less than that of simple ynamines. Thus, interaction with electrophilic reagents having a weakly nucleophilic anion, e.g. phenols, proceeds with the formation of vinylketene O,N-acetals, namely 1-dialkylamino-1-(aryloxy or alkoxy)-1,3-pentadienes, rather than cyclobutenium salts (VIII) as described above. Reaction proceeds regio- and stereo-specifically across the Δ^2-bond with formation of a *cis*-adduct.[12]

Ketenimminium salts (V) react with electrophilic reagents having strongly nucleophilic anions by addition of the anion A^-. Thus, treatment of 1-dialkylaminoalk-3-en-1-ynes with acetyl chloride or benzoyl chloride affords 1-dialkylamino-1-chloro-2-acetyl(benzoyl)-1,3-pentadienes (X) which are readily distillable.[13]

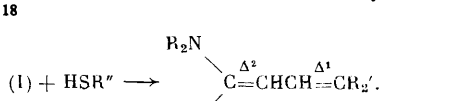


In certain cases, the ketenimminium salts (V) are sufficiently nucleophilic in themselves, and participate in Claisen rearrangement. Thus, branched dialkylamides of β-allenecarboxylic acids (XI) have been prepared by reaction of 1-dialkylamino-3-penten-1-ynes with propargyl alcohol.[14] Reaction with propargyl alcohol derivatives proceeds quite readily since the electron-accepting acetylene group increases the acidity of the alcohol.



Reaction of vinylacetylenic ynamines with nucleophiles proceeds only by acid catalysis. Thus, for nitrogen-containing analogues of propargyl alcohol the amino-Claisen rearrangement does not take place.

In catalysed reactions of 4-alkyl-1-dialkylamino-3-penten-1-ynes with primary amines, the amino group attaches to the C_1-atom of the multiple bond, but the interaction is complicated by protropic rearrangement involving the participation of the second labile hydrogen of the amino group with the formation of per-N-substituted amidines of 4-alkyl-3-pentenoic acids (XII).[15]



Reactions of 1-dialkylamino-4-methyl-3-penten-1-ynes with secondary aliphatic, aromatic and heterocyclic amines proceed regioselectively and with *cis*-stereospecificity across the acetylenic bond with formation of conjugated vinylketone aminals (XIII).[16,17]

From data on the reactivity of primary and secondary amines, it is clear that weakly basic amines are more reactive than highly basic amines since the latter inhibit acid catalysis. However, this is only true within a limited range of the basicity constant. Butylamine (pK_B = 3.2) and cyclohexylamine (pK_B = 3.34) are far less reactive than aniline (pK_B = 9.37). Secondary heterocyclic amines (piperidine, pK_B = 2.88) react far less than N-alkylaromatic amines (N-methylaniline, pK_B = 9.15) even though there is significant steric hindrance in the latter. *p*-Nitroaniline does not take part in the addition since its nucleophilic acitivity is low.

The addition of aliphatic and aromatic thiols proceeds across the acetylenic bond with the formation of vinylketone N,S-thioacetals (XIV).[18]

Reaction is not stereospecific. Reaction is regioselective and proceeds in the same manner as those described above, i.e. by attack of the nucleophile at the C_1-atom of the aminoenyne. However, mixtures of *Z*- and *E*-Δ^2-isomers are formed. The isomeric composition varies significantly and reproducible results cannot be achieved. This is because sulphur-functionalised ethylenes readily isomerise—a well-known observation in sulphur chemistry.

It cannot be excluded that a radical mechanism is involved in parallel with an electrophilic process. The interaction of (I) with RSH differs significantly from the reaction of simple ynamines. Thus, addition of propenethiol to the latter is accompanied by thio-Claisen rearrangement with formation of thioamides.[5]

The group $R_2NC{\equiv}C-$, is a masked carboxylic acid amide function. Thus, addition of compounds of the type H_2X (X = O, S, Se) to 1-dialkylamino-3-alken-1-ynes affords β,α-ethylenecarboxylic acid amides, thioamides and selenoamides, respectively (XV).[19,20]

$$(I) + H_2X \longrightarrow R'-C(R')=CH-CH_2-\overset{\overset{X}{\|}}{C}-NR_2. \quad (XV)$$

The thiol group displays significantly higher acidity and nucleophilicity than the hydroxyl group in similar compounds. Thus, reactions with H_2S and H_2Se proceed far more readily than reaction with water, the reactivity of the reagents increasing in the order O < S < Se.

In the case of thioamides, reaction can be reversed, i. e. synthesis of ynamines can be based on thioamides. The corresponding amides do not participate in the reverse reaction.[5]

$$C_6H_5-CH_2-\overset{\overset{S}{\|}}{C}-N(CH_3)_2 \xrightarrow{NaNH_2} C_6H_5-C{\equiv}C-N(CH_3)_2. \quad (XVI)$$

By comparison, the hydration of aminoenynes is not in itself of great interest. However, one should recall that this reaction has been applied in the dehydrative syntheses of functionalised carboxylic acid derivatives and in peptide synthesis.[5,20]

Thus, summarising the reactions of vinylacetylenic ynamines with simple nucleophiles, it should be noted that the nucleophile attacks the C_1-atom of the hetero-substituted acetylene bond, as is the case with the reactins of ynolethers, ynamines and enynolethers.

Alkenylynamines react with compounds containing polar multiple bonds, e. g. $>C=O$ (aldehydes, ketones, carboxylic acid esters) via intermediate formation of cycloaddition products, as is the case with simple ynamines.[26] Thus, substituted amides of unsaturated carboxylic acids (XVIII) are obtained in 60–65% by reaction of (I) with both aliphatic and aromatic aldehydes in the absence of catalyst.[21]

$$(I) + R''-CHO \rightarrow \left[R'-C(R')=CH-C(R''(H)-O)=C-NR_2\right] \rightarrow R'-C(R')=^{\Delta^1}CH-\overset{\overset{O}{\|}}{C}-CH_AR''-NR_2.$$

(XVII) (XVIII)

It is likely that reaction proceeds through an intermediate oxete, formed by the synchronous addition of the carbonyl atom group to the triple bond. Thus, for the reaction of 1-diethylamino-4-methyl-3-penten-1-yne with butanal, the ^1H NMR spectrum displays, in addition to signals from product (XVIII), a weak triplet (4.23 p. p. m.), which would correspond to the protons of the oxete ring in (XVII). This signal was absent when the spectrum was retaken after 2 days. Intermediates of type (XVII) have been isolated from the reaction of ynolethers with ketones.[22]

The ^1H NMR spectrum of (XVIII) (Table 1) confirms the formation of only one Δ^2-isomer. For structural confirmation, the experimental values of the chemical shifts of proton H_A were in agreement with those calculated according to the formula:[54]

$$\delta_H = 5.25 + Z_{gem} + Z_{cis} + Z_{trans}.$$

From the data presented, it is clear that the experimental values are close to the values for the *cis*-isomer, and noticeably different from those calculated for the *trans*-isomer. The *cis*-structure for (XVIII) is consistent with the proposal that reaction proceeds via a stereo-defined oxete ring. The isomeric composition at the Δ^1-unsaturation corresponds approximately with the proportion of double bond isomers in the starting ynamine — 30% *trans*-isomer and 70% *cis*-isomer. Thus, the double bond in the starting ynamine (I) does not take part in the reaction.

Table 1. Chemical shifts of vinylic protons

$$CH_3-C(CH_3)=CH-C(=O)-C(=CHR'')-NR_2,$$

where R″ = CH_3 (XVIIIa), C_2H_5 (XVIIIb), C_3H_7 (XVIIIc).

for *cis*- and *trans*-isomers at the Δ^2-bond.

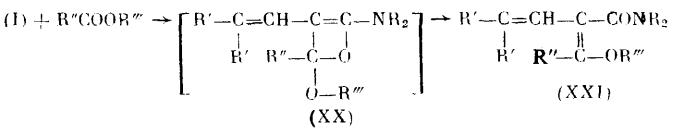
Compound	δ_H (found) p.p.m.		δ_H(calculated), p.p.m.	
	cis	*trans*	*cis*	*trans*
(XVIIIa)	5.52	—	6.00	6.45
(XVIIIb)	6.36	—	6.74	7.42
(XVIIIc)	6.56	—	7.01	7.69

According to the literature,[23] alkylamines readily react with ketones. However, reaction of alkenylynamines with ketones, under the conditions of the aldehyde addition, was not possible, except in the case of alkenylynamines (II) with cyclohexanone. Here, the yield is only 50% and the amount of catalyst had to be doubled.

Acetone and acetophenone react with alkenylynamines in the presence of a stoichiometric amount of $MgBr_2$. The latter is known to activate the carbonyl group of ketones by complex formation which increases the δ^+ charge on the carbon atom.[21]

$$(I) + R''R'''CO \xrightarrow{MgBr_2} R'-C(R')=^{\Delta^1}CH-\overset{\overset{\Delta^2}{\|}}{C}(CR''R''')-CONR_2.$$

(XIX)

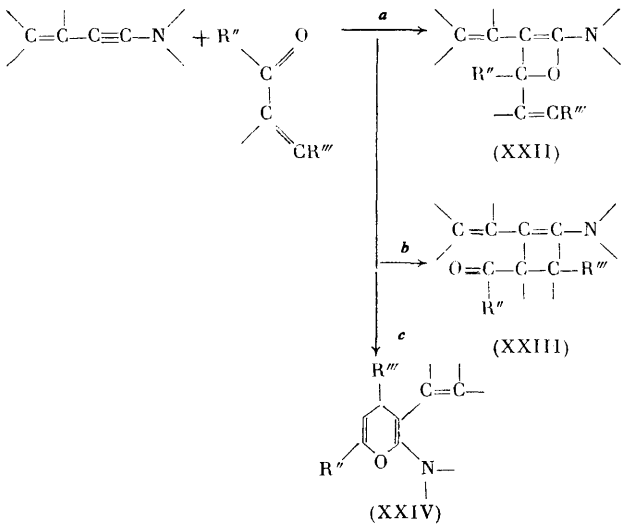


Reaction is regioselective, as with aldehydes; however, in the case of acetophenone stereospecificity is reduced with the formation of Δ^2-isomers in 67 : 33 proportion.

Thus, it has been shown, that alkenylynamines react with aldehydes regioselectively and stereospecifically at the triple bond in the presence of a catalytic amount of BF_3-etherate. Ketones only participate in the reaction in the presence of stoichiometric amount of $MgBr_2$ with the same regioselectivity, but reduced stereo-specificity.

The decrease in the electrophilic activity of the carbonyl group from ketones to carboxylic acid esters explains the lower activity of the latter in reactions with alkenylynamines. $MgBr_2$-ethereate serves as catalyst only with addition of ethyl acetate, and only on heating.

With carboxylic acid esters, there is a marked difference of reactivity between aliphatic and aromatic compounds. Methyl

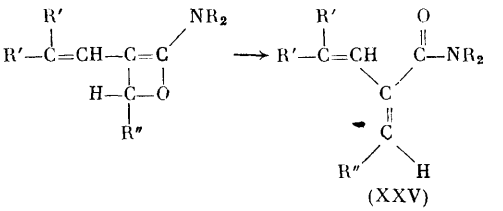


benzoate adds to alkenylynamines only in the presence of a stoichiometric amount of boron fluoride, the product yield being around 6–7%. The majority of unreacted methyl benzoate can be removed by distillation. The unconverted alkenylynamines polymerise, which evidently explains the low yield of adducts (XXI).[24]

(XX) (XXI)

Cycloaddition is strictly chemoselective, reaction taking place only at the triple bond of ynamine. A [2 + 2]-cycloaddition is involved. The intermediate oxete (XX) is unstable, and is immediately converted to the dialkylamides of the corresponding carboxylic acid.

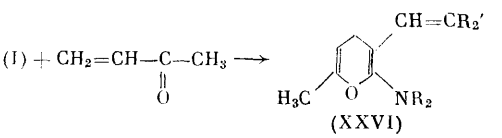
For cycloaddition of α,β-unsaturated aldehydes and ketones to alkenylynamines, there are several possible pathways (*a*–*c*).[25]



(XXII) (XXIII) (XXIV)

The more probable cisoid conformation should favour route *c* ([4 + 2]-cycloaddition), and the transoid conformation should favour route *b*. It has been shown, in fact, that [2 + 2]-cycloaddition of carbonyl compounds across the C=C bond (route *b*) is characteristic of cyclic ketones having a fixed transoid conformation.[26]

On the same theme, a study has been made of the reaction between alkenylynamines and α,β-unsaturated carbonyl compounds. Here is it assumed that rotation around the C–C bond is more rapid than the interconversion of the *cis*- and *trans*-conformers. For cinnamaldehyde one might anticipate reaction by all three pathways. It has been shown that, on reaction with 1-diethylamino-1-propyne, adducts are formed only by routes *a* and *c*.[27,28] In this particular example reaction takes place only on the carbonyl group (route *a*).



Phenylpropional might be expected to add with formation of products via a cyclobutadiene intermediate, as is characteristic of the reaction of alkenylynamines with activated acetylenes.[29,30] However, in the case of alkenylynamines, addition takes place only across the aldehyde group (route *a*) via an oxete intermediate.

^{1}H NMR spectral data confirms that only Δ^2-isomer is formed. The intermediate oxete undergoes electrocyclic ring opening by the most sterically favourable pathway. Thus, as with aliphatic and aromatic aldehydes[26], the *E*-isomer is formed.

(XXV)

Alkenylynamines react with methyl vinyl ketones by [4 + 2]-cycloaddition (route *c*) to give (XXVI).[25]

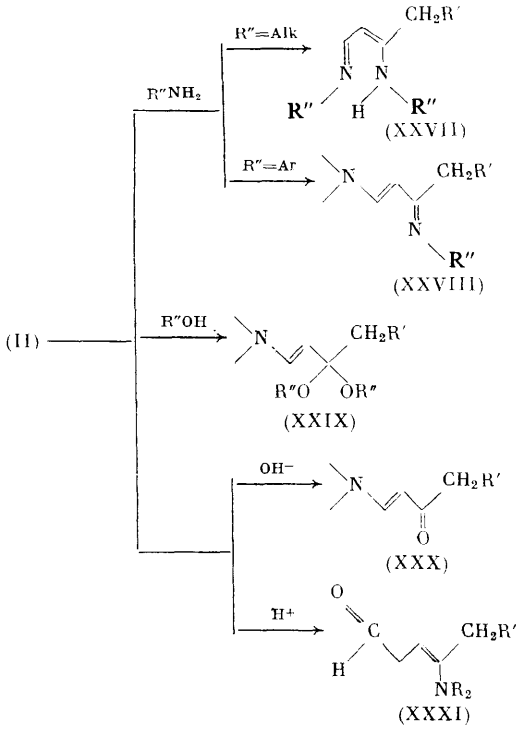
(XXVI)

Only scant reference to 4*H*-pyrans is given in the literature. Nevertheless, interest in this class of compound is great, primarily because 4*H*-pyrans are useful starting materials for the synthesis of pyrylium salts and unsaturated 1,5-diketones.[31] It is interesting to note that methyl vinyl ketone reacts with enamines either by heterocyclisation to give dihydro-4*H*-pyrans or by proton transfer to give unsaturated carboxamides.[32] Such proton transfer is not possible with ynamines since the system is fully unsaturated. As illustrated above, alkenylynamines can serve as valuable reagents for the synthesis of dialkylamino-4*H*-pyrans.

Summarising, the relative reactivity of the C=C and C=O group in α,β-unsaturated aldehydes and ketones determines the mode of addition to alkenylynamines.

2. Reactions of vinylacetylenic enamines, $R_2N-CH=CH-C\equiv CR'$, with mono-functionalised agents

In contrast with acetylenic hydrocarbons, en- and yn-amines readily participate in electrophilic reactions, and as a consequence the addition of nucleophilic reagents can take place, both in the presence and absence of mineral acid. However, with aminoenyne systems, the nature of the addition process is dependent on whether the amino group is attached to the ethylenic or acetylenic fragment.



Thus, enamines $R_2N-CH=CH-C\equiv CR'$ (II) react with primary aliphatic amines to give vinylogous and potentially tautomeric aminocrotonaldimines (XXVII) via transamination; on the other hand, reaction with arylamines proceeds with formation of (XXVIII) (Scheme 2).[33,34]

Base-catalysed addition of alcohols leads to vinylogous amide acetals (XXIX).[35] Depending on reaction conditions, hydration of (II) can provide β-aminovinyl ketones or β-aminocrotonoaldehydes.[35,37]

It should be pointed out that compounds (XXVII) are of potential synthetic utility. Thus, subsequent C-alkylation and hydrogenation affords N-monosubstituted 1-aminoalkanes as synthons for the nucleophilic incorporation of the 4-aminobutyl group (R = H).[36]

It is interesting to note that the reaction of 1-alkoxy-1-butene-3-ynes with alcohols affords primarily the C_1-adducts, hydration of

Scheme 2

which leads to β-ketoacetals, thence β-alkoxyvinyl ketones by thermolysis.[4]

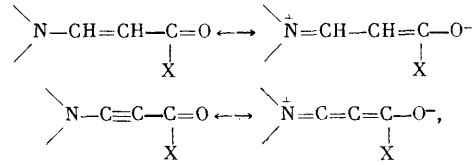
$$RO{-}CH{=}CH{-}C{\equiv}CH \xrightarrow{ROH,\ HOH(H^+)} \underset{RO}{\overset{RO}{\diagdown\!\!\diagup}}CH{-}CH_2{-}CO{-}CH_3 \longrightarrow$$
$$\longrightarrow RO{-}CH{=}CH{-}CO{-}CH_3.$$

According to Engelhardt[38], vinylacetylene undergoes 1,4-addition with secondary amines.

$$R_2NH + CH_2{=}CH{-}C{\equiv}CH \rightarrow R_2N{-}CH_2{-}CH{=}C{=}CH_2.$$

Badanyan reported the same mode of addition with tert-aminomethyl derivatives[39], i.e. the additional amino function has no effect on the reaction.

$$R_2N{-}CH_2{-}C{\equiv}C{-}CH{=}CH_2 + R_2'NH \rightarrow$$
$$\rightarrow R_2N{-}CH_2{-}CH{=}C{=}CH{-}CH_2{-}NR_2'.$$



Because the chemistry of enamines (II) has already been the subject of a review[1] and a monograph[4], the present article covers only general trends in the reactions of this compound class in relation to other types of amine.

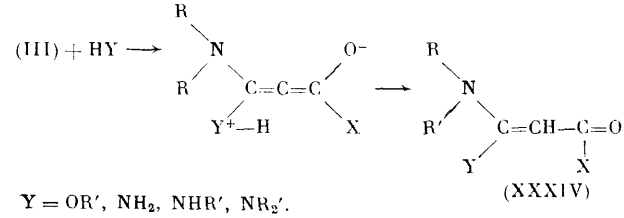
3. Reaction of ynaminocabonyl compounds, $R_2NC{\equiv}CCOX$ (III), with mono-functionalised reagents

The chemistry of enaminocarbonyl compounds has been well documented in a monograph[40] and in a number of review articles published in recent years[2,41]. Acetylene analogues of carbonyl compounds, first prepared some 100 years after the corresponding ethylenic derivatives, have been studied somewhat less. Data on their relative reactivity are few, and there have been no surveys in this area.

A study has been made of the electronic effects of donor and acceptor groups in ethylenic and acetylenic dialkylaminocarbonyl compounds on the electron density in the molecule by ^{13}C NMR spectroscopy. The constants for spin-spin interaction, $^{13}C-{}^{13}C(^1J_{CC})$, of the double and triple bonds in en- and yn-amines have been determined (Table 2) (pulse sequence inadequate with decoupling of the signals from ^{13}C-isomers[42]).

It has been shown that, in the case of en- and yn-aminocarbonyl compounds, the value is somewhat less than that calculated by the simple additive principle. This is a consequence of the delocalisation of the multiple bonds as a result of direct polar conjugation, through the double (triple) bond, involving the lone pair on the nitrogen atom and the π-system of the carbonyl fragment. This can be expressed by the following canonical forms:

X = H, R′, OR′.



The contribution of the bipolar resonance forms was computed to be around 30% for enaminocarbonyl compounds and in excess of 50% for the acetylene analogues.

By analysis of the chemical shifts in the ^{13}C NMR spectra of the carbon atoms of the triple bond of substituted ynamines, relative to the corresponding values for ethylenic analogues, there is evidence of opposite polarisation of the orthogonal π-system of the triple bond in ynamines containing acceptor groups. This effect explains the unusually low value for the shielding contribution from the dialkylamino group adjacent to the C-atom of the multiple bond.

The data obtained on the structure of ynaminocarbonyl compounds confirms that the conjugation of donor and acceptor groups with the multiple bond has a profound effect on the distribution of electron density in the molecule, and, thereby, on the reactivity of this class of compound. Carbonyl-containing dialkylaminoacetylenes thus have unique properties, differing from those of both simple ynamines[5,26] and acetylenic ketones.[43]

While simple ynamines react with mono-functionalised compounds only after initial protonation,[44] ynaminocarbonyl compounds react with alcohols, ammonia and amines in the absence of catalyst even at room temperature (ynaminoaldehydes) or at 60–70 °C (ynamino-ketones and -carboxylic acid esters).[45,46]

A detailed study of the mechanism, stereochemistry and kinetics of addition[47] have shown that the limiting step in the process is the nucleophilic attack of the alcohol or amine at the C_3 carbon atom. The bipolar compound formed is stabilised by proton transfer, so that in polar aprotic solvents the (*E*)-isomer is formed (by intramolecular proton transfer) whereas in protic solvents the product is a mixture of *E*- and *Z*-isomers (possibly formed via intermolecular protonation). Interconversion of the *E*- and *Z*-forms takes place on increasing the temperature.

Y = OR′, NH_2, NHR′, NR_2'.

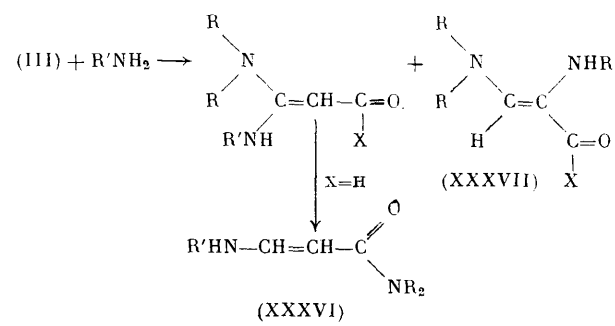
[a] *trans*-Isomers: chemical shifts given in p.p.m. (TMS) with a precision of ±0.05 p.p.m.; $^{13}C-^{13}C$ spin-spin coupling constants given in Hz and with a precision of ±0.2 Hz. [b] In compound 3 the signals from atoms C(1) and C(2) are doublets, and in compounds 4 and 5 there is noticeable broadening due to restriction of internal rotation around the C–N bond. [c] C(7) 15.47 p.p.m. [d] C(7) 194.98 p.p.m.; C(8) 26.96 p.p.m.

The addition of mono-functionalised nucleophiles to activated acetylenes is a second order reaction. The rate of reaction increases in parallel with 1) the basicity of the reagents (amines add more easily than alcohols, and secondary amines more rapidly than primary amines and ammonia), 2) the electrophilicity of the reactive centre at C_3 (the rate of addition decreases in the order: ynamino-aldehydes > ynaminoketones > aminoacrylic acid esters), and 3) the polarity of the solvent (as a result of enhanced solvation of the bipolar transition state).

It has been shown that the products obtained by addition of simple alcohols to ynaminodehydes undergo rearrangement to the isomeric aminoacrylic acid esters on heating or on treatment with protic or Lewis acids. Formally, the alkoxy group migrates from C_3 to the carbonyl group. Ynamino-ketones and -esters do not undergo such a transformation.[45,48]

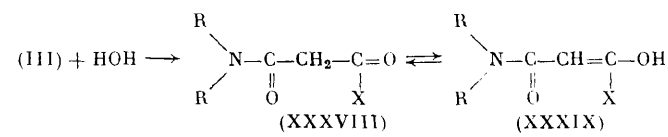


(III) + HY → N–C=CH–C=O → N–C=C–C=O, (XXXV)

X = H, Y = OCH_3, OC_2H_5.

3-Dimethylaminoacrylic acid esters are obtained in the *E*-configuration in 55–60% yield.

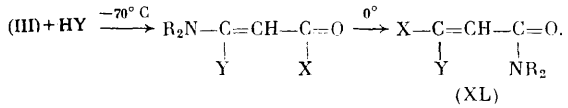
The rearrangement takes place via an oxete intermediate with migration of an oxygen atom and the dimethylamino group.[45]



The products of addition of amines to ynaminoaldehydes underwent rearrangement far less smoothly, and a low yield of 3-aminoacrylic acid dimethylamide was obtined, i.e. a similar oxygen migration takes place with participation of an amino group.

(III) + R′NH₂ → N–C(R)(R′NH)–CH=C(X)–C=O + N–C(R)(H)–C=C(NHR′)–C=O (XXXVII); X=H → R′HN–CH=CH–C(=O)–NR₂ (XXXVI)

By addition of ammonia and amines to ynamino-aldehydes and -ketones, isomeric adducts are also formed by inverse attack of nitrogen at the C_2-atom of the multiple bond to give (XXXVII).[49]

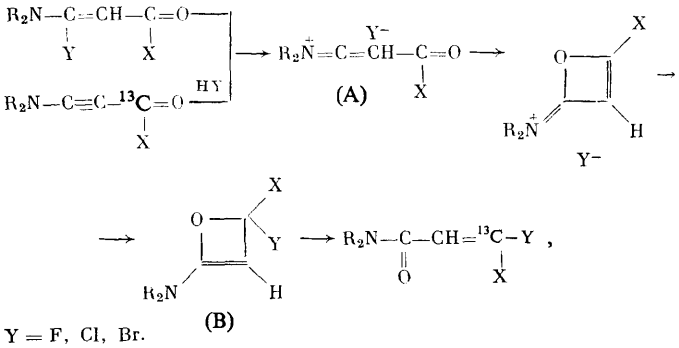


Hydration of ynaminocarbonyl compounds proceeds in neutral media at 20 °C (with ynaminoaldehydes) and at 60–70 °C (with ynamino-ketones and -esters).[45]

(III) + HOH → N–C(R)(R)–CH_2–C=O (XXXVIII) ⇌ N–C(R)(R)–CH=C(X)–OH. (XXXIX)

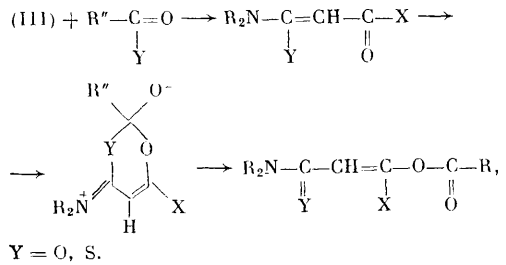
The β-ketoamides obtained exist as a mixture of keto and enol tautomers. According to ^{1}H NMR spectral data the proportion of the enol form in $CDCl_3$ varies from 4% (for esters, X = OMe) to 20% for ketones (X = Me). Acids readily add to the triple bond of ynaminocarbonyl compounds.[45,48] The geometry of the product is determined by the nature of the acceptor group. For aldehydes, the reaction is stereospecific, for ketones it is highly stereoselective in favour of the *trans*-adduct (*Z*-configuration), while esters afford both *cis*- and *trans*-adducts in approximately equal amount.

In the overwhelming majority of cases the initial adducts undergo facile rearrangement to the corresponding substituted α,β-ethylenic carboxylic acid dialkylamides (XL) (amino-, mercapto- and hydroxycarboxylic acid derivatives).



(XL)

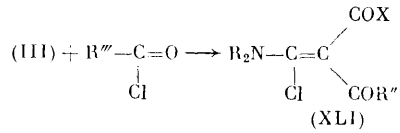
Rearrangement does not take place, or proceeds to a small extent, only in the case of dimethylaminopropiolic acid esters (X = OMe) or on addition of HF (Y = F). The adducts formed in these reactions are stable, even on heating.



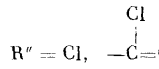
An oxete mechanism has been invoked only for the addition of hydrogen halides to ynaminocarbonyl compounds, as shown in Scheme 3.[45,50,51]

Scheme 3

Y = F, Cl, Br.



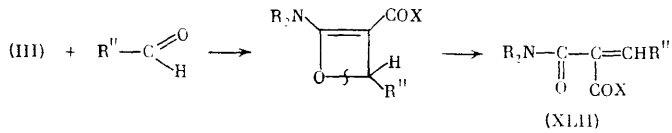
The mechanism of the rearrangement is quite different for the addition of carboxylic and thiocarboxylic acids. Here, there is intramolecular formation of an intermediate six-membered bipolar compound, which is subsequently cleaved stereospecifically.[50]



Y = O, S.

In such cases, the obtained *cis*-product isomerises to the thermodynamically more stable *trans*-product on heating to 60–70 °C.

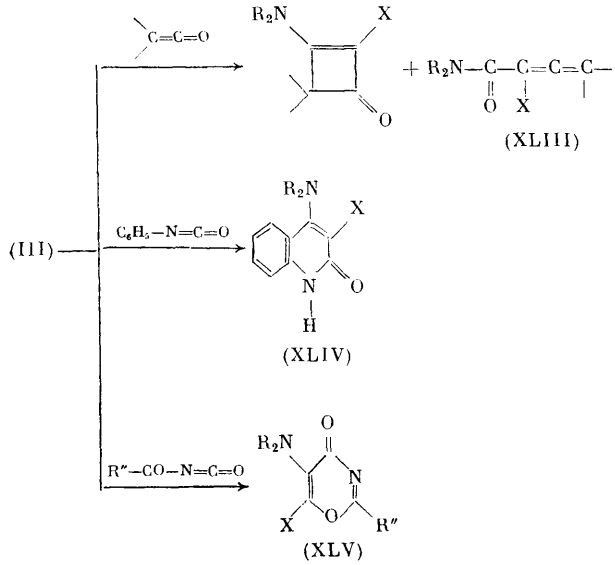
Acylation of ynaminocarbonyl compounds has been examined by a study of the reaction with phosgene and oxalyl chloride.[52] It has been shown that these reagents add across the triple bond of activated ynamines to give (XLI), as would be anticipated from considerations of the electron density.



(XLI)

The products obtained are extremely reactive, participating in heterocyclisation with a number of bifunctional reagents.

The interaction of aldehydes with ynaminocarbonyl compounds proceeds in a totally different manner. Here, there is an analogy with the reactions of ynamines (I). Thus, [2 + 2]-cycloaddition of the carbonyl group to the triple bond of the activated acetylene takes place at 0–5 °C in methylene chloride with formation of an oxete intermediate.

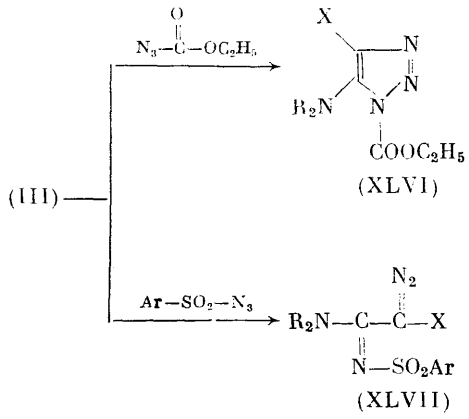


(XLII)

Stereospecific ring opening of the oxete leads to the corresponding unsaturated carboxylic acid amides (XLII), having a *cis*-configuration.[53]

The reaction of heterocumulenes with ynaminocarbonyl compounds affords cyclic products by [2 + 2]- [4 + 2]-cycloaddition[54,55] (Scheme 4)

Scheme 4



(XLIII)

(XLIV)

(XLV)

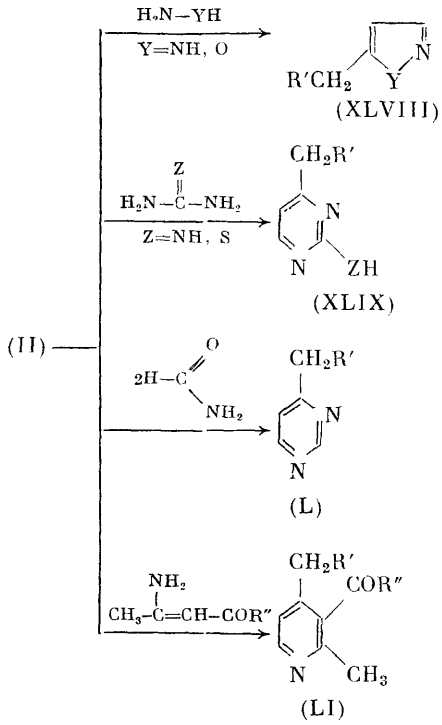
Ynaminocarbonyl compounds participate in reaction with 1,3-dipolar compounds in the same way as ynamines and acetylenecarbonyl compounds.[45] Thus, substituted triazoles are formed in high yields by interaction with ethyl azidoformate at 65 °C.

Arylsulphonyl azides, however, yield products derived primarily by triazole cleavage, the corresponding triazole analogues of (XLVI) being formed only in small amounts.[56]

III. Heterocyclisation involving *p*,π-unsaturated amines and bifunctionalised reagents

The reactions of enamines (II) with bifunctional compounds provide a general route to five- and six-membered heterocycles. In this capacity, enamines (II) have been described in reviews[1,2] as three-carbon synthons.

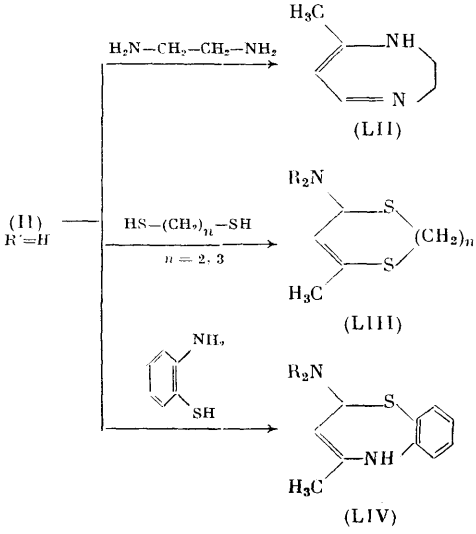
In acidic media, enamines (II) are protonated with the formation of a conjugated carbenium ion, ($R_2N-CH=CH-\overset{+}{C}=CH_2 \leftrightarrow R_2\overset{+}{N}=CH-CH=C=CH_2$), which, on further reaction, dictates the structure of the final product. Thus, reaction of the conjugated carbenium ion with reagents having adjacent functionality proceeds with participation of the C_1- and C_3-atoms, leading to the formation of 5-substituted isoxazoles and pyrazoles (XLVIII),[57,58] 2-substituted 4-alkylpyrimidines (XLIX), (L)[59–61] and 3-substituted 2,4-dialkylpyridines (LI)[57,62–65] (Scheme 5).



Since under acid catalysis the reaction of the carbocation with the nucleophile is the key step prior to cyclisation, the structure of the final product will, to a large extent, be determined by the activity of the electrophilic centres at C_1 and C_3 of the conjugated carbocation. For enamines (II), the electrophilic centre at C_1 has the greater effect, which accordingly determines the direction of the reaction.[66]

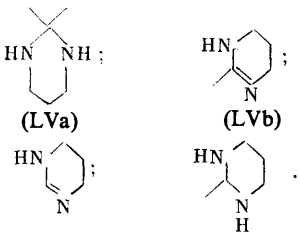
In this connection, one should especially emphasise the preparative value of the method since, by using β-dicarbonyl compounds or 1-alkoxy-1-alken-3-ynes as starting material in such ring syntheses, one obtains a mixture of 3- and 5-substituted isoxazoles and pyrazoles and a mixture of 2,4- and 2,6-dialkyl-substituted pyridines.[66]

Ring syntheses with enamines (II) take place via direct nucleophilic attack. Thus, 4-alkylpyrimidines (L) are obtained in high yield by treatment of (II) with formamide. Evidently, reaction proceeds by transamination of the dialkylamino group with the formation of a foramido compound which decarbonylates to give an imine; the latter then reacts with a second molecule of formamide to give the 4-methylpyrimidine (L).[61]



The same is true for the reaction of β-amino-α,β-ethyleneketones which afford 3-functionalised 4-alkylpyridines (LI).[64] Of the several possible routes by which reaction takes place, the most likely involves transamination of the function at the C_1 electrophilic centre with the primary amine group; this would be accompanied by intramolecular cyclisation via attack of the methine function at C_3, leading to the formation of the 2,4-disubstituted pyridine. The isolation of transamination products and literature data on the configuration of enaminoketones and enaminonitriles would support this pathway.[66]

Scheme 5

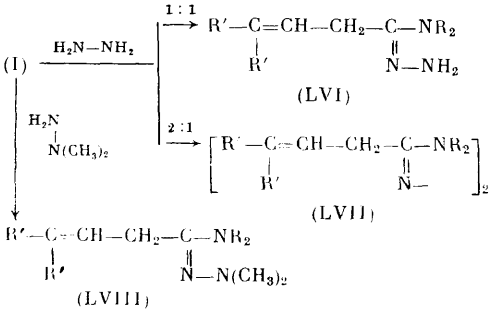


The formation of 2,3-dihydro-1,4-diazepines (LII) by reaction of enamines (II) with 1,2-diaminoethane is in accord with the above-described cyclisation via transamination (Scheme 6).[67–69]

Scheme 6

The interaction of 1-dialkylamino-1-buten-3-ynes with 1,2-ethanedithiol 1,3-propanedithiol also proceeds with involvement of the reactive C_1- and C_3-atoms of the conjugated system with the formation of 7-dialkylamino-5-methyl-7*H*-2,3-dihydro-1,4-dithiepines and 2-alkylamino-4-methyl-8*H*-6,7-dihydro-1,5-dithiocins, respectively (LIII).[70,71] In contrast with the reaction of 2-aminothiophenol with alkenylynamines, interaction with enamines (II) proceeds by 1,3-attack of the conjugated system to give the corresponding 2-dialkylamino-4-methyl-5*H*-1,5-benzothiazepines (LIV).[70,72]

Normally, the reaction of enamines (II) with 1,3-difunctionalised reagents would be expected to give heterocyclics with a large ring size. However, this is not always the case. Thus, the reaction of 1,3-butadiyne with 1,3-diaminopropane leads to the formation of a bis-adduct of the type XXVII, rather than an 8-membered ring; C-cleavage of these adducts affords the corresponding tetrahydro- and hexahydro-pyrimidines (LV):[35]



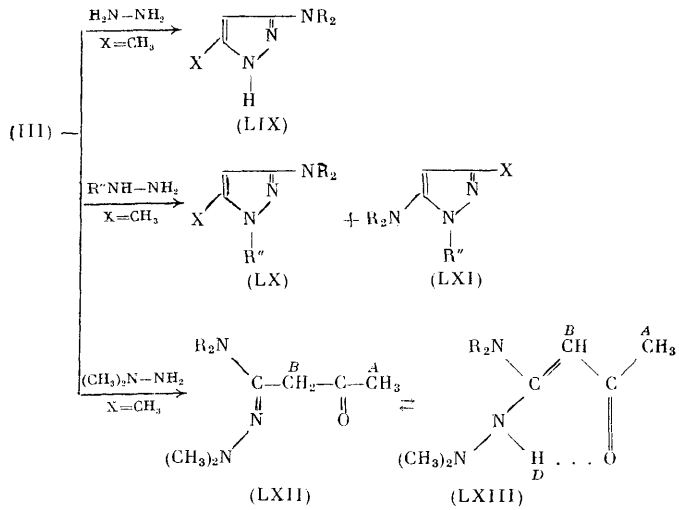
(LVa) (LVb) (LVc) (LVd)

Pyrroles with a variety of substitution patterns are obtainable by other routes, notably via 1,4-addition. Here, the synthesis can be achieved with butadiyne and ammonia or primary amines in the presence of copper salts.[1,4,73]

Since the starting enamines (II) can be obtained by direct interaction of diacetylene with secondary amines, the syntheses described above are potentially interesting from an industrial viewpoint. However, in planning synthetic routes from enamines (II), the commercially available 1,1-dimethoxy-3-butanone, which is obtaining from diacetylene, cannot be used as an equivalent.[74]

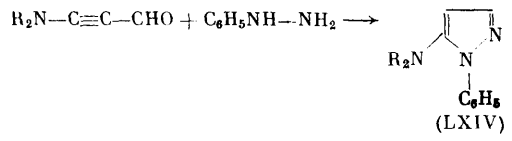
Ynamines (I) behave in a quite different way with bifunctional reagents. Thus, reaction with compounds having adjacent nucleophilic centres, such as hydrazine and hydroxylamine, affords acyclic adducts with participation of only the C_1 electrophilic centre of the ynamine (Scheme 7).[75] Amidrazones (LVI) based on 3-pentenoic acids are thereby produced in a manner not unlike the addition of hydrazine to ω-diethylaminophenylacetylene.[76]

Scheme 7



By adjusting the proportion of the reactants, e.g. by increasing the amount of hydrazine, it is possible to isolate adducts (LVII).[57] The reaction of ynamines (I) with non-symmetrical dialkylhydrazines leads in the same way to poly-N-substituted amidrazones (LVIII).[75]

The reaction of vinylacetylenic ynamines with hydrazine is markedly different from the reaction of vinylacetylenic enamines in that only the acetylene bond participates with the formation of monoadducts; the latter readily react with a second ynamine molecule. This observation is in keeping with the unusual mechanistic features of nucleophilic attack at an acetylenic bond in conjugation with a donor group.[77]



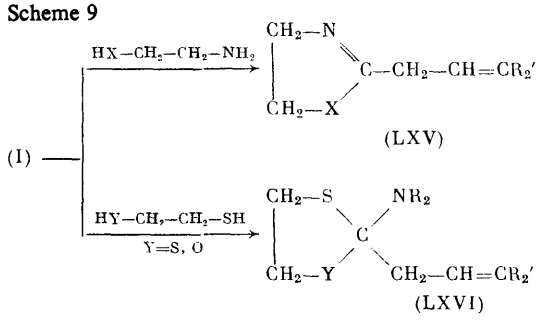
A study has also been made of the interaction of ynaminocarbonyl compounds (III) with supernucleophiles, such as hydrazine, alkyl- and phenyl-hydrazines, and unsymmetrical dimethylhydrazine. The reaction of 4-dialkylamino-3-butyn-2-ones with hydrazine proceeds with involvement of the C_1 and C_3 electrophilic centres to give 3(5)-dialkylamino-5(3)-methylpyrazoles in 56–63% yield (LIX) [78,79] (Scheme 8).

Scheme 8

The interaction of 4-dialkylamino-3-butyn-2-ones with monosubstituted hydrazines (methyl, propyl, and phenyl) leads in all cases to a mixture of isomeric products (LX) and (LXI),[79] as a result of the alternative approaches of the hydrazine group to the reactive centre of the ynaminoketone. According to ^{1}H NMR spectroscopic data and GLC analysis, the proportion of the two isomers in all cases is 3:4.

The obtained results would indicate that the reactivity of the two electrophilic centres in (III) is approximately equal. However, with ynaminoaldehydes, in which the activity of the carbonyl group is higher, the free amino group of the hydrazone predominantly attacks the carbonyl group. Thus, reaction of diethylaminopropynal with phenylhydrazine afforded predominantly isomer (LXIV) by attack of the free amino group on the carbonyl group.[80]

Ynaminoketones react on heating with the unsymmetrical dimethylhydrazine by exclusive attack at the reactive C_1 centre to give the corresponding N,N-dimethyl-3-oxobutanamidrazones (LXII, LXIII).[79]



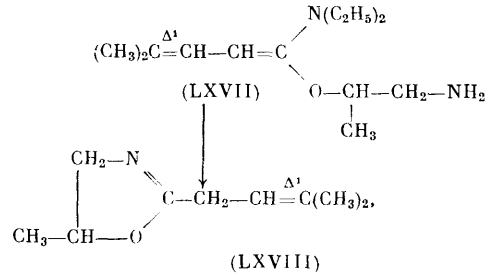
The ^{1}H NMR spectrum of (LXII) displayed signals in the region 2.10 p.p.m. corresponding to the methyl group of the acetyl fragment (H_A) and at 3.40 p.p.m. corresponding to the protons of the methylene group (H_B).

However, the enol tautometer (LXIII), stabilised by intramolecular hydrogen bonding, is present together with the keto form. The enol form is responsible for the signal at 1.84 p.p.m., corresponding to the methyl group (H_A), the signal at 5.00 p.p.m. corresponding to the vinyl proton (H_B), and the weak signal at 7.30 p.p.m. corresponding to the proton (H_D) of the hydroxyl group. The infrared spectra also reveal absorption at around 3400 cm^{-1} which can be ascribed to the associated hydroxyl group.

Thus, ynaminoketones react with hydrazine and its monosubstituted derivatives at both the C_1 and C_3 reactive centres affording a regioisomeric mixture of the corresponding pyrazoles. The unsymmetrical N,N-dimethylhydrazine adds exclusively across the triple bond of 1-dialkylamino-1-butyn-3-one with the formation of an acyclic product existing as a tautomeric mixture of keto and enol forms.

Treatment of alkenylynamines with aliphatic 1,2-dinucleophiles containing nitrogen, oxygen and sulphur functionality afford five-membered heterocyclics by attack of the two nucleophilic centres at the C_1 electrophilic centre (Scheme 9).

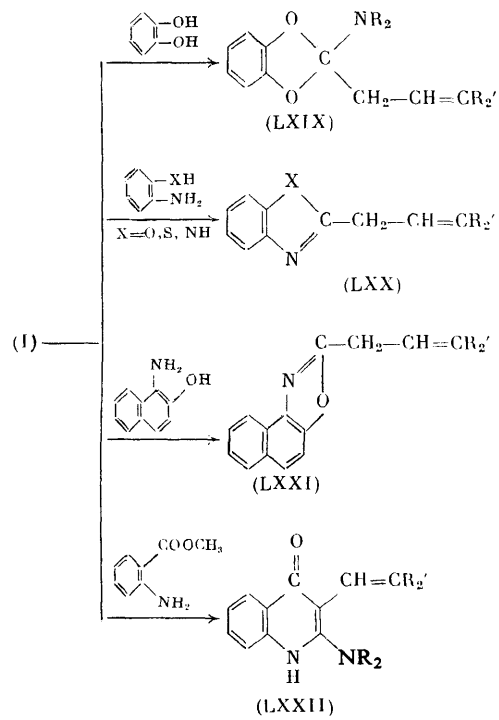
Scheme 9



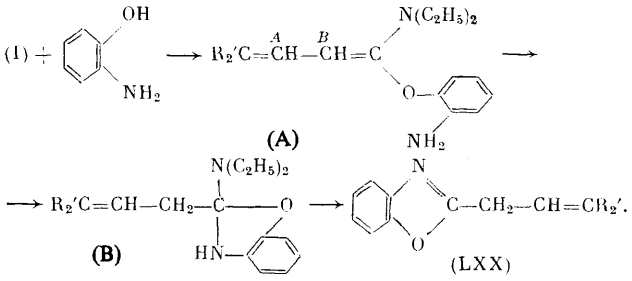
Thus, interaction of 1-dialkylamino-3-penten-1-ynes (I) with 1,2-diaminoethane and ethanolamine gave the corresponding 2-(2-buten-1-yl)imidazolines and 2-(2-buten-1-yl)oxazolines (LXVI), respectively.[81] In these reactions, 2-substituted imidazolines and oxazolines were formed by cleavage of the dialkylamino group. The non-conjugated ethylenic group at the 2-position of the side chain is thereby left intact, confirming the regioselectivity of reaction at the triple bond.

Regioselectivity is the same with sulphur-containing binucleophiles (2-mercaptoethanol, ethanedithiol), the corresponding products being 2-dialkylamino-(2-buten-1-yl-1,3-oxathiolanes and 2-dialkylamino-(2-buten-1-yl)1,3-dithiolanes (LXVI).[81]

The reactivity of nitrogen-, oxygen-, and sulphur-containing reagents towards alkenylynamines (I) increases with their acidity as a consequence of electrophilic catalysis of the addition process. Reagents which are more acidic than water (2-mercaptoethanol and 1,2-ethanedithiol) interact with alkenylynamines (I) in the absence of acid, while reactions with 1,2-diaminoethane and ethanolamine require the presence of a catalytic amount of acid, which is in accordance with the rule outlined above.[12,17]



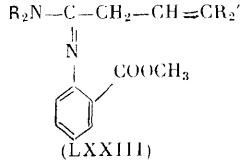
Reactions of alkenylynamines (I) with ethanolamine proceed similarly, but a two-stage process is involved with methylethanolamine. Thus, according to ^{1}H NMR spectral data, the product of reaction between methylethanolamine and 1-diethylamino-3-penten-1-yne affords, in addition to the expected cyclic product, a vinylketene O,N-acetal (LXVII), which is converted into the oxazoline (LXVIII) during the course of the reaction.[82] The isolation of the acyclic product (LXVII) is evidently a consequence of steric hindrance in the formation of the ring.



In order to determine the effect of the structure of the reagent and the stereochemistry of ring closure, a study has been made of reactions with aryl and naphthyl 1,2-dinucleophiles in which the nucleophilic residues are stereo-defined (Scheme 10). The interaction of alkenylynamines (I) with catechol (pK_a 9.44) proceeds on cooling to give the corresponding 2-dialkylamino-2-[3-methyl-2-buten-1-yl]-1,3-benzodioxoles (LXIX) in 70% yields.[83,84]

The reaction of alkenylynamines (I) with *o*-aminophenol, *o*-aminothiophenol, and *o*-phenylenediamine afforded the respective benzoxazole,[84,86] benzothiazole[85] and benzimidazole[84,87] derivatives of general structure (LXX), in which the side chain unsaturation at the 2-position is non-conjugated.

Scheme 10

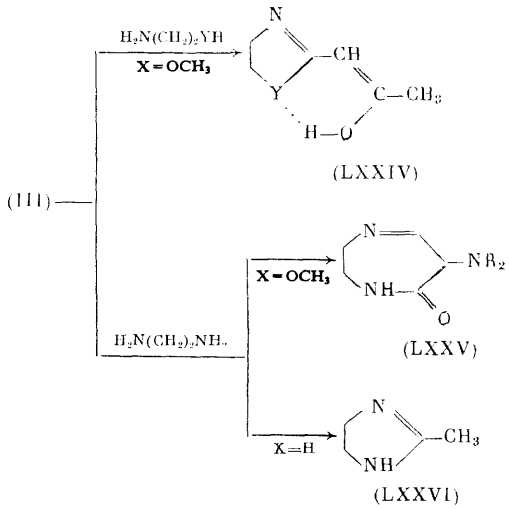


In the reaction of 1-diethylamino-(4-methyl)3-penten-1-yne with *o*-aminophenol it is possible to isolate all the intermediates.[84] Reaction proceeds smoothly and is exothermic; moreover, it is initiated by attack of the hydroxyl group since phenols react with ynamines at a much greater rate than amines. This is also confirmed by ^{1}H NMR spectral measurements during the reaction, which display proton signals at 4.78 p.p.m. (H_B, 1H) and 5.85 p.p.m. (H_A, 1H); according to the literature values for fragment $R_2'C=CH-CH=C(OPh)NR_2$ [12], these correspond with the signals for the vinylic protons of compounds of type (A). At the end of the reaction these signals have completely disappeared. When (A) could no longer be detected, the residue was shown to contain compound (B) which, on distillation, affords (LXX) by cleavage of the diethylamino group.

It was also shown that the condensation takes place with naphthalene derivatives. Thus, 1-amino-2-naphthol gave naphth[1,2-*d*]oxazoles (LXXI).[88]

If the difunctionalised reagent possesses groups which are different in nature, e.g. methyl anthranilate, then reaction with alkenylynamines takes place at C_1 and C_2 to give a six-membered ring without cleavage of the dialkylamino group, i.e. 2-dialkylamino-3-(2-methyl-1-propenyl)-4-quinolones (LXXII).[89] Reaction proceeds in two stages under acid catalysis. The intermediate (LXXIII), formed by initial addition of methyl anthranilate to the starting ynamine (I), was isolated.[69]

In the above-described reaction, the alkenylynamines (I) behave as rather unusual acylating agents, from which a number of 5-membered benzo-condensed 1,3-heterocyclics can be prepared with a non-conjugated unsaturated residue at the 2-position. Ynamines participate in the same type of heterocyclisation.[90]



By comparing reactivity data for the reactions of alkynamines and alkenylynamines with *o*-phenylenediamine, *o*-aminothiophenol, and *o*-aminophenol, one arrives at the qualitative conclusion that, in the absence of acidic catalysis, addition becomes more facile with an increase in the acidity of the functional group in the order $NH_2 < OH < SH$. This is possibly associated with autocatalysis of the nucleophilic addition.

Thus it has been shown that the reaction of alkenylynamines (I) with bifunctional reagents containing nitrogen, oxygen and sulphur proceeds stepwise via initial atack at the electrophilic C_1 atom of the ynamine to give 5-membered heterocyclics with two heteroatoms and an unconjugated phenyl-type group at the 2-position. The interaction of aromatic *o*-substituted dinucleophiles proceeds by a concerted mechanism through a cyclic, 5-membered, resonance-stabilised transition state.

Acetylenic ynaminocarbonyl compounds (III) should display electrophilicity by virtue of the ynamine residue in conjugation with a polar carbonyl group. In fact, reactions with both mono- and dinucleophiles proceed without acid catalysis. Data on the reactivity of ynaminocarbonyl compounds show that they react in a different manner to ynamines[26], alkenylynamines and acetylenic ketones.[43]

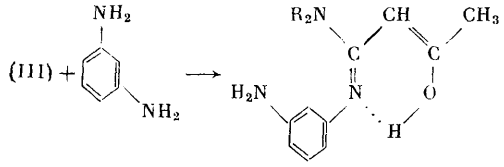
Thus, in reactions with aliphatic 1,2-dinucleophiles, the nature of the heteroatom and the carbonyl group have a pronounced effect. For example, reactions of 4-dialkylamino-3-butyn-2-ones with 1,2-diaminoethane and 2-aminoethanol afford the corresponding 1-(2-imidazolinyl)-1-propen-2-ols[91,92] and 1-(2-oxazolinyl)-1-propen-2-ols (LXXIV) [91] (Scheme 11).

Scheme 11

The formation of imidazoline and oxazoline derivatives takes place as a result of a two-fold attack at the α-carbon atom of the acetylene group, i.e. the orientation of attack is the same as in reactions with ynamines[90] and conjugated ynamines.[81] According to one finding[93], 1-mercapto-2-aminoethane adds to acetylenic ketones at the β-carbon atom of the acetylene group under basic catalysis.

The geometry of the final product (LXXIV) is determined by stabilisation of the enol form through intramolecular hydrogen bonding. The literature does make reference to imidazolines having a completely enolised β-ketoalkyl residue.[94]

The course of the reaction is dependent on the nature of the carbonyl group. Thus, dialkylaminopropiolates react with 1,2-diaminoethane with the participation of both electrophilic centres to give 5-dialkylamino-2,3-dihydro-1,4-diazepin-7-ones (LXXV) in 68% yield.



Evidently, the lower electrophilicity of the C_1 and C_3 centres in ynaminoesters, compared with ynaminoketones, is responsible for the concerted 1,3-attack of the bifunctional nitrogen-containng bases, the final outcome being the formation of diazepine derivatives. The facile intramolecular nuclophilic replacement of the methoxy group of the ester also dictates this mode of cyclisation.

With ynaminoaldehydes (III, X = H) the electrophilicity of the two centres is so high that two 1,2-diaminoethane molecules attack each of the reaction centres twice, affording a bis-adduct which

undergoes carbon-carbon bond cleavage with formation of 2-methyl-2-imidazoline (LXXVI).[97] This type of reaction is similar to that described earlier.[35]

The interpretation of ynaminocarbonyl compounds with aromatic 1,2-dinucleophiles leads to a different result. The reduced nucleophilicity of *o*-phenylenediamine relative to 1,2-diaminoethane, is responsible for the different mode of reaction with ynaminoketones. Thus, 4-dialkylamino-3-butyn-2-ones react with o-phenylenediamine to give seven-membered heterocyclic derivatives, namely 7(α)-R'-2-dialkylamino-4-methyl-3H-1,5-benzodiazepines (LXXVII) [95] (Scheme 12).

An NMR spectral study of the reaction between 4-dimethylamino-3-butyn-2-one and *m*-phenylenediamine was conducted in an NMR tube (i.e. non-preparatively) in order to elucidate the initial attack of the aromatic diamine. On heating in $CDCl_3$, *m*-phenylenediamine adds slowly to the ynaminoketone across the triple bond with the formation of an iminoenol tautometer (LXXXIII) as the final product.

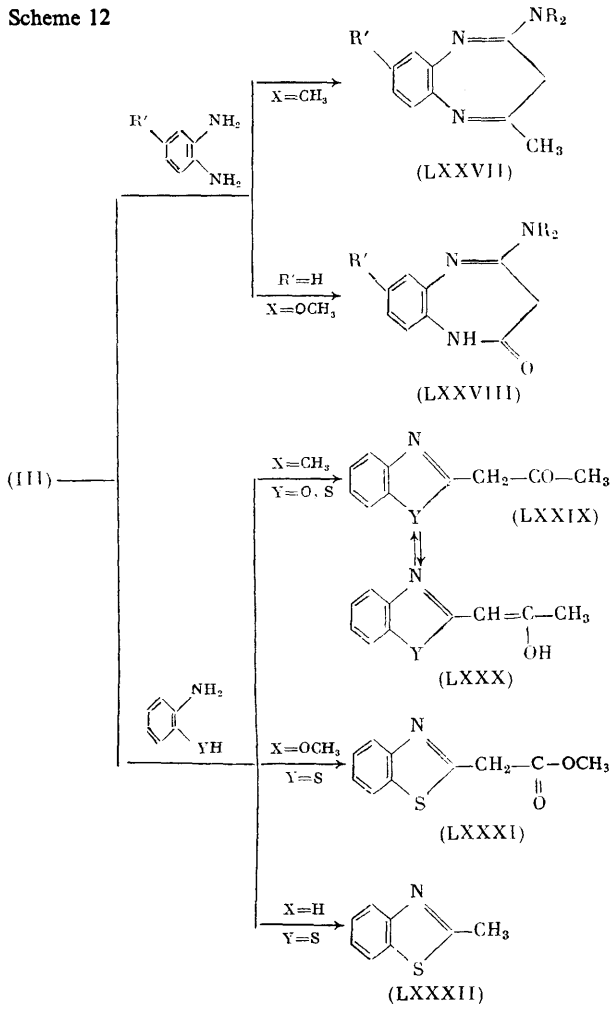
X = CH_3.

(LXXXIII)

Of all the nucleophilic reagents studied, only *m*-phenylenediamine reacted to give a sufficiently stable iminoenol tautometer. The extent of conjugation, involving the two double bonds (C=C and C=N), the aromatic ring, and the hydroxyl group, is sufficient to provide such stabilisation. It is likely that, in the case of *o*-phenylenediamine, enolisation of the intermediate adduct favours ring closure to the benzodiazepine (LXXVIII).

The 1,3-mode of attack with *o*-phenylenediamine is again evident in the reaction with methyl 3-dialkylaminopropiolate, providing LXXVIII.[96]

The orientation of the reaction of acetylenic ketones with *o*-phenylenediamine is the same as that of ynaminoketones.[98]



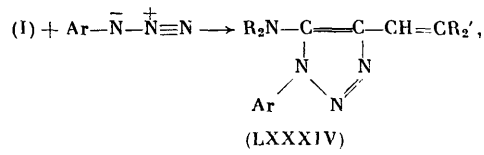
Treatment of 4-dialkylamino-4-butyn-2-ones with *o*-aminophenol and *o*-aminothiophenol afforded the corresponding fused 5-membered heterocyclics, namely 1-(2-benzoxazolyl)-2-propanone and 1-(2-benzothiazolyl)-2-propanone, which exist as a mixture of keto (LXXIX) and enol (LXXX) tautomers.[91]

Reaction of methyl 3-dialkylaminopropiolate with *o*-aminophenol and *o*-aminothiophenol affords 2-carbomethoxymethylbenzoxazole and 2-carbomethoxymethylbenzothiazole, respectively, (LXXXI).[96]

Just as in reaction with ethylenediamine, 3-(dialkylamino)propynal with *o*-aminothiophenol affords a product via double addition across both reaction centres; C–C bond cleavage then takes place to give 2-methylbenzothiazole (LXXXII).[97]

Thus, it has been shown that ynaminocarbonyl compounds react in the same way as simple ynamines, irrespective of the nature of the acceptor group. The course of the heterocyclisation of conjugated ynamines with acceptor groups depends both on the character of the carbonyl group and the nature of the nucleophile. Cyclisation with aliphatic nucleophiles depends on the acceptor ability of the carbonyl function. With weak nuclophiles (aromatic diamines) only 1,3-addition takes place, independent of the nature of the carbonyl group, and only the ynamine residue is involved in the reaction with nucleophiles containing hydroxyl and sulfhydryl groups. The preparation of five- and seven-membered heterocyclics containing two

Scheme 12

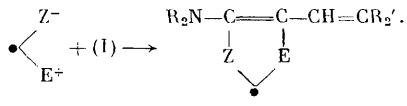


heteroatoms (nitrogen, oxygen, or sulphur) can thus be achieved by choosing a suitable carbonyl-containing ynamine and dinucleophile.

IV. 1,3-Dipolar cycloaddition

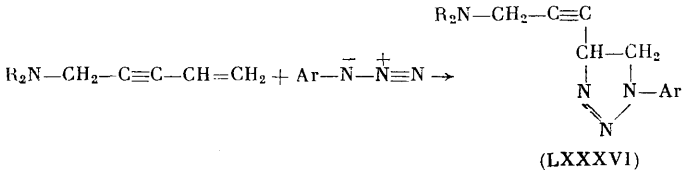
The 1,3-dipolar activity of both types of amine, (I) and (II), has been studied in order to assess the activating effect of the dialkylamino group on the reactivity of the α,β-unsaturation in conjugation with the π-system. It is known that acetylenic ynamines react with 1,3-dipoles to give 5-membered heterocyclics.[5,99] In the 1,3-dipolar cycloaddition of a variety of vinylacetylenic compounds, the double bond of the conjugated enyne system is significantly more reactive than the disubstituted triple bond.[99]

1-Aryl-4-vinyl-5-dialkylamino-1,2,3-triazoles (LXXXIV) were obtained by interaction of 1-dialkylamino-3-buten-1-ynes with aromatic azides.[100,101]



(LXXXIV)

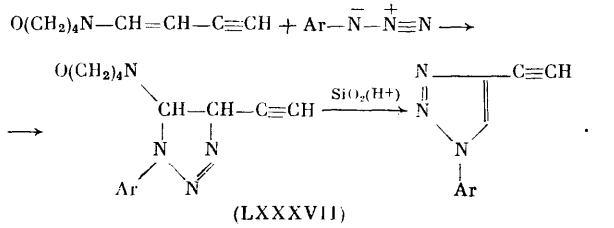
Thus, the 1,3-dipole attacks the acetylenic bond rather than the terminal ethylenic bond with retention of the dialkylamino group.



In all cases, addition of aryl azides to alkenylynamines (I) proceeds regiospecifically with the formation of only one isomer as has been confirmed by TLC and NMR spectroscopic studies of the product. The data accord well with literature values for the 1,3-dipolar cycloaddition of aryl azides with compounds having highly polar unsaturations, e.g. alkoxyacetylenes,[102] ynamines,[103,104] and acetylenic ketones and acids.[105,106]

The results obtained by studying the reactions of other octet-stabilised 1,3-dipoles (benzonitrile *N*-oxide, C-*p*-F-phenyl-*N*-nitrilimines) with alkenylynamines confirm the generality of the cycloaddition, which proceeds regioselectively at the acetylenic function independent of the structure of the ethylene fragment (LXXXV).

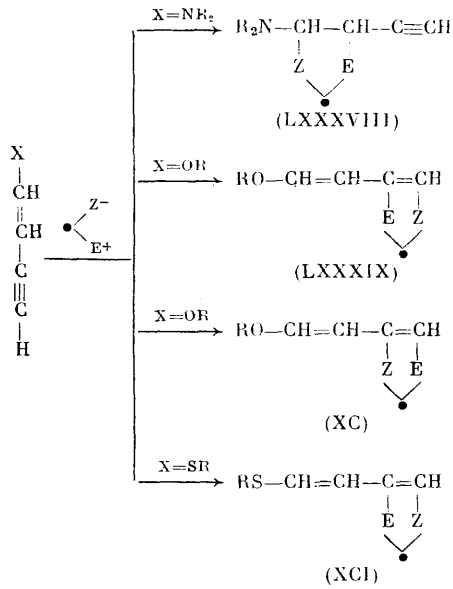
(LXXXV)



It is important to note that the incorporation of a methylene group between the nitrogen function and the vinylacetylene group significantly affects the order of addition of the 1,3-dipole, by comparison with alkenylynamines (I). The interaction of 1-diethylamino-4-penten-2-yne with aromatic azides leads to 1-aryl-4-(3-diethylamino-1-propynyl)-Δ^2-triazolines (LXXXVI).[101] In this reaction it is generally found that the terminal double bond of the vinylacetylene group is the more reactive unsaturation.[99]

(LXXXVI)

Thus, in vinylacetylenic compounds having an amino group on an unsaturation, the nitrogen atom activates the α,β-unsaturation for the addition of 1,3-dipoles. Where the amino group is not bonded to the unsaturation, the regioselectivity is determined by the position of the bond. This is supported by data obtained from the reaction between 1,3-dipoles and enamines (II).



Thus, 1-morpholino-1-but-3-yne with aromatic azides affords 1-aryl-4-ethynyl-5-*N*-morpholino-Δ^2 triazolines (LXXXVII),[101] i.e. addition of the 1,3-dipole proceeds exclusively at the disubstituted ethylenic bond.

(LXXXVII)

In contrast, addition of 1,3-dipoles to 1,3-enynyl ethers and thioethers takes place at the terminal acetylene group with formation of 5-membered heterocyclics (LXXXIX), (XC) and (XCI) [101,107] (Scheme 13).

Scheme 13

(LXXXVIII)

(LXXXIX)

(XC)

(XCI)

Thus a study of 1,3-dipolar cycloaddition with both types of vinylacetylenic amine, (I) and (II), has shown that the conjugated *p*,π-system serves as dipolarophile, interacting with 1,3-dipolar systems in the usual manner. However, the amino group in such dipolarophiles has a specific directing influence on the cycloaddition.

The fact that conjugation with the amino group activates the α,β-unsaturation confirms the electrophilic nature of the reaction. However, the readiness of amines (I) and (II) to undergo electrophilic addition, as mentioned in earlier sections, and the requirement of an acid catalyst for nucleophilic addition, would suggest that the anomalous behaviour of the nitrogen-containing *p*,π-conjugated system is associated with the involvement of the nitrogen atom in the initial stage the cycloaddition, as is observed in the reactions of α,β-unsaturated tri-valent phosphorus compounds.[99,108]

The subsequent stabilisation of the system is effected by formation of the heterocyclic ring with participation of the α,β-unsaturation.

Nucleophilic reactions of quinones

A A Kutyrev, V V Moskva
The S M Kirov Chemical-Technological Institute, Kazan

ABSTRACT. Nucleophilic addition to, and substitution of, quinones have been systematically reviewed. Particular attention has been paid to establishing general trends in reactivity in the light of our present-day understanding of mechanistic chemistry.

The bibliography contains 188 references.

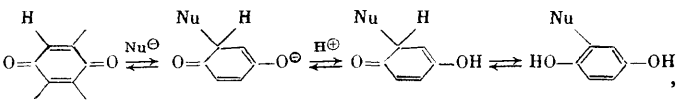
I. Introduction 72
II. Nucleophilic addition to quinones 72
III. Nucleophilic substitution of quinones 83

I. Introduction

Quinones are widely distributed in nature and are produced industrially in all the developing countries. Historically the first, and still the major, application of quinones has been in the dye industry. At the present time, quinoidal compounds are used as dyes and luminophores in photography and electrophotography, in optical quantum generators (lasers), liquid crystalline and photochromic materials, and as scintillators.[1–5] However, the value of quinones is not restricted to dye chemistry. Our knowledge of the biological activity of quinones has developed enormously, not only with the discovery of the vitamin K group, but also with the preparation of drugs, herbicides, fungicides, and plant-growth regulators.[6–16] Quinones have also been used as analytical reagents, polymer modifiers, photoresistors, and catalysts.[17–21] Halogeno- and cyano-quinones are used in organic synthesis as indispensable dehydrogenating agents, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone being one of the most powerful organic oxidants.[22] No doubt applications of quinones will become even more widespread.

LCAO–MO calculations for 1,4-benzoquinone have shown that the distribution of π-electron density is very uneven,[23] as depicted below.



The wide variation in the electron density of quinones explains the broad spectrum of activity of this class of compound. In fact, quinones participate in an enormous number of homolytic and heterolytic reactions. This review is devoted to the most interesting of the heterolytic processes; nucleophilic reactions, which exemplify the rich synthetic potential of quinones. Electrophilic reactions are less varied, being limited to the interaction of quinones with hydrogen- and metal-containing reducing agents to give hydroquinones or semi-quinoidal complexes.[24–37]

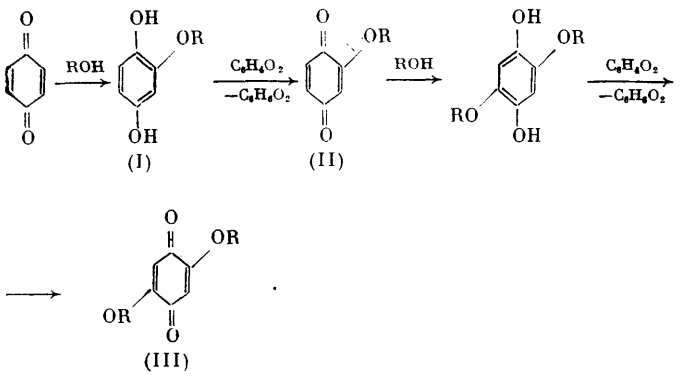
In recent reviews devoted to various aspects of the chemistry and use of quinones, there is a notable absence of information on the nucleophilic and electrophilic reactions of quinones.[38–43] We have sought in this review to make good this deficiency. Data are presented here on the reactions of quinones with nucleophilic reagents in the light of our present-day understanding of mechanistic chemistry.

II. Nucleophilic addition to quinones

The general scheme of nucleophilic addition to 1,4-quinones is presented below (1,2-quinones interacting in a similar way).

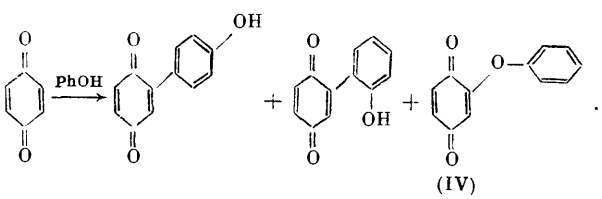
$Nu^{\ominus}$ – nucleophile.

The final step in the scheme is shown as a reversible process. However, as a rule it is irreversible since it leads to the formation of a stable aromatic system. Here, a proton is depicted as the electrophile. With other electrophiles, the overall scheme is the same; only the detail changes.



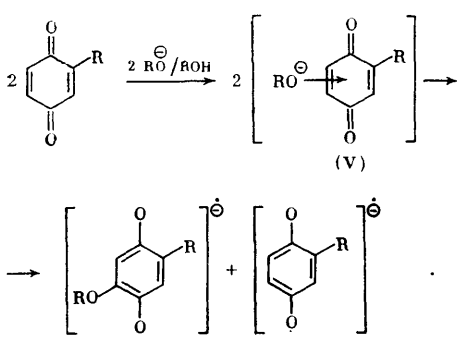
From molecular orbital calculations, the coefficients for the higher, occupied and lower, unfilled molecular orbitals have been determined for substituted 1,4-benzoquinones and 1,4-naphthoquinones. From this data, rules have been established for the orientating effects of substituents on nucleophilic addition. Thus, for 2-substituted 1,4-benzoquinones, the order of reactivity of ring positions is 5 > 2 > 6 for donor substituents, and 3 > 6 > 5 for acceptor or unsaturated substituents. The 2-position of 1,4-naphthoquinone is activated by donor substituents at C_2 and C_6 and by acceptor and unsaturated substituents of C_5. The 3-position activates donor substituents at C_5; an *anti*-5-OH group acts as a donor, while a *syn*-5-OH group acts as an acceptor.[44]

The calculations are generally in accord with resonance theory, as will be seen later, and are confirmed by experimental data except in the case of nucleophilic addition to carbon without a donor substituent.



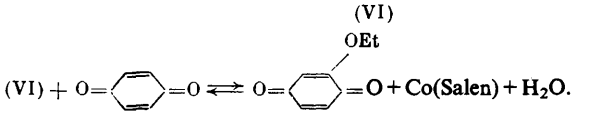
1. Reactions with *O*-nucleophiles

Normally, direct addition of water to quinones to give an adduct is not possible; one exception has been reported but it has no preparative value.[45] Primary alcohols react with quinones only in the presence of catalysts: zinc, cadmium, calcium and magnesium.



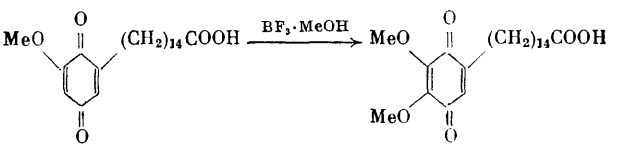
However, the highly active 2-acetyl-1,4-benzoquinone does react without a catalyst. Reaction involves initial nucleophilic addition of the alcohol to the quinone with formation of alkoxyhydroquinone (I); this is then oxidised by the starting quinone to alkoxyquinone (II). A second molecule of the alcohol adds to the latter to give the corresponding 2,5-dialkoxy-1,4-benzoquinone (III) as final product.

There are isolated examples of the reaction of secondary alcohols with quinones, but tertiary alcohols are unreactive. C-Arylated quinones are generally obtained by reaction of phenols with quinones. The yield of aryloxy derivatives (IV) is no more than 5%.[45]



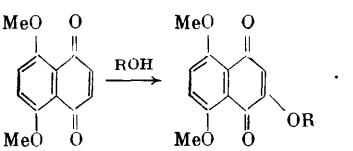
A kinetic study of the reaction of 1,4-quinones with alkoxide ion in alcoholic media has shown that the process involves initial formation of a charge-transfer complex (V) between the 1,4-quinone and alkoxide ion, followed by its conversion into quinol radical anions, the ratio of which depends on the nature of the alkoxide ion, the substituent on the 1,4-quinone ring, and the medium.[46]

There is virtually no reaction of 1,4-benzoquinone with ethanol in the absence of catalyst. Reaction is facile in the presence of bis(*N*,*N*-salicylideneethylenediaminato)cobalt, Co(Salen), and oxygen. It is thought that reaction involves three stages:

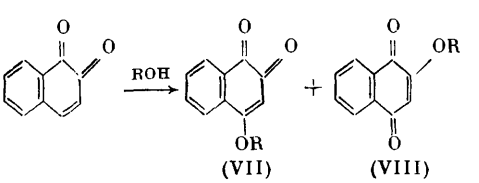


$$2\text{Co(Salen)} + O_2 \rightleftarrows 2\text{Co(Salen)}-O,$$

$$\text{Co(Salen)}-O + \text{EtOH} \rightleftarrows \underset{\text{(VI)}}{\text{EtO}-\text{Co(Salen)}-O},$$



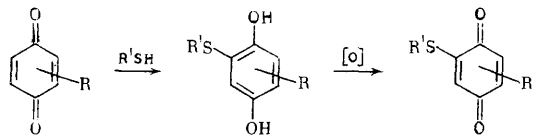
The last step is rate-determining. It has been suggested that Co(Salen) forms a 2:1 complex with O_2, existing as a dimer (with a Co–O–O–Co bond) in the solid state and in alcoholic media. The formation of complex (VI) requires cleavage of the O–O bond by attack of an alcohol molecule on cobalt. Increase in the size of the alcohol molecule hinders this cleavage for steric reasons, which explains the reduction is yield. ^{1}H NMR spectroscopic data indicated that complex formation between Co(Salen) and alcohols is a reversible process. Reaction is inhibited by the addition of chloroform [which forms a simple adduct with Co(Salen)] or benzene [which also associates with Co(Salen)], resulting in elimination of oxygen.[47]



BF_3 may be used as catalyst for the reaction of quinones with alcohols. Methoxylation of substituted 1,4-benzoquinones takes place in the presence of BF_3.MeOH complex.[48]

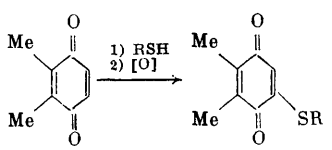
1,4-Naphthoquinones with donor substituents in the 5 and 8 position react with alcohols to give 2-alkoxy derivatives in the presence of sulphuric acid and a little iron sulphate as catalyst.[49]

1,2-Quinones react with alcohols in the same way as 1,4-quinones in the presence of catalyst. A study has been made of the reaction of 1,2-napthoquinones with alcohols in the presence of sodium iodate and a metal salt ($CoCl_2$, $CoCl_2.6H_2O$, $NiCl_2.6H_2O$, $CuCl_2.2H_2O$, $LaCl_3.7H_2O$, $CeCl_3.7H_2O$).[50] The yield of the resulting 4-alkoxy-1,2-naphthoquinone (VII) increases according to the sequence of reagents shown, being 3% with $CoCl_2$ and 79% with $CeCl_2.7H_2O$. Quinone (VII) is not formed in the absence of catalyst. 2-Alkoxy-1,4-naphthoquinones (VIII) are formed in addition to (VII) on prolonging the reaction and increasing the temperature.



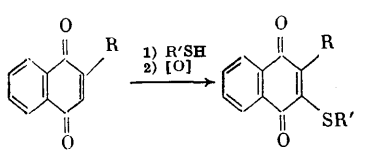
Alcoholysis of acenaphthoquinone and the related *o*-pleiadienoquinone leads to the formation of the corresponding quinone ketals.[51]

2. Reactions with *S*-nucleophiles



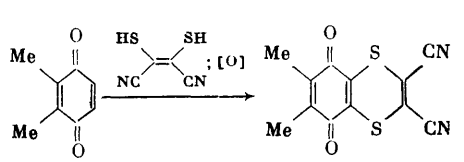
(a) With thiols

Thiols and thiophenols react with 1,4-quinones to give 1,4-adducts (IX), which, in the course of reaction, are oxidised by air or by the starting quinone to provide the corresponding alkylthio- or arylthioquinones (X).



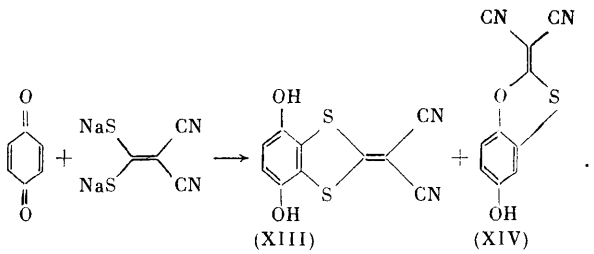
(IX) (X)

By using an excess of thiol, the organothio group may be introduced at various ring positions, depending on the nature of the substituents in the starting quinone. The following trend has been noted: quinones with donor substituents give mainly 2,5-isomers while quinones with acceptor substituents give 2,3-isomers. In such cases, and others, the corresponding 2,6-isomers are also formed. 1,4-Quinones with alkylthio and arylthio groups in the side-chain have attracted the attention of microbiologist and pharmaceutical chemists, as well as organic chemists, since such compounds display high biological activity. In particular, the products of the reaction between 2,3-dimethyl-1,4-benzoquinone and thiophenols are inhibitors of the enzymes succinoxidase and NAD-oxidase. In this respect, compound (XI) (where R = 2-naphthyl) is the most active.[52]



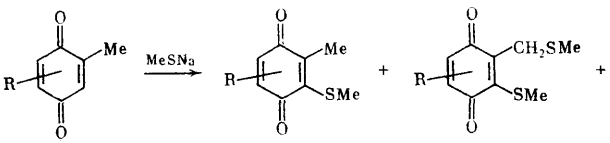
(XI)

Antimicrobial activity has been found with substituted naphthoquinones (XII), prepared as shown below.[53,54]

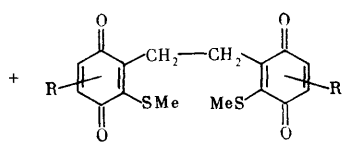


(XII)

While the reactions of thiols with quinones involve two stages (addition and oxidation), the interaction with dithiols involves four steps: (1) addition to the quinone of one mercapto group; (2) oxidation of the intermediate; (3) addition of the other mercapto group; (4) oxidation to give the final product. 2,3-Dimercaptomaleonitrile interacts with 2,3-dimethyl-1,4-benzoquinone according to this scheme with the formation of a rare class of compound, namely 1,4-dithiabenzo-5,8-quinones.[55]

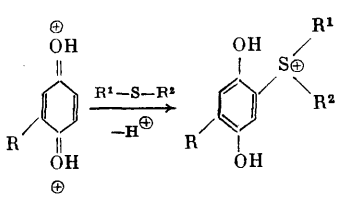


Metal dithiolates react with quinones in a more complex manner to give, in the example below, a mixture of the corresponding benzo-1,3-dithiole (XIII) and benzo-1,3-oxathiole (XIV) in 40% and 20% yield, respectively.[56]

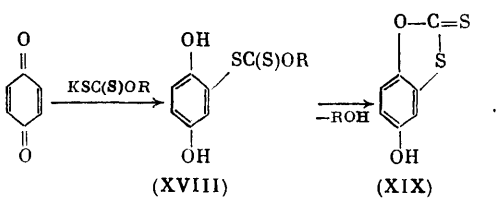


(XIII) (XIV)

Metal thiolates are extremely active nucleophiles, and their reactions with quinones are far more selective than reactions with thiols. The interaction of sodium methylmercaptide with methyl-substituted quinones produces mainly methylthio derivatives (XV)–(XVII) (by addition-oxidation), of which two, (XVI) and (XVII), are substituted in the side-chain.[57,58]

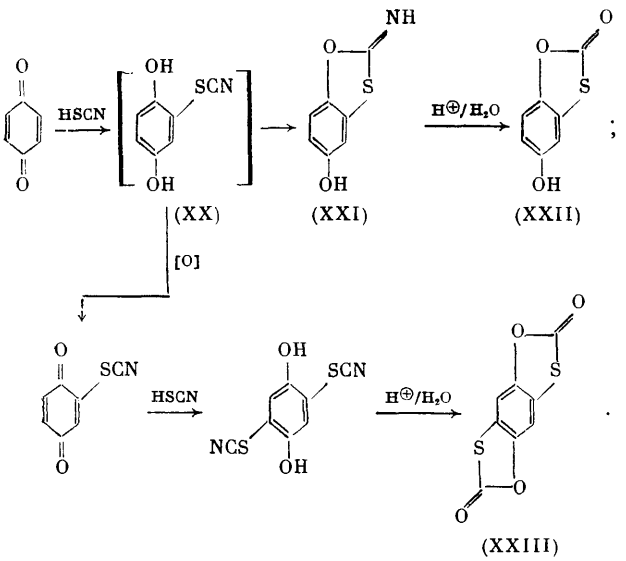


(XV) (XVI)



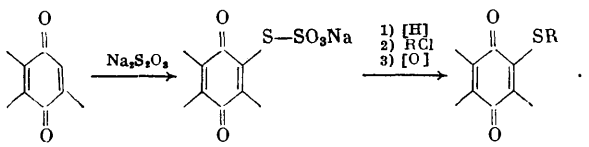
(XVII)

Thioethers on the other hand, are inert towards quinones. However, activation of the latter with 50% H_2SO_4 leads to the formation of sulfoniohydroquinones.[45,59]



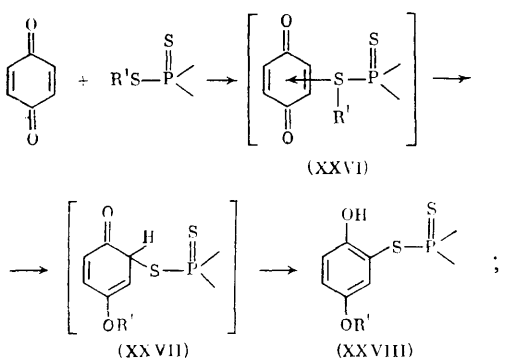
(b) With thiolic acids

In this section, we examine the reactions of quinones with SH-acids containing divalent sulphur. 1,4-Quinones interact with dithiocarboxylic acids and their salts. Reaction with potassium xanthate affords the condensation product (XIX) via the 1,4-adduct (XVIII).[45]



(XVIII) (XIX)

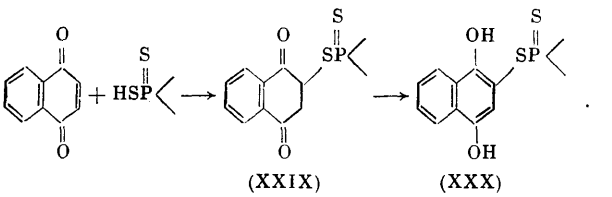
The interaction of thiocyanic acid with 1,4-benzoquinone gives the 1,3-benzoxathiolones (XXII) and (XXIII) rather than the thiocyanatohydroquinone (XX), as might have been expected. The reaction conditions determine which of the products (XXI–XXIII) are isolated.[60]



(XX) (XXI) (XXII) (XXIII)

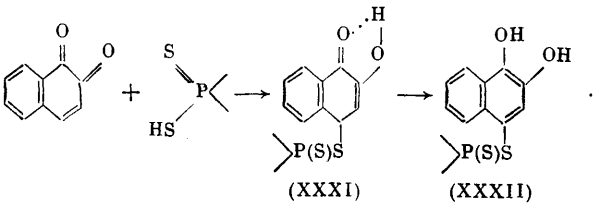
Since the thiolic sulphur of the thiosulphate ion is the nucleophilic centre, the reaction of sodium thiosulphate with quinones leads to the formation of sulfothiohydroquinones (XXIV), which in certain cases have been used for the synthesis of alkylthio-1,4-benzoquinones (XXV).[45]

(XXIV) (XXV)



The interaction of dithiophosphoric acids and their trimethylsilyl esters with quinones is interesting. A detailed study of the reactions by kinetic and spectrophotometric methods has shown that a *p*,π-type complex (XXVI) is formed initially; this leads to intermediate (XXVII), and then to the final 1,4-adduct (XXVIII).

(XXVI) (XXVII) (XXVIII)

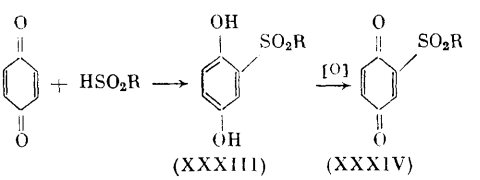


R' = H, SiMe .

The interaction with 1,4-naphthoquinone takes place by another route.

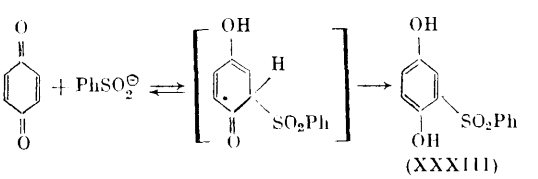
(XXIX) (XXX)

Initially, addition takes place across the C=C bond of the quinone to give (XXIX), which is converted into the thiophosphorylated dihydroxynaphthalene (XXX). The reaction of dithiophosphorus acids with 1,2-naphthoquinone is unusual. The intermediate (XXXI), which can be detected by IR-spectroscopy, isomerises as reaction progresses to give the 1,4-adduct (XXXII) as the final product.



(XXXI) (XXXII)

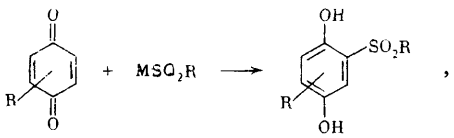
The stability of the enol form of intermediate (XXXI) is energetically favourable by virtue of stabilisation by intramolecular hydrogen bonding.[61–63]



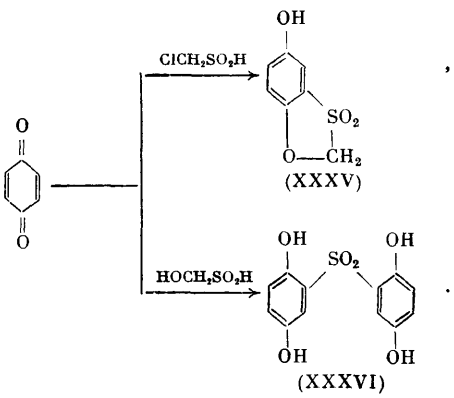
c) With sulphinic acids and sulphurous acid salts

Nucleophilic addition of sulphinic acids to 1,4-benzoquinone proceeds smoothly in the absence of catalyst to give the corresponding 2,5-hydroxy-1-alkyl(or aryl)sulphonylbenzenes (XXXIII), which can be converted to the corresponding sulphonylquinones (XXXIV).

(XXXIII) (XXXIV)

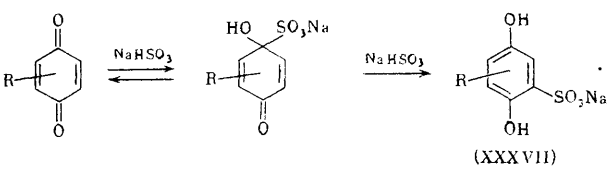


The mechanism of the reaction between 1,4-benzoquinone and phenylsulphinic acid in an aqueous medium has been established by kinetic studies with isotopes. Initially, there is a reversible addition of sulphinate anion to the ring system of the quinone to give an unstable adduct, which then isomerises to the sulphonylhydroquinone (XXXIII) as final product.

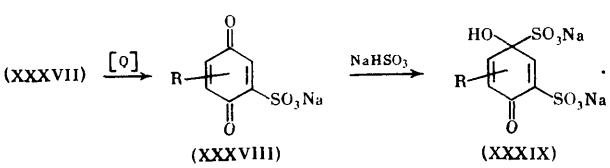


(XXXIII)

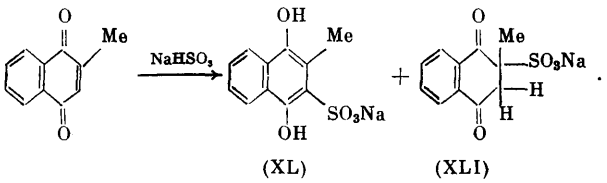
Kinetic data are in accord with a second order process, being first order in each reactant. The limiting step of the reaction is dependent on the pH of the medium. Thus, below 3.1, the rate-limiting step is the initial addition, while above pH 4.0 the isomerisation is the rate-determining stage.[64]



Sulphinic acid salts are stronger nucleophiles than the parent acids. They react with quinones to give sulphonylhydroquinones:[65]

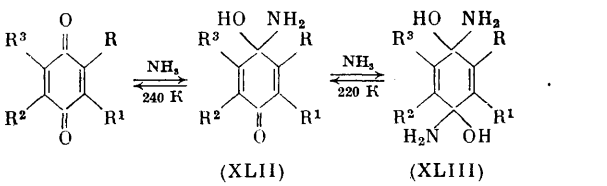


where M is an alkali or alkaline-earth metal or an organic cation. Chloromethanesulphinic and hydroxymethanesulphinic acid, as well as other sulphinyl compounds, interact with 1,4-benzoquinone to give unstable 1,4-adducts, which undergo intra- and inter-molecular condensation with the formation of the corresponding sulphones (XXXV) and (XXXVI).[45]

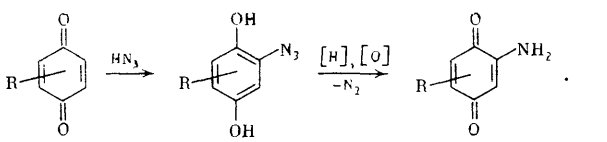


Reaction of sodium bisulphite with 1,4-benzoquinones involves a rapid, reversible, formation of a carbonyl-bisulphite adduct, followed by addition of bisulphite anion to give the hydroquinone-monosulphonates (XXXVII) as final product.[66,67]

A study of this reaction in buffered medium at pH 5–10 has shown that the highly reducing species (XXXIX) is formed. Its redox potential is more negative than that of hydroquinone. Thus, it is reasonable to conclude that compound (XXXIX) plays an important role in the mechanism of the action of hydroquinone-type indicators. It has been shown that compound (XXXIX) is formed by oxidation of the monosulphonate (XXXVII), followed by addition of sodium bisulphite to the carbonyl group of (XXXVIII).[68]

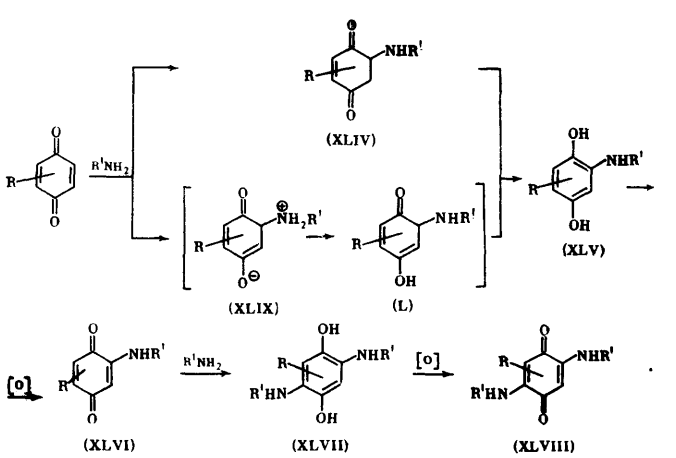


In the reaction of sodium bisulphite with 2-methyl-1,4-naphthoquinone a 1,2-adduct (XLI) is formed as well as the expected 1,4-adduct (XL). This 1,2-adduct arises by an unusual nucleophilic addition to the carbon-carbon double bond of the quinone.[68]

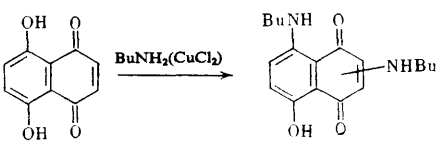


3. Reactions with *N*-nucleophiles

Gaseous ammonia interacts with unsubstituted quinones to give unstable amorphous products. Liquid ammonia reacts with substituted 1,4-benzoquinones at 240 K to give 1:1 adducts (XLII). At 220 K the diadduct (XLIII) is formed. The reaction is reversible: by addition of methylene chloride, followed by removal of ammonia, the starting 1,4-benzoquinones may be recovered.[69]

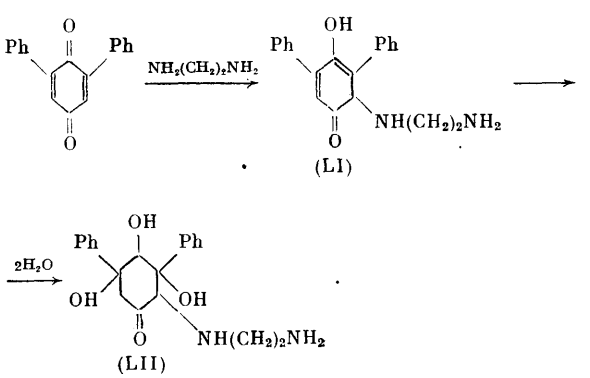


Nucleophilic addition of hydrazoic acid to 1,4-quinones provides a key method of preparing azidoquinones, from which aminoquinones can be obtained.[45,64]

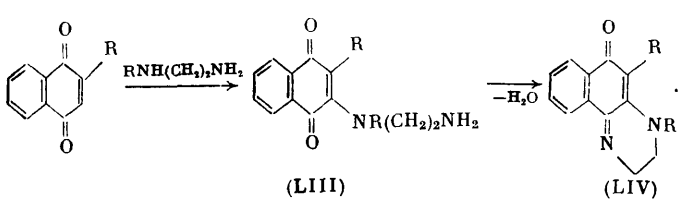


a) With primary amines

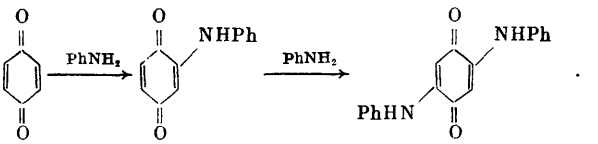
1,4-Benzoquinones react with primary aliphatic amines to give 2,5-diamino-1,4-benzoquinones (XLVIII), which are formed via oxidation of the intermediate 2,5-diaminohydroquinones (XLVII). It was not possible to isolate the initially-formed mono-aminated derivatives, (XLIV) and (XLVI).[70] This is possibly the reason why 2-amino-1,4-benzoquinones have not been reported.



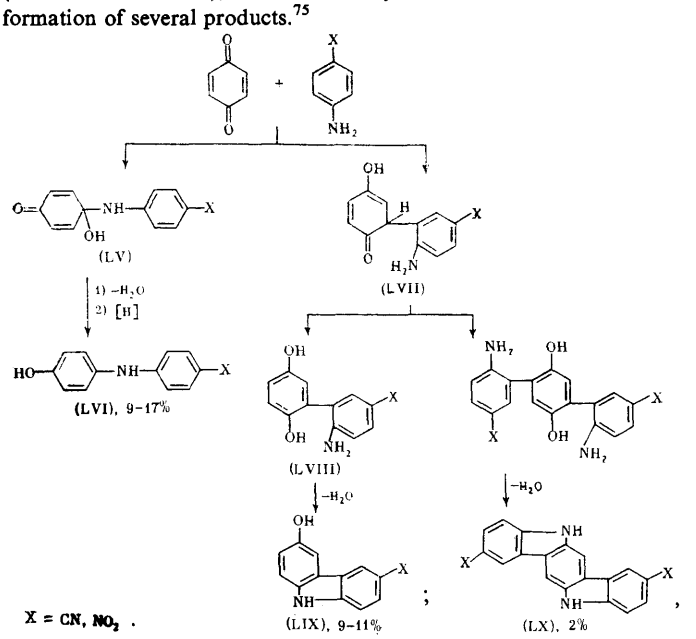
As shown above, the mechanism of the reaction involves an initial addition of the amine across a carbon-carbon double bond to give intermediate (XLIV), which isomerises into the aminohydroquinone (XLV) followed by oxidation to the monoaminoquinone (XLVI). Addition of a second amine molecule then gives the diaminoquinone (XLVIII).[45] In our opinion, reaction involves initial formation of a bipolar intermediate (XLIX), which isomerises into the cyclohexadienone (L) and thence to the aminohydroquinone (XLV). Such a scheme accords with the generally accepted mechanism of nucleophilic addition to unsaturated carbonyl compounds.[71]



The interaction of 1,4-naphthoquinones with aliphatic amines leads to the formation of 2-amino-1,4-naphthoquinones. If there is a hydroxy substituent in the 1,4-naphthoquinone, then substitution takes place as well as addition-oxidation. 5,8-Dihydroxy-1,4-naphthoquinone reacts with butylamine in the presence of $CuCl_2$ to give 2,8- or 3,8-bis(butylamino)-5-hydroxy-1,4-naphthoquinone as the main product. The yield is less in the absence of catalyst.[72]

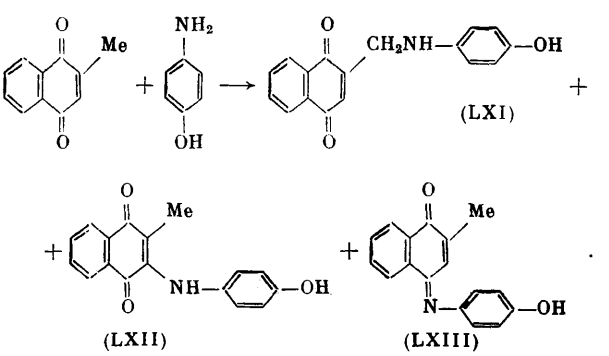


Reactions of 1,4-quinones with aliphatic diamines leads to the formation of a more complex product. The interaction of 2,6-diphenyl-1,4-benzoquinone with 1,2-diaminoethane, for example, affords an intermediate cyclohexadienone (LI), to which two water molecules add to give the cyclohexanone (LII) as final product. 1,6-Diaminohexane and piperazine react similarly.[73]

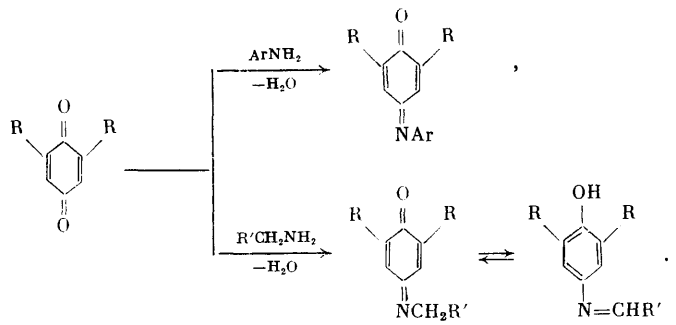


1,4-Naphthoquinone with diamines provides an initial 1,4-adduct (LIII), which subsequently loses a molecule of water to give a cyclic quinone imine (LIV).[74]

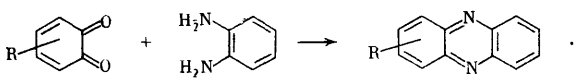
Aromatic amines are less active than aliphatic amines in their nucleophilic addition to quinones. As aniline is relatively inert, it has been possible to isolate both 2,5-dianilino-1,4-benzoquinone and 2-anilino-1,4-benzoquinone.[45]



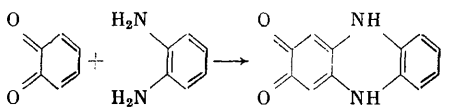
In a study of the interaction of substituted anilines with quinones (Nenitzescu reaction), low selectivity was recorded with the formation of several products.[75]



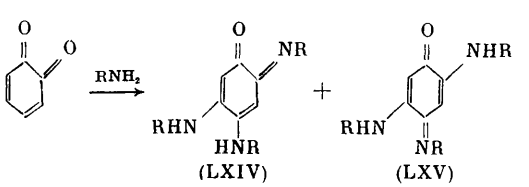
A reaction scheme was proposed according to which the final products (LVI, LIX, LX) were formed in parallel sequences: 1) 1,2-addition of aniline to a carbonyl group of the quinone to give the quinone aminoacetal (LV), followed by dehydration and reduction to produce the diphenylamine (LVI); 2) 1,4-addition of aniline to the conjugated system of the quinone to give the intermediate cyclohexadienone (LVII), which aromatises to the substituted hydroquinone (LVIII); the latter then dehydrates to give the carbazole (LIX). A second molecule of the starting aniline may also add to the cyclohexadienone, ultimately providing the dicarbazole (LX).



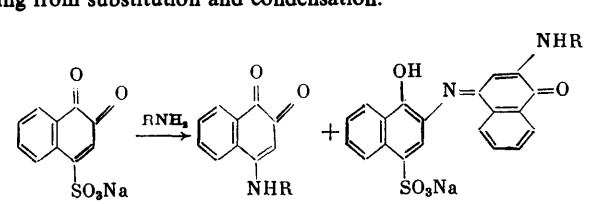
Several products are formed by interaction of 2-methyl-1,4-naphthoquinone with *p*-aminophenol. Thus, radical substitution affords quinone (LXI), while nucleophilic addition gives quinone (LXII) and quinone imine (LXIII).[76,77]



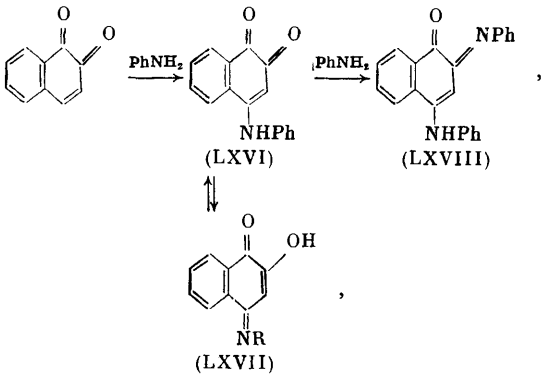
2,6-Disubstituted 1,4-benzoquinones, in which 1,4-addition is prevented by steric and electronic factors, react with primary aromatic amines by a condensation mechanism.[45,78]



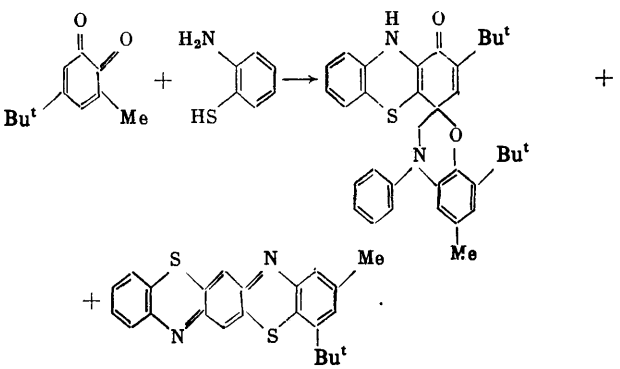
1,2-Quinones react vigorously with both aliphatic and aromatic amines in the same way as 1,4-quinones. However, it is possible to distinguish between 1,2- and 1,4-quinones by treatment with *o*-phenylenediamine: 1,2-quinones afford phenazine derivatives, whereas 1,4-quinones are unreactive



In the case of 1,2-benzoquinone itself, such a condensation does not take place; instead, an addition-oxidation leads to the formation of another type of cycloadduct.[45,64]



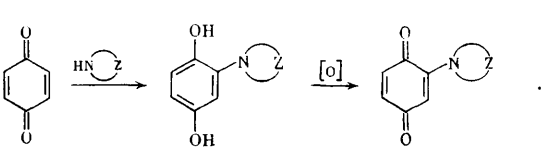
In general, unsubstituted 1,2-quinones react with amines by 1,4-addition. In the case of aromatic amines reaction is selective, but with aliphatic amines reaction is complicated by a concurrent condensation. For example, treatment of 1,2-benzoquinone with methyl-, ethyl-, propyl- and butyl-amine gives two types of product: 1,2-quinone imines (LXIV) and 1,4-quinone imines (LXV), formed as a result of consecutive double addition-oxidation and condensation.[79]



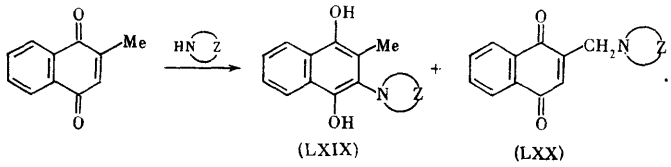
1,2-Naphthoquinone and substituted derivatives react with primary aliphatic amines to give several products, the most important resulting from substitution and condensation.[80]

Aniline participates in 1,4-addition with 1,2-naphthquinone, affording, after air oxidation, 4-anilino-1,2-naphthoquinone (LXVI) as the only isolable product.

If the reaction is carried out in the liquid phase, a second aniline molecule is added to give the quinone imine (LXVIII) as the final product.[45] It has been established that the substituted 1,2-quinone (LXVI) exists in the quinoidal form in the solid state or in alcoholic media, whereas it exists in the 1,4-quinone imine form (LXVII) in trifluoroacetic acid.[81] The reaction of 1,2-quinones with amines can be applied successfully for the preparation of complex structures which may be difficult or impossible to prepare by other means. The condensation of equimolar amounts of *o*-aminothiophenol and substituted 1,2-benzoquinones in the presence of $FeCl_3$ leads to the formation of unusual phenothiazines.[82]



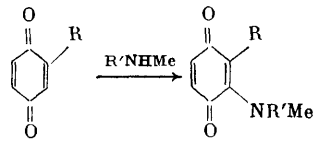
Quinone oximes with a variety of substituents are obtained by reaction of 4-substituted 1,2-naphthoquinones with ethylenediamine.[83]



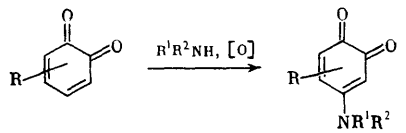
4,4'-Bis(1,2-naphthoquinone) interacts with aromatic amines in the same way as other 4-substituted 1,2-naphthoquinones to give condensation products involving the carbonyl group at the 2-position.[84,85]

b) With secondary amines

Secondary C_1-C_4 amines yield monoamino-substituted 1,4-benzoquinones exclusively.[64] Treatment of 1,4-benzoquinones with heterocyclic amines affords 2-substituted hydroquinones which are oxidised in air to give the corresponding quinones.[86]



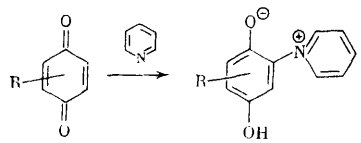
2-Methyl-1,4-naphthoquinones with pyrrolidine, piperidine, and heptamethyleneimine give stable 1,4-adducts (LXIX) as well as products derived by substitution of hydrogen at the methyl group (LXX).[87]



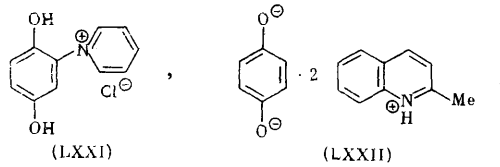
(LXIX) (LXX)

The study of the reaction of quinones with secondary amines has led to the development of the chemistry of biologically active quinones. Thus, aminoquinones (LXXI) have been prepared by interaction of 1,4-benzoquinone, 2-methyl-1,4-benzoquinone, 2-methyl-1,4-naphthoquinone and other 1,4-quinones with the following psychopharmacologically active amines: desipramine, nortryptyline, protryptyline, maprotyline and benzooctamine.[88–91]

(LXXI)



Treatment of 1,2-quinones with secondary amines affords 1,4-adducts which are converted to 4-amino,1,2-benzo(naphtho)-quinones in air.[45]

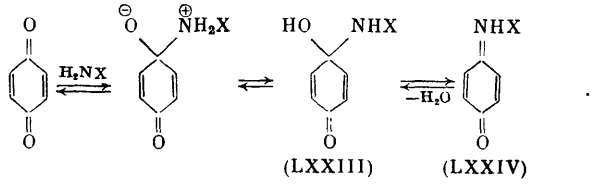


c) With tertiary amines and pyridine

In contrast with primary and secondary amines, tertiary amines do not react with quinones by nucleophilic addition. However, they do react with quinones by forming 1:1 or 1:2 charge-transfer complexes. In certain cases, complexes have been isolated and characterised as distinct entities,[92] but mostly they have only been detected by spectroscopic methods. The absorption of the complexes accords with a $p-\pi^*$-type transfer from the HOMO of the donor (amine) to the LUMO of the acceptor (quinone). The stability of the complexes depends markedly on the donor-acceptor properties of quinone-amine pair.[93]

The reaction of quinones with pyridine which, like tertiary amines lacks a labile hydrogen, is interesting in that there is no distinct complex-forming stage. Reaction proceeds directly to a bipolar compound.

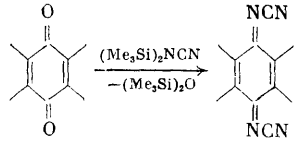
2-Pyridiniohydroquinone chloride (LXXI) is obtained in the presence of HCl. A similar adduct is formed by reaction of quinones with quinoline. The salt (LXXII) is isolated from the interaction with quinaldine.[45]



(LXXI) (LXXII)

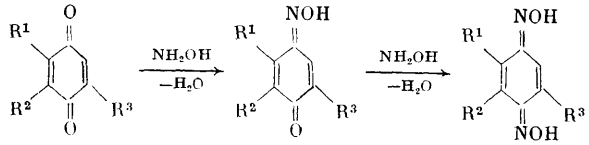
Charge-transfer complexes are not only formed with tertiary amines. Others participate in the same way, e.g. aniline, toluidine, ethylamine, diethylamine, piperidine, and polyvinylpyridine.[94–96]

Thus, in the overall scheme for nucleophilic addition of amines to quinones, as illustrated above, there could be an additional stage involving the formation of a charge-transfer complex. However, it is clear that certain reactions of amines with quinones do not involve complex formation.

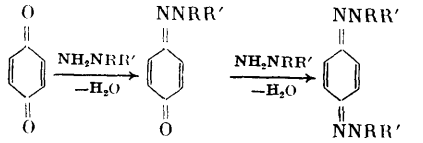


d) With cyanamide, hydroxylamine, hydrazines and hydrazides

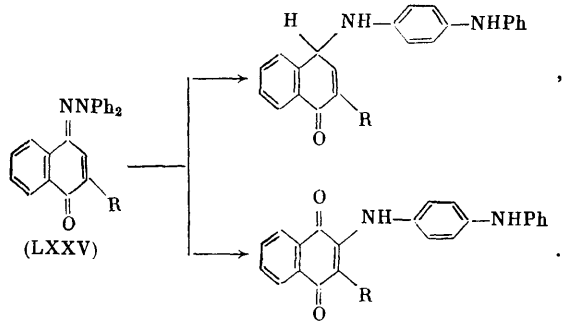
This section is devoted to the reaction of quinones with *N*-nuclophiles, H_2NX, where X = CN, OH, NRR', NHC(O)R and $NHP(O)R_2$. Here, reaction takes place at a carbonyl function rather than by addition to the conjugated double bond (C=C–C=O). The mechanism of the reaction involves several reversible steps, of which the most important are nucleophilic addition of the nitrogen atom to the carbonyl group with formation of quinol (LXXIII), and dehydration of the latter with formation of quinone imine (LXXIV).



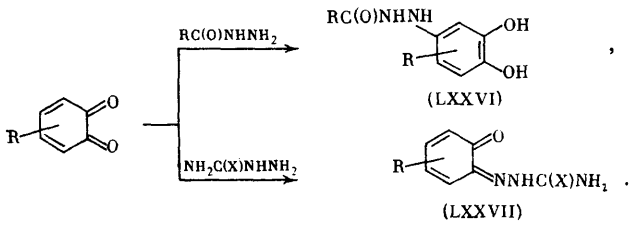
(LXXIII) (LXXIV)



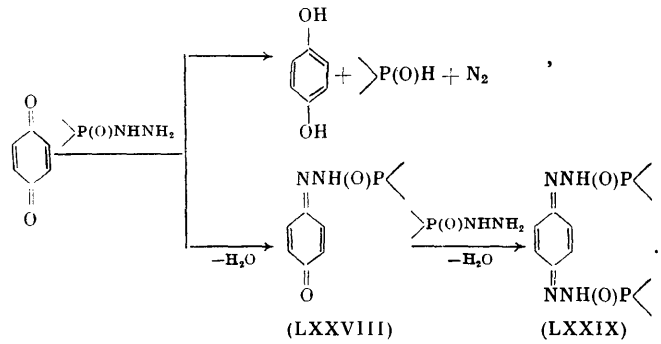
Quinones do not react with cyanamide. However, they react with silylcyanamides.[97]



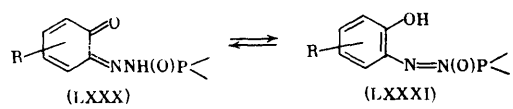
Hydroxylamine converts quinones into quinone mono- and di-oximes, which are particularly interesting as precursors for the synthesis of certain aromatic dinitroso compounds. More details on the oximation of quinones can be found in a monograph.[98]



Hydrazine derivatives react with 1,4-quinones to give the corresponding quinone mono- and di-hydrazones.[99]



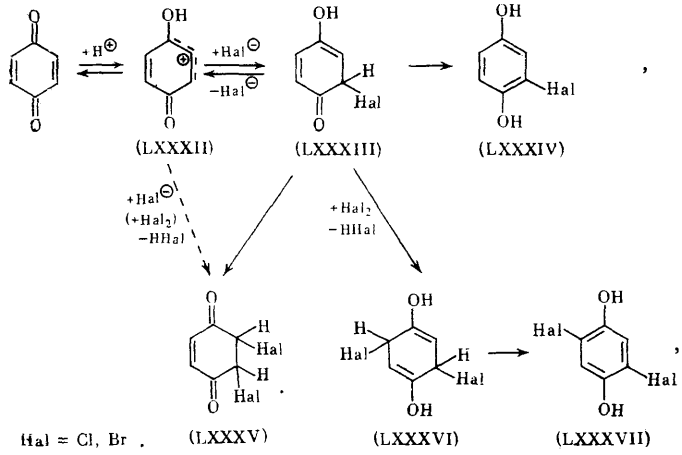
A redox reaction has been noted in certain cases, notably in the reaction with phenylhydrazine.[100–103] In this respect, we have focussed on the reaction of 1,4-naphthoquinones with diphenylhydrazine. Depending on the nature of the ring substituent, the initial condensation product (LXXV) is either converted to a semidine derivative or undergoes prototropic rearrangement.[104,105]



However, the nature of the hydrazine derivative, itself, largely determines the outcome of the reaction of 1,2-quinones. Thus, treatment of 1,2-quinones with hydrazine affords pyrocatechols by reduction. Acylhydrazines convert 1,2-quinones into 1,2-dihydroxy-3-acylhydrazinobenzenes (LXXVI), while semicarbazides and thiosemicarbazides condense to give the corresponding quinone semicarbazones (LXXVII).[45]

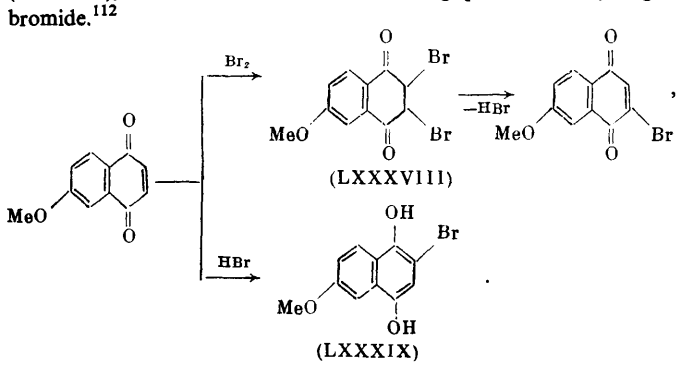
Phosphorohydrazidates react with quinones in a rather peculiar manner. Under mild conditions condensation takes place with the formation of phosphorylated quinone hydrazones (LXXVIII) and (LXXIX); however, above 20 °C in polar solvents, a redox reaction is set up, leading to hydroquinone, the corresponding phosphorus(III) acid, and nitrogen.[106–108]

Monohydrazones (LXXX) are formed with 1,2-quinones. There was no dihydrazone formation, probably because of steric hindrance.



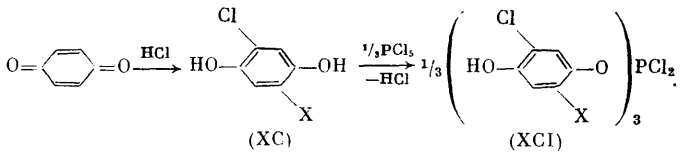
It has been established that the position of the quinone hydrazone ⇌ azophenol (LXXXI) equilibrium is largely determined by the nucleophilicity of the medium and the nature of the substituent on the quinoidal ring.[109]

Quinone hydrazones have been scrutinised for their biological activity. Notably, 1,4-naphthoquinone 4-aryl(aroyl)hydrazones have been prepared and shown to possess antimicrobial activity; they are potential tuberculostatic agents.[110]



4. Reactions with halogen nucleophiles

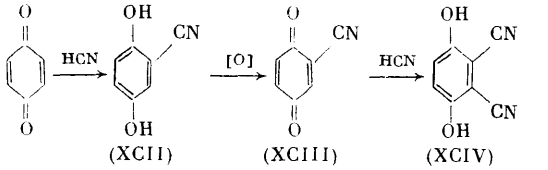
Hydrogen iodide does not add to quinones, but reduces them to hydroquinones. Other hydrogen halides participate in 1,4-addition to give halogenohydroquinones (LXXXIV).[45,64,111]



Reaction is initiated by protonation of the quinone with formation of cation (LXXXII); this undergoes attack by halide ion to give the corresponding 1,4-adduct (LXXXIII), which subsequently isomerises to the corresponding halogenohydroquinone (LXXXIV) as the final product. If free halogen is present in the medium, then adduct (LXXXIII), which by virtue of its unusual structural features is a very active nucleophile, adds a further halogen atom to give the dihalogenoquinone (LXXXV) or the cyclohexadiene (LXXXVI), stabilised in the dihalogenohydroquinone form (LXXXVII). It has been noted that the route (LXXXII → LXXXIII → LXXXIV) is more favourable than the route (LXXXII → LXXXIII → LXXXVI → LXXXVII) for steric reasons.[111]

In this section, it has also been considered appropriate to examine reactions of quinones with electrophilic reagents where the key step in the process involves nucleophilic addition. For example, the interaction of 6-methoxy-1,4-naphthoquinone with bromine affords, in addition to adduct (LXXXVIII), the nucleophilic addition product (LXXXIX), which is formed from the starting quinone and hydrogen bromide.[112]

The reaction of PCl_5 with 1,4-benzoquinones proceeds in a similar way.

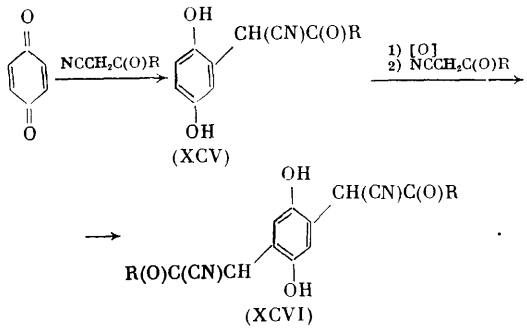


(XC) (XCI)

The interaction involves an autocatalytic chain process, the initial stage being the addition of hydrogen chloride to the quinone. The resulting chlorohydroquinone (XC) condenses with PCl_5 to give the dichlorophosphorane (XCI) as the final product with elimination of hydrogen chloride. The latter then adds to the starting quinone, thereby perpetuating the chain reaction.[113,114]

5. Reactions with *C*-nucleophiles

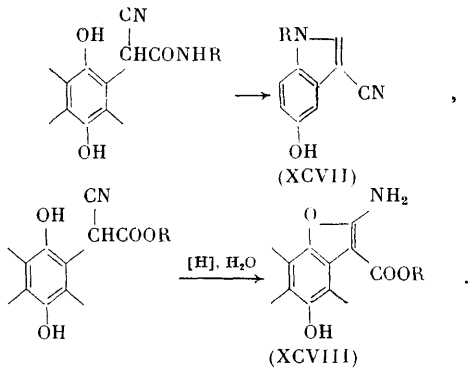
(a) With CH-acidic compounds



Hydrogen cyanide adds to 1,4-benzoquinone to give adduct (XCII), which is oxidised to the cyanoquinone (XCIII).

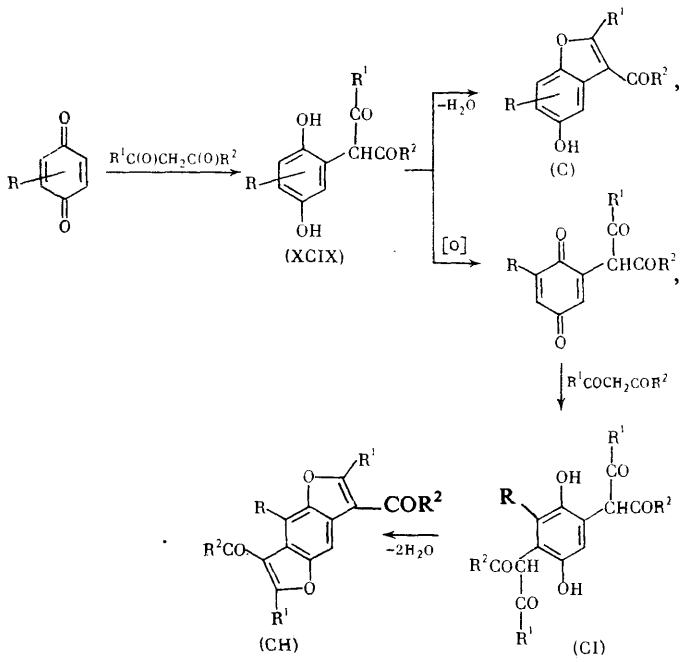
(XCII) (XCIII) (XCIV)

The interaction of a second HCN molecule with the cyanoquinone (XCIII) proceeds in an anomalous manner. Usually, all reactions of mono-substituted 1,4-quinones involve addition of nucleophiles at the 5-position (i.e. the *para*-position relative to the substituent). However, in the above case, the cyano group enters at the 3-position of the quinone to give (XCIV). There is no convincing explanation of this anomaly in the literature. Nevertheless, this reaction is preparatively very important for the synthesis of a number of cyanoquinones, amongst which the oxidant, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.[115]



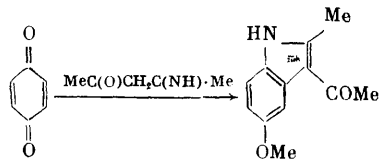
Of CH-acidic compounds, those with active methylene groups have been most studied in connection with quinone substitution. Carbonyl and nitrile substituents normally serve as activators.

(XCV) (XCVI)



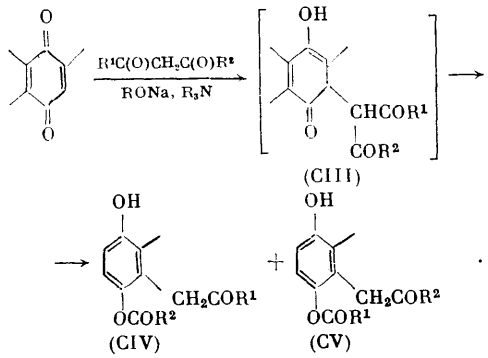
Thus, interaction of 1,4-quinones with 3-oxocarbonitriles involves initial 1,4-addition, followed by isomerisation of the resulting adduct to give the alkylhydroquinone (XCV). Oxidation of the latter, followed by addition of a second molecule of the nucleophile, may lead to the corresponding 2,5-dialkylhydroquinone (XCVI).[45,116,117]

Certain products undergo intramolecular cyclisation to give indoles (XCVII) and furans (XCVIII).[117,118]

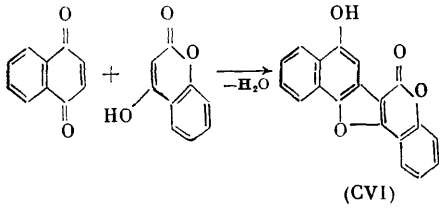


(XCVII) (XCVIII)

1,3-Dicarbonyl compounds and their derivatives react with quinones in a similar manner. The initially-formed 1,4-adduct (XCIX) is subsequently converted to benzofuran (C) via cyclodehydration, or undergoes oxidation-addition [to adduct (CI)] followed by cyclodehydration to the difuran (CII).[119,120]

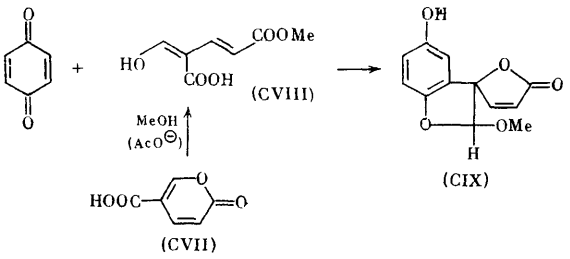


(XCIX) (C) (CH) (CI)

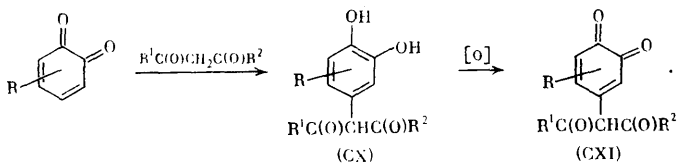


In certain cases, other processes are involved. Thus, the interaction of 1,4-benzoquinone with acetylacetone imine affords, unexpectedly, an indole derivative with a methoxy substituent in the benzene ring.[121]

In the presence of strong base, the reaction of substituted 1,4-benzoquinones with 1,3-diketones proceeds with the formation of substituted phenols (CIV) and (CV), rather than an adduct of type (XCIX). This is associated with an acylotropic conversion of intermediate (CIII).[122–125]



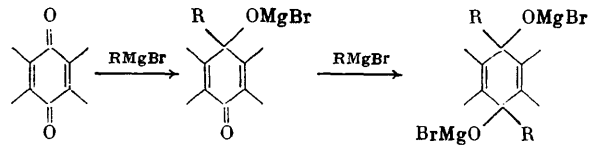
The reaction with 4-hydroxycoumarin is worthy of consideration here since, although it is not formally a CH-acidic compound, it can be viewed as the tautomeric form of a 1,3-dicarbonyl compound. Treatment with 1,4-naphthoquinone affords an adduct which subsequently cyclodehydrates to give furan (CVI).[126]



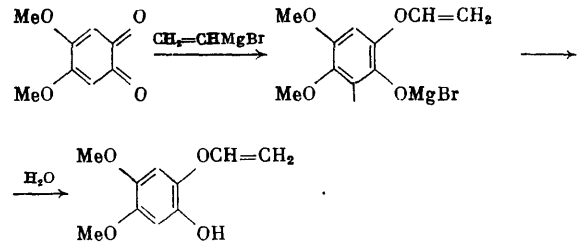
(CVI)

The spirobutenolide (CIX) is obtained by reaction of 1,4-benzoquinone with coumalic acid (CVII) in the presence of methanol, sodium acetate and acetic acid.

It is thought that acetate ion initiates pyrone ring opening with formation of enol (CVIII), which serves as a reactive form of coumalic acid.[127]



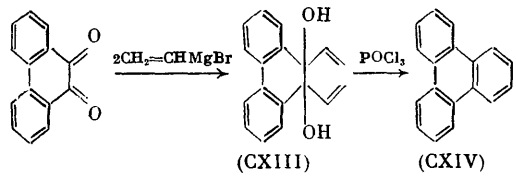
1,2-Quinones react with CH-acidic compounds in the same manner as 1,4-quinones to yield adducts (CX).[128–130]



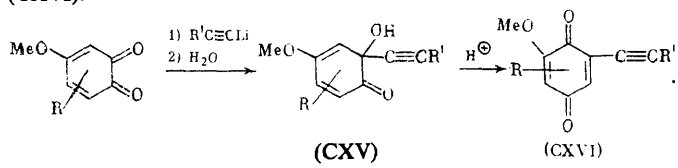
However, contrasting with the 1,4-quinone adducts (XCIX), which undergo a variety of reactions, the adducts (CX) are only oxidised with the formation of the corresponding 1,2-quinones (CXI).

b) With organometallic compounds

Substituted quinones react with the strongly nucleophilic Grigard reagents by nucleophilic addition. Addition to *p*-quinones involves one or both carbonyl groups.[45]



The reaction of vinylmagnesium bromide with 4,5-dimethoxy-1,2-benzoquinone leads to an adduct which is hydrolysed to a pyrocatechol vinyl ether (CXII).[131]

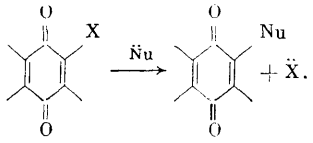


CXII

The interaction of vinylmagnesium bromide with phenanthraquinone yields the divinyldiol (CXIII) which is converted to triphenylene (CXIV) on treatment with $POCl_3$. Polycyclic hydrocarbons can thus be prepared by this route.[132]

Lithium acetylide adds to a carbonyl group of 1,2-benzoquinones with the formation of cyclohexadienones (CXV). In acidic media, the latter is hydrolysed to the relatively inaccessible alkynylquinones (CXVI).[133,134]

In this way, highly active nucleophiles, such as organometallic compounds, may add to one of the carbonyl groups of a quinone if the other is sterically hindered.



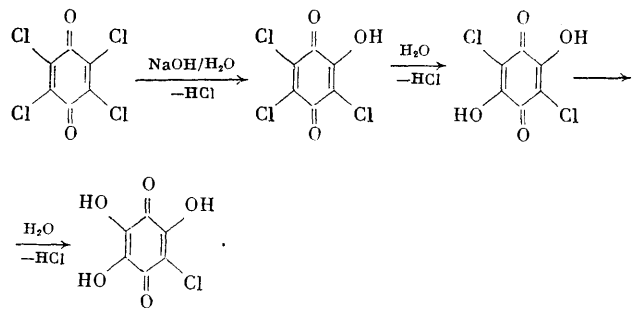
6. Reactions with *P*-nucleophiles

A vast amount of data is available on the interaction of organometallic compounds with quinones. In the majority of cases, the central atom of the organoelemental compound is not the reactive centre. Other reports deal with nucleophilic processes where

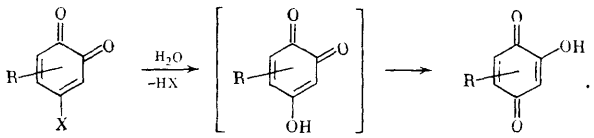
a heteroatom (in most cases phosphorus or arsenic) serves as the nucleophilic centre. In organophosphorus chemistry, it has been shown that almost all derivatives of di-, tri- and tetra-coordinated phosphorus acids, where the phosphorus atom is the reactive centre, interact with quinones via nucleophilic addition. A variety of products are obtainable depending on a number of factors, the most important being the nature of the substituents in the organophosphorus compound. More detailed information on the reactions of organophosphorus compounds with quinones are given in an earlier review.[135]

III. Nucleophilic substitution of quinones

The reactivity of quinones towards nucleophiles is dependent to a large degree on the π-acceptor character of the quinones. The π-acceptor properties are dependent primarily on the energy and symmetry of the lower unfilled molecular orbital (LUMO). In its turn, the energy of the latter is a function of electron affinity. Complex formation is one way to enhance electron affinity.[136–149] For example, in the complexes between 1,4-benzoquinone and $GaCl_3$ or $AlCl_3$, the structure of the LUMO is not changed, but its energy decreases from 0.15 to −1.7 eV.[145] This leads to an increased reactivity of the complexed quinone towards nucleophiles. Although quinone complexes with proton,[45] Lewis acids[137,141,142] and metal ions[139,140,147] have been used preparatively, the full potential of such quinone activation towards nucleophiles has not yet been explored. Electron affinity can also be increased by appropriate substitution of the quinone. Thus, the electron affinity of unsubstituted 1,4-benzoquinone is relatively low (1.91 eV),[146] but replacement of hydrogen by other atoms leads to a shift in electron affinity. Alkyl substitution, for example, lowers the value (1.59 eV for duroquinone), while halogens and, in particular, the cyano group, effect a marked increase (2.78 eV for chloranil, 2.50 eV for bromanil, and 3.40 eV for tetracyano-1,4-benzoquinone).[64,146] Thus, halogeno- and pseudohalogeno-quinones are the most reactive of substituted quinones towards nucleophiles.



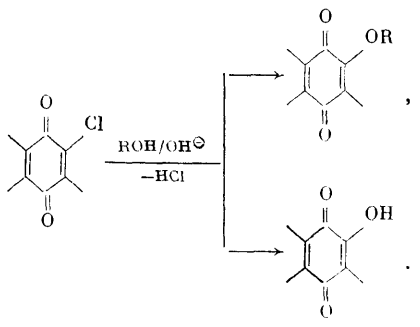
Both anions and neutral compounds with a free lone pair may be used as nucleophiles. The quinone may be substituted by halogen or a pseudohalogen or, in fact, any other electron-accepting group where polarisation of the C−X bond is possible.



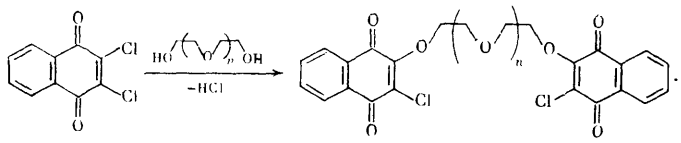
1. Reactions with *O*- and *S*-nucleophiles

The hydrolysis of halogenoquinones to hydroxyquinones is a classical example of a nucleophilic substitution of a quinone. Replacement of the halogen by a hydroxyl group proceeds most simply in the presence of a base—alkaline or pyridine. Acid-catalysed hydrolysis is rare. The completion of the reaction depends to a large extent on the effect of the ring substituent. Nevertheless, catalytic hydrolysis of substituted quinones normally proceeds readily and selectively in high yield.

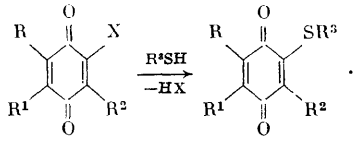
With chloranil, exchange of chlorine atom by a hydroxyl group takes place in the presence of aqueous NaOH. Mono- and di-substituted hydroxyquinones can be prepared as required.



Hydrolysis of bromanil and fluoranil proceeds in the same way. With iodanil replacement of only one halogen atom is possible.[150] Quinones with alkoxy-, aryloxy-, alkylthio-, or arylthio-groups participate in a catalytic reaction with water. In each case, replacement of the substituents by a hydroxyl group takes place. However, substituted 1,2-quinones hydrolyse by a different route. The initially formed hydroxy-1,2-quinones (CXVII) are spontaneously converted into the energetically more favourable hydroxy-1,4-quinones (CXVIII).[45]



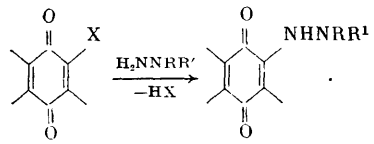
(CXVII) (CXVIII)



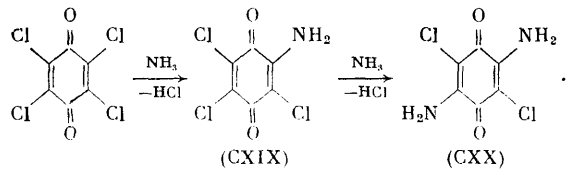
The interaction of halogenoquinones with alcohols and phenols normally proceeds in the presence of a base as catalyst, principally alkali metal alkoxides and aroxides or NaOH. As a rule, alkyoxylation or aryloxylation of the quinones takes place, although hydrolysis to hydroxyquinones has sometimes been observed.[151–153]

The alcoholysis of 2,3-dichloro-1,4-naphthoquinone was studied as long ago as the last century, and nowadays has found practical applications, notably in the synthesis of crown ethers with naphthoquinone fragments.[152,153]

The interaction of substituted quinones with aliphatic mercaptans and thiophenols is important since it permits the preparation of quinones with a sulphur functionality at a defined position.

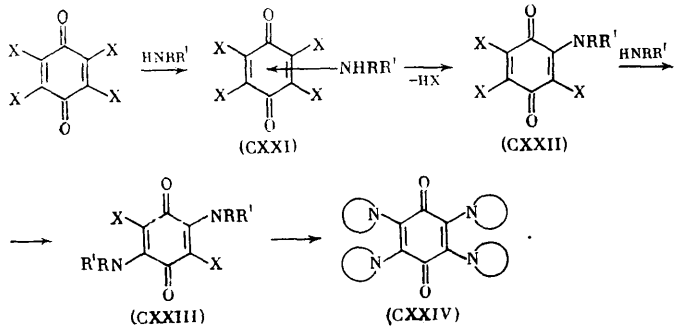


A base is required for the reaction of quinones with aliphatic mercaptans, and references have been made to the use of catalysts for the reaction with thiophenols.[45,64,154]

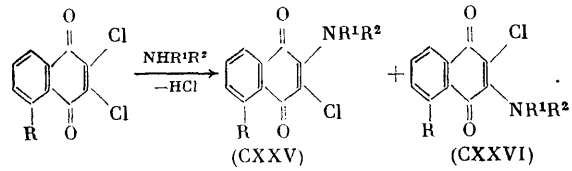


2. Reactions with *N*-nucleophiles

Nucleophilic substitution of quinones has been studied mostly with amines and other *N*-nucleophiles. The reactivity of *N*-nucleophiles decreases in the order: hydrazines ≥ ammonia > primary amines > secondary amines. The reactivity of aromatic amines is lowered by bulky substituents. Electron-accepting substituents in the benzene ring of aromatic amines also inhibits the reaction.

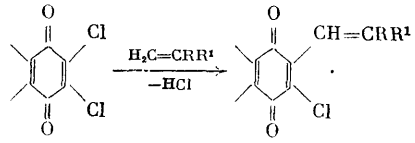


Hydrazines react with 1,4-quinones to give hydrazinoquinones.[155–157]



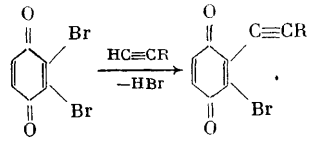
Treatment of chloranil with ammonia initially affords a monoaminoquinone (CXIX), which is further aminated to the diaminoquinone (CXX). The structure of the latter has been established by X-ray spectroscopy.[158]

The mechanism of the reaction of halogenanils with amines with a single N–H bond involves an initial complex formation to give (CXXI), which is subsequently converted into mono-, di- and tetraaminoquinones (CXXII–CXXIV).[159–164]



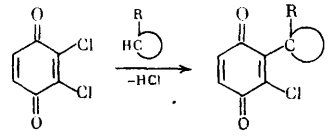
Such replacement of all halogen atoms is only possible with active cyclic amines (pyrazoles, imidazoles, 1,2,3- and 1,2,4-triazoles).[165,166] Treatment of halogen-substituted naphthoquinones with amines affords mono-amino derivatives, (CXXV) and (CXXVI). Both halogen atoms can be replaced by using nitrogen-containing heterocyclics.[167–185]

Studying this reaction has furnished much information: the ratio of 2-chloro- and 3-chloro-isomers (CXXV and CXXVI) is dependent on the structure of the amine;[169–172] this ring substituent influences the reactivity of the amine and the spectral characteristics of the products;[169] optimum conditions have been established for the synthesis of intensely coloured light-sensitive materials;[173] a convenient method of aminating halogenonaphthoquinones by phase transfer catalysis has been found;[174] and water-soluble naphthoquinones have been synthesised.[175,176]

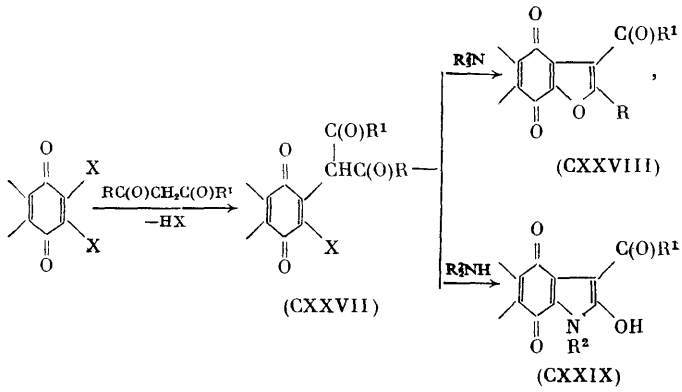


3. Reactions with *C*-nucleophiles

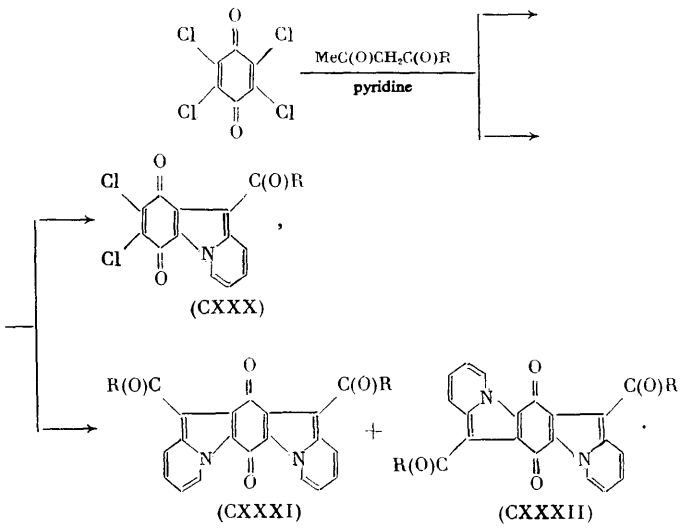
Halogenoquinones condense with *C*-nucleophiles to give quinoidal products with a new carbon–carbon bond. Olefins with an activated double bond interact with chloranil and 2,3-dichloro-1,4-naphthoquinone, providing alkenyl-substituted quinones.[177–180]



R = R¹ = OAlk, NAlk₂



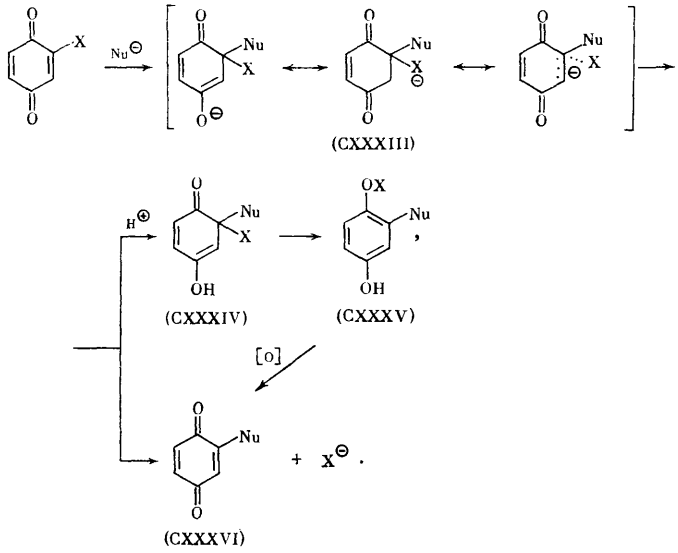
Acetylenes react similarly with halogenoquinones, yielding alkynylquinones in one step.[181]



Cyclic hydrocarbons having a labile hydrogen also interact with halogenoquinones by nucleophilic substitution.[182,183]

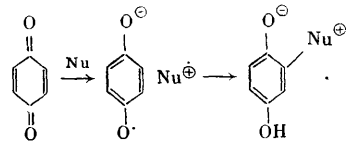
The reaction of 1,3-dicarbonyl compounds with halogenoquinones is complex. It is initiated by replacement of a halogen to give quinones (CXXVII), which are converted to furan derivatives (CXXVIII) on treatment with tertiary amines; primary amines, however, yield indole derivatives (CXXIX).[180,184–186]

Many of the resulting furans (CXXVIII) and indoles (CXXIX) are biologically active. A rare three-component condensation is achieved by interaction of halogenoquinones with 1,3-dicarbonyl compounds and pyridine. Pyridoindoloquinones (CXXX) or benzodiindolizine-quinones (CXXXI and CXXXII) are formed depending on the proportion of the reactants.[180,187]



The overall scheme for this three-component conversion is exemplified by the reaction of 2,3-dichloro-1,4-naphthoquinone with indan-1,3-dione and pyridine.[188]

4. Reactions with *P*-nucleophiles



Detailed information on the interaction of quinones with organophosphorus compounds, where the phosphorus atom is the nucleophilic centre, is available in an earlier review.[135] It suffices only to point out that nucleophilic substitution is generally achieved by interaction of a phosphorus(III) compound (phosphines, phosphites, amidophosphites) with polyhalogenoquinones (e. g. chloranil, 2,3-dichloro-1,4-naphthoquinone). The substitution product is either a bipolar ion or a phosphonate with a quinone residue.[135]

Sometimes quinones are viewed as α,β-unsaturated carbonyl compounds. However, such is unrealistic, even in a formal sense, as the quinone system cannot be considered strictly as a carbonyl-conjugated structure, nor its chemical properties studied systematically on this basis. As an overview of the multitude of quinone reactions, the following should be borne in mind: 1) the main distinguishing feature of quinones and their derivatives is their readiness to form energetically favourable aromatic or semiquinoidal systems; 2) an important chemical property of quinones is their ability to exchange ring substituents without destroying the quinoidal system; 3) mechanistically, the majority of quinone reactions proceed by a heterolytic pathway with the formation of addition or substitution products. Nucleophilic reactions can be represented by a general scheme, the first step of which is unique for both Ad_N and S_N mechanisms. This comprises addition of the nucleophile, Nu^-, to a carbon atom of the ring with formation of a resonance structure (CXXXIII). Its stabilisation is achieved either by addition or substitution.

If the substituent (X) is a poor leaving group, e. g. hydride anion, then a proton (H^+) adds to the intermediate, followed by isomerisation of the adduct (CXXXIV) with formation of hydroquinone (CXXXV). With highly nucleofugal substituents (X = Hal^-, RO^-, R_2N^-), the intermediate (CXXXIII) is stabilised by cleavage of anion, X^-, and formation of quinone (CXXXVI). The arrow linking compounds (CXXXV) and CXXXVI) signifies that hydroquinones (CXXXV) with donor substituents are readily oxidised to the corresponding quinones (CXXXVI).

In certain cases, single electron transfer from the nucleophile to the quinone can be achieved with formation of a radical pair, the recombination of which leads to the formation of a betaine.[135]

Cyclisation reactions involving carbene complexes in the inner coordination sphere of transition metals

A Z Rubezhov
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The literature data on inner-sphere cyclisation reactions involving carbene complexes in the coordination sphere of transition metals are summarised.

The bibliography includes 136 references.

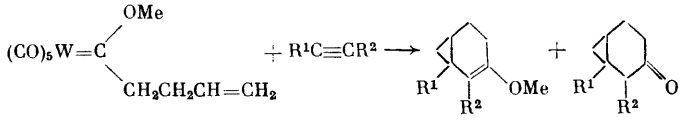
Contents

I. Introduction 89
II. Reactions that lead to the formation of three-membered rings 89
III. Reactions that lead to the formation of four-membered rings 90
IV. Reactions that lead to the formation of five-membered rings 94
V. Reactions that lead to the formation of six-membered rings 99

I. Introduction

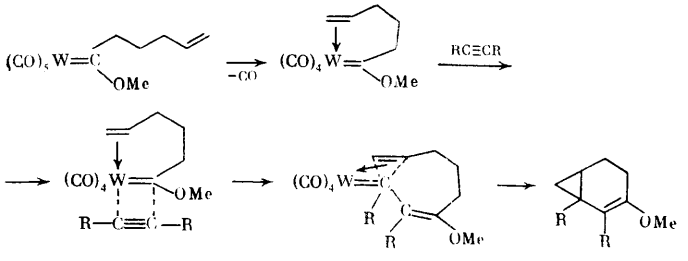
Cyclisation reactions that involve carbene complexes have been known for quite a long time, but they have mainly been studied in relation to the use of organometallic reagents in organic synthesis (see several reviews),[1–6] primarily for the synthesis of derivatives of naphthalene, indene, etc. In the present review we shall summarise those reactions of carbene complexes during which the carbene ligand combines with a molecule of substrate to form a cyclic (or metallacyclic) ligand, with all of the reactions occurring in the inner coordination sphere of the metal. It should be emphasised that there are no strict criteria which could be used to classify a given reaction as intramolecular. Very frequently it is only the structure of the final products that suggest the inner-sphere nature of the processes, since in the majority of cases the corresponding reactions are not typical for the uncoordinated ligands. Thus the term "inner-sphere cyclisation" is fairly arbitrary.

In the present review we shall mainly examine the processes which result in the reaction between a ligand that is already present and a molecule of reagent to form a new cyclic ligand which remains in the coordination sphere. Reactions of the formation of a cyclic ligand on a transition metal atom (template reactions) will be included subsequently, and it is also proposed to include data on catalytic cycloaddition reactions in the presence of transition metal complexes.



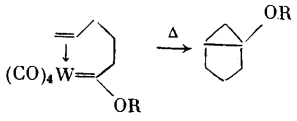
In general cycloaddition reactions have been covered in sufficient detail in the literature, so in this review there is no need to dwell on a detailed examination of them. With regard to cycloaddition reactions in the inner coordination sphere of transition metals, the number of theoretical studies in this area is clearly insufficient to raise the question now about finding a correspondence between theory and practice. In those cases where it was possible to do this, specific examples are given.

This review covers the original literature up to the end of 1989.



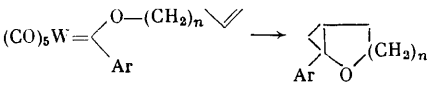
II. Reactions that lead to the formation of three-membered rings

Carbenes are known[6] to react with olefins to give cyclopropanes. The use of carbene complexes of transition metals as transfer agents of a carbene to an olefin in the synthesis of cyclopropanes was first described by Fischer.[7] In the present review there are examples of the formation of cyclopropanes from carbene complexes and acetylenes that occur without the formal cleavage of the metal–carbene bond at the intermediate stages of the reaction.

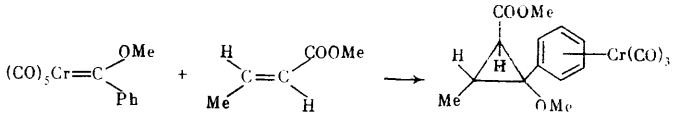


Carbene complexes of tungsten containing a multiple bond on the "periphery" of the carbene ligand react with disubstituted acetylenes to form condensed cyclopropanes:[8,9]

The reactions occur in the following way: at the first stage the alkyne is inserted into the metal–carbene bond to form a dienyl-substituted carbene intermediate in which intramolecular cyclopropanation of the double bond by the carbene ligand then occurs, as described by Fischer.[7] Initially the carbene complex may undergo isomerisation with elimination of CO and formation of a π-olefin carbene complex which can be isolated:[10,11]

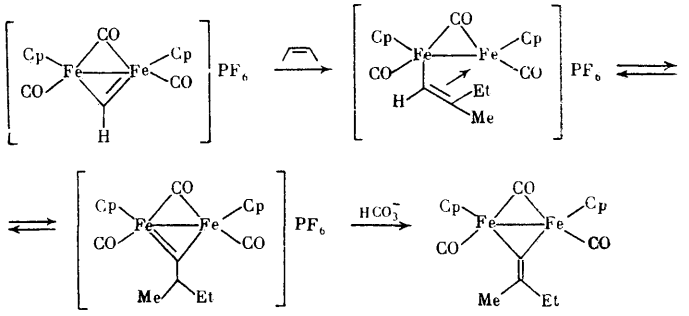


The intermediate π-olefin carbene complex may also form a cyclopropane derivative through intramolecular cyclopropanation:[10,11]



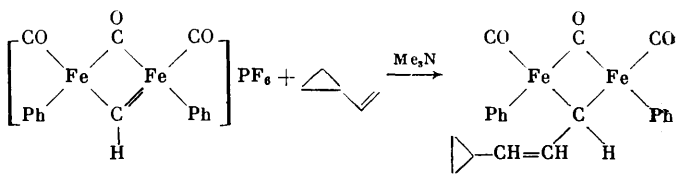
R = Me, Et.

Similar reactions have been reported for carbene complexes with an unsaturated alkoxyl residue:[12]

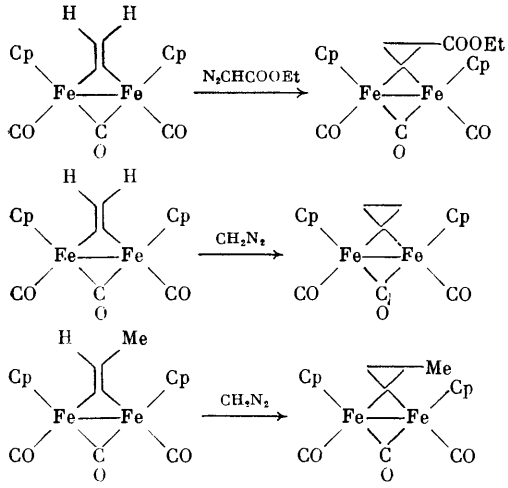


Ar = 4-MeC$_6$H$_4$; n = 2, 3.

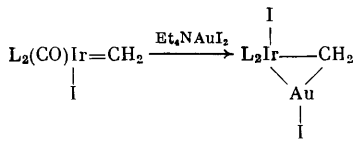
When n = 1 only an allyl aryl ketone was isolated. A tungsten π-arene complex was obtained as a by-product. The formation of such π-arene complexes was detected in the cyclopropanation of olefins with chromium π-alkoxybenzylidene complexes:[13]



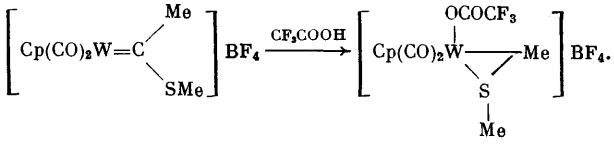
The reaction is stereoselective—a *trans*-cyclopropane is formed from a *trans*-olefin. The enantioselective synthesis of cyclopropanes using chiral iron carbene complexes has been reported.[14]



Cationic iron complexes with bridging carbene ligands react with olefins to form diferracyclopropanes:[15]



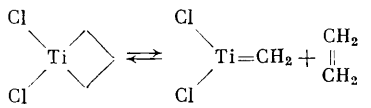
The reaction occurs via σ,π-olefin complexes which are formed as a result of the insertion of the olefin into the "double" C=Fe bond followed by a 1,3-hydrogen shift. Vinylcyclopropane reacts somewhat differently:[16]



Iron alkylidene complexes obtained by reaction of olefins with bridging carbene derivatives react with diazoalkanes to form diferraspiropentanes:[17–19]

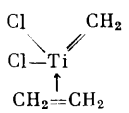
The formation of a three-membered dimetallacycle has been observed[20] in the reaction of an iridium carbene complex with tetraethylammonium diiodoaurate:

This reaction may be regarded as the addition of :AuI to the iridium–carbon double bond. The addition of trifluoroacetic acid to a tungsten–carbon double bond gives a thiatungstacyclopropane:[21]



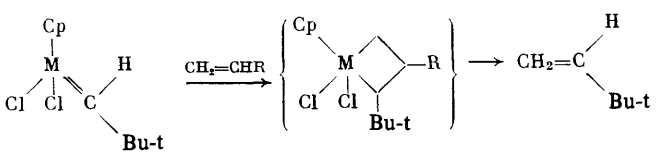
It may be concluded from the material examined that [1 + 2] cycloaddition reactions with the formation of π-cyclopropene or η^3-cyclopropenyl complexes are not typical for carbene compounds of transition metals.

III. Reactions that lead to the formation of four-membered rings



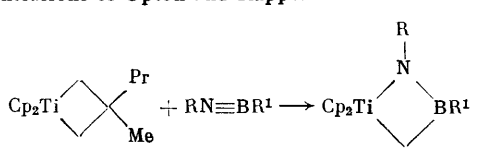
The formation of four-membered rings involving carbene complexes is possible as a result of either [1 + 3] cycloaddition or a [2 + 2] process. In the first case the formation of cyclobutenyl or cyclobutadienyl complexes are to be expected for an inner-sphere reaction, in the second case metallacycles are to be expected. This is true for all concerted reactions; but in the chemistry of organometallic compounds, as a result of a metal atom participating in the reaction, unconcerted multistage reactions are possible. It is

therefore probable that the formation of cyclisation products in the inner coordination sphere cannot always be strictly interpreted in terms of a given limiting mechanism.



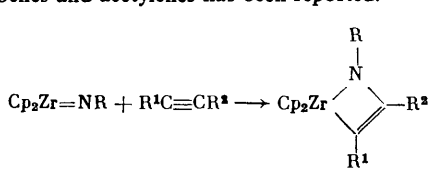
A theoretical analysis of $2\pi + 2\pi$ reactions that occur within the coordination sphere of a transition metal has been carried out for the system titanium alkylidene complex – olefin.[22]

It was found that the intermediate olefin(methylidene) complex



has an energy which exactly corresponds to that of the transition state of the reaction. The initial titanacyclobutane is 11.5 kcal mol^{-1} more stable than the intermediate complex and the conversion to the final products requires a further 10.4 kcal mol^{-1}. Thus, the reaction of olefins with metal carbene complexes with the formation of four-membered metallacycles is thermodynamically favourable. It is likely that the metathesis of olefins with niobium and tantalum (π-cyclopentadienyl)(neopentylidene) dichlorides occurs in this manner:[23]

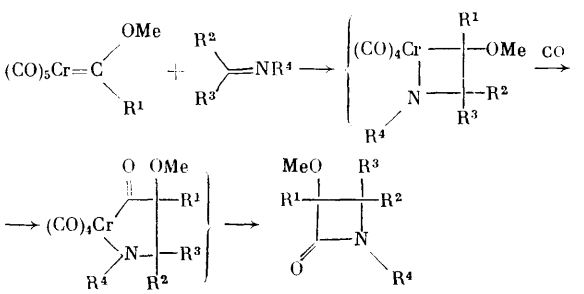
M = Ta, Nb; R = H, Me, Ph.



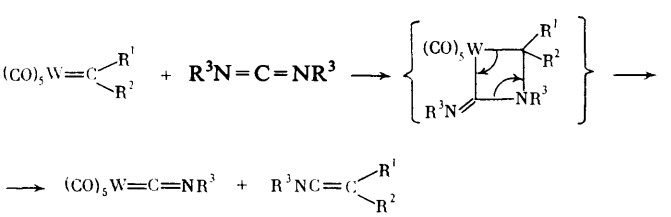
The suggestion of Paetrold et al.[24] that the reaction of a titanacyclobutane complex with RNBR^1 occurs via the formation of the intermediate carbene complex $Cp_2Ti{=}CH_2$ is not consistent with the conclusions of Upton and Rappe.[22]

R = iso-Pr, t-Bu; R^1 = iso-Pr, Bu, t-Bu, C_6F_5.

It is clear that the formation of azaboratitanacyclobutenes occurs in some other way, or the presence of the two geminal substituents in the four-membered ring of the initial complex considerably assists the elimination of an olefin with the separation of a methylene complex.

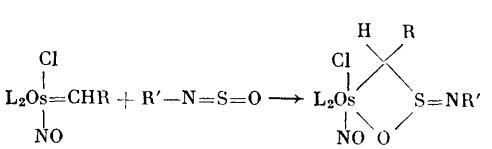


The formation of azazirconacyclobutenes from the aza analogues of carbenes and acetylenes has been reported.[25]



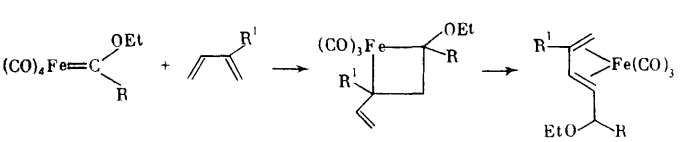
R	R^1	R^2
t-BuC$_6$H$_4$	Me	Ph
t-Bu	Ph	Ph
2,6-Me$_2$C$_6$H$_3$	Me	Me

The initial imidozirconocenes are generated by thermolysis of the respective products $Cp_2Zr(R^3)NHR$ (R^3 = Me, Ph) or by thermolysis of the bisamides $Cp_2Zr(NHR)_2$. In the case of a bulky substituent (R = t-Bu) the corresponding imide was isolated as an adduct with THF and its structure was established by X-ray diffraction analysis.[25] It is interesting that in the reaction of an imide with the asymmetric MeC≡CPh only one isomer is formed with the methyl group at the α-position relative to the nitrogen of the heterocycle, i.e., cycloaddition takes place contrary to Markownikoff's rule. The isoelectronic titanamethylidene complex $Cp_2Ti{=}CH_2$ undergoes similar reactions with alkynes.[26–28]

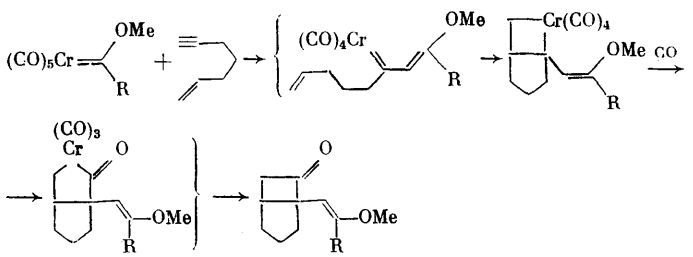


According to McGuize et al.[29,30] β-lactams are obtained in reactions between chromium carbene complexes and imines via azachromacyclobutanes, which are [2 + 2] cycloaddition products:

The metathesis of carbodiimides on treatment with tungsten carbene complexes to form intermediate four-membered metallacycles occurs in a similar manner:[31]

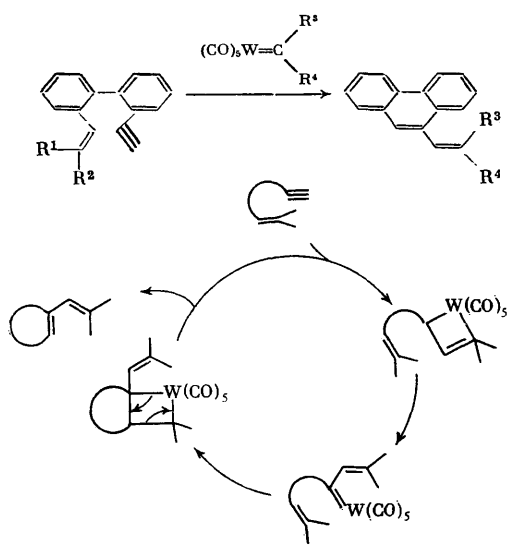


The reaction of sulphinylamines with osmium alkylidene complexes occurs as a [2 + 2] cycloaddition only on the S=O bond pseudocumulene [sic]:[32]

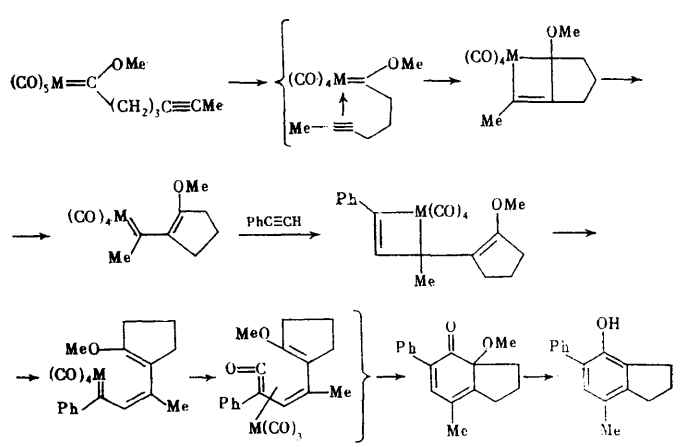


L = PPh_3, R = H, COOEt, R′ = Ts.

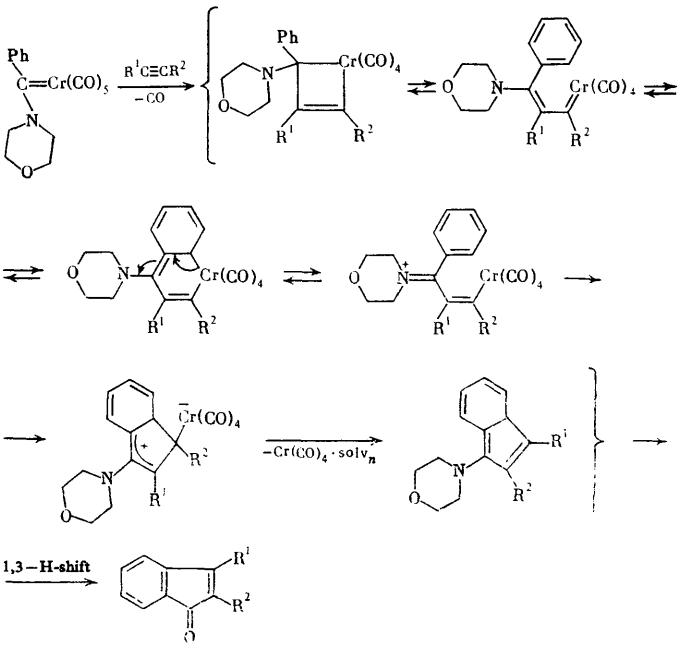
The reaction of 1,3-dienes with iron carbene derivatives also only takes place on one of the two double bonds:[33,35]



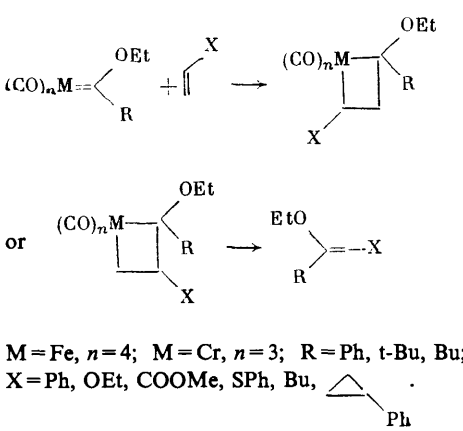
It should be noted that the idea of intermediate four-membered metallacycles being formed has been used to quite a significant extent to account for both catalytic and stoichiometric reactions of transition metal carbene complexes with olefins or acetylenes.



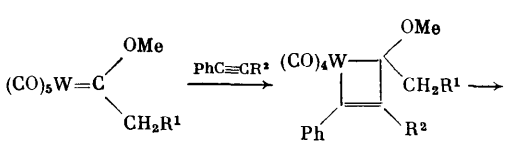
For example, the following scheme has been put forward for the stoichiometric reaction of hept-1-en-6-yne with chromium methoxycarbene complexes, which gives 1-vinyl-substituted bicyclo-[3.2.0]heptanones:[35]



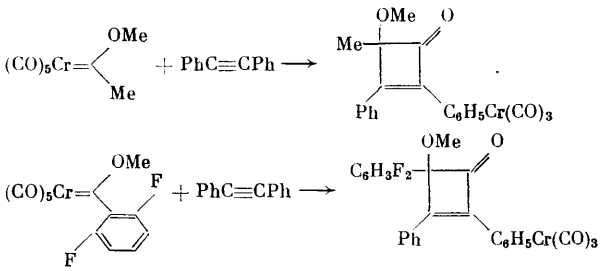
At the first stage acetylene is inserted into the metal–carbene bond, then intramolecular cyclisation, insertion of CO, and elimination take place. The formation of a metallacyclobutane can also occur at the first stage, as has been proposed for the catalytic reaction to obtain 9-vinylphenanthrenes from 1,1′-alkynyl(vinyl)biphenyls:[36]



The reactions between alkynes and (1-methoxyhept-5-ynylidene)-pentacarbonylchromium[37] and between acetylenes and [(phenyl)-(morpholino)carbene]pentacarbonylchromium also occur in a similar manner:[38]

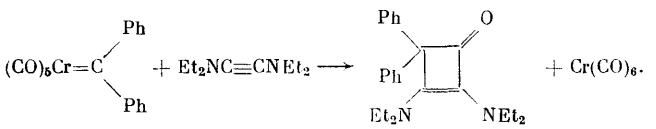


The metathesis of olefins on iron and chromium carbene complexes also occurs via intermediate metallacyclobutanes:[39]



M = Fe, $n = 4$; M = Cr, $n = 3$; R = Ph, t-Bu, Bu;
X = Ph, OEt, COOMe, SPh, Bu, .

as does the addition of coordinated carbene ligands to acetylenes:[40]



R^1	R^2	(A), %	(B), %

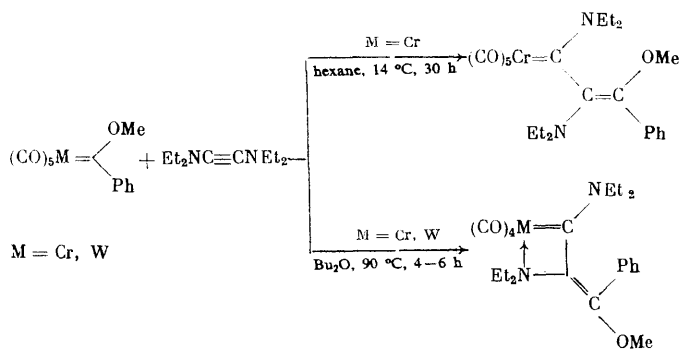
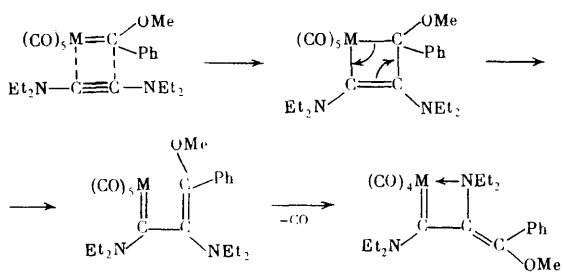
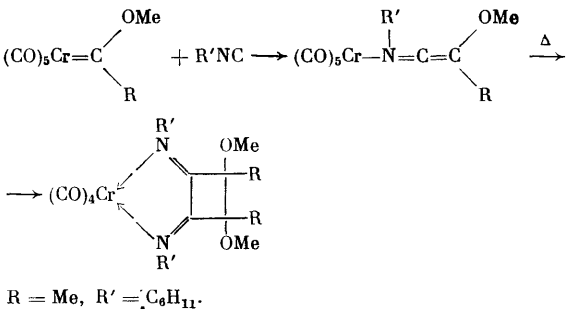
Me	Me	19	42



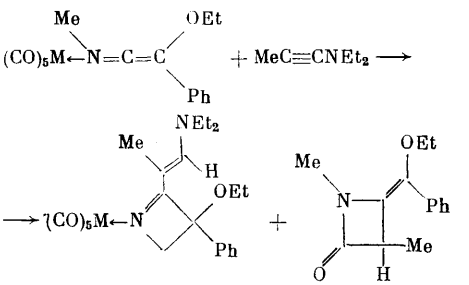
In the case of the addition of diphenylacetylene to a chromium methoxycarbene complex the $Cr(CO)_3$ residue remains coordinated in the reaction products:[41,42]



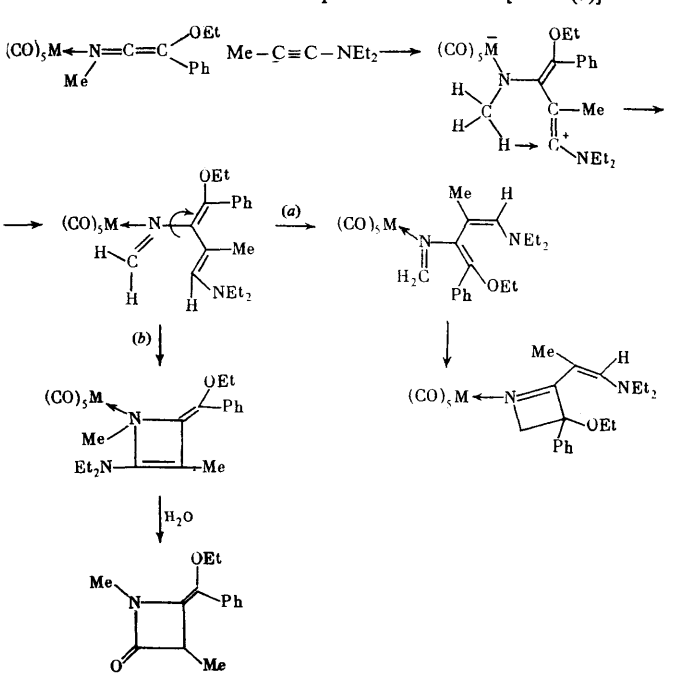
Confirmation of the coordination of $Cr(CO)_3$ with an aryl group of diphenylacetylene is provided by the reaction of bis(diethylamino)-acetylene with a chromium diphenylcarbene complex:[41]



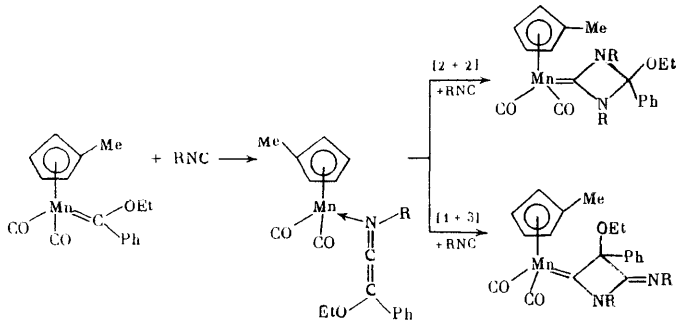
Interestingly, the reaction of bis(diethylamino)acetylene with chromium and tungsten (methoxybenzylidene)pentacarbonyls takes place in a different manner;[43]



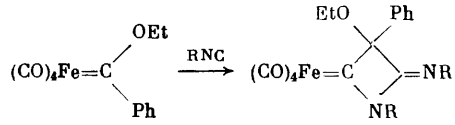
However, even in this case the formation of both complexes can be accounted for in terms of a four-membered metallacyclic intermediate:



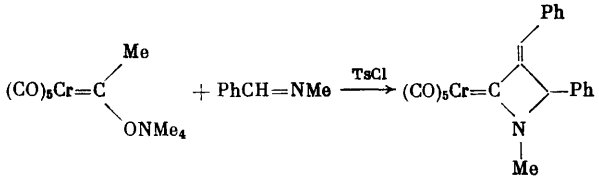
There have been instances reported where reactions of carbene complexes with isonitriles result in the formation of four-membered rings which remain within the coordination sphere of the metal atom by means of Cr–NC bonds with imine groups. These reactions occur as a [2 + 2] cyclisation of intermediate ketenimine complexes:[44,45]



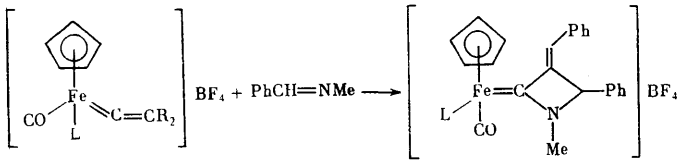
Interestingly, uncoordinated ketenimines dimerise differently, giving azetidines.[44] A similar type of cyclisation occurs[46] occurs in the reaction between chromium and tungsten ketinimine complexes and 1-diethylaminopropyne:



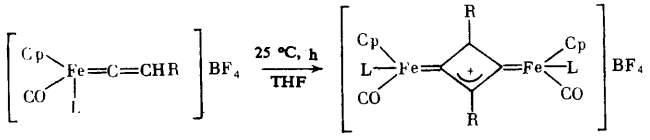
The formation of an azetine complex has been attributed[46] to the initial addition of alkyne to the N=C double bond of the coordinated imine, resulting in a zwitterionic dienamide derivative in which intramolecular addition of hydrogen from the methyl group to the carbocation site occurs with regeneration of an imine complex. The latter may undergo rotation about the C–N bond and a [2 + 2] cyclisation to an azetine [route (*a*); "normal" [2 + 2] cyclisation without rotation results in a complex with a lactam [route (*b*)]:



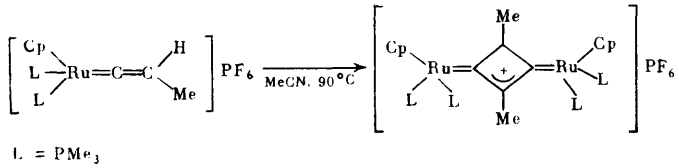
Intermediate ketenimine derivatives can react with excess isonitrile to form products of both [2 + 2] and [1 + 3] cycloaddition:[47]



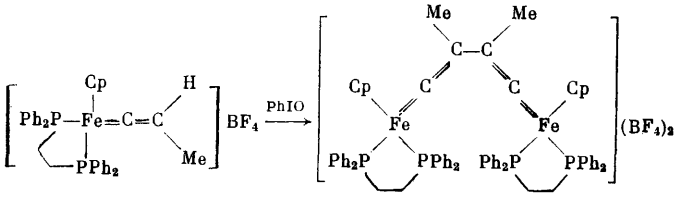
In the case of an iron complex only [1 + 3] cycloaddition occurs:[48]



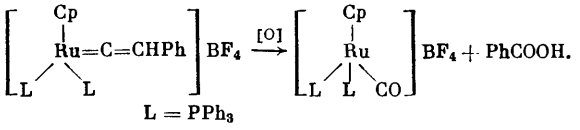
Schiff bases react with chromium[49] and iron[50] carbene complexes in a similar manner



In the case of the chromium derivative the reaction route depends on the solvent—in CH_2Cl_2 or t-BuOH only cyclisation occurs while in MeOH the linear product $(CO)_5Cr=C(OMe)CH=CHPh$ is also formed.[49] Cationic iron[51–53] and ruthenium[54] vinylidene complexes can undergo a [2 + 2] homocyclisation to give very interesting products.

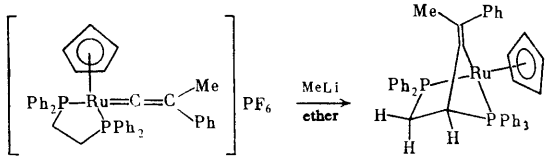


L = CO, PPh_3, $P(C_6H_{11})_3$;
R = H, Ph.



L = PMe_3

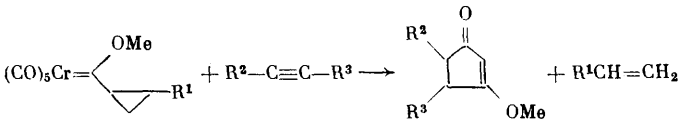
An iron vinylidene complex with a chelate diphosphine ligand also dimerises on treatment with iodosylbenzene, but forms a "linear" product:[55]



Under these conditions the ruthenium analogue doe not dimerise but its C=C bond is cleaved to form carbonyl derivatives and an acid:[56]

L = PPh_3

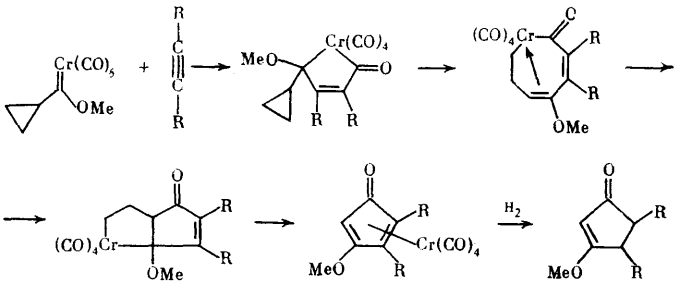
Ruthenium vinylidene complexes react with methyllithium quite differently:[57]



Protophilic attack on the α-CH_2 group of the diphosphine and intramolecular cyclisation with the formally carbocationic α-carbon atom of the vinylidene ligand occur.

In summarising the material presented in this section, it may be concluded that "pure" [1 + 3] cycloaddition reactions of the carbene ligand to form four-member π-ligands do not occur. There is a predominance of [2 + 2] cycloaddition processes to form metallacycles, cyclobutylidene complexes, and azacyclobutane derivatives bound to the metal atom by a coordination bond.

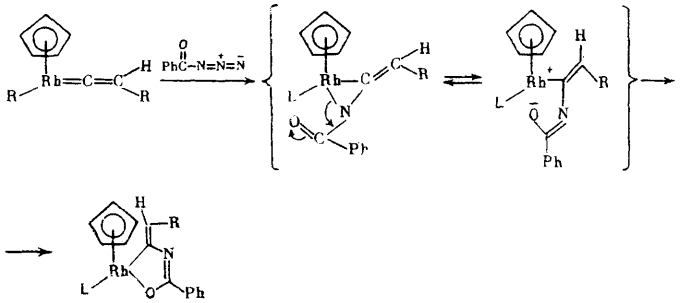
IV. Reactions that lead to the formation of five-membered rings



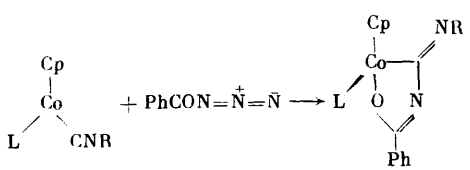
As the material of the previous section demonstrates, attempts to consider inner-sphere cyclisation reactions involving carbene complexes in terms of [*n* + *m*] cycloaddition processes are too formal, since in the majority of cases formation of the final products results from secondary reactions, a carbonyl ligand acting as the "supplier" of a further carbon atom to the ring may participate in ring formation. Strictly speaking, synchronism has not been demonstrated for a single reaction and the stereochemical result of the reactions is not always clear. In the present section an attempt will be made to classify the reactions according to the nature of the final products. Three types of reaction can be distinguished from the existing literature data: the formation of metallacycles, cyclopentylidene complexes, and five-membered rings that remain in the coordination sphere because of the *N*-donor groups present in them. Herndon et al.[58,59] have reported the formation of

cyclopentenes in the reaction between acetylenes and chromium (cyclopropyl)-(methoxy)carbene complexes:

R^1 = H, Ph; R^2 = H, Me, Pr, Ph; R^3 = Pr, Ph, C_5H_{11}.



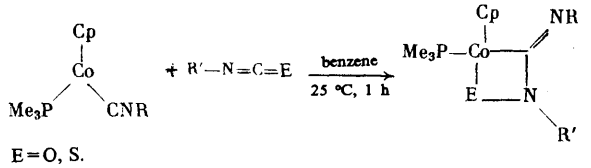
The following reaction scheme has been proposed:[58]



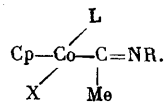
Because of this scheme, which includes intermediate five-membered metallacycles, the two studies of Herndon et al.[58,59] can formally be covered in the present section.

1. Formation of five-membered metallacycles

The reactions of rhodium and osmium vinylidene complexes with benzoyl azide gives metallaoxazoline derivatives,[60,61] these being accompanied by the elimination of nitrogen. It is possible that they take place as a [3 + 2] cycloaddition of the dipolar azide to the polar Ph=C group with initial formation of a five-membered metallacycle, which after elimination of nitrogen is converted to a three-membered metallacycle. The following reaction scheme has been proposed:[61]

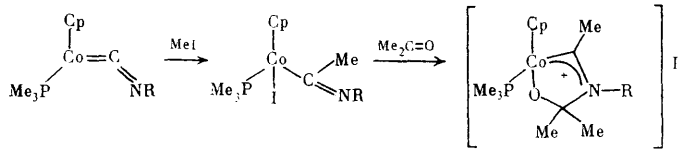


Similar cobaltaoxazoline derivatives are formed in the reaction between benzoyl azide and cobalt isonitrile complexes:[62]

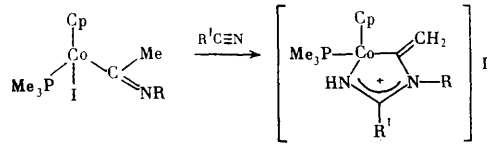


L = PMe_3; R = Ph, Me.

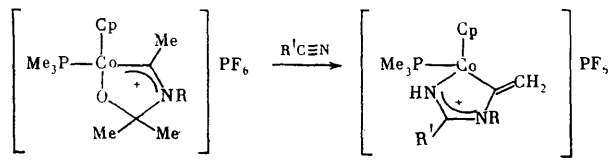
Interestingly, isocyanates and isothiocyanates react with cobalt isonitrile complexes to give four-membered metallacycles:[63]



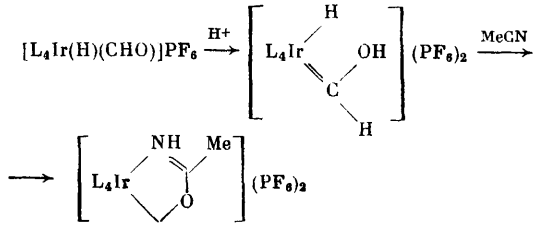
E = O, S.



A series of studies[64–67] is devoted to the [3 + 2] cycloaddition reactions of different substrates (carbonyl compounds,[64] nitriles,[65] isothiocyanates,[66] and carbon disulphide[67]) to imidoylcobalt complexes of the type

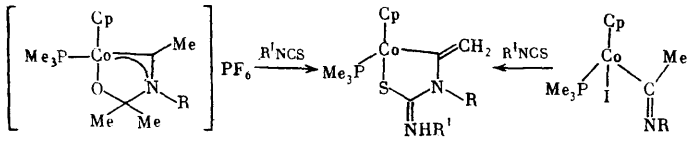


They are readily generated by addition of MeI to the corresponding isonitrile complexes;[64,65] in acetone solution[64] cyclisation to form cobaltaoxazoline occurs:[64]

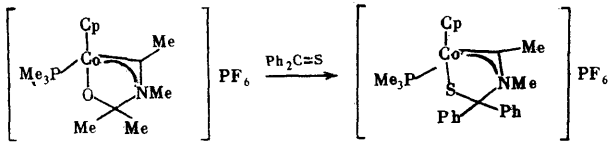


The reaction with aldehydes[64] and nitriles[65,68] occurs in a similar manner:

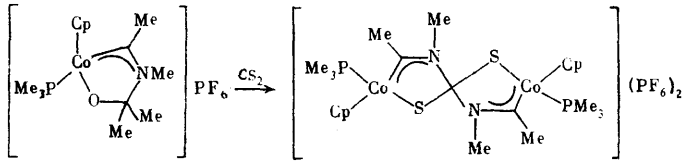
The same cobaltamidoazolines are formed when the cycloadducts with acetone are treated with nitrile:



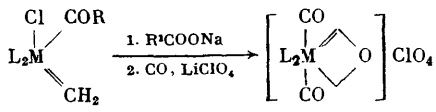
Interestingly, similar metallacycles have been obtained[69] by reaction of acetonitrile with an iridium hydroxycarbene complex:



L = PMe_3

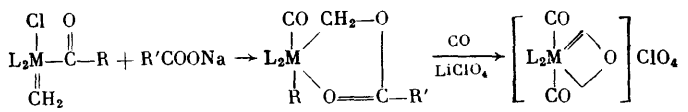


Isothiocyanates react[66] with imidoylcobalt complexes or with their acetone adducts to form cobaltathiazoline derivatives:

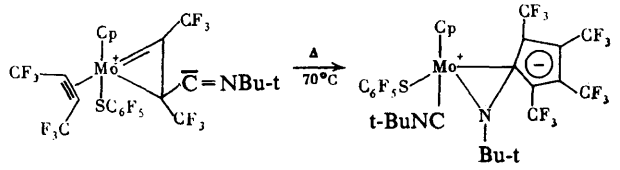


Diphenyl thioketone also displaces acetone from its adduct, giving a new heterocycle:[67]

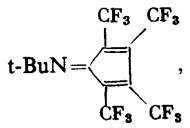
Under these conditions carbon disulphide forms a spirocyclic complex:[67]



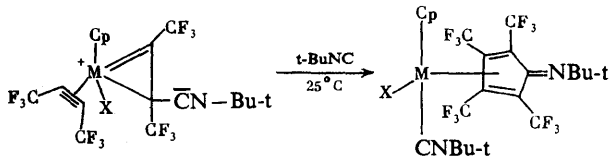
The complexes obtained by Werner et al.[64–67] contain a metallacycle with a multiple carbon–metal bond. Formally they are products of addition to the M=C bond in pseudocarbene complexes. Bohle et al.[70] have reported an example of intramolecular combination of a carbene ligand with an acyl residue:



M = Ru, Os; L = PPh_3; R = Ph, $MeOC_6H_4$.

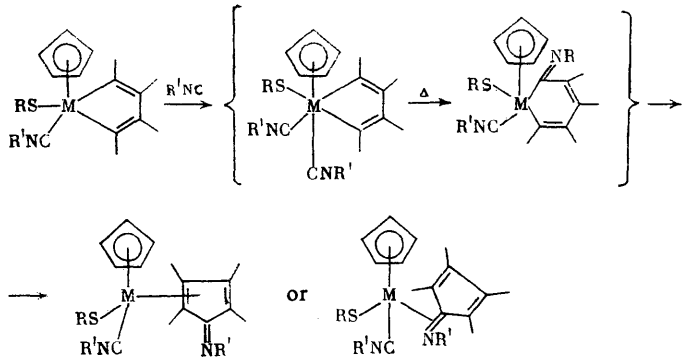


These authors assume that initially a five-membered metallacycle is formed through the addition of R'COONa to the $M=CH_2$ bond:



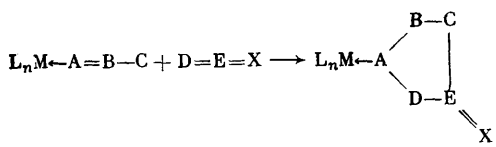
The preparation of a quite unusual cyclopentadienyl anion has been reported:[71]

On heating the cyclic carbene complex in a sealed ampoule, the sole product isolated is a complex containing the iminocyclopentadiene ligand

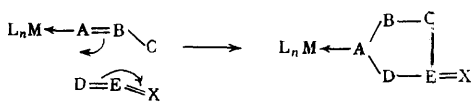


which does not have η^4-type coordination as occurs for the complexes reported by Carlton and Davidson[72]

M = Mo, W; X = CF_3, Cl.



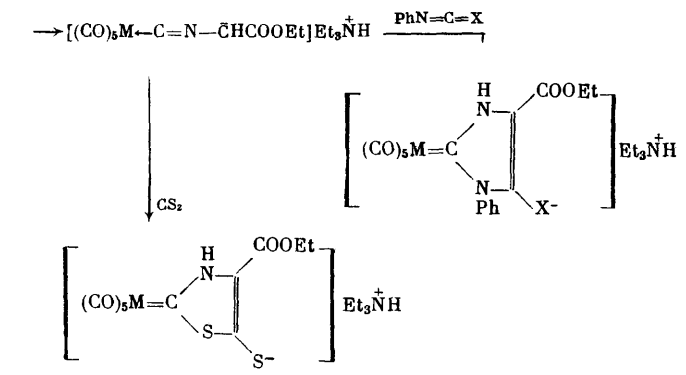
but has η^2-coordination via the imine bond. The preference for a given form of coordination in an iminocyclopentadiene is dictated by thermodynamic and kinetic factors. It is possible that the η^2-bonded isomer is generated from an initially formed η^4-complex.[71]



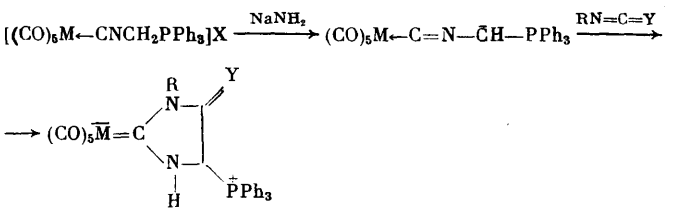
It is thought[71,73] that both isomers are derived from the same metallacyclopentadiene precursor.

2. Formation of cyclopentylidene complexes

In the present subsection we shall consider reactions of the following type:

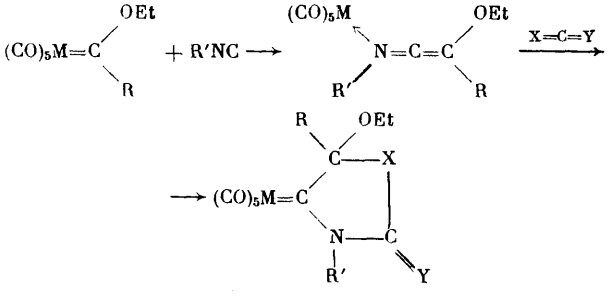


This is, in effect, a [3 + 2] cycloaddition:



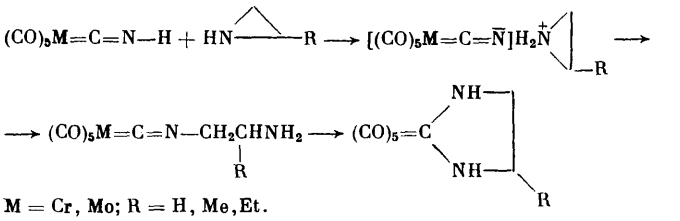
Whether these reactions are concerted or occur in stages is a question which most frequently remains outside the scope of investigation, but the authors of all the studies cited below adhere to the terminology of [*m* + *n*] processes. A necessary condition for

such reactions to occur is the presence in the initial complex of a multiple A=B bond. It is also desirable that the A=B–C residue should have a 1,3-dipole nature. This is achieved in various ways. For example, in the reaction of isocyanates, isothiocyanates,[74] and carbon disulphide[75] with chromium or tungsten ethoxycarbonylmethylisocyano derivatives, a base (Et_3N, t-BuOK) is used as a catalyst, removing a proton from the methylene group, as a result of which a 1,3-dipolar intermediate is formed. The latter undergoes cyclisation:



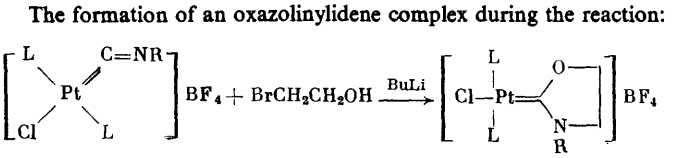
X = O, S.

In the case of complexes with triphenylphosphoranylmethylisonitrile deprotonation occurs on treatment with sodamide.[76,77] The resulting isocyanomethylenephosphoranes undergo a [3 + 2] cycloaddition reaction with isocyanates, isothiocyanates, carbon disulphide, nitriles, olefins, and acetylenes:



M = Cr, W; R = Ph, Me; X = Cl, PF_6; Y = O, S.

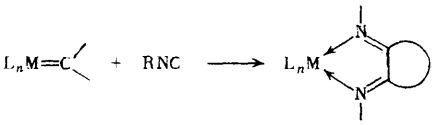
The reactions are similar[78,79] for metal ketenimine complexes (mention has been made of ketenimine complexes in Section III), which are formed by treatment of carbene derivatives with isonitriles:[78–80]



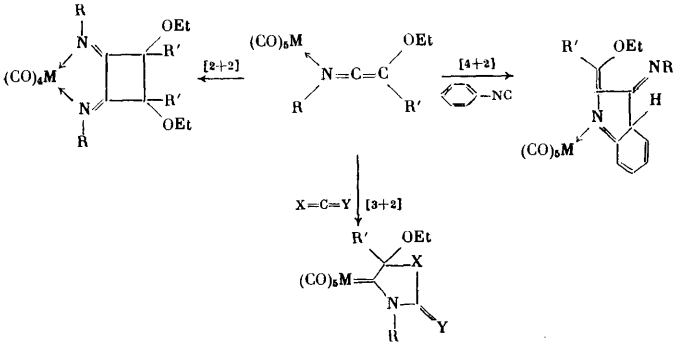
M = Cr, Mo; R = Ph, C_6H_{11}, $C_6H_3Me_2$-2,6;
R' = Ph, 2-thienyl;
X = O, NPh, NMe;
Y = O, NBu-t, NC_6H_{11}.

Isonitrilic acid complexes react with aziridines to form cyclic diaminocarbene derivatives.[81] In this case the aziridine acts both as a base and as part of the ring being formed:

M = Cr, Mo; R = H, Me, Et.

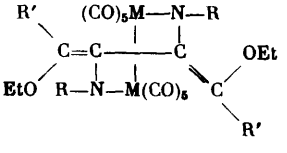


The formation of an oxazolinylidene complex during the reaction:

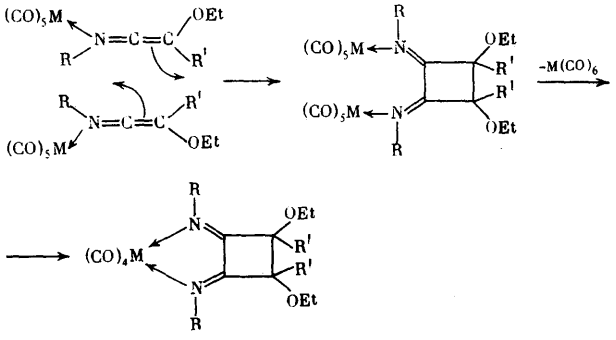


can be interpreted as attack by the dianion $^-CH_2CH_2O^-$ on the suitably polarised C=N bond of the isonitrile ligand.[82]

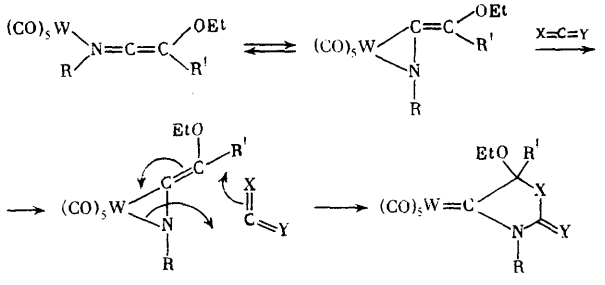
3. Formation of five-membered rings coordinated with *N*-donor groups



In this subsection we shall summarise reactions of the following type:

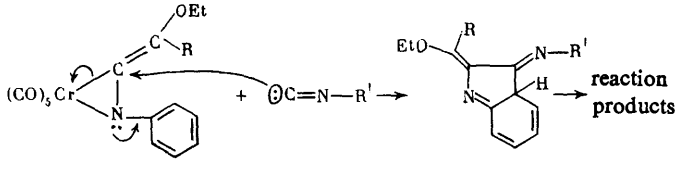


All of these reactions take place with the formation of intermediate ketenimine complexes $L_uM{\leftarrow}N(R){=}C{=}C\lessdot$ (see Section III), which have been isolated in a number of cases.[83–85] According to the data of Aumann et al.,[44,45,79] the ketenimine residues can undergo [2 + 2], [2 + 3], and [2 + 4] cycloaddition:

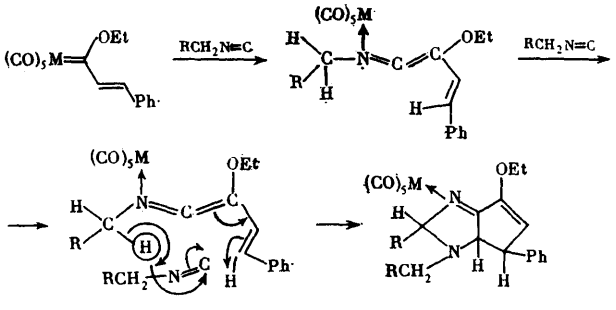


The [2 + 2] cycloaddition takes place via an intermediate of the type:

which is formed by treatment of the initial ketenimine complexes with isonitrile. The occurrence of a concerted process should also not be excluded:

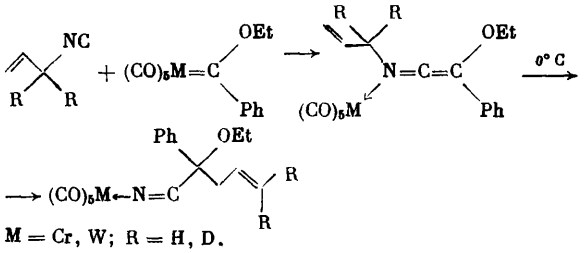


In order to account for the [3 + 2] reaction, the concept of an equilibrium between *N*- and π-coordinated ketenimine complexes (see Section III) has been adopted;[79] the π-imine derivative then undergoes a normal [3 + 2] cycloaddition:

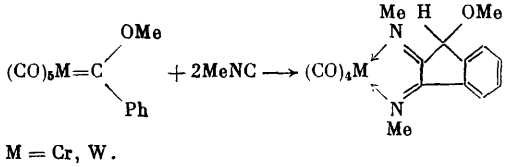


The choice between [2 + 2] and [3 + 2] processes is governed by steric factors—as steric hindrance increases the [3 + 2] cycloaddition predominates.

The interpretation of the [4 + 2] reactions is somewhat more complex.[79] The participation of a π-ketenimine intermediate and the C=C bond of the aromatic ring has been suggested:

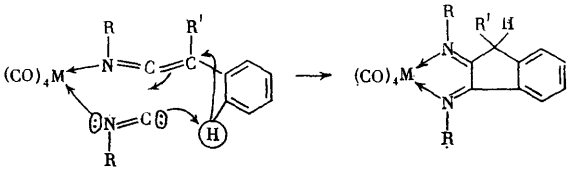


The formation of five-membered rings in two studies by Aumann et al.[83,85] is accounted for in terms of a [4 + 1] cycloaddition involving four double bonds and a single α-C–H bond of the isonitrile ligand:



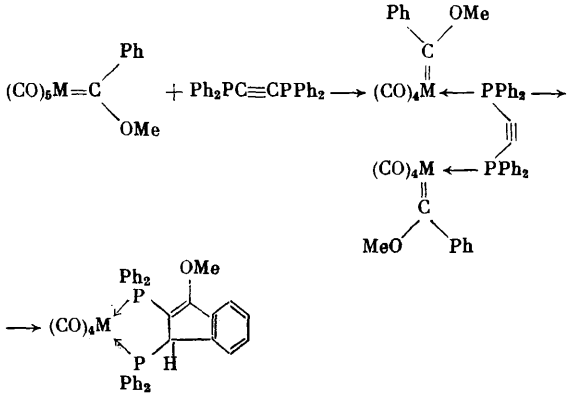
M = Cr, W ; R = H, Ph, CH_2=CH.

Allylisonitriles react with carbene complexes that do not contain a multiple bond in the carbene ligand without forming cyclic products. At low temperatures the intermediate ketenimine complexes rearrange to but-4-enylisonitrile complexes:[84]



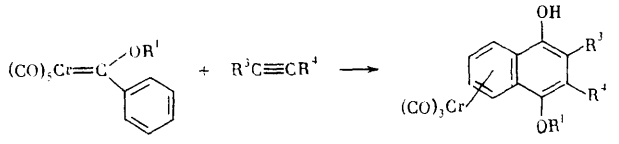
M = Cr, W; R = H, D.

In some cases the intermediate ketenimine adduct is not isolated:[86]



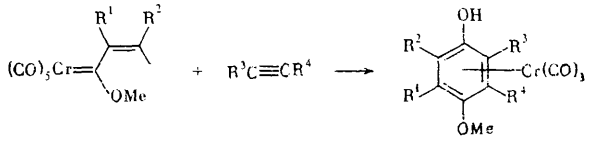
M = Cr, W.

In this case α- and *ipso*-carbon atoms of the aryl group of the carbene ligand participate in reaction. It is quite clear that this reaction is not synchronous. At the first stage a ketenimine intermediate is formed which adds a second isonitrile molecule, while the hydrogen on the α-carbon atom undergoes a 1,3-shift



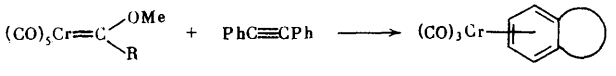
The formation of a chromium phosphine complex as described by Dötz et al.[97] is likely to occur in a similar manner:

Thus, despite the formalism of the concept of [*n* + *m*] cycloaddition (see beginning of Section IV) the attempt to classify the reactions according to the final products has essentially led to the same concept. It is clear from the material in this section that the formation of five-membered rings involving carbene complexes can result from [4 + 1], [3 + 2], and [2 + 2] reactions. In the latter case metallacycles are formed because of the participation of the metal atom.



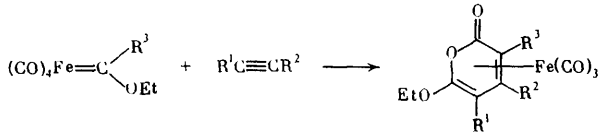
V. Reactions that lead to the formation of six-membered rings

There exists a considerable number of studies (see several reviews)[1-5,88] in which is described the formation of chromium arene complexes by reaction of alkynes with pentacarbonylchromium carbene derivatives containing an aryl substituent on the carbene carbon atom:



It is quite clear that the α-carbon atom of the phenyl group of the carbene ligand and one of the carbonyl groups bound to chromium participate in the reaction.

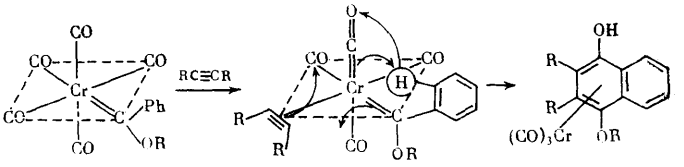
Another type of reaction that leads to arene complexes is characterised by the presence of a vinyl group on the carbene carbon atom:



It is possible that this is a special case of the process shown above, since methoxyallylidene complexes can be formed by the reaction of alkynes with carbene complexes.

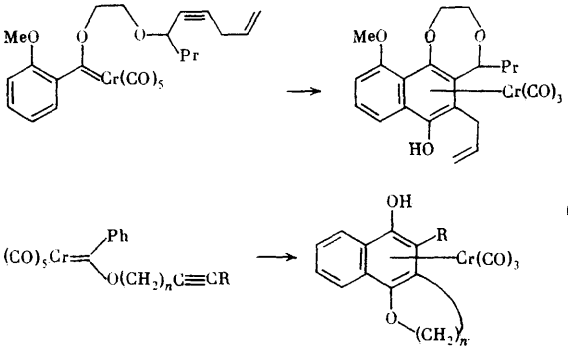
The synthesis of arene complexes from carbene derivatives with a five-membered ring on the carbene carbon atom has also been reported:

R = ferrocenyl, cycloalkenyl, pyrrolidinyl, furyl, thienyl, pyrrolyl.



It is likely that in this case the formation of arene complexes is a secondary process. And finally, there is a small group of reactions leading to the formation of α-pyrone complexes:

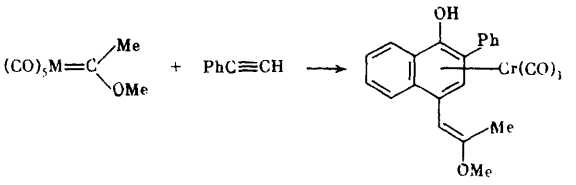
These reactions take place in the presence of CO.



1. Formation of arene complexes from α-alkoxybenzylidene derivatives

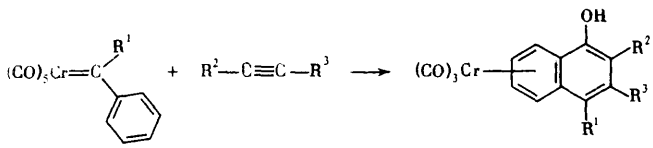
In order for the formation of arene complexes from metal α-alkoxybenzylidene derivatives to occur successfully it is necessary for three components—alkyne, carbene, and carbonyl—to coordinate with the metal site at the same time. In order to coordinate the alkyne it is necessary to displace one carbonyl ligand from the coordination sphere. According to the data of two studies,[89,90] the CO ligand that is situated *cis* to the carbene ligand in chromium pentacarbonyl carbene complexes is the most readily replaced. As a result a *fac*-(alkyne)(carbene)carbonyl intermediate is formed, and the subsequent reaction may be regarded as a [3 + 2 + 1] cycloaddition:[2]

Under kinetically controlled conditions (low temperatures, short reaction time) a complex is obtained in which the metal is bound to the newly formed ring (1-8*a*-η^6-coordination). At higher temperatures and long reaction times the $Cr(CO)_3$ group migrates to the free ring, and the naphthalene ligand has 4*a*-8*a*-η^6-coordination in the complexes isolated. The literature data on the synthesis of chromium arene complexes starting from alkynes and α-alkoxybenzylidenepentacarbonylchromium are summarised in Table 1.



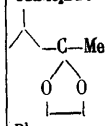
An intramolecular form of the reaction is possible when all three components—alkyne, carbene, and carbonyl—are present in the same molecule:[101,102]

n = 2 ÷ 4; R = H, Me



These reactions represent key stages in the synthesis of anthracyclinone antibiotics (desoxyfrenolicin, daunomycinone).[2] The regioselective reaction in the case of the *ortho* substituent in the benzene ring attacts attention. Two studies[103,104] have been devoted to this phenomenon.

In a number of cases[105,106] chromium tricarbonyl complexes of α-naphthols are formed in reactions with chromium carbene derivatives in which there is no aryl substituent on the carbene carbon atom:



It is quite clear that a phenyl group of phenylacetylene participates in the formation of the naphthalene skeleton. It is thought[105] that in contrast to the [3 + 2 + 1] mechanism (see beginning of

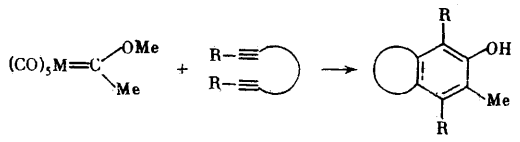
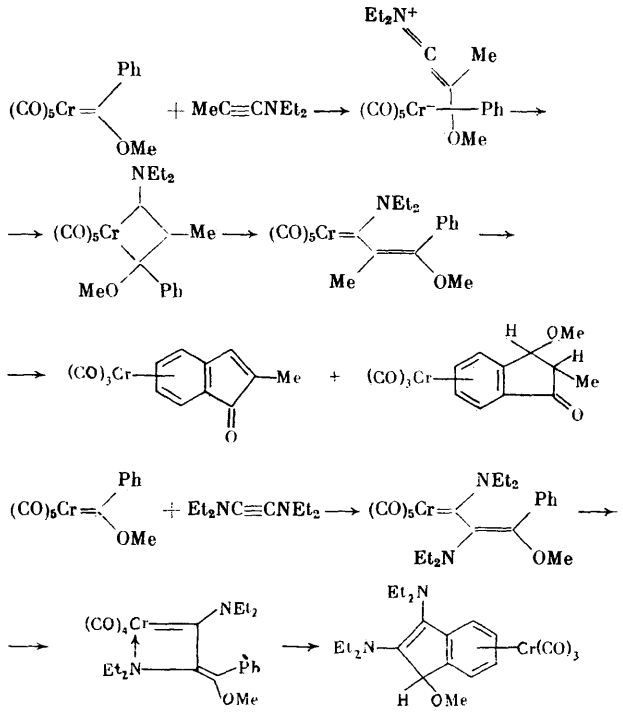
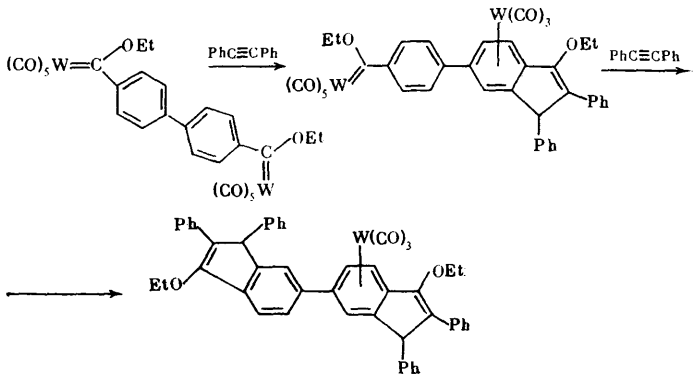
Section V.1), in this case a [2 + 2 + 2] cycloaddition involving two alkyne molecules occurs:



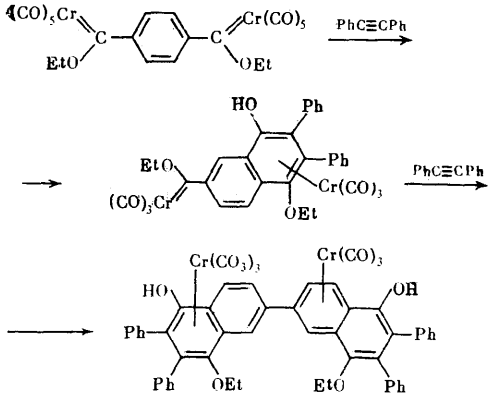
When R = alkyl, cyclohexadienone complexes rather than naphthalene complexes are formed, which is attributed[105] to the presence of two isomers in the hexa-2,4-dienylidene intermediate:



R = Me, Pr.

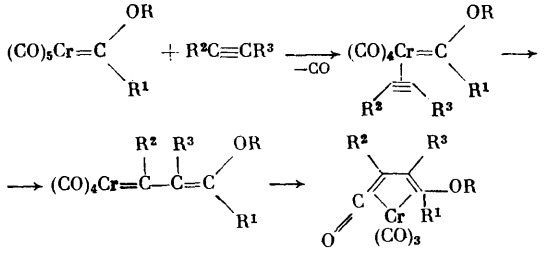


Annelation reactions involving two alkynyl residues can be carried out in an intramolecular form:[106]

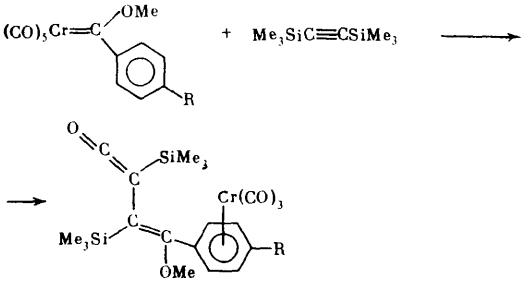


Derivatives of indene and naphthalene are obtained in this manner.[107] According to Dötz,[2] the formation of compounds with an indene skeleton occurs by insertion of alkyne into the metal–carbene bond, possibly via a four-membered metallacyclic intermediate. Nucleophilic alkynes as a rule participate in such reactions:[108–110]

However, the formation of indenes is also possible in reactions with normal alkynes such as diphenylacetylene.[92,111] An interesting reaction has been reported by Hoa and Lefloch.[112]



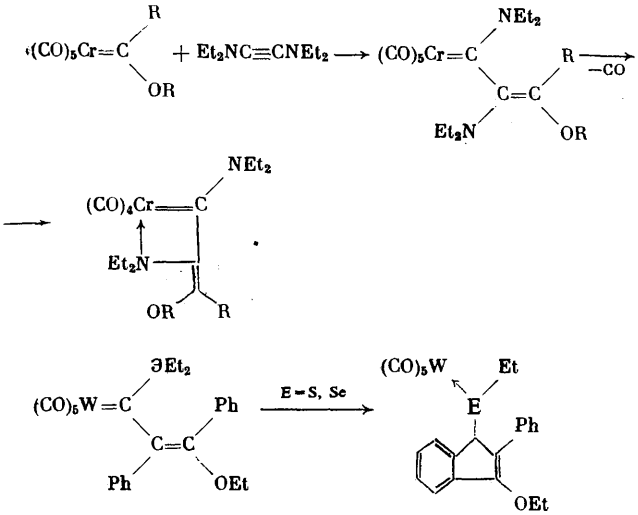
In the case of the chromium analogue a chromium naphthalene complex is formed:[122]



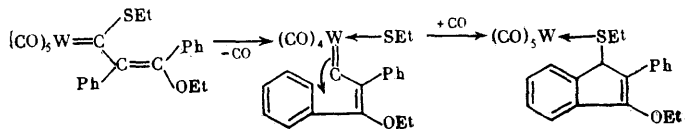
In contrast to tungsten the μ-η^6:η^6-derivative was isolated.

2. Formation of arene complexes from α-alkoxyallylidene derivatives

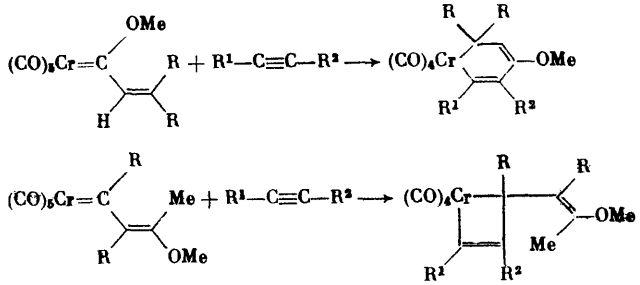
As was indicated above, α-alkoxyallylidene intermediates can be formed by reaction of alkynes with transition metal carbene complexes. In some instances[97,105] this is only postulated, but in a number of cases, especially for nucleophilic alkynes,[113–118] these intermediates have been isolated. They can participate in subsequent reactions. One of these is the insertion of a carbonyl ligand into the metal–carbene bond to form ketene derivatives:[97,117,119]



In fact, in a number of cases[97] such ketenes have been isolated, for example

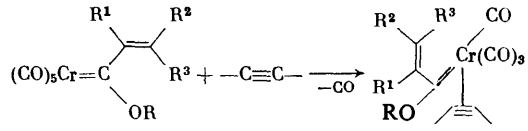


R = H, Me, OMe, CF_3.

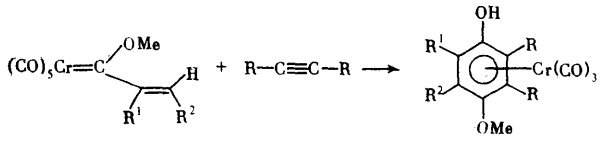


Another reaction is intramolecular cyclisation through coordination of the metal atom with *N*-donor groups present in the alkyne molecule:[110,120]

The latter reaction appears to be unusual. It can be given by a scheme, one of the stages of which is formation of a three-membered metallacyclic intermediate. This metallacycle subsequently decomposes through cleavage of the metal–carbon double bond of the carbene ligand, with a five-membered ring being formed:



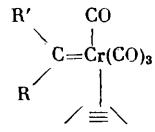
The formation of "true" metallacycles with metal–carbon σ-bonds is also possible:[105,121]



Interestingly, whatever the size of the ring in the resulting intermediate, in the latter two cases the same final product—2-methoxy-2-methyl-3,4,5,6-tetrasubstituted cyclohexa-3,5-dienone—was isolated, although Tang and Wulff[121] in the case of the six-membered metallacyclic intermediate expected to obtain a 3-methoxycyclopentadiene—a product derived from the β-elimination of $HCr(CO)_5$. However, Herndon et al.[122] on reacting pentacarbonyl[(methoxy)(cyclopropyl)carbene]chromium with diphenylacetylene isolated 4,5-diphenylcyclopent-3-enone—the expected reaction product.

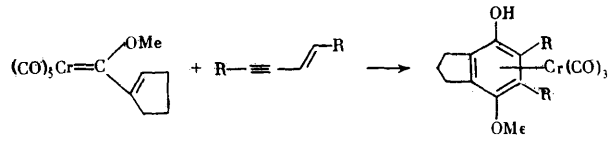
Thus, all reactions of α-substituted allylidene complexes with alkynes can be represented[2] by the formation of an (alkyne)(carbene)carbonyl intermediate:

This is essentially the same intermediate as that depicted at the beginning of Section V.1, and its subsequent fate depends on the nature of substituents R^1, R^2, and R^3. When R^3 = H, arene complexes are formed:[123–126]



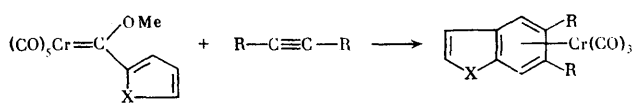
R^1 = Me, H; R^2 = H, Me, Ph; R^1, R^2 = $-(CH_2)_n-$, where n = 3, 4.

Terminal acetylenes react regioselectively, the substituent going into the *ortho* position relative to the OH group.[125]



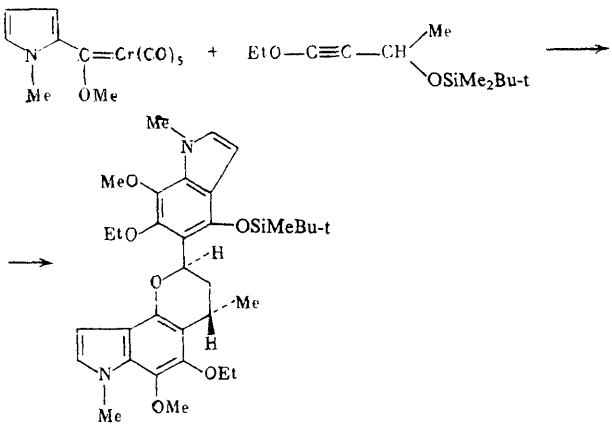
3. Formation of arene complexes from carbene complexes with a five-membered ring on the carbene carbon atom

The five-membered ring on the carbene carbon atom in carbene complexes can be a heterocycle,[117,127–132] alicycle,[125,127] or cyclopentadienyl ring of a ferrocenyl residue.[133] In all cases the results (alkyne)(carbene)carbonyl intermediate (see Section V.1) takes the following form:

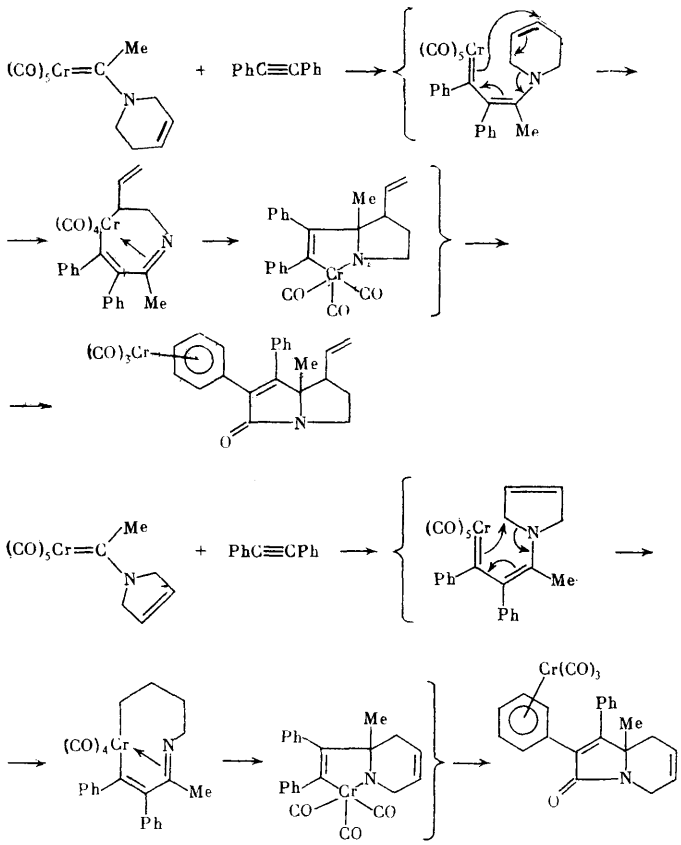


R′ = five-membered ring.

The fate of this intermediate is known[125,127] when R′ is an alicyclic group—η^6-indane derivatives are formed. It is interesting that in the reaction

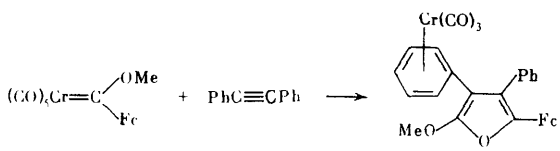


the C=C double bond of the ring rather than that of vinylacetylene is involved in the cycloaddition process.[125] When R′ - α-pyrrolyl,[129] α-furyl,[127,132] and α-thienyl[127] annelation also occurs in a normal manner—the corresponding benzo derivatives of the heterocycles are formed:



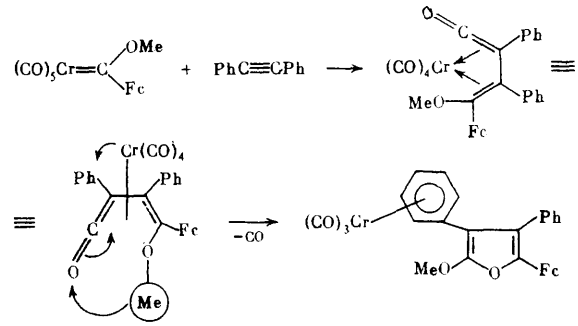
X=O, S, NMe; R = H, Me, Et, EtO, COOMe, Bu, Ph.

However, there are exceptions. For example, the reaction of a chromium α-pyrrolylcarbene derivative with 1-ethoxy-3-[dimethyl-



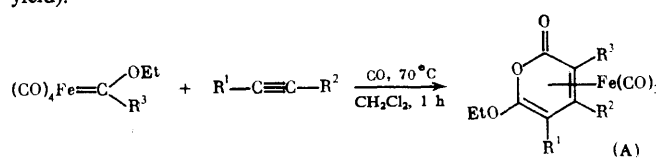
(t-butyl)siloxy]but-2-yne yields its dimer rather than the expected indole:[128]

Annelation can also occur through a more remote double bond:[130,131]



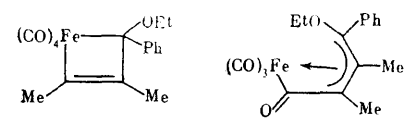
In the case of an α-ferrocenylcarbene complex a furan derivative is formed:[133]

Fc = C_5H_4FeCp.



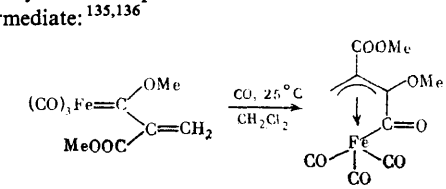
It is possible that the reaction occurs via a ketene intermediate:

The structure of the resulting ferrocene-benzenechromium tricarbonyl derivative has been established by X-ray diffraction analysis.[133]



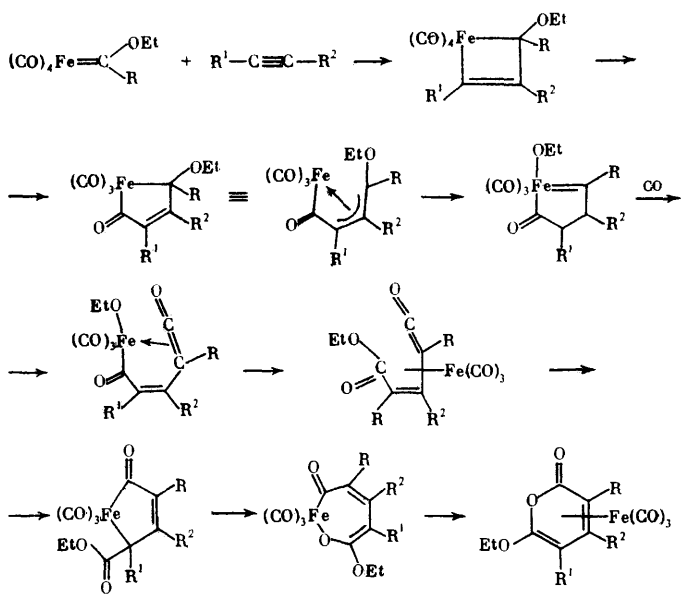
4. Formation of iron α-pyrone complexes

The reaction of iron alkylidene compounds with various alkynes under pressure in an atmosphere of carbon monoxide leads to the formation of complexes of iron with an α-pyrone ligand (in high yield):[134]



R^1	R^2	R^3	Yield (A), %
Me	Me	Ph	89
Ph	H	Ph	74
Et	H	Ph	33
Ph	Ph	Ph	93
COOMe	Me	Ph	15
Me	Me	t-Bu	60
Ph	H	t-Bu	39
Me	Me	Bu	33

The structure of the complexes obtained (A) has been established by X-ray diffraction analysis. The formation of the α-pyrone skeleton requires the participation of two carbonyl ligands. Moreover, migration of the ethoxyl group from the carbene carbon atom occurs during reaction. When the reaction was carried out in the absence of carbon monoxide, an unstable product was isolated, for which two alternative structures—metallacyclic and π-allylacyl—were proposed on the basis of the ^1H NMR and IR spectra:



The fact that a π-allylacyl complex is formed when carbon monoxide reacts with a (1-methoxy-2-methoxycarbonylprop-2-enylidene)tricarbonyliron compound is evidence in favour of the second intermediate:[135,136]

However, Semmelhack et al.[134] favour a metallacyclic intermediate, since in the ^{13}C NMR spectrum of the isolated complex there is no signal due to an acyl carbon atom. They

proposed the following scheme for formation of α-pyrone complexes:[134]

This scheme includes the two alternative intermediates. The formation of intermediate ketene complexes is also known,[97] so this sequence of reactions reflects the process mechanism sufficiently objectively.

---o0o---

Thus, the "carbene site" in transition metal complexes represents a unique matrix on which the most varied cyclic ligands can be built up as a result of an inner-sphere reaction. These processes are treated as [*n* + *m*] cycloaddition reactions, although they are not such types and occur in an unconcerted manner, including stages that are typical of the chemistry of π-complexes such as the initial coordination of substrate, insertion of ligands, elimination, etc. These ring-formation processes in the inner coordination sphere involving carbene complexes are of interest to organic chemists since they act as convenient models for an understanding of the reaction mechanisms of organic compounds in the presence of transition metal complexes.

Electron phototransfer in the initiation of polymerisation

M N Usacheva, I I Dilung
Pisarzhevskii Institute of Physical Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. The results of studies on the participation of exciplexes and other products of electron phototransfer in the initiation of polymerisation are correlated in this review. The relationship between the nature of the primary radical species and the mechanism of formation of a polymerisation chain is discussed. Particular attention is given to the effect of the electronic structure of the photoinitiator, the chemical nature of the activator and monomer, and the polarity of the medium on the mechanism of photoinitiation and its efficiency.

The bibliography includes 165 references.

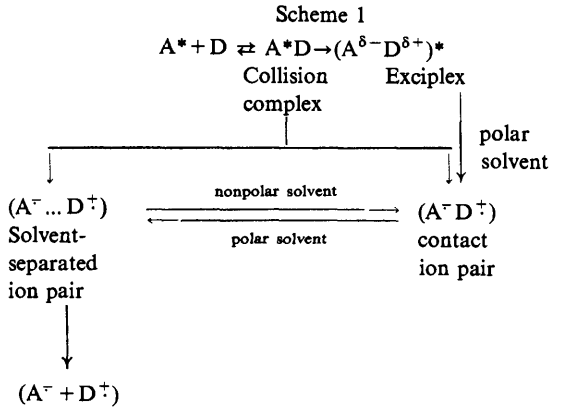
IV.	Conclusion	118

I. Introduction

Photopolymerisation processes have been widely applied in current practical methods.[1–4] They are carried out with the participation of active products that are generated in various photochemical reactions. These can be products of unimolecular photodissociation[5–9] or products of bimolecular reactions involving electron or hydrogen atom transfer.[10–19] Recently a large number of reports have been published on the participation in polymerisation photoinitiation processes of different intermediates of electron phototransfer, principally exciplexes,[20–26] which help to increase the efficiency of the process.

The role of photoinitiators in polymerisation processes is very important. They determine the region of spectroscopic sensitivity of the polymerising compositions,[2,25] and the kinetics and mechanism of not only the initiation process but also that of the overall polymerisation reaction.[20–29] To a certain extent they influence the physicochemical and mechanism properties of the polymer materials obtained.[2,28] Meanwhile the question of the mechanism of photoinitiation with the most effective binary systems that are susceptible to electron phototransfer has received virtually no study.

This review attempts to correlate the existing literature data on the participation of exciplexes and other electron phototransfer products in the initiation of polymerisation in order to establish the scientific principles for the choice of initiating systems that can achieve effective polymerisation over a wide spectroscopic range.

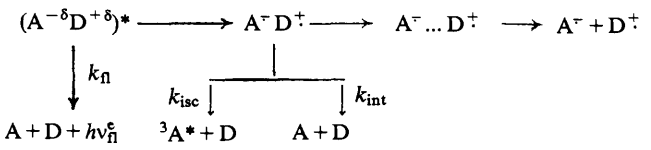


We shall consider the main questions relating to the phenomenon of electron phototransfer.

II. Main mechanisms of electron phototransfer

1. Classification of the intermediates of electron phototransfer

The formation of exciplexes and their photophysics have formed the subject of a number of reviews.[30–35] An exciplex is an excited molecular complex of a given stoichiometric composition which is stabilised in an excited state and unstable in its ground state.[31] It has a specific geometry that is characterised by a bond energy of the order of 5–200 kcal mol^{-1}, a significant dipole moment which is to a certain extent a measure of the charge transfer,[36] and a lifetime that is sufficient for emission of fluorescence or phosphorescence (depending on its multiplicity). An exciplex is one of the intermediates formed during electron phototransfer (EPT). According to the ideas put forward in one of the most recent reviews,[35] the scheme for electron transfer (ET) can be depicted as follows:



Scheme 1

In this case all the intermediate products are classified according to lifetime, distance between the partners, and number of solvent molecules inserted between them. The lifetime of the collision complex (of the order of 10^{-9}–10^{-10} s) is sufficient for "quenching" of the excited state of the photoactive component by an ET mechanism to occur.[35–37] In this case the collision complex is initially converted to a contact ion pair going via or avoiding the formation of an exciplex, depending on the conditions. It follows from Scheme 1 that the solvent, depending on its polarity, can stabilise contact or solvent-separated ion pairs, combined under the general title of geminate ion pairs. Solvent-separated radical ions that are situated at considerable distances from each other in solution are known as free solvated radical ions. They are completely independent of their partner and in a similar manner to free radicals can exist as independent species for a relatively long period.

If a strong interaction occurs between A* and D in the collision complex, it is converted to an exciplex. When stabilisation of the exciplex is determined to a considerable extent by a charge-transfer interaction, with an increase in polarity of the medium all the electron transfer processes described above can also occur via an exciplex in accordance with Schemes 1 and 2. Deactivation of an exciplex occurs through radiationless processes of internal conversion and intersystem crossing as well as through fluorescence (if a singlet exciplex is involved).[22]

Scheme 2

Fluorescence occurs when there is a transition from the equilibrium state of the exciplex to the dissociative ground state in accordance with the Franck–Condon principle. If the intramolecular transitions are accompanied by a considerable nuclear rearrangement of the components, emission is absent, namely, the exciplex does not fluoresce and its properties are similar to those of a contact ion pair.[35]

Triplet exciplexes exist in addition to singlet exciplexes, and these have been discussed in detail in reivews.[31,38,39] They are formed either through the interaction of a triplet-excited molecule with an electron donor or acceptor[40] or through the intersystem crossing of a singlet exciplex or weak charge-transfer complex occurring in the ground state.[39,41]

The wave function of the exciplex, whatever its multiplicity, can be represented as a combination of wave functions of states with the excitation localised on one of the components of the complex and a state with complete charge transfer:[42]

$$\psi_{ex} = c_1\psi(D^*A) + c_2\psi(DA^*) + c_3\psi(D^+A^-), \quad (1)$$

where c_1, c_2, and c_3 are coefficients denoting the contribution of each of the states of Ψ_{ex}.

If $c_3 \gg c_2$ and $c_3 \gg c_1$, the contribution of charge-transfer states to the stabilisation energy of the exciplex is very large.

The EP scheme involving a singlet exciplex considered above can be applied equally to a triplet exciplex with the distinction that in the latter case a triplet radical ion pair is formed instead of a singlet solvent-separated radical ion pair.

Singlet fluorescing exciplexes are readily identified from the appearance of a structureless emission band which is shifted to longer wavelength in the spectrum relative to the fluorescence band of the uncomplexed photoactive component. Similarly, formation of triplet exciplexes can be monitored (in extremely rare cases in the condensed state because of the very low quantum yields, it is true) from the formation of a structureless fluorescence band, which is shifted to the "red" region relative to phosphorescence from the initial molecule.[43]

Fast kinetic methods can now be used to study singlet and triplet exciplexes, making it possible to record short-lived intermediates with a lifetime of the order of 10^{-11} s or more and to follow the kinetics of their deactivation.[44–46]

2. Thermodynamic and kinetic aspects of electron phototransfer

Electron phototransfer takes place whenever the changes in free energy of the processes $\Delta G_{ET} \ll 0$. Whatever the pathway of electron transfer, the expression for ΔG_{ET} has the following form:[35]

$$\Delta G_{ET} = E_{D^+/D} - E_{A/A^-} - e^2/\varepsilon R - E_{00}, \quad (2)$$

where $E_{D^+/D}$ and E_{A/A^-} are the values of the half-wave potentials of polarographic oxidation of the donor and polarographic reduction of the acceptor, $e^2/\varepsilon R$ is the Coulombic interaction energy between components A and D, ε is the dielectric constant of the solvent, R is the distance between the centres of molecules A and D, E_{00} is the energy of the excited state of molecule A.

Expression (2) does not take into account the structural changes which occur in electron donor-acceptor (EDA) systems during electron phototransfer. However, in a number of cases it is these which determine the probability of electron transfer. In the theory of Marcus,[47–50] which describes a mechanism for outer-sphere electron transfer, the effect of configurational changes, including changes in bond angles and bond lengths of the reactants, their steric configuration and the reorientation of the solvent molecules around them, in the initial and final states is examined. According to this theory the expression for the rate constant of the electron transfer has the following form:[50]

$$k_{ET} = Zk\exp(-\Delta G^{\neq}/RT), \quad (3)$$

where Z is the number of collisions, equal to 10^{11} litre mol^{-1} s^{-1}, k is a constant that depends on the magnitude of the electronic reaction barrier, and $\Delta G^{\neq}$ is the free energy of activation, including the contribution of the nuclear reaction barrier.

The electronic reaction barrier depends on the degree of overlap of the filled orbital of donor with the vacant unoccupied orbital of acceptor, their symmetry and relative steric configuration.

The nuclear reaction barrier is taken to mean the energy needed to change the bond angles and bond lengths and to change the molecular orientation resulting from both intramolecular factors and solvation effects during electron transfer.

The expression for the free energy of activation of electron transfer for neutral organic molecules has the form

$$\Delta G^{\neq} = (\lambda/4)(1 + \Delta G_{ET}/\lambda)^2, \quad (4)$$

where λ is the internal reaction barrier. It is equal to

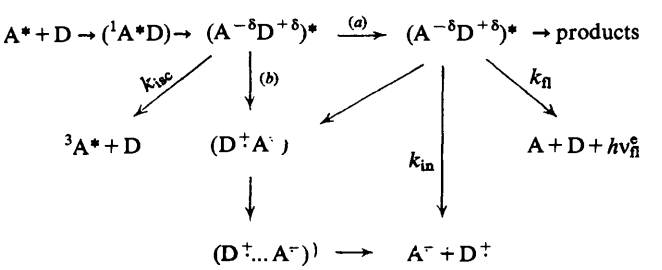
$$\lambda = \lambda_i + \lambda^0, \quad (5)$$

where λ_i is a component that takes into account the energy expended on the change in bond lengths and λ_0 is a component that takes into account the energy expended on the reorientation of solvent molecules.[47,48]

Eqn. (4) gives the parabolic dependence of $\Delta G^{\neq}$ on ΔG_{ET}. The region of highly exothermic values of ΔG, where the free energy of activation starts to increase and the rate constant of electron transfer correspondingly decreases is known in the literature as the "inverted" region.[49]

The efficiency of EPT is determined to a considerable extent by the lifetime of the excited state of the photoactive component. It must be sufficiently long for EPT to occur in preference to the other deactivation processes competing with it. The probability of the latter depends on the photophysical properties of the excited

molecules (electron configuration and multiplicity of the excited state of the photoactive molecules) and their photochemical activity.



Electron transfer that involves an exciplex is the most rapid process, since in this case the maximum possible overlap of the orbitals of the electron donor and acceptor occurs.[35] Obvious examples of this are provided by exciplexes of the "sandwich" $\pi\pi$-type, formed between polynuclear aromatic amines, where favourable conditions for effective electronic interaction are created because of the similar symmetry of the overlapping orbitals.[51]

Together with this during electron transfer many systems involving an exciplex exhibit hindrances which increase the height of both the nuclear and electronic reaction barriers. In this case there are differences between the non-equilibrium Franck–Condon state $(A^{-\delta}D^{+\delta})^*$ and the equilibrium state of the exciplex $(A^{-\delta}D^{+\delta})^*$.[38,52,53] The first of these has a new electronic configuration as a result of charge transfer, distinct from the electronic configuration of the ground state and a nuclear configuration which corresponds to the electronic configuration of the initial state. In the non-equilibrium state the structure of the exciplex is flexible. During relaxation, which is accompanied by changes in bond lengths and bond angles in the molecules making up the complex and a reorientation of solvent molecules around them, the system changes to an equilibrium state from which the exciplex emits (if the probability of the radiative transition is sufficiently high). In such systems a significant Stokes shift of the fluorescence of the complex due to the molecular rearrangements which occur in them has been recorded.[54]

Non-equilibrium and equilibrium states of the exciplex were detected during emission of the system pyrene–tri(n-butyl)amine.[55] The nuclear electron transfer barrier in this system increased because of the unfavourable (tetrahedral) configuration of the amine molecule for formation of a complex relative to the pyrene molecule. The high values of the Franck–Condon energy of destabilisation of the exciplexes in the ground state (~90 kJ mol^{-1}) and the large Stokes shift of fluorescence of the exciplexes of aromatic azines with *N,N*-dimethylaniline (DMA) is also in all probability due to the two-stage nature of their formation.[56] In this case the geometric hindrance for formation of a complex is due to bending of the π-skeleton of molecules of the photoactive components during excitation. On the other hand, the exciplex of the "sandwich" $\pi\pi$-type structure between anthracene and DMA is formed in a single stage, as shown by the results of study over a picosecond timescale.[57]

The subsequent deactivation processes of exciplexes (internal conversion and intersystem crossing, dissociation in low-polarity or polar media, the formation of secondary products) can occur from both an equilibrium and a non-equilibrium state in accordance with Scheme 3.[58] As ε increases the probability of deactivation by route (*b*) increases.

Scheme 3

The probability of each of these will be determined by kinetic factors. Kuzmin et al.[53] have proposed a method for determining the probability of a Franck–Condon state participating in secondary reactions.

The kinetics of radiationless transition processes are governed by the energy gap principle but together with this principle the values of the rate constants of these processes show a significant dependence on characteristics of the electronic structure of the components of the exciplex. Thus a relatively slow relaxation of the Franck–Condon state of the exciplex to the equilibrium state caused by the unfavourable steric configuration of the components for electron transfer (perpendicular or inclined relative configuration of the planes of the partner molecules) is a prerequisite for the occurrence of a "rapid" intersystem crossing to a triplet state from the non-equilibrium state of the complex. The high rate constant for intersystem crossing ($k_{disc} \approx 10^9 - 10^{10}$ s^{-1}) is due, in the opinion of several authors,[58–61] to the considerable dependence of the matrix element of the spin-orbit interaction between the charge-transfer state of the singlet exciplex and the locally excited triplet state of the photoactive component on the geometry of the components in the exciplex. When the respective orbitals of the partner molecules of the complex are perpendicular to each other, the value of k_{isc} increases sharply.[59–61] In the case of a parallel orientation of the partner molecules, which is typical of exciplexes of polycondensed hydrocarbons with aromatic amines, intersystem crossing occurs relatively slowly ($k_{isc} \approx 10^8$ s^{-1}) from the equilibrium state of the exciplex.[62]

3. Relationship between the rate constant of fluorescence quenching and the efficiency of photodissociation with a change in free energy during electron transfer

One of the arguments in support of EPT is the existence of a correlation between the efficiency of quenching of the photoexcited state of the molecules being studied and the electron-donating (electron-acceptor) properties of the quencher. The efficiency of quenching in this case is determined by the expression[35]

$$\Phi_{ET} = \varphi_{S(T)} \frac{k_q[Q]}{k_q[Q] + k_d + k_q'[Q]}, \qquad (6)$$

where $\varphi_{S(T)}$ is the quantum yield of formation of the respective excited state, k_q and k_q' are the bimolecular rate constants of quenching due to electron transfer and other reactions respectively, k_d is the rate constant of monomolecular deactivation processes, [Q] is the concentration of quencher.

If the quenching process is due to electron transfer, the expression for k_q has the following form:[63]

$$k_q = \frac{2 \cdot 10^{10}}{1 + 0.25[\exp(\Delta G^{\neq}/RT) + \exp(\Delta G_{ET}/RT)]} \qquad (7)$$

According to this equation a linear dependence must occur between $\lg k_q$ and ΔG_{ET} with a plateau being reached at values of k_q close to the diffusion-controlled rate constant.[63,64] The slope of the linear section of this curve is equal to $1/RT$,[65] which can serve as evidence for the existence of electron transfer in a study of bimolecular quenching processes of excited states.

However, it should be remembered that the rate constant of quenching k_q is not always identical to the rate constant of electron transfer. When electron transfer is slow, $k_q = k_{ET}$. During rapid electron transfer ($k_{ET} \gg k_{diff}$) the rate constrant of quenching is

limited by the rate constant for diffusion. It was shown in two studies[66,67] that this is one of the reasons for the absence of an inverted region in the experimentally observed dependences of $\lg k_q$ on ΔG_{ET}.

In the diffusion-controlled region of the rate constants of quenching there is no systematic relationship between the quantum yield of photodissociation and the value of ΔG_{ET}.[52,68] Thus, the quantum yields of photodissociation for systems containing naphthalene derivatives as the electron donor are considerably higher than would be expected from their values of ΔG_{ET}. At the same time the efficiency of photodissociation for systems with electron donors containing a nitrogen, oxygen, and sulphur atom is considerably lower than the expected values.

However, there is a significant effect of the chemical nature of the reacting compounds and the multiplicity of their excited states on the quantum yield of photodissociation φ_D. In terms of the values of φ_D, the most frequently used quenchers of the excited state of photoactive compounds can be divided into 4 classes: amines, nitriles, esters, and anhydrides.[52] Within each class of quenchers it is already possible to establish some correlations between the values of φ_D and ΔG_{ET}. Thus, in a series of donors or acceptors of a single type φ_D decreases with an increase in oxidising potential of the electron donor or reducing capacity of the electron acceptor, in other words, with the shift of ΔG_{ET} to the exothermic region. The observed mechanism is quite obvious if account is taken of the fact that when $\Delta G_{ET} < 0$, in addition to the increase in probability of photodissociation processes, the probability of a competing process of radiationless transfer to the ground state also increases due to the decrease in the energy gap between it and the state with complete electron transfer.

4. Effect of solvent on the process of electron phototransfer

The solvent has a considerable effect on the mechanism of electron transfer. In this respect electrostatic (dipole-dipole and dipole-polarisation) interactions of the excited complex and its partners with the medium must be taken into consideration. These interactions are of a universal nature and are determined by such factors as the dielectric constant ε and refractive index n of the solvent. As a result of the solvating effect of the solvent a change in the electronic structure of the exciplex and its geometry is possible as is a change in the kinetics of electron transfer.[52] The polarity of the medium determines the dynamics and succession of stages in electron transfer (see Scheme 1). It is known that with an increase in the dielectric constant of the solvent, the probability of electron transfer in the collision complex increases, with the stage involving formation of an exciplex being absent.[52] With an increase in polarity of the medium ($\varepsilon > 7$) the final products of deactivation of the exciplex or contact ion pair are solvent-separated radical ions or geminal ion pairs possessing sufficient energy for subsequent conversions classified as secondary reactions of electron transfer.

It was noted earlier that the quantum yield of photodissociation (φ_D) depends strongly on the chemical properties of the partners that participate in electron transfer. Along with this there is a specific relationship between φ_D and the dielectric constant of the solvent[52]

$$\lg(1/\varphi_D) = A/\varepsilon + B, \qquad (8)$$

where A and B are constants that do not depend on ε. This equation is identical to the expression obtained from the Onsager model of ionic recombination.[69]

According to expression (8), an increase in φ_D is to be expected as ε increases, namely, with a shift of ΔG_{ET} towards the exothermic region. In fact, this type of dependence occurs in many cases.[69]

Donor-acceptor systems of a similar chemical nature having approximately the same values of ΔG_{ET} but which have φ_D values that differ considerably in polar solvents are known.[70] Recently it has been possible to account for these apparent contradictions by taking into account the nature of the solvating effect in vibrational relaxation processes during electron transfer.[70–73] The expression obtained by Mataga et al.[70–73] was used in an analysis of the magnitudes of the rate constants of charge separation v_S and recombination v_R at the following stages of electron transfer:

$$A^*...D \rightarrow A^{\cdot-}...D^{\cdot+} \rightarrow A...D.$$

As a result of this analysis the following conclusions were made. The rate constant of charge separation (dissociation constant) v_S is virtually independent of the magnitude of the energy gap between the initial ($A^*...D$) and final ($A^{\cdot-}...D^{\cdot+}$) states since the energy of activation of this process is extremely small. This conclusion is in complete agreement with the dependence of $\lg k_{eq}$ on ΔG_{ET} in the inverted region.[63] The rate constant of recombination v_R depends to a considerable extent on the energy gap between the initial ($A^{\cdot-}...D^{\cdot+}$) and final ($A...D$) states. Apart from this, the magnitude of v_R, in contrast to v_S, is determined to an appreciable extent by the individual properties of the participants in electron transfer (their donor-acceptor properties, steric configuration, relative orientation, etc.). It may be assumed that the ratio of the rate constants for charge separation and for recombination which depend on ΔG_{ET} will also determine the true value of the quantum yield of photodissociation.

One of the reasons for the existence of an inverted region may be related to secondary proton-transfer reactions.[67]

5. Secondary proton-transfer reactions

We shall only consider below those systems in which proton transfer follows electron transfer. Protonation can occur in one of the intermediates: in the collision complex,[74,75] exciplex,[76] contact radical ion,[77] or solvent-separated ion pair[78] in accordance with Scheme 4:

Scheme 4

$$^{1,3}A^* + DH \xrightarrow{k_q} {}^{1,3}(ADH)^* \xrightarrow{k_{PT}} (AH^{\cdot}...D^{\cdot}) \xrightarrow{k_{sep}} AH^{\cdot} + D^{\cdot}$$

$$k_{int}: \quad A + DH \qquad k_{fl}: \quad A + DH + h\nu_{fl} \qquad k_{diss}: \quad A^{\cdot-} + DH^{\cdot+}$$

where $^{1,3}(ADH)^*$ is any of the intermediates of EPT.

The formation of intermediates naturally reduces the potential barrier of proton transfer through the convergence of the partners and as a rule it produces a more favourable orientation for their interaction. Apart from this, the radical cations formed as a result of EPT are stronger acids and the radical anions are correspondingly stronger bases than their electron-neutral precursors.[78] Thus EPT assists an increase in not only kinetic but also thermodynamic acidity of proton donors, by increasing their reactivity. According to Marcus,[79] the expression for the rate constant of proton transfer is similar to expression (3) and has the form:

$$k_{PT} = Z \exp(-\Delta G^{\neq}_{PT}/RT), \qquad (9)$$

where $\Delta G^{\neq}_{PT}$ is the Gibbs free energy of activation

$$\Delta G^{\neq}_{PT} = W_R + (\lambda/4)(1 + \Delta G_{PT}/\lambda^2). \quad (10)$$

Here W_R is the change in free energy needed for convergence of the components and their rearrangement required for proton transfer. In turn

$$W_R = \omega^R - RT \ln S^r s^r, \quad (11)$$

where ω^R is the Coulombic interaction energy between the reaction partners expended on their convergence to a distance r, S^r and s^r are values representing steric and statistical factors.

During exothermic proton transfer (this occurs in all of the systems examined in this section), the rate-limiting stage of the overall process is proton transfer. Its rate constant depends on the relative orientation of donor and acceptor in the complex, the chemical nature of the reaction partners, and in particular on the type of hydrogen bond undergoing cleavage and the polarity of the medium.

If the resulting intermediate has a geometry which is favourable for proton transfer, the latter occurs freely with a rate constant exceeding the diffusion constant. Thus, in the system benzophenone–triethylamine in acetonitrile the formation of a ketyl radical occurs within 1.5×10^{-12} s after flash photolysis. Its precursor is an excited charge-transfer complex (CTC) ($\tau < 10^{-11}$ s), which comprises a superposition of radical ions[19]. Here the C–H bond of the α-carbon atom is positioned parallel to the half-filled orbital of the unshared electron pair of the nitrogen atom. In the system benzophenone–*N,N*-dimethyl(diethyl)aniline the corresponding process is slower. Formation of a ketyl radical occurs only 2×10^{-9} s after flash photolysis, and its generating contact pair is formed after $\tau = 3 \times 10^{-10}$ s.[77] The triplet exciplex of benzophenone with *N,N*-dimethylaniline is known to have two conformations of $n\pi$ and $\pi\pi$ type.[80] The second conformation corresponds to free proton transfer. In all probability the slight delay in the proton transfer time in this system is due to the need to transform the geometry of the contact ion pair. The rate constant of proton transfer in this case is equal to 2×10^{-9} s.

Proton transfer in the system anthracene–*N,N*-dimethylaniline, where a stable sandwich-type exciplex is formed, is considerably inhibited. On the basis of calculated data, the rate constant of proton transfer in this case is equal to $\sim 1-5 \times 10^6$ s^{-1}.[81]

The efficiency of proton transfer and the type of radical products formed depend to a considerable extent on the chemical nature of the proton donor. Thus, if tertiary amines are used as the donor, the proton of the α-C–H bond proves the most active. In this case an α-aminoalkyl radical is formed as a result of deprotonation. Radicals of this type have a low ionisation potential because of the formation of a three-electron bond (>N̈–Ċ<), and they are excellent reducing agents.[82] The rate constant of proton transfer by these amines depends on the size of the alkyl substituent (it increases in the series isopropyl < ethyl < methyl),[84] on the symmetry of their configuration relative to the nitrogen atom, and on the donor-acceptor properties of the substituents.

The most active proton in secondary amines is that of the N–H bond. In many cases it can participate in the formation of a hydrogen bond with the acceptor molecule, which gives additional stabilisation to the exciplex. Such a situation occurs in exciplexes of pyrene with primary and secondary amines.[84] The resulting hydrogen bond between the partners reduces the energy of cleavage of the N–H bond compared to the α-C–H bond and gives rise to a favourable geometry of the complex for proton transfer. As a result of deprotonation, radical cations of primary and secondary amines form mainly aminyl radicals.

Together with these, the formation of α-aminoalkyl radicals cannot be excluded. An increase in electron-accepting capacity of the partner[85] and an increase in polarity of the medium weakens the hydrogen bond and reduces the proton-donating activity of primary and secondary amines. It was established that as the polarity of the medium increases, the yield of aminyl radicals decreases relative to α-aminoalkyl radicals.[86]

The probability of proton transfer can vary according to the solvating properties of the solvent. With an increase in the dielectric constant of the solvent the exciplex becomes more polar and with complete electron transfer it is converted to a radical ion pair. As already mentioned, this results in a significant increase in the acidity of the proton donor and the basicity of the acceptor. It may be assumed that the type of EPT intermediate in which proton transfer occurs is determined by the thermodynamic condition $\Delta G_{PT} \leqslant 0$ for this process. The change in free energy of proton transfer ΔG_{PT} has the following form:[87]

$$\Delta G_{PT} = 2.3RT[pK_a(DH^{+\cdot}) - \pi K_a(AH^{\cdot})]. \quad (12)$$

If the acidity of the proton donor and the basicity of the acceptor are sufficient high, proton transfer is thermodynamically possible even in a collision complex which achieves a convergence of partners.[74,75] If the acidity of the donor is low, an initial complete electron transfer is necessary for proton transfer to occur. In this case the process only occurs in the radical ion pair.[77] For high values of ε, when the efficiency of the dissociation process competing with proton transfer (see Scheme 5) increases markedly, the rate of the latter decreases sharply. This is very clear in the case of the benzophenone–*N,N*-dimethylaniline system, in which the quantum yield of photodissociation of the complex increases from zero to unity with an increase in polarity of the medium while the quantum yield for formation of ketyl radicals correspondingly falls.[8] At high values of ε the molecules of the polar solvent stabilise the solvent-separated radical ions. This conteracts the convergence of the partners that is necessary for subsequent proton transfer. It follows from this that the role of a polar medium involves control of the kinetic and thermodynamic conditions for proton transfer.

III. Photoinitiation of polymerisation with organic redox systems

1. General ideas about the initiation of photopolymerisation with electron donor-acceptor systems

Thus, electron phototransfer between the components of a redox system can result in the formation of two types of active product that are energy-rich. These are radical ions or radical ion pairs which are formed as a result of complete electron transfer and free radicals that are the secondary products of proton transfer. Depending on the nature of the substrate that converts a monomer molecule to a lower-valence species, polymerisation is classified as being initiated by free radicals, ions, or radical ions (electron transfer).[147] In addition to this there is another classification, which does not take into account the nature of the initiated species. In this case the nature of the end of the growing chain (free radical or ionic) is the distinctive feature. Subsequently, in establishing the

mechanisms of polymerisation initiation and chain propagation we shall use the latter classification, which is based on the combination of features listed in Table 1, in each specific case. But at the same time we shall adhere to currently accepted principles. As a rule free radicals initiate radical polymerisation and ions initiate ionic polymerisation. Systems in which initiation is achieved using radical ions are conventionally grouped under ionic polymerisation in the majority of cases, since it is impossible to determine *a priori* which function—ionic or radical—generates the chain.[39,147]

Table 1. Distinctive features of free-radical and ionic polymerisation.

No.	Distinctive feature	Type of polymerisation		
		free-radical	ionic	
			cationic	anionic
1	Effect of polarity of the medium on polymerisation rate	Has almost no effect (with an increase it even decreases slightly)	Rate increases sharply with an increase in polarity of the medium	
2	Dependence of V on [M]	$V \approx k[M]^1$	$V \approx k[M]^n$ ($n \gtrsim 1-2$)	
3	Induction period in the presence of O_2	Occurs	None	
4	"Post-effect"	Occurs	None	
5	Value of k_p/k_t	$k_p^2/k_t \approx 10^{-2}-10^{-1}$	$k_p/k_t \geqslant 10^2$	
6	Effect of acceptors of primary active products	On introducing radical acceptors (eg., nitrobenzene, diphenylphosphate, 1,1-diphenyl-2-picrylhydrazyl, etc.) termination of polymerisation chain occurs	Polymerisation terminates in the presence of added amines or water	Polymerisation terminates in the presence of added oxygen
7	Temperature system	$T > 20$ °C	$T \ll 20$ °C	

Data on the most familiar redox systems that initiate polymerisation by light excitation at $\lambda > 300$ nm are given in Table 2. For the majority of them (systems 1–18) the primary photochemical stage is interaction of an excited molecule of photoinitiator (PI) with a molecule of monomer, resulting in the formation of primary active products of the monomer (free radicals or radical ions) which produce a polymerisation chain. In the absence of a PI, polymerisation does not occur on exposure to low-energy light quanta.

There are a number of systems (19–41) that consist of an initiator whose range of photosensitivity can vary from 300 to 700 nm and a so-called activator,[13,112] co-activator,[113] or promoter[90] between which electron transfer occurs. The activator is an electron donor or acceptor that is insensitive to light with $\lambda > 300$ nm and inert (as a polymerisation initiator) under these conditions. In contrast to this, the photoactive component of the redox system (PI) can independently initiate polymerisation which, however, takes place at a low rate. When it is used in combination with an activator it is possible to accelerate the process by a factor of 10^1-10^2 or more.

The fundamental processes for generation of radicals $R^\cdot$ that generate the polymerisation chain can be given in the form of Scheme 5;

Scheme 5

$$P \xrightarrow{h\nu} {}^{1,3}P^*, \quad {}^{1,3}P^* + A \xrightarrow{k_1} {}^{1,3}(PA)^*,$$

$${}^{1,3}(PA)^* \xrightarrow{k_2} R^\cdot, \quad {}^{1,3}(PA)^* \xrightarrow{k_3} P + A,$$

$$R^\cdot + M \xrightarrow{k_4} M^\cdot, \quad M^\cdot + M_{m-1} \xrightarrow{k_p} M_m^\cdot,$$

$$M_m^\cdot + M_n^\cdot \xrightarrow{k_o} M_{m+n},$$

where P and A are molecules of photoactive component and its partner in complexation (monomer or co-initiator) respectively.

It can readily be demonstrated that the solution of differential equations derived from a formal kinetic scheme such as Scheme 5 using the steady-state concentration method gives the following expression for the initial rate of polymerisation V:[133]

$$V = BI^{n_1}[P]^{n_2}[A]^{n_3}[M]^{n_4}, \tag{13}$$

where B is a proportionality constant that is dependent on the ratio k_p/k_o of the polymerising monomer and on the rate constants of the mono- and bi-molecular deactivation processes of the excited state of the PI; I is the intensity of incident light; [P], [A], and [M] are the concentrations of the PI, co-initiator, and monomer, n_1, n_2, n_3, and n_4 are exponents that are dependent on the polymerisation mechanism and the initiation mechanism. When the monomer is involved in the initiation process, $n_4 \geqslant 1$ and $n_3 = 0$.[93,119] Comparison of expression (13) for V obtained from treatment of the formal kinetic scheme with the experimentally observed value proves to be productive for study of the mechanism of polymerisation.

2. Photoinitiation of polymerisation with secondary products of proton transfer

In the photoinitiation systems (19–30 in Table 2) studied in this section, the thermodynamic condition for electron transfer is fulfilled. It is therefore to be expected that the probability of proton transfer between the components of these systems is high. In fact, in systems 20 and 22 the formation of an exciplex is detected while in systems 23–27 and 29 the quenching of fluorescence is established or bimolecular deactivation of the triplet state of the PI occurs, on which the mechanism of electron transfer is based. Since photopolymerisation initiated with these systems (see Table 2) corresponds to a free radical mechanism in accordance with the criteria indicated in Table 1, it may be assumed that the only possible active products are protonated and deprotonated free radicals that have left the solvent "cage". In accordance with the ideas put forward in Section II, it may be assumed that the initial formation of some form of intermediate involving electron transfer should be conducive to proton transfer.

It follows from Table 2 that amines, in particular tertiary amines †, are used as activators in the vast majority of cases in these redox systems. It was mentioned earlier (see Section II.5) that they

† We will not stop to analyse dye–activator photoinitiation systems in this review. These systems have been described in detail.[13] We shall merely point out that in addition to amines other classes of compounds, including sulphonates, carboxylates, organometallic compounds, etc., are used as activators in these systems.

Table 2. Systems that photoinitiate polymerisation.

No.	Initiating system	Monomer	Acceleration effect	Solvent	Evidence for ET or exciplex	Expression for initial rate of polymerisation	Polymerisation mechanism	Evidence for initiation mechanism	Refs.
1	2	3	4	5	6	7	8	9	10
1	^{3}Anthracene* + ^{3}Pyrene* + ^{3}Chyrsene	Styrene	×5	Benzene (no O_2)	Rate constant of deactivation of triplet states k_q^T varies in same way as the electron-donating properties of quenchers	$V \approx I^{0.5}[P]^1$	Free-radical		[11, 92]
2	^{1}Naphthalene* and its derivatives			Dimethyl formamide (no O_2)	k_q of fluorescence varies in the same way as the electron-donor properties of the photoinitiator, % conversion of monomer to polymer varies in the same way	$V \approx I^{0.57}[P]^{0.2-0.4} \times [M]^{1.1-1.5}$	"	Inhibition with oxygen	[93, 94]
	^{1}Anthracene* + monomer ^{1}Pyrene* ^{1}Fluorenone* ^{1}Diphenyl*	Acrylonitrile	×2–6						
3	^{3}Phenazine* ^{3}Acridine* + ^{3}Anthracene* monomer	Butylmethacrylate	×4–6	Toluene tetrahydrofuran (no O_2)	k_q^T of quenching varies in proportion to EA of photoinitiators ($k_q \approx 10^5-10^7$ litre mol^{-1} s^{-1})	$V = I^{0.5}[P]^{0.4-0.6}[M]^{1.0}$	"	"	[95, 138]
4	^{1,3}*N*-Vinylcarbazole* + triethylamine	*N*-Vinylcarbazole		Benzene (no O_2), acetone (in the presence of O_2)	k_q of fluorescence of *N*-vinylcarbazole with amines varies in the same way as their electron-donating capacity		Free-radical (α-aminoalkyl radical causes polymerisation)	1. Inhibition of polymerisation with O_2 2. Proton transfer from TEA to monomer takes place	[91, 96]
5	^{1}*N*-Vinylcarbazole* + CBr_4	"		Dichloroethane, nitrobenzene, benzene	Quenching of fluorescence of *N*-vinylcarbazole CCl_4 and CBr_4. Fluorescence band of exciplex appears		Free-radical and cationic	Bromine free radical and active cationic sites with C–Br bond occur	[97, 98, 140, 141]
6	^{3}*N*-Vinylcarbazole* + azobutyronitrile	"	more than 10 times	Dichloromethane, benzene	Excited triplet complex of *N*-vinylcarbazole with the solvent rate constant of quenching diffusion controlled	$V_p = \frac{k_p}{k_t^{0.5}} I^{0.5}[A]^{0.5}[M]^{1.5}$ $V_{cat} = \frac{k_p}{k_t} I[A]^{1.0}[M]^{1.0}$	Free-radical and cationic mechanism (at high concentrations of monomer)	Cationic polymerisation is terminated in the presence of dimethylformamide—a trap of cationic sites. Distribution of polymerisation products varies according to the polarity of the solvent	[27]
7	^{1}*N*-Vinylcarbazole* + fumaronitrile	"		Dichloromethane, benzene	Band of exciplex in fluorescence spectrum; rate constant of fluorescence quenching of the same order as the diffusion constant		Cationic and free-radical		[99, 123]
8	^{1}*N*-Vinylcarbazole* + diethyl fomarate	"		Acetone, acetonitrile, dimethyformamide	Fluorescence quenching, band of exciplex in fluorescence spectrum		Free-radical and cationic	Ratio of polymerisation products varies in solvents of different basicity	[100]
9	*N*-Vinylcarbazole* + benzoyl peroxide	*N*-vinylcarbazole		Benzene, dichloromethane	Cation radicals of *N*-vinylcarbazole detected using pulsed methods in dichloromethane but not in benzene		Free-radical and cationic	Agreement between effect of basicity on formation of radical cations and ocurrence of corresponding polymerisation products	[101]
10	*N*-Vinylcarbazole* + chloranil	"					Free-radical	Inhibition with oxygen	[102]
11	^{1}Thiobenzophenone* + *N*-vinylcarbazole	"		Benzene, toluene, acetonitrile (in a current of argon)	Forms singlet exciplex		Cationic	Polymerisation occurs in the presence of thiobenzophenone, which is a free radical trap	[90, 103]
12	^{3}α-Methylstyrene* + tetracyanobenzene	α-Methylstyrene		Dichloroethane (no O_2)	Singlet and triplet exciplex formed. Photoconductivity recorded		"	Water and amines inhibit polymerisation	[18, 104, 105]
13	^{3}α-Methylsytrene* + pyromellitic dianhydride	"		"	Exciplex formed		"	"	[106]
14	Styrene* + maleic anhydride	Styrene		Acetonitrile	Radical cation of styrene observed in absorption spectra (pulsed excitation)		"	Addition of tertiary amines terminates polymerisation	[107]
15	Styrene* + acrylonitrile	Styrene and acrylonitrile (copolymer)		Dichloromethane			"	Addition of water and amines inhibits polymerisation	

Table 2 (continued).

No.	Initiating system	Monomer	Acceleration effect	Solvent	Evidence for ET or exciplex	Expression for initial rate of polymerisation	Polymerisation mechanism	Evidence for initiation mechanism	Refs.
1	2	3	4	5	6	7	8	9	10
16	Nitroethylene* + cyclohexene oxide	Nitroethylene	more than 10 times	Tetrahydrofuran	Band of weak charge-transfer complex in absorption spectrum		Cationic and anionic simultaneously	Traces of HCl inhibit polymerisation by 20%. Polynitroethylene (0.73) and polycyclohexene (0.27) identified by fractional analysis	[109]
17	Maleic anhydride* + tetrahydrofuran	methyl methacrylate	×2–4	Tetrahydrofuran	Photocurrent recorded		Anionic and free-radical	Polymerisation occurs in the presence of free-radical traps—1,1-diphenyl-2-picrylhydrazyl. It slightly lowers the rate of polymerisation	[110]
18	^{1}Benzyl-1,4-dihydronicotinamide* + monomer	Styrene, methyl methacrylate	×10	Dichloromethane, acetonitrile, methanol	Fluoroescence quenching of photoinitiator varies in the same way as the donor-acceptor properties of partners	$V \approx [P]^{0.5}$	Free-radical	Polarity of medium has virtually no effect on rate of polymerisation. Linear dependence of reverse polymerisation stage on inhibitor concentration	[111]
19	^{3}Benzophenone* + triethylenetetramine	Methyl methacrylate		Benzene, toluene, acetone, methanol (in a current of nitrogen)		$V \approx [P]^{0.5}[A]^{0.5}$	"	With an increase in ε of the medium the rate of polymerisation decreases, $k_p^2/k_t = 1.06 \times 10^{-2}$ litre mol^{-1} s^{-1}	[22]
20	^{3}Benzophenone* + tertiary amines	Methyl methacrylate		t-Butyl alcohol (no O_2)	Deactivation of triplet state of benzophenone with amine, formation of a radical ion pair	$V = k[M]^{1-1.5}[A]^{0.5}$	Free-radical	Higher rate of proton transfer $k_{PT} \geqslant 10^9$ s^{-1}	[24, 75, 114]
21	^{3}Benzophenone* + triethylamine (tributylamine, di-n-butylamine, n-butylamine)	Acrylonitrile	×11	Benzene dimethylformamide (in a current of nitrogen)	Deactivation of triplet states of benzophenone by amines with $k_q^T = 2.3 \times 10^9$ litre mol^{-1} s^{-1}	$V \approx [P]^{0.3-0.4}[M]^{1.3}$		Rate of polymerisation remains almost the same on going from benzene to dimethylformamide	[115]
22	^{3}Benzophenone* + aliphatic amines (primary, secondary, tertiary)	Methyl methacrylate	×10	Benzene, carbon tetrachloride, dimethylformamide	Triplet exciplex formed	$V \approx [P]^{0.38}[A]^{0.5}[M]^{1.5}$	Free-radical	Induction period occurs in the presence of O_2. Hydroquinone inhibits polymerisation. $k_p^2/k_t = 1.54 \times 10^{-3}$ litre mol^{-1} s^{-1}	[116, 117]
23	^{3}Fluorenone* + triethylamine (*N,N*-dimethylethanolamine)	"	×7–10	Benzene	Quenching of singlet and triplet states of fluoroenone by amines with $k_q^T \geqslant 10^{10}$ litre mol^{-1} s^{-1}		"	With an increase in ε of the medium the rate of polymerisation decreases. $k_p^2/k_t = 1-4 \times 10^{-3}$ litre mol^{-1} s^{-1}	[20]
24	^{1}Anthracene* (Phenanthrene, naphthalene, acetonaphthone)* + (di- and tri-ethylamine, aniline, *N*-methyl- and *N,N*-dimethylaniline	Methyl methacrylate, acrylonitrile	×15 to 16	Dimethylformamide (in a current of nitrogen)	Fluorescence quenching of photoactive components by amines with $k_q > 10^9$ litre mol^{-1} s^{-1}	$V \approx [P]^{0.5}[A]^{0.5}[M]^{1.0}$	Free-radical or ionic		[15]
25	Fluorenone* (acetophenone, Michler Ketone) + aliphatic amines	Acrylonitrile	×5–10	Dimethylformamide, benzene (in a current of nitrogen)	Quenching of triplet states of photoactive components by amines with $k_q \geqslant 10^9$ litre mol^{-1} s^{-1}	$V \approx [P]^{0.35}[M]^{2.20}$	"	Polymerisation does not occur in a nonpolar solvent	
26	^{3}Thioxanthone* + aliphatic amines	Methyl methacrylate		Benzene, acetonitrile	Quenching of triplet state of photoactive component by amines with $k_q^T \geqslant 10^9$ litre mol^{-1} s^{-1}. Polarity of medium did not affect k_q^T		Free-radical	Formation of free radicals—partners of initiating mixture—detected. Lack of dependence on polarity	[118]
27	^{3}Benzophenone salts* + triethylamine (triethanolamine, methylethanolamine)	Acrylamide	×3–15	Water (in a current of nitrogen)	Quenching of triplet states of photoinitiator by amines with $k_q^T \geqslant 10^9$ litre mol^{-1} s^{-1}	$V \approx I^{0.5}[P]^{0.5}[A]^{0.5}[M]^{1.5}$	Free-radical, but anionic not excluded	Ketyl radical of benzophenone occurs	[119]
28	Iron tetraphenyl porphin* + aliphatic amines + carbon tetrachloride	Methyl methacrylate	×5–10	Methanol (no O_2)			Free-radical		[120]

Table 2 (continued).

No.	Initiating system	Monomer	Acceleration effect	Solvent	Evidence for ET or exciplex	Expression for initial rate of polymerisation	Polymerisation mechanism	Evidence for initiation mechanism	Refs.
1	2	3	4	5	6	7	8	9	10
29	Dyes* (thiazine, xanthine, acridinone) + activator (amines, enolates, organometallic compounds, thiols)	Acrylamide, vinyl alcohol, cellulose acetate, vinyl chloride	more than 10 timees	(no O_2)	Quenching of triplet states of photoactive component by activator with $k_q \geqslant 10^9$ litre mol^{-1} s^{-1}. Correlation between k_q and value of Δq_{ET}		"		[13]
30	^{3}Fluorenone* (benzanthrone, acridine, 9-phenylacridine)* + hetero aromatic thiols	Methyl methacrylate derivatives	more than 10 times	In thin layers	Quenching of triplet states of photoinitiators with activators by electron and energy transfer mechanism		Free-radical		[121]
31	^{3}Phenazine and its derivatives* + benzophenone and its derivatives	Butyl methacrylate	more than 200 times	Toluene, acetonitrile (no O_2)	Quenching of triplet stages of phenazine with benzophenone derivatives. Correlation between k_q^T and Hammett σ-constants of substituents in benzophenone molecule. Photocondutivity in acetonitrile	$V_{exp} = I^{0.5}[P]^{0.3-0.5} \times [A]^{1.0}[M]^{1.8}$ $V_{calc} = k[P]^{1.0}[A]^{1.0} \times [M]^{>1.5}$	Ionic (involving radical ion pairs)	Rate of polymerisation increases sharply with ε of medium. In a nonpolar solvent polymerisation does not occur, $k_p/k_t \approx 3-3.8 \times 10^2$ litre mol^{-1} s^{-1}. Solvent-separated radical ions detected in acetonitrile	[26, 122]
32	^{1}Acridine* (^{1}phenazine, 1anthracene)* + *N,N*-dimethylaniline	"	× 15 to 30	Toluene, acetonitrile (no O_2)	Formation of singlet fluorescing exciplexes between partners. Photodissociation in acetonitrile (photoconductivity occurs)	$V = I^{0.5}[P]^{0.5}[A]^{0.5}[M]^{2.0}$	Ionic (involving radical ion pairs and ionic triads)	Rate of polymerisation increases sharply with ε of medium. Free radicals are absent. Solvent-separated radical ions and ternary complexes detected in acetonitrile	[123]
33	^{1}Perylene* + dicyanobenzene	*N*-Vinyl carbazole	× 6	Acetone, dimethyl sulphoxide (in the presence of O_2)	Fluorescence quenching of perylene by dicyanobenzene with $k_q > 10^9$ litre mol^{-1} s^{-1}. It increases as ε increases			Sharp increse in rate of polymerisation with ε of medium	[23]
34	^{3}Benzophenone (benzaldehyde)* with acceptor substituents + 4,4-bis-*N,N*-diethylaminobenzophenone	Methyl methacrylate		In a current of nitrogen	Quenching of triplet-excited states of photoinitiator with activator		Free-radical	Induction period in the presence of O_2	[124]
35	^{3}Benzophenone* + benzaldehyde + triethylamine	"	more than 10 times				"		[125]
36	^{3}Benzophenone* + tri-, di-, and monoethylenediamine + maleic acid		× 10		Quenching of triplet states of benzophenone with amines			Induction period occurs	[126]
37	^{3}Benzophenone* + diethanolamine + O_2	Hexane diol acrylate					"	"	[159,127]
38	^{3}Benzophenone* + 2-ethylhexyl *p*-(*N,N*-dimethylamino)benzoate + O_2	Epoxy acrylate	× 10 to 20	Films (in the presence of O_2)	Quenching of triplet states of benzophenone with amines		"		[128]
39	^{3}Benzophenone* + *N,N*-dialkylaminoethyl methacrylate	*N,N*-dialkylaminoethyl acrylate		Benzene (in the absence of O_2, in its presence, and in a current of argon)	Formation of excited charge-transfer complex		"	Induction period occurs. Free radicals detected	[129]
40	Benzoin isobutyl ether* + tetramethyl-*p*-phenylenediamine + O_2								[130]
41	^{3}(Xanthene, triazene, anthracene, phenanthrene)* + onium compounds	Cyclic ethers, epoxy compounds		In the presence of O_2, acetonitrile, water			Cationic mechanhism	No induction period	[162,163, 131,132]

act as donors of a hydrogen atom detached from a CH group at the α-position relative to the nitrogen atom. The α-aminoalkyl radical formed as a result of deprotonation is responsible for generating the polymerisation chain. The presence of nitrogen atoms in the polymer provides proof of this.[134]

It should be noted that there is a dependence of the rate of polymerisation on the size of the alkyl substituents in the aminoalkyl group that is similar to the dependence of the rate constant of proton transfer on the same parameters, as discussed in Section II.[83] Thus the rate of polymerisation V for system 25 is higher when triethanolamine is used as the activator than when tributylamine is used, while for system 24 it is higher when dimethylaniline is used compared to the use of diethylaniline and it varies in the same way as the rate constant of proton transfer.[15] The experiments conducted in parallel with two activators—triphenyl- and triethylamine in combination with benzophenone—showed that only in the second case, in which proton transfer occurs, does the polymerisation of methyl methacrylate occur (systems 20–22).[114] Meanwhile, electron transfer in both systems occurs at a rate that is higher than the diffusion rate. All of these facts suggest that proton transfer between the components of the initiating mixture plays a role in the generation of active radicals.

The same reaction of proton transfer with the formation of semi-reduced radical products forms the basis of the interaction of the photoactive components of a number of aromatic, heteroaromatic, and carbonyl compounds with proton-donating solvents.[135,136] However, the rate of polymerisation in this case is low, in contrast to systems in which the same photoinitiators are used in combination with amines.[15,135,137] As in fact the polymerisation mechanism (free-radical) does not change, why is there a preference for the latter?

In actual fact the rate of initiation of polymerisation with primary active products depends on the efficiency factor of the initiator β and the concentration of the primary radicals [R$^{\cdot}$]:[24,90]

$$V_i = \beta[R^{\cdot}]. \qquad (14)$$

The efficiency factor of the initiator β is governed by the proportion of radicals formed that participate in initiation of polymerisation. It is usually considerably less than unity, as a result of radicals participating in side reactions, and it is determined by the nature of both the initiator and the monomer. The concentration of primary radicals, [R$^{\cdot}$] depends on the rate constant for their formation, in these particular cases—on the rate constant of proton transfer k_{PT}. In the presence of photoinitiation mixtures in which proton transfer occurs rapidly, such as in benzophenone–triethylamine systems (18–19), $k_{PT} = 10^{12}$ s^{-1};[77] even with a comparatively low value of β for the α-aminoalkyl radical equal to $1-5 \times 10^{-3}$,[24] the polymerisation of methyl methacrylate is very active. On the other hand, when polymerisation is initiated by a deprotonated tetrahydrofuran radical, which has a value of $\beta = 5 \times 10^{-2}$,[24] because of the low value of $k_{PT} = 4.2 \times 10^6$ mol^{-1} s^{-1} its rate is considerably lower.[115] The very slow polymerisation initiated by the system aromatic hydrocarbon–propanol is apparently related to this.[15] It is known that in this system $k_{PT} = 6 \times 10^5$ mol^{-1} s^{-1}.[178] As has already been mentioned in Section II, an unfavourable geometry for proton transfer of the components in exciplexes of aromatic or heteroaromatic compounds with *N,N*-dimethylaniline (DMA) is responsible for the low value of k_{PT} in benzene. As a result, a low rate of polymerisation of butyl methacrylate is recorded in it (system 32), although in this system in a non-polar solvent the α-aminoalkyl radical of DMA should be present with almost the same efficiency as the α-aminoalkyl radical of triethylamine.[15]

Aminyl radicals which are formed as a result of deprotonation of primary and secondary amines are less effective than the α-aminoalkyl radical because of their increased tendency to undergo a disproportionation reaction.[103]

The least effective were protonated radicals of the photoactive components of the initiation system (ketyl radicals of benzophenone, semi-reduced radicals of phenazine, acridine, anthracene, etc.). Generation of a polymerisation chain in their presence occurs either at a very low rate or not at all (systems 20 and 32). On the contrary, in a number of cases they have an inhibitory effect by participating in chain termination reactions.[140] This accounts for the appearance of a descending curve on graphs of the rate of polymerisation against the concentration of photoinitiator.[15,94,115] Moreover, the semi-reduced radicals are consumed to form final products of the destructive bleaching of the photoabsorbent compound accompanying polymerisation.

The adoption of a free-radical photopolymerisation mechanism for the systems examined above is consistent with the ideas about the effect of the polarity of the medium on these processes (Table 2). In fact, in systems 19, 21, 23, 29, and 36 polymerisation occurs more rapidly in benzene than in any polar solvent. Careful analysis of the active products initiating polymerisation, their precursors—exciplexes or other intermediates of electron transfer—and the kinetics of electron and proton transfer also support the idea of a free-radical mechanism of polymerisation in these systems.

Unfortunately, a detailed study of the mechanism of polymerisation with identification of the intermediate stages of initiation has only been carried out for a narrow range of reactions (systems 19, 20, 23, 26). For the remaining systems given in Table 2, a free-radical mechanism of polymerisation has only been established from its similarity with the above systems. Meanwhile, such similarities are not always consistent. Thus, although for a number of systems such as 24, 25 and 27 a free-radical mechanism is maintained by the authors, the experimental evidence for such conclusions is insufficient. The study of polymerisation was conducted with the use of a polar solvent—dimethylformamide, acetonitrile, or water. The nature of the radicals generating the polymerisation chain was not verified. The authors did not take into account the fact that the photoactive components of the initiating systems studied by them—aromatic compounds (24) or carbonyl compounds (25, 27) with a $^3\pi^*$ lowest excited state—on reacting with amines have a greater tendency to undergo complete electron transfer reactions than to undergo secondary proton transfer reactions, especially in polar media[77,80] (see Section II). It cannot be excluded that it is this fact which accounts for the acceleration by a factor of 3–5 of the polymerisation of acrylonitrile in systems 24 and 25 on going from benzene to acrylonitrile. In adhering to their view of a free-radical mechanism, Kubota and Ogiwara[15] cannot account for the effect of the polarity of the medium on the rate of polymerisation.

There is no doubt that many factors such as the nature of the photoinitiator (the type of electronic transition responsible for excitation, its multiplicity), the activator, and monomer can affect the mechanism of initiation of polymerisation. It is therefore interesting to consider the behaviour of two photoinitiators from the class of aromatic ketones—benzophenone and fluorenone. They differ according to the electronic nature of the lowest excited states. In benzophenone the $^1S^*$ and $^1T^*$ states have an $n\pi^*$ electronic configuration.[141] The majority of reactions, including electron and proton transfer, occur in the $^1T^*$ state. The polarity of the medium does not affect the quantum yields of formation of triplet states,

formation of ketyl radicals, or the quantum yield of the overall reduction process.[141,142] In contrast to benzophenone, the $^1S^*$ and $^1T^*$ states of fluorenone have a $\pi\pi^*$ electronic configuration.[143] However, in view of the proximity of the $^2S^*_{\pi\pi^*}$ and $^1S^*_{\pi\pi^*}$ state and also the $^2T^*_{\pi\pi^*}$ and $^1T^*_{\pi\pi^*}$ states, the contribution of the $n\pi^*$ electronic configuration to the lowest $^1S^*$ and $^1T^*$ states is quite evident. Therefore the polarity of the medium has a substantial effect on the kinetics of the photophysical processes. With an increase in ε the quantum yield and duration of fluorescence increase by a factor of almost 10^2 and the quantum yield of intersystem crossing is halved.[144] The quantum yields of formation of ketyl radicals and the overall reduction reaction decrease by the same order of magnitude.[145]

The lowest triplet state of benzophenone participates in electron and proton transfer from amines. The latter reaction, as has aleady been mentioned, occurs with a high rate constant ($k_{PT} \approx 10^9$ s^{-1}).[19,77] The resulting free radicals generate the polymerisation chain. The polarity of the medium has virtually no effect on the rate of polymerisation[15,22,24] (systems 19–21, 26 in Table 2).

Fluorenone behaves in a similar manner in the initiation of the polymerisation of MMA (system 23).[113] The maximum rate V of photopolymerisation has been recorded in benzene. In acetonitrile V decreases by a factor of almost 5,[114] which is an argument in favour of a free-radical mechanism of polymerisation. However, an alternative explanation for this phenomenon is also possible. With an increase in ε the quantum yield of intersystem crossing decreases and the quantum yield of formation of ketyl radicals of fluorenone and deprotonated amine radicals correspondingly decreases.[144]

Fluorenone behaves quite differently in the polymerisation of acrylonitrile (system 25). The rate of polymerisation of this monomer, initiated with system 25, increases by a factor of 4 on going from benzene to acetonitrile, although the yield of radical products in this case is halved,[144] as in the example considered above. It is known, however, that with an increase in ε the lifetime of the $^1S^*$ state increases. It is sufficiently long for fluorenone in the $^1S^*$ state to interact with amines by a charge-transfer mechanism.[146] The rate constants of quenching of the $^1S^*$ state of fluorenone with triethylamine in benzene and acetonitrile are equal to 1×10^9 and 7×10^9 litre mol^{-1} s^{-1} respectively, whereas the rate constants of deactivation of the $^1T^*$ state with the same amine is two orders lower ($1.7-2.3 \times 10^7$) litre mol^{-1} s^{-1}.[145] Apparently at concentrations of amine greater than 10^{-2} mol $litre^{-1}$, which is commonly used in polymerisation, the excited fluorenone molecules mainly in the $^1S^*$ state interact with amines. Since with an increase in ε the probability of proton transfer decreases sharply in the system fluorenone–amine because of electron transfer competing with it,[145] the quantum yield of formation of free radicals must decrease. It can be expected that in system 25, where $\varepsilon \approx 20$, the photoinitiating mixture will exist as radical ion pairs as a result of light absorption. It is possible that acrylonitrile, being a stronger electron acceptor than MMA, can interact with such an ion pair to form a "loose" ternary complex. This will generate the polymerisation chain. Such a possibility has also not been excluded for MMA.[10] Similar views about the initiation of polymerisation of acrylontrile by means of radical ions have also been expressed.[113]

3. Photoinitiation of polymerisation with the final products of electron phototransfer

In this section we shall examine the polymerisation processes that are initiated by the products of complete electron transfer in redox systems of radical ions. This applies to polymerisation initiated by EPT.[147,148] It has a specific nature which at the present time is still far from understood.

The possibility of initiation of polymerisation by radical ion species is influenced by a considerable effect from the polarity of the medium, its acidity or basicity. Thus, polymerisation initiated with radical anions occurs preferentially in more basic solvents while that initiated with radical cations is preferred in more acidic solvents.[91,149]

No less important a factor is the stability of solvent-separated radical ions. Depending on this, either the rapid combination of radical ions or the formation of a neutral radical producing a polymerisation chain by a free-radical mechanism is possible.

a) Photoinitiation systems of monomer–activator

Table 2 lists a number of binary systems (1–18), one component of which is the monomer. In the majority of cases the latter functions as the photoactive partner of the mixture. *N*-Vinylcarbazole (VC) and α-methylstyrene, which participate in cationic polymerisation, are good electron donors. Their ionisation potentials are equal to 7.42 and 8.35 eV respectively.[114] Systems with styrene,[110] *p*-methoxystyrene,[152] and phenyl vinyl ether[153] which as a result of electron phototransfer form radical cations that cause cyclodimerisation have not been included in Table 2. The latter may be regarded as a chain reaction that differs from polymerisation in the length of the chain.

Cyclohexene oxide is a weaker electron donor. As a result of interacting with strong electron acceptors it forms a radical cation and causes polymerisation by a cationic mechanism. Interestingly, in the presence of nitroethylene (system 16) polymerisation occurs simultaneously by cationic and anionic mechanisms.[109] Weak electron acceptors such as maleic anhydride and methyl methacrylate in the ternary system tetrahydrofuran–maleic anhydride–monomer (system 17) cause polymerisation by an anionic mechanism.

Indirect evidence for the ionic polymerisation route and the presence in these systems of the respective radicals ions is given in Table 2. Direct evidence has only been obtained for two monomers—α-methylstyrene (systems 7 and 8) and VC (systems 5–7, 12, 13). Singlet and triplet exciplexes of α-methylstyrene with tetracyanobenzene and pyromellitic dianhydride have been detected using pulsed spectroscopic methods.[104, 105] In methylene dichloride and n-amyl alcohol these exciplexes dissociate to radical ions that have been recorded using pulsed photoconductivity. However, the rate of recombination of the radical ions which are formed from singlet-excited molecules is so high that they can only be reliably observed at low temperatures (below −40 °C).[121] The lifetime of ion radicals formed in a triplet route is considerably longer (of the order of tens of microseconds). This time is sufficient for the resulting cation radicals to undergo a chain propagation reaction. The sequence of reactions of a monomeric radical cation of α-methylstyrene to dimeric and trimeric forms, etc. has been observed from the respective absorption spectra. Introduction of air caused an almost complete cessation of the photocurrent and termination of polymerisation. Since the generation of cation radicals of α-methylstyrene capable of initiating a polymerisation chain has been carried out using a triplet route, these systems are unfortunately also sensitive to oxygen, like the photoinitiating components for free-radical polymerisation.

VC behaves differently. On excitation with light at $\lambda \geqslant 350$ nm it forms fluorescing exciplexes with dimethyl terephthalate, diethyl fumarate (system 8),[9] and with thiobenzophenone (system 11) (in the latter case, however, the thiobenzophenone molecule is excited).[90,103]

The rate constant of formation of exciplexes is of the same order as the diffusion constant. Radical cations of VC that are formed by photodissociation of singlet exciplexes have been recorded by pulsed methods.[154] They are involved in the generation of a polymerisation chain in systems 6–11. Arguments in favour of a cationic mechanism of polymerisation are provided by the results when it is carried out in nitrobenzene, which serves as a free radical "trap" (see Table 1) and by its inertness towards oxygen. Furthermore, it was established that in a number of cases oxygen assists the cationic polymerisation of VC. It can act as a co-initiator, interacting with VC to form a stable radical anion, being a counterion for the radical cation of monomer. Moreover, it promotes chain transfer during cationic polymerisation.[91,155]

The ability of VC in the presence of electron acceptors to initiate polymerisation by a cationic mechanism was discovered in the 1970s.[99,102] Before then it was assumed that it could only cause polymerisation by a free-radical mechanism. However, polymerisation, as a rule, was carried out in solvents with a high basicity (acetone, tetrahydrofuran, dimethylformamide). The generation of free radicals in this case was achieved from a triplet-excited state of VC. By changing to solvents with a higher acidity it was possible to alter the mechanism of polymerisation when mixtures of VC and acceptor-type activators were used. It appeared that the charge-transfer complexes and exciplexes formed by these mixtures could generate charged primary active products. At the same time the efficiency of initiation of cationic polymerisation with exciplexes is higher than with charge-transfer complexes.[104] The reason for this is not clear. One of the explanations put forward by the authors is the more favourable geometry for electron transfer in an exciplex than in a charge-transfer complex.

b) Initiation systems of photoinitiator – activator

The advantage of these over the systems examined above is obvious. Firstly, with a wide series of photoinititors and activators being available, it is possible to select those systems which achieve a high probability of free electron transfer and the formation of active products. Secondly, by using suitable photosensitive compounds it is possible to extend the spectroscopic sensitivity and increase the total sensitivity of the polymerising system. Unfortunately, the mechanism of the action of most photoinitiating systems of initiator–activator is so far unclear. However, as was mentioned above, it is highly probable that these systems (24 and 25) can generate radical ions that are capable of initiating and producing a polymerisation chain.

More definite information indicating a change in mechanism of initiation from free-radical to radical-ion has been obtained for the binary systems 31 and 32. The photoactive components in these are heteroaromatic (phenazine, acridine, and their derivatives) or aromatic (anthracene and its derivatives) compounds. Depending on their partner they act as an electron donor (system 31) or electron acceptor (system 32). Redox systems that include them initiate the polymerisation of butyl methacrylate. The latter can participate in chain propagation by both a free-radical and an anionic mechanism.[90] However, in benzene photopolymerisation occurs at an extremely slow rate. When acetonitrile is added the rate of polymerisation increases by a factor of 10^1-10^3. The dependence of $\lg V$ on the Kirkwood polarity function is linear and has a positive gradient.[122,123] With an increase in ε, semi-reduced radicals of heteroaromatic or aromatic compounds were not detected in any of these systems, nor were ketyl radicals of benzophenone, which would suggest proton transfer. On the other hand in acetonitrile a photocurrent developed, that was induced by excitation of photoactive mixtures with a pulsed laser. It originates from the solvent-separated radical ions formed as a result of complete electron transfer between the partners of the mixture.

Interestingly, in system 31 the signal due to the photocurrent disappeared after the introduction of atmospheric oxygen while in system 32 it persisted under these conditions.

There are other arguments that suggest the electron donor-acceptor nature of the interactions in these mixtures. Thus for system 31 there was a correlation between the rate constant for deactivation of triplet-excited molecules of phenazine derivatives and the Hammett σ-constants of substituents in the benzophenone molecule acting as an electron acceptor. The reaction constant $\rho = 1.1$ (Fig. 1*a*). It is significant that a value of $\rho = 1.0$ (Fig. 1*b*), which is similar to it, was obtained for the correlation between the rate of polymerisation V and the same parameters.[122] This is one of the most serious arguments in favour of the electron donor-acceptor interactions of triplet-excited phenazine molecules with electron acceptors playing a decisive role in the overall photopolymerisation process.

It was established for system 32 that the partners of photoinitiating mixtures form singlet fluorescing exciplexes with a considerable degree of charge transfer.[156,157] It is these which take part in the subsequent chemical reactions that are responsible for the generation of primary active products. As well as binary exciplexes, ternary singlet photoinitiator–activator–monomer exciplexes were detected, having a characteristic fluorescence band that is shifted towards the "red" end of the spectrum relative to the fluorescence of the binary exciplex (Fig. 2). Since charge-transfer interactions also make a considerable contribution to the stabilisation energy of a ternary exciplex, it may be assumed that with an increase in polarity of the medium it will be converted to a "loose" ionic triad occurring in a solvent cage.[160]

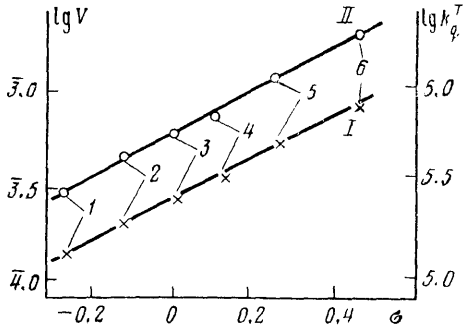


Figure 1. Dependence of the rate constant of deactivation of triplet states of 2-dimethylaminophenazine (line *I*) and the rate of polymerisation initiated with 2-dimethylaminophenazine in the presence of benzophenone (line *II*) on Hammett σ-constants of substituents in the acceptor molecule: *1*) 4-OCH_3; *2*) 4-CH_3; *3*) 4-H; *4*) 4-C_6H_5; *5*) 4-Cl; *6*) 4,4′-$(Cl)_2$.

From what has been stated it may be concluded that in systems 31 and 32 the primary active products in polar media are radical ion pairs, solvent-separated radical ions, and also "loose" ionic triads rather than neutral radicals which are mainly formed in a non-polar medium. They initiate polymerisation, which was taken into account in a kinetic scheme of initiation with systems 31 and 32. A whole

series of relationships confirming the experimental results follows from the expression for V obtained on the basis of this scheme. These are primarily the agreement between the values of the exponents in the equation for V (see Table 2) and the series of rate constants of the fundamental stages that are determined from this expression and by using independent experimental methods.[122] Consideration should be given to the value of the ratio k_p/k_t determined from this expression. It is equal $(3.1-3.8) \times 10^2$, which corresponds to values that are typical for the anionic polymerisation of vinyl monomers, in which generation of the chain involves radical ion pairs (see Table 1).[162] An argument in favour of the involvement of radical ion pairs rather than solvent-separated radical ions in initiation is the low reaction constant $\rho = 0.18$ for the correlation dependence of $\lg(k_p/k_t)$ on the Hammett σ-constants of substituents in the benzophenone molecule (system 31). In fact, by conducting the polymerisation in acetonitrile it is not possible to achieve a value of $\varepsilon > 20$. With such a value of ε it is doubtful whether the ionic "triads" can be converted to solvent-separated radical ions (we should note that the values of k_q are equal to 10^7-10^8 litre mol^{-1} s^{-1} for the quenching of fluorescence from the binary exciplexes with a monomer in this case).

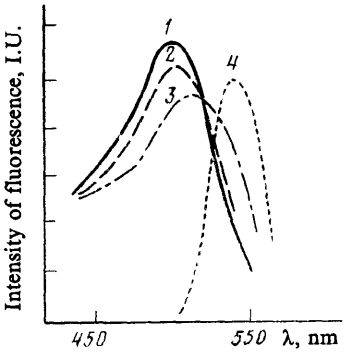

Figure 2. Effect of addition of butyl methacrylate (BMA) on the fluorescence intensity of the exciplex of anthracene with *N,N*-dimethylaniline. *1*) $C_{BMA} = 0$; *2*) $C_{BMA} = 1$ mol litre^{-1}; *3*) $C_{BMA} = 2.5$ mol litre^{-1}; *4*) differential fluorescence spectrum of ternary complex on a scale of 1 : 4.

From the expression obtained for V (Table 2) it is possible to account for the effect of the electronic structure of the photoactive components of system 32 on the rate of polymerisation. It results from the different thermodynamic and kinetic conditions of electron transfer between the components of the photoactive mixtures of system 32.[123]

The latter system is also of intereest in that for the first time the formation of a ternary excited complex involving a monomer has been detected in it. The possibility that it is formed followed logically from the results of more recent studies, including also those for system 31.[10,26,113] The advantage of agglomerates of this type is that polymerisation initiated and carried out with their participation is less sensitive to the effect of inhibitors.[89,147] Moreover, systems 31 and 32 demonstrate the real possibility of a change in the multiplicity of the excited state of the photoactive component participating in photoinitiation through a suitable choice of partners. This in turn suggests the possible ways of conducting polymerisation in the presence of oxygen during photogeneration of the primary active products in a singlet route and generation of the polymerisation chain by a cationic mechanism.

These conditions are met when photoinitiation system 33 is used, which is involved in polymerisation that occurs in the presence of oxygen. Perylene, which absorbs light with $\lambda \geqslant 436$ nm, serves as the photoactive component in it, dicyanobenzene is the activator, and VC is the monomer. As a result of light absorption the singlet-excited molecules of perylene donate an electron to dicyanobenzene. The rate constant of fluorescence quenching of perylene, which results from this process, is of the same order as the diffusion constant.[23] The resulting radical cation of perylene initiates polymerisation of vinylcarbazole through electron transfer from the latter. Photopolymerisation in acetonitrile in this case takes place under mild conditions—at room temperature in air. In strongly polar solvents with well-defined basic properties (dimethylformamide, dimethyl sulphoxide) it does not take place. A sixfold increase in the rate of photopoymerisation initiated with the binary mixture perylene–dicyanobenzene relative to initiation with perylene is recorded. It is likely that in the system perylene–activator–monomer an effective separation of charges is achieved, producing a marked acceleration of polymerisation.

IV. Conclusion

Thus photoinitiation systems whose action is based on electron phototransfer that occurs in an exciplex or another of its intermediates are highly effective. Neutral protonated and deprotonated radicals, radical ion pairs or solvent-separated radical ions can initiate polymerisation. In the first case the polymerisation chain is generated by a free radical mechanism while in the second case an ionic mechanism occurs. With all of the systems it is possible to carry out polymerisation by exposure to low-energy light quanta.

Radical polymerisation. The advantage of these initiating systems lies in the fact that by forming exciplexes or other electon transfer intermediates they create favourable conditions for the subsequent transfer of a proton between the partners. With a suitable choice of the components of photonitiating mixtures, based on an analysis of their thermodynamic and kinetic properties, it is possible to optimise their composition. Thus, for example, if tertiary aromatic amines that generate α-aminoalkyl radicals are used as activators, the latter can both initiate polymerisation and retard the inhibitory action of oxygen by reacting with it (see systems 37 and 38 in Table 2). In a number of cases systems that form a ternary complex with oxygen are used. The oxygen in them acts as an intermediate agent in electron transfer. Here, as in the previous case, peroxide radicals are formed, which also take part in the generation of the polymerisation chain (system 40).[130] The use of a monomer containing an amino group as the activator has future potential. The undesirable effect of oxygen can be inhibited in this way (system 40).[129]

Polymerisation initiated by electron phototransfer. In this case the choice of partners of the initiating mixture must guarantee a high probability of complete electron transfer followed by charge separation. An important condition for this to be fulfilled is $k_{ET} \gg k_{PT}$. It is necessary to bear in mind, however, that if anionic polymerisation occurs, whatever the multiplicity of the excited state of the photoinitiator it is not possible to exclude the inhibitory effect of oxygen.

If polymerisation occurs by a cationic mechanism and the photoinitiator "operates" in a singlet-excited state, oxygen does not

as a rule suppress it. The rate of polymerisation will depend to a large extent on the polarity of the medium and its acid-base properties. The latter influence the effectiveness of anionic polymerisation to the same extent.

Special requirements should be imposed on the choice of photoinitiator dictated by the mechanism of polymerisation. In this case it is mainly necessary to take into account the electronic configuration of the lowest excited states that take part in reaction and their multiplicity. Thus, if the formation of active primary radicals is based on secondary proton transfer reactions, the use of photoinitiators that have a considerable contribution of the $n\pi^*$ electronic configuration to the lowest excited state is preferred. This assists rapid proton transfer. When the secondary reaction is complete electron transfer with a passage of radical ions into the surroundings, systems with a significant or complete contribution of the $\pi\pi^*$ electronic configuration to the lowest excited state are more advantageous.

Finally, in order to improve the efficiency of initiation of polymerisation with radical ions it is necessary to ensure a more complete separation of charges. This can be achieved as a result of the formation of ternary initiating systems of photoinitiation–activator–monomer. In these one of the components acts as an electron transfer agent (mediator) between the second partner and the monomer (systems 31, 32, 35, 36). The second method involves the use of photoinitiators that have quaternary ammonium salts as a secondary substituent[164] or the use of activators connected to the π-electron skeleton of the molecule by a methine bridge.[165] Finally, very effective systems in which onium compounds are used as the partners of the photoinitiator (system 41) [131,132] have recently been developed.

Asymmetric epoxidation

Yu E Raifel'd, A M Vaisman
Lomonosov Moscow Institute of Fine Chemical Technology, Moscow

ABSTRACT. **The data on asymmetric epoxidation that have been obtained in recent years are correlated. Particular attention is given to the epoxidation of allylic alcohols with Sharpless reagent, which is a chemical complex of a titanium alkoxide with dialkyl tartrate. The structure of the catalyst, a model of the transition state, and the reaction mechanism are examined.**

The bibliography includes 242 references.

III. Asymmetric epoxidation in the presence of a chiral titanium–tartrate 125

I. Introduction

In recent years the epoxidation of olefins—an important and frequently used reaction in organic synthesis—has acquired increasing significance as a method for the synthesis of chiral compounds. Enantioselective epoxidation, which results in the formation of two chiral sites in a single stage, yields optically active oxiranes, which are synthons for the preparation of natural compounds and their analogues. Of particular importance is the use of oxiranes in an optically pure form in the production of drugs, pheromones, etc.[1,2]

Chiral oxiranes play a significant role in the active processes of plants and animals. They are intermediates in biological synthesis. For example, the important function of 2,3-epoxysqualene in the biosynthesis of terpenes and steroids is well-known. By studying asymmetric epoxidation (AE) it is possible to establish the mechanism of many biological processes. Epoxidation is one of the fundamental stages during the exchange of substances in plant cells and animal organisms.[3] In many cases oxiranes participate in the catabolism of pesticides, drugs, and other xenomorphic comounds.[3,4] Hydroxylation, which is a key stage in the metabolism of aromatic amino acids, drugs, and vitamins in living organisms, occurs via an epoxidation reaction.[5] Intermediates containing an oxirane ring that are formed during the oxidation of aromatic hydrocarbons function as carcinogenic, mutagenic, and cytogenic agents.[5] Some natural epoxy compounds have juvenile hormonal activity.[6–8]

The physiological activity of many natural compounds containing an epoxide ring and the important role of oxiranes in the synthesis of natural compounds have determined the need for research into effective methods and a study of the mechanism of enantioselective epoxidation. A survey of the methods of AE is the aim of the present review, in which epoxidation using Sharpless reagent, which has been studied the most comprehensively in direct relation to the mechanism of this reaction, occupies a central position.

II. Methods of asymmetric epoxidation

AE was first reported to have been carried out by Henbest in 1965.[9,10] By epoxidising olefins with an isolated double bond with (+)-peroxycamphoric acid it was possible to obtain oxiranes with an enantiomeric excess (EE) of less than 5%. Despite the low optical purity of the compounds obtained, this reaction played an important role since for the first time the possibility of synthesising chiral oxiranes from achiral precursors was demonstrated. The attempts made subsequently to carry out AE using other peroxides were not successful in increasing the optical purity of oxiranes above 10%.[11–18] In 1977 Pirkle again studied this method and found that the peroxycamphoric acid which had been used in previous experiments was insufficiently pure.[19] As a result of purifying the oxidising agent it was possible to increase the enantioselectivity of the reaction by a factor of more than 2. By using the purified peroxyacid in the epoxidation of imines it was possible to obtain oxaziridines with an EE of >60%. In the majority of the cases mentioned above the low asymmetric induction at the stage involving oxygen transfer is probably due to the considerable distance of the electrophilic atom of the peroxide oxygen from the asymmetric centre and hence to the weak interaction between this centre and the double bond in the transition state (Fig. 1*a*).[20]

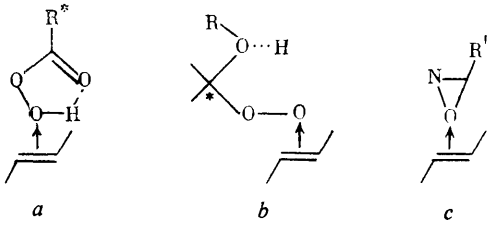

Figure 1. Transition state in the epoxidation of olefins with chiral peroxyacids (*a*), α-substituted hydroperoxyketals (*b*), oxaziridines (*c*).

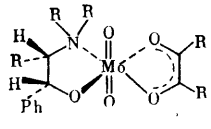
The epoxidation of olefins with different chiral α-substituted hydroperoxyketals occurs with low asymmetric induction (EE <5%).[21] This value, in the opinion of Finn and Sharpless,[22]

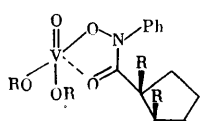
could be increased since in this case the chiral centre is closer to the reaction site than for chiral peroxyacids (Fig. 1*b*).

Considerable success was achieved in the epoxidation of olefins with oxaziridines. In the transition state (Fig. 1*c*) the interaction between the chiral centre and the double bond is greater than when peroxyacids are used.[23–25] The maximum EE of these reactions was 65%.[24,25]



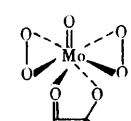
Use of the dioxiranes obtained by reaction of potassium peroxomonosulphate with chiral ketones for asymmetric induction in the epoxidation of olefins results in the formation of epoxy compounds with a low enantioselectivity (EE 4–13%).[26]

Epoxidation with hydrogen peroxide, t-butyl hydroperoxide (TBHP), or with hypochlorite of α,β-unsaturated acids, aldehydes, ketones, and other olefins whose double bond is conjugated with strongly electronegative substituents gives chiral epoxy compounds when a two-phase system and an optically active phase-transfer catalyst are used. In this case the enantioselectivity of the reaction varies from 1.2–5.4% EE (quaternary salts of quinone added to a polystyrene matrix comprise the phase-transfer catalyst),[27] 11% EE in the presence of cyclodextrins,[28–30] up to values of 55–78% EE when phase-transfer catalysts based on cinchona alkaloids[31] and quinine derivatives[32–37] are used. Much more effective phase-transfer catalysts are the so-called synthetic enzymes—polyamino acids—which can be used to epoxidise prochiral olefins with a high enantiomeric purity (EE up to 100%).[38–43] Epoxidation in this case takes place in a three-phase system—α-amino acid/aqueous phase/organic phase.



AE with hydrogen peroxide in an aqueous solution of sodium hydroxide under phase-transfer conditions using optically active solvents as the organic phase has been reported.[44] Chiral crown ethers have been used for asymmetric induction under phase-transfer conditions.[45] Epoxidation of olefins with aromatic substituents by hydrogen peroxide in the presence of (+)- or (−)-cyanoheptohelicene gives chiral oxiranes with an optical purity of 97–100%.[46]

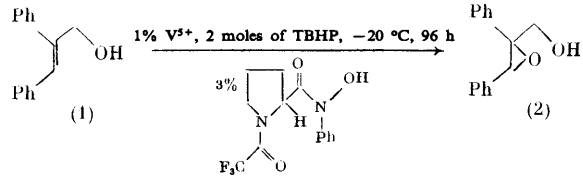
Oxiranes with an EE of about 10% have been obtained by Darzens condensation in the presence of chiral compounds such as quinine salts.[47,48] Quinine salts have also been used for asymmetric induction in the epoxidation of prochiral olefins with molecular oxygen.[49]



During the last twenty years there has been increased interest in transition metal complexes as catalysts for AE.[50,51] One of the advantages of processes catalysed by transition metals is the possibility of varying the structure of the ligands for modifying catalytic processes. In the case of chiral ligands, the substituents will in all probability be arranged asymmetrically about the chiral centre. On the basis of this assumption, Yamada[52] and Sharpless et al.[53] used chiral complexes of molybdenum (I) and vanadium (II) for the first time in order to carry out the asymmetric epoxidation of allylic alcohols with organic hydroperoxides.

(I)

(II)



(III)

R = CH_3

A number of reports were later published on the epoxidation of prochiral olefins with various chiral molybdenum oxodiperoxo complexes used in stoichiometric amounts[54–59] [this reaction was carried out for the first time using complex (III)] and on the asymmetric epoxidation of olefins with organic hydroperoxides when a catalytic quantity of chiral dioxomolybdenum complexes [similar to complex (I)] were used.[60–63] On treatment of molybdenum oxodiperoxo complexes in the presence of chiral diols it was possible to obtain an oxirane with an EE of 95.4% in the epoxidation of olefins with an isolated double bond.[59] Lower asymmetric induction occurred in the epoxidation of olefins with an isolated double bond by hydrogen peroxide in the presence of chiral platinum complexes modified with diphosphines (EE 41%)[64] and also chiral complexes of iron porphyrin (EE about 51%).[65] In the latter case oxo compounds obtained by oxidation of iron porphyrin with iodosylbenzene constitute the epoxidising agent. Chiral complex iron compounds have also been used for AE of styrene derivatives (EE about 50%).[66–68]

The use of aluminium alkoxides and chiral hydroxamate ligands for carrying out the AE of allylic alcohols with TBHP has been reported (EE 30–40%).[69]

The AE of substituted allylic alcohols catalysed by vanadium complexes involving more than 20 chiral hydroxamate ligands has been studied.[70–72] The maximum enantioselectivity was achieved in the epoxidation of (*E*)-α-phenylcinnamic alcohol (1) [EE of epoxyalcohol (2) was 80%]:

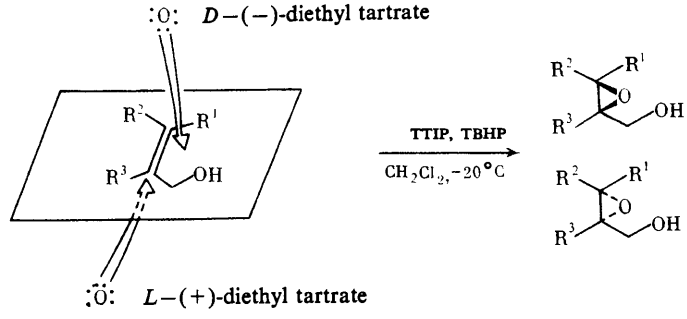


Figure 2. Asymmetric epoxidation of prochiral allylic alcohols.

In addition to chemical methods, other ways of obtaining chiral oxiranes are also known. One of these is the microbiological epoxidation of olefins.[73–82] The enantioselectivity of the reactions catalysed by the enzymes secreted by microorganisms depends on metabolic by-products of the microorganisms, which can cause inhibition of the reaction. Enzymatic epoxidation has been used to obtain oxiranes with a high EE.[83–87] For example, a high degree of enantioselectivity can be achieved when globular proteins such as bovine serum albumin (BSA) are used as catalysts.[88–91] In particular, AE of 2-substituted naphthoquinones with hydrogen peroxide and TBHP in a buffer solution containing an organic

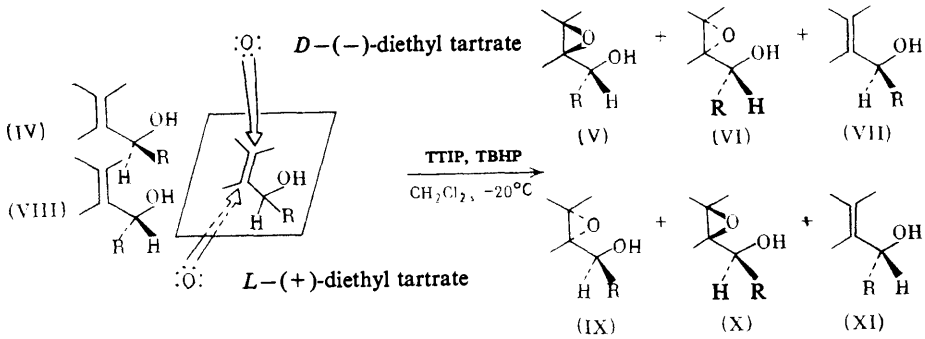

Figure 3. Kinetic resolution of racemic secondary allylic alcohols.

solvent and BSA results in the formation of chiral oxiranes with an EE of up to 100%. Asymmetric induction in this case is due to BSA occurring in the form of α-helices with hydrophobic groups capable of bonding with water-insoluble substrates situated between the helices. It should be noted that AE catalysed by enzymes is only suitable for a narrow range of substrates and its effectiveness is determined to a considerable extent by the reaction conditions.

III. Asymmetric epoxidation in the presence of a chiral titanium−tartrate complex

Directed research on chiral ligands was carried out in order to obtain an effective AE catalyst based on titanium and vanadium compounds.[71,72] This culminated in 1980 with the publication of the first report on an unusually effective method of enantioselective epoxidation that gave chiral oxiranes, the absolute configuration of which depended only on the configuration of the tartrate used and not on the structure of the substrate.[92,93] Soon afterwards Sharpless et al found that this unique combination of titanium alkoxide, optically active tartrate ester, and TBHP was sensitive to chirality existing in the substrate and could be used for the kinetic resolution of racemic allylic alcohols.[94,95]

AE has been used quite frequently and at the present time it is the most successful means of obtaining optically active oxiranes with high enantiomeric purity. Since the publication of the first report on AE using Sharpless reagent, a large number of studies and several reviews devoted to the use of this reaction and an investigation of its mechanism have been published.[20,22,96–106]

1. Reactivity of substrates and enantioselectivity of asymmetric epoxidation

A scheme for AE of allylic alcohols with Sharpless reagent is shown in Fig. 2. As a result of coordination of the titanium atom of a chiral complex consisting of titanium tetraisopropoxide (TTIP), dialkyl tartrate, and TBHP with the hydroxyl group of the compound undergoing epoxidation, the faces of the plane of the double bond become nonequivalent. For this reason attack by the oxygen atom of the peroxide occurs preferentially from one of these faces depending on the absolute configuration of the tartrate used, resulting in the preferred formation of one of the two possible enantiomers of the epoxy alcohol. By studying the stereochemical structure of a large number of α-hydroxyepoxides obtained by AE of allylic alcohols, it was possible for Sharpless et al[22] to develop a rule for the enantioselectivity of this reaction. If the allylic alcohol is drawn in a plane as shown in Fig. 3, attack by the oxygen atom on the double bond when *L*-(+)-tartrate is used occurs from below, while when *D*-(−)-tartrate is used attack occurs from above. This rule has no known exceptions amongst prochiral substrates at the present time. It can be used to predict easily and accurately the absolute configuration of the resulting epoxyalcohol, which is one of the significant merits of this reaction.

By comparing the results of epoxidation of allylic alcohols with different structures it is possible to establish the mechanism of AE.

1. The rate of the reaction, as when epoxidation is carried out by other methods, increases with an increase in electron density on the double bond of the olefin.[22,107] For example, a comparison of the rates of epoxidation of unsubstituted (4) and substituted cinnamic alcohols (Table 1) shows that the introduction of an electron-withdrawing nitro group reduces the rate of epoxidation [compound (3)] while an electron-donating methoxy or chloro group increases the rate of reaction [compounds (5) and (6)].

2. The rate of epoxidation of (*Z*)-allylic alcohols [compounds (7)−(24), Tables 2 and 3] with a substituent on the C(3)† carbon atom (Tables 2 and 3) is lower than for (*E*)-allylic alcohols [compounds (1), (4), (25)−(42), Tables 4 and 5].[108]

At the same time the enantioselectivity of the reaction is also somewhat less. For example, (*E*)-allylic alcohol (30) with a t-butyl substituent on the C(3) carbon atom is epoxidised with high optical purity, whereas the enantioselectivity of AE of (*Z*)-allylic alcohol (12) is low.

3. The optical purity of the α-hydroxyepoxides obtained from (*Z*)-allylic alcohols with a substituent on the C(3) carbon atom depends on the steric structure of the substituent (Table 2).[108] In compounds (7)−(9), (11), (15)−(20), containing an unbranched substituent, the enantioselectivity is high (EE 80−95%). In the case of compounds with a secondary [e.g. (10)] or tertiary [e.g. (12)] C(4)

† Here and subsequently, if the name of the compound according to the IUPAC nomenclature is not given, the carbon atom bearing the hydroxy group is designated C(1).

carbon atom, the optical purity of the α-hydroxyepoxide obtained is reduced. The same pattern is observed in the epoxidation of 2,3-, 3,3- and 2,3,3-substituted allylic alcohols [compounds (22)–(24), (43)–(49), Tables 3 and 6].

Table 1. Relative rates of asymmetric epoxidation of substituted cinnamic alcohols.[107]

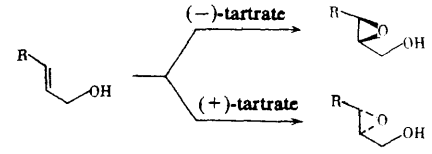
DIPT = diisopropyl tartrate; DET = diethyl tartrate; DMT = dimethyl tartrate.



As in the case of (*Z*)-allylic alcohols with a substituent on the C(3) carbon atom, steric factors have the effect of slightly reducing the EE in the epoxidation of alcohols with a branched substituent on the C(2) carbon atom [Table 7, compounds (55) and (56)] in comparison with the results of epoxidation of alcohols [compounds (50)–(54), (58–(60)] with an unbranched substituent.[108] For the same reason the EE of stilbene α-hydroxyepoxide decreases by 20% when a chlorine atom is introduced into the *ortho*-position of the aromatic group on the C(2) carbon atom.[159]

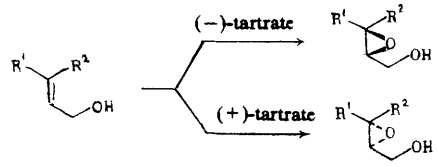
4. The results of epoxidation of optically active (*Z*)- and (*E*)-allylic alcohols with a chiral substituent on the C(3) carbon atom differ. While for (*E*)-isomers (61), (67), and (73)[121,160,161] the presence of a chiral centre has virtually no effect on the results of AE (EE is high whatever the absolute configuration of the tartrate used), in the epoxidation of a (*Z*)-isomer (64) and (70)[160,161] as a result of the interaction between the chiral substituent and the catalyst the stereoselectivity of the reaction depends on the absolute configuration of the catalyst—for one enantiomer of tartrate the diastereoselectivity is high while for the other it is virtually absent because of steric hindrance. (*Z*)-Allylic alcohol (76) is hardly epoxidised at all when either (+)- or (−)-DIPT is used,[121] since in this case the presence of a bulky substituent on the C(3) carbon atom has a substantial effect on the results of AE. It is clear from the examples given that AE of optically active (*Z*)-allylic alcohols can only be successfully achieved when the selected tartrate directs oxygen to the face of the plane of the double bond that is opposite to that in which the bond with the chiral substituent is situated.

Table 5. Asymmetric epoxidation of (*E*)-allylic alcohols with a substituent on the C(2) and C(3) atoms

Compound	R¹	R²	Tartrate	Reaction time, h	Temperature, °C	Yield, %	EE, %	Refs.
(36)	CH_3	CH_3	(+)-DET	–	–	77	94	[140]
(37)	CH_3	C_2H_5	(+)-DMT	16	−20	79	95	[125]
(38)	CH_3	CH_2OBz	(−)-DIPT	–	−15	87	90	[141]
(39)	CH_3	Ph	(+)-DIPT	2	−35	79	98	[109]
(1)	Ph	Ph	(+)-DET	–	–	70	96	[92, 109]
(40)	CH_3	$CH_2CH=C(CH_3)_2$	(+)-DET	12	−23	64	96	[144]
(40)	CH_3	$CH_2CH=C(CH_3)_2$	(−)-DET	12	−23	59	91	[144]
(41)		$-(CH_2)_3-$	(+)-DET	–	–	38	95	[145]
(42)		$-(CH_2)_4-$	(+)-DET	–	–	77	93	[109]

Like optically active (*Z*)-allylic alcohols with a substituent on the C(3) carbon atom, the diastereoselectivity of AE of an allylic alcohol with a chiral substituent on the C(2) carbon atom depends on the absolute configuration of the tartrate used, which follows from an analysis of the results of AE of (3*R*)-3,7-dimethyl-2-methylene-6-octan-1-ol (77):[162]



(77) (78) (79)

(+)-DIPT 96 : 1
(−)-DIPT 1 : 3

5. With an increase in reactivity of the allylic alcohols, the sensitivity of the resulting α-hydroxyepoxides towards opening of the oxirane ring increases, which in the presence of different nucleophiles (TBHP, isopropyl alcohol, titanium alkoxides) results in a decrease in effectiveness of the catalytic complex (the resulting diol is a catalyst inhibitor) and a reduction in yield of α-hydroxyepoxide.[102,107] For example, even with complete conversion of the substrate it is not possible to isolate an α-hydroxyepoxide in the AE of 4-methoxycinnamic alcohol (6), whereas 4-nitro- and 4-chlorocinnamic alcohols (4) and (5) are epoxidised in good yield. Glycidol

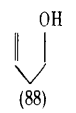
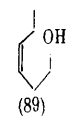
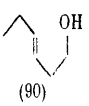
and α-hydroxyepoxides with a substituent on the C(2) carbon atom [compounds (50), (55), (56), (58), (59), Table 7] are particularly sensitive towards opening of the epoxide ring.[92,158]

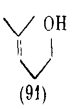
An interesting sequence of AE occurs for symmetric diallylic alcohol molecules. These results were first reported for the AE of (2*Z*, 6*E*, 10*Z*)-dodeca-2,6,10-triene-1,12-diol (80).[163,164] In the epoxidation of alcohol (80), α-hydroxyepoxide (81) is formed with high enantioselectivity together with a small quantity of epoxyalcohol (82). Epoxidation of the second double bond of enantiomers (81) and (82) occurs with the same enantioselectivity as takes place in the first epoxidation reaction. The three epoxides (83)–(85) are obtained as a result of double AE. Since the *meso*-compound (84) can be separated from the mixture and compound (85) is formed in insignificant quantity, the enantiomeric purity of the main product (83) is very high.

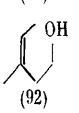
1,1-Substituted allylic alcohols are not effectively epoxidised by a titanium-tartrate complex. For example, AE of 2-methylbut-3-en-2-ol takes place very slowly and it was not possible to isolate the epoxyalcohol.[108] Epoxidation of 2-methyloct-3-en-2-ol results in the formation of the corresponding α-hydroxyepoxide in 67% yield and with an EE of 4%.[117] By replacing the C(1) carbon atom with a silicon atom it is possible to increase the optical purity of the resulting oxirane (87) because of the longer Si=C bond compared to the C=C bond.[165] The lower EE of compound (87b) compared to (87a) is probably due to the steric effect of the phenyl groups.

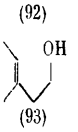


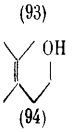








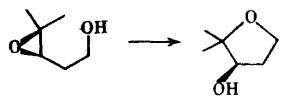




When R = CH_3, the yield of (87) is 50% and EE is 95%; when R = Ph, the yield of (87) is 70% and the EE is 20%.

The AE of homoallylic alcohols has several characteristic features when compared with the epoxidation of allylic alcohols (Table 8).[166]

1. The reactivity of homoallylic alcohols (88)–(94) is lower.

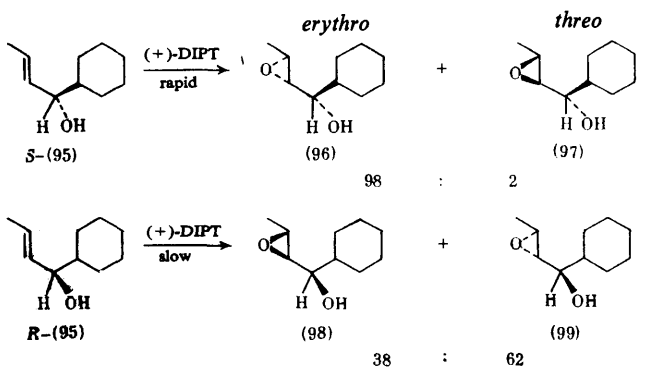


2. The absolute configurations of the hydroxyepoxides obtained by AE of allylic and homoallylic alcohols when the same tartrate ester enantiomer is used are of opposite sign.

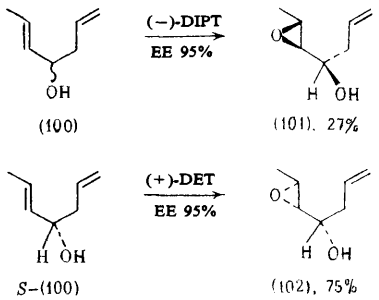
Table 8. Asymmetic epoxidation of homoallylic alcohols.[166]

Substrate	Configuration of epoxyalcohol	Yield, %	EE, %
 (88)	(3*R*)	11–25	[55]
 (89)	(3*T*, 4*S*)	30–50	[36–50]
 (90)	(3*R*, 4*R*)	34–50	[41]
 (91)	(3*R*)	41	[27]
 (92)	–	60	[23]
 (93)	–	15	[23]
 (94)	–	62	[48]

3. The enantioselectivity of AE of homoallylic alcohols is lower than the enantioselectivity of AE of the corresponding allylic alcohols (EE 20–55%). Since the reduction in enantioselectivity of AE of homoallylic alcohols is due to the lengthening of the carbon chain by one methylene unit, in order to study the possibility of increasing the EE of an α-hydroxyepoxide chiral complexes based on zirconium, hafnium, and tantalum, which have a longer metal–oxygen bond than in a titanium complex, were used.[20] It was shown that AE of homoallylic alcohols in the presence of a zirconium tetraisopropoxide complex and (+)-dicylohexyl tartramide occurs with the same enantioselectivity as for epoxidation using the titanium–tartrate catalyst and epoxidation of a (*Z*)-homoallylic alcohol takes place with an even greater EE (up to 77%).[20]



4. β-Hydroxyepoxides are more prone to isomerisation than α-hydroxyepoxides:

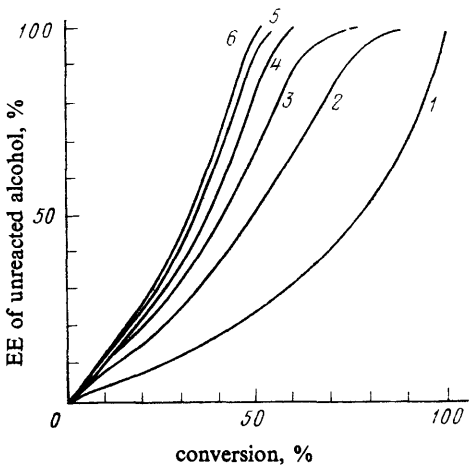


2. Kinetic resolution of racemic allylic alcohols by asymmetric epoxidation

In studying AE of racemic compounds with a secondary hydroxyl group, it is necessary to consider at the same time the enantioselectivity and diastereoselectivity of the reaction. As a result of coordination of the titanium atom of the chiral complex with the hydroxyl group of the compound undergoing epoxidation, two diastereomers of the intermediate complex are formed, AE of which occurs at a different rate, resulting in kinetic resolution of the racemate (Fig. 3).

As in the AE of prochiral allylic alcohols, the direction of attack by the oxygen atom on the double bond of the racemic allylic alcohol is determined by the absolute configuration of the tartrate selected, resulting in the preferential formation of one of the two possible *erythro*-(V) and (IX) or *threo*-(VI) and (X) diastereomers of α-hydroxyepoxide from each enantiomer of the racemate of alcohol (IV) and (VIII). However, as a result of the different orientation of the chiral substituent relative to the direction of attack by the oxygen atom the rates of epoxidation of the enantiomers differ; that enantiomer whose chiral substituent does not cause steric hindrance for attack by oxygen reacts rapidly, and hence its epoxidation leads to the formation of the *erythro*-epoxyalcohol (V) or (IX). For example, in the epoxidation of the allylic alcohol (95) in the presence of *L*-(+)-dialkyl tartrate attack on the double bond form below predominates in accordance with the proposed scheme (Fig. 3).[94,95] In this case the (*S*)-isomer of the allylic alcohol (95), whose chiral substituent does not hinder attack by the oxygen atom, reacts rapidly to form *erythro*-epoxyalcohol (96). For the (*R*)-isomer, because of the interaction between the substituent on the C(1) carbon atom and the catalyst, attack from below is inhibited so the reaction occurs slowly and with low selectivity, the *threo*-diastereomer (99) being predominant. The use of *D*-(−)-dialkyl tartrate gives the opposite result—the (*R*)-isomer of the allylic alcohol (95) is the rapidly reacting one and its epoxidation lead to the formation of *erythro*-epoxyalcohol (98).

Thus, for the reaction of AE with kinetic resolution of racemic allylic alcohols, a high *erythro* selectivity occurs since the isomer that gives an *erythro*-epoxyalcohol is the rapidly reacting one, while the isomer which forms a *threo*-diastereomer is epoxidised slowly and with a correct choice of reaction conditions remains in the mixture as unreacted (VII) and (XI) (Fig. 3). For example, the use of (−)-DIPT in the epoxidation of allylic alcohol (100) results in the formation of epoxyalcohol (101) with an EE of 95%.[167–169] The (*S*)-enantiomer of allylic alcohol (100) remains unreacted and can be epoxidised again in the presence of (+)-DET to form *erythro*-epoxyalcohol (102) with a high yield and EE.



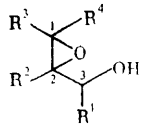


Figure 4. Graph of dependence of EE on conversion for different values of K_{rel}: *1*, 2; *2*, 5; *3*, 10; *4*, 25; *5*, 200; *6*, ∞.

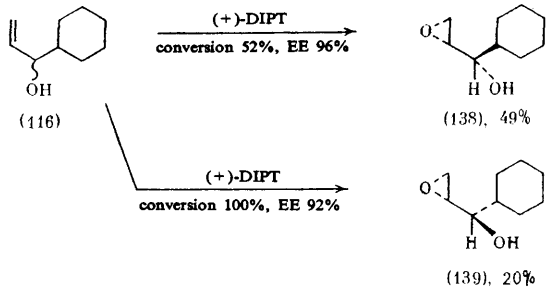

The considerable difference in the rates of epoxidation of the two enantiomers of a racemic allylic alcohol [compounds (103)–(137)] makes it possible to obtain both the α-hydroxyepoxide (Table 9) and the unreacted alcohol (Table 10) with high optical purity. The efficiency of resolution is determined by the relative rate of epoxidation of the allylic alcohols (K_{rel}), which constitutes the ratio of rates of epoxidation of the rapidly reacting to slow reacting enantiomers ($K_{rel} = K_r/K_s$) and varies over a wide range (Table 11).[22] When $K_{rel} = 100$ the reaction is almost as effective as when $K_{rel} = \infty$. Even when $K_{rel} = 15-25$ good results can be obtained.[103] The dependence of the EE of the allylic alcohol remaining in the reaction mixture on the conversion of substrate for different values of K_{rel} is shown in Fig. 4.[94] Analysis of the graph shows that when $K_{rel} = 25$, in order to reach 100% EE of unreacted alcohol, conversion should be less than 60%, which is achieved by reducing the quantity

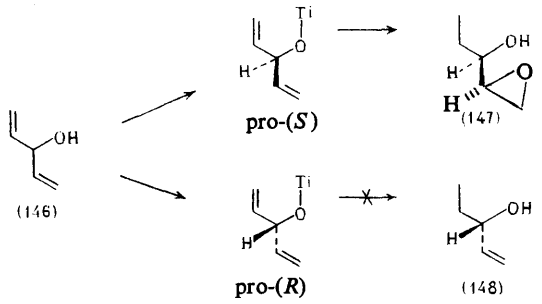
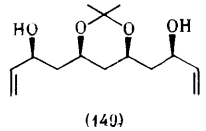
of oxidising agent. If the required reaction product is the optically active epoxyalcohol, a high EE can be achieved at 45% conversion.[108] For example, when AE with kinetic resolution of allylic alcohol (116) is carried out with a conversion of 52%, the *erythro*-epoxyalcohol (138) is formed with an EE of 96%, and with 100% conversion *threo*-epoxyalcohol (139) is isolated with an EE of 92%:[94,95]

For some substrates [compounds (126), (134), (135), and (137), Table 11] the rate of epoxidation of the rapidly reacting enantiomer is low, and the reaction takes quite a long time.[108] In the majority of cases the difference in the rates of epoxidation of the two enantiomers in the resolution of (*Z*)-allylic alcohols is less than for (*E*)-allylic alcohols and the efficiency of kinetic resolution is lower (Table 11).[94,95,107,176] In this case the optical purity of the preferentially formed (*Z*)-*erythro*-epoxyalcohol may be high, whereas (*Z*)-*threo*-epoxyalcohols are similar to racemates.[176] If the substituent on the C(3) carbon atom of the (*Z*)-allylic alcohol is branched, resolution of the enantiomers becomes virtually impossible, which is consistent with the general tendency towards a reduction in rate and enantioselectivity of AE for the analogous prochiral allylic alcohols. For example, asymmetric epoxidation with kinetic resolution of (*E*)-allylic alcohol (140) is complete after 15 h and results in the formation of α-hydroxyepoxide (141) and allylic alcohol (*R*)-(140) with a high EE (>96%), the (*Z*)-isomer (142) is ineffectively resolved (EE 10%):[94,95]



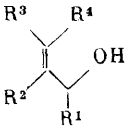
An interesting case of diastereoselectivity and enantioselectivity in AE with kinetic resolution of the racemic diene (143) using a titanium–tartrate system has been described by Sharpless:[123]



In this case it is possible to obtain eight monoepoxides. The

mechanism of AE of secondary allylic alcohols causes the preferential formation of a single monoepoxide. Firstly, from the dependence of the rate of epoxidation of allylic alcohols on the electron density of the double bond, it is to be expected that the reactivity of the disubstituted double bond is higher than that of the monosubstituted double bond. Secondly, the choice of tartrate enantiomer dictates the direction of attack on the double bond by the oxygen atom of the peroxide. And finally, the *erythro*-selectivity in AE with kinetic resolution of secondary allylic alcohols gives rise to the formation of a single monoepoxide. Thus, when (−)-DIPT is used, as a result of AE with kinetic resolution of the racemic diene (143), the (*R*)-*erythro*-epoxycarbinol (144) is mainly formed. A second asymmetric epoxidation of (144) using (+)-DIPT leads to the formation of the diepoxide (145).

Secondary allylic alcohols that have two identical substituents, such as divinylcarbinol (146), do not contain a chiral centre, but when they react with a chiral titanium complex the two double bonds become stereochemically nonequivalent (diastereotopic).[108,189–193] In this case AE occurs selectively on one double bond, the choice of which is dictated by the same factors as in the process of AE with kinetic resolution. The same factors that determine the selectivity of AE of chiral allylic alcohols cause the preferential formation of the pro-(*S*)-conformation. Hence, epoxidation of divinylcarbinol (146) gives (2*R*,3*S*)-epoxyalcohol (147).



It should be noted that as a result of AE of the divinylcarbinol a small amount of epoxyalcohol (148), which is enantiomeric to the main epoxyalcohol (147), is also formed, resulting in a reduction in optical purity of the final compound. However, the configuration of the unreacted group of the allylic alcohol in this isomer is favourable for a second epoxidation to take place, and this isomer is converted to the diepoxide at a high rate, so the optical purity of α-hydroxyepoxide (147) increases as a result.[192,194] For divinylcarbinols a mathematical equation relating the optical purity of the product with the rate of epoxidation was obtained. A similar analysis can also be used in the AE of prochiral compounds such as (149).[195]

(149)

The efficiency of kinetic resolution increases when iodo-, chloro-, stannyl-, or silicon-containing substituents are present on the C(3) carbon atom of secondary (*E*)-allylic alcohols [compounds (150)–(167), Table 12].[184–188,196,197] AE of these substrates was used for the first time to obtain compounds such as (2*S*,3*S*)-3-trimethylsilylglycidol from (*E*)-3-trimethylsilylallylic alcohols and 2-trimethylsilylglycidols from 2-trimethylsilylallylic alcohols (124) and (125) (Table 10),[183] and in the latter case it was shown that it occurs with a satisfactory difference in rates of epoxidation of the two enantiomers, although it is less than in the case of kinetic resolution of (*E*)-3-trimethylsilylallylic alcohols.

A study of the effect of steric and electronic properties of the silyl group on the rate of epoxidation showed that the decrease in the overall rate of the process on replacing a carbon substituent by a silyl group was due to differences in the composition of the electron shells of carbon and silicon atoms while the increase in K_{rel} is due to the steric effect of the bulky trimethylsilyl group.[184] The same increase in K_{rel} occurs when a t-butyl group is introduced into the C(3)-position.[184] By studying the AE with kinetic resolution of the racemates of fluoroalkyl-(*E*)-vinylcarbinols (163)–(166) (Table 12), Hanzawa et al[198] were able to conclude that the electronegativity of the fluorine atom plays an important part in this process.

Kinetic resolution during the AE of secondary allylic alcohols with the hydroxyl group in a ring[94,108,123,200–203] occurs with lower optical purity than for acyclic allylic alcohols.

Although asymmetric epoxidation with kinetic resolution has been used most frequently for the resolution of allylic alcohols with a substituent on the C(1) atom, this reaction can be used to resolve the racemate of allylic alcohols (168)–(175) with chiral substituents on other carbon atoms (Table 13). AE of allylic alcohols with a chiral centre that is remote from the hydroxyl group can lead to results that do not conform to the general rules that apply in the epoxidation of secondary allylic alcohols. For example, the efficiency of kinetic resolution of the (*E*)-allylic alcohol (168) is low (although the enantioselectivity of epoxidation is high) while resolution of the (*Z*)-isomer (170) is effective (EE of unreacted alcohol is 95%).

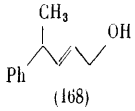
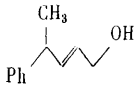
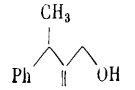
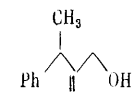
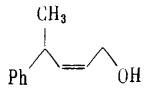
3. Mechanism of asymmetric epoxidation

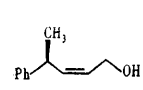


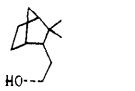


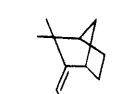


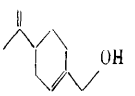


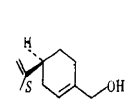


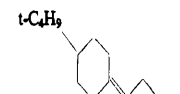


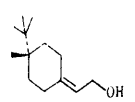


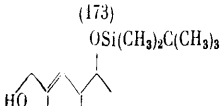


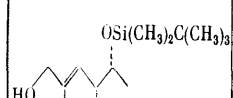


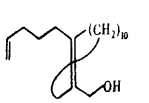


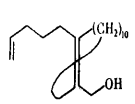








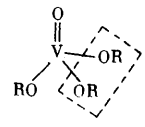




The mechanism of AE and the structural features of the catalyst that govern the high degree of enantioselectivity of reaction for allylic alcohols with different structures have been examined in several studies.[22,107,108,206]

a) Advantage of complex titanium compounds as catalysts for the asymmetric epoxidation of allylic alcohols

Asymmetric epoxidation of allylic alcohols with Sharpless reagent takes place in a similar manner to epoxidation reactions catalysed by other transition metal complexes (Fig. 5).[22,53,70,107,207–216]



The $ML_n(OR)_m$ catalyst [L = oxo ligand, (OR) = alkoxide ligand, $n = 0-2$, $m = 2-4$ depending on the metal M][106,213,214] bonds covalently with the alkyl hydroperoxide and allylic alcohol, thus activating the peroxide. Epoxidation of the substrate occurs via the intermediate complex (XIV).[22,53,70,207-216] Although titanium alkoxides are not the most effective of the known epoxidation catalysts, these compounds have a high catalytic activity in the Sharpless method of AE. The success of AE using titanium alkoxides is determined by several properties of these systems.[107]

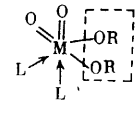


Table 13. Kinetic resolution of primary allylic alcohols.

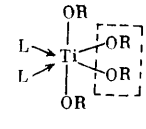

Substrate (configuration)	Recovered allylic alcohol		Refs.
	configuration	EE, %

 (171), (+)-enantiomer		85	[123]
 (172)		48	[123]
 (173)		70	[123]
 (174)		95	[204]
 (175), (+)-enantiomer		>95	[205]

1. Exchange of monodentate alkoxide ligands in solution takes place rapidly, which is also typical for other epoxidation catalysts such as complex compounds of vanadium, molybdenum, and tungsten.

2. In contrast to other highly active catalysts acting as complexing agents, titanium has the four covalent bonds needed for carrying out AE (two for bonding of divalent chiral tartrate, one for TBHP, and one for the allylic alcohol). Formation of a Ti=O bond is difficult, whereas the vanadium complex (XVII) is stable with one and complexes of molybdenum or tungsten (XVIII) are stable with two oxo ligands, which reduces the number of potential sites for bonding chiral ligands.[71,72]

(XVII)

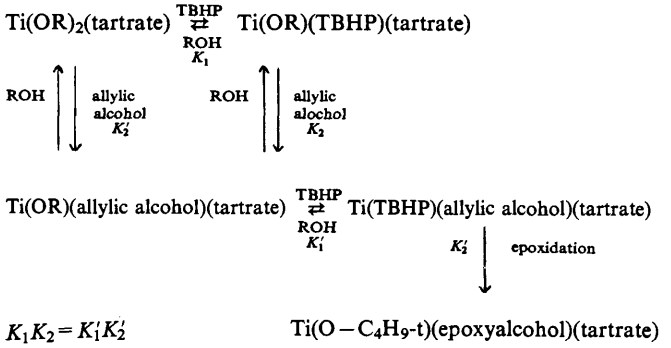
(XVIII)
M = Mo, W

(XIX)

Thus, these compounds can covalently bond three (for vanadium) and two (for molybdenum and tungsten) alkoxide ligands and hence cannot be coordinated simultaneously with allylic alcohol, TBHP, and a bidentate chiral ligand, thus accounting for the low degree of enantioselectivity when AE is carried out in the presence of complexes of these metals.[52-70]

3. Titanium alkoxides are weak Lewis acids and hence to a certain extent they activate the coordinated alkylperoxo ligand for nucleophilic attack on the olefin.[210]

4. The coordination number of the titanium atom can vary.[213-215] This property is also typical for other transition metals, but when they are used as complexing agents for the preparation of chiral catalysts with dialkyl tartrates, AE of allylic alcohols using TBHP takes place slowly and with a low symmetric induction. The absolute configuration of the α-hydroxyepoxides thus obtained is usually the opposite of that which occurs when titanium is used (Table 14).[52-70,106] Evidently the formation of an effective chiral catalyst is determined by titanium's unique set of properties.



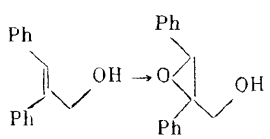
b) Reaction kinetics

On mixing equimolar solutions of titanium alkoxide and dialkyl tartrate, an equilibrium is established, as given by equation (1):[107]

$$Ti(OR)_4 + \text{tartrate} \rightleftarrows Ti(\text{tartrate})(OR)_2 + 2ROH. \quad (1)$$

In the majority of cases this system rapidly reaches equilibrium. However, when bulky alkoxides or tartrates are used to form a complex considerable time may be needed. For example, not less than 20 min is needed from a mixture of $Ti(O-C_4H_9\text{-}t)_4$ and (+)-DIPT, otherwise the EE of the epoxyalcohol obtained is significantly reduced.[22] The equilibrium in Eqn. (1) is considerably shifted to the right, since the binding constant of the diol with the titanium atom is much higher than that with monodentate alcohols. NMR spectroscopic and gas chromatographic data suggest that two moles of aliphatic alcohol occur in solution.[22,107,108] The rapid exchange of ligands continues when peroxide and allylic alcohol are introduced into the reaction medium. In this case the concentration of aliphatic alcohol increases, resulting in a shift of the equilibrium

in solution to the left [Eqn. (1)]. In the majority of cases this shift is insignificant and is suppressed by the addition of excess tartrate. On introducing the substrate and oxidising agent equilibrium is rapidly established, being represented by constants K_1 and K_2, which are equal to ~1 for TBHP and the majority of allylic alcohols.



When TBHP and allyl alcohol replace the two remaining alkoxide ligands of the same titanium atom [as for example in compound (XX)],[210] the oxygen is transferred and t-butanol and a chiral epoxyalcohol are formed, which are again replaced by available allylic alcohol and TBHP. The catalytic cycle is complete when complex (XX) is regenerated.[107] A study of the kinetics of AE showed that the rate of reaction is first order with respect to the concentration of catalyst, peroxide, and allylic alcohol:[107]

$$V_{\text{reaction}} = \frac{k[\text{Ti(tartrate)(OR}_2)][\text{TBHP}][\text{allylic alcohol}]}{[\text{OR}]^2}$$

Transfer of oxygen is the rate-limiting stage.[107]

Table 14. Asymmetric epoxidation with TBHP in the presence of transition metal alkoxides

c) Structure of the catalytic complex

Studies on the kinetics of AE made it possible to reach general conclusions about the reaction mechanism. However, these results do not explain the high enantioselectivity of the process, since there is no information on the structure and characteristics of the titanium–tartrate complex that cause the high enantioselectivity of the reaction for a large number of substrates. A determination of the structure of the complex is, in addition to purely theoretical interest, of practical significance since it can serve as the basis for the development of novel chiral catalysts.[217] For these reasons much attention has been given to studying the structure of the titanium–tartrate complex.[22,107,108,218–225]

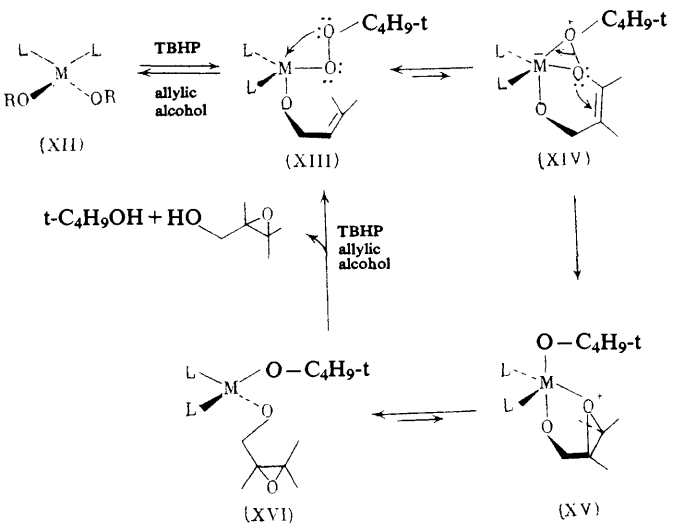

Figure 5. Epoxidation catalysed by transition metal complexes.

The complexity of the problem lies in the fact that because of the rapid exchange of ligands it is not possible to determine the structure of the titanium–tartrate complex participating in the catalytic cycle. Moreover, attempts to isolate the catalyst in crystalline form have proved unsuccessful. Some information about the structure of the complex in solution was obtained by physicochemical methods—mass spectrometry, osomometry, light dispersion, NMR and IR spectroscopy, and isopiestic methods.[22,107,108] In particular, it was shown that in solution a chiral catalyst with a 1:1 ratio of titanium alkoxide to dialkyl tartrate is mainly in the form of the dimer $Ti_2(tartrate)_2(OR)_4$. The formation of a dimeric chiral complex is supported by the nonlinear dependence of the EE of α-hydroxyepoxide on the EE of dialkyl tartrate. Since the enantiomeric purity of the epoxyalcohol is substantially higher than that expected from a linear dependence of the EE of the reaction product on the EE of the chiral ligand, it may be assumed that the high efficiency of the chiral catalyst is due to the inclusion of more than one tartrate ligand in the catalytic complex.[218] A dimeric structure for the catalyst was supported by the results obtained in a study of catalytic complexes containing novel tartrate, tartrate-like, and other ligands.[220–225] From the results of X-ray diffraction analysis of one of these complexes—Ti_2(dibenzyltartramide)$_2(OR)_4$—and assuming the similarity of this compound with the titanium–tartrate complex

$[Ti_2(tartrate)_2(OR)_4]$, the latter was suggested as having the equilibrium structure of a bisymmetric tricyclic dimer consisting of two residues of dialkyl tartrate, each of which is covalently bonded via the oxygen atom of a hydroxyl group with the two titanium atoms (Fig. 6)[224] (in contrast to the previously proposed ten-membered ring).[107] This structure has a C_2 axis of symmetry with the two titanium atoms in the same stereochemical environment. Each titanium atom (coordination number six) is bonded to six oxygen atoms: O(1) and O(2) are the oxygen atoms of the two alkoxy groups, O(3) and O(4) are the oxygen atoms of the hydroxyl groups, O(5) is from the ester group of the first tartrate ligand, and O(6) is the oxygen atom of a hydroxyl group of the second tartrate ligand. Thus, a bridging bond occurs between the two titanium atoms via the two oxygen atoms of hydroxyl groups of the two tartrate molecules, resulting in the formation of a dimeric pseudo-octahedral complex. At room temperature the signals from all of the tartrate groups in the NMR spectrum are identical. When the temperature is lowered the signals undergo a resolution that is typical of a system with asymmetrically bonded tartrate groups of a single type. From the results Finn and Sharpless[22] assumed that an equilibrium is established in solution between the two structures of the complex as depicted in Fig. 6. It should be noted that the geometric configuration of the ligands about each titanium atom in Fig. 6 is depicted for a complex with *L*-(+)-tartrate.[22] It is clear that when the *D*-(−)-enantiomer is used, the configuration of the ester groups of the tartrate will be a mirror image of the structure shown in Fig. 6. Sharpless et al.[22,108] have proposed that only one of the two titanium atoms is involved in the catalytic cycle of AE, but the possibility of both titanium atoms participting is not excluded.

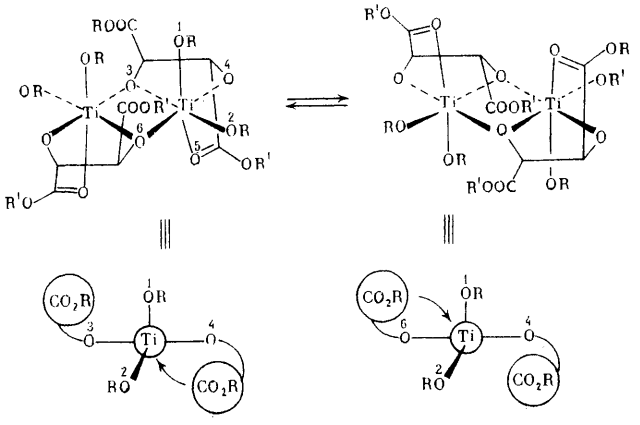

Figure 6. Equilibrium structure of a titanium–tartrate complex in solution.

d) Model of the transition state

The structure of catalyst proposed by Sharpless et al.[22,108] was the basis for a model of the transition state formed by the introduction of peroxide and substrate (Fig. 7). The frontier orbitals on the equatorial oxygen atom of the peroxide make it possible for the allylic alcohol to have four different orientations (Fig. 8).[22,219] The preferred orientation is determined by both stereochemical and stereoelectronic requirements.[22] The structures of (XXIII) and (XXIV) are sterically hindered because of the interaction between the ester group of the tartrate and the C(1) atom of the allylic alcohol. For the remaining structures (XXI) and (XXII) attack by the oxygen atom occurs from opposite sides of the plane of the double bond and hence the exclusion of conformations (XXIII) and (XXIV) does not account for the enantioselectivity of AE. However, the preferred formation of structures (XXI) and (XXII) governs the high stereoselectivity of kinetic resolution of secondary allylic alcohols. The conformation of the intermediate complex in which R^1 = H, R^2 = alkyl substituent is preferred to the conformation in which R^1 = Alk and R^2 = H because of greater steric hindrance in the latter case. For the same reason AE of tertiary allylic alcohols is ineffective.[108,117]

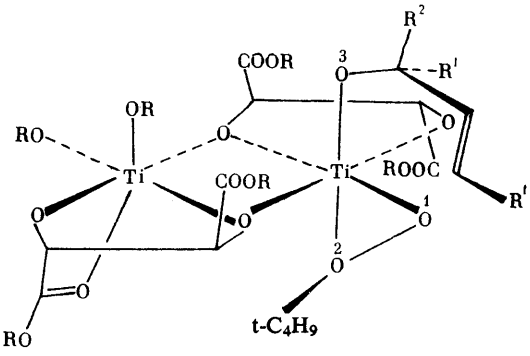

Figure 7. Model of intermediate complex; O(1) and O(2) are oxygen atoms of bidentate peroxide (by analogy with the coordination of TBHP with vanadium)[22,226] and O(3) is the oxygen atom of the allylic alcohol.

The preferred formation of one out of the two possible conformations of the intermediate complex (XXI) and (XXII), which gives rise to the high enantioselectivity of AE, is determined by stereoelectronic factors rather than by steric interactions.[22] An analysis of these factors shows that the *spiro*-orientation (XXI) of olefin and alkoxide with a small O–C/C=C dihedral angle (~30°) is the most probable one, rather than the planar orientation (XXII). The model of the transition state of complex (XXI) is confirmed by calculations using the frontier orbital method.[219] The enantioselectivity rule of AE is satisfactorily accounted for by the proposed structure of the transition state.

By choosing structure (XXI) as the preferred model of the transition state it is possible to account for the other rules of AE.[22] For example, the reduction in enantioselectivity that occurs for (*Z*)-allylic alcohols with a substituent on the C(3) atom is due to steric interactions between the substituent and the C–O bond of the allylic alcohol in conformation (XXI) (dehedral angle O–C/C=C is ~30°). This interaction is small when the substituent is hydrogen and increases as R becomes larger. When R = CH_3 or CH_2R, the

steric interactions result in a decrease in reaction rate while asymmetric induction remains high.

With a bulkier substituent (for example, R = cyclohexyl or phenyl) the rate decreases even more and there is a considerable reduction in EE.[22] The considerable efficiency of kinetic resolution of (*Z*)-allylic alcohols with a chiral substituent on the C(3) carbon atom (in contrast to a secondary (*Z*)-allylic alcohol) can be accounted for in the same way. For example, in the AE of allylic alcohol (170) (see Table 13), depending on the absolute configuration of the tartrate used the position of the phenyl and methyl groups is determined by the steric interactions when the oxygen atom of the hydroxyl group converges with the hydrogen atom on the C(4) carbon atom in the preferred conformation of the allylic alcohol in the transition complex. Thus, it is to be expected that the enantiomer remaining behind after kinetic resolution in the presence of (+)-DIPT will be the S-configuration. In the experiment this enantiomer was obtained with an EE of 95%.[123] The data given are consistent with the results on the dependence of enantioselectivity of AE of optically active (*Z*)-allylic alcohols (64) and (70) on the correspondence between the absolute configurations of the chiral substituent on the C(3) carbon atom and the tartrate used.

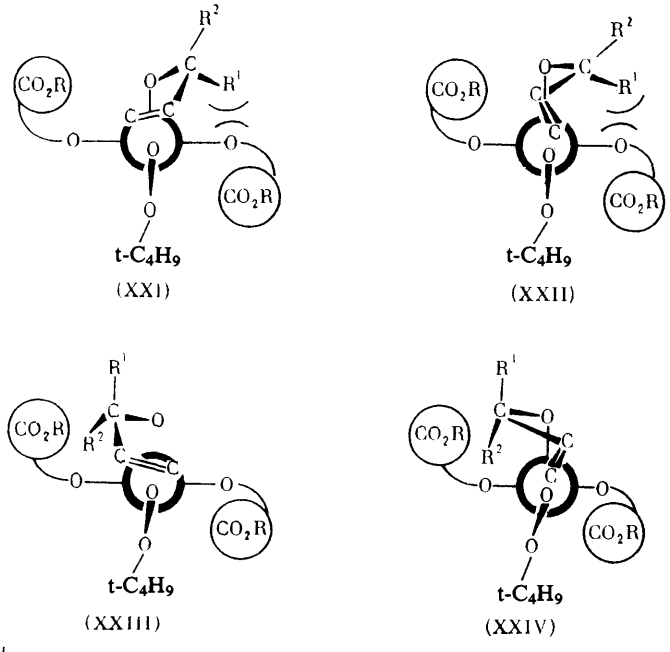

Figure 8. Possible orientations of ligands about the titanium atom in the transition state.

By using the model of the transition state (XXI) it is possible to account for other results of kinetic resolution of primary allylic alcohols with chiral substituents that are remote from the C(1) carbon atom. Thus, 2-(1′-phenylethyl)-2-propen-1-ol (169) (Table 13) in the intermediate complex exists in a conformation in which the hydrogen atom of the chiral site is directed towards the titanium–tartrate catalyst (Fig. 9).[22] By taking into account the steric interactions between the phenyl group (greater) or methyl group (smaller) with the substituent on the C(3) carbon atom of the (*E*)-allylic alcohol, a preferential formation of structure (XXV) is to be expected (Fig. 9). In fact, it was found that during AE with kinetic resolution of the racemate of (169), the (*S*)-isomer remains in the reaction mixture with 80% EE.[123]

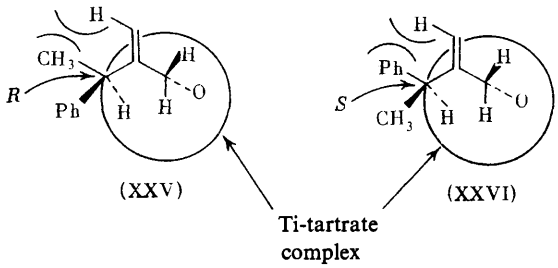

Figure 9. Kinetic resolution of 2-(1′-phenylethyl)-2-propen-1-ol.

Having created a model for the transition state similar to that given in Fig. 8, the low efficiency of kinetic resolution with high enantioselectivity of AE of the (*E*)-allylic alcohol of the α-phenylethyl group on the C(3) carbon atom (168) (Table 13) can be attributed to the spatial remoteness of this substituent from the chiral catalyst. This conclusion is consistent with the data obtained during AE of optically active alcohols when the chiral substituent on the C(3) carbon atom of (*E*)-allylic alcohols (61), (67) and (73) does not affect the results of epoxidation.

4. Reaction conditions

The unique feature of epoxidation with Sharpless reagent is the combination of high enantioselectivity of the reaction with the simplicity in carrying it out, the availability of all of the reagents, the uniformity of the reaction conditions, its preparative and technological significance, and the constancy of the results obtained. Nevertheless, in order to achieve the optimum results in each specific case it is necessary to control some process parameters. A detailed description of the conditions used in conducting AE has been given in several studies.[93,106,123,227–230]

a) Oxidising agent

TBHP is almost always used in AE as the oxidising agent; in certain cases cumyl hydroperoxide has been used.[109] Secondary hydro-peroxides such as phenyl and cyclohexyl hydroperoxides can serve as effective oxidising agents.[22] For enantioselective epoxidation of prochiral allylic alcohols and the kinetic resolution of secondary allylic alcohols, hydroperoxides with bulky tertiary groups such as trityl and tris(*p*-nitrophenyl)methyl have been successfully used.[22,130] The use of primary hydroperoxides is ineffective for AE.[22] For example, *n*-butylhydroperoxide gives rise to a substantially lower EE than does TBHP.

In order to achieve a high rate of AE of prochiral allylic alcohols, it is usual to employ 1.5–2.0 equivalents of oxidising agent. So as to ensure a large difference in the rates of epoxidation of the enantiomers of a racemic allylic alcohol during AE with kinetic resolution a smaller quantity of peroxide is used (~0.6 equivalents). Through careful control of the degree of conversion of alcohol to epoxide, it is possible to use >0.6 equivalents of peroxide, thus reducing the time of reaction.[106,108]

Normally AE using TBHP is carried out in a nonaqueous solution of methylene dichloride.[108] The absence of even trace amounts of water is an important factor, since water inhibits the rate of reaction and reduces the enantioselectivity of epoxidation.[22,53,70,208–212,227] This is because water in the presence of TBHP reacts rapidly with titanium alkoxide to form titanium peroxides and bridging compounds of the type Ti–O–Ti.[213] This results in a decrease in the number of coordination sites of the titanium atom participating in the formation of the intermediate complex and poisoning of the catalyst occurs. A study of the effect of adding water on the AE of (*E*)-α-phenylcinnamic alcohol showed that in the absence of water the EE is 99% and it decreases to 48% when one equivalent of water is added.[195] A detailed description of the methods of preparation, storage, and use of a nonaqueous solution of TBHP appears in three studies.[106,109,232]

An interesting case has been reported in which the source of oxygen for epoxidation is provided by the allyl hydroperoxide which is obtained from 2-t-butylpropene by photooxidation. The hydroperoxide is subsequently converted in the presence of the titanium–tartrate catalyst to 2-t-butoxy-2,3-epoxypropanol with an EE of 72% and yield of 79%.[116]

b) Catalyst

TTIP is used most frequently as a catalyst for AE, but other titanium compounds are used for special purposes. For example, in order to prevent the opening of an epoxide ring formed by AE which is unstable to nucleophilic attack, titanium tetraisobutoxide is used (see Table 7). Thus it was found that replacement of isopropoxide by the less nucleophilic t-butoxide makes it possible to increase the yield of hydroxyepoxide significantly (from 15–51%) in the AE of allylic alcohol (59).[153]

In certain cases $Ti(O-iso-C_3H_7)_2Cl_2$ is used instead of TTIP to obtain epoxyalcohols that are unstable under the reaction conditions.[158] In this case opening of the oxirane ring of the intermediate epoxyalcohol results in the formation of 3-chloro-1,2-diols in 60–80% yield and good regioselectivity. Treatment of the chlorodiols with a base gives epoxyalcohols with low enantioselectivity (20–70%). The absolute configuration of the intermediate epoxyalcohol is the opposite of that which occurs during traditional AE. Finn and Sharpless[22] relate the inversion of configuration of the enantiomer obtained to a strengthening of the titanium–carbonyl group interaction. The same pattern occurs when added quantities of electron-withdrawing monodentate ligands are introduced into the traditional catalyst (Table 15).[22]

The preparation and storage of a catalyst for AE has been described in three studies.[108,213,214]

Dialkyl tartrates and tartramides are used as ligands of the AE catalyst. Most frequent use is made of DMT, DET, and DIPT, which in the majority of cases are equally effective for carrying out AE.[106] It should be noted, however, that by using a tartrate with a bulkier ester group it is possible to increase the yield and rate of reaction when the epoxyalcohols formed are unstable under the reaction conditions. This is probably related to the fact that a bulkier ligand protects the epoxide ring from opening and formation of a diol.[106] For example, epoxidation of cinnamic alcohol when using DIPT occurs more rapidly and with a higher yield than when DET is used.[109] On the other hand, on changing from DIPT to DET there is a small increase in enantioselectivity (from 93 to 95%) in the epoxidation of (*E*)-substituted allylic alcohols such as (*E*)-2-hexen-1-ol.

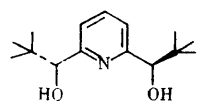

Table 15. Asymmetric epoxidation of *E*-α-phenylcinnamic alcohol.[22]

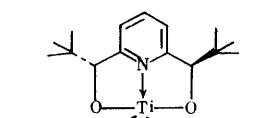
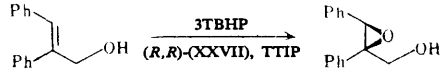
Added component	Ti	Tartrate	Added component	Configuration of epoxyalcohol	EE	Yield
	mol%				%	
–	2	2	0	(2*S*, 3*S*)	98	90
–	2	1	0	(2*S*, 3*S*)	80	90
O_2N–C$_6$H$_4$–OH	2	1	2	(2*R*, 3*R*)	80–85	50–70
$(F_3C)_2CH$–OH	2	1	2	(2*R*, 3*R*)	85	90
F_5C_6–OH	2	1	2	(2*R*, 3*R*)	90	93
PhOH	2	1	2	(2*R*, 3*R*)	6	90



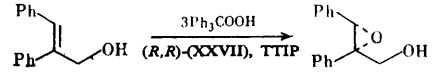
In contrast to the AE of prochiral primary allylic alcohols, the choice of dialkyl tartrate has a substantial effect on the efficiency of AE with kinetic resolution. In this case DIPT provides a better resolution in comparison with DET and DMT, which is of particular importance for substrates with only a small difference in rates of epoxidation of the enantiomers.[22] When dicyclohexyl and dicyclododecyl tartrates are used in the kinetic resolution of a number of allylic alcohols the EE of the products obtained is higher than when DIPT is used, but the yield is slightly lower.[109]

When diadamantyl and di-t-butyl tartrates are used as ligands in AE, the reaction takes place slowly and with a low EE of the resulting products.[22,106] Other dialkyl tartrates substantially reduced the efficiency of the catalytic system.[106]

Hawkins and Sharpless[225] carried out the AE of (*E*)-α-phenylcinnamic alcohol (1) in the presence of TTIP and the chiral reagent (*R*,*R*)-(XXVII).

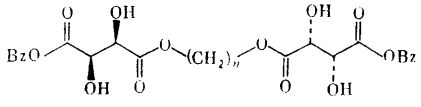


(*R*,*R*)-(XXVII)

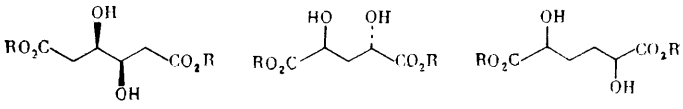


(XXVIII)

The use of TBHP resulted in the formation of the corresponding epoxyalcohol in high yield and with an EE of the predominant (2*S*)-enantiomer of ~40%.



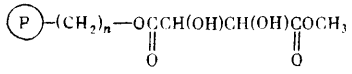
The use of trityl hydroperoxide resulted in the preferential formation of the (2*R*)-enantiomer with an EE of 64%:



In these cases the epoxidation catalyst is the optically active complex (XXVIII), which exists in solution as a monomer.[225] Asymmetric induction during epoxidation in the presence of complex (XXVIII) depends on the size of the alkyl group of the peroxide, in contrast to reactions in the presence of the titanium–tartrate complex, in which TBHP and trityl hydroperoxide have no effect on the absolute configuration of the resulting epoxyalcohol.

Catalysts based on the novel esters of tartaric acid (XXIX) (n = 3–5) which incorporate two equivalents of titanium tetraisobutoxide provide a high enantioselectivity of AE but are ineffective for kinetic resolution.

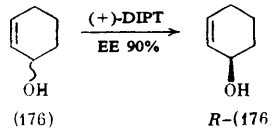
(XXIX)



More recently the three tartrate-like ligands (XXX)–(XXXII) have been synthesised.[223] It was shown that (3*R*,4*R*)-diisopropyl 3,4-dihydroxyadipate (XXX) and (2*S*,4*S*)-diisopropyl 2,4-dihydroxyglutarate (XXXI) mainly form dimeric titanium–ligand complexes in the same way as the titanium–tartrate complex, while (2*S*,5*S*)-diisopropyl 2,5-dihydroxyadipate (XXXII) gives seven complexes.

(XXX) (XXXI) (XXXII)

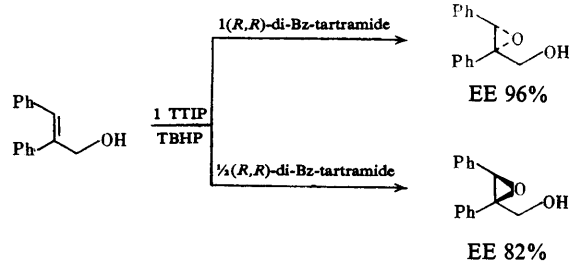
Thus epoxidation in the presence of a titanium–diol (XXX) complex takes place very slowly and inactively; the titanium–diol (XXXI) complex is as effective as the titanium–tartrate complex in the epoxidation of primary allylic alcohols (EE > 93%, but is ineffective as a catalyst of kinetic resolution; and epoxidation in the presence of a titanium–diol (XXXII) complex, which probably consists of several active catalysts, occurs with low selectivity.[223]



In order to establish the possibility of the repeated use of a chiral tartrate, the tartrate ester (XXXIII) was synthesised, being bonded via the ester with a hydroxymethyl (n = 1) or hydroxyethyl (n = 2) group of a polymer.[233]

(XXXIII)

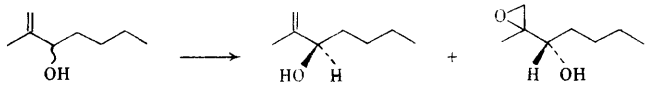
The epoxidation of geraniol using TBHP in the presence of compound (XXXIII) and TTIP results in the formation of an epoxyalcohol with an EE of 49% (n = 1) and 65% (n = 2). The tartrate bonded to the polymer can be returned to the catalytic cycle and used again, although with reduced efficiency. Although the enantioselectivity of AE using (XXXIII) is less than for a homogeneous catalyst, this reaction has played an important role as it was the first attempt to use a heterogeneous catalyst that made possible the use of a chiral tartrate ester for the second time.



An important factor that determines the successful realisation of AE is the ratio of TTIP : tartrate in the complex catalyst. In contrast to the previously suggested ratio of 1 : 1,[92,93] in order to obtain the maximum possible EE Sharpless recommends the use of the tartrate in at least 10% excess relative to the titanium alkoxide.[94] This is because in the presence of a lesser quantity of tartrate in the system unsubstituted titanium alkoxide remains, which, like the complex Ti(tartrate)$(OR)_2$, is an active epoxidation catalyst and because of its achirality even a small percentage of it in the reaction mixture results in a reduction of enantioselectivity of AE. Of particular importance is the use of excess tartrate in AE reactions of substrates with low reactivity. For example, AE with kinetic resolution of compounds (142) and (176) does not occur when a ratio of titanium : tartrate equal to 1 : 1 is used; with a ratio of 1 : 1.5 the EE of compounds (*S*)-(142) and (*R*)-(176) is 10 and 30% respectively.[94,95]

(176) *R*-(176)

Thus, for reducing the content of titanium alkoxide to a minimum it is necessary to use more than one molecule of tartrate per titanium atom. However, when the excess of tartrate is increased by more than 10–20% the rate of reaction decreases, which is due to the formation of a $[Ti(tartrate)_2]_x$ structure, which is catalytically inactive because of the impossibility of displacing the bidentate tartrate with monodentate allylic alcohol and TBHP.[106] Hence in selecting the ratio of titanium : tartrate for carrying out AE, it is necessary to bear in mind that an increase in the tartrate content will lead simultaneously to an increase in enantioselectivity and a reduction in the rate of reaction.



As has already been mentioned, a titanium–tartramide complex is an effective catalyst of AE. When this complex is used asymmetric induction is determined by the ratio of the components in the catalytic complex.[22] For example, AE of allylic alcohols using a TTIP–dibenzyltartramide system in the ratio 1 : 1 as the catalyst takes place with the same enantioselectivity as occurred when a titanium–tartrate complex was used.[158] It should be emphasised that on changing the ratio of titanium : dibenzyltartramide to 2 : 1 inversion of the absolute configuration of the α-hydroxyepoxide occurs:

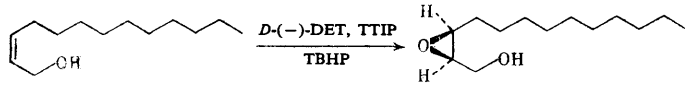
c) Ratio of substrate to catalyst. Heterogeneous catalysis

Until 1986 a stoichiometric quantity of the catalytic system was used in the majority of cases to carry out AE, and only for a small number of allylic alcohols did AE give good results in the presence of a catalytic amount (5–10%) of titanium–tartrate complex.[106] Thus, the yield of AE of cinnamic alcohol under stoichiometric conditions was 65% and under catalytic conditions it was 80%. For epoxidation of 4-chloro- and 4-nitro-cinnamic alcohol only 5% catalyst is required. The epoxidation of less reactive substrates was also successfully carried out under catalytic conditions. For example, the epoxidation of (*Z*)-2-hexen-1-ol with < 10% catalyst takes place with high enantioselectivity, although at the same time the rate of reaction is slower than with a stoichiometric quantity of catalyst and it is difficult to achieve 100% conversion of the initial compound.[228]

Catalytic quantities of titanium–tartrate complex can also be used to carry out AE with kinetic resolution of allylic alcohols.[94,95] For example, allylic alcohol (127) is effectively resolved when 0.25 equivalents of the TTIP–(+)-DIPT complex is used. It should be noted that the enantioselectivity of kinetic resolution decreases slightly in the presence of the titanium–tartrate complex in catalytic amount as compared to a stoichiometric reaction. To obtain the best results with a catalytic quantity of complex, dicyclohexyl tartrate and dicyclododecyl tartrate are used instead of DIPT.[108]

(127)

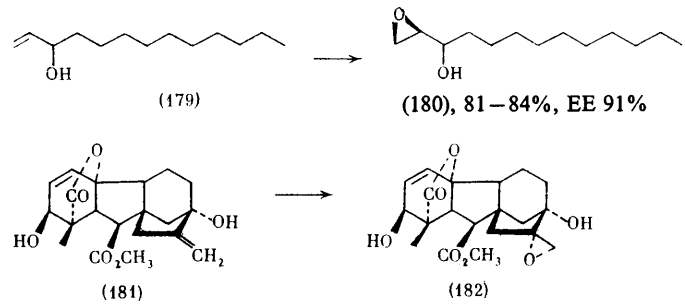
A substantial improvement in AE was achieved by introducing molecular sieves into the reaction medium, making it possible to carry out virtually all of the reactions with catalytic quantities of titanium–tartrate complex.[109,232] For example, epoxidation of many simple allylic alcohols (such as 2-hexanol, cinnamic alcohol, 2,4-pentadien-1-ol) using a 5 mol.% titanium–tartrate complex in the absence of molecular sieves occurs with partial conversion (5–50%), while in their presence (3 or 4 Å sieves) reaction moves rapidly to complete consumption of the initial alcohols. When molecular sieves are used the EE decreases slightly (to 85–95%) but it can be increased by subsequent purification. For example, 4-nitrocinnamic alcohol is epoxidised in the presence of 2 mol.% TTIP–DIPT and molecular sieves with an EE of 90%. The resulting α-hydroxy-epoxide is crystallised to give an EE equal to 100%.[22]



It should be noted that it is possible to reduce the concentration of catalyst to a given limit, after which a decrease in the optical purity of the resulting epoxyalcohol occurs, which is probably due to replacement of tartrate in the catalytic complex, without which asymmetric induction is impossible, by allylic alcohol or hydroxy-peroxide residues.[108] Thus, a study of the epoxidation of cinnamic alcohol showed that there was a substantial decrease in EE on reducing the catalyst content below 5 mol.% (Table 16).[108] At the present time it is recommended to use 5–10% mol.% TTIP and 6–12% mol.% tartrate to carry out AE in the presence of molecular sieves.[109]

In all probability the role of the molecular sieves is to protect the catalyst from water that could penetrate the reaction medium or could be formed in small quantities in side reactions during epoxidation.[108] A detailed description of the principles that should be followed when molecular sieves are used during AE is given in several studies.[22,106,108,109]

Asymmetric epoxidation in the presence of catalytic quantities of titanium–tartrate complex has the following advantages:[109]



1. The quantity of reagent used is reduced while the rate of reaction is kept at the same level.
2. The reaction is carried out under milder conditions.
3. The yield of the reaction increases (Tables 4, 6, and 7).
4. In contrast to stoichiometric conditions substrates with a low molecular weight are effectively epoxidised.
5. Isolation of the reaction product is simplified.
6. The possibility of obtaining epoxyalcohol derivatives arises.
7. The concentration of substrate can be increased (as in contrast to AE with a stoichiometric amount of catalyst an increase in concentration of the allylic alcohol when there is a catalytic amount of chiral complex does not result in the increased probability of side reactions occurring).

In a number of cases the use of AE is limited by the long reaction time, which can amount to several weeks. It is possible to reduce the reaction time substantially by introducing a catalytic quantity of calcium hydride and silica gel into the reaction mixture.[234–237] For example, the time of epoxidation of (*Z*)-2-tridecen-1-ol (177) in the presence of 5–10 mol.% calcium hydride and 10–15 mol.% silica gel can be reduced from 96 to 8 h, whereas the yield and EE of the epoxyalcohol (178) remains unchanged.[234]

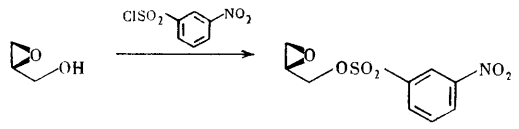
(177) (178)

The time of kinetic resolution of 1-tridecen-3-ol (179) in the presence of 5–10 mol.% calcium hydride and 10–15% mol.% silica gel decreased from 360 to 25 h.[234] AE of methyl giberellate (181) using traditional methods is ineffective. The use of calcium hydride and silica gel results in the formation of the corresponding epoxyalcohol (182) in 70–80% yield and with an EE of 75–80%.[235]

(179) (180), 81–84%, EE 91%

(181) (182)

Table 16. Effect of catalyst concentration on enantioselectivity of asymmetric epoxidation of cinnamic alcohol.[108]

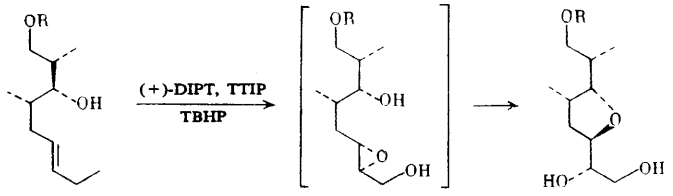


TTIP, mol%	(+)-DIPT, mol%	EE, %
5.0	6.0	92
4.0	5.2	87
2.0	2.5	69

When the reaction is carried out in the presence of calcium hydride alone (or sodium or potassium hydride), the reaction time is reduced but at the same time the optical purity of the product is also reduced. The use of silica gel alone does not reduce the enantioselectivity but shortens the time of epoxidation.[234,236]

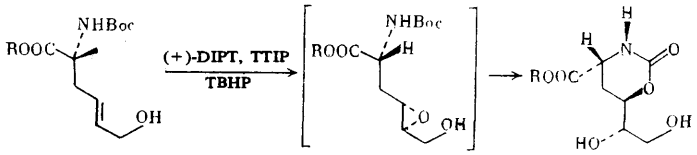
d) Preparation of epoxyalcohol derivatives *in situ*

Because of the sensitivity of a number of epoxyalcohols to the action of nucleophiles and their solubility in water, isolation of the reaction product can be difficult. Of particular importance in this case is the preparation of epoxyalcohol derivatives *in situ*, which can be used to carry out AE with a catalyst content of 5–10 mol.%. For example, low molecular-weight alcohols such as glycidol (183) are



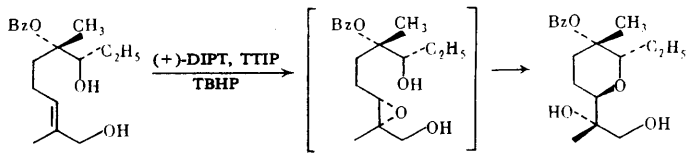
readily isolated from the reaction mixture as their ester derivatives, such as *p*-nitrobenzoate or 3-nitrobenzenesulphonate (184).[109,238]

(183) (184)



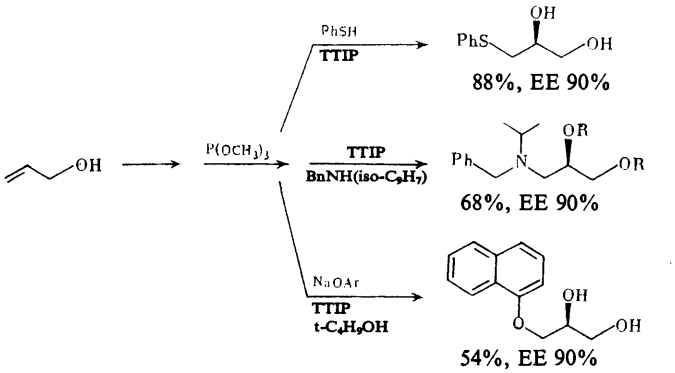
The increase in yield of 2,3-epoxypropanol in the preparation of derivatives *in situ* can be seen from the data of Table 7. With a stoichiometric quantity of titanium–tartrate complex the 2-methylallylic alcohol is epoxidised with an EE of 90% but in low yield. By carrying out the reaction under catalytic conditions and preparing derivatives *in situ* it is possible to isolate the *p*-nitrobenzoate in 70% yield and an EE of 98% and the 3-nitrobenzenesulphonate (184) in 55% yield and an EE of 93%.[108]

It is possible to obtain derivatives *in situ* by nucleophilic opening of the epoxide ring using the TTIP which is already contained in the reaction medium and is an effective reagent that accelerates regioselective attack by nucleophiles on 2,3-epoxyalcohols.[239] In this case the required compounds can be obtained with a given configuration of the functional groups relative to the double bond of the allylic alcohols. In particular, compound (187) is formed as a result of AE of allylic alcohol (185) followed by intramolecular cyclisation.[158]



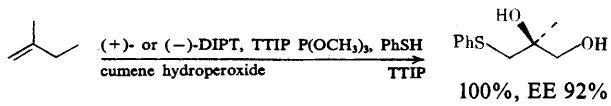
(185) (186) (187)

In the same way, in the epoxidation of alcohol (188) cyclisation of the intermediate epoxyalcohol (189) occurs during reaction and results in the formation of the cyclic urethane (190).[240]



(188) (189) (190)

Epoxyalcohol (192), obtained from allylic alcohol (191), gives the ether (193) as a result of intramolecular cyclisation.[174]



(191) (192) (193)

The preparation of derivatives *in situ* not only assists the isolation of the reaction product, but it can also be used to obtain chiral compounds in a suitable form for further synthesis. For example, *in situ* opening of the epoxide ring of glycidol using nucleophiles such as thiols, secondary amines, and phenols results in the formation of intermediates in the synthesis of adrenalin blockers, antidepressants, etc.[162,241,242]

Thus, methallylic alcohol gives a diol that is used in the synthesis of important organic compounds:

Sulphonation, silylation, and esterification *in situ* result in the formation of derivatives that are intermediates in the synthesis of natural derivatives.

- - -o0o- - -

This literature survey on AE has shown that the most effective method of obtaining optically active oxiranes is the Sharpless reaction, which has the following main advantages.

1. Simplicity, availability, and economical price of all components.
2. Reliability (AE of the majority of prochiral and optically active allylic alcohols, and also the AE with kinetic resolution of the racemate of allylic alcohols occur successfully).
3. High enantioselectivity (EE of 90–95% or more in many cases).
4. Preparation of oxiranes with a given absolute configuration.

The possibility of regioselective opening of the epoxide ring could be used for Sharpless epoxidation in a number of multistage syntheses of optically active compounds, amongst which natural compounds such as sugars, pheromones, and products used as drugs are of the greatest importance. The number of studies devoted to a directed synthesis of natural compounds using the Sharpless asymmetric epoxidation as the key stage continues to grow.

Synthesis of heterocycles by the aza-Wittig reaction

N I Gusar
The Institute of Organic Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. **This review is devoted to the synthesis of *N*-heterocyclics by the interaction of phosphazo groups (either preformed or prepared *in situ*) with carbonyl or thiocarbonyl groups. Examples are presented systematically only for syntheses by an intramolecular aza-Wittig reaction or where the latter is incorporated in a multi-step route. The feasibility of preparing various types of heterocycle by this method has been examined.**

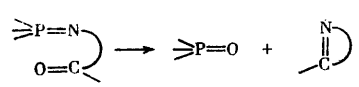
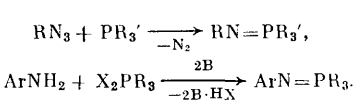
III. Syntheses where the aza-Wittig reaction is included in a multi-step route 152



I. Introduction

Phosphazo compounds (phosphine imines) can react with carbonyl compounds in the same manner as phosphonium ylids, i.e. as aza-analogues of the latter. The reaction is thus analogous to the Wittig synthesis,[1] the end product being the corresponding imine.

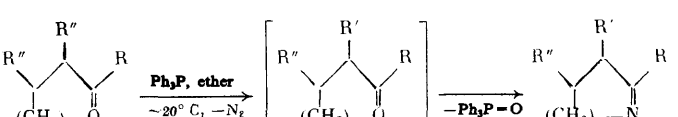


Because of this analogy, it is generally referred to nowadays as the aza-Wittig reaction, although, in fact, it was first discussed by Staudinger and Meyer[2] independently of the work of Wittig.

If the phosphazo and carbonyl groups are in the same molecule, intramolecular condensation can take place to give a nitrogen-containing heterocycle:

Many types of five-, six- and unusual seven-membered *N*-heterocylics, including natural products and their analogues, have been prepared by this route, notably in the last two decades. However, up to now, there has been no systematic survey of literature data on this reaction, except in Zbiral's review[3] of 1974, in which there is a small section on the synthesis of heterocyclics with phosphine imines.

The mild conditions of the cyclisation and the ready availability of the starting materials are normally considered as the principal advantages of the aza-Wittig synthesis. Azides and aromatic amines are very often used as precursors of phosphazo compounds, the first being converted into the latter by treatment with the corresponding phosphine or phosphite, while aromatic amines afford phosphazo compounds by treatment with dihalogenotriorganophosphoranes in the presence of base:

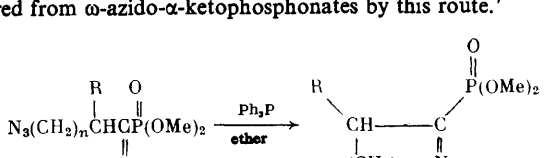


In many cases, reaction can be undertaken with *in situ*-generated phosphazo compounds.

II. Syntheses by aza-Wittig reaction

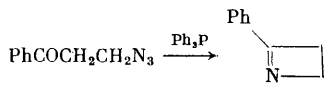
1. Cyclisation of phosphazoketones and phosphazoaldehydes

Ketones and aldehydes are normally used as the carbonyl function in the aza-Wittig reaction. Reaction with phosphazo groups proceeds under comparatively mild conditions—in many instances at room temperature. Notably, this reaction has been applied with readily available ω-azidoketones, from which five-, six-, and seven-membered cyclic imines (I) can be obtained. Such compounds are intermediates for alkaloids. There are a number of advantages of this method over other known procedures. For example, as reaction can be conducted in non-aqueous media under non-reductive conditions, the method can be applied to ring systems with substituents which are sensitive to reductants and water.[4,5]



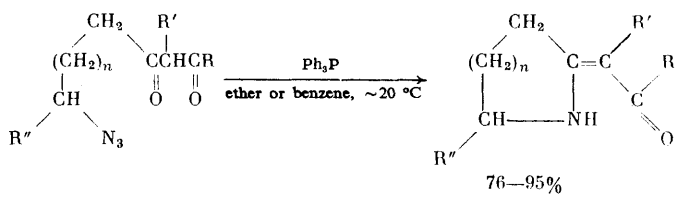
(I), 60–92%

$n = 1–3$; R, R′, R″ = H, Me, Et, PhS, 4-BrC$_6$H$_4$.



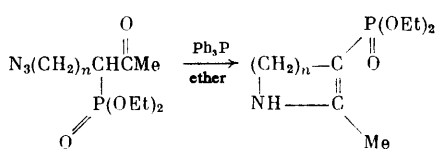
The synthesis of 1-pyrrolines (I, n = 1) by the aza-Wittig reaction has already been discussed.[6]

2-Phosphonyl-Δ^1-pyrrolines and -Δ^1-piperideines have been prepared from ω-azido-α-ketophosphonates by this route.[7]



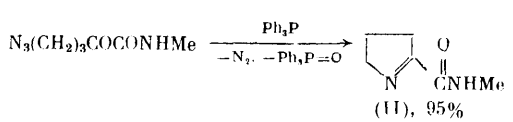
n=2,3; R=H, Me, allyl.

Azetines cannot be obtained by the aza-Wittig reaction in preparative yield.[8] Thus, 4-azidobutan-2-one and methyl 3-azidopropionate do not cyclise on treatment with triphenylphosphine, even under harsh conditions. However, it is possible to prepare 2-phenyl-1-azetine in very low yield by reaction of β-azidopropiophenone with triphenylphosphine.



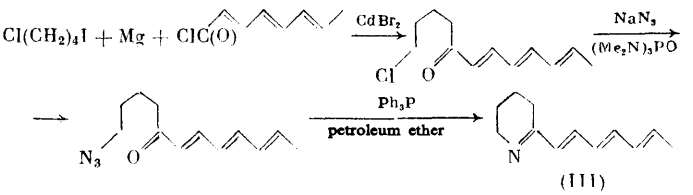
The reaction of ω-azido-β-diketones or ω-azido-β-ketoesters with triphenylphosphine is accompanied by migration of a labile hydrogen atom from carbon to nitrogen to provide heterocyclics with an exocyclic double bond. Such products, obtainable in quantitative yield, may be regarded as vinylogous amides or urethans.[6,7,9]

$n = 1-3$

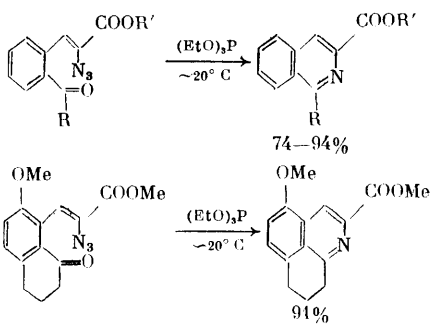


Attempts to prepare eight-membered heterocycles in this way failed when the starting materials were heated in toluene.[9]

Transfer of hydrogen from carbon to nitrogen also takes place on intramolecular aza-Wittig cyclisation of ω-azido-α-(diethoxyphosphinyl)ketones, there affording 3-diethoxyphosphinyl-2-pyrrolines and -2-piperideines in ~75% yield.[6]

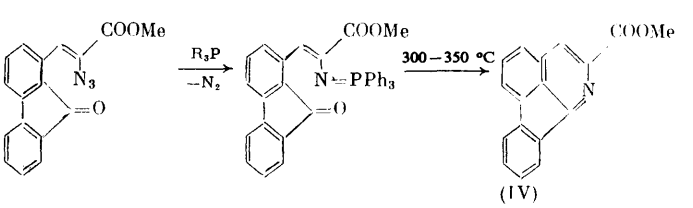


$n = 2, 3$

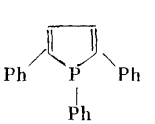


The amide (II) is obtained in high yield by interaction of *N*-methyl-5-azido-2-ketovaleramide with triphenylphosphine in benzene. It is reported that this method is suitable for preparing the relatively inaccessible 1,2-dehydroproline system. However, it is not possible to prepare seven-membered heterocyclics by such ring closure of ketoamides.[10]

The method has also been applied in the final step of a multistage route to the alkaloid nigrifactine (III), which possesses high physiological activity. The intermediate chloro- and azido-ketones, with four double bonds in conjugation, and nigrifactine itself, are all very unstable and are isolated in low yield.[11]

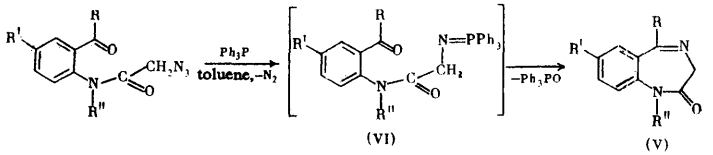


Intramolecular aza-Wittig reaction with *o*-carbonyl-substituted α-azidocinnamates and analogous 1-tetralone derivatives readily cyclise at room temperature to isoquinolines without isolation of intermediate phosphazo compounds.



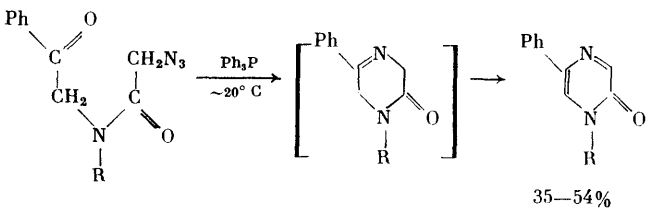
R = H, Me, Ph; R′ = Me, Et.

The phosphazo compounds obtained from fluorenone and triphenylphosphine or triethyl phosphite do not cyclise on heating in xylene; however, the azafluoranthene (IV) is obtained at 300–350 °C in 12 and 19% yield, respectively. The product can be obtained in somewhat higher yield (34%) by cyclisation of the phosphazo compound obtained by reaction of the starting azide with 1,2,5-triphenylphosphole (see p. 152). In this case reaction is complete within two minutes at 300 °C.[12,13]



R = Ph, EtO or R$_3$P =

Benzodiazepine derivatives, including the psychotherapeutic drugs diazepam and nitrazepam (Va, b),[14] as well as the analogues (Vc–e),[15] have also been prepared by intramolecular aza-Wittig reaction. The intermediate phosphazo compound (VIe), formed by reaction of triphenylphosphine with 2-(azidoacetylamino)4-chlorobenzophenone, is stable at room temperature and may be isolated as

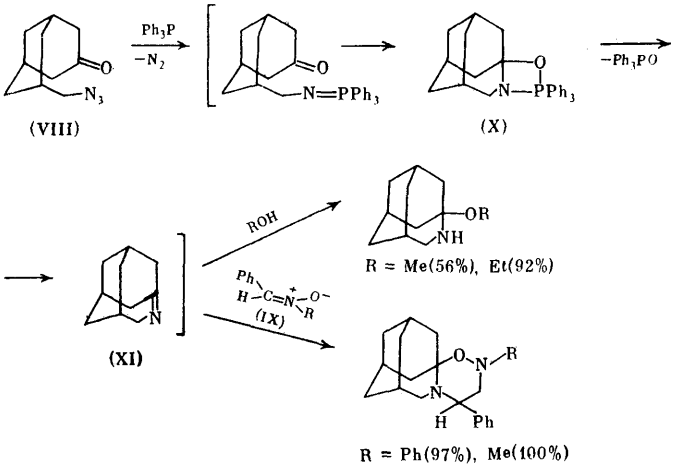


the hydrochloride; on heating in toluene it is converted into the corresponding benzodiazepine (Ve) in 80% yield.[15]

(VI) (V)

	a	b	c	d	e
R	Ph	Ph	H	Ph	Ph
R′	Cl	NO_2H	H	Cl	
R″	Me	H	H	Me	H

The analogous cyclisation of azidoacetyl(phenacyl)amines leads to 2-pyrazinones, even on conducting the reaction under argon, rather than the corresponding dihydro derivatives as would have been anticipated for an intramolecular aza-Wittig reaction.[15]

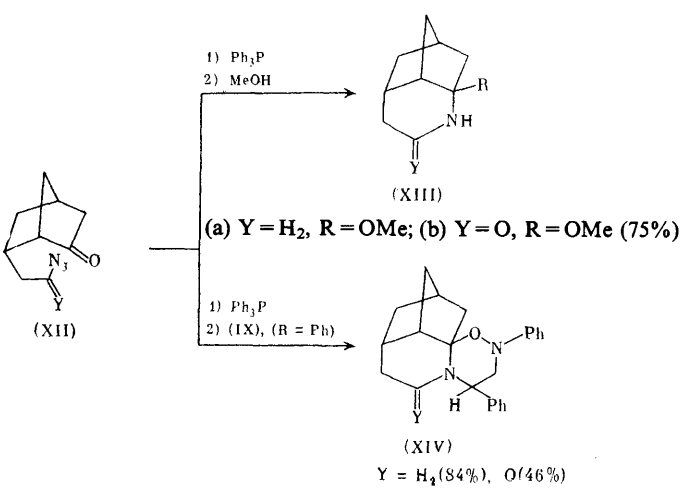


35—54%

The tricyclic system, 5,9-diazabenz[*c*,*d*]azulene, is formed by heating the phosphazo compound (VII) in toluene. The product is very unstable, but may be characterised as an iron tricabornyl complex.[16]

(VII) 35% 66%

Similarly, heating 3-azidomethylbicyclo[3.3.1]nonan-7-one (VIII) with triphenylphosphine in alcoholic media gave alkoxy-4-azahomoadamantanes, while reaction with triphenylphosphine and nitrones (IX) in benzene afforded compounds having the oxadiazinohomodamantane skeleton. By following the reaction of azide (VIII) with triphenylphosphine in deuteriochloroform with the aid of ^{1}H- and ^{13}C-NMR spectroscopy, it was shown that the conversion of the intermediate phosphazo compound into the oxazaphosphetane (X) is a rapid process by virtue of a favourable entropy factor, while the cleavage of (X) to the highly strained imine (XI) is slow. As a consequence, it is possible to characterise compound (X) spectroscopically.

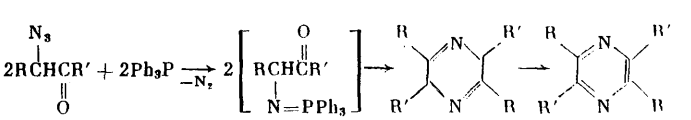


(VIII) (X) (XI)

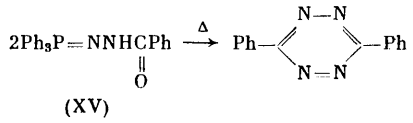
R = Me(56%), Et(92%)

R = Ph(97%), Me(100%)

Azide (XII) affords 4-aza-4-homobrendane derivatives (XIII, XIV) in high yield with the same reagents under the same conditions. The unstable aminoacetal (XIIIa) was reduced with $LiAlH_4$ to the stable imine (XIII; Y = H_2, R = H) in 87% yield.[17]



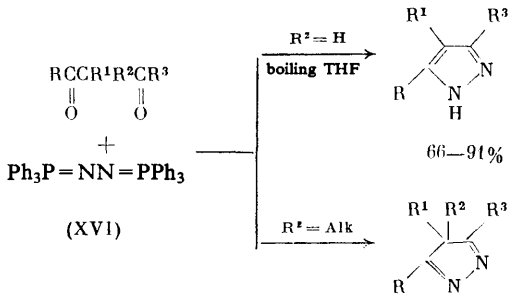
(XII) (XIII) (XIV)



(a) Y = H_2, R = OMe; (b) Y = O, R = OMe (75%)

Y = H_2(84%), O(46%)

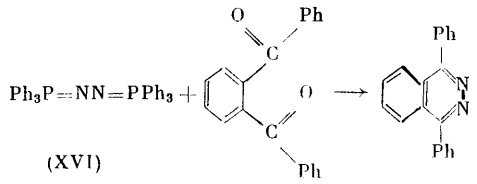
A number of heterocyclic systems has been obtained by double aza-Wittig reaction. Thus, pyrazine derivatives can be prepared conveniently by reaction of α-azidoketones with triphenylphosphine. In this case, two molecules of phosphazo compound, formed in the initial step of the reaction, participate in a "head-to-tail" double aza-Wittig coupling providing dihydropyrazines which undergo dehydrogenation to pyrazines during the reaction.[18]



A similar sequence is involved in the preparation of 2,6-diphenyl-*s*-tetrazine from phosphazo compound (XV).[19]

(XV)

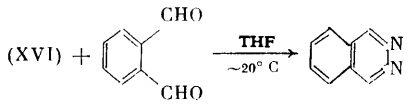
An original method has also been reported for the preparation of pyrazoles by condensation of β-ketones with phosphazine (XVI).[20] If there is one hydrogen atom on the α-carbon atom of the β-diketone, the reaction provides 1*H*-pyrazoles, but if the α-carbon is disubstituted by alkyl groups a double aza-Wittig reaction takes place to give 4*H*-pyrazoles.



(XVI)

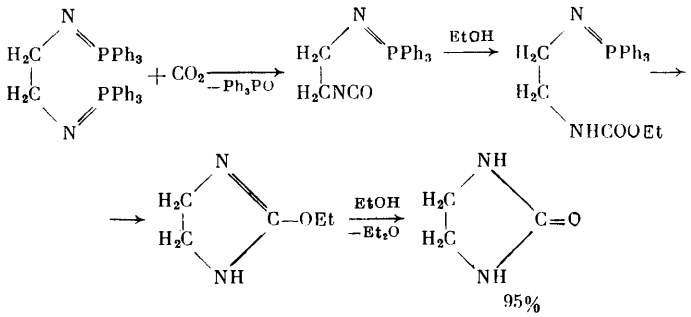
66—91%

R = Me, Ph; R^1 = H, Me; R^2 = H, Me; R^3 = Me, Ph.



R = R^1 = R^2 = R^3 = Me, 38,4%

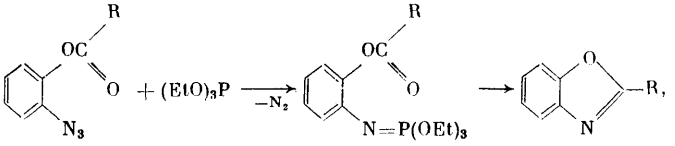
Treatment of *o*-dibenzoylbenzene with phosphazine (XVI) affords 1,4-diphenylphthalazine,[20] while *o*-phthalaldehyde gives phthalazine itself.[21]



(XVI)

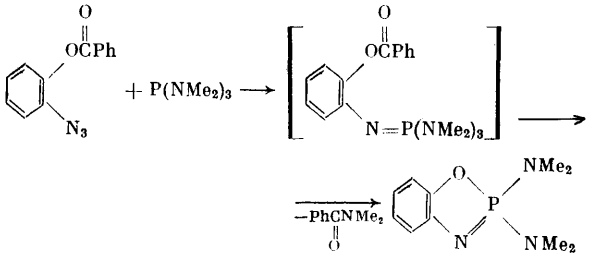
55%

77%



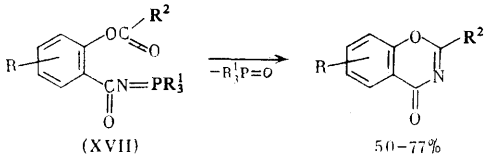
An excellent yield of 2-imidazolidone was obtained by passing carbon dioxide into an alcoholic solution of 1,2-*bis*(triphenylphosphazo)ethane. It is likely that reaction proceeds via isocyanate and urethan intermediates.[20]

95%



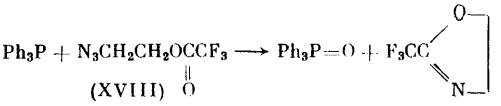
2. Cyclisation of phosphazoesters (of carboxylic acids)

The intramolecular condensation of phosphazo groups with esters requires somewhat harsher conditions than the condensation with ketones. Thus, cyclisation of the phosphazo compounds obtained by the exothermic reaction of *o*-acoxyazides with triethyl phosphite proceeds by prolonged heating in cyclohexane to give 2-substituted benzoxazoles.[22]



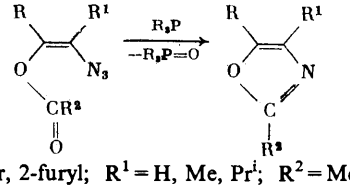
R = Me (69%), Ph (71%).

Interestingly, heating *o*-azidophenyl benzoate with hexamethylphosphorous triamide in cyclohexane for 24 h is accompanied by evolution of *N,N*-dimethylbenzamide, rather than hexamethylphosphoramide, to give 1,3,2-benzoxazaphosphole derivatives.[23]



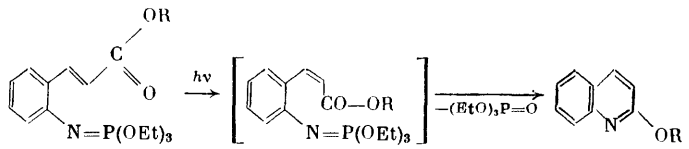
With salicyclic acid derivatives (XVII), intramolecular aza-Wittig reaction proceeds at room temperature in toluene, or on heating in a mixture of acetone and petroleum spirit, to give 4*H*-1,3-benzoxazin-4-ones, including the previously unknown 2-alkoxy derivatives.[24,25]

(XVII)



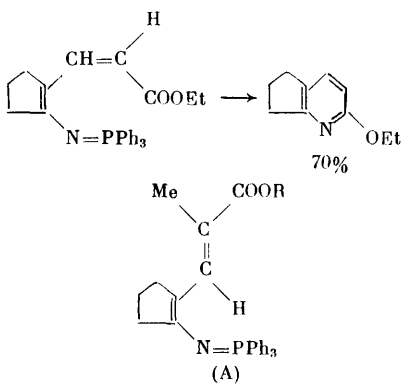
50—77%

At the same time, the azidoester (XVIII) reacts immediately with triphenylphosphine in the cold to give a high yield of 2-trifluoromethyl-2-oxazoline.[26]



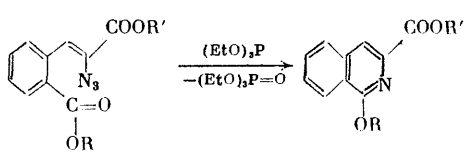
80%

The cyclisation of β-acoxyvinyl azides with trivalent phosphorus compounds (preferably triethyl phosphite) provides a suitable method of preparing oxazoles, which are used not only as blocking groups, but also as intermediates and as key components of alkaloids and macrocyclic antibiotics.[27]



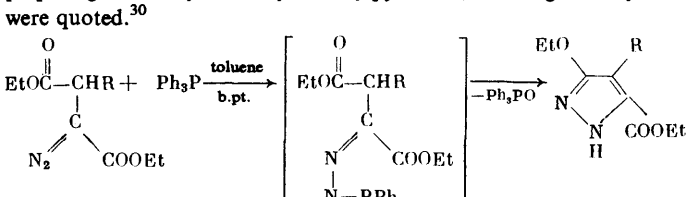
R = Ar, 2-furyl; R^1 = H, Me, Pr^i; R^2 = Me, Et, cyclopropyl, 2-furyl, 3-pyridyl.

Heating is not necessary for the cyclisation of *o*-phosphazocinnamic acids and their esters. Reaction takes place on irradiation (365 nm) for 30 minutes to give a high yield of 2-hydroxy-, 2-alkoxy- or 2-phenoxy-quinolines, probably as a result of an initial *trans*→*cis*-isomerisation.[28]

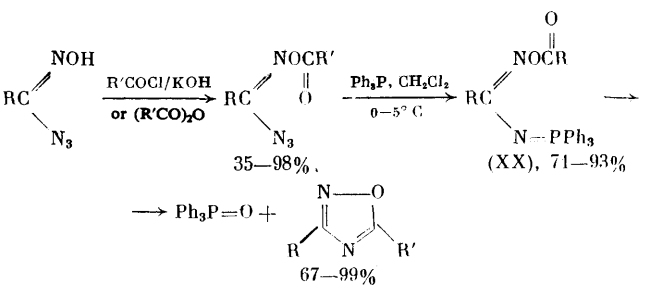


R = H, Me, C_6H_{11}(>75%), Ph(95%).

By studying the analogous cyclisation of 3-(2-triphenylphosphazocyclopent-1-enyl)-acrylates and -methacrylates, it was found that the ethyl acrylates react under harsh conditions (at 207 °C in boiling tetralin) to give a high yield of 2-ethoxycyclopenteno[*b*]pyridine. The corresponding methacrylate derivative did not cyclise under these conditions, probably as a result of the steric repulsion between the methyl and the phosphazo group. This stabilises the structure in the (*E*)-form (A) which is unfavourable for cyclisation.[29]

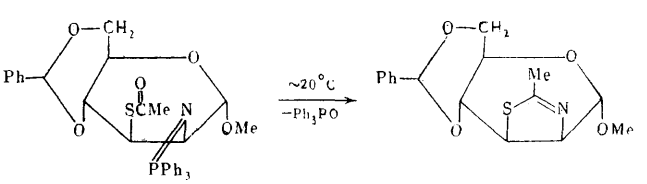


α-Azido-*o*-carboxy- and α-azido-*o*-carbethoxycinnamates react with triethyl phosphite at 20–50 °C to give the corresponding esters of 1-hydroxy- or 1-ethoxy-isoquinoline-3-carboxylic acid esters.[12]



70—90%

The reaction of β-diazoesters with triphenylphosphine in heated toluene may be used for the preparation of 3-ethoxypyrazoles. The phosphazine (XIX) is an intermediate in this conversion. The authors of this work consider this to be a general method of preparing 3-ethoxy-5-ethoxycarbonylpyrazoles, although no yields were quoted.[30]

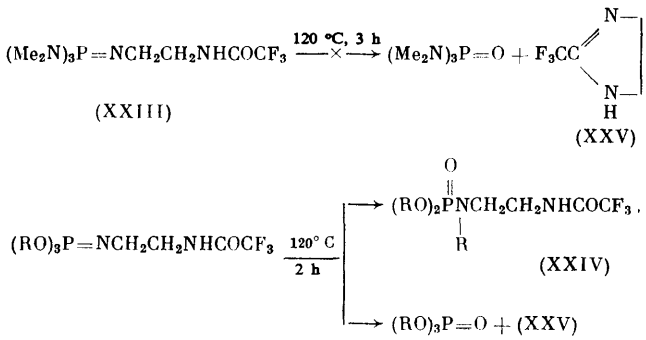


R = H, NHCOOEt. (XIX)

The carbonyl group of *O*-acyloximes may also participate in the aza-Wittig reaction. This has been incorporated as the final step in a convenient synthesis of 3,5-disubstituted 1,2,4-oxadiazoles, based on acylation of 1,1-azido-oximes, treatment of the intermediate with triphenylphosphine, and then heating the resulting phosphazo compound in toluene.[31] It was not possible to prepare 5-alkylamino-1,2,4-oxadiazoles by this route because the intermediate 1,1-phosphazo-oxime carbamates (XX, R′ = MeNH, EtNH) give a complex mixture of compounds on heating in toluene.

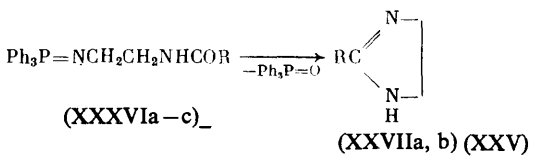
R = Ar; R′ = Me, EtO, Ar.

Ring closure of acetylthio compounds to give acid-resistant thiazole derivatives can be achieved by condensation with a neighbouring phosphazo group. This has been adapted for the protection of the 2-aminomercaptan function in the synthesis of thiosugars with potential biological activity. The phosphazo compound (XXI), obtained from the corresponding azidodeoxy-mannose derivative, has been shown to be stable in ether but is immediately converted into the thiazoline (XXII) on dissolution in chloroform.[32]



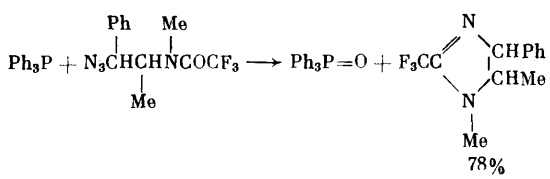
(XXI) (XXII)

3. Cyclisation of phosphazoamides

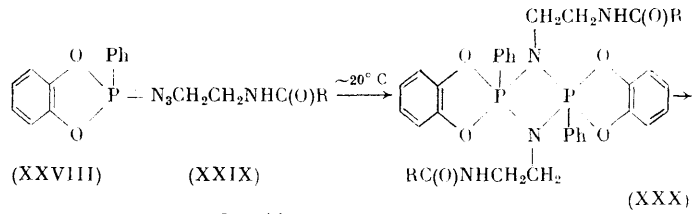


As the electrophilicity of the amide carbonyl group is lower than that of the ester group, phosphazo compounds generally do not react with carboxylic acid amides unless the amide group is activated by an additional acceptor group (see, for example, Ref. 33).

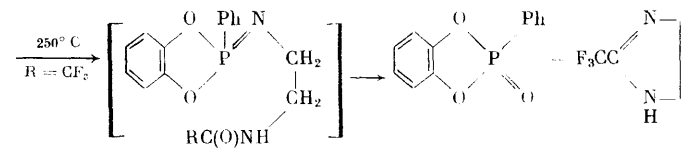
In those instances where intramolecular aza-Wittig reaction does take place with amides, the readiness to cyclise depends largely on the nature of the substituents on the phosphorus and amide nitrogen atoms. Thus, it has been found that phosphazo compound (XXIII) with dimethylamino groups on the phosphorous atom do not react,[34] while the analogues *N*-(trialkoxyphosphazoethyl) amides, based on trifluoroacetic acid, are converted to trialkyl phosphate and 2-trifluoromethyl-2-imidazoline (XXV), in addition to amide (XXIV) derived via imine-amide rearrangement. The more facile the



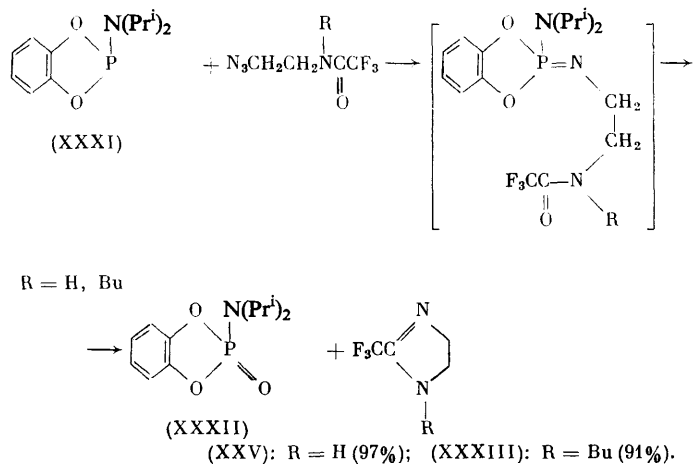
rearrangement into amide (XXIV), the lower the yield of imidazoline (XXV), being 1–1.5% for R = Et, and 27% for R = Bu.[35]



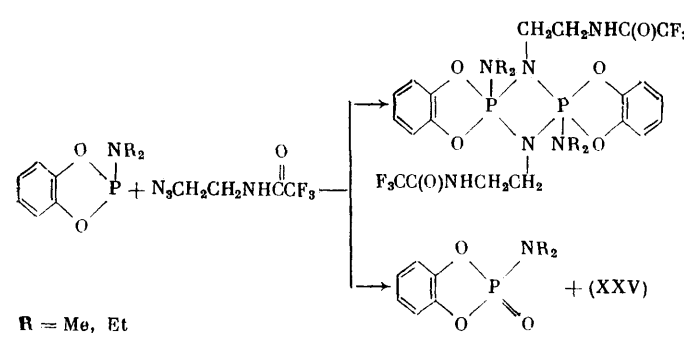
The tendency of phosphazoamides to cyclise is greater for compounds with a phenyl group on the phosphorus atom. Heating such compounds affords a high yield of imidazolines substituted in the 2-position by alkyl or aryl groups. Thus, triphenylphosphazo compounds (XXVI) based on acetamide and benzamide are converted into triphenylphosphine oxide and the corresponding 2-imidazoline (XXVIIa, b) at 180 °C; similarly, the trifluoroacetamide derivative (XXVIc) provides the imidazoline (XXV) at 120 °C, the yield of the three products being 72%, 91% and 80%, respectively.



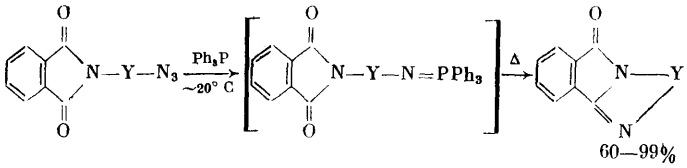
Substituted imidazolines are formed more readily by using phosphazo compounds derived from azidoamides with substituents on the chain linking the two reactive functions. Thus, in the reaction of triphenylphosphine with the azide obtained from racemic pseudoephedrine cyclisation to 4,5-disubstituted 2-imidazolines can be effected, even at room temperature, with associated cleavage of triphenylphosphine oxide. The intermediate phosphazo compound cannot be isolated.[26]



Phosphazo compounds derived from cyclic phosphorus(III) acid esters exhibit a noticeably different mode of cyclisation. Thus, interaction of the cyclic phosphonite (XXVIII) with azides (XXIX) affords exclusively the corresponding dimeric phosphazo compound (XXX), which may be converted to 2-imidazolines on heating to 250 °C, as exemplified below with (XXXc). It is possible that reaction is facilitated via initial thermal cleavage to a monomeric phosphazo compound.[26]



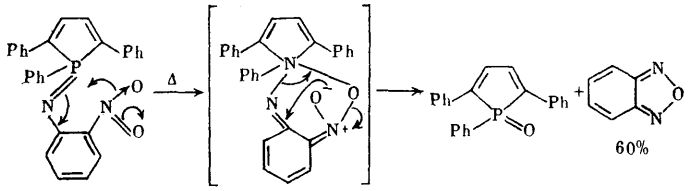
R = Me (a), Ph (b), CF_3 (c)



On the other hand, treatment of the pyrocatechol amidophosphite (XXXI) with azide (XXIXc) and its *N*-butyl derivative, even at 80 °C, affords the P-oxide (XXXII) and imidazolines (XXV) and (XXXIII), respectively. An intermediate situation obtains with the dimethylamino- and diethylamino-analogues of (XXXI). In each case, the interaction with azidoamide (XXIXc) proceeds with the simultaneous formation of a phosphazo compound and a mixture of imidazoline (XXV) and the corresponding catechol dialkylamidophosphate.[34,35]

(XXV): R = H (97%); (XXXIII): R = Bu (91%).

One of the carbonyl groups of cyclic imides (phthalimides, succinimides, glutarimides) participates in the aza-Wittig reaction by heating the appropriate phosphazo compounds in toluene or xylene. Five-, six- and seven-membered 1,3-diazaheterocyclics are thereby obtained.[36]

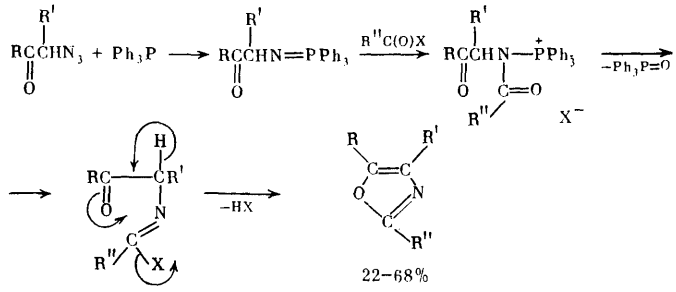


Y = $(CH_2)_n$ (n = 2—4), o-$CH_2C_6H_4$, o-$CH_2C_6H_4CH_2$

n = 2,3 92%

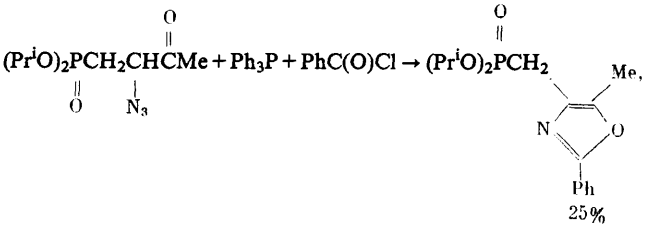
4. Cyclisation of nitrophosphazo compounds

On heating the *o*-nitrophosphazobenzene (XXXIV), derived from 1,2,5-triphenylphosphole, in mesitylene, aza-Wittig ring closure takes place with participation of the nitro group to give benzofurazan in 60% yield. The nature of the substituent on the phosphorus atom has a marked effect on the course of this reaction. Thus, the analogous phosphazo compound derived from triphenylphosphine and triethyl phosphite do not undergo ring closure, while the trichlorophosphazo analogue affords benzofurazan in the same way.[37]



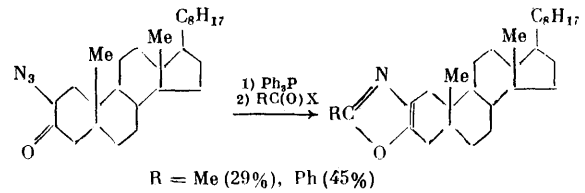
(XXXIV)

III. Syntheses where the aza-Wittig reaction is included in a multi-step route

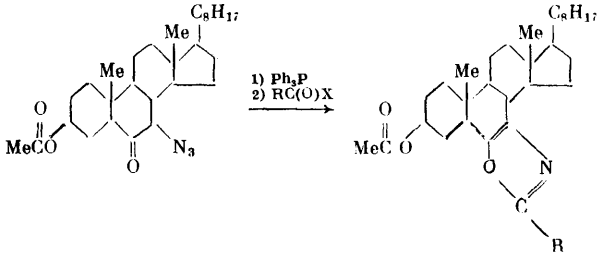


1. Acylation and aza-Wittig reaction

Oxazoles with a wide variety of substituents may be obtained by three-component reaction of triphenylphosphine, acyl halides, and α-azidoketones possessing an α-hydrogen atom. The synthesis, which takes place at room temperature, involves an initial Staudinger reaction, followed by acylation of the *in situ*-formed phosphazo compound, and aza-Wittig cyclisation of the resulting β-ketoimidoyl halide with liberation of triphenylphosphine oxide.[38]

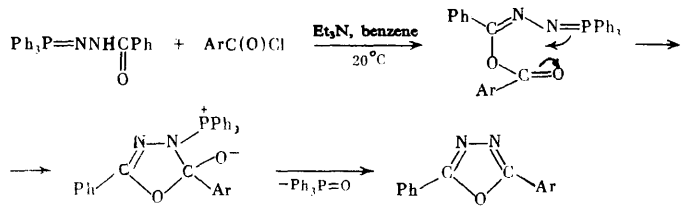


Although hydrogen halide is formed in the last step of the reaction, no additional base is required to trap it. This is possibly why 1.5—2 equivalents of triphenylphosphine are required, and may explain the moderate yield of oxazole.



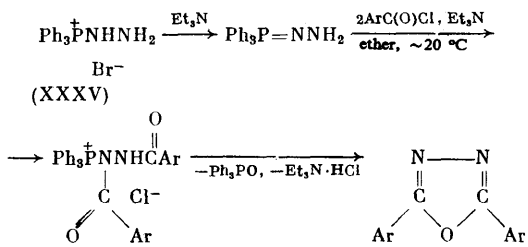
The same reaction has been applied for the preparation of phosphorylated oxazoles.[39]

It has also been adapted for annelation of the oxazole ring to the steroid skeleton for the synthesis of cholest-2-eno[2,3-*d*]oxazoles and cholest-6-eno[7,6-*d*]oxazoles.[40]



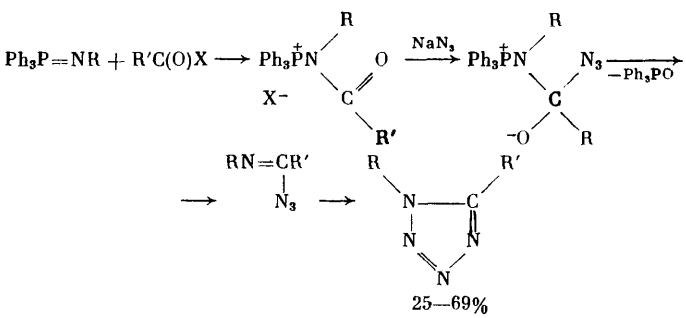
R = Me (29%), Ph (45%)

R = Me (29%), Ph (21%), $PhCH_2$ (36%), EtOOC (42%).



Extension of this reaction to phosphazo compounds having an acylamino group on the imine nitrogen leads to an effective mixture of preparing 1,3,4-oxadiazoles. In this case, reaction is carried out in

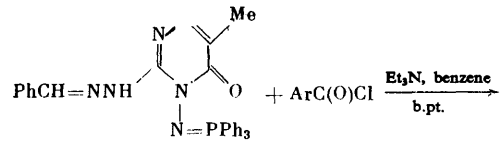
the presence of base (butyllithium[3] or triethylamine[19]), and the yield exceeds 90% in certain cases.



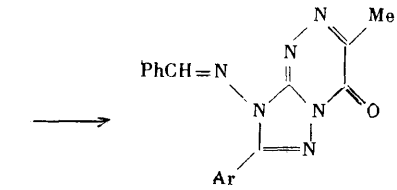
Ar = Ph, $4\text{-}O_2NC_6H_4$, $3,5\text{-}(O_2N)_2C_6H_3$, $4\text{-}BrC_6H_4$.

In a similar way, symmetrically substituted 1,3,4-oxadiazoles are obtained by treatment of phosphonium salts (XXXV) with an excess of triethylamine and two equivalents of aroyl halide.[19]

Tetrazoles may be obtained by interaction of phosphazo compounds with acyl halides and sodium azide under mild conditions (in benzene at room temperature). In certain cases, acyl azides may be used efficiently in place of the acyl halide and NaN_3.

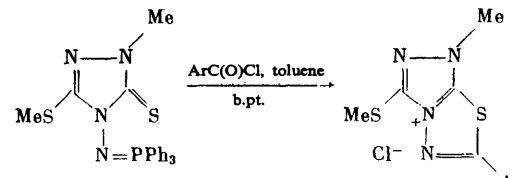


25—69%

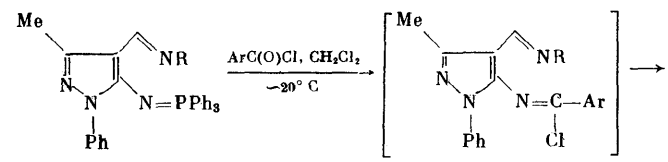


R = Ar, 2-pyridyl, R′ = Alk, alkenyl, alkadienyl.

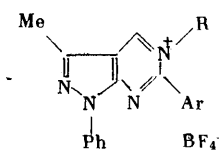
Under these conditions, trifluoroacetic acid derivatives are converted to acylic imidoyl azides which exist in equilibrium with the corresponding tetrazole. Phosphazo compounds with trimethylsilyl, *tert*-butyl and methoxymethyl groups do not form tetrazoles as reaction proceeds by another pathway.[41]



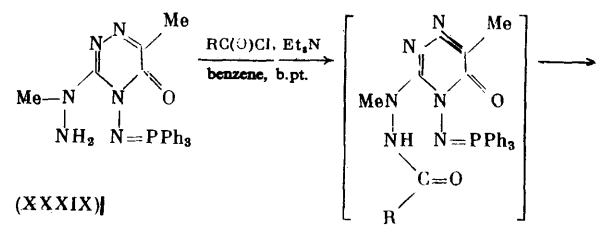
N-Phosphazohetaryls with adjacent benzylidenehydrazino, thione or aldimine groups undergo ring closure with acyl chlorides to give bicyclic systems. Thus, heating triazine (XXXVI) with aromatic aroyl chlorides and triethylamine in benzene affords 1,2,4-triazolo-[5,1-c][1,2,4]triazines,[42] while heating triazole (XXXVII) with acyl chlorides in toluene gives 1,2,4-triazolo[3,4-*b*][1,3,4]thiadiazolium salts;[43] the interaction of pyrazoles (XXXVIII) with aroyl chlorides yields pyrazolo[5,4-*d*]pyrimidinium fluoroborates at room temperature.[44]



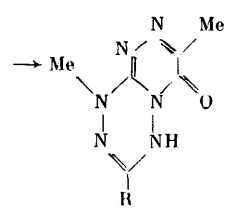
(XXXVI)



68—80%

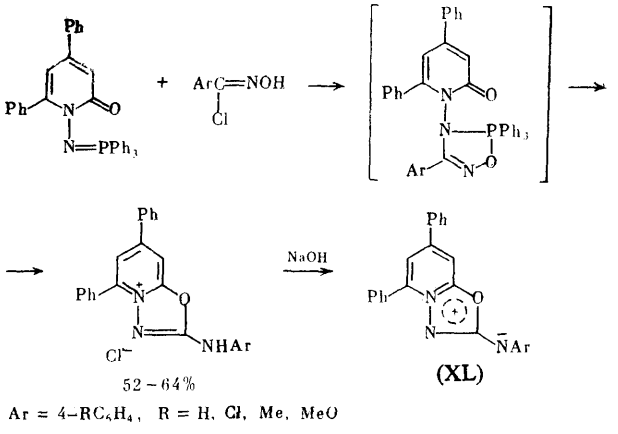


(XXXVII) 48—67%



(XXXVIII)

In a similar way, the 4-triphenylphosphazo-3-(1-methylhydrazino)-1,2,4-triazine (XXXIX) with acyl chlorides yields the corresponding *N*-condensed 1,2,4,5-tetrazine derivatives on heating in benzene containing triethylamine.

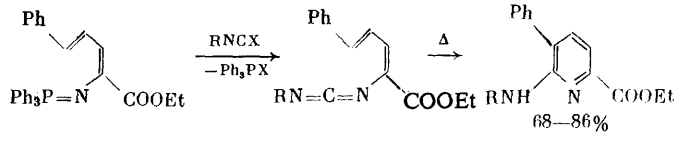


(XXXIX)

37—64%

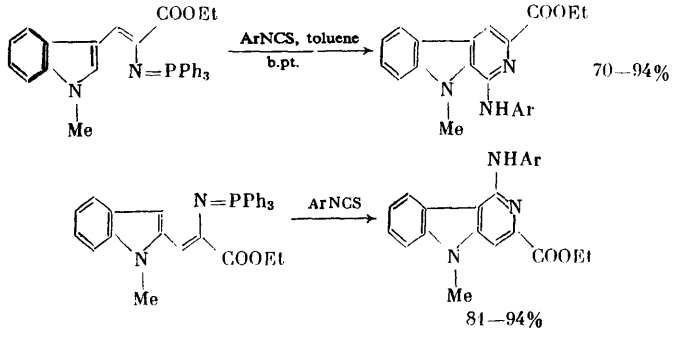
An intermediate acylhydrazine has been isolated by acylation of the triazine (XXXIX) at room temperature.[45]

The interaction of 1-triphenylphosphazo-4,6-diphenyl-2-pyridone with 1,1-oximinochlorides on heating in benzene is accompanied by C→N-aryl migration to give 1,3,4-oxadiazolo[3,2-*a*]pyridinium chlorides in moderate yield. The structure of the product has been confirmed by its dehydrochlorination to the mesoionic heterocycle (XL) which has been prepared by an independent route.[46]



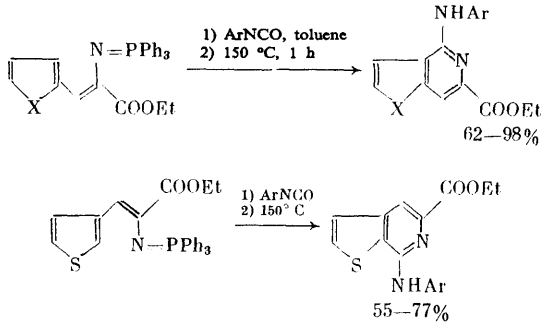
Ar = 4-RC$_6$H$_4$, R = H, Cl, Me, MeO

2. Aza-Wittig reaction and cyclisation

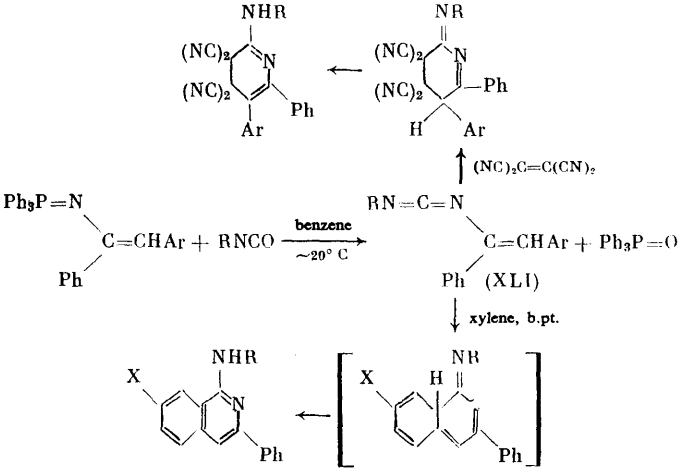


The commonest sequence of this type comprises the interaction of phosphazo compounds with heterocumulenes, such as isocyanates and isothiocyanates. Reaction proceeds via ring closure of an intermediate carbodiimide which, in most cases, is not isolated.

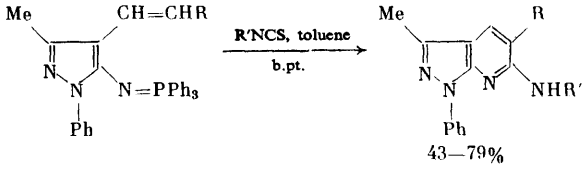
Pyridine derivatives were the first to be prepared by this route, involving ring closure of unsaturated carbodiimides. The preparation of 6-arylaminopicolinic acid esters illustrates the methodology. Here, the phosphazo compound interacts with alkyl or aryl isocyanates or isothiocyanates in toluene at room temperature to give the corresponding carbodiimide which cyclises on heating in the same solvent. The intermediate carbodiimides can be isolated as oils following column chromatography.[47,48]



R = Et, Bu^t, Ph, Ar; X = O, S.

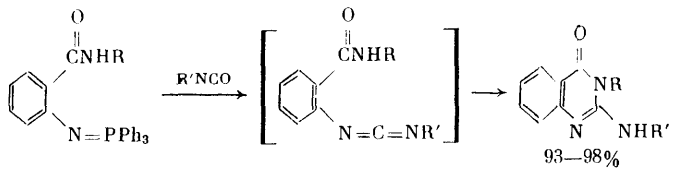


Derivatives of β- and γ-carbolines have been prepared similarly:[49]

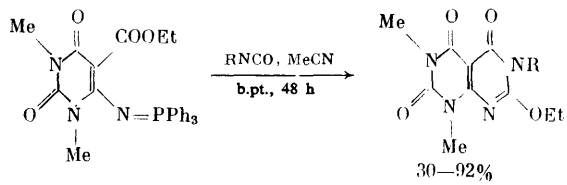


The method has also been applied to the synthesis of thieno- and furo-[3,2-*c*]pyridines as well as thieno[2,3-*c*]pyridines.[50,51]

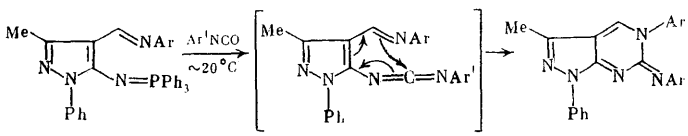
1-Arylaminoisoquinolines have been synthesised by high-temperature ring closure of unsaturated carbodiimides (XLI), obtainable from the corresponding phosphazo compound and isocyanate. [4+2]-Cycloaddition of this enecarbodiimide to tetracyanoethylene leads to tetrahydro- or dihydro-pyridines, depending on the nature of the substituent.[52]



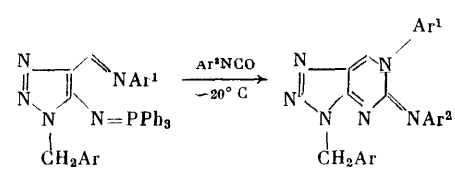
The carbodiimide group can also interact with a neighbouring carbon-carbon double bond activated by a strong electron-accepting group. This is exemplified by the synthesis of 6-aminopyrazolo-[3,4-*b*]pyridines, formed by annelation of the pyridine ring onto a pyrazole derivative.[53]

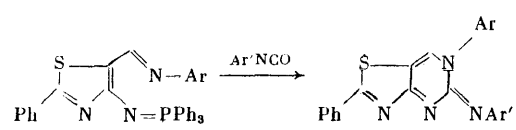


R = MeCO, NO_2; R' = Me, allyl, Ar.

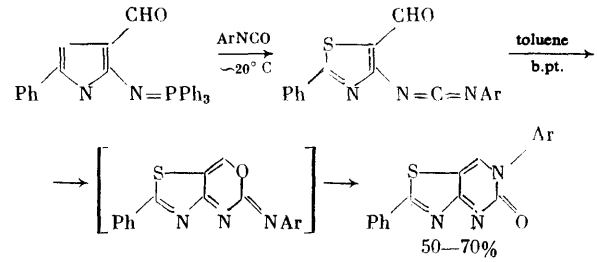


Quinazoline derivatives have been prepared in almost quantitative yield by reaction of *o*-phosphazobenzamides with isocyanates. This is the first example of an intramolecular addition of an amide group to a carbodiimide. The intermediate formation of a carbodiimide is confirmed both by its isolation in the case of *N,N*-disubstituted amides and by the formation of *o*-ureidobenzonitriles by reaction of *N,N*-unsubstituted benzamides.[54]

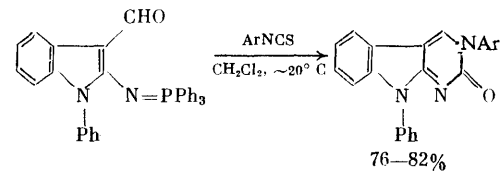


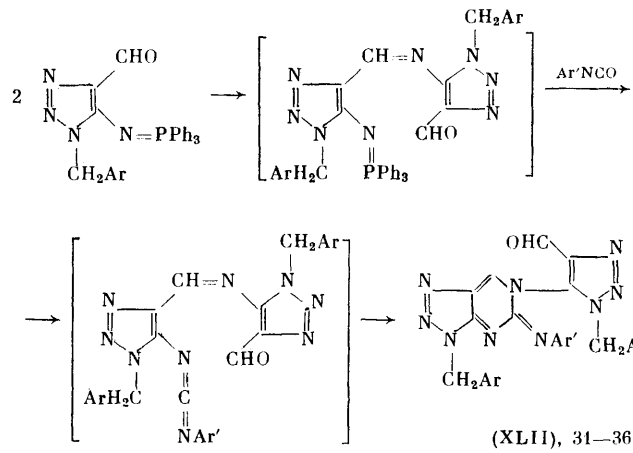


Annelation of the pyrimidine ring can be achieved by cyclisation of a carbodiimidoheterocycle having an *o*-substituted carbethoxy group. Reaction proceeds in refluxing acetonitrile without isolation of the carbodiimide. The resulting pyrimido[4,5-*d*]pyrimidines display a variety of physiological activities.[51]

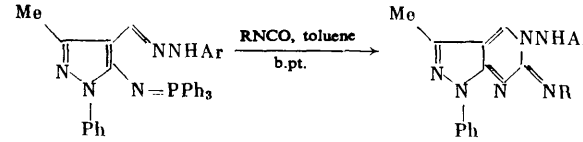


Similarly, annelation of the pyrimidine ring to pyrazole, triazole and thiazole derivatives can be achieved, even at room temperature, by ring closure of carbodiimides with neighbouring aldimine groups. In this way, pyrazolo[5,4-*d*]pyrimidines, 1,2,3-triazolo[5,4-*d*]pyrimidines and thiazolo[4,5-*d*]pyrimidines, having an arylimino group in the 2-position of the pyrimidine ring, have been prepared in high yield,[44,55]

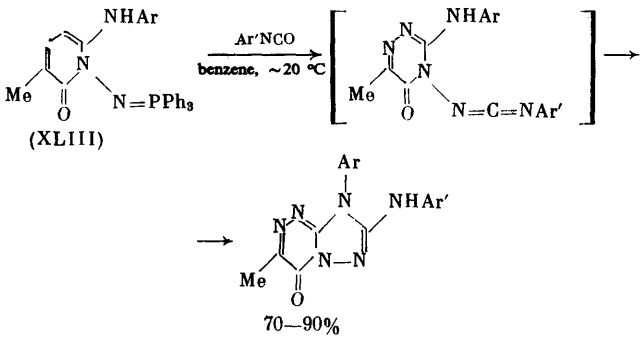




Carbodiimides have also been prepared by interaction of 2-phenyl-4-triphenylphosphazothiazole-5-carboxaldehyde with aryl isocyanates at room temperature. However, the subsequent ring closure to thiazolo[4,5-*d*]pyrimidin-5-ones requires heating in toluene, and is evidently associated with Dimroth rearrangement of the intermediate thiazolo[4,5-*d*]-1,3-oxazines.[44]

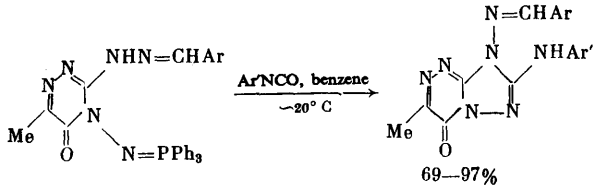


Dimroth rearrangement is also evident in the reaction of a 2-phosphazoindole-3-carboxaldehyde with aryl isothiocyanates, providing pyrimido[4,5-*b*]indoles in methylene chloride at room temperature.[49]

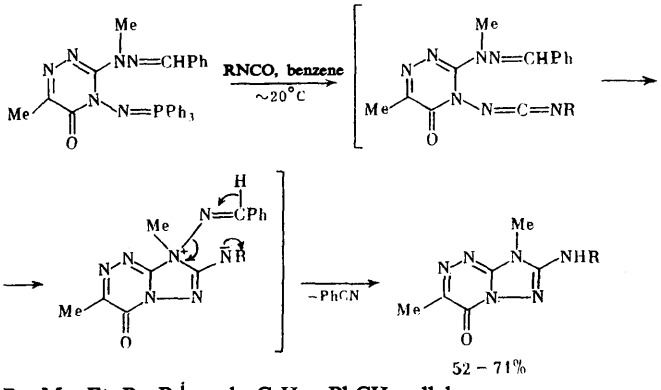


There is no reaction between 5-triphenylphosphazo-1,2,3-triazole-4-carboxaldehydes and aryl isocyanates at room temperature, while heating in toluene affords a more complex product (XLII). Formation of the latter can be explained by an initial aza-Wittig reaction involving the phosphazo group of one molecule with the aldehyde group of a second molecule; the aryl isocyanate then condenses with the remaining phosphazo group, and the intermediate carbodiimide cyclises as before.

Aryl isocyanates react readily on heating with 4-hydrazono-5-phosphazopyrazoles in toluene to give pyrazolo[5,4-*d*]pyrimidines having an arylamino group on a nitrogen atom of the pyrimidine ring.[44]

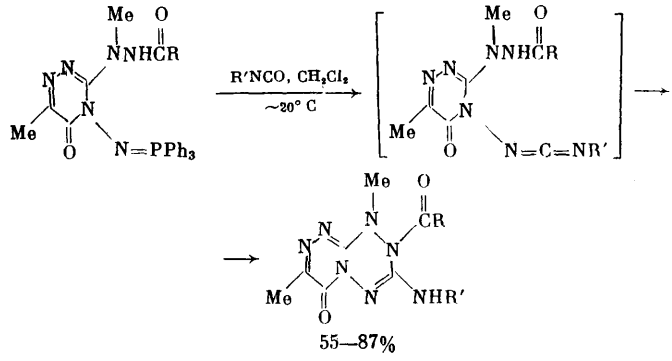


Annelation of the 1,2,4-triazole ring can be achieved by interaction of aryl isocyanates with hetaryls having a phosphazo group on an endocyclic nitrogen atom and an adjacent *o*-arylamino functionality. Thus, 1,2,4-triazolo[5,1-*c*]-1,2,4-triazines are obtainable in high yield by reaction of aryl isocyanates with phosphazotriazines (XLIII), even at room temeprature.[56]

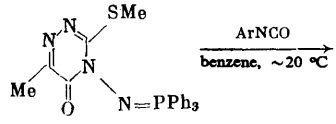


(XLIII)

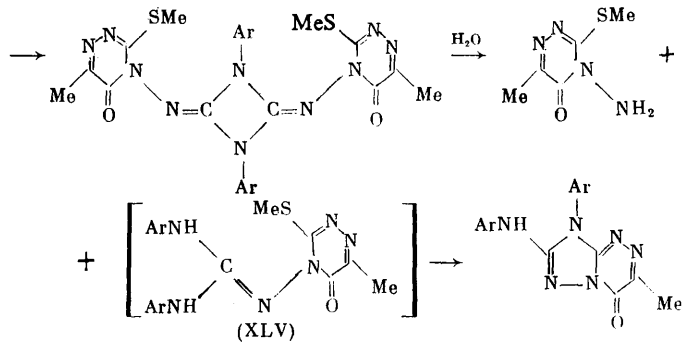
The reaction also proceeds smoothly on replacing the arylamino group in the starting phosphazo compound by a benzylidenehydrazino group. In this case, the method provides 1,2,4-triazolo-[5,1-*c*][1,2,4]triazines having a benzylideneamino group on the triazole ring.



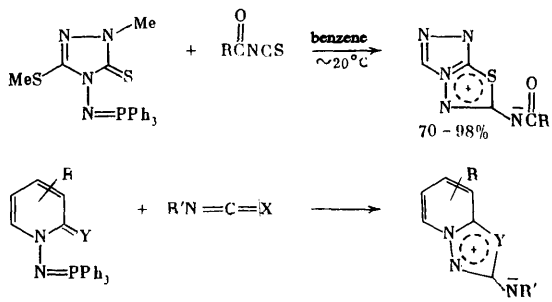
Reaction with the *N*-methylbenzylidenehydrazino analogue of the above phosphazo compound also proceeds under mild conditions, but in this case the benzylideneamino group is eliminated as benzonitrile.[57]



R = Me, Et, Pr, Pr^i, cyclo-C_6H_{11}, $PhCH_2$, allyl.

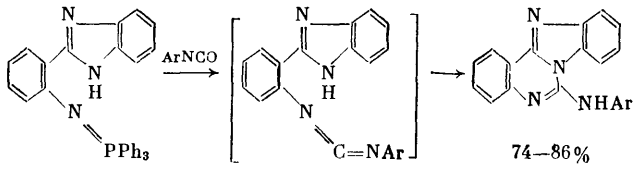


Molina et al. have reported what in their view is the first example of ring closure of a carbodiimide with a hydrazide group. Thus, 1,2,4-triazino[4,3-*b*]-1,2,4,5-tetrazines have been obtained by reaction of aryl isocyanates with 1,2,4-triazines having a phosphazo group at the 4-position and an acylhydrazino group at the 3-position.[57]

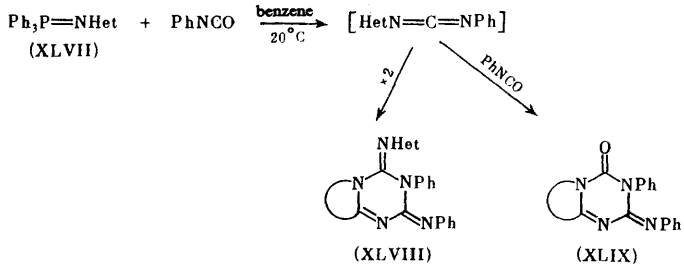


On the other hand, the 2-methylthio analogue (XLIV) reacts quite differently. Treatment with aryl isocyanates at room temperature affords a stable carbodiimide dimer, which can be converted to 1,2,4-triazole[5,1-*c*][1,2,4]triazines by prolonged heating in 85% aq. ethanol. It is likely that reaction proceeds via a guanidine intermediate (XLV).[42]

(XLIV)

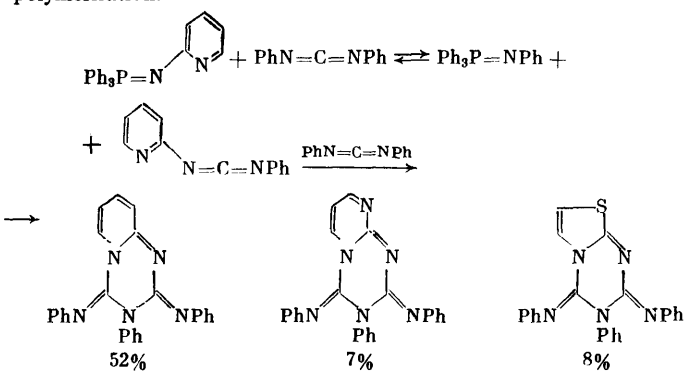


Fusion of a ring onto an *N*-phosphazohetaryl is also possible by reaction of the intermediate carbodiimide with a neighbouring oxo or thioxo group. However, in such cases mesoionic bicyclic systems are formed. Thus, 1,2,4-triazolo[3,4-*b*]-1,3,4-thiadiazolium-6-aminides[43] are obtained by interaction of 4-triphenylphosphazo-1,2,4-triazoline-3-thiones with acyl isothiocyanates at room temperature, while salts (XLVI) are formed by reaction of 1-phosphazo-2-pyridones and -2-pyridinethiones with isocynates and isothiocyanates under the same conditions.[46,58,59]



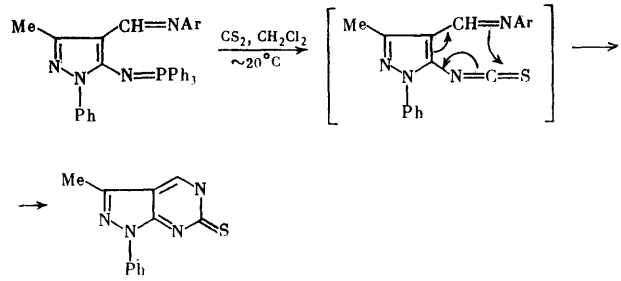
X, Y = O or S.

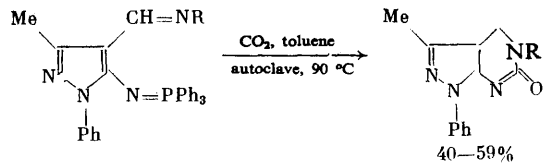
Ring closure of the carbodiimide function with an imino group can also take place, as in the synthesis of benzimidazo[1,2-*c*]-quinazolines from 2-(*o*-phosphazophenyl)benzimidazoles.[54]



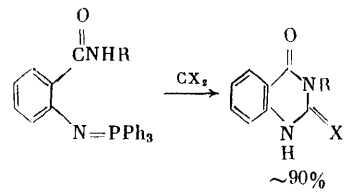
2-Triphenylphosphazohetaryls (XLVII) without an associated functionality react with phenyl isocyanate via intermediate carbodiimides to give either the corresponding carbodiimide dimers (XLVIII) or the bicyclic compound (XLIX), formed by cycloaddition of the carbodiimide with a second isocyanate molecule. In each case, reaction provides an *N*-condensed 1,3,5-triazine system. The proportion of the two products depends on the order of addition of the reactants: by addition of the phosphazo compound (XLVII) to phenyl isocyanate only compound (XLIX) is formed, whereas gradual addition of the isocyanate to the phosphazo compound normally affords a mixture of both products; the phosphazo-quinoline derivative is an exception in that only the product of type (XLIX) is obtained under the latter conditions.

The interaction of phosphazo compound (XLVII) with phenyl isothiocyanate requires a higher temperature than the corresponding reaction with phenyl isocyanate, and the reaction time is much longer. It leads primarily to the product of type (XLVIII).[60]

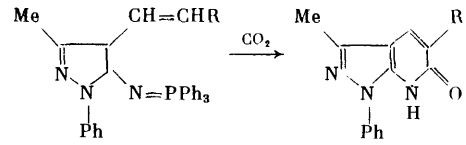




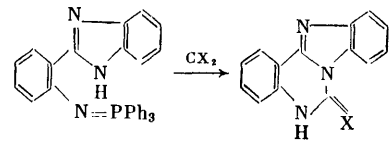
Het = 2-pyridyl, 2-quinolyl, 2-pyrimidyl, 2-thiazolyl



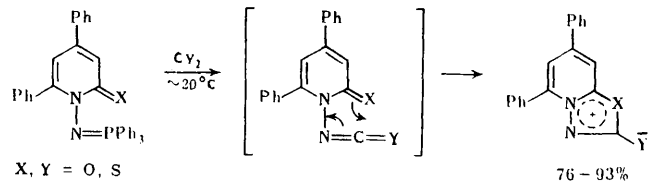
Phosphazohetaryls react with diphenylcarbodiimide on heating in benzene. As with phenyl isocyanate, the reactants condense in 1 : 2 proportion, affording again a condensed 1,3,5-triazine system with two phenylimino groups. The yield of the pyrido[1,2-*a*]-[1,3,5]triazine analogue, from 2-(triphenylphosphazo)pyridine and diphenylcarbodiimide, is respectable (52%), but normally the yield is poor, as in the case of the pyrimidino- and thiazolo-analogues (7–8%), because of the susceptibility of the carbodiimide to polymerisation.[61]



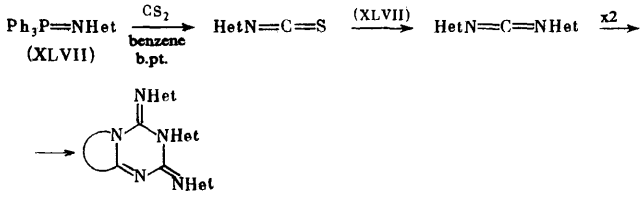
A variety of condensed ring systems have been secured by reaction of carbon dioxide or carbon disulphide with phosphazo compounds via intramolecular condensation of the resulting isocyanates or isothiocyanates with neighbouring aldimine,[44,45] amide or imine groups,[54] as well as with electron-deficient carbon-carbon double bonds.[53] Bicyclic α-oxo- or α-thioxo-*N*-heterocyclics are thereby obtained, for example:



X = O, S,

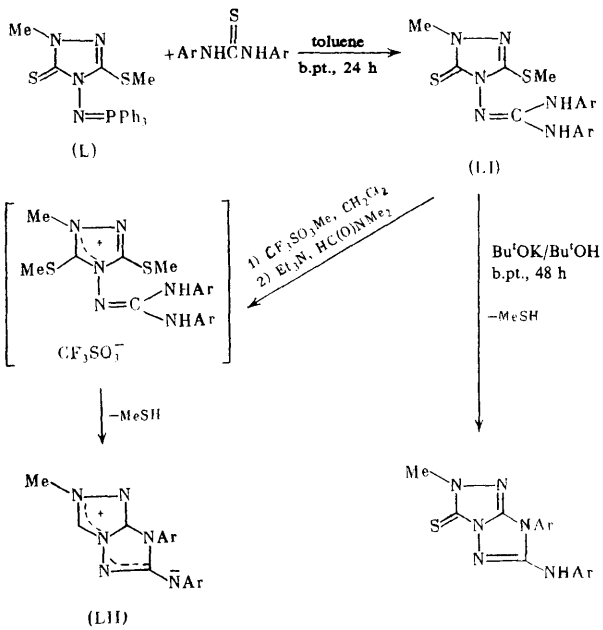


R = MeC(O), NO_2

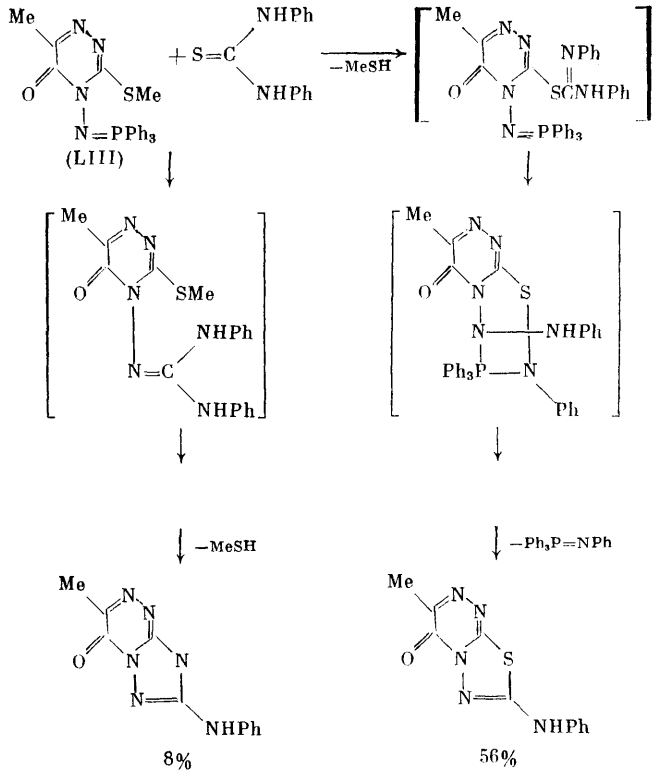


X = O, S.

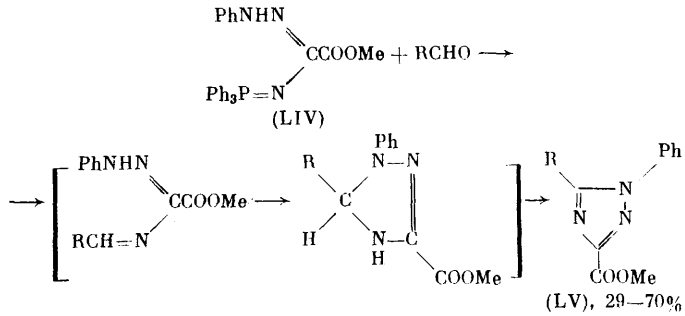
Mesoionic bicycles are formed by interaction of *N*-phosphazo-α-oxo- or *N*-phosphazo-α-thioxo-*N*-heterocyclics with carbon dioxide or carbon disulphide.[58,59]



In the absence of a neighbouring functionality, the isothiocynates, obtained as intermediates by reaction of 2-triphenylphosphazohetaryls with carbon disulphide, condense with a second molecule of the phosphazo compound to give the corresponding *N,N'-bis*(hetaryl)carbodiimides which cyclodimerise as shown below.[60]



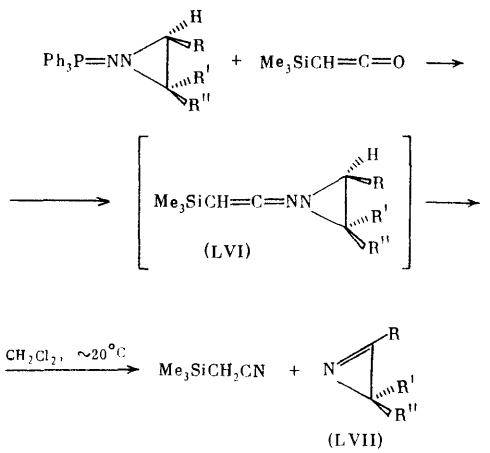
Het = 2-pyridyl, 2-thiazolyl, 2-quinolyl, 2-benzothiazolyl



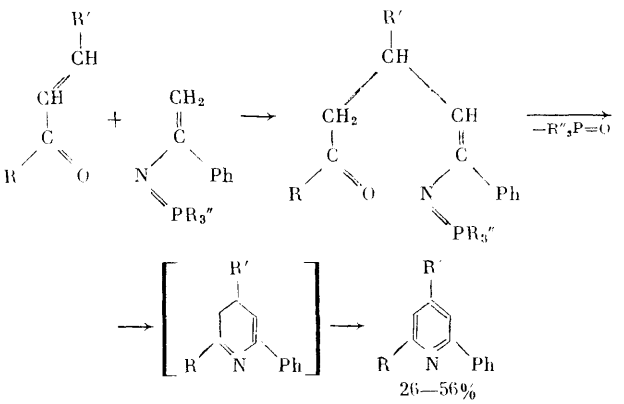
Ring closure to bicyclics can also be achieved by aza-Wittig reaction of phosphazohetaryls with *N,N'*-diarylthioureas. Thus, heating the latter with methylthio-substituted phosphazo compound (L) in toluene affords the guanidine derivative (LI) which cyclises to 1,2,4-triazolo[4,3-*b*]-1,2,4-triazoles in strongly basic media. However, treatment of the guanidine (LI) with methyl triflate followed by triethylamine in dimethylformamide provides the bicyclic betaine (LII).[62]

Two reactions take place in parallel on heating the related 4-phosphazo-1,2,4-triazine (LIII) with *N,N'*-diphenylthiourea in benzene: a small amount of 1,2,4-triazolo[5,1-*c*]-1,2,4-triazine is formed by the same route as shown above for the reaction with (L); however, the principal product is a fused thiadiazole—a 1,3,4-thiadiazolo[2,3-*c*]-1,2,4-triazine derivative—formed by condensation of the thiourea with the methylthio group of (LIII) followed by intramolecular condensation of the intermediate isothiourea with the phosphazo group.[42]

5-Substituted monocyclic 1,2,4-triazoles (LV), including derivatives with heterocyclic residues, may be prepared from phosphazohydrazones (LIV) and the appropriate aldehyde in benzene or toluene. Such products have potential pharmacological activity. It is suggested that the intermediate triazolines are oxidised in the last step of the reaction by atmospheric oxygen.[63]



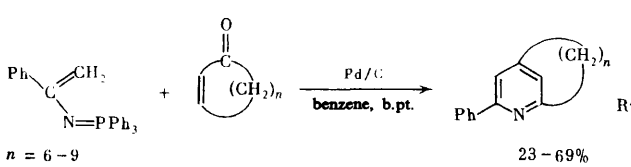
R = H, Me, Pr^i, 4-O2NC6H4, 4-pyridyl, 2-furyl, 2-pyrrolyl.



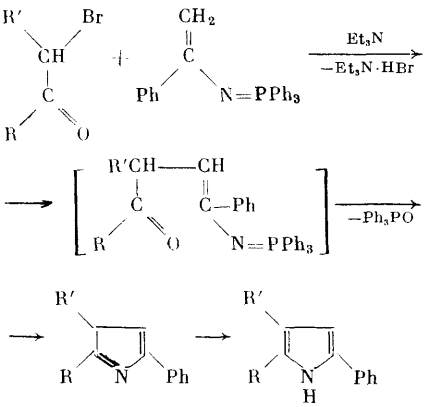
3. Other syntheses incorporating an aza-Wittig reaction

N-(1-Aziridinyl)trimethylsilylketenimines (LVI), obtained by aza-Wittig reaction from *N*-(triphenylphosphazo)aziridines and trimethylsilylketene, may be converted to 2*H*-azirines (LVII) by

elimination of trimethylsilylacetonitrile. The facility of this process depends on the nature of the substituents on the ring and their relative stereochemistry: the *cis*-2,3-diphenyl derivative (LVI, R = R″ = Ph, R′ = H) decomposes at room temperature to give azirine (LVII, R = R′ = Ph; R″ = H) in 70% yield (half-life 15 min), while the *trans*-isomer affords only 25% of this product with a half-life of 24 h.[64]

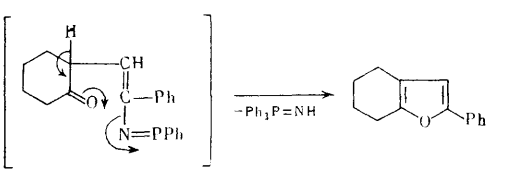


It is considered that the formation of 2-phenylpyridines from α-phosphazostyrenes and α,β-unsaturated ketones involves an initial Michael addition followed by an intramolecular aza-Wittig reaction. Evidently, reaction proceeds via oxidation of the intermediate dihydropyridines.[65,66]

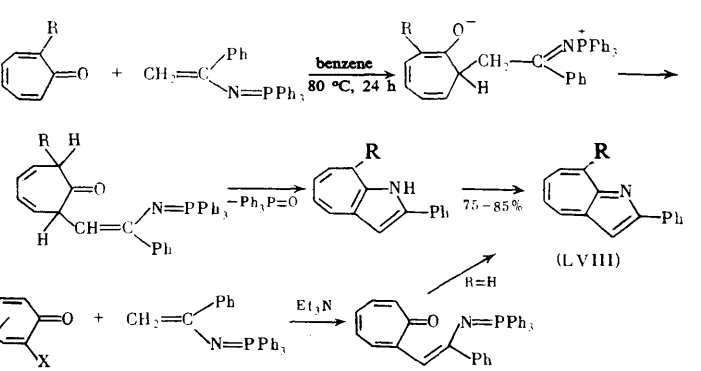


R = Me, Ph; R′ = H, Me, Ph; R″ = Ph, Bu.

[*n*](2,4)Pyridinophanes have been prepared similarly from cyclic α,β-unsaturated ketones with 9 – 12 carbon atoms.[67]

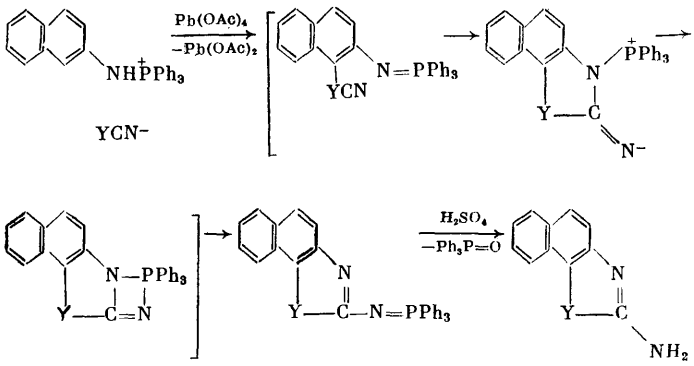


The synthesis of 2-phenylpyrroles from α-phosphazostyrenes and α-bromoketones in the presence of triethylamine is also thought to involve an initial carbon-carbon bond formation, followed thereafter by intramolecular aza-Wittig reaction.[65,68]

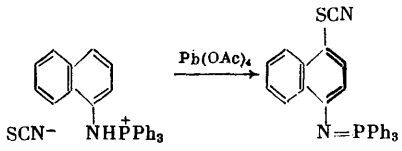


R = Ar, Me; R′ = H, Me, Ph or R + R′ = $(CH_2)_n$ (*n* = 4,5).

The same reaction with 2-bromocyclohexanone proceeds similarly to give the anticipated 2-phenyltetrahydroindole in 20% yield, together with 12% of 2-phenyl-4,5-tetramethylenefuran. The latter arises by ring closure of the intermediate γ-phosphazoketone with elimination of triphenylphosphine imine.[68]

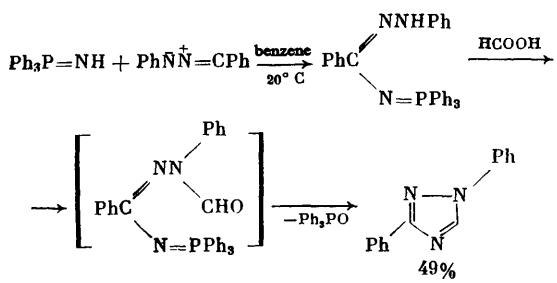


Two methods of preparing 2-phenyl-1-azaazulenes from α-phosphazostryenes have been reported. In a two-step procedure, 2-substituted tropones condense with an α-phosphazostyrene on heating in benzene to give 2-phenyl-8*H*-cycloheptanopyrroles, which are oxidised with nickel peroxide or manganese dioxide to give (LVIII). However, treatment of 2-halogenotropones with an α-phosphazostyrene in the presence of triethylamine leads to the 2-phenyl-1-azaazulenes (LVIII) in one step.[69,70]

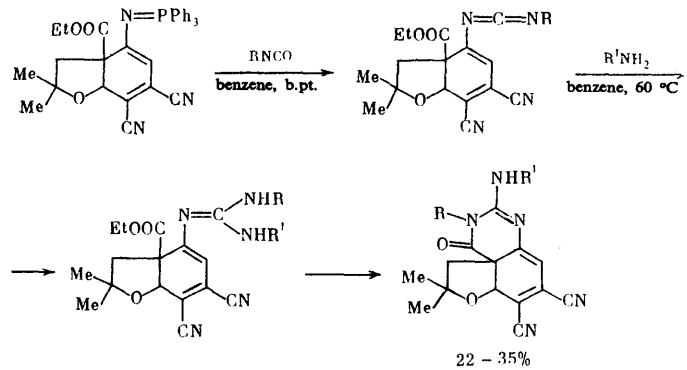


2,7-Diobromo-, 2,4,7-tribromo- and 2,3,5,7-tetrachloro-tropones react similarly to give the corresponding 1-azaazulenes in low yield.[70]

It is likely that oxidation of (2-naphthylamino)triphenylphosphonium thiocyanate and selenocyanate with lead tetraacetate also proceeds through an intermediate phosphazo compound. The interaction involves incorporation of the pseudohalide ion in the 1-position of the naphthalene ring, followed by a rather unusual cyclisation, which can be considered as an aza-Wittig reaction with participation of the cyano group; this is accompanied by an *N*-triphenylphosphino group migration. 2-Triphenylphosphazonaphtho[2,1-*d*]-thiazole and -selenazole are thereby obtained in 60–70% yield, and may be converted to the corresponding 2-aminoderivatives in 70–80% yield on hydrolytic cleavage.[71]



Y = S, Se



The suggested formation of a 1-thiocyano-2-phosphazonaphthalene in the first stage of the reaction was confirmed by the fact that similar oxidation of 1-naphthylaminotriphenylphosphonium thiocyanate, in which the 1-position is occupied, results in incorporation of the thiocyano group at the *para*-position to give 4-thiocyanato-1-triphenylphosphazonaphthalene in 65% yield.[71]

1,3-Diphenyl-1,2,4-triazole may be prepared via addition of triphenylphosphine imine to the 1,3-dipole, diphenylnitrilimine, followed by cyclisation of the resulting phosphazohydrazone on treatment with formic acid. It is most likely that ring closure proceeds by intramolecular aza-Wittig reaction after *N*-formylation of the intermediate hydrazone.[72]

The pyrimidine ring can be obtained via ring closure of an intermediate carbodiimide having a neighbouring carbalkoxy group, as shown below.

In the presence of an amine, reaction is complicated by formation of an intermediate guanidine, which condenses with the carbalkoxy group to give a low yield of furo[3,2-*e*]quinazolines.[73]

As is apparent from the data which has been collected, many types of N-heterocycle can be synthesised by the aza-Wittig reaction. These range from simple monocyclic compounds to complex polycyclic systems. The phosphazo groups—one of the components of this reaction—is readily prepared, notably from azides, and is resistant to a wide range of reagents. It can thus be retained while adjacent functionalities are manipulated, and then undergo intramolecular condensation as required to give heterocyclic compounds with a variety of different substituents.

In many cases, the resulting compounds are physiologically active or are of potential value as intermediates in the synthesis of physiologically active compounds including analogues of natural products.

A whole range of polycyclic compounds is available for the first time, and for many syntheses the aza-Wittig route is clearly more advantageous than alternative methods. The structures of the new heterocyclic compounds have been established, in most cases, by spectral data, by independent syntheses, and/or by studying their chemical properties.

Compounds of dicoordinate arsenic: chemical properties

E N Dianova, E Ya Zabotina
Butlerov Kazan Chemical Institute at the Ul'yanov-Lenin Kazan State University

ABSTRACT. The present review presents the known types of compounds of dicoordinate arsenic ($\lambda^3\sigma^2$As) with the exception of compounds with a formally charged dicoordinate arsenic atom. Data on the reactivity of the $\lambda^3\sigma^2$As systems are surveyed and described systematically. It is shown that the most characteristic and the most thoroughly investigated property is addition to a multiple or diene bond involving an arsenic atom. Certain cyclic $\lambda^3\sigma^2$As derivatives are known to exhibit the properties of aromatic compounds. The ability of derivatives of dicoordinate arsenic to behave as ligands in complex formation reactions involving the As atom, the As–X bonds (X = C, As, P), or the entire π-bond system is reported.

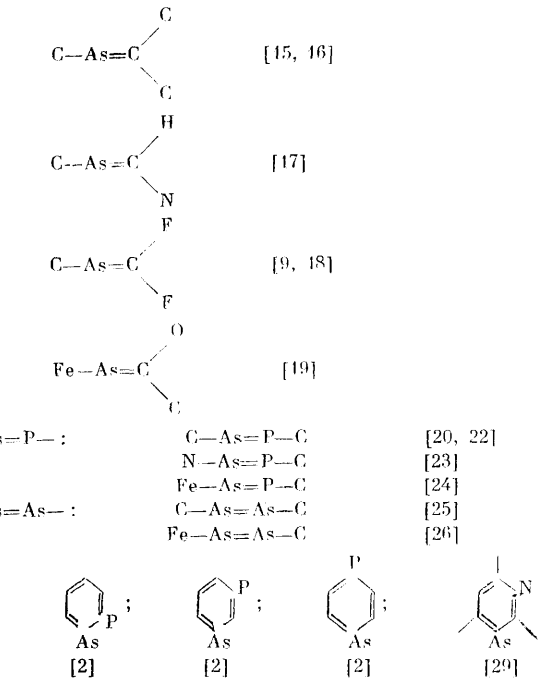
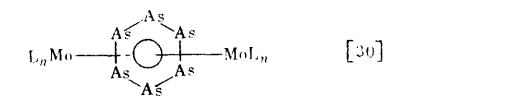
VI.	Complex formation	170



I. Introduction

As a consequence of the unusual coordination and the unusual reactivity, compounds of phosphorus and arsenic atoms involved in a low coordination have continually attracted the attention of chemists. Studies in the field of monocoordinate and dicoordinate phosphorus have appreciably overtaken the development of the chemistry of analogous organoarsenic derivatives. A whole series of review articles have been devoted to compounds of dicoordinate phosphorus ($\lambda^3\sigma^2$P).[1–12] There are virtually no reviews on $\lambda^3\sigma^2$As systems. As regards compounds of monocoordinate arsenic, the existence of a single representative is known: 2,4,6-t-$Bu_3C_6H_2$–C≡As.[13] This review surveys the results of the authors' own studies and the literature data on the reactivity of $\lambda^3\sigma^2$As compounds.



The known types of $\lambda^3\sigma^2$As derivatives are presented below {the literature references are given for the first representatives of the series [the numerals in square brackets denote references (Ed. of Translation)]}.

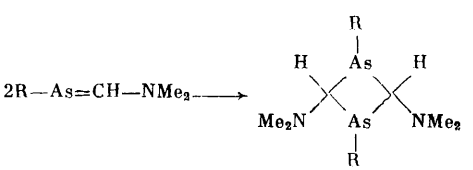
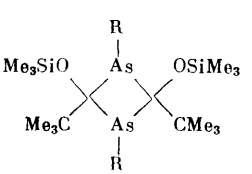
II. Dimerisation and 1,2-addition

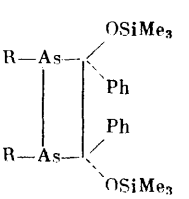
The first data on the chemical properties of derivatives of dicoordinate arsenic concern their instability and tendency to dimerise. Thus, when an attempt was made to synthesise 9,10-diarsaanthracene,[32] its dimer was obtained:



In the synthesis and on prolonged storage of 2,5-diphenyl-1,2,3-diazaarsole, we observed[42] its partial dimerisation. It was noted that there is a mobile equilibrium between the monomer and the dimer, the displacement of which in one direction or another depends on the nature of the solvent. Thus, in ether, benzene, and CH_2Cl_2, diazaarsole dimerises, while in solution in isooctane the dimer associates into the monomer, which was established with the aid of UV spectra:

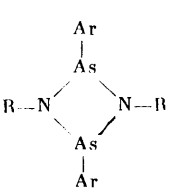


2,5-Diphenyl-1,2,3-diazarsole dimerises faster than it interacts with trichloroacetyl isocyanate or diphenyldiazomethane at room temperature.



Dimerisation also takes place in the case of acyclic $\lambda^3\sigma^2$As compounds. Thus the ready dimerisation of compounds with the $\lambda^3\sigma^2$As=C bond has been noted:[17]

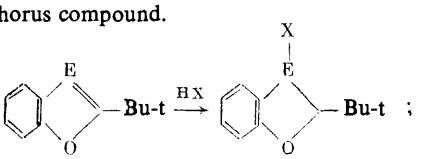
Two types of dimerisation with formation of 1,2- or 1,3-diarsaethanes have been observed:[43]



R = Me, Et, $PhCH_2$

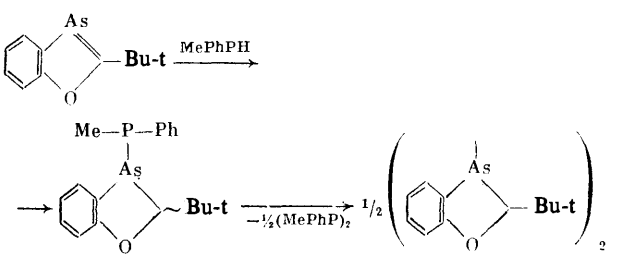
R = iso-Pr

In the case of perfluoroheteroalkenes[9] $F_3C-E=CF_2$ (E = P, As), a much greater tendency towards the dimerisation of arsaalkenes than of phosphaalkenes was noted.[9]

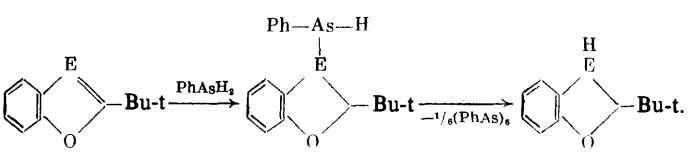


The attempts to obtain derivatives with the $\lambda^3\sigma^2$As=N bond[44,45] led to a negative result. The authors isolated diazadiarsetidines.

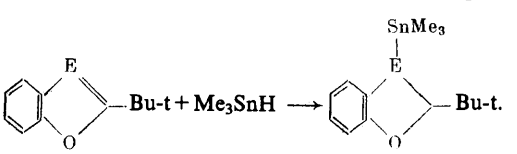
The structure of the compound with R = *p*-BrC_6H_4 was demonstrated by X-ray diffraction.



1,3-Benzoxa- and benzaza-arsoles can be classified as unsaturated compounds in terms of their tendency to undergo 1,2-addition reactions.[46]

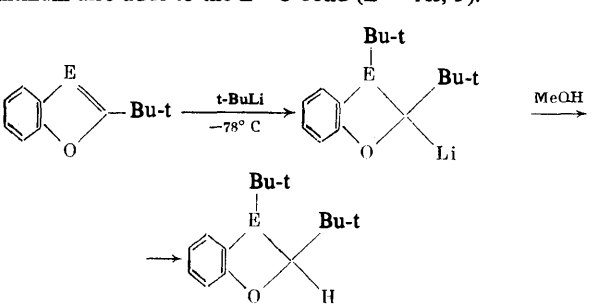


2-t-Butyl-1,3-benzoxazarsoles and the corresponding phosphole combine with "soft" bases at the E=C bond (E = As, P). The arsenic-containing compound is more reactive than the analogous phosphorus compound.

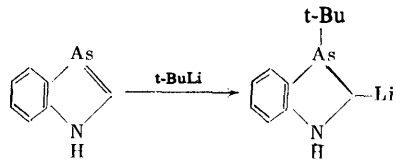


X = I, LL, SPh.

The higher reactivity of the compound with the As=C bond has been observed also in the reactions with methylphenylphosphine and phenylarsine. The reactions proceed in accordance with the following mechanism:



The addition of trimethyltin hydride takes place at the As=C and P=C bonds in 1,3-benzoxaarsole and 1,3-benzoxaphosphole:



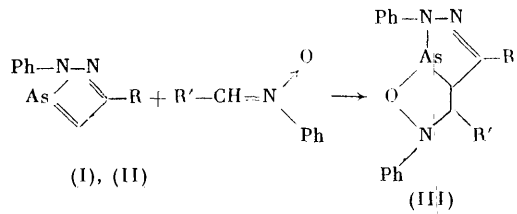
t-Butyllithium also adds to the E=C bond (E = As, P):

In contrast to 1,3-benzoxaarsoles, 1,3-benzazaarsoles show a greater tendency to undergo alkylation or metallation reactions (see Section V) than 1,2-addition reactions with participation of the As=C bond. Thus, among the known 1,3-benzazaarsoles, only the

unsubstituted 1,3-benzazaarsole reacts with t-butyllithium via the 1,2-addition mechanism:[47]

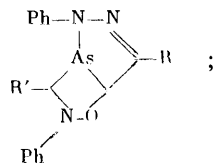
In the case of substituted 1,3-benzazaarsoles or other organolithium reagents, metallation in the 1- or 2-position in the ring takes place.

The above difference in the chemical behaviour of 1,3-benzazaarsoles and 1,3-benzoxaarsoles has been explained[46] by their different aromatic stabilisations. In the case of the oxygen-containing heterocycles, the latter is lower owing to the greater amount of double bond character in the E=C bond.



III. [2 + 3]Cycloaddition

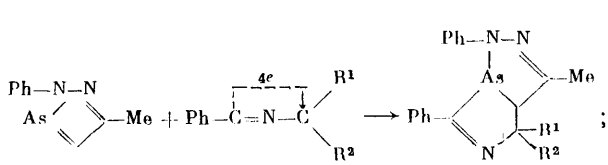
Until recently, the first and only objects of the study [2 + 3]cycloaddition were 2*H*=1,2,3-diazaarsoles. In 1986, examples of [2 + 3]cycloaddition to 1*H*=1,2,4-diazaarsoles appeared.



1. 2*H*-1,2,3-diazaarsoles

(a) Reactions with nitrones, nitrile oxides, and nitrile ylides

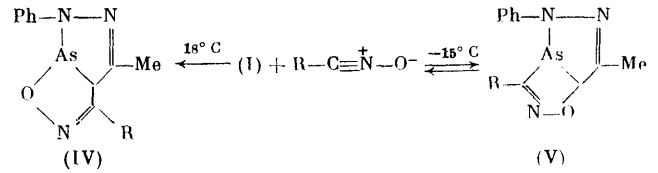
Cycloaddition to the $\lambda^3\sigma^2$As=C bond was achieved for the first time in the reaction of 2*H*=1,2,3-diazaarsoles (I) and (II) with nitrones:[48–50]



(I), (II) (III)

R=Me (I), R=Ph (II), R′=Ph, *p*-$NO_2C_6H_4$.

It has been established by X-ray diffraction[48] that, of the two possible isomers, 2,7-diphenyl-4-R-6-R′-1-arsa-2,3,7-triaza-8-oxabicyclo[3.3.0]oct-3-ene (III) is formed. Similar compounds based on 2*H*-1,2,3-diazaphosphole could not be obtained.



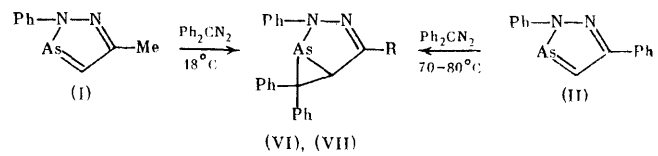
Carrie and co-workers showed that 2*H*-1,2,3-diazaarsoles as well as diazaphospholes react with nitrile oxides[51,62] and nitrile ylides[53] via the $\lambda^3\sigma^2$E=C bond. 2*H*-1,2,3-Diazaarsole (I) reacts with nitrile ylides to form one regioisomer:

(I)

R^1 = Ph, R^2 = H; R^1 = R^2 = H; R^1 = R^2 = Me.

Depending on the conditions, one or other regioisomer is formed in the case of nitrile oxides:

(IV) (V)



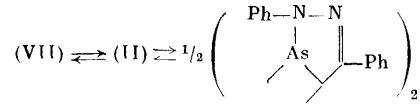
R=*p*-ClC_6H_4, t-Bu, Me, Ph.

The stable isomer (IV) was obtained at room temperature, while at −15 °C the product was the regioisomer (V). At room temperature in solution in toluene, the product (V) is converted quantitatively into compound (IV) via retrocycloaddition.

It may be that in the reaction of 2*H*-1,2,3-diazaarsoles with nitrones described above[48–50] the product (III) is also a thermodynamically controlled stable isomer, while its regioisomer could not be detected.

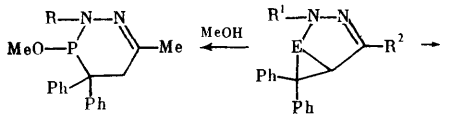
(b) Reactions with diphenyldiazomethane

The reaction of 2*H*-1,2,3-diazaarsoles (I) and (II) with diphenyldiazomethane leads to the bicyclic arsines (VI)[49] and (VII).[42,54] The formation of the arsirans (VI) and (VII) can be represented by the intial formation of the [2 + 3]cyclic adduct with the subsequent liberation of nitrogen. It has been demonstrated by a special experiment that diphenylcarbene does not afford the arsirans (VI) and (VII) on its reactions with diazaarsoles:



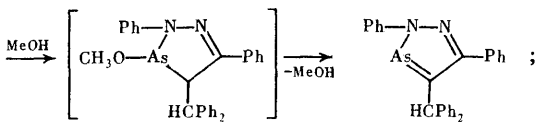
(I) (VI), (VII) (II)

R = Me(VI); R = Ph(VII).



The diazaarsole (I) is more reactive in this reaction than the diazaarsole (II). Compounds (VI) and (VII) obtained are the first representatives of bicyclic arsirans. The structure of the product (VII) was established by X-ray diffraction.[55] Comparison of the X-ray diffraction data for the bicyclic compound (VI) and the analogous phosphorus-containing system[56] revealed a greater strain in the arsiran ring, which explains its lower stability.

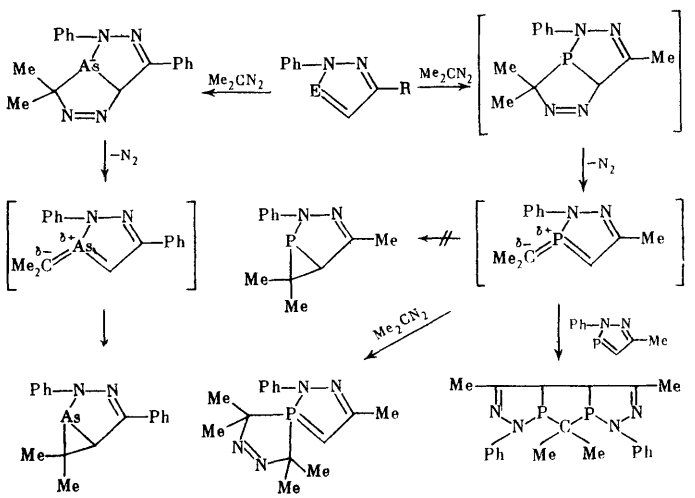
The bicyclic arsiran (VII) is stable only when stored in the dark in the absence of solvents. In solutions at room temperature, it exists for 24 h. It then decomposes to diazaarsole (II), which dimerises:



The difference between the strains in the arsiran and phosphiran rings is reflected in their different behaviour in relation to methanol. The addition of the alcohol to the phosphorus derivative (VIII) is accompanied by the dissociation of the inner P–C bond.[57] The addition of the alcohol to the bicyclic arsiran (VII) is apparently accompanied by the dissociation of the outer As–C bond with the subsequent liberation of the alcohol and the formation of 2,5-diphenyl-4-diphenyl-1,2,3-diaza-arsole. A new 2,4,5-trisubstituted 1,2,3-diazaarsole, whose structure was demonstrated by X-ray diffraction, has been obtained.[58] This is the first example of the $\lambda^3\sigma^3$As→$\lambda^3\sigma^2$As isomerisation in the series of diazaarsoles. In the

known [see, for example, Märkl[2] and Section (V) of the present review]:

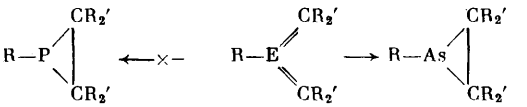
(VII), (VIII)



E = As(VII), P(VIII).

(c) Reactions with 2-diazopropane

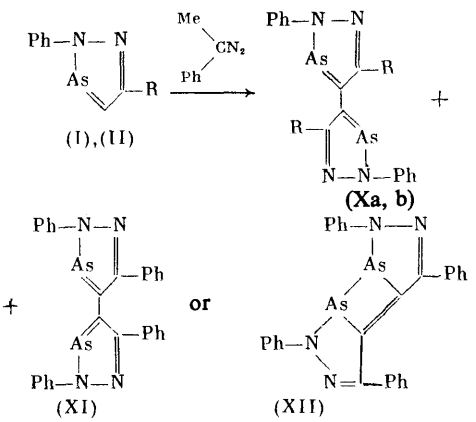
Whereas 2*H*-1,2,3-diazaarsoles and 2*H*-1,2,3-diazaphospholes react with diphenyldiazomethane similarly to form stable bicyclic arsirans and phosphirans,[55,59] 2-diazopropane[60–66] introduced its characteristic features into these reactions. When 5-methyl-2-phenyl-1,2,3-diazaphosphole reacts with 2-diazopropane,[60–65] the closure to the phosphiran ring does not occur and the intermediate diazaphosphole ylide behaves both as a dipole and as a dipolarophile in the subsequent [2 + 3]cycloaddition reactions with both initial reactants: diazaphosphole and 2-diazopropane. As a result, reactions which led to previously unknown types of organophosphorus compounds were discovered.



In the reaction with 2*H*-1,2,3-diazaarsole, 2-diazopropane[66] behaves similarly to diphenyldiazomethane. The final product is 2,4-diphenyl-6,6-dimethyl-1-arsa-2,3-diazabicyclo[3.1.0]hex-3-ene (IX). The bicyclic arsiran (IX) is formed via a crystalline cyclic adduct, detected at −70 °C. On further increase in temperature, the adduct evolves nitrogen and is probably converted into the product (IX) via a diylide:

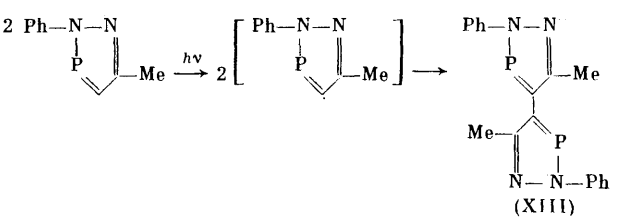
(IX)

The results reported[67] for acyclic phosphorus and arsenic diylides are similar to those obtained in the reaction with 2-diazopropane.



The arsenic diylide undergoes closure to the arsiran ring:

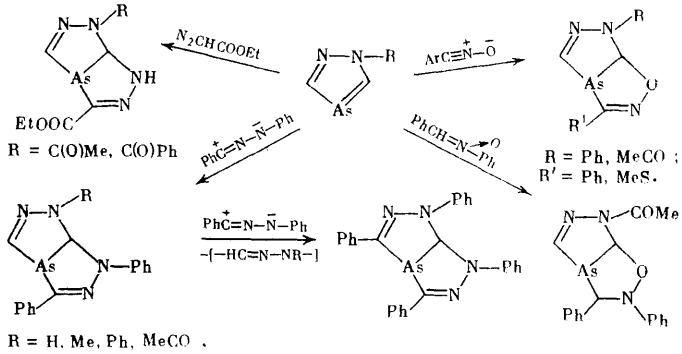
E = As, P; R = Ph, t-Bu; R′ = $SiMe_3$.



(d) Reactions with methylphenyldiazomethane

The reaction of 2*H*-1,2,3-diazaphospholes with methylphenyldiazomethane afforded in earlier studies[68,69] bicyclic phosphirans as two geometrical isomers. Similar isomers of bicyclic arsirans were not isolated in the reactions of 2*H*-1,2,3-diazaarsoles with the given diazo-compound. 1,4-Diarsabuta-1,3,-dienes (Xa, b) were obtained for the first time:[40]

R = Me (a), Ph (b).



In addition, in the case of 2,5-diphenyl-1,2,3-diazaarsole (II) a second isomer, (XI) or (XII), was isolated. It could not be studied by X-ray diffraction owing to the insufficiently high quality of the crystals. *trans*-4,4′-Didehydrobis(5-methyl-2-phenyl-1,2,3-diazaarsole) (Xb) proved to be a full analogue (on the basis of X-ray diffraction data) of *trans*-4,4′-didehydrobis(5-methyl-2-phenyl-1,2,3-diazaphosphole) (XIII).[40,70,71] The data for the reactivity of diazaarsoles available at the present time, permit inferences about the mechanism of the formation of 1,4-diarsabuta-1,3-dienes (Xa, b). The phosphorus-containing product (XIII) was obtained under other conditions—on UV irradiation of 5-methyl-2-phenyl-1,2,3-diazaphosphole:

2. 1*H*-1,2,4-diazaarsoles

1*H*-1,2,4-Diazaarsoles enter under mild conditions into [2 + 3]-cycloaddition reactions with diazoacetic ester, nitrile imines, nitrile oxides, and nitrones.[41] It has been noted that the reactivity of *N*-acyl- and *N*-benzoyl-1,2,4-diazaarsoles is higher than that of the *N*-alkyl- and *N*-aryl-derivatives, which the authors explain by the reduced stabilisation of the aromatic system of the diazaarsole ring

in the acyl- and benzoyl-substituted compounds:

R = C(O)Me, C(O)Ph

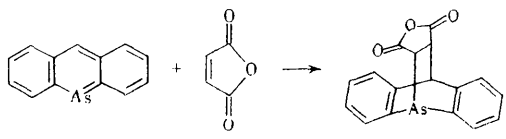
R = Ph, MeCO ; R' = Ph, MeS.

R = H, Me, Ph, MeCO .

The [2 + 3]cycloaddition of nitrile oxides to 1*H*-1,2,4-diazaarsoles leads to a single regioisomer. In contrast to the reactions of 2*H*-1,2,3-diazaarsole (I) with nitrile oxides described previously,[51] the inversion of regioselectivity is not observed in this instance.

The reaction with diphenylnitrile imine results in the formation of cyclic adducts even at room temperature. At a higher temperature, they decompose to 1,3-diphenyl-1,2,4-diazaarsole. The latter enters again into the cycloaddition reaction with diphenylnitrile imine.

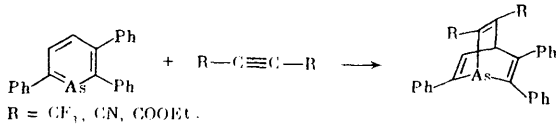
1-Acetyl-1,2,4-diazaarsole reacts with diphenyl nitrone to form a bicyclic adduct. It is of interest to note that the reactions of 2-phenyl-1,2,3-diazaarsoles (I) and (II) with diphenyl nitrone afforded in earlier studies[48–51] the product (III) with the opposite orientation of the nitrone relative to the $\lambda^3\sigma^2$As=C bond.



We did not encounter any data in the literature on the polarity of the $\lambda^3\sigma^2$As=C bond. Nevertheless, the formation of different regioisomers from 2*H*-1,2,3- and 1*H*-1,2,4-diazaarsoles and diphenyl nitrone shows that the regioselectivity of the addition to the As=C bond is determined not only by the charges on the atoms but also by the polarisability of the bond and the molecular-orbital characteristics of the reactants.

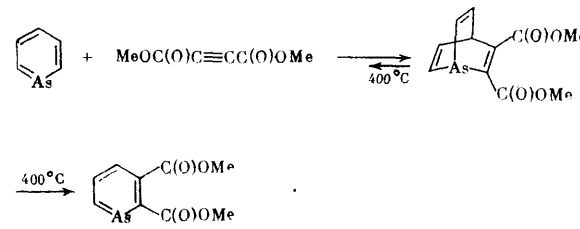
IV [2 + 4]cycloaddition

Depending on their structure, the $\lambda^3\sigma^2$As derivatives are capable of entering into the diene synthesis reaction as dienes and dienophiles.



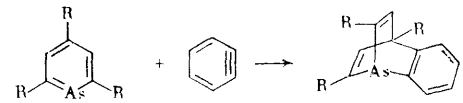
1. 9-Arsaanthracene

The unsubstituted 9-arsaanthracene exists only in solutions. After the addition of maleic anhydride, it gives rise to the [4 + 2]cyclic adduct.[33] This reaction was the first example of diene synthesis with participation of a $\lambda^3\sigma^2$As derivative:

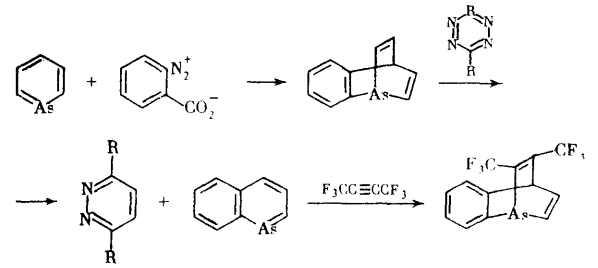


2. λ^3-Arsenins

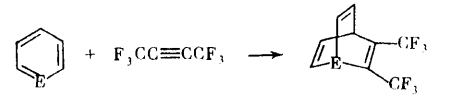
The reactivity of arsenins as dienes was first reported by Märkl:[72]



R = CF_3, CN, COOEt .



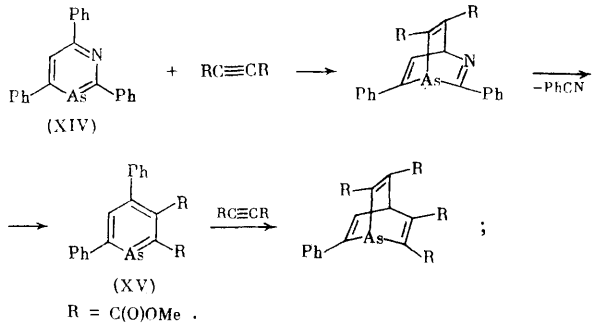
Arsenins exhibit a higher diene reactivity than phosphorins. In contrast to phosphorins, the [2 + 4]cycloaddition of dimethyl acetylenediacarboxylate to arsenins was achieved.[72–76] The thermal reversibility of the formation of arsabarrelenes was demonstrated in relation to the unsubstituted arsenin:[76]



The 2,3-dimethoxycarbonylarsenin obtained at 400 °C enters into the diene synthesis reaction with arynes, which leads to benzarsabarrelenes:[72]

Ashe et al.[31] achieved a series of reactions during which [2 + 4]cycloaddition with participation of the $\lambda^3\sigma^2$As derivatives takes place: (1) reaction of arsenin with benzenediazonium-2-carboxylate and (2) reaction of 1-arsanaphthalene with hexafluorodimethylacetylene:

Comparison of the diene reactivities of benzene, pyridine, phosphorin, arsenin, antimonin, and bismin in relation to hexafluorobutyne showed[76] that the less electronegative the heteroatom in the ring the easier the Diels–Alder reaction:



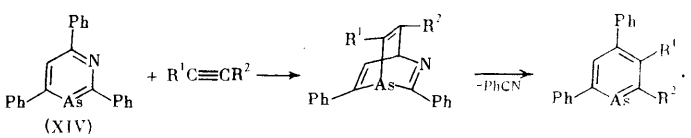
E = CH, N, P, As, Sb, Bi.

3. 1,3-Azaarsenines

The 1,3-azaarsenines synthesised by Märkl and Dietl[29] proved to be preparatively valuable.

2,4,6-Triphenyl-1,3-azaarsenine (XIV) enters into the Diels–Alder reaction with dimethyl acetylenedicarboxylate to form 1,3-azarsabarrelene, which decomposes during the reaction to the arsenin (XV). The latter is involved in a further diene synthesis reaction

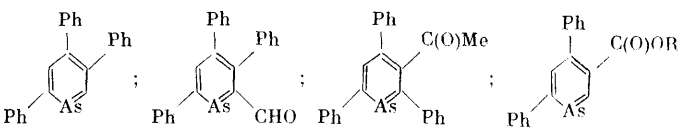
with the initial dimethyl acetylenedicarboxylate:[77]



(XIV)

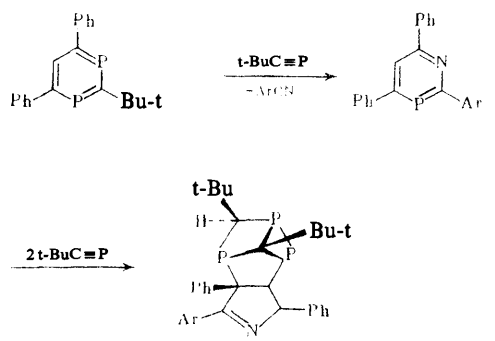
(XV)

R = C(O)OMe .



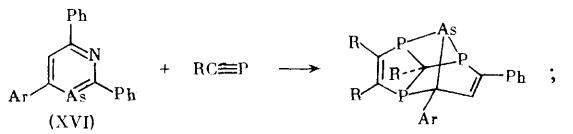
In contrast to the azaarsenine (XIV), the reaction of 2,4,6-triphenyl-1,3-azaphosphorine with acetylenedicarboxylate esters stops at the stage involving the formation of derivatives of $\lambda^3\sigma^2$P-phosphorins analogous to compound (XV). The phosphorins do not react further with acetylenedicarboxylate, which is consistent with the lower diene reactivity of phosphorins compared with arsenins.

1,3-Azaarsenines (XIV) react similarly with less reactive dienophiles. The azaarsabarrelenes obtained are converted into arsenins which do not enter into the Diels–Alder reaction:[77]



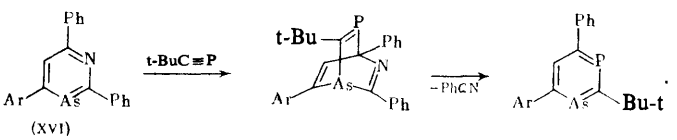
(XIV)

The following arsenins were obtained in this way:



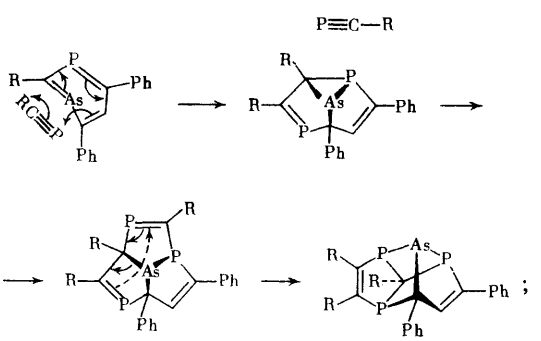
R = Me, H

Interesting data have been secured by Märkl and co-workers in the study of the reaction of 1,3-azaphosphorines[78,79] and 1,3-azaarsenines[80] with t-butyl-1-phosphaacetylene. 1,3-Azaphosphorines give rise to pentatetracyclic compounds in this reaction:



1,3-Azaarsenines (XVI) behave differently in this reaction: a compound with the 1,3-composition is formed. X-Ray diffraction analysis showed that the reaction product consists of a system comprising three five-membered and one four-membered ring:

(XVI)

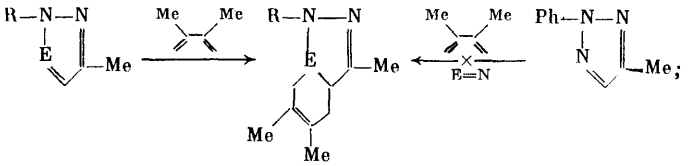


R = t-Bu.

The different behaviour of azaphosphorines and azaarsenines in this reaction has been explained[80] by the lower electrophilicity of the $\lambda^3\sigma^2$As atom in the azaarsenine compared with the electrophilicity of the $\lambda^3\sigma^2$P atom in the azaphosphorine, which leads to different mechanisms of their reactions. Whereas the reaction of the azaphosphorine with t-butylphosphaacetylene is induced by the nucleophilic attack of the acetylene *sp*-carbon atom on the $\lambda^3\sigma^2$P atom of the azaphosphorine in the case of the azaarsenine (XVI) the Diels–Alder reaction takes place initially. A phosphaarsabarrelene is formed. After the introduction of benzonitrile, it is converted into 1,3-phosphaarsenin:

(XVI)

The authors believe that the latter reacts with phosphaacetylene via the following mechanism:



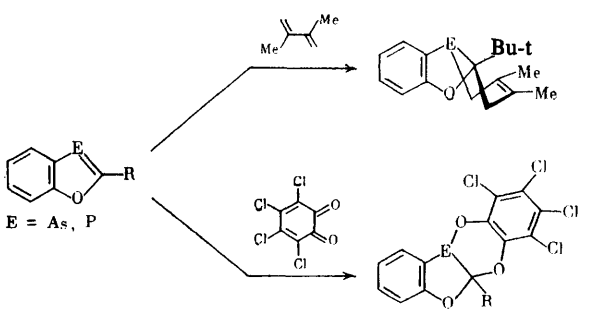
R = t-Bu.

Thus Märkl and co-workers carried out a brilliant series of studies in the field of diene synthesis involving six-membered $\lambda^3\sigma^2$P and $\lambda^3\sigma^2$As derivatives. The investigations led to new substituted λ^3-arsenins and λ^3-phosphorins. In addition the higher reactivity of arsenines compared with phosphorines in the Diels–Alder reaction was demonstrated and justified.

4. 2*H*-1,2,3-Diazaarsoles

We showed earlier[57] that 2*H*-1,2,3-diazaphospholes, which are derivatives of dicoordinated phosphorus, enter into the diene synthesis reaction with hexachlorocyclopentadiene. The ability of 2*H*-1,2,3-diazaarsoles to react with dienes was reported by Carrier and co-workers[81] in relation to the interaction with cyclopentadiene and 2,3-dimethylbutadiene. The reactivity of 5-methyl-2-phenyl-1,2,3-diazaarsole, 2,5-dimethyl-, 5-methyl-2-phenyl, and 2-acetyl-5-methyl-1,2,3-diazaphospholes, and 5-methyl-2-phenyl-1,2,3-triazole

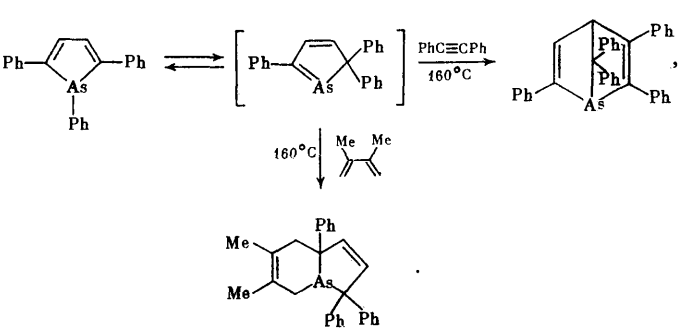
in relation to 2,3-dimethylbutadiene were compared:



E = P, R = MeCO, Ph; E = As, R = Ph (I).

2-Acetyl-5-methyl-1,2,3-diazaphosphole and 5-methyl-2-phenyl-1,2,3-diazaarsole are the most reactive in this reaction. Cyclic adducts with 2,5-dimethyl-1,2,3-diazaphosphole and the corresponding triazole were not obtained. The absence of the reaction between the triazole and 2,3-dimethylbutadiene clearly demonstrates the greater reactivity of the $\lambda^3\sigma^2P=C$ and $\lambda^3\sigma^2As=C$ bonds compared with the $\lambda^3\sigma^2N=C$ bond in the reactions considered.

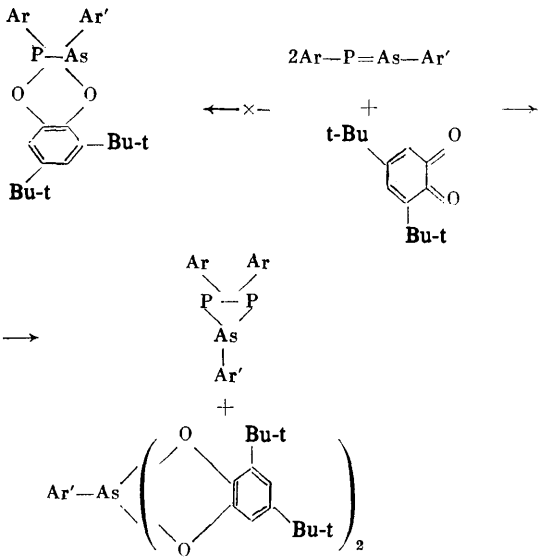
5. 1,3-Benzoxaarsoles



1,3-benzoxaarsoles and 1,3-benzoxaphospholes react [82] with 2,3-dimethylbutadiene and tetrachloro-*o*-benzoquinone to form [2 + 4]-cyclic adducts. The $\lambda^3\sigma^2As$ derivative is more reactive in these processes than the $\lambda^3\sigma^2P$ compound.

R = Me, t-Bu.

6. 2,5,5-Triphenylarsole

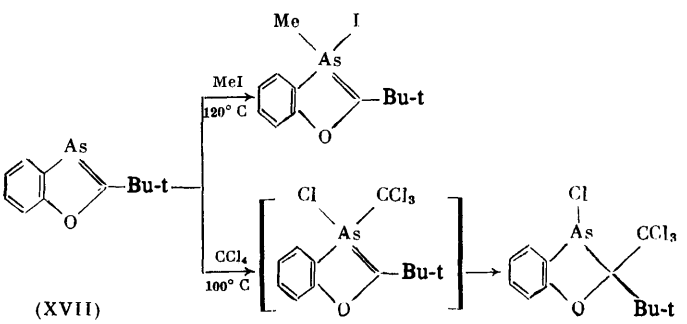


At a high temperature, 1,2,5-triphenylarsole isomerises to 2,5,5-triphenylarsole, which enters into the Diels–Alder reaction both as a diene (in the reaction with tolane) and as a dienophile (in the reaction with 2,3-dimethylbutadiene):[37]

Similar results were obtained for a phosphorus-containing compound — 1-phenylphosphole.[37] The Diels–Alder reaction proceeds more readily with arsoles than with phospholes, because, according to the authors, the lone pair of the arsenic atom is less reactive than that of the phosphorus atom.

7. Phosphaarsaethylenes

Data on reactions involving cycloaddition to acyclic $\lambda^3\sigma^2As$ compounds are almost absent in the literature. There is a communication[83] stating that an attempt to obtain the [2 + 4]cyclic adduct by the reaction of *P*-(2,4,6-tri-t-butylphenyl)-*As*-(2,4,6-tri-isopropylphenyl)phosphaarsaethylene with 3,5-di-t-butyl-*o*-benzoquinone was unsuccessful, diphosphaarsiran and arsine being obtained:

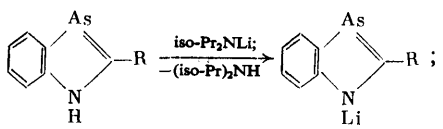


V. Aromaticity

The chemical properties described above (Sections II–IV) characterise $\lambda^3\sigma^2As$ compounds as systems related to unsaturated compounds. However, individual representatives of cyclic derivatives of dicoordinate arsenic exhibit also the properties of aromatic systems.

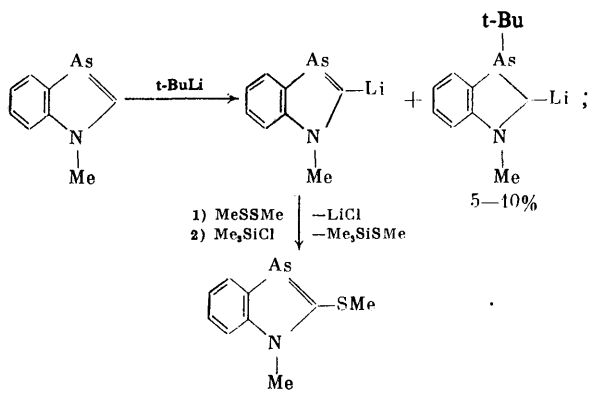
1,3-Benzaza- and 1,3-benzoxa-arsoles and 1,3-benzaza- and 1,3-benzoxaphospholes can be classified as aromatic compounds in terms of the nature of the delocalisation of the π-electrons (according to UV-spectroscopic and X-ray diffraction data).[84,85] X-Ray diffraction data for unsubstituted benzazaarsole[84] (bond lengths, bond angles, and planarity of the molecule) indicate the aromaticity of the latter. Comparison of the structural parameters of benzimidazole, benzazaphosphole, and benzazaarsole demonstrated their electronic and structural similarly.[85]

2-t-Butyl-1,3-benzoxaarsole (XVII) exhibits a low reactivity in relation to electrophiles. However, under severe conditions it reacts with MeI to form λ^5-1,3-benzoxaarsole:[46]



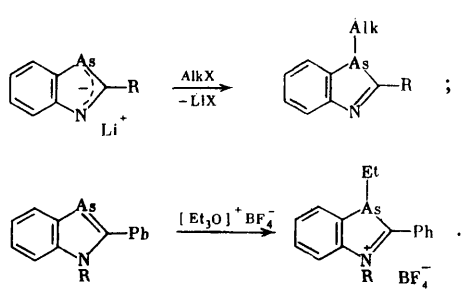
(XVII)

The reaction with CCl_4 proceeds differently. The primary 1,1-adduct rearranges under these conditions to λ^3-dihydrobenzoxaarsole.

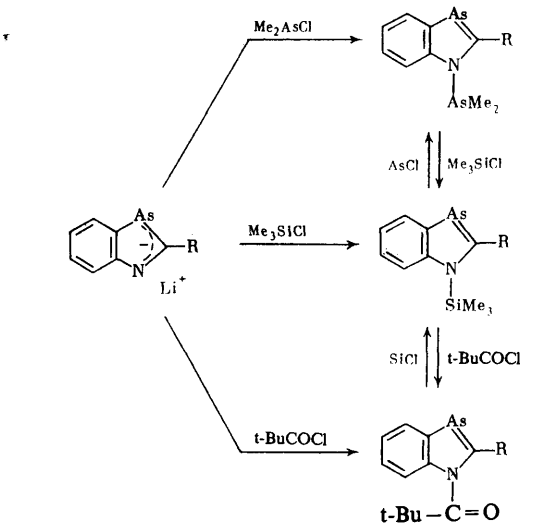


1,3-Benzoxaarsole and 2-t-butyl-1,3-benzoxaphosphole do not react with "hard" bases,[46] which also indicates their aromaticity.

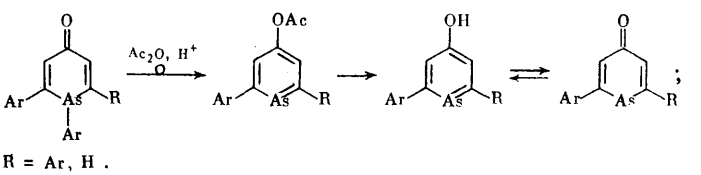
The metallation of 2R-1,3-benzazaarsoles[47] takes place in the 1-position in the azaarsole ring:



R = H, Me, t-Bu, iso-Pr.

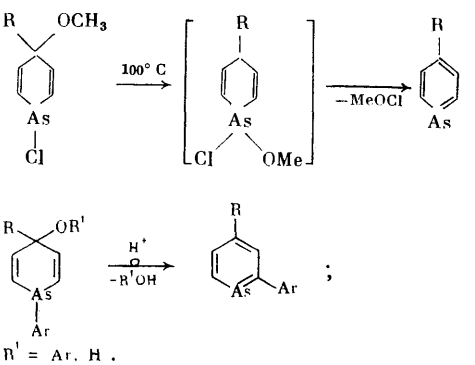


In contrast to unsubstituted 1,3-benzazaarsole, which reacts with t-butyllithium via the 1,2-addition mechanism, 1-methyl-1,3-benzazaarsole is metallated by t-butyllithium in the 2-position. The metallation product reacts with dimethyl disulphide, forming 1-methyl-2-methylthio-1,3-benzazaarsole:

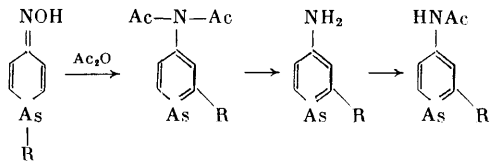


Whereas unsubstituted 1,3-benzaazaarsole does not react with MeI,[86] substituted 1,3-benzazaarsoles are alkylated[47] at the arsenic atom:

An interesting chain of substitutions has been achieved by Heinicke et al.:[47]

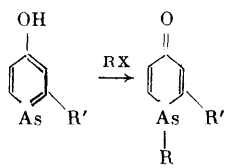


The properties of aromatic systems are also shown by representatives of another class of $\lambda^3\sigma^2$As compounds—arsenins. Thus 1-aryl- and 1,2-diaryl-arsacyclodienones[87,88] in acetic anhydride undergo, in the presence of a catalytic amount of H_2SO_4, the arsacyclohexadienone-arsaphenol rearrangement, corresponding to the rearrangement in the aromatic series, forming 2-aryl-6R-4-hydroxyarsenin. Alkaline hydrolysis of the latter gives rise to 2,6-diarylarsacyclodien-4-ones, which exist in solution in equilibrium with their enolic forms. In contrast to the 2,6-disubstituted 4-hydroxyarsabenzenes unsubstituted 4-hydroxyarsabenzene[89] exists exclusively in the enolic form and there is no tautomeric conversion into the cyclodienone.



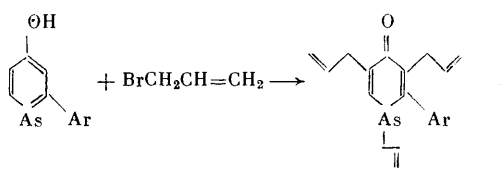
R = Ar, H .

The conversion of $\lambda^3\sigma^3$As derivatives into $\lambda^3\sigma^2$As compounds, which are more conjugated systems,[2,88,90,91] is known to occur in a number of instances:



R' = Ar, H .

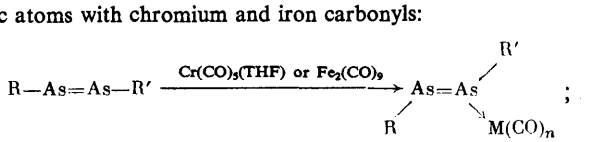
An interesting series of transformations was achieved by Märkl and Rampal[92] in the oxime–aminoarsenin series:



4-Hydroxyarsenins[87] are alkylated preferentially in the hydroxy-group with the subsequent migration of the alkyl substituent to the arsenic atom:

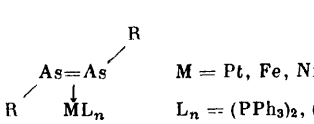
$R' = Ar, H;\ X = I, Br$.

In the reaction of 2-aryl-4-hydroxyarsenin with 3-bromopropene, substitution in the arsabenzene ring also takes place:



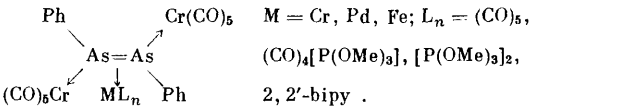
Among the chemical properties of arsinines considered (Sections IV and V), one may note their dual reactivity. On the one hand, they enter into the diene synthesis reaction as dienes and on the other they undergo reactions characteristic of aromatic compounds. Admittedly, both types of reactions characterise arsinines as conjugated systems. The ability of arsinines to enter into complex formation reactions (see the next Section) involving the $\lambda^3\sigma^2$As atom as well as the entire π-system also indicates the wide variety of their properties.

VI. Complex formation

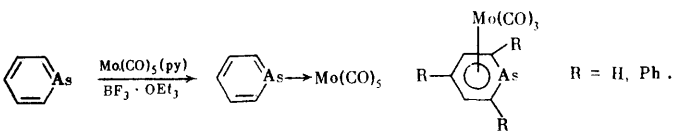


There are some data on the complex formation reactions of derivatives of dicoordinate arsenic. They are partly included in a review article.[7] So far η^1-, η^2-, and η^6-complexes of $\lambda^3\sigma^2$As compounds are known.

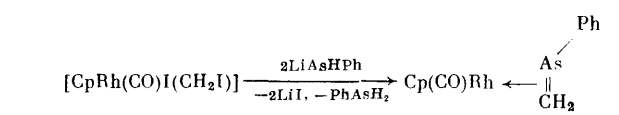
Diarsenes[93,94] are capable of forming η^1-complexes via one of the arsenic atoms with chromium and iron carbonyls:



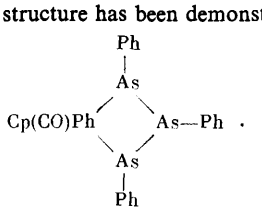
$R = 2, 4, 6\text{-}(t\text{-}Bu)_3C_6H_2$, $R' = (Me_3Si)_2CH$.



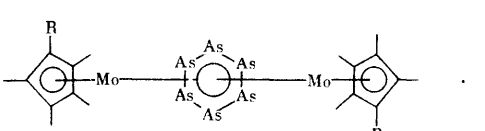
The η^2-complexes of diarsenes have been obtained:[94–97]



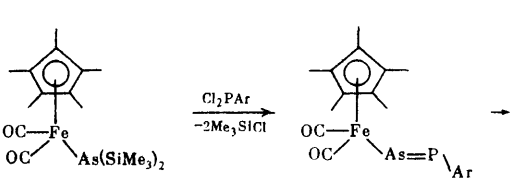
Diphenyldiarsene can enter into the complex formation reaction involving both the double bond and the arsenic atoms,[98–100] forming the following compounds:



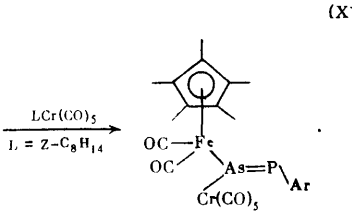
In the case of λ^3-arsenin, the η^1-complexes[101] and the η^6-complexes[101,102] are known:



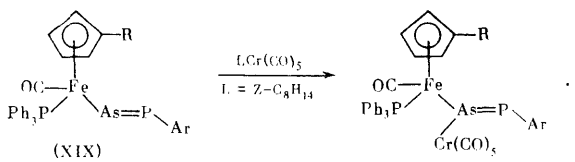
It has been noted that complex formation promotes the stabilisation of $\lambda^3\sigma^2$As atoms. Thus phenylarsene Ph–As=CH_2 does not exist in a free state but its η^2-complex has been obtained:[103,104]



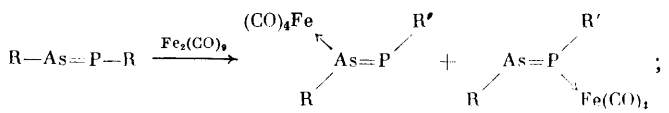
On recrystallisation, the latter is partly converted into a compound whose structure has been demonstrated by X-ray diffraction:



Hexaarsabenzene is known[30] at the present time only in the form of η^6-complexes:

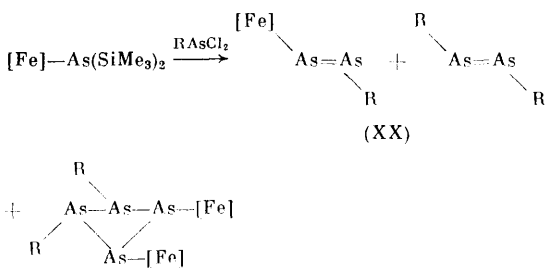


The formation of the phosphaarsene (XVIII) has been detected spectroscopically in the reaction mixture and its complex has been isolated.[105,106] The structure of the latter has been demonstrated by X-ray diffraction:

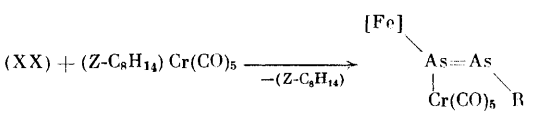


(XVIII)

In contrast to compound (XVIII), the phosphazaarsene (XIX) is stable. Its reaction with $Cr(CO)_3$ afforded[107] an η^1-complex:



Phosphaarsenes are capable of forming complexes not only via the $\lambda^3\sigma^2$As atom but also via the $\lambda^3\sigma^2$P atom. A mixture of such complexes has been obtained.[108,109] They could not be separated, but they were identified spectroscopically by $^{31}P\{^1H\}$ NMR:



$R = 2,4,6\text{-}(t\text{-}Bu)_3C_6H_2$, $R' = (Me_3Si)_2CH$.

The synthesis of the diarsene (XX) [26] is not ambiguous, in contast to the analogous synthesis of the phosphaarsene (XVIII):

$[Fe] \equiv (\eta^5\text{-}C_5Me_5)(CO)_2Fe$; $R = 2,4,6\text{-}(t\text{-}Bu)_3C_6H_2$.

Compound (XX) is unstable, but its $Cr(CO)_5$ derivative proved to be stable:

- - - o 0 o - - -

The experimental data examined in this review indicate the high reactivity of $\lambda^3\sigma^2$As derivatives. The wide variety of the properties shown by these compounds opens a route to various chemical reactions, new types of reactions, and the synthesis of new organoarsenic compounds. Further study of the chemical properties of dicoordinate arsenic is therefore of current interest.

Functionalisation of heterocycles by Ni- and Pd-catalysed reactions

V N Kalinin
The A N Nesmeyanov Institute of Elementoorganic Compounds, Academy of Sciences of the USSR

ABSTRACT. The review covers carbon–carbon bond formation at heterocyclic ring positions by Ni- and Pd-catalysed cross-coupling, alkenylation and alkynylation. The influence of the catalyst and the metal of the organometallic component on the facility of cross-coupling has been analysed, and the limitations emphasised.

The bibliography contains 228 references.

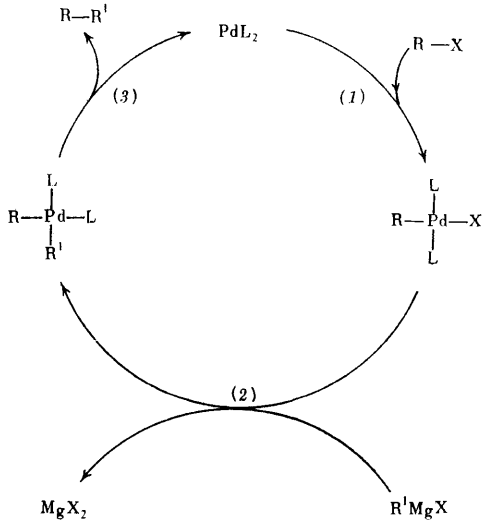
I. Introduction

The substitution of heterocyclics is a key step in the synthesis of many physiologically active compounds. A carbon–carbon bond can be formed conveniently by reacting lithiated heterocyclics with sufficiently reactive electrophiles, such as alkyl halides.[1] However, the method cannot be used for coupling aryl, alkenyl and heterocyclic halides where the halogen is at an sp^2-hybridised carbon atom, since here the halogen is not reactive enough.

Cross-coupling is defined as a process where a simple carbon–carbon bond is formed between two carbon radicals. The reaction of organometallic compounds with organic halides or other electrophiles falls in this category:[2]



$$R^1M + R^2X \rightarrow R^1{-}R^2 + MX.$$

Although the above scheme appears simple, this type of cross-coupling is complicated by side-reactions. The classical Wurtz synthesis is a variation on this theme, where a halogen-metal exchange is followed by homo-coupling. If the halide has a branched alkyl group, α- and β-elimination takes place. Uncatalysed cross-coupling does not take place with unsaturated halides where the halogen is bonded to an sp^2- or *sp*-carbon atom.

In 1972 Corriu and Masse[3], and Kumada et al.,[4] introduced nickel-catalysed cross-coupling between reactive Grignard compounds and organic halides. Later, palladium and other Group VIII complexes were found to catalyse this reaction. The main advantages of using Ni and Pd complexes for such catalysed cross-coupling are the higher selectivity of the reaction, the mild conditions, and the possibility of using unsaturated halides. As a result, synthetic organic chemistry has benefited significantly.

Organolithium compounds have rarely been used in catalysed cross-coupling. The use of Grignard reagents in this capacity has been limited to some extent by their reducing properties towards transition metal salts. Organo-zinc, -boron and -aluminium compounds are more compatible with complex metal catalysis and are highly reactive towards organic halides. The same is true of organotin compounds in view of their high stability and the potential of introducing functionalised residues. The following catalysts are usually used for cross-coupling: $Ni(acac)_2$, $M(PPh_3)_4$, $MCl_2(PPh_3)_2$, MCl_2(dppe), MCL_2(dppp), MCl_2(dppb), MCl_2(dppf)† (where M = Ni or Pd), $Pd(OAc)_2[P(o\text{-}Tol)_3]_2$ and others. Usually the zero-valent complexes, M(0), are generated from the corresponding M(II) complexes *in situ*. Palladium catalysts are the more widespread. The catalytic cycle is based on the redox couple, Pd(0) ⇄ Pd(II), and comprises the following three stages: (*1*) oxidative addition, (*2*) transmetallation, and (*3*) reductive elimination, as shown below.[5]

Scheme 1

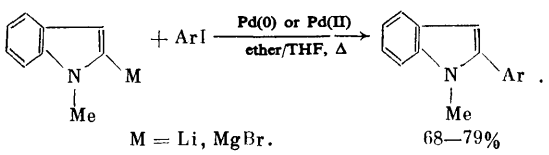
Cross-coupling is complicated if the transferred alkyl group has a β-hydrogen atom since here transfer of β-hydrogen in the Pd-intermediate is dominant with the formation of a Pd–H complex on elimination of olefin. Catalysed cross-coupling is most effective with alkenyl, aryl and heterocyclic halides.

General aspects of catalysed cross-coupling have already been reviewed[6–9] or covered in monographs.[5,10–13] However, cross-coupling with heterocyclic compounds has not been adequately surveyed. Negishi's review[14] is based on literature published up to 1982.

† dppe = $Ph_2PCH_2CH_2PPh_2$, dppp = $Ph_2PCH_2CH_2CH_2PPh_2$, dppb = $Ph_2P(CH_2)_4PPh_2$, dppf = $(\pi\text{-}Ph_2PC_5H_4)_2Fe$.

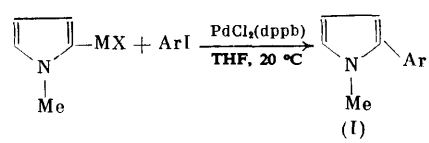
The present review covers cross-coupling with heterocyclic systems in the presence of Ni and Pd complexes. It focusses on cross-coupling with heterocyclic organometallic derivatives and heterocyclic halides. There is also a section on the reactions of heterocyclic halides with alkenes and terminal acetylenes which lead to vinyl- and alkenyl-heterocyclics under metal complex catalysis. Homo-coupling of heterocyclic halides is considered separately.

In discussing the data, the accent is placed on synthetic aspects of cross-coupling and preparative applications.

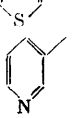


II. Cross-coupling between heterocyclic halides and heterocyclic organometallic derivatives

For the synthesis of substituted heterocyclic compounds by catalysed cross-coupling, one can consider three possible routes: a) cross-coupling of heterocyclic organometallic compounds with organic halides, b) cross-coupling of organometallic compounds with heterocyclic halides, and c) cross-coupling of heterocyclic organometallic compounds with heterocyclic halides.

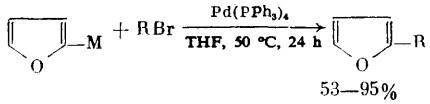


1. Organo-lithium, -magnesium and -zinc compounds

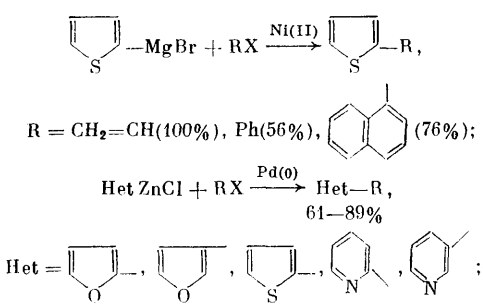


Organolithium compounds are not normally used in cross-coupling. As a rule, they are used as precursors of other organometallic compounds, e. g. organo-zinc, -boron and -tin compounds, etc.

1-Methylindol-2-yl-lithium and -magnesium bromide readily react with aryl iodides in the presence of Pd(0) or Pd(II) complexes to give 2-arylindoles.[15,16]

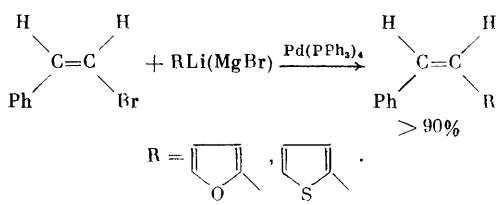


1-Methyl-2-pyrrolyl-magnesium bromide and -zinc chloride react with aromatic or heterocyclic halides in the presence of palladium phosphine complexes to give the corresponding 2-substituted pyrroles:[15]



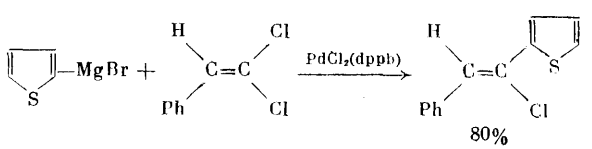
MX	Ar	Yield (I), %
MgBr		87
		71
MX	Ar	Yield (I), %
ZnCl		73
		66

2-Furyl-lithium and -zinc chloride readily interact with aryl, benzyl and cinnamyl bromide in the presence of Pd(0).[17]

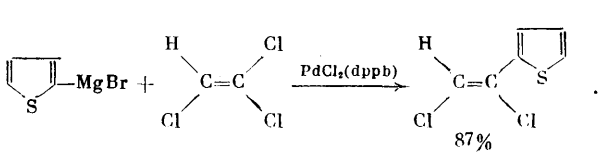


R = Ph, 4-MeC_6H_4, 3-MeC_6H_4, 4-$MeOC_6H_4$, 3-$MeOC_6H_4$, 3,4-$(MeO)_2C_6H_3$, 4-$O_2NC_6H_4$, $PhCH_2$, $PhCH{=}CHCH_2$.

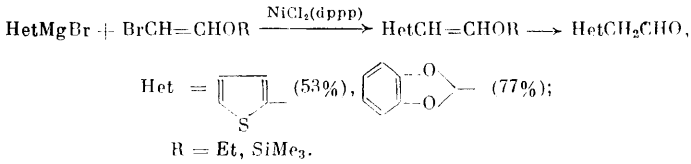
Unsaturated groups may be introduced at heterocyclic ring positions by cross-coupling of the corresponding heterocyclic organomagnesium[18] or -zinc[19] compounds with vinyl chloride or bromide, bromo- or iodo-benzene, bromonaphthalene, and with 1-bromooct-1-yne in the presence of a Ni or Pd catalyst.



β-Styrylheteroarenes can conveniently be prepared by interaction of β-styryl bromide with 2-furyllithium, 2-thienyllithium and 2-furylmagnesium bromide in the presence of a Pd(0) catalyst.[20]

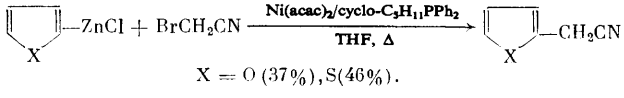


Reaction proceeds with complete retention of configuration, *trans*-β-styryl bromide affording the corresponding *trans*-β-styryl-heteroarene.

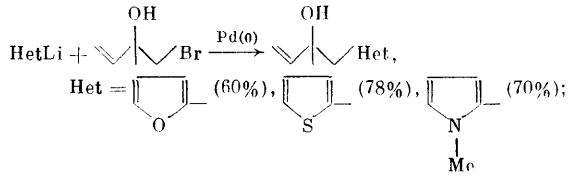


The reaction between 1,1-dichloroalkenes with 2-thienylmagnesium bromide also proceeds with high stereoselectivity.[21]

The corresponding *cis*-dichloroalkenes are obtained with trichloroethylene:

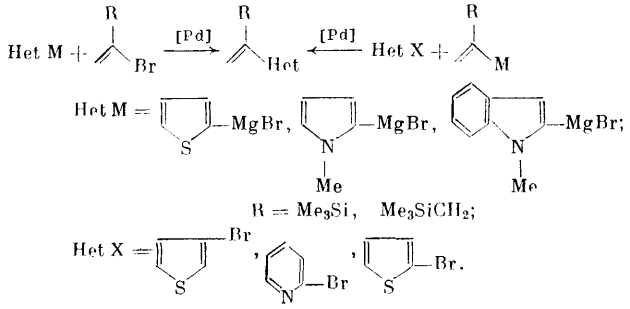


A one-pot bishomologisation of heterocyclic Grignard compounds can be achieved by cross-coupling with β-bromovinyl ethers.[22,23]

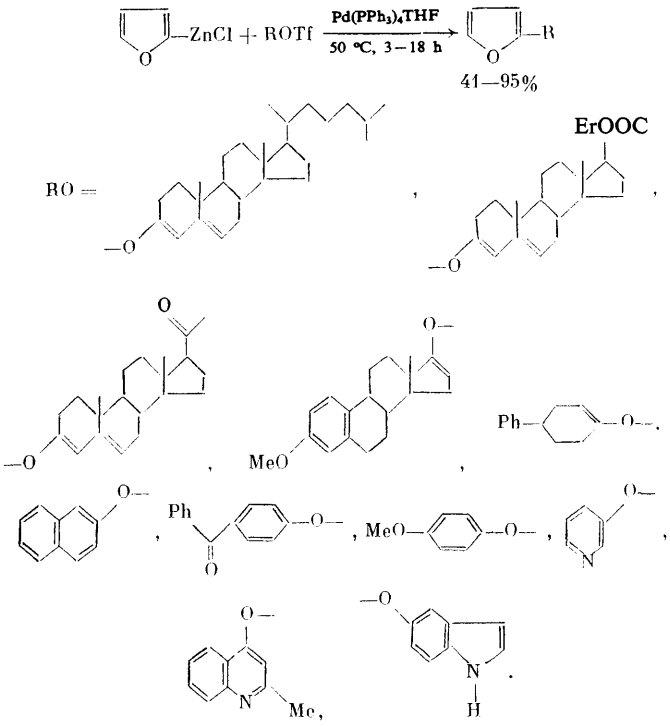


As the resulting vinyl ethers are readily hydrolysed to aldehydes, the above cross-coupling may be viewed as a formylmethylation of Grignard compounds.

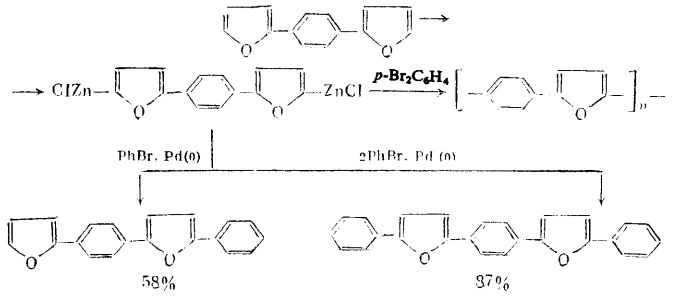
2-Furyl- and 2-thienyl-zinc chloride react with bromoacetonitrile to give the corresponding cyanomethyl derivatives in the presence of a Ni catalyst:[24]



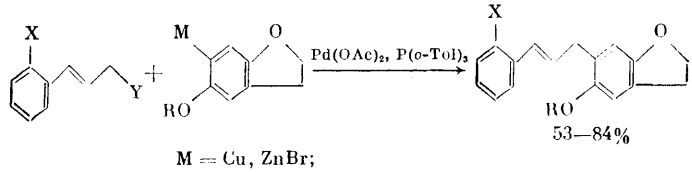
Characteristically, lithiated heterocyclics react with ispropene bromhydrin in the presence of a Pd catalyst to give the corresponding unrearranged allyl alcohol with complete regioselectivity.[25]



In contrast, alkyl and aryl Grignard compounds react with allyl rearrangement.[26]

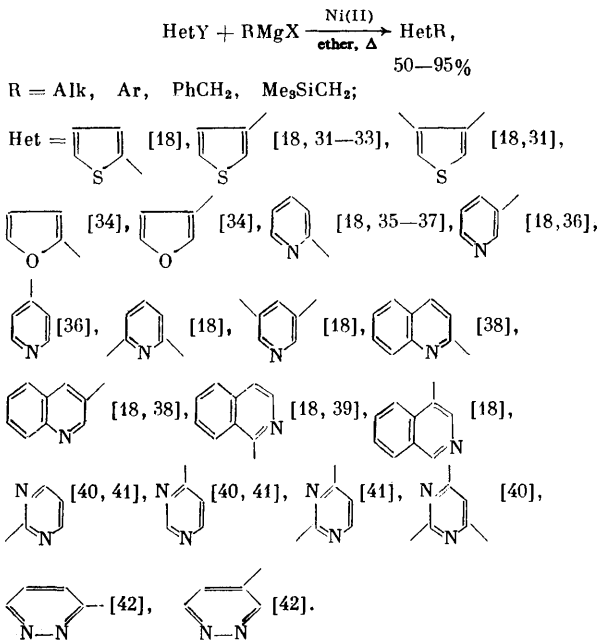


Palladium-catalysed cross-coupling of 1-halogenovinyl- or 2-halogenoallyl-silanes with heterocyclic organo-magnesium or -zinc compounds affords the corresponding heterocyclic vinyl- or allyl-silanes in high yield. Alternatively, these products can be obtained by cross-coupling of heterocyclic halides with the corresponding silylated organometallic compounds:[27]

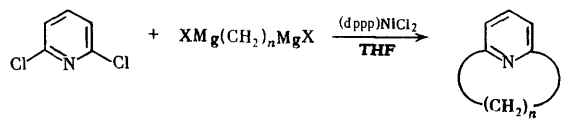


Triflates (ROTf) may be used in place of halides for cross-coupling. Thus 2-substituted furans are readily formed by coupling 2-furylzinc chloride with various vinyl and aryl triflates:[28]

The bis(2-furylzinc chloride) obtained from 1,4-bis(2-furyl)benzene reacts with bromobenzene or 1,4-dibromobenzene to give oligomers or polymers:[29]

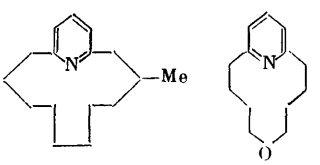


Palladium-catalysed allylic alkylation of organometallic derivatives of dihydrobenzofuran with cinnamyl bromides or acetates leads to the corresponding cinnamyl derivatives which are of interest as antipyretic agents.[30]



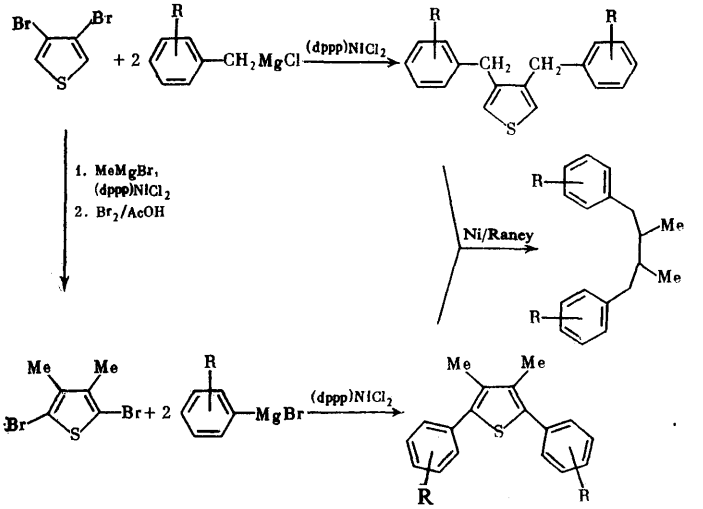
Various types of heterocyclic halides couple with Grignard compounds in the presence of nickel catalysts to give the

corresponding substituted heterocyclics in high yield:



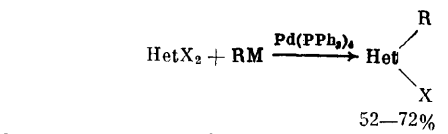
Extension of cross-coupling to heterocyclic dihalides and trihalides leads to the corresponding di- and tri-alkyl or di- and tri-aryl derivatives. Best results have been obtained with catalysts having a bidentate phosphine ligand—dppe, dppp, dppb and dppf.

Interestingly, cycloalkylation takes place on coupling 2,6-dichloropyridine with bis(Grignard compounds) to give 2,6-pyridophanes:[43]

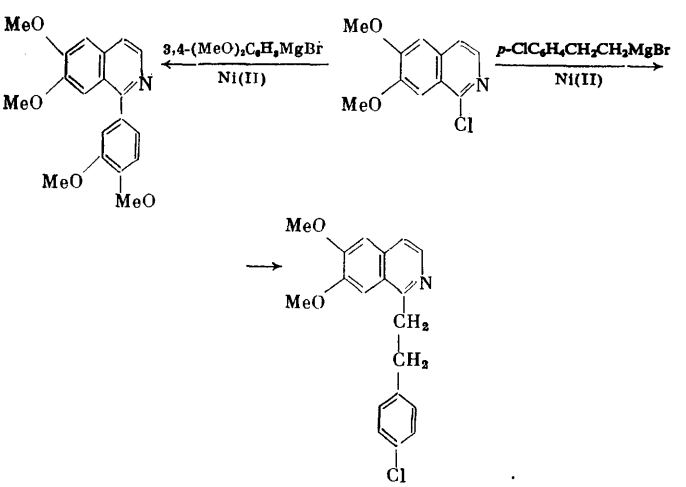


p=6 (11%), 7 (10%), 8 (16%), 9 (15%), 10 (33%), 12 (26%).

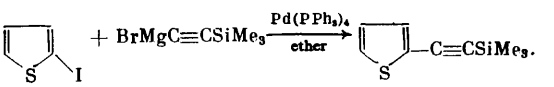
Racemic muscopyridine (II) and the oxapyridophane (III) have also been prepared by this route:



(II), 20% (III), 20%

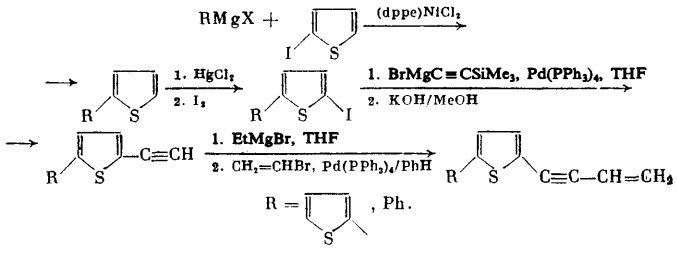


The thiophene molecule has been used as a four-carbon synthon in the synthesis of 2,3-disubstituted butanes, the basic structure of certain ligands. The key step is the cross-coupling of the appropriate dihalogenothiophene with Grignard or organozinc compounds in the presence of a nickel or palladium catalyst:[44]

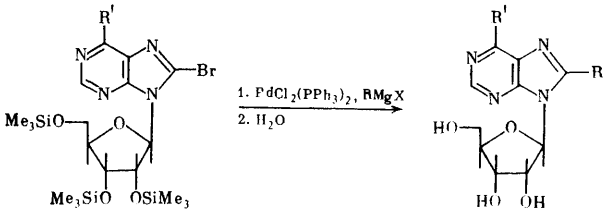


It is also possible to prepared unsymmetrically substituted heterocyclics by Pd-catalysed mono-benzylation or -arylation of the corresponding heterocyclic polyhalides:[45]

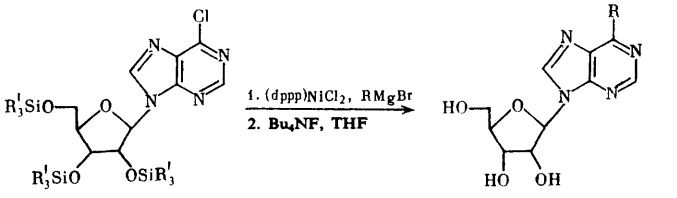
The reaction of 1-chloro-6,7-dimethoxyisoquinoline with 3,4-di-methoxyphenylmagnesium bromide and *p*-chlorophenylethyl-magnesium bromide leads to intermediates *en route* to pharmacologically active isoquinoline alkaloids.[18]



2-Iodothiophene cross-couples with trimethylsilylethynyl-magnesium bromide:[46]

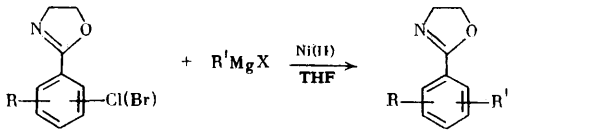


98%



This reaction has been used for the synthesis of natural products containing a thiophene residue, which possess nematocidal activity.[47] One such route is based on a sequential cross-coupling using both nickel and palladium catalysts:

Silyalated 8-bromopurine nucleosides and 8-bromoadenosine-3′,5′-cyclic monophosphate cross-coupling with Grignard compounds in the presence of a Pd catalyst to give the corresponding 8-substituted derivatives;[48]

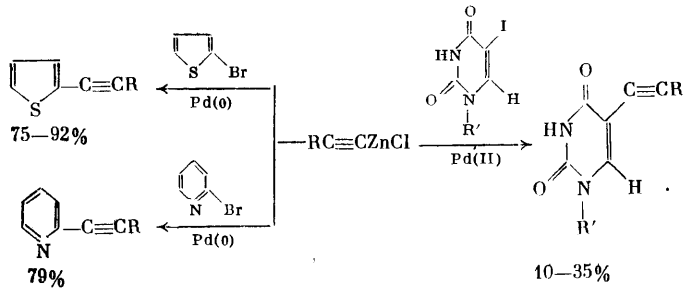


Biologically active 6-substituted purine nucleosides may be obtained similarly by nickel-catalysed cross-coupling of the corresponding 6-chloropurine nucleoside with Grignard compounds:[49]

R = Et, cyclo-C_6H_{11}, Ph, $PhCH_2CH_2$, $PhCH_2CH_2CH_2$, $Me_2C{=}CHCH_2CH_2$.

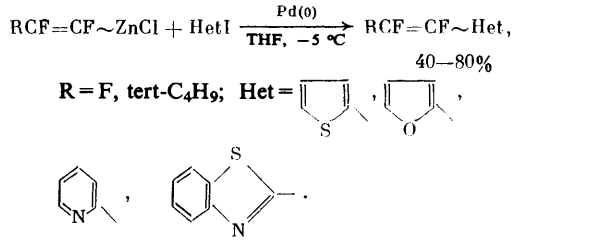
It has been shown that a halogen atom at the 2-, 3- or 4-position of (Δ^2-oxazolin-2-yl)arenes is readily replaced by an alkyl or aryl group in high yield:[50]

With (Δ^2-oxazolin-2-yl)dichlorobenzenes there is the possibility of regioselective introduction of one or two substituents into the benzene ring, depending on the relative proportion of Grignard compound and substrate.



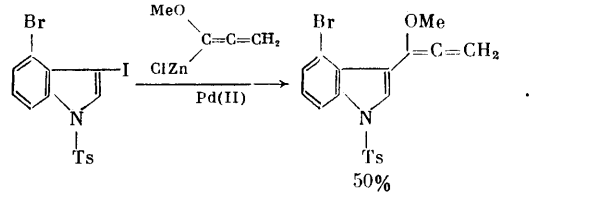
Both simple and functionalised organozinc compounds participate in Pd-catalysed cross-coupling with heterocyclic halides. Thus, 2-, 3- and 4-halogenopyridines, 2, 4- and 5-halogenopyrimidines, and 2-halogenoquinolines readily couple with functionalised organozinc compounds, including the Reformatskii reagent:[51,52]

$$HetX + IZn(CH_2)_nX \xrightarrow{Pd} Het(CH_2)_nX, \quad \sim 95\%$$

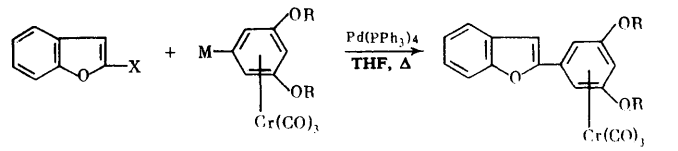


$p = 2, 3, 4$; X = Cl, CO_2Et.

The 2- and 4-halogenopyridines are more active than 3-halogenopyridines in this reaction.

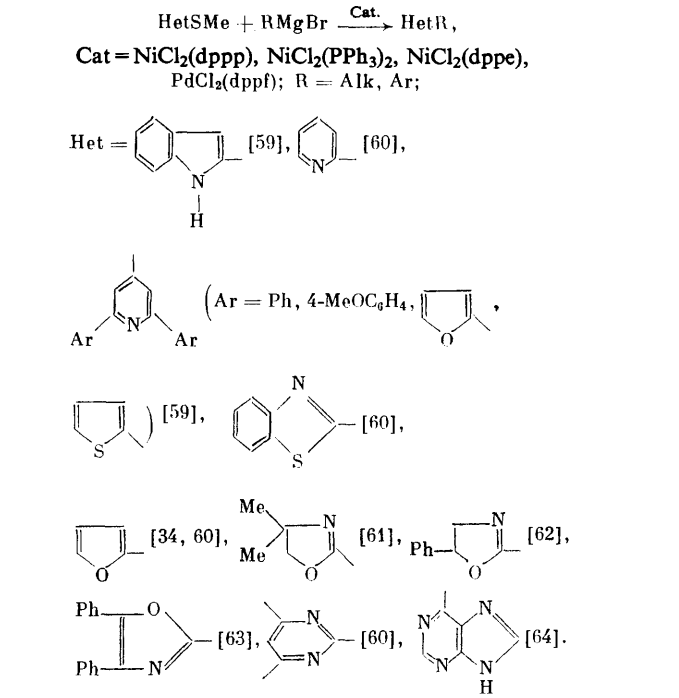


Alkynylzinc chlorides also couple smoothly with 2-bromo- or 2-iodo-thiophene[53] and with 2-bromopyridine[19], and react with 5-iododeoxyuridines to give the corresponding 5-alkenyl derivatives:[54]



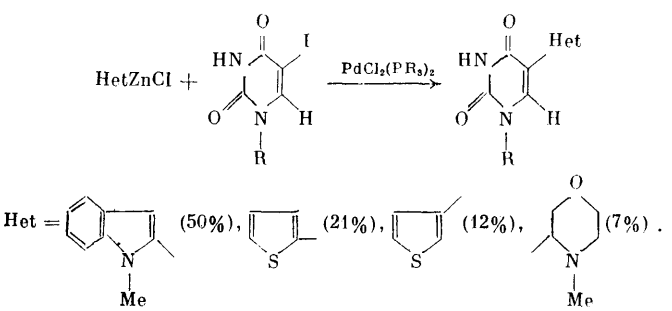
Perfluorovinylzinc compounds cross-couple effectively with a variety of heterocyclic halides:[55,56]

Allenylzinc chlorides have been used to introduce an unsaturated function at the 3-position of the indole ring.[57]



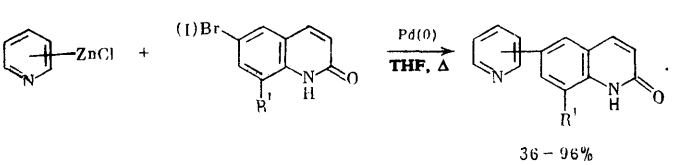
Moracin, a member of a family of biologically active compounds[58], has also been prepared by cross-coupling. The strategy involves Pd-catalysed cross-coupling of two aromatic systems: 2-metallated (or 2-halogenated) benzofurans and 5-halogenated (or-metallated) resorcinols, the latter as their chromium tricarbonyl complexes:

X = I, Br, $ZnBr$, $SnMe_3$,
M = $ZnBr$, I, Cl; R = H, SiR_3', Me.



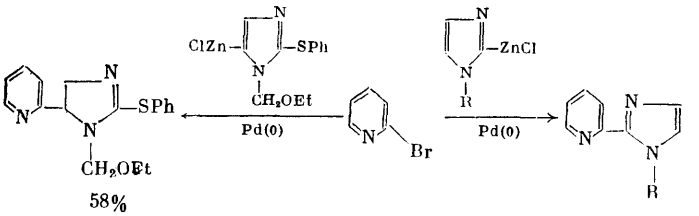
Alkylthio derivatives may be used in place of halides for cross-coupling. Thus, methylthio-substituted *N*-, *O*-, and *S*-heterocyclics undergo Ni- and Pd-catalysed cross-coupling with Grignard

compounds to give the corresponding alkyl- or aryl-heterocyclics.

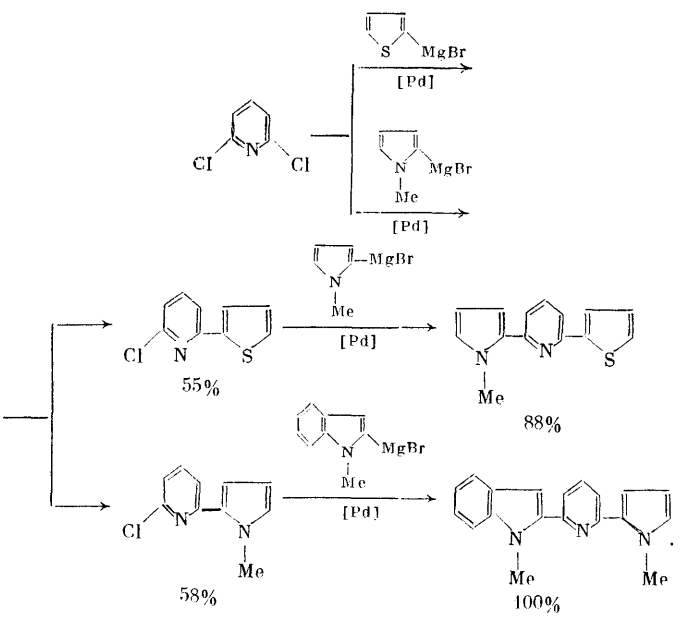


Alkyl- and aryl-derivatives of indole, pyridine, furan, benzothiazole, oxazoline, oxazole, pyrimidine and purine have all been prepared by this route.

Various biheterocyclics are generally available by catalysed cross-coupling of heterocyclic Grignard or organozinc compounds with heterocyclic halides. Thus, interaction of 5-iododeoxyuridines with HetZnCl affords a low yield of the corresponding nucleoside with a heterocyclic substituted in the 5 position:[65]

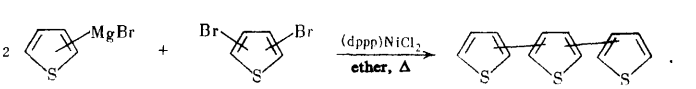


The above reactions proceed in the presence of a Pd catalyst.



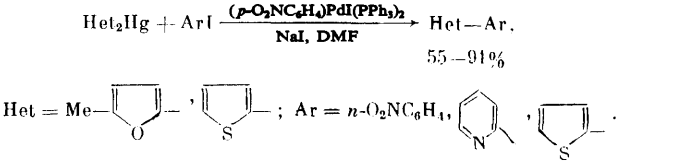
Cross-coupling of pyridylzinc chlorides with 6-halogeno-2(1*H*)-quinolines is a convenient method of preparing 6-pyridyl-2-(1*H*)-quinolines:[66,67]

2-Bromopyridine readily reacts with *N*-substituted 2- and 5-imidazolylzinc chlorides in the presence of a Pd(0) catalyst to give the corresponding imidazolylpyridines:[68]

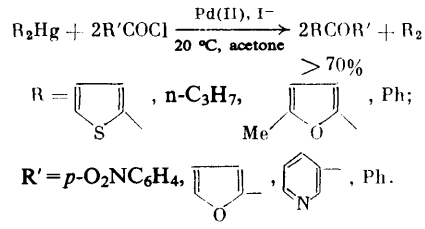


Reactions of dihalogenopyridines with 2-thienyl-, 2-pyyrolyl-, and 2-indolyl-magnesium bromides can be preformed in a variety of sequences to give the corresponding tri-nuclear systems,[69] e. g.

This is the basis of a method of preparing linear polyheterocyclic compounds.

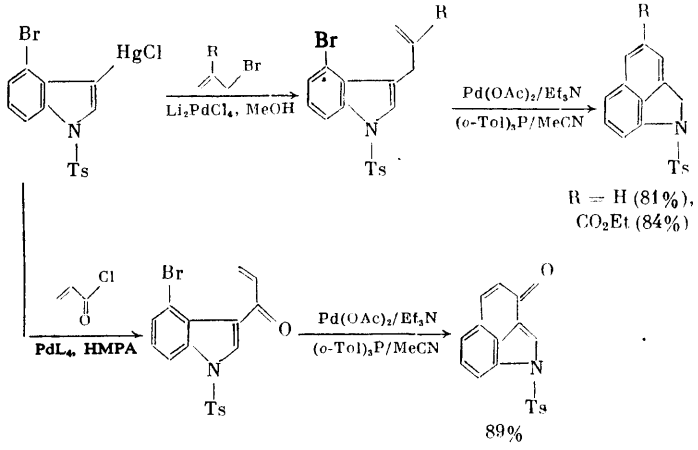


Nickel- or palladium-catalysed cross-coupling of 2- and 3-thienylmagnesium bromides with 2- and 3-bromothiophenes or isomeric dibromothiophenes (in varying proportions) leads to bi-, ter- and oligo-thienyls:[18,70–72]



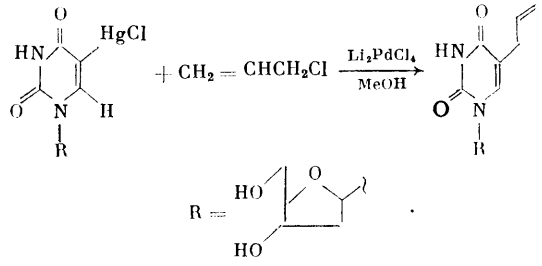
Biheterocyclics of the type furan-thiophene[46] and thiophene-uracil[73] have also been synthesised.

2. Organo-mercury and -copper compounds

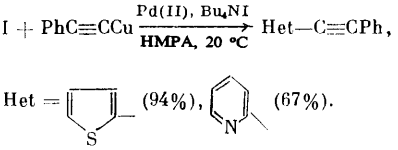


In addition to the organometallic compounds mentioned in section 1, cross-coupling with heterocyclic derivatives can also be achieved with organomercury compounds. Thus, symmetrical diorganomercury compounds react with aryl and heteroaryl iodides in the presence of a Pd-catalyst:[74]

Heterocyclic ketones have been prepared by acyldemetallation of organomercury compounds in the presence of a Pd complex.[75] Thus, the reaction of diorganomercurials, R_2Hg, with acyl chlorides proceeds readily in acetone at 20 °C during 5–30 min in the presence of a Pd(II) salt:

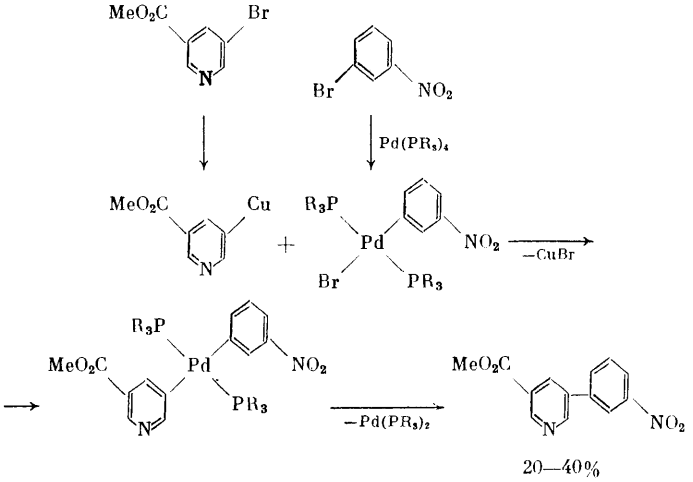


Palladium catalysts have been used in the synthesis of indole derivatives.[76] Thus, 3-substituted indoles are obtained in high yield by treatment of 3-chloromercuri-4-bromoindole derivatives with allyl halides in the presence of Li_2PdCl_4. Feaction proceeds via Hg → Pd transmetallation, followed by insertion of the olefin group into the resulting indolylpalladium complex then elimination of β-halogen. The products readily undergo intramolecular Heck reaction with simultaneous isomerisation of the formed tricyclic indole into the thermodynamically more stable benz[*c*,*d*]indole system.[57]



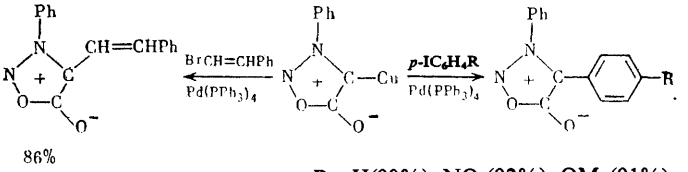
Similarly, 3-chloromercuriindole reacts with acryloyl chloride in the presence of Pd(0) to give the corresponding 3-acylindole which cyclises into a tricyclic ketone in high yield.

5-Chloromercuri-2-deoxyuridine condenses with allyl chloride in the presence of 20 mol% Li_2PdCl_4 to give the corresponding 5-allyl derivative:[77]



The use of substituted allyl chlorides in this reaction leads to a mixture of regioisomers.[78]

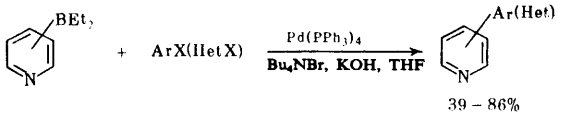
Beletskaya et al.[79] showed that cuprous phenylacetylide reacts quite readily with 2-iodothiophene and 2-iodopyridine to give the corresponding 2-alkynylheterocyclics:



Tetra-π-butylammonium iodide, which increases the solubility of CuI (used for the preparation of the acetylide), has a significant effect on the rate of reaction and the yield of product.

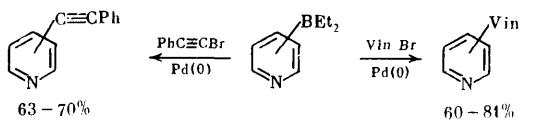
Coupling 5-bromonicotinates with *m*-bromonitrobenzene in the presence of Cu and a Pd(0) catalyst affords the corresponding 5-arylnicotinates which have been used in the synthesis of physiologically active compounds.[80] The mechanism of the reaction is thought to involve formation of a 5-cupronicotinate which couples with the palladium compound formed by oxidative addition of Pd(0) to *m*-bromonitrobenzene; reductive elimination then takes place in the final step:

$Pd(PR_3)_4 = Pd(PPh_3)_4$, $Pd[P(Tol\text{-}o)_3]_4$.



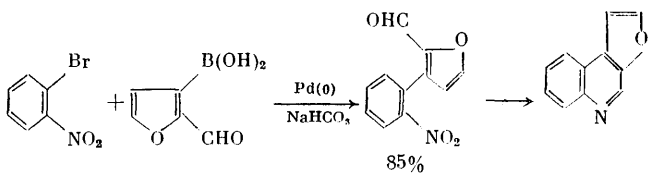
Palladium-catalysed cross-coupling of 4-cuprosydnone with aryl and vinyl halides is the basis of a general method of introducing a 4-substituent into the 3-phenylsydnone ring.[81]

R = H(90%), NO_2(92%), OMe(91%).

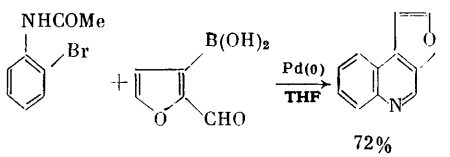


3. Organo-boron, -aluminium and -zirconium compounds

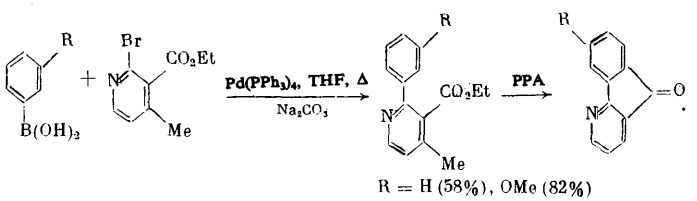
Three-coordinate boron compounds have also been used in cross-coupling. 3-Pyridyl- and 4-pyridyl-boranes react efficiently with various bromo- or iodo-arenes and heterocyclic halides in the presence of a Pd(0) catalyst:[82–84]



Reaction has been carried out with a wide variety of aryl halides having different functional groups and with a number of heterocyclics, such as substituted pyridines, quinolines, thiophenes, benzoaxoles, pyrimidines and indoles.

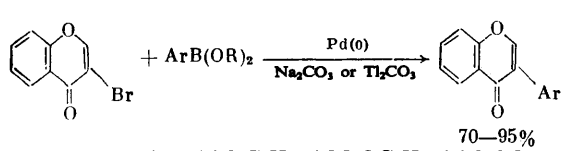


Vinyl and alkynyl bromides couple readily with 3- and 4-pyridyldiethylboranes to give the corresponding vinyl- and alkynylpyridines:[85]



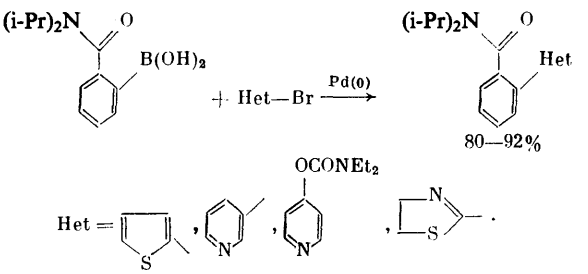
Cross-coupling has been applied in a multi-step route to pharmaceutically interesting furoquinoline alkaloids. Thus, 2-formyl-3-furylboronic acid couples with 2-bromonitrobenzene to produce 2-formyl-3-(2′-nitrophenyl)furan:[86]

A more effective route is based on coupling 2-bromoacetanilides with 2-formyl-3-furylboronic acid, which leads directly to the desired furoquinoline:



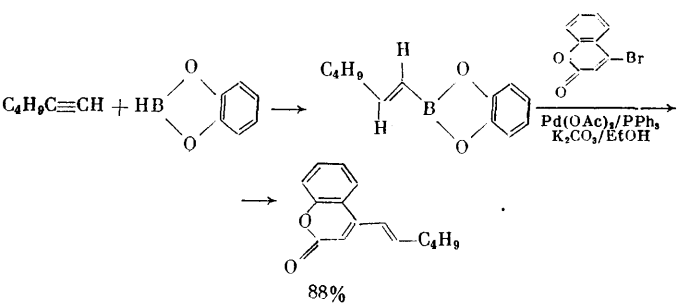
An interesting application of cross-coupling between arylboronic acids and heterocyclic halides has been reported in the synthesis of alkaloids with the azafluorenone skeleton.[87] Palladium-catalysed coupling of arylboronic acids with 2-bromonicotonic acid esters affords dimeric products which subsequently cyclise to give the desired alkaloids.

R = H (58%), OMe (82%)

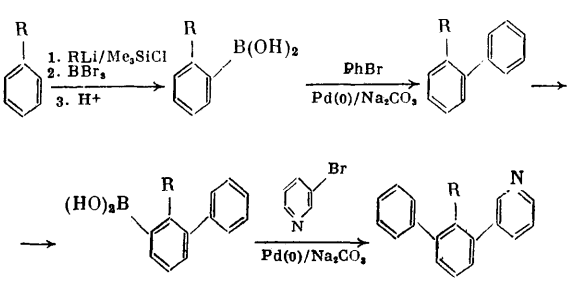


However, in this case, the best results have been achieved with arylstannanes.[87]

Cross-coupling of 3-bromochromones with arylboronic acids or their esters in the presence of a Pd catalyst provides a convenient preparative route to isoflavones:[88]

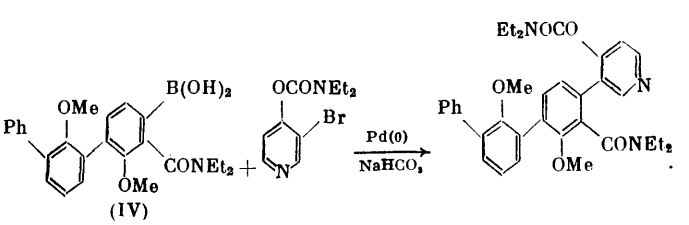


R = H, n-Bu; Ar = 4-MeC$_6$H$_4$, 4-MeOC$_6$H$_4$, 2-MeOC$_6$H$_4$, Ph, 4-FC$_6$H$_4$, 4-O$_2$NC$_6$H$_4$, 1-C$_{10}$H$_7$, 2,4,6-Me$_3$C$_6$H$_2$.

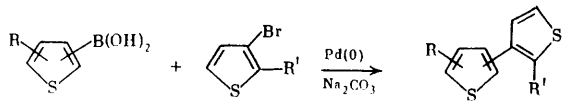


Heterocyclic residues can effectively be incorporated into unsaturated systems by cross-coupling of aryl- and vinyl-boronic acids with heterocyclic halides.[80,89,90] Thus:

2-Alkenyl-1,3,2-benzodioxaboroles, readily formed by hydroboration of acetylenes with catecholborane, are suitable synthons for preparing 2,4-alkadienoates by cross-coupling. The method is applicable to cyclic analogues, such as 4-alkenylcoumarins:[91]

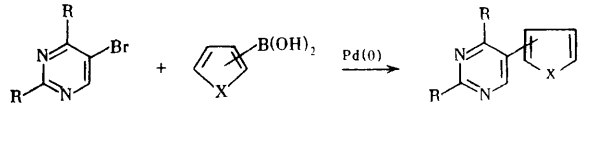


Reference has been given to an original method of preparing *m*-terphenyls containing heteroarene residues.[92] Aromatic compounds with substituents which faciliate *o*-metallation may be used for the preparation of *o*-substituted boronic acids. The latter couple effectively with hererocyclic halides, e. g. 3-bromopyridine:



R = $CO_2N(Pr\text{-}i)_2$, $OCONEt_2$, OCH_2OMe, $NHCO_2Bu\text{-}t$.

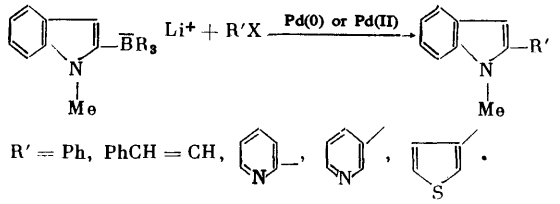
To illustrate the possibility of preparing polyfunctionalised heteroarenes, we show below the synthesis of pyridotetraphenyl by cross-coupling of (IV) with a 4-pyridyl carbamate:[93]



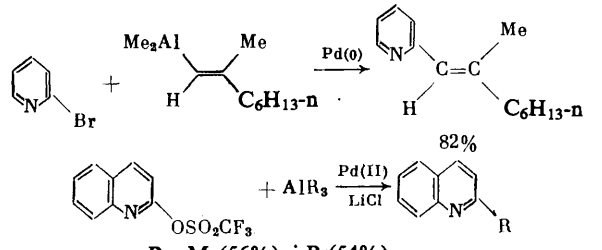
Palladium(0)-catalysed cross-coupling of 2- and 3-thienylboronic acids with mono- and poly-halogenothiophenes provides the basis of a method of preparing bi- and poly-thienyls.[94–96] It has been adapted to the synthesis of compounds with a variety of

substitutents in the thiophene rings, e. g.

R = H, 2-CHO, 4-CHO; R′ = H, 2-CHO, 2-NO_2, 2-SMe.



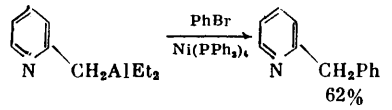
The method has been adapted to the synthesis of other linearly condensed polyheterocycles — thienopyridines,[97,98] thieno- and selenopheno-pyrimidines,[73] benzo- and thieno-condensed quinolines and naphthyridines,[99,100] e. g.



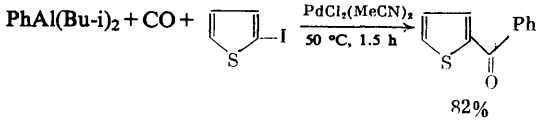
48 – 84%

X = S, Se

Palladium-catalysed coupling of indolylborates with vinyl, aryl and heterocyclic halides has proved of value for the synthesis of 2-substituted indoles:[101]

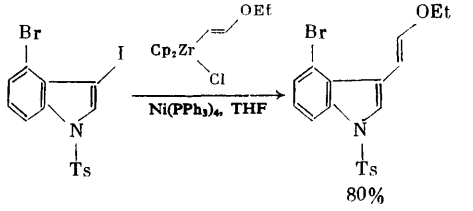


Cross-coupling can also be performed in many instances with organoaluminium compounds. Thus, chloropyrazines,[102] chloropyrazine *N*-oxides,[103] 2-bromopyridine,[19] and 2-quinolinyl triflate[104] react smoothly with organoaluminium compounds in the presence of a palladium catalyst.



R = Me(56%), i-Pr(54%).

In addition to this, 2- and 4-picolinyl-aluminium and -zinc reagents readily react with aryl and heterocyclic halides in the presence of a Ni(0) catalyst,[105] e. g.

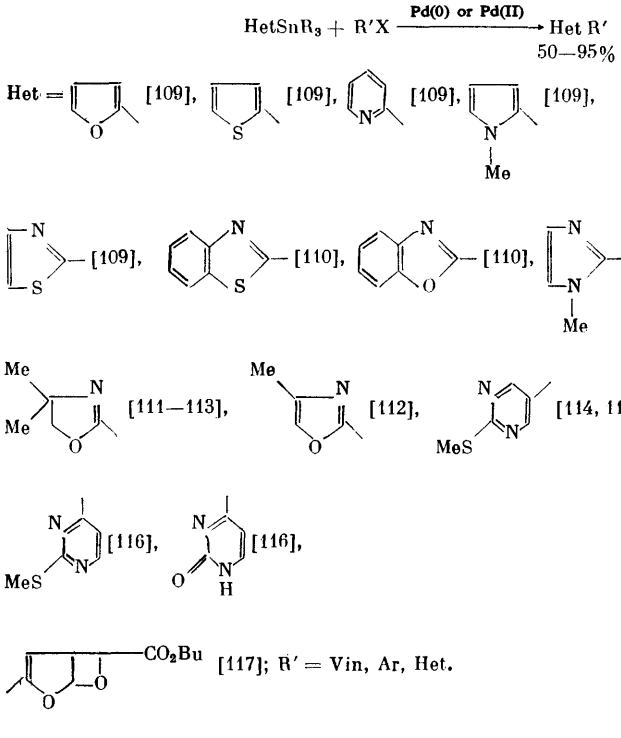


62%

2-Benzoylthiophene is formed smoothly on carbonylation of 2-iodothiophene in the presene of phenyldiisobutylalane:[106]

82%

The 2-ethoxyvinyl group may be effectively transferred from zirconium to the 3-position of indole via Ni(0)-catalysed oxidative addition-transacetalation:[107]

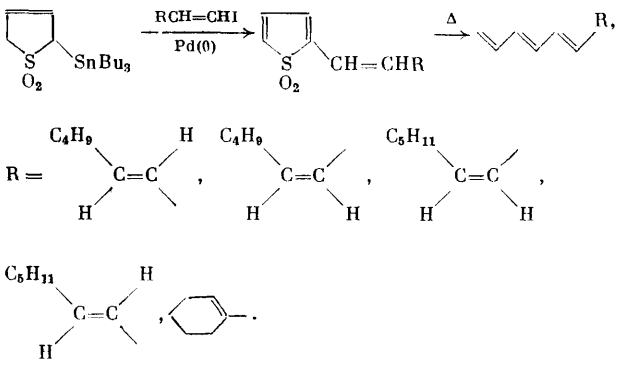


80%

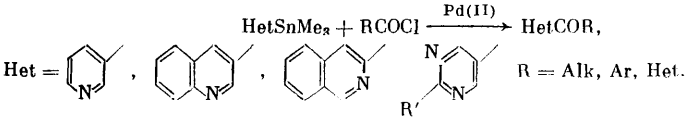
5-Alkenyldeoxyuridines have been prepared by Pd-catalysed coupling of vinylzirconium compounds with deoxyuridine.[108]

4. Organotin compounds

Organotin compounds have been widely used in cross-coupling in view of their chemical stability, the simplicity of their purification, and the possibility of incorporating a variety of functionalised residues. Five- and six-membered heterocyclics with a F_3Sn group have been coupled with aryl, heterocyclic, and vinyl halides:

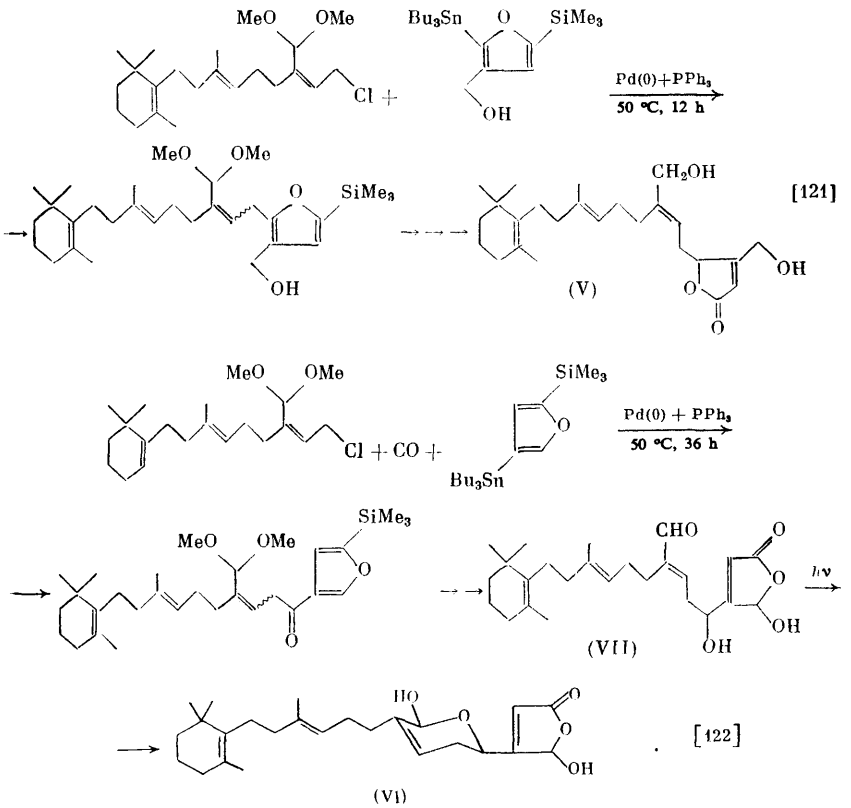


R′ = Vin, Ar, Het.

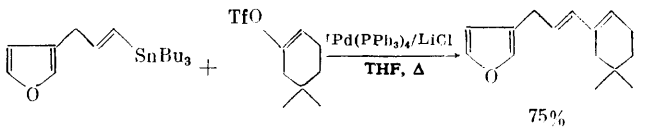


Cross-coupling with oxazolines is particularly interesting since such compounds serve as synthons for preparing carboxylic acids, aldehydes, nitriles and other functionalised derivatives.[118]

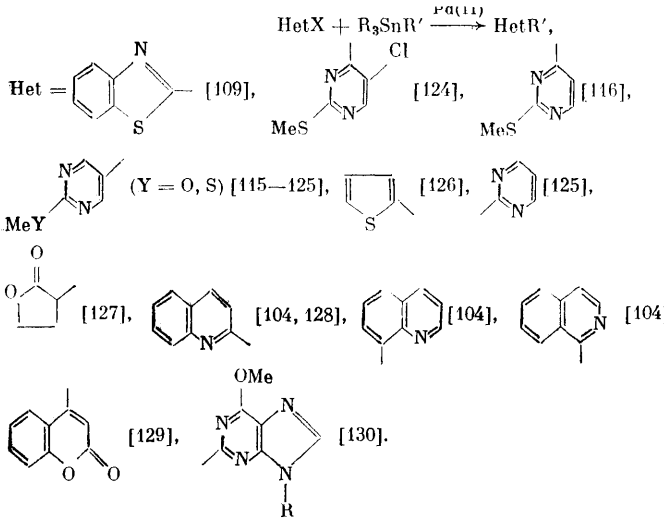
The cross-coupling of 2-tributylstannyl-2,5-dihydrothiophene *S,S*-dioxide with vinyl iodides is the key step in the preparation of conjugated trienes, which are generated in desulfonylation of the



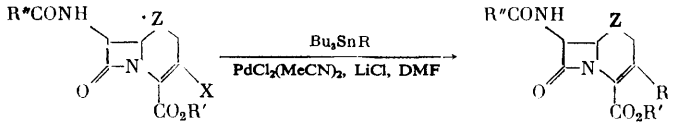
intermediate 2-vinyl derivatives.:[119]



Ketones have been prepared by treatment of trimethylstannyl derivatives of pyridine, quinoline, isoquinoline and pyrimidine with acyl halides in the presence of a Pd catalyst:[114,120]

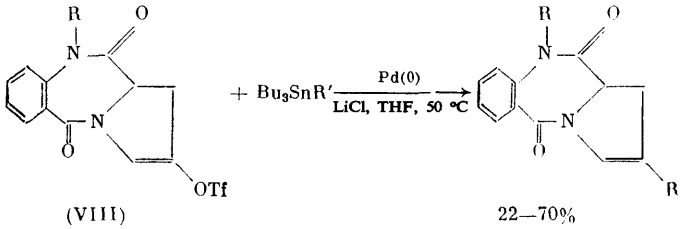


Cross-coupling with stannylfurans has been applied to the synthesis of the biologically active terpenoids, (*E*)-neomanoalide (V), manoalide (VI), and secomanoalide (VII). These compounds possess antiinflammatory and antifungal activity and have an effect on phospholipid metabolism.[121,122]



Pd-catalysed coupling of vinyl triflates (TfOR) with organostannanes has been adapted in an elegant synthesis of pleraplysillin:[123]

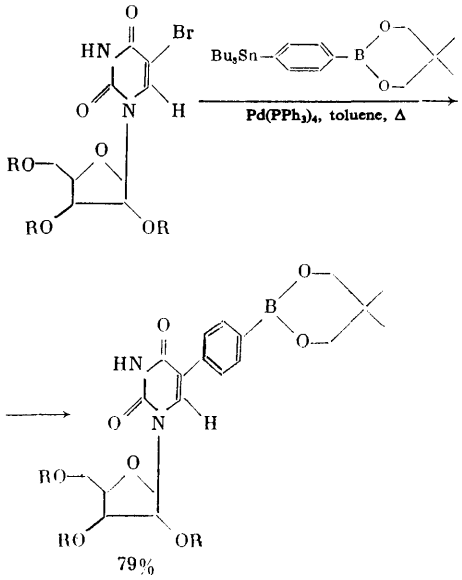
Various heterocyclic halides and triflates participate in catalysed coupling with organostannanes:



Substituents may be introduced into the 3-position of the caphalosporin and 1-carbacephalosporin nuclei by Pd-catalysed cross-coupling:[131–133]

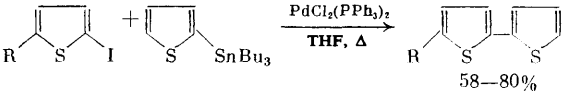
$Z = CH_2$, S; X = OTf, Br.

Anthramycin analogues have been synthesised by cross-coupling of triflate (VIII) with various unsaturated compounds having a Bu_3Sn residue:[134]



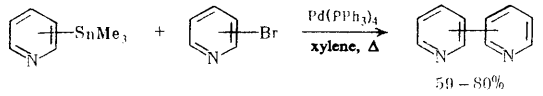
R = Me, CH_2OMe; R′ = CH_2=CH, EtO_2CCH=CH,

MeO_2CCH=CH, H_2NCCH=CH.



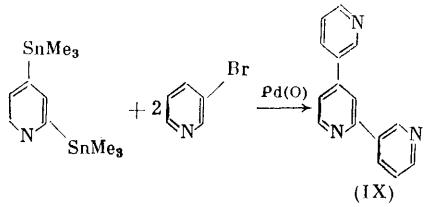
The same products have been obtained independently by interaction of triflate (VIII) with acrylic acid amides and esters in the presence of a Pd catalyst.

Cross-coupling of halogenonucleosides with boron-substituted arylstannanes has been extended to the synthesis of ^{10}B-containing nucleosides which are of value in neutron-capture therapy:[135]

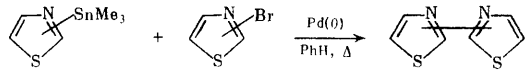


R = $SiMe_2$(Bu-t).

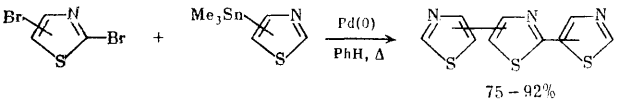
Bi- and poly-nuclear heterocyclics have been synthesised by reaction of heterocyclic halides with trialkylstannylheterocyclics. 2,2′-Bithienyls have thus been prepared in high yield by cross-coupling of 2-iodothiophenes with 2-stannylthiophenes:[136]



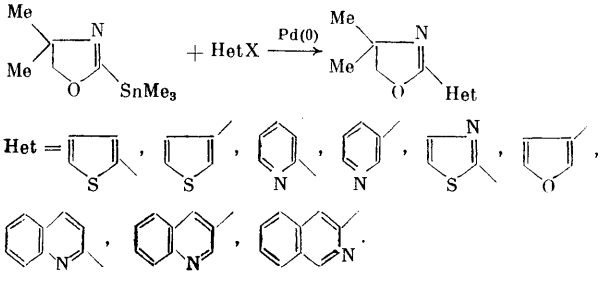
R = H, CH_2OAc, CH_2OH, CHO, CH_2OCOCH_2Pr-i, $C{\equiv}CCH_2CH_2OCOCH_2Pr$-i.



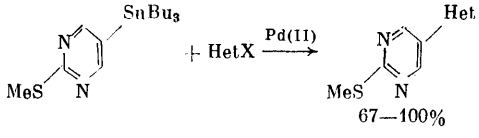
Isomeric bipyridyls are formed by interaction of trimethylstannylpyridines with bromopyridines:[137]



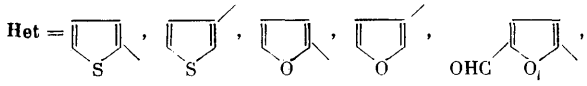
The reaction has been extended to the preparation of substituted quinolines. The synthesis of nicotelline(IX) is of particular interest:

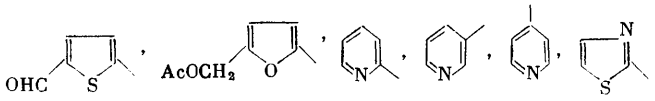


Bi- and ter-thiazolyls have been obtained by cross-coupling of stannyl- and halogeno-thiazoles:[138]

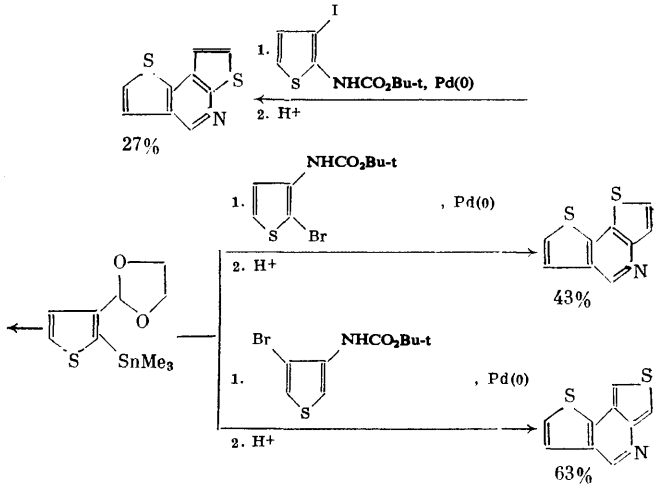


Double cross-coupling takes place readily with dibromothiazoles.





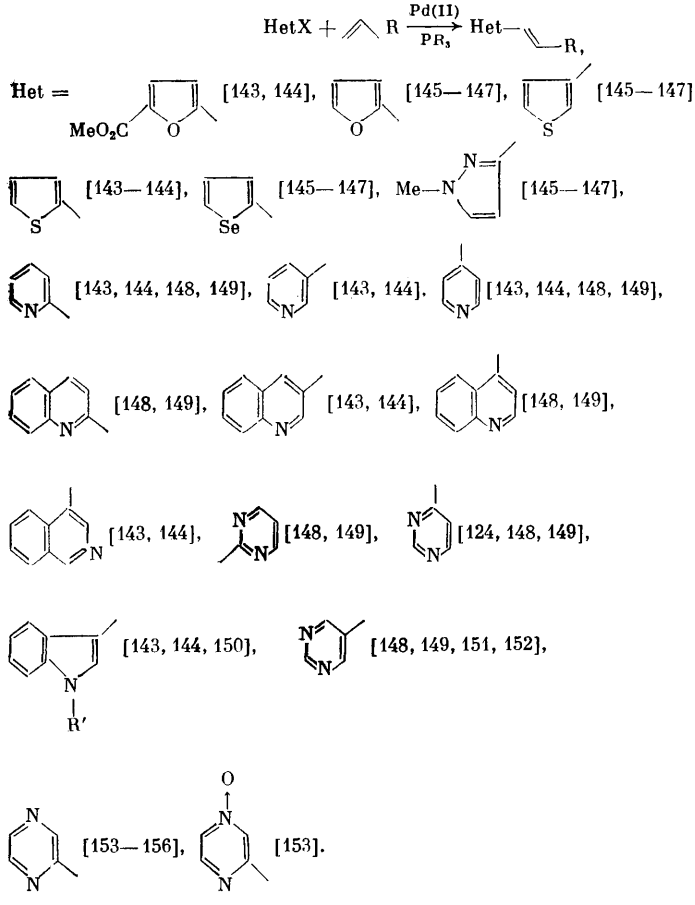
Catalytic cross-coupling of stannyl-oxazoles or -oxazolines with a variety of heterocyclic halides has been applied to the synthesis of oxazol-2-yl- and oxazolin-2-yl-heterocyclics which are intermediates *en route* to carboxylic acid derivatives,[112] e. .g.



5-(Tributylstannyl)pyrimidines couple effectively with various heterocyclic halides to give the corresponding unsymmetrical biheterocyclics:[139]

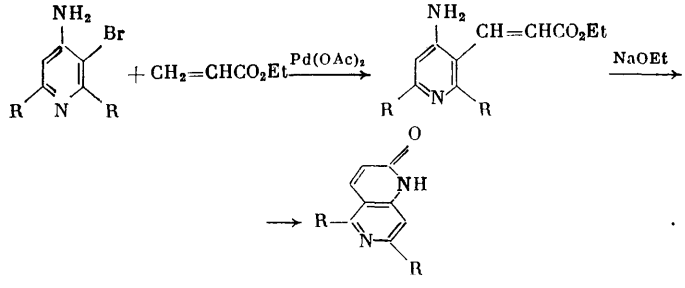
Het = 

Isomeric dithienopyridines have been prepared by a novel route involving Pd-catalysed coupling of 2-(2′-trimethylstannyl-3′-thienyl)-1,3-dioxolane with tert-butyl *N*-(*o*-halogenothienyl)carbamates followed by acidic hydrolysis. The ultimate cyclisation takes place instantaneously under the conditions of the hydrolytic step.[140,141]



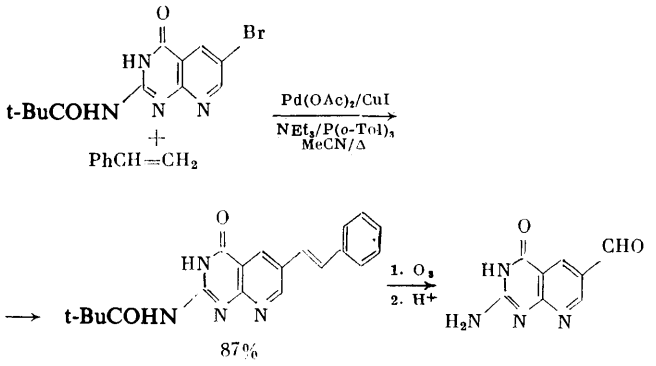
III. Reactions of heterocyclic halides with alkenes and alkynes

1. Reactions of heterocyclic halides with alkenes



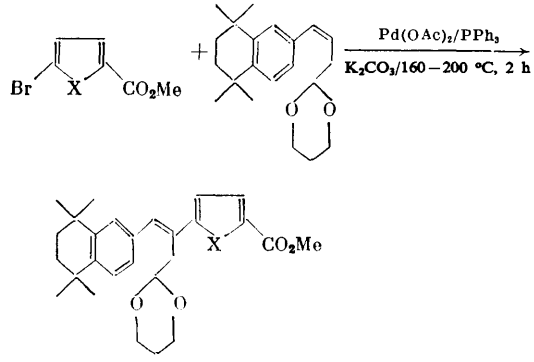
Palladium-catalysed vinylation of organic halides provides a route to substituted heterocyclics by carbon–carbon bond formation.[5,142] This method has been widely used with organic halides which do not possess a β-hydrogen atom, such as aryl, benzyl, vinyl and heterocyclic halides. In the previous sections of this review we have examined cross-coupling of heterocyclic halides with metal alkenyls as a route to vinylheterocyclics. Clearly, palladium-catalysed reaction of heterocyclic halides with alkenes themselves is more preferable. This is the basis of the Heck reaction.

Vinylheterocyclics can thus be prepared by Pd-catalysed condensation with a wide spectrum of alkenes—alkyl acrylates, acrylonitrile, styrene, vinylpyridines, butenylphthalimide, vinyltrimethylsilane, α-acetamidoacrylates, indole, etc.



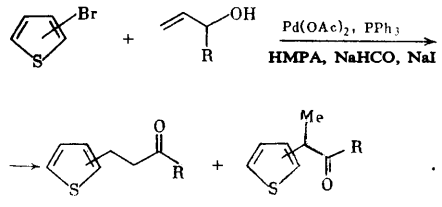
Heterocyclic triflates also participate in the Heck reaction with activated olefins.[104] Palladium catalysis is effective in the functionalisation of the pyrimidine ring of nucleosides.[130]

Isomeric naphthyridines have been prepared by a novel two-step conversion involving Pd-catalysed cross-coupling of *o*-amino-substituted 2-, 3- and 4-halogenopyridines with ethyl acrylate followed by cyclisation,[157–161] e.g.



6-Formyl-5-deazapterin, a key intermediate in the synthesis of various 5-deaza-analogues of folic acid, has been readily prepared by Pd-catalysed cross-coupling of 2-pivaloyl-6-bromo-5-deazapterin with

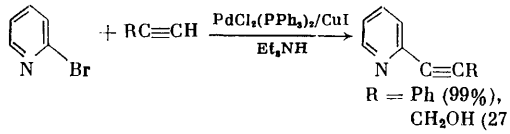
styrene, followed by ozonolysis and hydrolysis



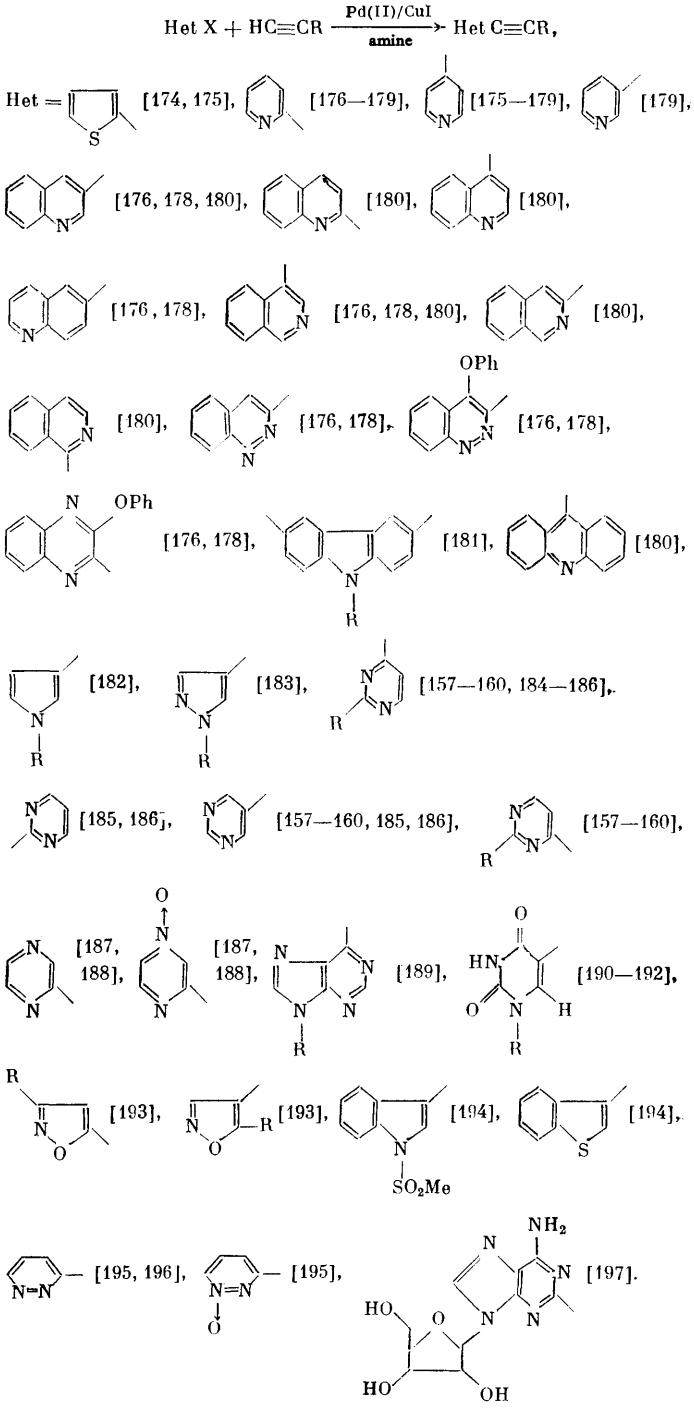
The Heck reaction is particularly useful for the preparation of synthons *en route* to retinoids.[163] Thus, bromo-furans and -thiophenes readily couple with ω-substituted styrenes to give the corresponding (*E*)-stilbenes:

X = O, S.

Treatment of 2- and 3-bromo-thiophenes with allyl alcohols affords aldehydes and ketones with a thienyl residue.[164–166] β-Thienylcarbonyl compounds are formed as the major products:



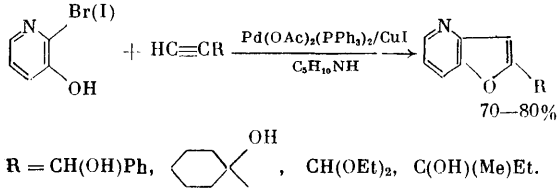
3-Bromopyridine reacts with allyl alcohols similarly.[167]



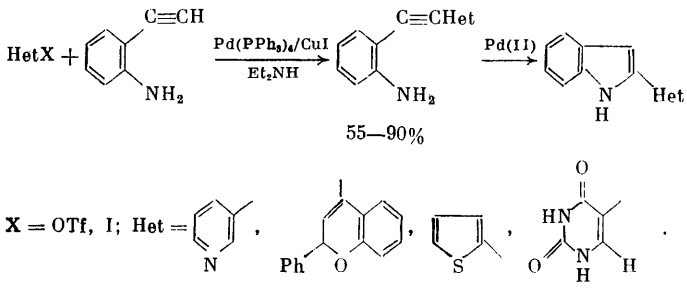
Heterocyclic mercurials react with alkenes in the same way as heterocyclic halides. Thus, 5-alkenyluracil nucleosides and nucleotides have been synthesised by Pd-catalysed cross-coupling of the appropriate mercuriuracil derivatives with a variety of alkenes.[168–170]

2. Reactions of heterocyclic halides with alkynes

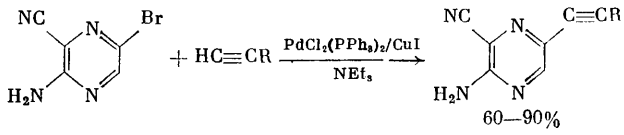
The preparation of alkynylarenes by Pd-catalysed reaction of aryl halides with terminal alkynes was pioneered in 1975.[171–173] Sonogashira et al.[171] showed that reaction was most efficient with CuI as co-catalyst. In this way, 2-alkynylpyridines were prepared by reaction of 2-bromopyridine with acetylene derivatives:



Subsequently, the method was extended to the preparation of a variety of alkynylheterocyclics. As a rule, the yield of the latter is high and the method is preparatively useful.

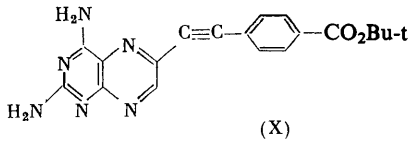


Bis(alkynyl)heterocyclics are formed by reaction of heterocyclic dihalides, e.g. diiodopyrimidines[185,186] and dibromopyridines[198], with terminal acetylenes. Mono-alkynyl derivatives may be isolated by mixing the appropriate proportion of the two reactants. Pyridyl triflates react with terminal acetylenes in the same way as pyridyl bromides.[198]

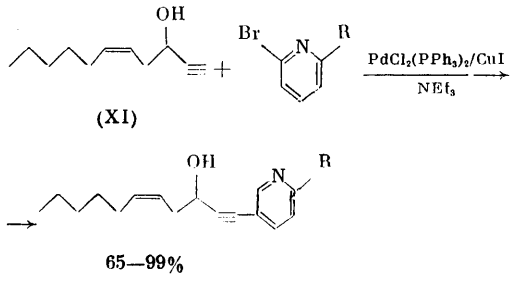


Palladium-catalysed reaction of 3-hydroxy-2-halogenopyridines with terminal acetylenes leads directly to furo[3,2-*b*]pyridines:[199]

2-Substituted indoles have been prepared by coupling heterocyclic triflates or halides with 2-ethynylaniline, followed by Pd(II)-catalysed ring closure of the product:[200]

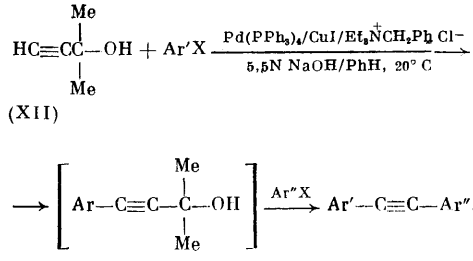


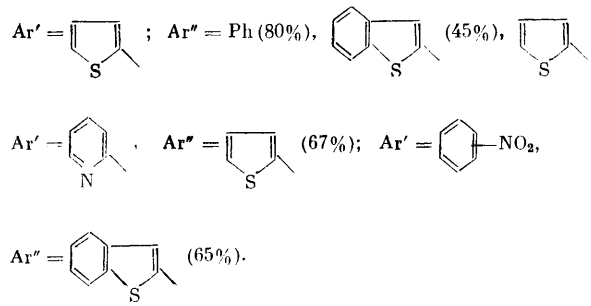
2-Amino-3-cyano-5-bromopyrazine couples with acetylenes as follows:[201,202]



R = Ar, Bu, t-Bu, $MeOCH_2$.

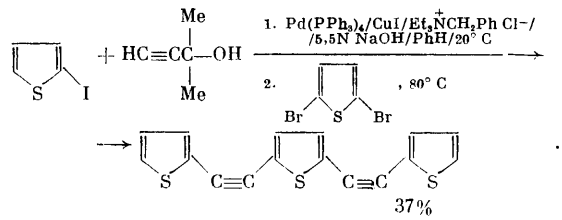
This method is effective for the synthesis of pteridine (X), an intermediate *en route* to the anticancer drug, methotrexate.





(X)

Synthons for the preparation of leukotriene B_4 antagonists have been synthesised by reaction of 6-substituted 2-bromopyridines with acetylene (XI):[203]



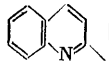
The readily available dimethylethynylcarbinol (XII) couples effectively in the presence of a Pd-catalyst to yield symmetrically and unsymmetrically disubstituted diarylacetylenes in one step.[204] The reaction of (XII) with heterocyclic halides affords the corresponding arylalkynols quantitatively under phase transfer catalysis. The addition of a second molecule of aryl or heterocyclic halide during the reaction leads to the corresponding disubstituted acetylene on raising the temperature to 70—80 °C:

Bisacetylenic compounds, such as 2,5-bis(2'-thienylethynyl)-thiophene, may also be prepared by this route.

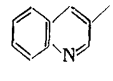
Cross-coupling of azinyl and diazinyl halides with trimethylsilylacetylene, followed by desilylation, provides a preparative route to the corresponding ethynylheteroarenes:[205]

IV. Other reactions

Homo-coupling of heterocyclics can be effected by complex metal catalysis. Thus, reductive dimerisation of heterocyclic halides takes place in the presence of both Ni and Pd catalysts. The following systems have been used for homocoupling: $Zn/NiCl_2/PPh_3$ [206—210], $Zn/NiCl_2(PEt_3)_2$ [211], $Ni(COD)_2$ [212],



Pd–C/NaOH/HCOONa/H_2O/$Et_3\overset{+}{N}CH_2PhCl^-$ [213], Raney nickel [214], $Ni(OAc)_2$/NaH/PPh_3/*t*-BuOK [215], and $NiBr_2(PPh_3)_2$/Zn/Et_4NI [216]:



HetX $\xrightarrow{\text{catalyst}}$ Het—Het,

Het =  [206, 210—212],  [211],

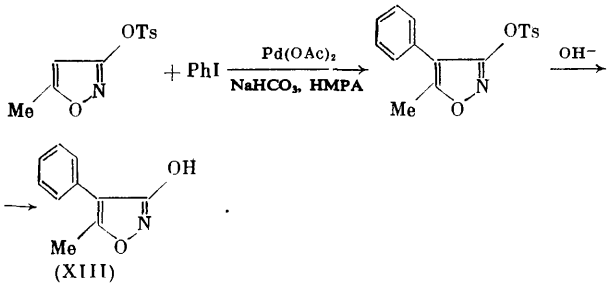
 [207—210, 213—216],

 [200—202, 208, 209],  [200—202, 206, 208],

 [200—202, 209],  [208—210, 216],  [211],

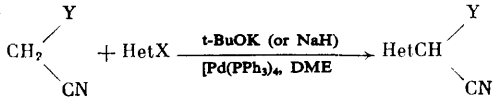
 [211],  [216]  [216],  [216].

Heterocyclic halides also participate in Pd-catalysed cross-coupling with phosphorus compounds possessing a P–H bond. Thus, 2-thienyl bromide reacts with monobutyl alkyl- or aryl-phosphonites in the presence of a Pd(0) catalyst:

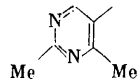


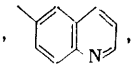
R = Me (70%) [217], Ph (53%) [218].

Diethyl 3-pyridylphosphonate is obtained by coupling of 3-bromopyridine with diethyl phosphite:[219]

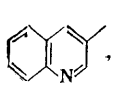


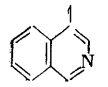
77%





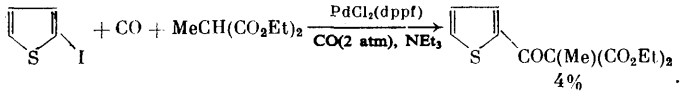
Isoxazole derivatives couple with aryl iodides in the presence of a Pd catalyst to give 4-arylisoxazoles.[220] 4-Phenylmuscimol (XIII), an important neuro-pharmacological drug, has been obtained by this route.





(XIII)

The incorporation of active methylene groups into "unreactive" positions of *N*-heteroarene ring can be conveniently achieved under Pd catalysis. Thus, heterocyclic halides react with the carbanions derived from malononitrile and ethyl cyanoacetate to give the corresponding heteroarylmalonitriles and ethyl α-cyano(heteroaryl)-acetates. Reaction is of a general nature:[221]

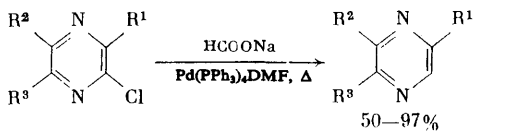


X = Br, I; Y = CO_2Et, CN; Het =  ,  ,  ,

 ,  .

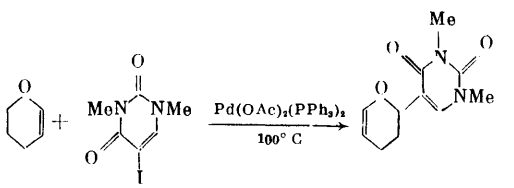
Although $Pd(PPh_3)_2Cl_2$ may be used as catalyst for such coupling with aryl halides[222,223], it is unsuitable for the reactions with heterocyclic halides shown above.

It should be noted that 2-iodiothiophene, like iodobenzene, couples with active methylene groups on carbonylation to give a low yield of the corresponding ketone:[224]



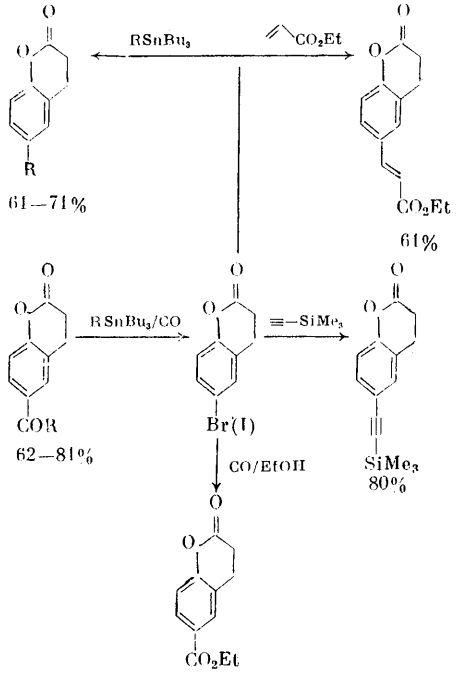
4%

A general synthesis of 2-cyanopyrazines by Pd(0)-catalysed replacement of chlorine by cyano group has been reported:[225]



31—98%

Dicyanopyrazines are obtained similarly from the corresponding dichloropyrazines. However, 2-chloropyrazine, as well as its 1- and 4-oxides, are readily dechlorinated on heating with sodium formate in the presence of a Pd(0) catalyst:[226]



50—97%

Dihydropyran couples with 1,3-dimethyl-5-iodouracil in the presence of a Pd(II) catalyst:[227]

Functional groups may be introduced into the 6-position of the dihydrocoumarin ring by Pd-catalysed coupling (Scheme 2).[228]

Scheme 2

R = Vin, Ph, PhC≡C.

The catalytic formation of a carbon—carbon bond in heterocyclic systems, as described in this review, is potentially very useful in the synthesis of physiologically active compounds and natural products.

Regulation of the adsorption and chromatographic properties of polymeric adsorbents by varying their porous structure

L G Belyakova
Institute of Physical Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The review surveys the results of studies (using various physicochemical methods) of the geometrical structures of 2,3-epoxypropyl methacrylate–ethylene dimethacrylate and styrene–divinylbenzene copolymers as well as ultracross-linked polystyrenes ("Styrosorbs")—both the initial structures and those modified by amines and aminoalcohols. The influence of the porous structure of the aminated polymers on the adsorption and chromatographic properties was examined mainly in relation to the absorption of carbon and sulphur dioxides. The importance of the optimisation of the structures of the polymeric adsorbents in their practical application is demonstrated.

The bibliography includes 132 references.

I. Introduction

Studies of the chemistry of the surfaces of solids, adsorption, and chromatography have developed appreciably in recent times. This was promoted by the creation of new adsorbents—in particular porous polymers. Polymeric adsorbents are widely used as sorbents in gas, liquid, ion-exchange, and ion chromatography, sieve (exclusion) chromatography of oligomers and polymers, biospecific (affinity) chromatography, and the ligand exchange chromatography of optical isomers and also as catalysts and selective absorbers of substances polluting the atmosphere.[1–3] Furthermore, the creation of polymeric adsorbents promotes the development of the molecular theory of adsorption on inhomogeneous surfaces.

Porous polymers have many important advantages over traditional adsorbents such as silicas, zeolites, and charcoals. They can be obtained not only as spherical grains corresponding to a narrow fraction comprising different sizes but also in the form of fabrics, films, and membranes.[4–7] The selection of monomers in the synthesis of porous polymers makes it possible to regulate their thermal stability and resistance to acids and alkalis. Porous polymers are highly permeable. They actively adsorb substances from both dry and moist atmospheres and from solutions. Finally, porous polymers can be readily regenerated by heating or by washing with acids and alkalis, which is important in their practical application.

In order to employ porous polymers in chromatography and also for the adsorption of gases and vapours, it is essential to be able to regulate their adsorption and selective properties. By varying the conditions in the synthesis of porous polymers, namely by carrying out the copolymerisation reactions of the monomers in inert solvents of different nature and composition and using different amounts of the cross-linking agent, it is possible to regulate the steric structure of the resulting three-dimensional polymer network and to obtain adsorbents with different porosities, i.e. their adsorption properties can be varied. By changing the chemistry of the surfaces of polymers during synthesis (by using monomers with specific functional groups) and by modifying the porous framework already formed (by carrying out polymer-analogue reactions), one can obtain adsorbents with a great variety of narrowly specific functional groups, i.e. one can regulate within wide limits their adsorption capacity and selectivity in relation to a wide variety of compounds.[1,8]

There have been so far no reviews of this problem, although extensive data have accumulated. In this review an attempt is made to survey studies on the geometrical structures of various porous polymers and its influence on the adsorption and chromatography of molecules of different natures. The elucidation of this problem is associated with the development of a specific synthesis of porous polymers with the optimum structure, which is imnportant in their practical application.

II. Classification of polymeric adsorbents in terms of their geometrical structures

Porous polymers are usually obtained by copolymerising mono- and di-vinyl monomers in the presence of inert solvents (pore-forming agents), which effectively dissolve the mixture of monomers and precipitate the polymer formed but do not participate in the copolymerisation reaction.[9–29] In the synthesis of porous polymers, a mixture of a solvent and a precipitant is sometimes used.[30] Low-molecular-weight and high-molecular-weight compounds of the solvating and non-solvating type are used most often as pore-forming agents.[9–29] After the removal of the solvent occupying the interstructural spaces, cavities or pores remain in the copolymer.

Since the porous structures of the majority of organic polymers of the polymerisation type as well as inorganic xerogels are formed on drying the gel, pore structures of the same type are therefore observed for them. Inorganic xerogels—silica gels and alumina gels—have corpuscular and especially globular structures (see the list of references in Kiselev and Yashin's book[31]). Electron microscope

studies on a series of organic porous polymers showed that their structures are also globular.[32–40,54] The suspension copolymerisation process consists in the construction of gel microparticles and their agglomeration into globules. The pores consist of the channels between the globules.

Table 1 presents a classification of the polymeric sorbents in terms of the nature of their geometrical structures on the basis of ideas developed for traditional adsorbents: the structure is believed to be macroporous if the pore diameter (d) is greater than 200 nm, mesoporous if $d = 3-200$ nm, and microporous if d is less than 3 nm.[41] Pore diameters $d > 100$ nm, $d = 4-100$ nm, and $d < 4$ nm respectively have been adopted by Gregg and Sing.[42] Copolymers of the methacrylate type are mesoporous adsorbents, but, under certain conditions of synthesis, macroporous specimens can also be obtained. Styrene–divinylbenzene copolymers have a mesoporous structure, but they contain as a rule a small number of micropores as a result of the parallel divinylbenzene–divinylbenzene copolymerisation.[105] Cross-linked macronetwork isoporous polystyrene copolymers (Styrosorbs) can have mesoporous and microporous structures and the mesoporous specimens can also contain micropores, i.e. can have a biporous structure. The polymers obtained on polycondensation of *m*-aminophenol with formaldehyde have only a macroporous structure, while phenol–formaldehyde resins have a mesoporous structure.[106,107] Thus polymeric adsorbents of different structural types have now been synthesised.

Table 1. Classification of the polymeric adsorbents investigated in terms of the nature of their porosity.

Type	Polymer chain	Designation or brand of the initial and modified polymers	$d>200$ nm (macropores)	$d=3$ to 200 nm (mesopores)	$d<3$ nm (micropores)	Refs.
I	2,3-Epoxypropyl methacrylate (glycidyl methacrylate)–ethylene dimethacrylate	EPMA–EDMA, GMA–EDMA, EPMA–EDMA–modifying agent (60 wt.% EPMA), G-60–modifying agent	+	+	–	[30, 37–40, 43–57]

III. The study of the porous structures of polymeric adsorbents of different types

Polymeric adsorbents swell appreciably in many solvents. In gas-chromatographic studies and also in the study of the adsorption of gases and vapours, where the adsorbates have a comparatively low vapour pressure, kinetic measurements have shown that mainly adsorption processes take place. However, in certain cases absorption, the extent of which is determined by the nature of the polymer and of the adsorbed molecule as well as by the nature and regularity of the cross-linking of the polymeric skeleton, may occur. Fairly complete and reliable information about the nature of the porous structure of such "non-rigid" adsorbents can therefore be obtained by employing a set of different techniques.

1. Methods for the measurement of the parameters of the porous structures of polymers

In the analysis of the porous structures of polymers, we shall consider the adsorption method using adsorbates of different nature—nitrogen, cyclohexane (in the vapour of which partial swelling of the polymers takes place), and perfluoro-n-octane (in the vapour of which polymers hardly swell). The use as the adsorbate in the adsorption method of perfluoro-n-octane, which is adsorbed as a result of weak non-specific interactions with the polymer surface, makes it possible to investigate the porous structures of both initial (as a rule non-polar) matrices and the anion-exchange resins obtained from them.[73,108] This review considers also the mercury porometric method[108] whose application to polymers is complicated by the possibility that the skeleton may be compressible.[23]

The isotherms for the adsorption of nitrogen by porous polymers presented in this review were measured by the vacuum volumetric method at –195 °C. The specific surfaces of the specimens S_{N_2} were then calculated from them by the Brunauer–Emmett–Teller (BET) method. The specific surfaces were also measured by the dynamic method involving the thermal desorption of nitrogen or argon (S_{N_2}, S_{Ar})[109] on the Quantosorb apparatus (USA) or on the Sorbtometr apparatus (USSR). The calculation was carried out by the BET method on the basis of three adsorption points or using as the standard a polymer specimen with a known value of S calculated by the BET method from the nitrogen adsorption isotherm at –195 °C. In calculating S for the polymers, use was made of the surface area per nitrogen molecule in a dense monolayer $\omega_m = 0.162$ nm^2. This value is usually employed for adsorbents such as carbon blacks and silica gels.[110] However, one should bear in mind that ω_m for nitrogen depends on the chemical nature of the adsorbent. The influence of the chemical state of the surface on the packing density of the nitrogen adsorption layers has been studied.[111] Loose layers are formed on non-polar and polar organic surfaces with $\omega_m^{N_2} = 0.20$ nm^2. The value $\omega_m = 0.22-0.28$ nm^2 has been obtained by a comparative method[112] for organic polymeric sorbents. The values of S calculated using such values of ω_m are greater, but the observed features are not altered.

This review presents and analyses the adsorption isotherms for nitrogen vapour on polymers measured at –195 °C with the temperature of the specimen raised to 30 °C.[73] One measures initially the degree of adsorption at –195 °C by the generally accepted method and the specific surface S_{N_2} is then calculated from this isotherm by the BET method. Subsequently the experiment is carried out as follows: the adsorption isotherm is measured at –195 °C up to a certain point (for example, up to the equilibrium pressure $p = 8$ mmHg) and the specimen, contained in a small closed volume, is then heated to 30 °C. As a result of desorption, the nitrogen pressure over the specimen increases under these conditions. After this, the adsorbent is again cooled to –195 °C and is maintained at this temperature until the attainment of equilibrium. For certain polymers, the equilibrium pressure does not change under these conditions, while for others the equilibrium pressure

diminishes, the decrease being appreciable in certain cases—for example from 8 to 0.5 mmHg. In the latter case, the degree of adsorption of nitrogen is measured at −195 °C, the heating−cooling operation described above being repeated, and a second isotherm is obtained. It lies above the first. The specific surface S_2 is calculated from this isotherm using the BET equation. Comparison of S_{N_2} and S_2 permits certain conclusions about the structures of the porous polymers.

The adsorption isotherms for the vapours of organic substances quoted in this review were measured at 25 °C with the aid of a McBain−Baker vacuum balance (with quartz springs) on specimens evacuated beforehand to 10^{-4} kPa at 70−80 °C.[109] S was estimated from the degree of sorption of n-C_8F_{18} vapour using the area ω_m = 1.06 nm^2. The specific surface $S'_{C_8F_{18}}$ of the adsorption film formed on the sorbent at the beginning of the capillary condensation was also calculated from the n-C_8F_{18} vapour sorption isotherm.[109,113] For polymers containing mesopores and micropores, S_{meso} was determined by a comparative method,[114,115] using the sorption isotherm for the n-C_8F_{18} vapour on a coarsely porous styrene copolymer with 12% of divinylbenzene as the reference standard.[73]

The volume of the pores was calculated from the degree of sorption of the n-C_8F_{18} ($V_{C_8F_{18}}$) and cyclohexane ($V_{C_6H_{12}}$) vapours at p/p_0 = 1. For polymers containing mesopores and micropores, the volume of the micropores V_{micro} was initially determined by the comparative method and then the volume of the mesopores V_{meso} was calculated. For comparison, the limiting volume of the absorbed liquid sorbate was determined from the degree of swelling of the polymer in the latter (in the case of cyclohexane, this will be designated by $V^L_{C_6H_{12}}$).[116] The pore volume can also be calculated from mercury porograms in terms of the amount of mercury forced into the specimen (designated by V_{Hg}). The overall volume of the cavities in the initial sorbents was calculated from the true and apparent densities of the polymer (the designation V^p is introduced in this case) or was estimated from its bulk density ($V^{b.d}$).[117]

The effective pore diameters at the maxima on the pore volume distribution curves were calculated from the mercury porograms (d_{Hg}) and from the desorption branches of the n-C_8F_{18} isotherms using the Thompson−Kelvin equation ($d_{C_8F_{18}}$).[118] The average pore diameter was calculated from the formula $\bar{d} = 4V/S$.[37]

2. The porous structure of polymers of the methacrylate type

Methacrylate polymers were obtained by the suspension radical copolymerisation of epoxypropyl methacrylate with different amounts of ethylene dimethacrylate as the cross-linking agent and different proportions of solvent (cyclohexanol) and precipitant (dodecanol) in the inert phase.[43–57] Depending on these factors, specimens with different structures can be obtained. Electron microscope studies[38,39,48] showed that the structure of the methacrylate polymers is globular: the porous structure is formed as a result of the formation of gel microparticles and their agglomeration into globules. The porosity of the polymers is determined by the size of the globules and the distance between neighbouring globules, which depends on their packing.[37] The nature of the aggregation of the microparticles on the surface and in the bulk of the globules is significantly different. The microparticles on the surface and in the bulk of the globules have the same sizes, but on the surface they aggregate in a more compact manner. The pore size in the surface layer is smaller than in the bulk phase. It is believed[55,57] that the surface layer of the globules consists of relatively mobile poly(glycidyl methacrylate) chains. In the case of highly cross-linked methacrylate copolymers, the large values of S can be explained by the presence of very fine microspheres—nodules (whose size is about 10 nm), from which the globules are formed. Using gel permeation chromatography (GPC),[54,56] it has been shown that the characteristics of the porous structures of copolymers in the dry and swollen states are different: the average pore diameter, determined by mercury porometry, is greater for the dry copolymers than the value determined for the swollen copolymers by gel permeation chromatography.

In order to be able to distinguish the geometrical modifications of the copolymers, the following notation has been introduced: the fraction of one of the monomers and the solvent/precipitant ratio are quoted. Thus the EPMA-EDMA-40-91/9 (G-40-91/9) copolymer is obtained by the copolymerisation of 2,3-epoxypropyl methacrylate (2,3-EPMA) (40 wt.%) and ethylene dimethacrylate (EDMA) (60 wt.%) with a cyclohexanol/dodecanol ratio of 91/9. Table 2 presents certain characteristics of such copolymers. The study of the porous structure of EPMA−EDMA by mercury porometry and on the basis of the sorption of nitrogen vapour[30,40,51] showed that, for highly cross-linked copolymers, the pores with d = 3−60 nm (which some authors refer to as micropores) make a large contribution to the value of S. In the presence of a small amount of the cross-linking agent, pores with d < 20 nm are absent. The pore volume determined by mercury porometry is much lower than the pore volume determined from the swelling of the polymers in cyclohexane. This is evidently associated with the partial swelling of the specimens.

*G denotes the EPMA−EDMA copolymer (see Table 1).
**Here and henceforth the average value of $\bar{d}$ is given in brackets, while the figure without brackets denotes the effective value.

The structure of certain aminated EPMA−EDMA specimens has been investigated by various methods (Table 3).[30,40,51,108] The isotherms of the adsorption of cyclohexane vapour, in which the polymers partly swell (for low values of p/p_0 the isotherms are irreversible), were measured on these specimens (Fig. 1). The n-C_8F_{18} adsorption isotherms on the modified specimens are reversible in the initial region of relative pressures and have a distinct and narrow capillary-condensation hysteresis loop of the H1

type, which is characteristic of sorbents with cylindrical pores. The structural parameters of polymers were estimated from such isotherms (Table 3). Table 3 shows that the specific surfaces of the adsorption film $S'_{C_8F_{18}}$ and $S_{C_8F_{18}}$ virtually coincide and the values of S determined from the adsorption of the small nitrogen molecule and the fairly large n-C_8F_{18} molecule are also similar. This indicates the absence of micropores in the test specimens. The values of S_{Hg} exceed in certain cases those of S obtained from adsorption data, sometimes by a factor of two. In all probability, such specimens contain an appreciable number of pores with constrictions (or widened regions), since it is in fact in such cases that $S_{BET} < S_{Hg}$.[118]

Table 3 shows that the parameters of the porous structure of the polymers (S, V, d) hardly change on modification with amines and aminoalcohols. Only on amination with ammonia does S increase for all degrees of cross-linking of the copolymer, possibly owing to the additional cross-linking of the framework. It has been shown[51] that, when copolymers are aminated by amines and aminoalcohols, the volumes of small (8–50 nm) and very large (d > 100 nm) pores diminish and the number of pores with d = 60–80 nm increases sharply, so that the overall pore volume hardly changes and remains ~1 $cm^3 g^{-1}$.

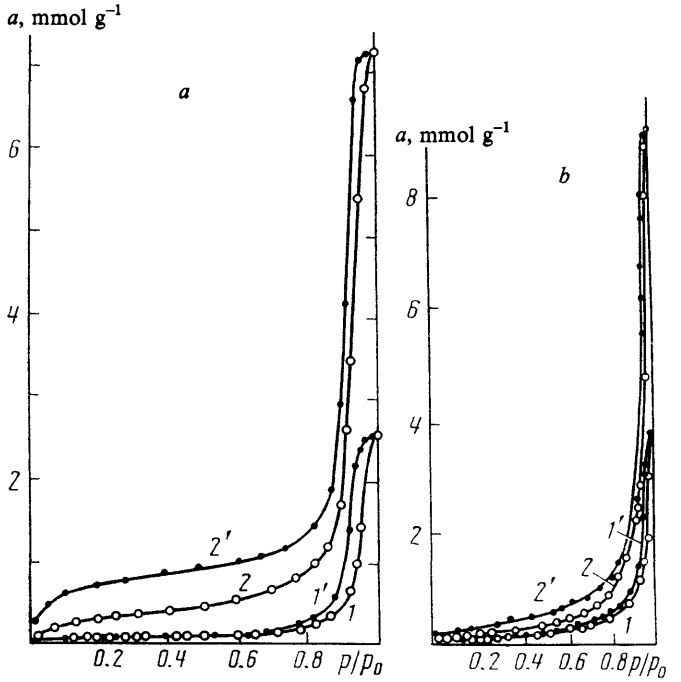

Figure 1. Adsorption (curves *1* and *2*) and desorption (curves *1'* and *2'*) isotherms for n-C_8F_{18} (curves *1* and *1'*) and cyclo-C_6H_{12} (curves *2* and *2'*) vapours at 25 °C: (*a*), on the styrene–divinylbenzene (8%) copolymer modified with diethylenetriamine (AN-511 anion exchanger) obtained in n-decane (100%) as the pore-forming agent; (*b*) on the 2,3-epoxypropyl methacrylate–ethylene dimethacrylate copolymer (60% of 2,3-epoxypropyl methacrylate) modified with diethylenetriamine.

The low-temperature adsorption of nitrogen on specimens of methacrylate polymers with the specimens heated in a closed space have been investigated.[73] For all the specimens, $S_{N_2} = S_2$, i.e. the polymers have a very regular structure. This can be explained by the following causes. Polymers containing in their chains an appreciable number of polar groups are fairly rigid structures. Furthermore, in the synthesis of these polymers it is possible to obtain a uniformly cross-linked framework, which does not contain highly cross-linked microporous sections.

Determination of the pore volume from the adsorption of C_8F_{18} and C_6H_{12} vapours showed that the values of $V_{C_8F_{18}}$ and $V_{C_6H_{12}}$ are virtually identical (Table 3) despite some swelling of the polymers in cyclohexane vapour (Fig. 1). For the highly cross-linked specimen (40% EDMA), $V_{Hg} \simeq V_{ads}$. This shows that either the framework does not change at elevated pressures and the specimen does not contain an appreciable number of macropores with d > 200 nm or the framework is compressed but the specimen contains pores with d > 200 nm, the effects cancelling out. The first hypothesis appears more probable. For the weakly cross-linked specimen, $V_{Hg} > V_{ads}$ ($d_{Hg} > d_{ads}$). Possibly the specimen becomes more coarsely porous under the conditions of mercury porometry.

The method of determining the pore volume from the adsorption of liquid, for example, cyclohexane,[117] yields unduly high results owing to the more extensive swelling of the polymers in liquids than in vapours. However, formal calculation of the average pore diameter $\bar{d}$ using $V^L_{C_6H_{12}}$ and S_{N_2} yields values close to d_{Hg}.

Table 2 and Fig. 2 show that the values of S for the methacrylate polymers increase with increase in the amount of ethylene dimethacrylate and depend on the solvent/precipitant ratio. With increase in the fraction of ethylene dimethacrylate to 40%, the pore volume also increases, but, on still further increase in the fraction of ethylene dimethacrylate (to 60%), it changes little. With increase in the amount of the pore-forming agent (cyclohexanol) in the mixture with the precipitant (dodecanol), S_{N_2} increases, while $V_{C_6H_{12}}$ diminishes, i.e. the specimen acquires a more finely porous structure.

The porous structures of methacrylate copolymers obtained by cross-linking monomers of different polarity with ethylene dimethacrylate have been investigated.[44,49] It was found that the specific surface and the pore volume diminish with increase in the content of the polar monomer: $S_{MMA} > S_{HEMA} > S_{AN}$ (MMA = methyl methacrylate, HEMA = hydroxyethyl methacrylate, AN = acrylonitrile). The polymers contain no pores with $d > 100$ nm and the preferred pore size is $d = 40-80$ nm. The pore structure of sulphur-containing methacrylate copolymers is also regulated by varying the content of ethylene dimethacrylate and the solvent/precipitant ratio. With increase in the amount of ethylene dimethacrylate in the copolymers, S and V increase, while the content of epithio-groups falls.[119,120]

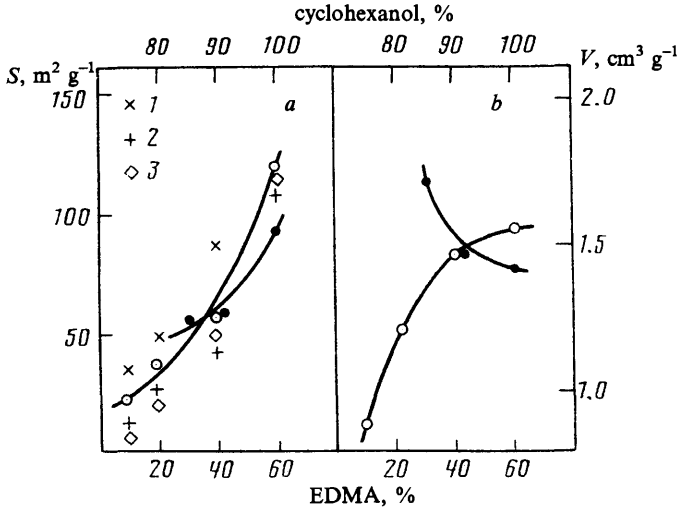

Figure 2. Dependence of the specific surface S (*a*) and pore volume V (*b*) on the content of the cross-linking agent (open symbols) and the solvent (cyclohexanol) (filled symbols) for the epoxypropyl methacrylate–ethylene dimethacrylate copolymers. Fig. 2*a* also presents the values of S for polymers with different degrees of cross-linking modified by ammonia (*1*), ethylenediamine (*2*), and diethylenetriamine (*3*).

Thus methacrylate polymers have an extensive porosity. These are mainly mesoporous adsorbents. The pore structure of the polymers is regulated by varying the amount of the cross-linking agent (ethylene dimethacrylate) and the solvent/precipitant ratio and by introducing a polar monomer. On modification of these copolymers, the parameters of the porous structure do not change greatly.

3. The porous structure of polymers of the styrene – divinylbenzene type

Porous styrene–divinylbenzene copolymers are obtained by the suspension copolymerisation of styrene with divinylbenzene. The principal factors influencing the porosity of these copolymers are the degree of cross-linking of the three-dimensional copolymer framework, which is determined by the amount of the cross-linking agent (divinylbenzene) and by the nature of the pore-forming agent and its concentration in the mixture of the polymerising monomers. The structure of the styrene–divinylbenzene copolymers has been investigated by the adsorption method (from the adsorption isotherms of water vapour and methanol) and by mercury porometry (see the literature references in Table 1). The present review deals primarily with the porous structures of anion exchangers obtained from styrene–divinylbenzene copolymers. The study of the adsorption and desorption isotherms of methanol, n-hexane, perfluorobenzene, and perfluoro-n-octane on the AN-221 anion exchanger containing ethylenediamine groups showed that, as for the epoxypropyl methacrylate–ethylene dimethacrylate copolymers, the anion exchanger does not swell only in the vapour of the fully fluorinated saturated hydrocarbon, the interaction of the molecules of which with the surface of the polymer are not only non-specific but also weak (Fig. 1). The isotherm is fully reversible. At high values of p/p_0, a distinct capillary-condensation hysteresis is observed, as for inorganic adsorbents with a rigid skeleton.

In order to be able to distinguish the geometrical modifications of the styrene–divinylbenzene copolymers, the following notation has been introduced: the ratio of the amounts of the cross-linking agent and the pore-forming agent is stated and then the pore-forming agent is indicated. Thus the 12/80, BR-1 copolymer is obtained by copolymerising 88% of styrene with 12% of divinylbenzene in the presence of 80% of petrol of type BR-1 as the pore forming agent.

The porous structure of a number of anion exchangers has been investigated by various methods (Table 4). The surface area S of the test specimens varies in the range from 11 to 130 m^2g^{-1}, V varies from 0.05 to 1.29 cm^3g^{-1}, and d varies from 24 to 100 nm, which is associated mainly with the nature and amount of the cross-linking and pore-forming agents. The ranges of variation of S, V, and d obtained for 8 specimens of AN-221 (12/80, BR-1) have been published:[26] $S = 75-120$ m^2g^{-1}, $V = 0.4-0.8$ cm^3g^{-1}, and $d = 20-100$ nm; similar data have been published for 12 specimens of AN-511 (8/100, n-decane): $S = 25-40$ m^2g^{-1}, $V = 1.0-1.3$ cm^3g^{-1}, and $d = 100-200$ nm. This indicates some non-reproducibility of the conditions in the synthesis of the given polymers.

Table 4 shows that the specific surfaces of the film S' and S, determined from the adsorption of C_8F_{18}, are virtually identical. Furthermore, the values of S determined from the adsorption of the small nitrogen molecule and the fairly large C_8F_{18} molecule are also similar. This indicates the absence of an appreciable number of micropores in the test specimens.

Comparison of the pore volumes determined by mercury porometry and from the adsorption of vapours shows that, within the limits of the reproducibility of the measurements, $V_{Hg} \simeq V_{ads}$. This indicates the absence of an appreciable number of macropores with $d > 200$ nm in the test specimens. The above conclusion is confirmed also by the pore volume distribution curves. Thus both adsorption methods using adsorbates in which the polymers hardly swell and mercury porometry are applicable to the study of the structures of the test polymers.

In order to elucidate the influence of the polymer-analogue reactions on the structural characteristics of the polymers, measurements were made of the adsorption isotherms of C_8F_{18} on the initial styrene–divinylbenzene copolymer (8/100, n-nonane), the chloromethylated copolymer (CMC) and the anion exchangers AN-221, AN-511, and AN-541 (specimens *1–5* in Table 4). A narrow pore distribution is observed for these substances and virtually all the specimens have $d_{eff} \simeq 60$ nm. Changes in the structure occur mainly in the chloromethylation stage, whereupon V

falls somewhat as a result of the removal of pores with sizes ranging from 20 to 30 nm. On subsequent amination, these parameters hardly change. After the introduction of highly basic groups, the parameters of the porous structure change more appreciably.

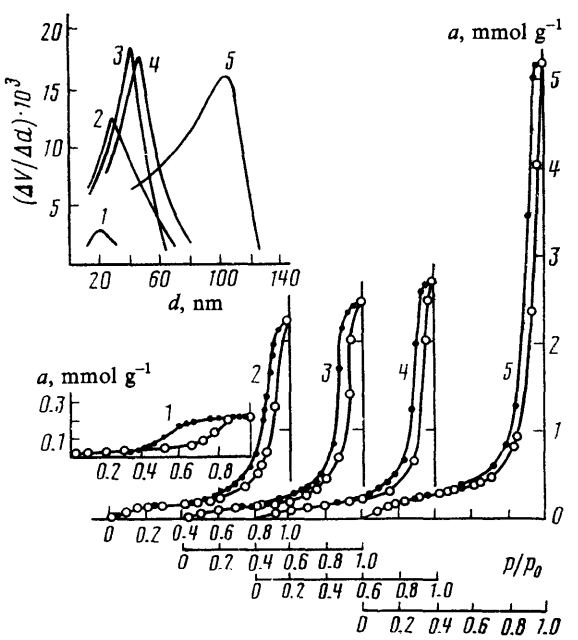

Figure 3. Isotherms for the adsorption (open circles) and desorption (filled circles) of n-C_8F_{18} vapour on the AN-221 anion exchanger (BR-1 pore forming agent, specimens *6–10* in Table 4) at 25 °C. The inset shows the corresponding curves for the distribution of pore volumes with respect to the effective diameters. Amount of divinylbenzene (%): (*1*) 8; (*2*) 12; (*3*) 15; (*4*) 20; (*5*) 30.

The influence of the amount of the cross-linking agent on the structure of the AN-221 anion exchangers has been investigated. Fig. 3 presents the adsorption and desorption isotherms for C_8F_{18} vapour on the anion exchangers with different degrees of cross-linking. The parameters of the porous structure listed in Table 4 were calculated from the isotherms. With increase in the amount of divinylbenzene in the anion exchanger matrix from 8 to 30%, S, V, and the pore size increase. Similar relations have been observed for styrene–divinylbenzene copolymers. With increase in the amount of the cross-linking agent, the polymer framework becomes more rigid and its contraction after the removal of the solvent during synthesis diminishes, which leads to an increase in the size and volume of the pores. The highly cross-linked specimen (30% DVB) contains a larger number of fine pores, which explains its higher value of S.

The dependence of the structure of the AN-221 and AN-511 anion exchangers on the molecular size of an inert solvent (hydrocarbon) has also been investigated. The largest pores ($\geqslant$100 nm) are present in anion exchangers whose matrix has been obtained in the presence of a solvent such as n-decane.[26,73] The porosity of the styrene–divinylbenzene copolymer in the dry state is greater the lower the degree of solvation of the copolymer by the solvent.[64] With increase in the molecular size of the solvent in the series petrol < isooctane < n-nonane < n-decane, the solvating power of the solvent diminishes, as a result of which the contraction of the copolymer on removal of the solvent during synthesis diminishes and the fraction of large pores in the adsorbent increases.

The porous structure of the anion exchangers has also been investigated by the static nitrogen adsorption method at −195 °C with the specimen being warmed during the measurement of the adsorption isotherm. S_{N_2} and S_2 were determined in this way.[73] In contrast to methacrylate polymers, $S_2 > S_{N_2}$ for the styrene–divinylbenzene copolymers and anion exchangers. Thus an appreciable increase (up to 200%) in S after the specimen heating–cooling cycle has been observed for styrene–divinylbenzene copolymers. Apparently, when the specimen is heated, as a result of the increase in the pressure of nitrogen its molecules can

permeate into pores with constrictions or micropores which are inaccessible to the adsorbate under the usual experimental conditions. This phenomenon is analogous to the effect of activated breakthrough, i.e. to the increase in the degree of adsorption with increase in temperature which is characteristic of microporous adsorbents.[118] There is then a possibility of the enforced elastic deformation of the polymer pore walls[121] which persists on subsequent cooling to a greater extent the more elastic the polymer and the smaller its rigidity. In the chloromethylation of the copolymer, a polar group ($-CH_2Cl$) is introduced into the polymer, which leads to the additional cross-linking of the polymer chains[122] and to an increase in the rigidity of the polymer and hence to a decrease in the difference between S_{N_2} and S_2. The introduction of amino-groups into the polymer makes it still more rigid and the enforced elastic deformation on desorption of nitrogen during heating diminishes. With increase in the amount of the cross-linking agent in the anion exchanger matrix, the difference between S_{N_2} and S_2 increases owing to the dominant influence of the factor associated with the increase in the amount of highly cross-linked sections containing micropores in the anion exchangers. The values of S measured by the nitrogen thermal desorption method agree with those of S_{N_2} (with the exception of highly cross-linked specimens).

Thus the application of various methods to the study of the porous structure of polymers permits a more detailed characterisation of the structures of these complex objects. The porous structure is readily regulated by the introduction of different amounts of the cross-linking agent (in the given instance divinylbenzene), by the alteration of the divinylbenzene/pore-forming agent ratio, and by the nature of the pore-forming agent.

4. The porous structure of copolymers of vinylpyridine derivatives and divinylbenzene

Porapak S as well as Polysorb N, which are vinylpyridine–divinylbenzene copolymers, are widely used in chromatography. Porous copolymers of this class are obtained by the suspension copolymerisation of the initial monomers—vinylpyridine derivatives containing ionogenic groups, with divinylbenzene or divinylpyridine. Porous copolymers of 4-vinylpyridine with ethylene dimethacrylate and 2,5-divinylpyridine having specific surfaces up to 400 m^2g^{-1} have also been synthesised and investigated.[103,104] The synthesis of such ion exchangers consists of a single stage and their structure is formed in the copolymerisation stage and does not undergo further changes. The porous structure of such copolymers has been investigated by the adsorption method (in relation to nitrogen and methanol) and by mercury porometry (see the literature references in Table 1). The structure of the vinylpyridine–divinylbenzene anion exchangers has been investigated[73] by the nitrogen thermal desorption method and by the low-temperature adsorption of nitrogen with warming of the specimen in a closed volume. For these copolymers, $S_2 > S_{N_2}$. As for the styrene–divinylbenzene copolymers, the heating of the vinylpyridine–divinylbenzene specimens can entail, as a result of the increased pressure of nitrogen, the penetration of its molecules into the pores with constrictions or micropores which are inaccessible to the sorbate under the usual conditions. The difference between S_{N_2} and S_2 for AN-251, cross-linked by divinylpyridine, is smaller than for AN-251 cross-linked by divinylbenzene, which can be explained by the increased rigidity of the polymer framework when divinylpyridine is used as the cross-linking agent. The introduction of polar groups into the polymer chains increases their rigidity to a greater extent the more polar the group and the greater their number introduced into the chain. On passing from AN-251, containing pyridine nitrogen, to AN-451, containing also tertiary nitrogen, the difference between S_{N_2} and S_2 therefore diminishes.[73] The quantity S, determined by the nitrogen thermal desorption method, corresponds to S_2 and not to S_{N_2}, as in the case of the styrene–divinylbenzene copolymers.

5. The porous structure of ultracross-linked polystyrenes (Styrosorbs)

The macronetwork isoporous polymers based on polystyrenes (see the literature references in Table 1) are porous in the dry state and have an extensive inner surface only in the presence of large amounts of the cross-linking agent (>30%). The Styrosorb (I) sorbents are obtained using a method involving the cross-linking of linear polystyrene (PS) chains dissolved in an organic solvent [in most cases dichloroethane (DCE)] by *p*-xylylene dichloride (XDC), 4,4′-bis(chloromethyl)biphenyl, chloromethyl methyl ether (CMME), or methylal in the presence of a Friedel–Crafts catalyst.

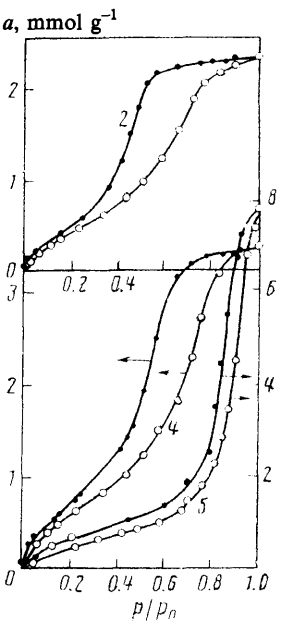

Figure 4. Isotherms for the adsorption (open circles) and desorption (filled circles) of n-C_8F_{18} vapour on Styrosorbs I (specimens *2*, *4*, and *5* in Table 5) at 25 °C.

The study of the structure of Styrosorbs obtained in dichloroethane by electron microscopy, small angle X-ray scattering, and gel permeation chromatography showed that they are microporous sorbents in which the main fraction of pores have diameters of the order of 1 nm.[83,89,90] The Styrosorbs (I) examined in this study were obtained by cross-linking linear polystyrene dissolved in cyclohexane (CH) with chloromethyl methyl ether. The molecular weight of the polymer varied from 13×10^3 to 3×10^6. A Styrosorb (II) specimen, synthesised by the cross-linking with chloromethyl methyl ether of a copolymer of styrene with 2% of divinylbenzene swollen in dichloroethane, was also investigated (Table 5).[90] All the polymers investigated had a degree of cross-linking of 100%. In the study of the porous structure of the Styrosorbs, n-C_8F_{18} was used as the sorbate. In its vapour the Styrosorbs swell to a lesser extent than in other organic solvents.

Table 5. Structural characteristics of Styrosorbs I (specimens *2*–*6*) and II (specimen *1* with 2% DVB).[92]

Specimen	Molecular weight of initial polystyrene × 10^{-3}	Solvent	S, $m^2 g^{-1}$				V, $cm^3 g^{-1}$				d, nm

**3a* represents specimen *3* chloromethylated and aminated by DETA.

Fig. 4 presents the n-C_8F_{18} sorption isotherms on three specimens of Styrosorbs (specimens *2*, *4*, and *5*, Table 5) obtained in cyclohexane by cross-linking polystyrenes having different molecular weights. They differ in the position and form of the hysteresis loop, which can provide some idea about the size and shape of the pores present in the given sorbents. It is possible to distinguish two varieties of Styrosorbs I. The first includes polymers obtained by cross-linking polystyrene having a high molecular weight ($3 \times 10^6 - 8 \times 10^4$) dissolved in cyclohexanes. Such Styrosorbs have sorption isotherms with a hysteresis loop which belongs to the H2 type according to de Boer's classification. The second variety of Styrosorbs I is obtained by structure formation in polystyrene having a low molecular weight ($13-17 \times 10^3$). Their sorption isotherms exhibit a narrow capillary-condensation hysteresis of the H1 type. The comparatively large degrees of sorption of n-C_8F_{18} on Styrosorbs for low values of p/p_0 and the slight irreversibility of the isotherms in the initial region are striking. The latter feature may be associated both with the low degree of swelling of the polymers in the given sorbate and with the slow rate of sorption of n-C_8F_{18} in the micropores present in these specimens.

Analysis of the data in Table 5 permits the following conclusions. The cross-linking of polystyrene chains in dichloroethane, which is a thermodynamically effective solvent, leads to the formation of microporous sorbents with $d \simeq 1$ (specimen *1*). This is also indicated by the low value of $S_{C_8F_{18}}$ compared with S_{Ar}. It is noteworthy that solvents such as hexane and methanol, in which polystyrene does not dissolve, are capable of solvating vigorously the polymer chains of ultra-cross-linked polystyrene, as a result of which $V^L_{C_6H_{14}}$ and $V^L_{CH_3OH}$ reach 4 $cm^3 g^{-1}$.[83,89,90] The appearance of micropores in the given Styrosorbs is a consequence of the loose packing of the polymer chains in the single-phase network cross-linked by a large number of rigid bridges, which hinder the mutual approach of the polymer chains when the solvent is removed from the swollen polymer produced. The high strain in the structure of Styrosorbs in the dry state imparts to them a unique capacity to swell in any medium even in inert media such as perfluorooctane.[90]

When the thermodynamically effective solvent dichloroethane is replaced by cyclohexane (a solvent with a lower affinity for polystyrene), the structure of the sorbents changes. They contain not only micropores but also mesopores (specimens *2*–*6* in Table 5 and Fig. 4). Such Styrosorbs swell least in the n-C_8F_{18} vapour. The rigid n-C_5F_{12} fills the cavities in the polymer, whereupon the specimen hardly swells. The weak swelling of Styrosorbs I in fluorinated hydrocarbons is indicated primarily by the form of the isotherms and the closeness of the values of $V_{C_8F_{18}}$ to V^{ρ} or $V^{b.d.}$ (specimen *3* containing a large number of micropores is an exception). For specimens *2*–*4*, $V < 1$ $cm^3 g^{-1}$, while S_{meso} is the same as S' and less than $S_{C_8F_{18}}$, which indicates the presence in the specimen of fine pores ($d \simeq 3$ nm) accessible to C_8F_{18} molecules. Specimens *5* and *6* have $V > 1$ $cm^3 g^{-1}$. Their effective pore diameter is much greater than for specimens *2*–*4* and amounts to 20–30 nm. As in the case of specimens *2*–*4*, S_{meso} for specimens *5* and *6* is approximately equal to S' and is less than $S_{C_8F_{18}}$, while V_{micro} is not large.

Fig. 5 presents the dependence of the effective pore diameters of the Styrosorbs on the molecular weight of the initial polystyrene. A decrease in the polymer chain length leads to an increase in d. The high mobility of the low-molecular-weight polystyrene facilitates the phase decomposition of the solution. Pores whose size amounts to several tens of nanometers therefore arise in the final polymer. If the rate of the chemical reaction is sufficiently high while the mobility of the chains is, on the other hand, limited (a polystyrene with a fairly high molecular weight), then the chains are fixed in the three-dimensional structure very rapidly and in such a system there are no favourable conditions for microlayer formation. The mesopores in the given Styrosorbs consist of gaps between individual coils of polystyrene macromolecules (or their aggregates), which exist in the initial solution and are fixed by cross-links.[92,93]

Thus the nature of the porous structure of the Styrosorbs can vary within wide limits and depends both on the nature of the solvent and on the molecular weight of the polystyrene.

In the chloromethylation and amination of Styrosorb (I) by DETA, its structure (specimen *3a*, Table 5) changes, $S_{C_8F_{18}}$ and $V_{C_8F_{18}}$ increase, while d_{eff} remains unchanged. The polymer-

analogue reactions probably involve the formation of small ($d \simeq$ 3 nm) pores, which are nevertheless still accessible to C_8F_{18} molecules.

The anion exchanger obtained from Styrosorb I by chloromethylation and amination using ethylene and diamine and additionally ammonia has been investigated by the low-temperature nitrogen adsorption method with the specimen being warmed in a closed space. In this case, S increases by only 14%, i.e. the specimen has very regular cross-links, because the reactivity of all the polystyrene units is the same and the network polymer obtained has statistically distributed cross-links. Furthermore, the anion exchanger framework is cross-linked to the extent of 100%, i.e. it is rigid, and the enforced elastic deformation is small, which is manifested by the significant increase in S on heating the specimen.

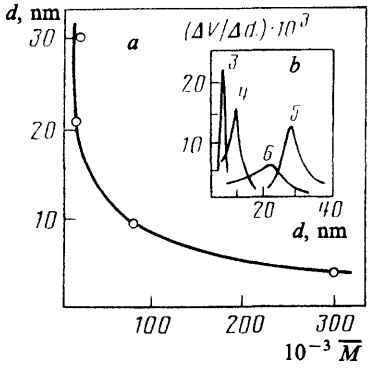

Figure 5. Dependence of the pore diameter for Styrosorbs I on the molecular weight of the initial polystyrene (*a*) [points corresponding to the maxima on the curves for the distribution of the pore volumes with respect to the diameters (*b*)].

When the Styrosorb is sulphonated, it becomes non-porous. This probably takes place as a result of the increase in the volume of the sulpho-groups caused by the binding of the water molecules and as a result of the high cohesion energy, which holds together the highly cross-linked but mobile polymer network.

IV. The influence of the porous structure of polymers on their adsorption and chromatographic properties

1. Characteristic features of the adsorption of organic vapours

The study of the influence of the porous structure of methacrylate polymers on their gas-chromatographic properties has shown that the less cross-linked polymers possess better chromatographic properties (more symmetrical peaks, lower retention times of all substances and lower heights equivalent to the theoretical plate) since they contain the smallest number of bottle-shaped pores and pores with $d < 5$ nm.[38,43–47,49–52,54] With increase in the specific surface of the methacrylate polymers, the specific retention volumes of all the substances also increase. The relative retention volumes of the non-specifically sorbed n-hydrocarbons increase with increase in the amount of the cross-linking agent (ethylene dimethacrylate) (owing to the increase in S and in the contribution of dispersion interactions), while those of specifically sorbed substances (for example, benzene, alcohols, ethyl methyl ketone, nitromethane, and pyridine) fall, which can be explained by the decrease, with increased S, in the concentration of surface functional groups responsible for the specific interactions with these molecules.[25,47,120,123]

The gas-chromatographic properties of vinylpyridine–divinylbenzene copolymers have been investigated in relation to the AN-251 anion exchangers obtained with the same amount of n-heptane as the pore-forming agent (80% of the total monomers) for different contents of divinylbenzene.[124] The retention volumes V_R of n-hydrocarbons increase on passing from the AN-251-15/80 specimen to the AN-25-30/80 specimen and diminish somewhat for the AN-251-40/80 specimen, while the specific surfaces of this series increase monotonically. The decrease in retention volumes for the AN-251-40/80 specimen can probably be accounted for by the decrease in the degree of swelling and in the overall pore volume of this highly cross-linked ion exchanger. The values of V_R for the specifically adsorbed molecules are appreciably higher than those for the non-specifically adsorbed molecules and, on passing to highly cross-linked specimens, they decrease owing to the decrease in the number of functional groups in the polymer.

The methacrylate and styrene–divinylbenzene polymers poorly sorb hydrocarbon vapours and undergo partial swelling in C_6H_{14} vapour; the C_6H_{14} adsorption isotherms on the initial (S = 25 m^2g^{-1}) and chloromethylated (S = 32 m^2g^{-1}) copolymers as well as the copolymer aminated by ethylenediamine (S = 31 m^2g^{-1}) are the same, i.e. the introduction of functional groups into the polymer does not alter the sorption of the n-alkane, since the sorption takes place as a result of a non-specific interaction. The same features have been observed for the sorption of CH_3OH, i.e. the contribution of specific interactions is in this case small.

Styrosorbs, which have a more extensive porous structure, effectively sorb hydrocarbon vapours.[84,90] In a study[125] of the kinetics of the sorption of n-heptane and n-hexane by Styrosorb, it has been shown that the process takes place in two stages: the first, rapid stage involves a rearrangement of the sorbent structure and the second, slow stage is associated with the permeation of the n-C_5H_{12} and n-C_6H_{14} molecules into the microcavities formed as a result of the segmental mobility of the polymer chain units. The degree of sorption of CH_3OH and H_2O vapours by Styrosorbs is not high. The CH_3OH vapour sorption isotherm on Styrosorb II (a microporous specimen) lies above that on Styrosorb I (a biporous specimen containing micropores and mesopores) and has a different form—it is linear up to $p/p_0 = 0.6$. On the other hand, on being immersed in CH_3OH or H_2O, these polymers absorb up to 6.0 and 4.0 cm^3g^{-1} of these liquids respectively.[92]

The cyclohexane sorption isotherms on the initial and DETA-modified polymers of this type are similar up to $p/p_0 \simeq 0.8$; for higher values of p/p_0, the sorption isotherm on the initial copolymer lies in a much higher position, evidently due to its greater swellability at high pressures. On sulphonation, the specimen becomes non-porous and the degree of sorption of n-C_6H_{14} and cyclo-C_6H_{12} diminishes almost to zero.[80]

Thus the study of the sorption of organic substances on the test specimens showed that their capacity is determined to a large extent by the geometrical structure of the sorbent. Styrosorbs exhibit a high capacity with respect to organic compounds.

2. Characteristic features of the absorption of carbon and sulphur dioxides

It was shown above that the geometrical structure of the polymeric sorbents is determined by the amount and nature of the components involved in their synthesis. The influence of these factors on the adsorption and chromatography of certain adsorbates,

in particular carbon and sulphur dioxides, has therefore been investigated. These gases were selected because they are, firstly, of interest from the practical point of view and, secondly, they are effectively adsorbed by polymers containing amino-groups.

(a) The influence of the amount and nature of the cross-linking agent

Anion exchangers based on styrene–divinylbenzene and vinylpyridine–divinylbenzene (divinylpyridine) copolymers and Styrosorbs.[1,80,126–130] Measurements were made of the CO_2 adsorption isotherms by the static volumetric method and of the output curves (frontal chromatograms) for CO_2 and SO_2 on AN-221 specimens with different degrees of cross-linking (Fig. 6). Table 6 presents the ratios of the amounts of divinylbenzene and of the pore-forming agent for the AN-221 anion exchanger containing ethylenediamine groups, the static exchange capacities (SEC) with respect to 0.1 M HCl, S_{N_2}, S_{CO_2}, as well as the capacities with respect to CO_2 and SO_2 before break-through (E_0); data for anion exchangers based on Styrosorbs are not included. For styrene–divinylbenzene copolymers not containing functional groups, an increase in capacity before the break-through of SO_2 is observed with increase in the amount of divinylbenzene (with increase in S), since the molecules are adsorbed mainly as a result of dispersion interactions. Figs. 6 and 7 show that the capacities of the AN-221 anion exchangers with respect to CO_2 and SO_2 diminish with increase in the amount of cross-linking agent in them and that the same behaviour is observed for the AN-251 exchangers (Fig. 8). With increase in the divinylbenzene content, S_{N_2} and the overall pore volume (V) of the anion exchangers increase. On the other hand, with increase in divinylbenzene content in the polymerising system, the number of monomer units carrying functional groups diminishes. In the styrene–divinylbenzene copolymers, these are styrene rings, which are subsequently chloromethylated and aminated, while in the vinylpyridine–divinylbenzene copolymers these are vinylpyridine rings. As a result, an increase in the divinylbenzene content in the anion exchangers entails a diminution of the overall number of functional groups (the SEC characterises the content of functional groups in the swollen ion exchanger, i.e. virtually the total number of functional groups). The decrease in the number of functional groups entails a decrease in the degree of adsorption of CO_2 and SO_2 adsorbed on anion exchangers as a result of dispersion interaction with the anion exchanger framework and specific interactions with the functional groups, i.e. the dominant factor is the interaction with functional groups. Therefore, a decrease in the SEC of the anion exchanger entails, despite the increase in S, a diminution in the degrees of adsorption of CO_2 and SO_2. Similar variations in the degrees of adsorption by the dry AN-221 anion exchangers have been obtained for SiF_4 [131] and the acrylonitrile–divinylbenzene copolymer (or acrylonitrile) in relation to phenol and aniline.[25] The weaker dependence of the capacity of the AN-251 anion exchanger before the break-through of SO_2 on the amount of divinylbenzene compared with the dependence of the total capacity shows that the capacity before break-through depends to a greater extent on S than the total capacity, which is mainly determined by the SEC of the anion exchangers (Fig. 8).

The absorption of SO_2 on the AN-251 anion exchangers cross-linked not by divinylbenzene but by divinylpyridine i.e. anion exchangers in which both the cross-linking agent and the monomer contain pyridine nitrogen, has also been investigated. For specimens with a similar structure, it has been shown that the time of the protecting action and hence also $E_0^{SO_2}$ for the AN-251-DVP,15/50 anion exchanger is greater than for AN-251-DVB,15/50, i.e. the use of divinylpyridine as the cross-linking agent increases the number of functional groups in the anion exchanger and its capacity with respect to SO_2.

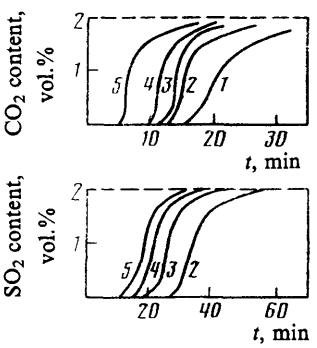

Figure 6. CO_2 and SO_2 output curves on the AN-221 anion exchanger (BR-1 pore-forming agent). Experimental conditions: carrier gas flow rate 250 cm^3 min^{-1}, CO_2 or SO_2 content in the carrier gas 2 vol.%, column diameter 15 mm, column length 50 mm for CO_2 and 25 mm for SO_2 and column temperature 20 °C. Amount of divinylbenzene (%): (*1*) 8; (*2*) 12; (*3*) 15; (*4*) 20; (*5*) 30.

Table 6. Characteristics of the AN-221 anion exchangers with different geometrical structures (specimens *1–8*) and anion exchangers based on Styrosorb I (specimens *9–11*) and their capacities with respect to CO_2 and SO_2.[80,126–130]

Specimen	Solvent	DVB/solvent	S_{N_2}, m^2 g^{-1}	S_{CO_2}, m^2 g^{-1}	SEC, mequiv. g^{-1}	$E_0^{CO_2*}$, mg g^{-1}	$E_0^{SO_2*}$, mg g^{-1}

11	DCE	XDC/100-EDA	710	64	3.0	18	–

For the highly cross-linked macronetwork polystyrene ion exchangers (Styrosorbs containing ethylene diamine groups—specimens *9–11* in Table 6), the values of $E_0^{CO_2}$ are close to those for highly cross-linked AN-221 anion exchangers.[80] The CO_2 adsorption isotherms on the macronetwork anion exchanger and on AN-221-30/100, having identical ethylenediamine groups and similar values of SEC (3.0–3.5 mequiv.g^{-1}), are identical despite the fact that the value of S for the macronetwork anion exchanger is almost 5 times greater than that for the AN-221 anion exchanger. The CO_2

adsorption isotherm on AN-221-15/100 (specimens 3), having a value of S smaller by a factor of 10 than the macronetwork specimen but a higher value of SEC, lies above the CO_2 adsorption isotherm on the macronetwork anion exchanger.

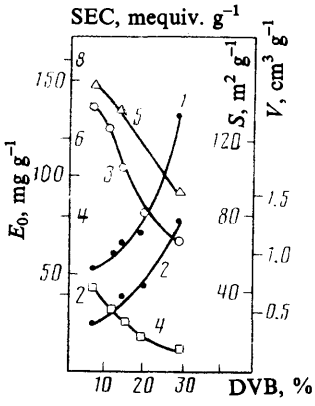

Figure 7. Dependence of the specific surface (curve *1*), pore volume (curve *2*), static exchange capacity (curve *3*), and capacities before the break-through of CO_2 (curve *4*) and SO_2 (curve *5*) on the divinylbenzene content in the AN-221 anion exchangers.

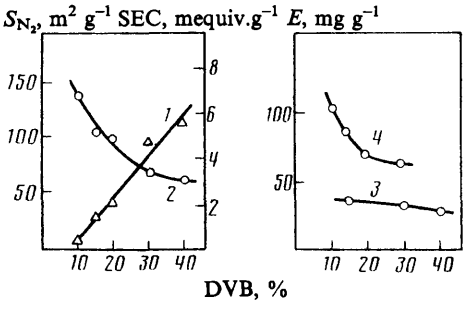

Figure 8. Dependence of the specific surface (curve *1*), static exchange capacity (curve *2*), the capacity before the break-through of $SO_2(E_0^{SO_2})$ (curve *3*), and the total capacity (E^{SO_2}) (curve *4*) on the divinylbenzene content in the AN-251 anion exchangers.

The CO_2 and SO_2 adsorption isotherms on the anion exchangers investigated are described approximately by the Langmuir equation. The monolayer capacity a_m were determined from the slopes of the linear plots of p/a against p and S_{CO_2} and S_{SO_2} were calculated (the values of S_{CO_2} are listed in Table 6; the area per CO_2 molecule in the monolayer is 0.171 nm^2). In the case of the weakly cross-linked polymer (specimen *1*), S_{CO_2} exceeds S_{N_2} almost by a factor of three, while in the case of the highly cross-linked anion exchangers it is much lower. This indicates an appreciable local interaction of CO_2 molecules with the amino-groups of the anion exchangers and, in the case of the weakly cross-linked anion exchangers, the adsorbed molecules permeate into the matrix. Calculations showed that the fraction of the amino-groups participating in the adsorption of CO_2 on the least cross-linked specimen (8% DVP) is somewhat greater than on the remaining specimens and hardly changes with increase in the amount of divinylbenzene to 30%. The static exchange capacity is by no means fully utilised in the adsorption of CO_2—at best to the extent of 50%. In the case of SO_2, it is possible to attain 100% utilisation of the amino-groups of the anion exchangers, which can be accounted for by the stronger acid properties of the SO_2 molecule compared with CO_2.

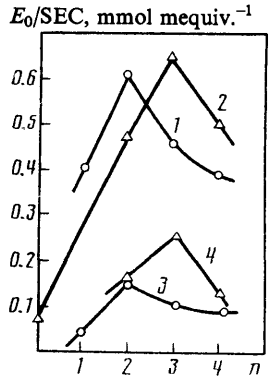

Figure 9. Dependence of the capacities of the anion exchangers before break-through (calculated per unit SEC) with respect to SO_2 (curves *1* and *2*) and CO_2 (curves *3* and *4*) on the number of amino-groups (n) in the aminating agent: (*1*) and (*3*) anion exchangers obtained from the styrene–divinylbenzene copolymer with d = 30 nm (12/80, isooctane); (*2*) and (*4*) ditto for the styrene–divinylbenzene copolymer with d = 60 nm (8/100, n-nonane).

(b) The influence of the amount and nature of the pore-forming agent

Anion exchangers based on styrene–divinylbenzene and vinylpyridine–divinylbenzene copolymers.[124,129,130,132] The change in the porous structure of the polymers induced by the change in the content and nature of the pore-forming agent influences appreciably their adsorption capacity. Firstly, the increase in the volume and size of the polymer pores with increase in the size of the hydrocarbon (pore-forming agent) molecule increases the accessibility of the functional groups to the molecules being adsorbed. Secondly, an increase in the size of the copolymer pores makes it possible to modify the copolymer by larger molecules containing several amino-groups. Fig. 9 presents the dependences of $E_0^{CO_2}$ and $E_0^{SO_2}$, referred to the SEC, on the number of amino-groups in the functional unit of the styrene–divinylbenzene anion exchangers having different pore sizes. An increased number of amino-groups in the molecule of the aminating agent increases the capacity of the anion exchanger, but the introduction of larger molecules (for example diethylenetriamine) into the copolymer with d = 30 nm is difficult. Furthermore, the configuration of the diethylenetriamine molecules in the pores is such that the amino-groups are inaccessible to the molecules being adsorbed. As a result, the capacity of the AN-511 anion exchanger with d = 30 nm diminishes. In the case of the more coarsely porous specimen with d = 60 nm, the configuration of the large molecule of the aminating agent (diethylenetriamine) in the copolymer pores is favourable for the molecules undergoing adsorption and the capacity of the anion exchanger increases.

The dynamics of the adsorption of CO_2 on different beds (ranging from 7 to 90 cm) of the AN-221 anion exchangers obtained in the presence of pore-forming agents of different natures (PR-1 petrol, n-heptane, isooctane, and n-decane) has been investigated. It has been shown that the anion exchanger whose matrix has been synthesised in n-decane (having the largest pores among the polymers investigated) exhibits the best dynamic characteristics together with a high capacity with respect to CO_2.

The influence of the nature and amount of the pore-forming agent on the absorption of SO_2 has been studied for anion exchangers of different types containing different amino-groups.[1,130] For the same divinylbenzene content (for the virtually identical value of SEC), the capacity of the anion exchangers before the breakthrough of SO_2 passes through a maximum as the amount of the solvent (pore-forming agent) increases. It is known that S also passes through a maximum under these conditions, while V and d increase. In the region of the SO_2 absorption maximum, the optimum ratios of the values of S, V, and d for the anion exchangers are apparently attained. The use of a solvent with a larger molecular size (white spirit instead of heptane) for AN-251 shifts the maximum towards lower concentrations of the pore-forming agent.

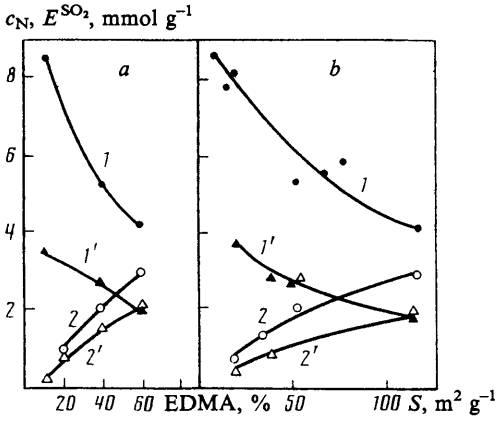

Figure 10. Dependence of the concentration of the amino-groups c_N (curves *1* and *1'*) and of the capacity with respect to SO_2 (E_0) (curves *2* and *2'*) on the amount of the cross-linking agent (*a*) and S (*b*) in the epoxypropyl methacrylate–ethylene dimethacrylate copolymers modified by dithylene triamine (curves *1* and *2*) and ethylmethylamine (curves *1'* and *2'*).

(c) The influence of the amount of the cross-linking agent and of the solvent/precipitant ratio

Methacrylate polymers.[40] Fig. 10 presents the dependences of $E_0^{SO_2}$ and of the concentration of amino-groups c_N on the percentage content of ethylene dimethacrylate and S. They differ from the similar dependences for the anion exchangers of the styrene–divinylbenzene series (Figs. 7 and 8). For the methacrylate polymers, an increase in the amount of the cross-linking agent (simultaneously with an increase in S and V and a decrease in c_N) in the polymers increases their capacity with respect to SO_2. The amount of SO_2 adsorbed by a weakly cross-linked polymer is much smaller than the amount of amino-groups, apparently because the values of S and V for such polymers are small and most of the amino-groups are not accessible to the SO_2 molecules undergoing adsorption. As a consequence of the increase in S and V, an increase in the amount of ethylene dimethacrylate entails an increase also in the content of the surface amino-groups and in their accessibility, so that the capacity with respect to SO_2 increases. This is confirmed by the fact that, with increase in the ethylene dimethacrylate content, the number of surface epoxy-groups rises.[30] It is important to note that, as the content of ethylene dimethacrylate increases, the ratio E_0/c_N tends to unity, i.e. the complete utilisation of the amino-groups is attained.

For the polymers differing in the cyclohexanol/dodecanol ratio, an increase in the adsorption capacity with respect to SO_2 with increase in S is also observed (Fig. 10*b*).

It is noteworthy that, despite the different forms of the dependences of E_0 on the amount of cross-linking agent for AN-221 and epoxypropyl methacrylate–ethylene dimethacrylate–ethylenediamine, containing identical functional groups, the optimum (as regards the absorption of CO_2 and SO_2) structure of the specimens is the same: $S \simeq 50$ m^{2}g^{-1} and $d \simeq 100$ nm, although in the former case the copolymer was obtained with 8% of the cross-linking agent (divinylbenzene), while in the latter case 40% of the cross-linking agent (ethylene dimethacrylate) was used. For such structural parameters, the maximum accessibility of the amino-groups to the molecule being adsorbed is apparently achieved regardless of the nature of the polymer matrix.

- - - o0o - - -

Thus the study of the porous structures of polymeric sorbents of different structural types by a set of physicochemical methods and the determination of the dependences of the parameters of the porous structure on the conditions of synthesis (the amount and nature of the cross-linking agent, the amount and nature of the pore-forming agent, and the molecular weight of polystyrene) permits the specific synthesis of porous polymers with a particular structure. It has been shown that, with increase in the amount of the cross-linking agent in the anion exchanger matrix, the specific surface and the pore volume and size increase; an increase in the molecular size of the pore-forming hydrocarbons also entails an increase in the size of the anion exchanger pores. The nature of the porous structure of Styrosorbs depends likewise on the nature of the solvent in which the cross-linked copolymer is formed and on the molecular weight of the initial polystyrene. The polymer-analogue reactions of the mesoporous styrene–divinylbenzene and epoxypropyl methacrylate–ethylene dimethacrylate copolymers do not lead to significant changes in their porous structure. The relations established for the adsorption of carbon and sulphur dioxides by modified polymers of different structure make it possible to optimise their porosity, for which the maximum accessibility of the functional groups to the molecules undergoing adsorption is ensured.

Emulsion polymerisation in the absence of an emulsifying agent and latexes based on it

V I Eliseeva, T R Aslamazova
Institute of Physical Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The results of studies on the emulsion polymerisation of monomers of different chemical nature in the absence of an emulsifying agent are analysed and treated systematically. When the physicochemical properties of the latexes are considered attention is concentrated on factors influencing their stability, especially in concentrated systems. Questions concerning film formation and the specific properties of films, which are important in the technology of the manufacture of glues and adhesives, are also touched upon.

The bibliography includes 131 references.

IV. Conclusion 221

I. Introduction

The chlorides obtained by the traditional emulsion polymerisation (EP) have found applications in various branches of science and engineering—as calibration standards in electron and optical microscopy, light scattering, and ultracentrifugation, in the counting of aerosol particles and small angle X-ray diffraction,[1] in the medical diagnosis of a number of diseases,[2–5] in the counting of viral particles, in the determination of the pore size in filters and biological membranes, for the stimulation of the growth of antibodies and their purification,[1] as model colloids in the study of their rheological behaviour, stability, flocculation, and adsorption,[6] and in the study of the mechanism and kinetics of the formation of films from latexes. However, the use for the above purposes of latexes obtained in the presence of emulsifying agents is difficult because of the need to seek special conditions for the attainment of a specified particle size, the poor reproducibility of the results, and also the presence of the emulsifying agent on the surfaces of the particles, whose removal involves complex procedures.

The latexes obtained with the aid of emulsifier-free emulsion polymerisation (EFEP) did in fact initially attract the attention of investigators as colloids with identical particle sizes and a "clean" surface. Other characteristics of the latexes are important for the above purposes: resistance to various influences, the chemical nature of the surfaces of the particles, their charge, etc. Recently, the number of studies devoted to the preparation of emulsifier-free latexes (EFL) with the required properties has been growing steadily. New advantages of EFEP, associated in particular, with the prospects for the industrial synthesis of latexes without the use of the surfactants employed in traditional emulsion polymerisation, have been discovered. This is very important ecologically: the pollution of industrial waste water and water-containing areas is prevented and, in addition, the properties of the polymers isolated are improved as regards their practical use.[7]

In each application, specific requirements must be met by the EFL. Whereas monodisparity and a controllable particle size are essential when they are used as calibration standards, for model colloids there is a need, apart from the above factors, to characterise the chemistry of the surface of the polymer phase; for immunodiagnosis, the surface must contain specific functional groups [in all these cases systems with low concentrations (up to 10 wt.%) are suitable]. For the EFL used for industrial purposes, for example for glues and adhesives, a necessary condition is a high polymer concentration (~50 wt.%) combined with a low content of electrolytes and other water-soluble substances. Ideally, such systems are hydrophobic polymer sols, whose particles, suspended in a pure dispersion medium, are stabilised solely by the chemical nature of the surface. The complexity of the production of industrial EFL on a large scale is associated with the need to overcome technological difficulties arising due to the inadequate colloidal stability towards various influences.

The present review analyses and treats systematically the results of studies on the EFEP of monomers of different chemical nature. When the physicochemical properties of the latexes obtained are considered, attention is concentrated on factors influencing their stability, in particular in concentrated systems. The questions concerning film formation and the physicochemical properties of films obtained, which are important in the technology of the manufacture of glues and adhesives, are also touched upon.

The possibility of obtaining relatively dilute latexes in the absence of an emulsifying agent was first demonstrated in the polymerisation, initiated by persulphuric acid salts, in the aqueous phase of monomers which are appreciably soluble in water, such as vinyl acetate[8] and methyl acrylate.[9] Subsequently, the range of monomers used for this purpose was expanded by including hydrophobic monomers such as styrene.[10] The tabulation of monodisperse polystyrene latexes with a controllable particle diameter in the range 97–5000 nm has been reported.[11–14] EFL have been obtained also in the copolymerisation of vinyl monomers with a small amount of comonomers containing ionisable groups: sulphate,[15–17] carboxy-,[18] and amino-groups.[19] In all cases persulphate was used as the initiator. It was assumed that the particles formed are stabilised by the ionisable surface groups of the macromolecules (in the initiation of the process by radical-ions) or by copolymerisation with ionisable monomers. EFL have also been obtained by

polymerisation initiated by azo-compounds—2,2′-azobisisobutyramidine,[20] 2,2′-azo-bis(2-amidinopropane)hydrochloride,[21] and 2,2′azobis-*N*,*N*′-di-methyleneisobutyramidine.[22] On decomposition of such compounds, nitrogen is evolved and free radicals containing positively charged amidine groups are formed. They apparently impart stability to the particles. Subsequently studies on the preparation of highly concentrated EFL began to develop. Thus, 50% latexes of styrene–butadiene copolymers with unsaturated acids have been obtained.[23] Other studies[24,25] produced 30% EFL based on ethyl acrylate and its copolymers.

The absence from the polymerisation system of a specially introduced emulsifying agent, to which a decisive importance has been attributed in the study of the mechanism and kinetics of emulsion polymerisation,[26,27] faced investigators with the task of elucidating the mechanism of the nucleation, growth, and stabilisation of particles on formation of EFL based on both polar and non-polar monomers.

II. Polymerisation of polar monomers in the absence of an emulsifying agent

1. Nucleation mechanism

The theory of the formation of particles via the micellar mechanism in traditional emulsion polymerisation[26–31] is apparently not applicable to monomers which are appreciably[32–39] and even slightly soluble in water.[38] It is assumed that, in the case of persulphate initiation, polymerisation begins not in the emulsifer micelles, but in the aqueous solution with formation of oligomeric radicals. The oligomeric radicals can participate in several reactions: they can combine with the molecules of the monomers soluble in the aqueous phase and can be precipitated after the attainment of a critical degree of polymerisation, n_{cr}, giving rise to primary charged particles; they can recombine with other dissolved radicals with formation of neutral surfactants; they can flocculate with other dissolved radicals on chain termination; they can be absorbed by particles or they can be adsorbed on their surfaces. Under these conditions, the emulsifier plays merely a stabilising function and increases the solubility of oligomeric radicals.[38] A particular reaction can introduce a greater or smaller contribution to the nucleation process depending on the solubility of the monomer (and the radical) in water.

The mechanism of the nucleation of particles in the EFEP of methyl methacrylate (MMA) (solubility in water 1.5×10^{-1} mol/litre at 319 K) and styrene (St) (2.6×10^{-3} mol/litre at 298 K) has been most thoroughly investigated.

As a result of studies on the EFEM of MMA in very dilute solutions (from 0.03 to 0.09 M) in the presence of Fenton's initiating system [potassium persulphate (PPS) (7.4×10^{-4} mol/litre H_2O) + sodium bisulphite (1.2×10^{-3} mol/litre H_2O) + Fe^{II}], the authors[39] concluded that each oligomeric radical $SO_4^-(M)_{\bar{n}}$ "coils up" after the attainment of $n_{cr} = 65-70$, forming a particle. The rate of formation of particles in this initial instant is equal to the effective rate of initiation W_{in}. The oligomeric radicals formed are subsequently captured by the particles at a rate W_c, whereupon the rate of formation of the particles dN/dt becomes

$$dN/dt = W_{in} - W_c. \quad (1)$$

The number of particles can be calculated by integrating this equation with respect to time.

It has been suggested[39] that W_c is proportional to the overall surface area of the captured particles with a radius r_p:

$$E_c = W_{in}\pi r_p^2 LN, \quad (2)$$

where L is the distance over which the oligomeric radical is able to diffuse before losing its solubility and precipitating from the solution. The probability of the capture of the growing radical before it forms a new particle increases with increase in L, i.e. the number of particles falls.

It follows from Eqn. (1) that the number of particles should increase with increase in the rate of initiation and should diminish with increase in the rate of capture. However, Eqns. (1) and (2) have certain limitations associated with the colloidal instability of the particles formed, which leads to their flocculation. Flocculation takes place at a high rate and is limited by the density of the surface charged groups for which the electrostatic potential barrier becomes sufficiently high to ensure the stability of the particles.[40] In view of this, the authors[39] supplement Eqn. (1) by a new term—the rate of flocculation W_f:

$$dN/dt = W_{in} - W_c - W_f. \quad (3)$$

The hypothesis that the rate of formation of radicals with n_{cr} is equal to the rate of formation of primary radicals[39] (see above) can be valid only for a very low rate of chain termination in the aqueous phase.

In considering the polymerisation of MMA in aqueous solution at a monomer concentration C_m ranging from 0.1 to 0.15 mol/litre H_2O (the limiting solubility of MMA), Arai et al.[41] assumed that the total number of particles is equal to the sum of the reactive (N_1) and inactive (N_0) particles: $N = N_1 + N_0$. In constrast to Fitch,[39] Arai et al.[41] and Barrett and Thomas[42] assume that, owing to the small size of the particles, at the beginning of the process the rate of capture of the radicals by the particles is not proportional to their overall surface area [see Eqn. (2)] and is controlled by the diffusion of the radicals, being expressed by the equation

$$W_c = 4\pi r \sum_{n=1}^{n=n_{cr}} D_n R_n, \quad (4)$$

where D_n is the diffusion coefficient and R_n is the concentration of the growing radicals. Neglecting the difference between the sizes of the primary particles, the authors[41] take into account the difference between the average numbers of reactive and inactive particles, the rate of formation of which is described by the following equations:

$$dN_1/dt = k_p M_L R_J N_A + 4\pi(r_0 N_0 - r_1 N_1) \sum_{n=1}^{J} D_n R_n N_A, \quad (5)$$

$$dN_0/dt = (1-\lambda)\frac{k_t}{2} \sum_{n=1}^{J} R_{n_{cr}+1} \sum_{n}^{n_{cr}} R_n N_A + 4\pi (r_1 N_1 - r_0 N_0) \sum_{n=1}^{n_{cr}} D_n R_n N_A, \quad (6)$$

where J is the length of the growing radical, t the time, k_p and K_t are the rates of chain propagation and termination, M_L is the monomer concentration in the aqueous phase (since the formation of the particles terminates at a low degree of conversion, M_L is assumed equal to the initial value of C_m), N_A the Avogadro number, and λ the ratio of the rate of the disproportionation reaction to the overall rate of the termination reaction.

The first terms in Eqns. (5) and (6) express the rate of nucleation of new particles and the second terms express the change in their number on capture of radicals. By setting up differential balance equations for the rate of increase of the overall volume of the reactive and inactive particles and by solving these equations in a system with known values of λ, M_L, k_{in}, k_p, and k_t (assuming that the rate of initiation is unity under these conditions), the authors[41] obtained the dependence of N on time for different values of n_{cr}. It follows from these relations that the particle formation process is rapid and terminates after several seconds. After this, the number of particles N remains constant, i.e. there is no flocculation of particles. For M_L = 0.15 M and C_{in} = 1 × 10^{-3} mol/litre H_2O, the final value of N depends little on the chosen value of n_{cr} (diminishing somewhat with increase of the latter) and is N = (4–6) × 10^{-14} H_2O molecules. In the region where C_{in} = 10^{-3}–10^{-2} M, the number of particles increases with increase in C_{in} and, for C_{in} > 10^{-2} M, the relation becomes weaker. The latter finding is attributed to the fact that, with increase in C_{in}, mainly "dead" particles are formed as a result of the termination of the growing radicals.

The number of particles calculated on the basis of the model proposed by Arai et al.[41] is much smaller than that found by Fitch.[39]

On comparing the theoretical[41] and experimental[43] results obtained in the polymerisation of MMA, Arai et al.[41] were unable to assess accurately the model which they proposed because of the approximate nature of the experimental value of N. However, N_{exp} is appreciably closer to the value obtained from the model of Arai et al.[41] than the value yielded by Fitch's model.[39] The approximate agreement between the theoretical[41] and experimental[43] values shows that, under the conditions employed (C_m = 0.9 M, C_{in} = 5 × 10^{-3} M, and T = 333 K [43]), the particles do not flocculate during the formation process.

Both models considered (Fitch's model[39] as well as that of Arai et al.[41]) refer to very dilute systems and, although they provide an idea about the possible mechanisms of the formation of colloids in the course of polymerisation, they do not simplify them significantly. Thus in the above models no account is taken of the possible presence of the monomeric phase and of neutral electrolytes; the probability of the new predominance of the rate of growth of radicals before their precipitation from the aqueous phase over the rate of termination is not estimated but is merely assumed on a speculative basis. As a consequence of this, the possible formation of water-soluble oligomers in the course of the mutual termination of radicals, which is an important factor, is not taken into account. Nevertheless, the presence of oligomers having the properties of surfactants, especially in the initial phase of the process where their formation is most likely, affects both the mechanism of the nucleation and the number of particles generated. Thus the mechanism of the nucleation and growth of particles in the absence of an emulsifying agent in real reaction systems and of the formation under these conditions of stable latexes appears much more complex than in the models.[39,41] This follows from the further consideration of the factors influencing the above mechanism.

2. Stability factors

(a) Surface-active oligomers

In the emulsifier-free polymerisation of MMA (C_m = 0.5 M, in the presence of the monomeric phase), initiated by 2.2 × 10^{-3} M ammonium persulphate (APS) at 353 K, yielded a latex with the following characteristics: concentration 4.7%, particle diameter d_p = 175 nm, surface tension σ = 60.5 mJ m^{-2},[45] and content of the sol fraction 1.4% relative to the mass of the polymer.[46] The nature of the surface tension isotherm for the sol fraction $\sigma = f(C)$ (Fig. 1) indicates the similarity of the water-soluble oligomers isolated to low-molecular-weight surfactants with a critical micelle-formation concentration (CMC) amounting to 1.4 wt.%. This indicates an appreciable contribution to the MMA polymerisation by the radical termination process in the aqueous phase involving the formation of water-soluble oligomers capable of micelle formation. Indeed, according to Solov'ev and Zuikov,[47] the instant of the formation of particles in the polymerisation of MMA coincides with the instant of the attainment of the CMC for the oligomeric surfactant.

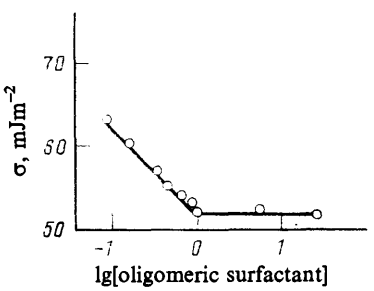

Figure 1. The surface tension isotherm for the sol fraction of the emulsifier-free PMMA latex (C_m = 0.5 M) synthesised in the presence of ammonium persulphate (C_{in} = 2.2 × 10^{-3} mol/litre H_2O) at 353 K.[46]

When higher concentrations of the monomers are employed (C_m = 1 M) and for lower potassium persulphate concentrations [C_{in} = (3.3–4.8) × 10^{-4} M] in the emulsifier-free polymerisation of MMA[48] (T = 353 K), latexes of a high-molecular-weight [MW = (0.98–1.25) × 10^6] with d_p = 288–300 nm and resistant to aggregation are produced; the surface tension σ = 67.8–68.5 mJ m^{-2} of these latexes indicates the presence in them of water-soluble surfactants. The content of surfactants in the aqueous phase found experimentally[48] is lower than the value obtained by Bogdanova et al.[45] in view of the lower value of C_{in}, while the volume and surface area of the disperse phase, adsorbing the surfactants, are higher, which leads to their more extensive exhaustion as a result of adsorption. Indeed, with increase in C_m to 1.5 M for the same value of C_{in}, the surface tension σ of the latex increases to 70 mJ m^{-2}.[49]

In the study of the conditions governing the formation of stable monodisperse MMA latexes, it was shown that oligomeric and polymeric surfactants, formed during the process and removed on dialysis of the latexes, participate in the stabilisation of the particles.[50] It has been demonstrated with the aid of gel permeation chromatography that the molecular weights of the polymer latexes isolated vary from 1.1 × 10^3 to 1 × 10^5, the fraction with MW = 4.9 × 10^3, corresponding to n = 49, predominating. These data refer to the latex obtained by the polymerisation of MMA (C_{in} = 5 × 10^{-3} M, T = 343 K) and indicate a radical termination

reaction in the aqueous phase with formation of oligomers, the degree of polymerisation of which is significantly lower than n_{cr} = 65–70 according to Fitch.[39]

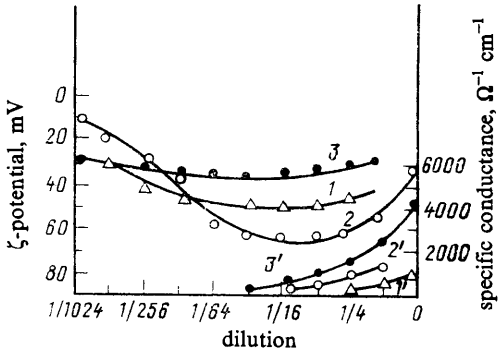

Figure 2. The ζ-potential of the particles (curves *1*–*3*) and the specific conductances (curves *1'*–*3'*) of PMMA latexes synthesised under the following conditions: *1* and *1'*, *T* = °4° K, potassium persulphate initiator; *2* and *2'*, °4° K, potassium persulphate + Cu^{2+}; and *3* and *3'*, °0° K, potassium persulphate + Cu^{2+} + sodium bisulphite.[50]

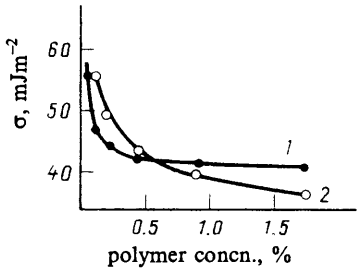

Figure 3. Surface tension isotherm for the butyl acrylate–methacrylic acid (80:20) copolymer at different pH: *1*, 2.7; *2*, 7.8.[18]

In order to analyse the surface activity of the oligomers present in the MMA latexes, the variation of their specific conductance and the ζ-potential of the particles on dilution with water containing the dispersion medium was investigated (Fig. 2).[50] The absolute value of the ζ-potential of the negatively charged particles increases on dilution with water, which is accompanied by a decrease in the specific conductance and then, after the attainment of the conductivity minimum, the ζ-potential falls. This relation shows that the dispersion medium contains a non-indifferent electrolyte, one of the ions of which (oligomeric) is capable of being adsorbed on the surface of the particles.[51]

Surface-active oligomers are or are not capable of forming micelles, for example in the copolymerisation of hydrophobic and ionising comonomers. Thus the low-molecular-weight copolymers (MW ≃ 2 × 10^4), formed on the emulsion-free copolymerisation (EFC) of lower alkyl acrylates with methacrylic acid (MAA) in the presence of ammonium persulphate, exhibit a pronounced surface activity associated with the diphilic nature of their molecules.[18,52] The form of the σ = *f*(*C*) isotherms for these products depends on the pH of the medium (Fig. 3); at pH 2.7, where the carboxy-groups are hardly dissociated and the oligomer molecules have a coiled conformation, the form of the isotherm is similar to that for micelle-forming surfactants: CMC ≃ 0.1–0.2 wt.%. On raising the pH to 7–8, the dispersions dissolve as a result of the dissociation of the carboxy-groups. The σ = *f*(*C*) isotherm steadily decreases with increase in the concentration and becomes similar to the isotherms for the non-micelle-forming low-molecular-weight surface-active homologues.[18,52]

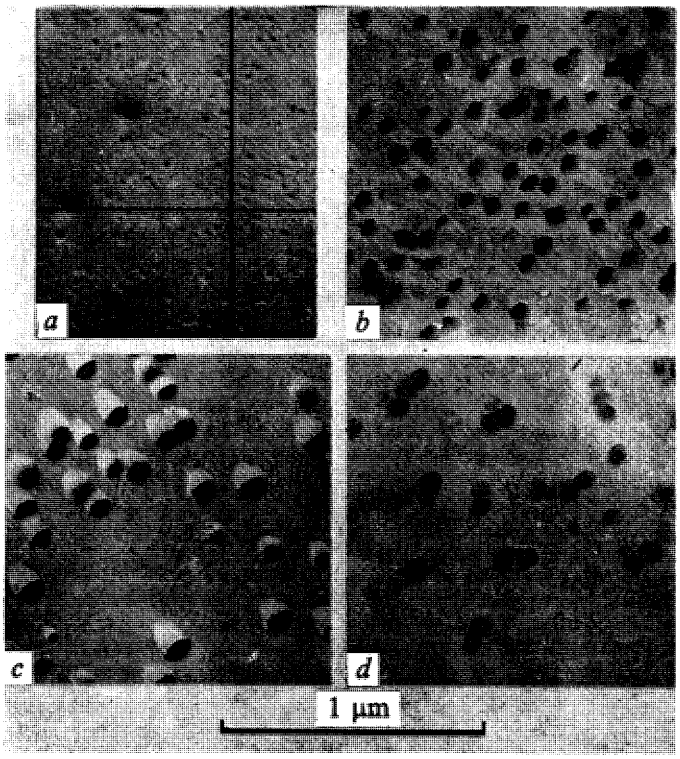

Figure 4. Electron photomicrographs of the latex particles formed in the emulsifier-free copolymerisation of butyl methacrylate and dimethylaminoethyl methacrylate (85:15) for different conversions (%): *a*, 9.9; *b*, 45; *c*, 65.5; *d*, 65.5 (after dialysis).[53]

The formation of non-micelle-forming surface-active electrolytes has been observed in the emulsifer-free copolymerisation of butyl methacrylate (BMA) with the water-soluble hydrochloride of dimethylaminoethyl methacrylate (DMAEMA) [85:15 (mol%)] at pH 5.4–5.5 in the presence of potassium persulphate as the initiator (6 × 10^{-3} mol/litre H_2O).[53,54] The water-soluble copolymer fraction

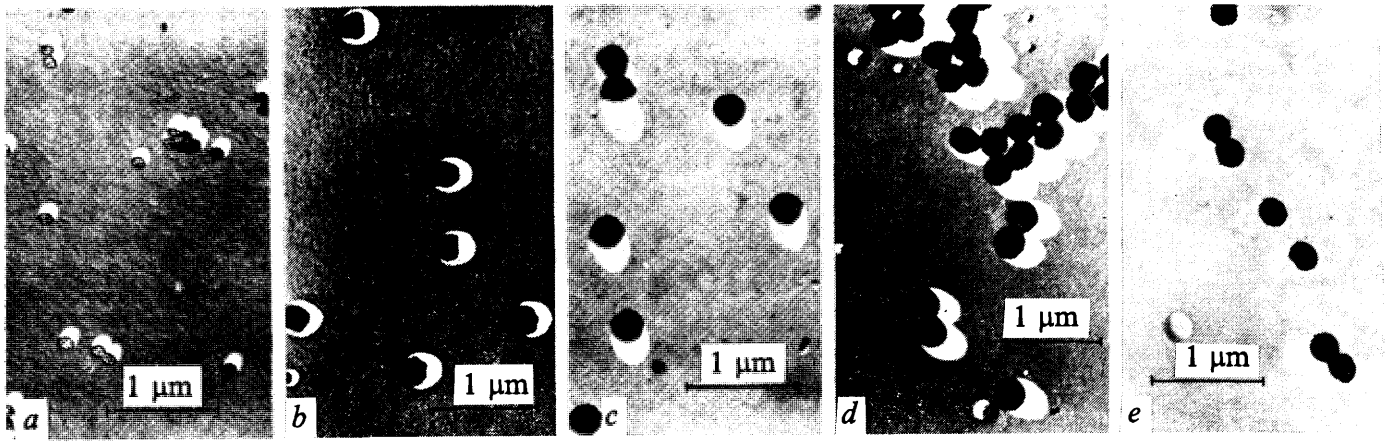

Figure 5. Electron photomicrographs of the latex particles formed in the emulsifier-free polymerisation of methyl methacrylate for different conversions (%): *a*, 5; *b*, 12; *c*, 42; *d*, 75; *e*, 100.[48]

enriched in DMAEMA [47:53 (mol%)] is formed initially; the surface tension of its aqueous solution (4 wt.%) is σ = 49 mJ m^{-2}. After the dialysis of the final latex, the BMA:DMAEMA = 87:13 (mol%) copolymer with a high molecular weight (intrinsic viscosity in benzene η = 2.5) remains. The latex formed at the beginning of the process is characterised by a high polydispersity (the ratio of the volume-average and number-average diameters is d_{vol}/d_{numb} = 1.4), while the final latex is fairly monodisperse (d_{vol}/d_{numb} = 1.1) (Fig. 4). A change in the polydispersity of the latex during polymerisation has been observed also in the study of the emulsifier-free copolymerisation of another hydrophobic monomer (styrene) with the sodium salts of styrene-*p*-sulphonic acid and 2-ethanesulphonylmethyl methacrylate.[55] Presumably the polymerisation in such systems begins in a molecular aqueous solution with formation of surface-active electrolytes enriched in the water-soluble ionised comonomer. After the attainment of very high molecular weights and a high degree of hydrophobicity, some of them are precipitated, forming associated species solubilising the hydrophobic monomer. The subsequent polymerisation process takes place in such associated species. The long duration of the nucleation process leads to a high polydispersity of the latex at the beginning of the process; it then diminishes as a result of the flocculation of the small particles.[40] The particles are stabilised by virtue of the diphilic nature of the macromolecules and the adsorption of the surface-active electrolytes. The latter stability factor is indicated by the partial flocculation of the latex on prolonged dialysis, which results in the desorption of the surfactant (Fig. 4*d*). In the emulsifier-free polymerisation of MMA (pH 3.7; C_{in} = 3.3 × 10^{-4} mol/litre H_2O), where the surface-active oligomers are capable of micelle formation, the particles are monodisperse already at the beginning of the process,[48] which indicates a high rate of nucleation (Fig. 5).

(b) The electrostatic factor

In order to obtain latexes differing in the charge of the particles, use is made of the emulsifer-free polymerisation of MMA (C_m = 1 M, T = 343 K) with different potassium persulphate concentrations (from 1.85 × 10^{-4} to 5.5 × 10^{-3} mol/litre H_2O).[56] The latexes were purified by dialysis and on ion-exchange resins.[1] Conductimetric titration of the purified latexes with alkali demonstrated the presence on the surfaces of the particles of only highly acid groups ($-SO_4^-$); the charge density on the particles varied from 0.53 to 6.6 mC m^{-2}. Its dependence on the concentration of the initiator consumed proved to be almost linear, while the ζ-potential of the particles, determined by microelectrophoresis, varied much less—from −20.7 to −33.7 mV.

A significant correlation has been established between the critical coagulation concentration (CCC) and the charge density as well as a very slight correlation between the CCC and the ζ-potential.[57] This shows that the stability of latexes in relation to electrolytes is influenced primarily by the SO_4^- groups bound covalently to the macromolecules and located on the surface of the particles.

The data quoted were obtained for latexes freed from electrolytes. However, in initiation with persulphate the unpurified latexes always contain low-molecular-weight electrolytes, which affects their stability and particle size. Thus, with increase in C_{in} from 1.85 × 10^{-4} to 5.5 × 10^{-3} mol/litre H_2O, a non-monotonic variation of d_p was observed: there was an initial decrease (from 212 to 167 nm) followed by a gradual increase (to 252 nm).[56] The behaviour was established in the polymerisation of ethyl acrylate (C_m = 1 M, T = 343 K):[24] with increase in C_{in} from 0.2 × 10^{-4} to 1.1 × 10^{-2} mol/litre H_2O, d_p initially fell from 430 to 416 nm and then increased monotonically to 510 nm. The number of surface charges increased under these conditions by a factor of 13. Since the ionic strength of the medium was not regulated,[24,56] the extremum in the dependence of the particle size on C_{in} can be explained by the salting-out effect of the neutral electrolytes with increase in C_{in}. At low values of C_{in}, an increase in the charge on the particles entails a diminution in their diameter, since there is no salting-out effect. The salting-out effect is manifested particularly strikingly in concentrated systems. Thus in the polymerisation of ethyl acrylate (3 M), when C_{in} is varied within the same limits (see above[24]), the maximum stability of the latexes during polymerisation and storage was attained for C_{in}(PPS) = 4.4 × 10^{-4} mol/litre H_2O.

The influence of potassium persulphate in the emulsifier-free copolymerisation of butyl acrylate with methyl methacrylate (T = 353 K) on the stability of the latexes, the ζ-potential of the

particles, the surface tension, and the electrical conductivity of dispersions at a concentration of 17–18% has been investigated.[58] It was shown that an increase in the potassium persulphate concentration from 1.18×10^{-3} to 5.9×10^{-3} mol/litre H_2O increases the ζ-potential, lowers the surface tension, and leads to a strong increase in the electrical conductivity, but has little effect on the stability and size of the particles. The inconsistency of these results with earlier data[56] can be associated, on the one hand, with the different chemical nature of the surface-active oligomers, which eliminated the salting-out effect of the neutral electrolytes and, on the other hand, with the higher polymerisation temperature.

An increase in temperature (increase in the rate of initiation) is important for the stability of the latexes. Thus an increase in the polymerisation temperature of ethyl acrylate (C_m = 3 M) from 343 to 359 K entailed an increase in the charge on the particles, a decrease in their size, and a sharp increase in the stability of the latex particles in the polymerisation process (a decrease in the coagulated component).[24] This result can be explained by the high rate of nucleation and stabilisation of the particles by the rapidly formed radicals. The same effect, associated with the increase in the rate of nucleation, occurs also when the potassium persulphate–sodium bisulphite–copper(II) oxidation-reduction system is used as the initiator (more disperse latexes with d_p = 170 nm compared with those obtained on initiation with potassium persulphate alone and having d_p = 600 nm are then formed).[59] The higher stability can also be explained by the increase in the rate of radical formation and in the rate of appearance of particles whose surfaces rapidly capture the primary and oligomeric radicals from the aqueous phase and are stabilised by the terminal SO_4^- groups of the macromolecules.

An increase in the potassium persulphate concentration from 4.8×10^{-5} to 2.2×10^{-3} M in the emulsifier-free polymerisation of ethyl acrylate (~30 vol.%) leads to an increase in the mechanical stability of the latexes;[25] the latter also increases with increasing process temperature. This has been explained by the increase in the concentration of the SO_4^- groups on the surfaces of the particles. However, latexes sufficiently resistant to mechanical influences could not be obtained by a further increase in C_{in} and T. In order to attain the desired effect, it is sufficient to achieve additional stabilisation, for example, as a result of the copolymerisation of the main monomer with a small fraction of an unsaturated acid.[25]

(c) The structural factor

The polarity of the polymer is known[60–62] to influence the stability of latexes synthesised in the presence of an emulsifier; however, the dependence of the stability of the emulsifier-free latexes on the nature of the polymer has not been examined. Evidently, the polarity of the polymer adjoining the aqueous phase is responsible for interfacial polar interactions,[63] which, by reducing the interfacial energy, influence the stability of the system as regards aggregation. A recent study of the emulsifier-free copolymerisation of methyl methacrylate and butyl acrylate, differing in their solubilities in the aqueous phase, established[64] that, with increase in the hydrophilicity of the polymer surface, estimated from the wetting angle θ_r (wetting by water) on the surfaces of latex films (modelling the surfaces of the particles), the stability of the dispersions during polymerisation increases and, conversely, diminishes as the surface becomes more hydrophobic. The hydrophilic-hydrophobic properties of the latex polymer were varied by varying its monomer composition. Under identical polymerisation conditions but for a lower concentration (or activity) of the intrinsic surfactant (i.e. for a higher value of σ), the latexes based on methyl methacrylate are more stable than those based on butyl acrylate, but their stability diminishes after the introduction of the butyl acrylate units into the polymer composition (Table 1). Since the ζ-potentials of the particles of poly(butyl acrylate) and poly(methyl methacrylate) latexes are approximately the same, −30 and −24 mV respectively, the observed difference between the stabilities of the latexes cannot be accounted for by electrostatic forces.

Table 1. Physicochemical properties of methyl methacrylate–butyl acrylate copolymers and of the films based on them.[64]

Monomer : H_2O	C_{in}^*, mg litre H_2O	C_m in latex, %	MMA : BA (by volume)	C_m in aqueous phase, %	Coagulated component, % (m_c)	r, nm	σ, mJ m^{-2}	pH	$10^3\chi$, Ω^{-1} cm^{-1}	θ_r, deg
20 : 80	180	18.6	1 : 0	1.5	0	166	68.2	3.27	0.69	63.0
			2 : 8	0.428	0.5	165	61.8	3.02	0.71	82.0
			0 : 1	0.16	2.0	135	54.4	3.17	0.67	84.5
30 : 70	270	27.7	1 : 0	1.5	1.5	185	68.5	3.01	0.54	72.5
			1 : 2	0.595	5.9	–	–	2.96	0.84	89.1
			0 : 1	0.16	15.9	153	57.3	2.88	0.92	89.0

* C_{in} per monomer was in all cases 810 mg litre^{-1}.

The dispersion components of poly(methyl methacrylate) and poly(butyl acrylate) should be similar, since their absorption spectra hardly differ (the Hanaker constants are in both cases in the range 4×10^{-21} to 1×10^{-20} J [65]). Thus the difference between the stabilities of the latexes cannot be explained by dispersion forces either. However, a correlation is observed between the stability of the latex and the hydrophobicity of the polymer (the angle for the wetting of the films by water). This suggests that the structural component of the stability plays a significant role in the stabilisation of the emulsifier-free latexes.[66,67] A theoretical calculation, carried out in order to achieve a semiquantitative test of this hypothesis, confirmed its validity.

If it is supposed that the mass of the precipitated coagulated components m_c is determined by the total number of particles N with a radius r falling into the nearest potential well per unit time, proportional to the number of collisions N, and the probability of overcoming the potential barrier V_{max},[68] then we have

$$m_c \sim Nr^3 \sim r^3 N_1 \exp(-V^{max}/kT) = n^2 \exp(-V^{max}/kT) r^3, \quad (7)$$

where n is the concentration of the particles. The ratio of the masses of the coagulated component in experiments i and l is given by

$$m_c/m_{c_l} = (n_i^2/n_l^2) \exp[-(V_i^{max} - V_l^{max})/kT]. \quad (8)$$

Eqn. (8), combined with the known expressions for the structural attraction of hydrophobic surfaces,[66,67,69] explains semiquantitatively the difference between the stabilities of the latexes presented in Table 1, provided that one attributes the change in the height of the potential barrier to the change in the structural component of the energy of attraction of the spherical particles. The latter can be formulated approximately[66,69] (for particles whose wetting angle is in the range 65–69°) as follows:

$$V_s^{max} = -k_a r \exp(-H^{max}/H_s), \quad (9)$$

where H_s is the scale length of the descent (the distance between the particles for which the energy of their interaction diminishes by a factor of e), H^{max} the distance corresponding to the potential barrier, and k_a the coefficient of structural energy which depends on the hydrophobicity of the particle. Fig. 6 shows that the values of k_a are in general correlated with the wetting angles, increasing in parallel with increase in the latter. It follows from the foregoing that the stability of the particles falls with increase in their wetting angle, which is correlated with the hydrophobic attraction forces and, conversely, increases with increase in the hydrophilicity of the surfaces of the particles, which is equivalent to an increase in the hydrophilicity of the polymer in the case of the emulsifier-free latexes. These data show that the monomeric composition of the emulsifier-free latexes influences their stability.

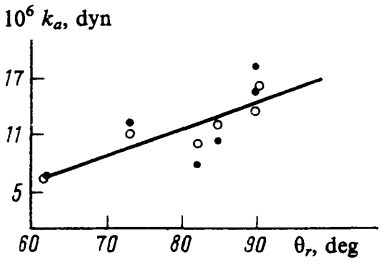

Figure 6. Dependence of the structural forces coefficients k_a on the wetting angle θ_r on the surfaces of polymers. Filled circles—calculation using Eqn. (8); open circles—calculation taking into account Eqn. (9).

3. Polymerisation kinetics

Comparison of the emulsifier-free and classical emulsion polymerisations[2] reveals significant differences between the kinetics of these processes.

Three stages are characteristic of emulsion polymerisation in the presence of an emulsifying agent: (1) a brief increase in the rate of polymerisation associated with the formation of the primary particles; (2) the constancy of the rate of polymerisation up to the disappearance of the monomer phase, which is associated with a constant concentration of the monomer and the radicals in small particles (on average 0.5 of a radical per particle); (3) the dependence of the rate on the balance between the decreasing C_m and the increasing concentration of the radicals in the particles (for the approximate mutual compensation of these factors, the rate continues to remain constant[70] until the process passes into the diffusion region).

The same stages are characteristic also of the emulsifier-free emulsion polymerisation, but their course and duration depend on the individual monomers, the recipe, and the polymerisation conditions.

A comparative dilatometric study of the kinetics of the polymerisation of ethyl acrylate (C_m = 1 M, C_{in} = 3.3 × 10^{-3} M, T = 318 K) in the absence and presence of the emulsifying agent E-30 (1.5% relative to the monomer) established that in the former case the rate at the beginning of the process is lower by more than an order of magnitude than in the latter case (Fig. 7).[71] However, with increase in the degree of conversion, it increases in the former case. Since the emulsifier-free latexes obtained were characterised under these conditions by a small particle diameter (~200 nm), the increase in rate during the polymerisation process was explained not by an increase in the number of radicals per particle but by the fact that in the absence of emulsifier the reaction takes place initially in the aqueous solution migrating into the polymeric-monomeric particles (PMP) as the polymer phase is formed: the rate of termination of the growing radicals diminishes sharply under these conditions, as a result of which the process is accelerated. The same explanation of the increase in the rate of the emulsifier-free polymerisation of styrene with increase in the degree of conversion has been put forward.[72] This idea has also been confirmed by the overall activation energy for the initial stage of the polymerisation of ethyl acrylate at T = 304–333 K: in the presence of an emulsifer, its value is 12.9 kcal mol^{-1}, which is characteristic of traditional emulsion polymerisation while in its absence it is 27.1 kcal mol^{-1},[72] which indicates polymerisation in solution.

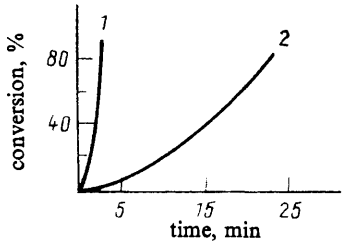

Figure 7. Kinetic curves for the polymerisation of ethyl acrylate in the presence of 1.5% of the E-30 emulsifier (curve *1*) and in its absence (curve *2*).[71]

The region where the rate of polymerisation increases may involve a variation in the surface tension of the system with an alternating sign (Fig. 8).[53] In the initial stages of the emulsifer-free copolymerisation of butyl methacrylate with dimethylaminoethyl methacrylate, the surface tension σ falls sharply due to the accumulation in the system of oligomeric surfactants as a result of the aqueous phase polymerisation. After the formation of the polymeric-monomeric particles, the surface-active oligomers are adsorbed by the polymer phase, which is accompanied by an increase in σ up to the equilibrium value. The duration of the formation of the surface-active oligomers depends on the solubility of the monomer, the initiator concentration, and temperature. For a low solubility of the monomer, a low initiator concentration, and a high rate of radical formation (high temperature), the nucleation is so rapid that this period cannot be detected on the kinetic curves (Fig. 9). This was observed in the polymerisation of methyl methacrylate (C_m = 1.5 M, C_{in} = 3.3 × 10^{-4} M, T = 348–353 K):[48] the process occurred at a constant rate virtually from the beginning and up to the exhaustion of the monomer phase (28% conversion). After this, a decrease in rate was observed, being particularly pronounced at advanced stages of the

reaction. The absence of a period with a low rate at the beginning of the process, in contrast to other data,[53,71] can be explained by the rapid migration of the process to the polymeric-monomeric particles formed, in which further polymerisation takes place. This is confirmed by the constancy of the number of particles ($\sim$°.5 × 10^{13} cm^{-3}), whose diameter increases (from 50 to °00 nm), and the high molecular weight ($\sim$1.4 × 10^6) of the polymer. The retardation of the polymerisation process in the final stages is associated with its transition to the diffusion region.

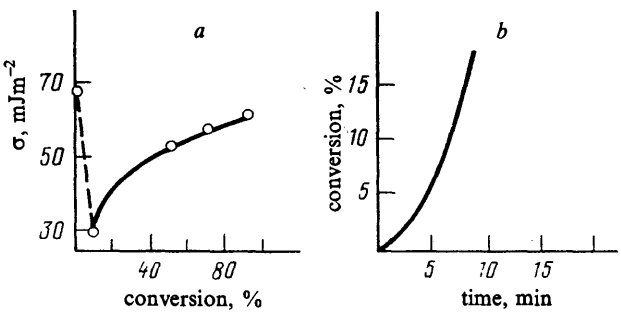

Figure 8. Variation of the surface tension of the system σ with conversion in the emulsifier-free copolymerisation of butyl methacrylate with dimethylaminoethyl methacrylate in the presence of potassium persulphate (*a*) (BMA : DMAEMA = 85 : 15, C_{in} = 7.4 × 10^{-3} mol/litre H_2O, T = 323 K, C_m = 2.5 M) and time variation of the conversion in the emulsifier-free copolymerisation of butyl methacrylate with dimethylaminoethyl methacrylate under the same conditions (*b*).[53]

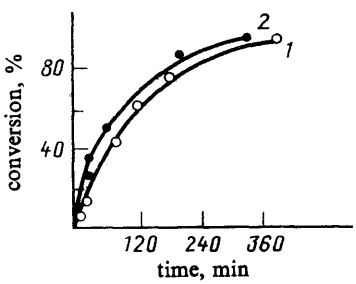

Figure 9. Kinetic curves of the polymerisation of methyl methacrylate in the presence of potassium persulphate (C_m = 1 M; 353 K):[48] *1*, C_{in} = 3.3 × 10^{-4} M; *2*, C_{in} = 6.6 × 10^{-4} M.

On formation of very large particles, the polymerisation kinetics are influenced by the accumulation of radicals within the bulk of the particles. Thus, in the analysis of the mechanism of the emulsifier-free polymerisation of methyl methacrylate, a theoretical calculation of the molecular weight of the polymer and of the rate of polymerisation was carried out on the assumption that the particle size is much greater than in the usual emulsion polymerisation;[73] the authors used the Stockmayer equation[74] to calculate the number of radicals as a function of the particle size taking into account the rates of diffusion and chain termination of the new radical within the particle. Calculation showed that the radical concentration in the particle can increase in the initial stages at a constant monomer concentration in the particle. The calculated and experimental data, obtained for the emulsifer-free polymerisation of methyl methacrylate (C_m = 1 M, C_{in} = 2.5 × 10^{-4}–4 × 10^{-3} M, T = 323 K), are compared in Fig. 10. The observed acceleration of the polymerisation (which is greater the higher the value of C_{in}) is attributed[73] to the accumulation of radicals in the particles.

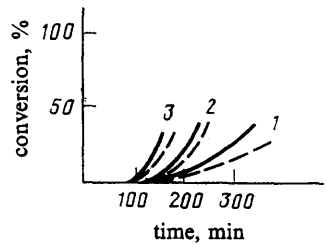

Figure 10. Experimental (continuous curves) and theoretical (dashed curve) time dependences of the conversion of the emulsifer-free polymerisation of methyl methacrylate in the presence of potassium persulphate (C_m = 1M, 323 K) for different concentrations of the latter 10^3 C_{in} (mol/litre H_2O): *1*, 0.25; *2*, 2.0; *3*, 4.0.[41]

(a) The influence of the hydrodynamic effect

It has been shown that the influence of stirring on the rate of the emulsifer-free polymerisation of methyl methacrylate (C_{in} = 1 × 10^{-3} mol/litre H_2O, T = 338 K) depends on C_m.[75] For C_m below saturation (10^{-1} M), the increase in the rate of rotation of the stirrer from 200 to 500 rev min^{-1} lowers the rate of the process slightly. In the presence of the monomer phase (C_m = 1 M), the rate decreases significantly following such a change in the rate of rotation. The number of particles and the molecular weight of the polymer are hardly altered in both cases when the rate of rotation is changed. It was concluded that the rate of transfer of the monomer from the drops to the aqueous phase (E_m), on which depends its concentration in the particles (M_p), is an important factor. (It is usually assumed the M_p retains its equilibrium value in the presence of drops[76]):

$$E_m = k_L A N_m (M_w^* - M_w), \qquad (10)$$

where k_L is the coefficient of the transfer of the monomer from the drop to the aqueous phase, A and N_m are the average specific surface of the drop and the number of drops per unit volume, and M_w^* and M_w are the saturation and non-stationary concentrations of the monomer in the aqueous phase. The relation between the parameters of Eqn. (10) and the rate E_m was analysed for different values of k_L. It was shown that a decrease in E_m entails a decrease in M_w and M_p. A slight decrease in M_p diminishes the degree of polymerisation, while an appreciable decrease leads to the reverse effect by virtue of the gel effect. The ratio $M_w/M_p = m$ depends on

the rate of rotation of the stirrer and is assumed to be constant for different degrees of conversion. An attempt was made to calculate theoretically the conversion–time curves for m ranging from 0.0231 to 0.329, which are values corresponding to rates of rotation of the stirrer from 200 to 400 rev min^{-1}. It was shown that the rate of polymerisation diminishes with increase in m.[76]

The influence of the rate of stirring on the kinetics of the emulsifier-free polymerisation of methyl methacrylate (C_m = 2.5 M, C_{in} = 10^{-3}–5 × 10^{-2} mol/litre H_2O, T = 333 K) has been investigated[77] with the rate of rotation of the stirrer varied within wide limits (from 0 to 960 rev min^{-1}). It was shown that the initial rate of the process passes through a maximum at 360 rev min^{-1}. The authors explained the increase in the initial rate of the process for low rates of rotation by the decrease in the drop size and hence by the acceleration of the transport of the monomer from the drop to the aqueous phase, where initiation and chain propagation takes place initially. The decrease in the rate of polymerisation after the attainment of the rate of stirring indicated is explained by the capture of the particles formed by the monomer drops or microdrops, which leads to the suppression of the gel effect. The latter is confirmed by the fact that the extremum in the initial rate is smoothed out with increase in C_{in} (from 5 × 10^{-3} to 10^{-2} mol/litre H_2O) as a result of its salting-out effect on the monomer drops.

(b) The influence of the solid phase

The emulsifer-free polymerisation of vinyl and diene monomers in the presence of organic and inorganic powders of different kinds has been described in a number of studies.[75,76,78–85] Powders encapsulated in the polymer and reinforced composites with a uniform distribution of the filler in the matrix are then obtained. In the polymerisation of methyl methacrylate, calcium sulphite,[75,76,78] barium sulphate,[85] graphite,[79,84] various metal oxides,[81–83] and aluminium and copper[80,82] powders were employed.

The emulsifier-free polymerisation of methyl methacrylate at a $CaSO_3$ concentration below and above the limit of its solubility (3 × 10^{-4} M), i.e. in the absence and presence of a solid phase, has been investigated.[75] In the first case, the kinetic curves for the polymerisation of methyl methacrylate have the same shape as those for the emulsifier-free polymerisation of pure methyl methacrylate (Fig. 11);[73] an increase in the $CaSO_3$ concentration entails an increase in the rate of polymerisation. The authors explained the latter by the promoting effect of calcium sulphite on the persulphate initiation reaction. Furthermore, $CaSO_3$ can itself exert an initiating effect on the polymerisation process.

In the presence of solid $CaSO_3$, the rate initially diminishes, increasing with increase in the calcium sulphite concentration (Fig. 12). This is accompanied by a change in the nature of the kinetic curves (cf. Fig. 10) whose shape becomes closer to that of the kinetic curve for emulsion polymerisation in the presence of an emulsifying agent. The initial retardation of the process can be attributed to the distribution of the monomer and initiator between the aqueous and solid phases.

It has been shown that the aqueous phase of latexes contains only a small amount of polymer particles, whose size is comparable to the size d_p in emulsion polymerisation in the presence of an emulsifier. This permits the assumption that the primary particles are adsorbed on the surface of the powder, which is apparently the main polymer formation region. It is known that the size of the polymethacrylate particles and their monomer content in the usual emulsion polymerisation are determined thermodynamically by the particle–water interfacial energy (σ_{12}).[86] This was also established in a later study of the polymerisation of methyl methacrylate.[87] After the adsorption of the polymethacrylate particles by the surface of the solid phase, the particles were in contact not only with the aqueous medium but also with the surface of the powder, i.e. σ_{12} and the overall area of the interface change, which influences the particle size and the content of the monomer in the particles, these being reflected in the rate of polymerisation. It has been shown[76] that on a solid surface there are two varieties of polymers, one of which is readily removed while the other is virtually inseparable from the powder even after prolonged extraction. It has been suggested that the latter variety is firmly bound to the surface via the electrostatic interaction between the latter and the terminal ionic groups of the macromolecules forming the nuclei of the particles directly on the surface; with increase in surface area, the number of particles also increases, as a result of which the process is accelerated. Another nucleation process takes place in the aqueous phase, whereupon the nuclei formed are adsorbed by the solid surface when they continue to grow.

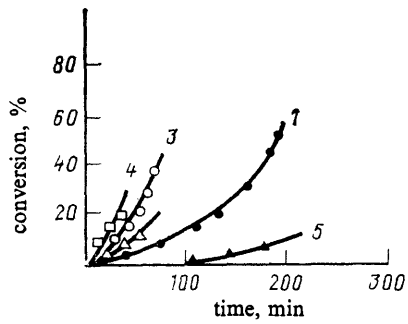

Figure 11. Kinetic curves for the emulsifier-free polymerisation of methyl methacrylate in the presence of potassium persulphate (C_{in} = 4 × 10^{-3} mol/litre H_2O) (curves *1*–*4*) and different calcium sulphite concentrations ($10^4 C_{CaSO_3}$, mol/litre H_2O) [*1*, 0; *2*, 1.34; *3*, 2.28; *4*, 3.44] and without potassium persulphate but in the presence of $CaSO_3$ at a concentration of 2.28 × 10^{-4} M (curve *5*). T = 323 K; C_m = 1 M.[73]

Thus the introduction of a highly disperse solid phase into the system alters its physicochemical characteristics and influences the process kinetics. In the emulsifier-free polymerisation of methyl methacrylate initiated by potassium persulphate (C_m = 0.5 M, T = 333 K) the presence of the inert $BaSO_4$ powder, which is almost insoluble in water, is reflected in the rate of polymerisation.[85]

The chemical nature of the solid surface influences the polymerisation process via the possible heterogeneous interactions with the reaction components.[75] Thus a relation between the chemistry of the surface and the crystallinity of the structure of the filler (highly disperse pyrophyllite and kaolinite powders) has been traced in the polymerisation in the aqueous phase of butyl methacrylate initiated by azobisisobutyrohydrazide in the course of the elementary polymerisation reactions—initiation and termination. With increase in the specific surfaces of these powders (up to 60 m^2 $litre^{-1}$ for pyrophyllite and up to 240 m^2 $litre^{-1}$ for kaolinite), the rate of polymerisation rises sharply.[88]

(c) The influence of the surface activity of the initiator

A number of studies on emulsion polymerisation in the presence of initiators exhibits a stabilising effect by virtue of the diphilic structure of their molecules have been published recently.[58,89–96] Although the polymerisation in such systems cannot be rigorously defined as emulsifier-free polymerisation, nevertheless under the conditions of a high degree of involvement of the surface-active initiator in the reaction one may expect the formation of latexes which virtually contain no free emulsifier and which are in this sense close to emulsifier-free latexes.

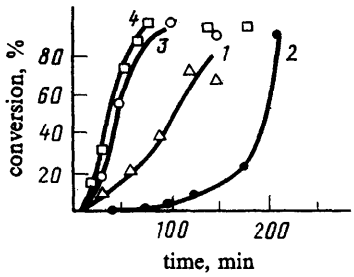

Figure 12. Kinetic curves for the emulsifier-free polymerisation of methyl methacrylate in the presence of potassium persulphate (C_{in} = 4 × 10^{-3} mol/litre H_2O) and a solid phase [$10^4 C_{CaSO_3}$ (mol/litre H_2O) *1*, 0; *2*, 0.1; *3*, 0.25; *4*, 0.57] at T = 323 K and C_m = 1 M.[73]

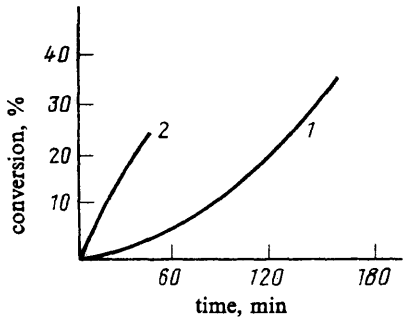

Figure 13. Kinetic curves for the polymerisation of methyl methacrylate in the presence of potassium persulphate (curve *1*) and the PAAI initiator (curve *2*). C_{in} = 6.58 × 10^{-4} mol/litre H_2O; T = 353 K; C_m = 2.4 M.[58]

Surface-active initiators contain in their molecules peroxide[90–94] and azo-groups,[58,95,96] which are typical for radical polymerisation initiators; the surface activity is imparted to the molecules of these compounds by fragments which usually represent residues of a poly(hydroxyethylated) alcohol or poly(ethylene glycol).

A series of studies, surveyed in two reviews,[91,93] have been devoted to the topochemistry and mechanism of the emulsion polymerisation of styrene in the presence of surface-active peroxides. It was shown that the rate constant for the decomposition of the micelle-forming peroxide k_d exceeds appreciably the rate constant for the decomposition of its non-micelle forming analogue, which is evidence that micellar catalysis has an effect. However, the efficiency of the initiation by surface-active peroxides is very low in view of the localisation of the rapidly formed radicals in a small volume in the reaction zone—adsorption layers; thus the overall effect of surface-active peroxides on the rate of initiation may be small.

We carried out a comparative study[58] of the characteristics of the emulsifier-free polymerisation of methyl methacrylate initiated by potassium persulphate and a sulphated poly(ethylene glycol)-azo-initiator (PAAI)[95] having a molecular weight of 780 and exhibiting surface activity. The polymerisation kinetics were investigated in the presence of equimolar concentrations of both initiators at C_{in} = 6.58 × 10^{-4} M (this value is lower than the critical micelle formation concentration for PAAI), which ruled out the micellar effect. It is seen from the kinetic curves (Fig. 13) that the initial rate of the process initiated by PAAI is higher than that of the process initiated by potassium persulphate. The efficiency of the initiation by both initiators was assumed close to unity, since they decompose in aqueous solutions into radical-ions bearing like (negative) charges; the cage effect is unlikely.[73] It follows from the calculated rate constants for the decomposition of potassium persulphate and the azo-initiator[24,58,97] that the observed difference between the initial rates of polymerisation (by a factor of 2.2) is associated not only with the different rates of initiation (difference by a factor of 1.5) but also with the difference between the mechanisms of nucleation and between the stabilising capacities of both initiators. The disposition of the peaks on the chromatograms of the molecular weight distribution (MWD) of the polymers isolated from the latexes (Fig. 14) shows that, for identical initiator and monomer concentrations, the molecular weight is higher and the distribution narrower in the case of polymers synthesised in the presence of PAAI compared with those synthesised in the presence of potassium persulphate. This indicates a greater contribution of the polymerisation in the rapidly stabilised polymethacrylate particles in the case of initiation by PAAI and a greater contribution of polymerisation in the aqueous solution on initiation by potassium persulphate. Electron miscroscope study of the latexes obtained using both initiators showed that the particle size in the case of PAAI initiation is smaller than that for initiation with potassium persulphate. The difference between the particle sizes and hence between the number of particles may be attributed to the different rates of nucleation; in both cases, the process begins in the aqueous solution with formation of the $SO_4^-[M]_n^\cdot$ and $PAAI[M]_m^\cdot$ radical species; in view of the decrease in the solubility of the high-molecular-weight azo-initiator following the addition of one or several monomeric methyl methacrylate units, the critical micelle formation concentration for the adducts diminishes rapidly, which leads to a high rate of formation of micelles, which become the predominant polymerisation zone. In order to impart surface activity to the $SO_4^-[M]_n^\cdot$ radical species, it is necessary to add to them a large number of monomer units (CMC = 1.4 wt.%),[45] which lengthens the period of polymerisation in the aqueous phase and lowers the rate of nucleation.

4. Emulsifier-free latexes on film forming systems

Film-forming emulsifier-free latexes must satisfy a series of specific conditions, which are sometimes difficult to fulfil, in order to obtain high-quality glues and adhesives from them. Thus the polymers based on such emulsifier-free latexes must be characterised

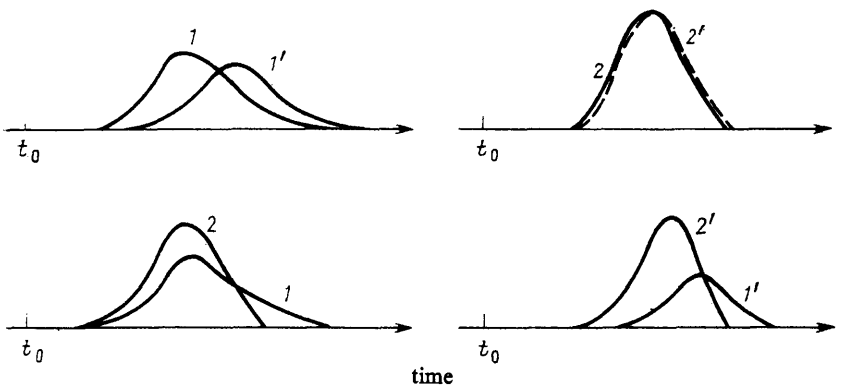

Figure 14. Gel-chromatographic curves for the molecular weight distribution of PMMA synthesised in the presence of potassium persulphate (curves *1* and *1'*) and the PAAI initiator (curves *2'* and *2'*). C_{in} = 3.29 × 10^{-4} M (curves *1* and *2*) and 6.58 × 10^{-4} M (curves *1'* and *2'*); T = 353 K; C_m = 1.0 M (curves *1* and *2*) and 2.4 M curves *1'* and *2'*).[58]

by the necessary elasticity (T_s) and hence by a minimal film formation temperature, a high resistance to water, and effective adhesion and dielectric properties. The latexes must be resistant to various influences, for example, mechanical influences, freezing, etc. When monomers, such as the widely employed alkyl methacrylates and acrylates, are used to obtain the traditional latexes, the problem of sedimentation stability arises (the density of PMA, PEA, PBA, and PMMA are respectively 1.23, 1.15, 1.06, and 1.19 [98]).

Alkyl methacrylates and acrylates as well as their copolymers having a fairly low T_s, namely ethyl acrylate[24,25,59] and the methyl methacrylate–butyl acrylate copolyer,[58] have been mainly used as monomers for film-forming emulsifier-free latexes

In the study of the resistance of the emulsifier-free latexes to mechanism influences, sedimentation, and freezing, it has been shown[25] that stabilisation solely by the initiator (the terminal ionised groups of the macromolecules) is insufficient and that additional hydration of the surface is necessary, for example, by introducing surface carboxy-groups into the particles. In the case of the ethyl acrylate latex, this is achieved either by the hydrolysis of ester groups by the sulphuric acid formed on decomposition of potassium persulphate[99] or by the copolymerisation of ethyl acrylate with the necessary amount (5 mol%) of acrylic acid (AA). The concentration of carboxy-groups on the surface of the particles formed as a result of the acid hydrolysis (heating at 348 K for 30 h) is only 0.13 mol%. An important factor in impairing stability to the latex is not the content of these groups in the copolymer itself but their location on the surface, i.e. the structure of the particles. It is known[100,101] that, in the copolymerisation of ethyl acrylate with acrylic acid, the carboxy-groups are distributed over the entire surface layer of the particle but the fraction of the groups localised directly on this surface is then very low, while in the case of hydrolysis the chemically bound carboxy-groups are directly on the surfaces of the particles.[102]

It has been shown[58] that the main sedimentation stability of the acrylate latexes obtained using PAAI as the initiator is ensured by the introduction into the surface layer of the particles of highly hydrated groups (polyoxyethylene) which apparently induce an increase in the local viscosity of the hydrated surface layers.

An important criterion of the quality of the film forming emulsifier-free latexes is the adhesion and water resistance of the film. The studies carried out on these lines[7] indicate that the effective adhesion properties of such films, is apparently associated with the absence of an emulsifier, which is deposited at the interface between the polymer and the support.

The water resistance of such polymers is due to the content in the latex of neutral electrolytes and other water-soluble substances, which is in its turn determined by the conditions in the synthesis of the emulsifier-free latex. This can be traced clearly on the basis of the curves for the water absorption by the films (Fig. 15) obtained from methyl methacrylate–butyl acrylate latexes;[58] the water absorption is greater the higher the concentration of the initiator employed in the preparation of the latex. Thus the absorption of water after 90 days by films obtained from a latex synthesised in the presence of potassium persulphate ($C_{in} \simeq 12 \times 10^{-4}$ mol/litre H_2O) is 4% and increases to 70% for films from a latex synthesised in the presence of $C_{in} \simeq 6 \times 10^{-3}$ M. The same rule holds also for ethyl acrylate latexes;[24,25] at a constant potassium persulphate concentration and with increase in polymerisation temperature, the degree of absorption of water diminishes, which is apparently associated with the increase in the fraction of potassium persulphate consumed in nucleation and with the decrease in its fraction involved in the formation of surface-active oligomers and electrolysis.

An increase in the concentration of PAAI (by a factor of 5) in the synthesis of latexes, accompanied by its accumulation in the dispersion medium, leads to an increase in the water absorption by the films from 3 to 25%.

Latex films are known to be bleached when they are immersed in water as a consequence of the diffusion of water molecules into the interparticle boundary region;[103] this effect occurs also for films of emulsifier-free latexes despite the low water absorption.[58]

Summarising the data presented, one may conclude that, in order to obtain film-forming emulsifier-free latexes with the required properties, one must employ in their synthesis factors which increase their stability as regards the state of aggregation, on the one hand, and factors promoting the suppression of the formation of electrolytes and other water-soluble substances, on the other. One of the conditions for the optimisation of the process is a decrease in the initiator concentration to the minimum necessary value with the simultaneous increase in the rate of radical formation by increasing the temperature or by using oxidation-reduction systems. Since the

ionisation of the surface of the particles involving solely the ionisable SO_4^- groups is insufficient to impart to concentrated latexes the necessary sedimentation stability and resistance to mechanical influences and freezing, their additional stabilisation as a result of the hydration of the surface of the particles, for example, by introducing carboxy-groups or polyoxyethylene units into the latter, is necessary.

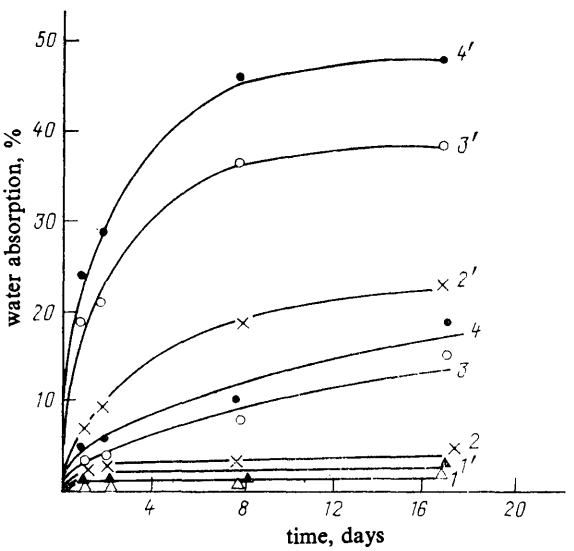

Figure 15. Kinetic curves for the absorption of water by films of methyl methacrylate–butyl acrylate latexes synthesised for equalised rates of decomposition [$10^9 V_d$ (mol litre^{-1} s^{-1}): *1* and *1'*, 0.82; *2* and *2'*, 1.64; *3* and *3'*, 3.28; *4* and *4'*, 4.10] at T = 353 K and C_m = 1.9 M in the presence of PAAI [$10^4 C_{in}$ (mol/litre H_2O): *1*, 8; *2*, 16; *3*, 32; *4*, 40] and potassium persulphate [$10^4 C_{in}$ (mol/litre H_2O): *1'*, 11.8; *2'*, 23.6; *3'*, 57.2; *4'*, 59.0].[58]

III. Polymerisation of non-polar monomers in the absence of an emulsifying agent

1. Mechanism of the nucleation and growth of particles

As already mentioned above, the mechanism of nucleation in the emulsifier-free polymerisation of polar monomers depends significantly on the nature of the monomers and the process parameters. This also applies to the emulsifier-free polymerisation of hydrophobic monomers, but their low solubility in water leads to significant differences in the process.

A study[104] of the emulsifier-free polymerisation of styrene (C_m = 0.87, C_{in} = 10^{-3} M, T = 343 K) showed that a large number of primary particles (5 × 10^{12} ml^{-1}) are formed initially. They are flocculated until the attainment of a constant number (10^{11}–10^{12} ml^{-1}). It has been established by gel chromatography that the molecular weight in the primary polymer particles is approximately 10^3 with a small content of the polymer having a molecular weight of $\sim 10^6$. The oligomer is present also in the finished latex. This permitted the assumption that nucleation takes place via micelles incorporating the surface-active oligomers formed as a result of the recombination of short-chain free radicals. The micelles formed absorb the monomers from the aqueous phase, after which the process migrates to the polymethacrylate particles. The question how the particles grow and are stabilised in the subsequent course of the polymerisation remains unelucidated.

The nucleation of the particles in the polymerisation of styrene initiated by potassium persulphate has been studied from the light scattering intensity and by photocorrelation spectroscopy at 333 K.[105] Three stages were observed in the light scattering intensity as a function of time: in the first stage, it remained unaltered, in the second it increased very rapidly (which could be explained by the formation of aggregates but not by the growth of particles or the absorption of the monomer by the latter), while in the third it increased slowly. Electron microscope data and granulometric analysis showed that in the initial stages the number of particles diminishes rapidly and then remains constant. The flocculation of the particles in the initial stage was not attributed[104] to their stability (in contrast to the study[39] of the polymerisation of methyl methacrylate). It is assumed that the "micelles", formed from the products of the recombination of soluble radicals with n = 2–4, are stable, but, as macromolecules having a high molecular weight accumulate in them, the nuclei lose their stability, since this entails a decrease in the concentration of charged groups on the surfaces of the growing particles. Theoretical calculation of the charge density on the nuclei of polystyrene particles after the introduction into the latter of polymers having different molecular weights, carried out on the assumption that the nuclei consist of 100 chains having a molecular weight of 10^3, that the macromolecules are formed as a result of the recombination of the radicals growing in the particles, and that their terminal SO_4^- groups are located on the surface, showed that the macromolecules with a molecular weight of 10^4–10^6 initially induce (before the attainment of d = 30 nm) a decrease in the charge (the particles flocculate) and then its increase—which is greater the higher the molecular weight of the added macromolecules; for a molecular weight of 10^6, the charge remains constant until the attainment of d = 126 nm (the number of the particles remains constant).[105] This calculation was performed for an ideal system without taking into account the real conditions, in particular, the ionic strength of the aqueous phase, which depends on the initiator concentration.

Among the three possible mechanisms of the nucleation of particles, namely association of surface-active radicals with formation of micelles, the adsorption of radicals on monomer drops, and the recombination (or growth) of radicals with formation of colloidally unstable macromolecules (RSO_4^-), preference is nevertheless given to the last mechanism.[106] In view of the colloidal instability of the insoluble macromolecules, they undergo association. The particles formed immediately absorb the monomer, and, in view of the low content of the chains, they have a low surface charge, as a result of which they rapidly flocculate; flocculation continues until the attainment of the surface charge density and particle radius necessary for their colloidal stability. The rate of flocculation is

$$W_f = -[dN/dt]_f = k_0 N^2/F,$$

where k_0 is the rate constant for the diffusion controlling flocculation and F is the Fuchs stability factor.[107] In order to achieve a qualitative understanding of the relevant questions, namely what is the size of the particles when the latter become stable, what is their charge under these conditions, and how many polymer chains are contained in the particle, a number of assumptions have been

made:[106] the particles are spherical, all the molecules have the same molecular weight (M_c), and each has two terminal (charged) groups located on the surfaces of the particles. Calculations of the stability of the hydrophobic sols carried out on the basis of the assumptions made, taking into account the ionic strength of the aqueous phase, make it possible to assume that

$$N_c = 4\pi r^3 \rho_L N_A / 3M_c = M_L / M_c,$$

where N_A is the Avogadro number, N_c the number of chains in the particle when its molecular weight is M_L, r the radius, and ρ_L the density. The number of charges on the end groups of the particle is

$$N_e = 2N_c = \frac{8\pi r^3 \rho_L N_A}{3M_c},$$

and the charge density

$$\sigma_s = \frac{N_e e}{4\pi r^2} = \frac{2\rho_L e N_A r}{3M_c}$$

is directly proportional to the particle radius. Assuming that $M_c = 1.5 \times 10^5$ (the usual value for the emulsifier-free polymerisation of styrene), it is possible to calculate σ_s for different values of r. The surface potential is[108]

$$\psi_s = \frac{4\pi r \sigma_s}{\varepsilon (1 + k_z)},$$

where ε is the dielectric constant of the medium and $k_z = 3.4 \times 10^7 I^{1/2}$ is the reciprocal of the thickness of the diffuse electrical double layer (I is the ionic strength). Next, plots of $\lg F$ against r (5–20 nm) were constructed for different ionic strengths I of the system (4.24×10^{-4}, 9.33×10^{-4} and 4.0×10^{-3}) on the basis of the values of ψ_s obtained, the Fuchs stability factor, and the Deryagin–Landau–Verley–Overbeek (DVLO) stability theory.[40,109,110] Assuming that the latexes are stable when only 1% of the particles flocculate after 1 h, it is easy to show that $\lg F = 6.26$. Hence it follows from the dependence of $\lg F$ on r obtained at different ionic strengths I that a sufficient stability of the particles is attained at the given ionic strength of the aqueous phase for a specific particle radius. Thus the particle size and hence the concentration of particles can be controlled by the ionic strength, which indicates, in its turn, the importance of the stage involving the flocculation of the primary particles for the final value of the radius obtained.

An empirical equation for the dependence of the particle size of the styrene latex on the parameters C_m, C_{in}, T, and I has been derived:[111]

$$\lg d = 0.238 \lg I + 0.41 \lg[M] - 0.238 \lg[PPS] + 1173T^{-1} - 0.827.$$

It has been shown[13] that, in the emulsifier-free polymerisation of styrene initiated by potassium persulphate, the size of the particles of the final latexes depends on the ionic strength of the aqueous phase, temperature, and the monomer and initiator concentrations. For the given $I = 2.22 \times 10^{-2}$ and $C_m = 0.87$ M, the particle diameter varies from 967 to 643 nm when the temperature is raised from 328 to 363 K. At the same monomer concentration and ionic strength $I = 11.3 \times 10^{-3}$, the particle diameter diminishes from 864 to 526 nm with increase in C_{in} from 0.34×10^{-3} to 2.76×10^{-3} mol/litre H_2O (the molecular weight increases from 1.41×10^5 to 5.46×10^5 with increase in the particle diameter). At $I = 1.92 \times 10^{-2}$ and $C_{in} = 2.76 \times 10^{-3}$ mol/litre H_2O, an increase in C_m from 2.2×10^{-3} to 8.71×10^{-1} M leads to an increase in d_p from 40 to 643 nm.

Monodisperse 10% polystyrene latexes with d_p ranging from 141 to 967 nm have been obtained.[13] An increase in temperature leads to more highly disperse latexes, while the application of seeded polymerisation leads to latexes with particles whose diameters are in excess of 4 μm. The hydrodynamic polymerisation conditions are important for the reproducibility of the results: the rate of stirring must ensure a sufficiently high dispersity of the monomer drops in order to maintain the saturation of the aqueous phase by the latter.

The presence on the surfaces of the particles of both sulphate and carboxy-groups has been established by the conductimetric titration method for styrene emulsifier-free latexes.[112] A large number of hydroxy-groups have also been detected. These evidently appear as a result of the tendency of the sulphate groups to hydrolyse; the oxidation of the hydroxyls leads to the formation of carboxy-groups:

$$RCH_2SO_4^- \rightarrow RCH_2OH \rightarrow RCOOH.$$

All these groups participate in the stabilisation of the particles mainly via the electrostatic factor (SO_4^- as well as COOH and OH). The structural factor is also important. The stability of the latexes obtained using potassium persulphate is sufficiently only for relatively dilute (10%) sols. This is associated with the insufficient content of ionised and hydrophilic groups on the surface of the particles. Thus, according to Goodwin et al.,[13] the surface area of the particles per SO_4^- and COOH groups varies (depending on the method of preparation of the latex) from 700 to 2000 Å and from 218 to 700 Å^2 respectively, which apparently does not ensure the stability of concentrated sols of the highly hydrophobic polymer. The degree of saturation of the emulsifier of the usual styrene and the styrene–butadiene latexes is known to be higher than 50%, which corresponds to an absorption area of the anionic emulsifier molecule of ~100 Å^2. The low degree of saturation of the particles of styrene emulsifier-free latexes by the end groups can be attributed to the very low solubility of the monomer in the aqueous phase, where initiation and nucleation take place.

2. Principles governing the increase in stability

A general principle governing the increase in the stability of emulsifier-free latexes obtained using initiation by persulphate is an increase in the charge and degree of hydration of the surfaces of the particles. The methods used for this purpose reduce to an increase in the solubility of the monomer in the dispersion medium, copolymerisation with monomeric acids[113–125] and their amides,[126,127] or the addition to the aqueous phase of an organic solvent.[128–130] The increase in the solubility of the monomer induces an increase in the fraction of the initiator consumed in initiation and the acceleration of the process, on the one hand, and an increase in the concentration of the surface SO_4^- groups as well as surface-active oligomers, on the other. This lyophilises the surfaces of the particles, reduces the hydrophobic interaction factor, and hence increases the resistance of the latex to aggregation.

(a) Copolymerisation with unsaturated acids

The copolymerisation of hydrophobic monomers with monomeric acids in emulsifier-free systems induces the acceleration of the process and leads to additional stabilisation via the carboxy-groups. Depending on the degree of hydrophilicity of the acid and its distribution between the monomeric and aqueous phases, the rate of the process and the location of the carboxy-groups differ greatly. Thus, in the copolymerisation of styrene with 2.4 mol% of acrylic acid, methacrylic acid (MAA), and itaconic acid (IC), methacrylic acid increases the initial rate to the greatest extent, while

itaconic acid is least effective (Fig. 16).[113] The observed difference is associated with the topochemical characteristics of the process: although in all cases polymerisation begins in the aqueous phase with formation of highly carboxylated oligomers, for the more hydrophobic methacrylic acid nucleation takes place at a higher rate and polymerisation migrates more rapidly into the particles, which accelerates the process. On the other hand, in the case of acrylic and itaconic acids, which are more soluble in water, the nucleation of the more hydrophilic oligomer is slower, which diminishes the overall rate of the process. It is striking that, in the course of the copolymerisation of styrene and with acrylic and itaconic acid, where the process migrates to highly hydrophilised particles, its rate not only attains but also exceeds the rate of copolymerisation of styrene with methacrylic acid, which takes place more uniformly (Fig. 16).

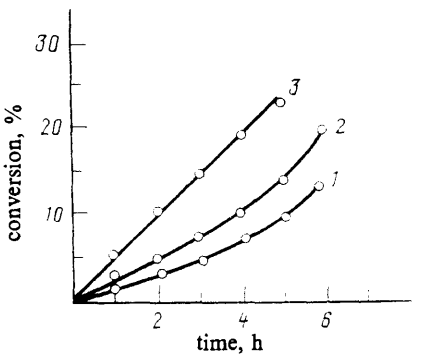

Figure 16. Kinetic curves for the emulsifier-free polymerisation in the presence of equimolar amounts (2.4 mol%) of acrylic (curve *1*), itaconic (curve *2*), and methacrylic (curve *3*) acids as well as potassium persulphate (3.7×10^{-4} mol/litre H_2O) at 343 K.[113]

Only the carboxy-groups localised on the surfaces of the particles are important for the stability of carboxylated emulsifier-free latexes (see above). It has been established that, in the emulsifier-free copolymerisation of ethyl acrylate[114] and styrene[115,116] with methacrylic and acrylic acids, the latter tends to concentrate in the surface region of the particles while the more hydrophobic methacrylic acid tends to be distributed throughout their bulk. The copolymerisation with the most hydrophilic itaconic acid leads to its preferential homopolymerisation in the aqueous phase.[117]

In terms of their influence on the resistance to electrolytes and the mechanical stability of highly concentrated butadiene–styrene latexes, dibasic acids [maleic, fumaric (FA), and itaconic acids] are significantly superior to monobasic acids (methacrylic and acrylic acids).[119]

Thus the individual characteristics of the acids are important for the stability of the latex.

In order to achieve the maximum fixation on the surface of the particles of the carboxy-groups of the acids, which ensure the formation of stable highly concentrated styrene–butadiene emulsifier-free latexes, the method of seeded polymerisation with variation of the pH of the medium during synthesis was employed.[118] In the first stage, carried out at a low pH, all the ingredients (including the acid) are introduced but only a proportion of the principal monomers are added in order to obtain a stable system at a reduced concentration. With increase in the pH of the seeding latex, the carboxy-groups introduced into the polymer ionise; the highly charged particles obtained in this process constitute the region of the subsequent polymerisation of the monomers introduced in the second stage. The high hydrophilicity of the carboxylate anions induces their localisation on the surfaces of the particles adjoining the aqueous phase, which imparts adequate stability to the final latexes. After the introduction of 2 wt.% of itaconic acid and an increase in the pH in the first and second stages from 2.5 to 9.5, a polydisperse 40% latex with $d_p = 50-130$ nm is obtained.

In order to compare the stabilities of styrene–butadiene copolymer latexes containing 4 mol% of methacrylic and acrylic acids (the partition coefficients between styrene and water are respectively 1.94 and 0.175 [120]), latexes with a 50% concentration were obtained; however, only in the copolymerisation with acrylic acid do they possess the necessary mechanical stability, which is associated with the high concentration of surface carboxy-groups.

The migration of the carboxy-groups in the particles is influenced by the mobility of the segments of the macromolecules. This has been observed[121] in the alkaline and subsequently acid treatments of the styrene–butyl acrylate–methacrylic acid terpolymer latexes (T_s = 343 K) during their heating. The number of surface COOH groups (A_s) was determined by conductimetric titration. It was shown that A_s increases as a result of heating the latexes at pH 10 to a greater extent the higher the temperature (293–343 K) and the more prolonged the heating process (1–3 h). The concentration of the acrylic acid dissolved in the aqueous phase changes very little under these conditions. On the other hand, as a result of the subsequent heating of the latexes at pH 3, A_s diminishes to a greater extent the higher the temperature and the longer the heating process. The observed changes are associated with the tendency of the ionised carboxy-groups to migrate to the interface with the aqueous phase; on their deionisation (neutralisation) and on decrease in the degree of hydration, the carboxyl-containing segments tend to return to the bulk of the particles.[121]

The influence of the degree of ionisation of acrylic and fumaric acids on the stability of 50% styrene latexes has been investigated.[122,123] The emulsifier-free polymerisation was carried out in the presence of a small amount (0.05 wt.%) of sodium dodecyl sulphate. The degree of neutralisation of the acid groups was regulated by adding $NaHCO_3$. It was shown that the degree of neutralisation, which influences the solubility of the oligomeric radicals formed in the aqueous phase, is very important for the rate of the process, the particle size, and the stability of the latex. The degree of neutralisation optimal for the stability of the latexes is 0.89–0.87, which corresponds to the highest concentration of the surface COOH groups; under these conditions, the area of the particle surface corresponding to each COOH group is 16–19 Å^2. For a degree of neutralisation of 0.85, the maximum rate is observed apparently as a consequence of the maximum degree of hydration of the surface and the smallest interfacial surface, which is the reason for the maximum concentration of the monomer in the particles.[86] With increase in the acrylic acid concentration from 0.5 to 5 wt.%, the rate of the process increases and the particle size diminishes.

The frost resistance of the carboxyl-containing styrene–isoprene emulsifier-free latexes also depends on the density of the distribution of the COOH groups on the surfaces of the particles and on the degree of their neutralisation.[127] Frost resistance is achieved if the

area per COOH group is 30–60 Å^2. The resistance of carboxyl-containing polystyrene latexes to electrolytes obeys the theory of the stability of hydrophobic sols[110,111] according to Sakota and Okayo.[125]

(b) Copolymerisation with acid amides and their derivatives

The use of the amides of acrylic and methacrylic acids as comonomers for the synthesis of stable emulsifier-free latexes is based on the increase in the hydrophilicity of the oligomeric radicals growing in the aqueous phase and on the involvement under these conditions of a greater proportion of the persulphate SO_4^- groups participating in the stabilisation process. The capacity of the NH_2 groups for the formation of strong hydrogen bonds with water increases not only the stability but also the viscosity of the sols formed.

The emulsifier-free copolymerisation of butadiene and styrene with the amide (AMA) and hydroxymethylamide (HMAMA) of acrylic acid (2 wt.%) in 50% systems with a high ammonium persulphate concentration (0.5–1.25 mol% H_2O) has been investigated.[115] In two-stage polymerisation (T = 353 K) and with the introduction of the functional comonomer only in the second stage (into the seeding 25% latex), electrolyte-resistant ($CaCl_2$) latexes are formed. In the case of the hydroxymethylamide of acrylic acid, a high resistance to mechanical influences is also achieved apparently as a consequence of the more effective interaction of the hydroxymethylamide groups with water.

The emulsifer-free copolymerisation of styrene with 0.1–0.5 parts of acrylamide by weight at pH 9 (C_{in} = 5 × 10^{-3} M, T = 343 K, phase rate 20:150) can be divided into three stages depending on the topochemistry of the process;[126] (1) copolymerisation in the aqueous phase with formation of oligomers which are rapidly rendered hydrophobic and are nucleated; (2) polymerisation of styrene in the particles formed until its almost complete exhaustion; (3) continuation of the copolymerisation of acrylamide with the styrene dissolved in the aqueous phase to form radicals with an increased hydrophilicity as a consequence of the low concentration of styrene. The kinetic curves for the overall rate of acrylamide–styrene copolymerisation and for the acrylamide content in the copolymer corresponding to different degrees of conversion are presented in Fig. 17, which also illustrates the variation of the viscosity of the system. The latexes obtained are stable and highly disperse (d_p = 150–300 nm). Depending on the ratio of the acrylamide and styrene, the initial stage of the process shifts to a greater or lesser extent into the aqueous phase, which influences the rate of nucleation and the particle size. With increase in the fraction of the dissolved monomer, the rate of initiation also rises and there is an increase in the number and a decrease in the size of the particles. This also occurs with increase in temperature. On reducing the pH from 9 to 3, at which acrylamide exhibits basic properties, the radicals formed in the first stage acquire an open-chain conformation, which decreases the number of nuclei in which styrene polymerises and hence increases the particle size (190–430 nm). The increase in C_{in} induces an increase in the charge on the particles, which alters the degree of hydration of the amide units. This leads to a decrease in the stability of the latex. Appreciable hydrolysis of the NH_2 groups at high pH is not observed during the reaction time (less than 6 h). In view of the high hydrophilicity of acrylamide, the latexes contain a large proportion of a water-soluble polymer; it has been suggested that the use of less water-soluble acrylamide derivatives leads to its diminution.[126]

Acrylamide and its derivatives, differing in the partition coefficients k at the styrene–water interface, have been investigated in copolymerisation with styrene:[127] acrylamide (k = 0.093), N-hydroxymethylacrylamide (k = 0.089), methacrylamide (MAMA, k = 0.159), N,N-dimethylacrylamide (DMAMA) (k = 0.293). Fig. 18 shows that the composition–conversion curves for the N-hydroxymethylacrylamide–styrene and N,N-dimethylacrylamide–styrene copolymers resemble the curve for the acrylamide–styrene copolymer (Fig. 17), i.e. for all three comonomers, the three-stage copolymerisation mechanism described above operates. On the other hand, the composition–conversion curve for the styrene–methacrylamide copolymer differs from them appreciably.

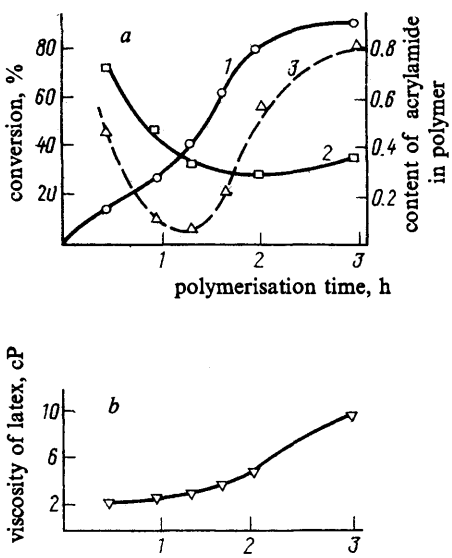

Figure 17. Time variation of the conversion (curve *1*) and of the fractions of acrylamide in the accumulated (curve *2*) and instantly formed (curve *3*) polymers in the emulsifier-free copolymerisation of styrene and acrylamide in the presence of potassium persulphate and at 343 K (C_m = 1.1 M) (*a*) and time variation of the viscosity of the finished latex (*b*).[126]

Certain characteristics of the emulsifier-free copolymerisation of the first three systems can be accounted for by the difference between the hydrophilic-hydrophobic properties of the comonomers and their reactivities in relation to styrene. The low value of k for acrylamide and N-hydroxymethylacrylamide, indicating a high concentration of the amide dissolved in the aqueous phase, induces an increase in the duration of the first stage as a result of the extensive growth of the water-soluble radicals. On the other hand, the high value of k for N,N-dimethylacrylamide is associated with a short first stage and the rapid precipitation of the radicals, which accelerates the transition of the process to the second stage. However, this entails the formation of larger particles (d_p = 329 nm) than in the first two stages (d_p = 144–147 nm), which can be

explained by the inadequate stability (lower degree of hydration) and flocculation of the styrene–*N*,*N*-dimethylacrylamide nuclei. The monomeric composition of this polymer, formed in the second stage mainly in the polymeric-monomeric particles, depends on the reactivity of the amides in relation to styrene and on *k*. The unfavourable constants for the copolymerisation of styrene and *N*,*N*-dimethylacrylamide are responsible for the low content of the latter in the copolymer.

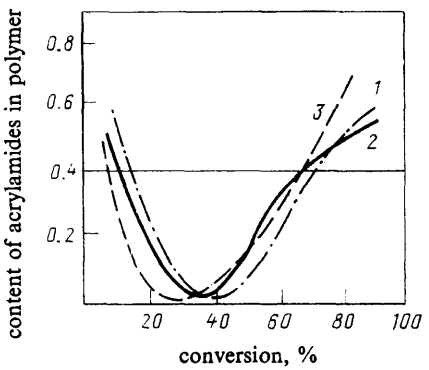

Figure 18. Variation of the composition of the polymer in the emulsifier-free copolymerisation of styrene with acrylamide (curve *1*), *N*-hydroxymethylacrylamide (curve *2*), and *N*,*N*-dimethylacrylamide (curve *3*) in the presence of ammonium persulphate (5×10^{-3} mol/litre H_2O) at 343 K and C_m = 1.25 M.[127]

The observed difference in the nature of the copolymerisation of styrene with acrylamide and *N*-hydroxymethylacrylamide (Fig. 17) is inconsistent with the closeness of the values of *k*; while the solubility of *N*-hydroxymethylacrylamide in water is somewhat greater, the duration of the first stage of the copolymerisation with this comonomer is shorter. This is associated with the different fractional composition of its copolymer, which contains a smaller water-soluble fraction appreciably enriched (to the extent of 97%) in the amide compared with the styrene–acrylamide copolymer.[126] The latter may be explained, in its turn, by the different reactivities in the aqueous phase of the copolymers being compared.

Pure monodisperse styrene–*N*-hydroxymethylacrylamide copolymer latexes containing a weight fraction of the latter comonomer of 0.09 have been obtained.[127]

(c) The addition of an organic solvent

The influence of methanol on the emulsifier-free copolymerisation of styrene in the presence of potassium persulphate and the properties of the latexes obtained from them has been investigated.[128] Methanol was chosen because of its unlimited miscibility with water and styrene and its inability to dissolve the polymer. It was shown that, after the addition of methanol to the extent of 60%, the rate of polymerisation as well as the degree of conversion increased significantly. The time of attainment of a high degree of conversion increases with increase in C_m (from 10 to 40%) and the particle size increases from 0.7 to 1.2 μm (C_{in} = 4.6×10^{-3} M). At a given concentration of the electrolytes, the particle diameter falls with increase in the initiator concentration.

The mechanism of the formation of particles is similar to that in the polymerisation of polar monomers (appreciably soluble in water) (see above). A constant rate is retained up to the attainment of 50% conversion, after which it increases,[128] which can be associated with the gel effect in view of the presence of more than one radical in the large particles.

The possibility of another mechanism for the increase in the rate of polymerisation in the presence of methanol has been postulated.[129] It consists in the interaction of methanol with potassium persulphate, which predominates over the thermal decomposition of the latter and is accompanied by the formation of the $^{\cdot}CH_2OH$ radical. This increases the concentration of surface OH groups with increase in the content of methanol and the latter can in turn promote the lyophilisation and an increase in the stability of the particles.

Okubo et al.[130] used acetone (up to 40 vol.%) instead of methanol in the emulsifier-free polymerisation of styrene. Acetone is also infinitely miscible with water and the monomer, but, in contrast to methanol, it can dissolve the polymer. Therefore, when acetone at a concentration in excess of 40% is introduced, a latex is not formed. A characteristic feature of acetone is an increase in the rate of decomposition of the initiator, which rises by a factor of 3.5 (compared with water) when the content of the solvent is 40 vol.%.[130] The rate of polymerisation of styrene increases with increase in acetone concentration from 0 to 40%, while the particle diameter diminishes under these conditions from 0.5 to 0.17 μm. The latter behaviour is also observed when C_{in}(PPS) increases from 10^{-4} to 10^{-2} M, and is attributed to an increase in the rate of nucleation of the particles. Conditions for the formation of highly stable 70% latexes with narrow particle size (d_p = 0.16 μm) and molecular weight distributions have been found. When such latexes are ultracentrifuged (27 000 rev min^{-1}), the precipitation of the deposit is not observed; after the removal of acetone, the stability of the latexes persists.

IV. Conclusion

The development and introduction into industry of the emulsifier-free polymerisation technology eliminates the pollution of wash waters and water reservoirs. The latexes obtained by this method are of great interest for a wide variety of purposes.

The principal problem in the preparation of such systems, which consist of hydrophobic sols, is their colloidal stability, which is achieved in traditional emulsion polymerisation by introducing an emulsifying agent into the system. For the formation of a colloidally stable emulsifier-free latex, it is essential to produce particles with a definite morphology as a result of the modification of their hydrophobic bulk by covalently bound highly hydrophilic surface groups, which are ionised or (and) capable of generating a sufficiently powerful hydration layer on interaction with the aqueous phase. An increase in the stability of the particles by the adsorption on their surface of the "intrinsic" diphilic low-molecular-weight oligomers is of some importance.

If the modification of the surfaces of the particles leads to a sufficient decrease in the interfacial Gibbs free energy, then stable polymeric sols are formed. In practice this is achieved when interfacial polymerisation of hydrophobic monomers is initiated by radical-ions and (or) when they are copolymerised with ionisable or highly hydrophilic comonomers.

Three stages are characteristic of emulsifier-free (as well as traditional) emulsion polymerisation: nucleation, particle growth, and polymerisation within the particles until its completion. The principal difference between emulsifier-free and classical emulsion polymerisation[26–30] involves the first stage — nucleation. Since this stage alway begins with polymerisation in the aqueous solution and the formation of diphilic oligomers, the rate and mechanism of nucleation depend on the solubility of the latter in water and their behaviour in the reaction system: chain propagation and termination by other radicals with formation of either the nuclei of particles (after the attainment of n_{cr}) or of water-soluble oligomeric surfactants and micelle-like aggregates, which constitute the nucleation zone.

In emulsifier-free emulsion polymerisation in very dilute systems — in the absence of the monomer phase — there is a possibility of homogeneous nucleation as a result of the "coiling up" of the growing radicals or their termination by reaction with other radicals on attainment of n_{cr}.[39,41] The monomer remaining in aqueous solution tends to pass into the nuclei because of the difference between its activity coefficients in the aqueous and organic phases.[130] When the entire solution has been exhausted, nucleation ceases. It has been suggested that the particles formed are stabilised by covalently bound surface ionised groups;[41] if the stabilisation is insufficient, then the particles flocculate until the size and charge density on the surface necessary for their stability are attained.[39,105]

Emulsifier-free polymerisation in very dilute systems[39,41] is of theoretical interest, but it does not model the real process occurring in the presence of the monomeric phase: in the latter case, the concentration of the monomer dissolved in water is kept constant until its equilibrium absorption by the particles as a result of mass transfer from the monomer drops through the aqueous solution. Nucleation via the formation of associated oligomeric species, which lose their solubility in water after the attainment of n_{cr} [105] or are characterised by micelle-forming properties,[14] acquires dominant importance; the associated species, which immediately solubilise the monomer, are converted into polymeric-monomeric particles in which the second and third polymerisation stages take place. The nucleation period, associated with the accumulation of water-soluble oligomers, becomes longer with increase in their solubility in water[53] and shorter with increase in the rate of radical formation and temperature, which promote the rapid displacement of the process into the particles.[24,25] The second stage (particle growth) can both proceed via the classical mechanism[26–30] and can be determined by the flocculation process for which the concentration of the electrolyte in the system plays an important role.[103–105] The first mechanism is more characteristic of polar monomers (methyl methacrylate, ethyl acrylate, etc.),[41,48] while the second is more characteristic of non-polar monomers (styrene). This difference can be accounted for by the structural factor governing the stability of colloids — the high degree of hydration of the particles of polar polymers, and, conversely, by the large contribution due to the forces associated with the hydrophobic interaction of the polystyrene particles.[64]

The concluding stage of the process with formation of the polymer-monomeric particles after the disappearance of the monomeric phase depends on their size and the initiator concentration. For a large volume of the polymeric-monomeric particles and a sufficiently high initiator concentration, when there is a possibility of the coexistence of several radicals in the particle, polymerisation is accelerated.[41] For a particle size characteristic of classical emulsion polymerisation,[26–30] at a low initiator concentration and at a high rate of radical formation (at a high temperature), where not more than one radical is present in the particles, the process in the concluding stage proceeds at a constant rate with subsequent transfer to the diffusion region.[48]

The electrostatic stability factor, determined solely by the persulphate initiation of emulsifier-free polymerisation, plays an important role in the preparation of latexes with limiting stability and a comparatively low concentration (~10 wt.%).[13,103,105] If it is necessary to increase the stability and to obtain more concentrated emulsifier-free latexes from high-molecular-weight polymers, it is essential to resort to an additional structural stabilisation factor, which depends on the hydration of the surface of the particles. This is achieved in different ways: by introducing into the aqueous phase an organic solvent which increases the solubility of the monomer,[127–129] by using an initiator whose molecules have surface-active properties,[58] and by the hydrolysis of the ester groups of the polymer (polymethacrylate or polyacrylate).[25,120] However, in practice the copolymerisation with hydrophilic[125,126] and especially with ionisable comonomers[25,112,117,118] is most often used for this purpose. In the latter case, a necessary condition is the localisation of the hydrophilic groups on the surface of the particles. In selecting the comonomer, for example a monomeric acid, its partition coefficient between the monomeric and aqueous phases[119] becomes important as do the mobility of the carboxyl-containing segments of the macromolecules, which is responsible for the possibility of their migration in the bulk of the particles and their localisation at the interface with the aqueous phase.[120]

Concentrated emulsifier-free polymer latexes with sufficiently low T_g, characterised by a low content of oligomers and electrolytes, can be used as glues and adhesives, since they exhibit an increased hydrophilicity and are capable of adhering to various supports more effectively than traditional latexes.[7]

I. Introduction

The kinetics of the catalytic degradation of polyolefins in the presence of electrophilic reagents differ considerably from the kinetics of their thermal degradation.[1,2] This is due primarily to differences in the initiation of decomposition reactions of the polymer products. In general, in both thermal[3–5] and catalytic[6,9] reactions of polyolefins two mechanisms of initiation can be distinguished: a) initiation of depolymerisation of the macromolecules on the terminal groups; b) initiation of decomposition of macromolecules randomly. To date it has not been possible to determine the contribution of each of these mechanisms using the existing theoretical and experimental approach to a study of the kinetic reaction parameters.[10] A new method of determining the apparent constants of initiation and length of the kinetic chain of competing processes[11] has made it possible to bring closer the development of a general theory concerning the processes of selective catalytic degradation of polyolefins.

II. Thermal degradation of polyolefins

The thermal degradation of polyolefins as an independent process became a topic of interest for research workers at the end of the 1940's, primarily in order to achieve the selective extraction of valuable gaseous hydrocarbons from a polymer feedstock.[12–14] However, with rare exceptions [poly(α-methylstyrene), poly(methylmethacrylate)] very low selectivity with respect to the yield of monomer has been recorded in the thermal degradation of polyolefins. For the majority of polyolefins the formation of a wide range of low-molecular weight products—gaseous, liquid, and waxy—during degradation was typical.[15] The experimental data, in particular the change in molecular weight of the polymer as a function of the temperature and degree of degradation, the observed composition of volatile and nonvolatile degradation products, and the rate of the process, showed that reactions involving chain scission with hydrogen transfer and depolymerisation of the macromolecules are the most probable.[4,15] The degradation of polyolefins can in a number of cases be accompanied by side reactions, such as cross-linking of macromolecules. Moreover in some cases, particularly in the degradation of polyethylene, an active site is formed at a point of branching followed by detachment of a side-chain residue.

The combination of successive parallel reactions that form the basis of the complex chemical process of thermal degradation of polyolefins predetermines the complex task of studying and defining the process. Nevertheless, in relation to the decomposition of polyolefins the main reactions that determine the chemical nature of the overall process are: chain depolymerisation to form the corresponding monomer and its isomerisation and hydrogenation products and random decomposition of the macromolecules with the formation of sequences of polymer molecules of different length (degradation) resulting in a decrease in the molecular weight of the polymer.

As a rule initiation of decomposition of macromolecules is related to the occurrence of various kinds of defects in the polymer chain (structural irregularities) that are formed, for example, during polymerisation. Groups that are formed by addition of a monomer according to the "tail-to-tail" principle, and when there are side-chain substituents, internal double bonds of various types,[15] etc. can become labile. The resulting primary macroradicals decompose in chain propagation reactions, undergoing β-cleavage (Rice's rule) to form lower olefins, and also decompose in chain transfer and chain termination reactions leading to the formation of heavier hydrocarbons. Typically, during the thermal decomposition of polymer products the role of chain transfer to the polymer is very important,[10] which is a determining factor in the formation of a series of reaction products of variable composition.

Of the reactions that occur during the thermal degradation of polyolefins, the three most typical reactions that govern the yield and distribution of products can be distinguished: 1) radical decomposition (degradation) of macromolecules; 2) reactions that occur with hydrogen transfer; 3) radical substitution reactions (chain transfer to the polymer). The role of these reactions can vary according to the chemical structure of the polyolefins. Thus, for

Table 1. Yield and composition of gaseous products from thermal and catalytic degradation of polyolefins.

Catalyst	Polyolefin	T, K	Yield of gas, wt.%	Composition of gaseous products*, wt.%

*Traces of hydrogen were identified in the gaseous products.

example, for polyethylene (PE) all three types of reaction are equally probable, while for polyisobutylene (PIB), which has two methyl substituents on every second carbon atom, only reactions 1) and 3) are typical. This has the result that in the degradation of PE formation of the monomer in appreciable quantities is improbable and, moreover, is thermodynamically unfavourable, while in the degradation of PIB up to 20% monomer is formed (Table 1). When internal double bonds occur in the polyolefin, such as in butyl rubber (BR), the role of hydrogen transfer reactions once again increases (Table 1). As a consequence the yield of monomer is very small.

Chain transfer reactions with removal of a hydrogen atom from the main chain and a substituent (for PE, branching, which in the vast majority of cases consists of ethyl or *n*-butyl groups, should be regarded as a substituent) during the thermal degradation of PE and BR are of equal probability. For PIB, on the other hand, chain transfer reactions with removal of a hydrogen atom from the internal hydrocarbon atoms are typical, with the result that hydrocarbons of an isomeric structure are mainly formed (Table 1).

On the whole it can be seen that the thermal decomposition of PE, PIB, and BR, as for the majority of other polyolefins, leads equally to the formation of such a wide range of reaction products that the concept of selectivity in relation to the thermal degradation of polyolefins loses its meaning. Nevertheless, from a practical viewpoint, the derivation of hydrocarbon fractions by thermal degradation may be of interest not only as a method of processing various polymer waste products in order to destroy them but also as one of the methods of obtaining liquid hydrocarbons for use as solvents, additives, or fuel.[16] Catalytic methods of treating polyolefins to obtain gaseous and liquid fuels are also possible.[17,18]

III. Catalytic degradation of polyolefins

The electrophilic catalytic degradation of polyolefins that occurs by a cationic mechanism[8] is very interesting from the theoretical viewpoint as an example of the decomposition of polymer products by terminal group or random mechanisms.

Compared to a purely thermal process, the electrophilic catalytic degradation of polyolefins in the presence of $AlCl_3$ takes place with a higher yield of low-molecular weight products (Table 1) at considerably lower temperatures, but it is insufficiently selective with respect to the yield of monomer. In the presence of strongly acidic systems there is an intensification not only of the decomposition processes of the macromolecules but also of secondary processes, in particular isomerisation and cross-linking. The formation of primary polymer carbocations on treatment with aluminium chloride (probably in the form of $H^+(AlCl_3 \cdot OH^-)$),[19] occurs in the degradation of PE with the random removal of a hydride ion:

$$R{-}CH_2{-}CH_2{-}CH_2{-}CH_2{-}R' + H^+[AlCl_3 \cdot OH]^- \rightarrow$$

$$\rightarrow R{-}CH_2{-}\overset{+}{C}(CH_3){-}CH_2{-}R'[AlCl_3 \cdot OH]^- + H_2,$$

$$R{-}CH_2{-}CH(CH_3){-}CH_2{-}R' + H^+[AlCl_3 \cdot OH]^- \xrightarrow[-H_2]{}$$

$$\rightarrow R{-}CH_2{-}CH(\overset{+}{C}H_2){-}CH_2{-}R'[AlCl_3 \cdot OH]^- \rightarrow$$

$$\rightarrow R{-}\overset{+}{C}H_2 \cdot [AlCl_3 \cdot OH]^- + CH_2{=}CH{-}CH_2{-}R'.$$

Initiation of degradation of polyolefins is also probable on the defect groups of macromolecules, for example, on vinylidene double bonds:

$$RR'C{=}CH_2 + H^+[AlCl_3 \cdot OH]^- \rightarrow RR'CH{-}\overset{+}{C}H_2[AlCl_3 \cdot OH]^-.$$

The primary ion isomerises to give a more stable tertiary carbocation:

$$RR'CH-\overset{+}{C}H_2[AlCl_3\cdot OH]^- \rightleftharpoons R-\overset{R'}{\underset{CH_3}{\overset{|}{\underset{|}{\overset{+}{C}}}}}[AlCl_3\cdot OH]^-.$$

In the decomposition of polymer carbocations a wide range of products is formed: gaseous products from CH_4 (detachment of methyl branches) to C_4H_8 (skeletal isomerisation of a macroion followed by β-cleavage) and liquid and waxy products from C_5 hydrocarbons and above (Table 1). A typical feature is that in the degradation of PE the yield of just the monomer (ethylene) is low.

Terminal double bonds play a considerable role in chain initiation reactions. However, the proportion of reactions that occur on the terminal groups is small in the case of PE degradation because of the high content of internal defect groups. An increase in the content of the terminal double bonds in PIB and BR macromolecules increases the probability of initiation of the process by a terminal group mechanism, although the expected increse in selectivity of the process also does not occur (Table 1). It is evident that successive chain-transfer reactions to the polymer by the random mechanism play a fairly large part in degradation processes of polyolefins in the presence of strongly acidic catalysts.

Side reactions are usually suppressed in electrophilic processes when the acidity of the catalyst is reduced. This phenomenon together with a high activity and selectivity has been established in the catalytic degradation of polyolefins in the presence of complexes of the type $MCl_n\cdot AlCl_3$ (M = Li, Na, K, Mg, Ca, Ba, n = 1–2).[20–22] Fused $MCl\cdot AlCl_3$ salts, which are familiar as ionic media,[23,24] exhibit properties of weakly acidic catalysts. The decrease in the ionic strength of the outer-sphere cation of an $MCl\cdot AlCl_3$ complex on going from Li^+ to Na^+ is consistent with the order of change in rate of conversion of the polymer (Table 1). A decrease in acidity of the catalysts relative to $AlCl_3$ has a favourable effect on the ratio of chain propagation to chain transfer by considerably reducing the contribution of chain transfer reactions. This in turn results in a considerbale increase in selectivity of the process with respect to the yield of C_4 hydrocarbons. The gaseous reaction products contain up to 90–95% hydrocarbons (Table 1).

Amongst individual salts—metal chlorides of Groups I and II of the Mendeleev Periodic Table—$MgCl_2$ has high activity and selectivity with respect to the yield of monomer during catalytic degradation of PIB and BR (Table 2). The water of crystallisation plays an important role in the formation of catalytically active magnesium chlorides.[25] The aqua complexes $MgCl_2\cdot H_2O$ and $MgCl_2\cdot 2H_2O$ proved to be the most effective. Quantum-chemical calculations confirmed the possibility of the water of crystallisation having an activating effect (Table 3). The catalytic activity of the aqua complexes $MCl\cdot AlCl_3\cdot H_2O$ and $MgCl_2\cdot H_2O$ is caused by the fairly large positive charges on the hydrogen atoms. The stability of the $MAlCl_4\cdot H_2O$ aqua complex, determined from the energy of complexation with water, is somewhat less than for aqua complexes of magnesium chlorides. Therefore, despite the higher charges on the hydrogen atoms, the activity of $MAlCl_4\cdot H_2O$ during the degradation of polyolefins is somewhat lower than that of $MgCl_2\cdot H_2O$ (Table 3). It should also be noted that the quantum-chemical calculations are in agreement with the experimentally determined series of activity of $MAlCl_4$ catlaysts: $LiAlCl_4$ > $NaAlCl_4$ > $KAlCl_4$, namely, the acidity $P_{k\alpha}$ and charges q_{H^+} on the hydrogen atoms of the aqua complexes diminish with an increase in ionic radius of the cation.

Thus, weakly acidic complex catalysts of the type $MCl_n\cdot AlCl_3\cdot H_2O$ and $MgCl_2\cdot H_2O$ are fairly active and selective during the electrophilic catalytic degradation of polyolefins.

Table 2. Catalytic degradation of polyolefins in the presence of some aqua complexes of metal chlorides.

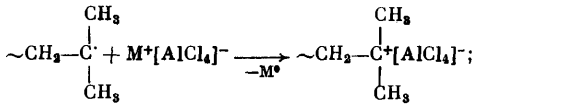
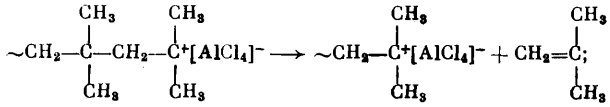
IV. Mechanism of catalytic degradation

The mechanisms of the thermal and thermocatalytic degradation of polyolefins differ. The purely thermal decomposition of polymer products takes place by a radical mechanism,[5] while for the degradation of polyolefins in the presence of electrophilic catalysts an ionic mechanism occurs.[26,27]

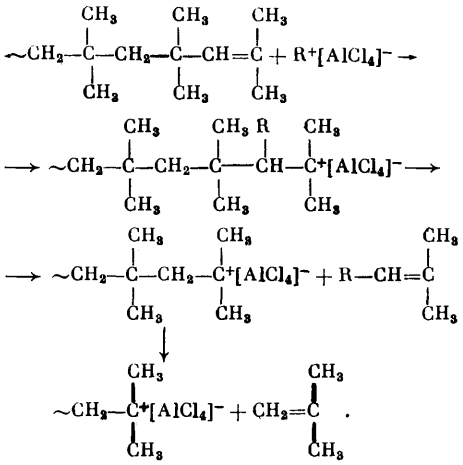


In early studies on the catalytic degradation of polyolefins in the presence of $MAlCl_4$ complexes, a cationic process mechanism was interpreted on the basis of a possible single-electron oxidation of primary radicals formed by the action of heat on the polymer:[1,2]

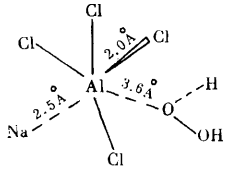
a) thermal decomposition by the random mechanism, preferentially on the defect groups ("head-to-head" addition of



monomer) contained in the macromolecules, for example

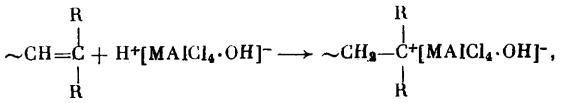


b) a redox reaction with the formation of a polymer carbocation

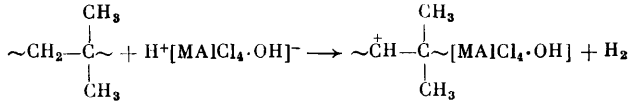


c) depolymerisation of macroions to form the monomer

d) chain transfer to the polymer followed by depolymerisation of the macroions by the terminal group mechanism

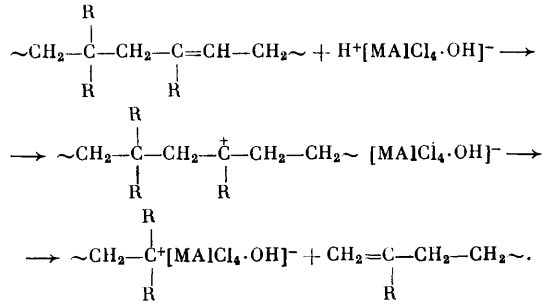


When $MAlCl_4 \cdot H_2O$ aqua complexes are used, initiation of degradation of polyolefins takes place on $H^+(MAlCl_4 \cdot OH)^-$, which has the structure

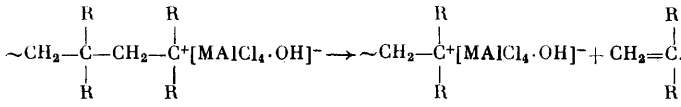


An aqua complex can initiate decomposition both randomly and on the terminal groups. Interaction of the catalyst with the weak bonds of the polymer chain by the random mechanism is governed by the structure of the polyolefin. In PE, degradation of macromolecules is initiated mainly on vinylidene and *trans*-vinylene internal double bonds, while for BR it occurs on the sites where the isobutyl residues are connected to an isoprenyl unit. Initiation by the terminal group mechanism occurs on the terminal double bonds.

a) Terminal group mechanism

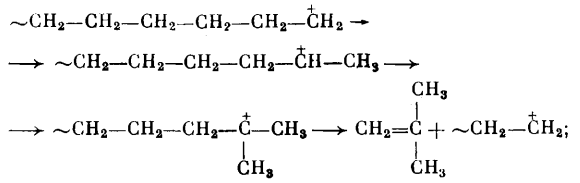


where R = CH_3 PIB, BR) or H (PE).

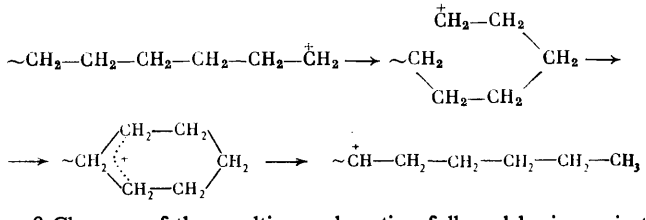


b) Random mechanism

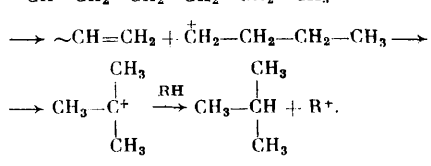
or (what is more probable for BR and PE)



Chain propagation reactions of macrocations can differ considerably according to the chemical nature of the polymer used. For example, for PIB and BR the resulting carbocations mainly undergo β-cleavage with elimination of an isobutylene monomer (Table 1):

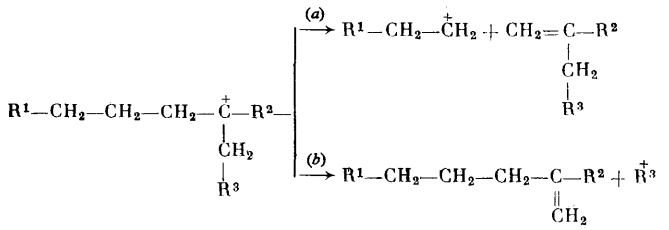


A linear carbocation $R-\overset{+}{C}H_2$ formed during the degradation of PE undergoes conversions by two main routes:



1) skeletal isomerisation with the formation of a tertiary carbocation that subsequently undergoes β-cleavage to give isobutylene

2) isomerisation of a macroion with transfer of excess positive charge to the sixth carbon atom via an intermediate cyclisation reaction of "flexible" methylene sequences



β-Cleavage of the resulting carbocation followed by isomerisation and removal of a hydrogen atom from a neutral molecule gives isobutane:

This reaction does not correspond to the classical route for depolymerisation and can be defined as an associated reaction of degradation and chain transfer.

In the case of the thermocatalytic degradation of PE, which always contains branching, the formation of carbocations can occur on a tertiary carbon atom. The subsequent decomposition of the macrocation occurs by two routes: decomposition of the main chain (*a*) and elimination of the side chain (*b*).

In both cases a new carbocation which undergoes further decomposition and an "inert" polymer with a vinylidene double bond are formed.

Thus, initiation of thermocatalytic destruction of polyolefins with different chemical structures in the presence of $MAlCl_4 \cdot H_2O$ and $MCl_n \cdot H_2O$ aqua complexes has the general characteristics: formation of an active site on the terminal double bonds of the macromolecule (terminal group mechanism) and random scission of the macrochains on defect groups and weak bonds. The mechanism of the chain propagation reaction is determined by the structure of the polyolefin; the presence of bulky substituents results either in depolymerisation reactions mainly occurring (PIB, BR) or depolymerisation (in parallel) with initial isomerisation of the carbocation. The absence of such groups in a linear polymer (PE) results in degradation with chain transfer to the polymer.

V. Kinetic features of the catalytic degradation of polyolefins

The chemical nature of the catalyst determines the sequence of degradation reactions of polyolefins and hence also the characteristics of the kinetic scheme of the process. When weakly acidic ionic catalysts of the type $MAlCl_4$, $MAlCl_4 \cdot H_2O$, and $MCl_n \cdot H_2O$ are used, the kinetics of the process are given by the following scheme:

$$\left.\begin{array}{l} P \xrightarrow{W_r} 2R^{\cdot} \\ P + cat \xrightarrow{k} 2R^{\cdot} \\ R^{\cdot} + cat \xrightarrow{k_{in}} R^{+} \end{array}\right\} \text{(random mechanism)}$$

$$P + cat \xrightarrow{k_{in}} R^{+} \text{ (terminal group mechanism)}$$

$$R_n^{+} \xrightarrow{k'_{dep}} R^{+}_{n-z} + zM; \quad R_n \xrightarrow{k_{dep}} R^{\cdot}_{n-z} + zM$$

$$R^{\cdot} \xrightarrow{k_{deg}} R_n^{\cdot} + R_m; \quad R^{+} \xrightarrow{k'_{deg}} R_n^{+} + R_m$$

$$R^{\cdot} + P \xrightarrow{k_{ct}} RH + P^{\cdot}; \quad R^{+} + P \xrightarrow{k'_{ct}} RH + P^{+} \quad + \Pi^{+}$$

$$R^{+} \xrightarrow{k_t} P.$$

In this case k'_{in}, k_{in}, k'_{dep}, k_{dep}, k'_{deg}, k_{deg}, k'_{ct}, k_{ct} and k_t are the rate constants of initiation, depolymerisation, and degradation by ionic and radical sites, chain transfer of ionic and radical sites, and chain termination respectively.

For degradation of the polymer by the random mechanism, the change in concentration of macrocations $[R^+]$ is given by the equation

$$d[R^+]/dt = k_{in}[cat][R^{\cdot}] - k_t[R^+]. \quad (1)$$

For a steady state

$$[R^+] = k_{in}[cat][R^{\cdot}]/k_t,$$

where

$$[R^{\cdot}] = -\frac{k_{in}[cat]}{2k_1} + \sqrt{\left(\frac{k_{in}[cat]}{2k_1}\right)^2 + \frac{W_r}{k_1}} =$$

$$= \frac{k_{in}[cat]}{2k_1}\left[\sqrt{\frac{4k_1(W_t + k_1[cat])}{(k_{in}[cat])^2}} + 1 - 1\right]. \quad (2)$$

Here $W_r = W_t + k_1[cat]$ is the rate of formation of radicals as a result of thermal scission of the polymer chain and by catalytic action.

Let us consider two limiting cases:[1]

a) There is only a small quantity of catalyst, in other words, only a small proportion of the radicals that are formed is converted to polymer carbocations. This corresponds to the condition

$$4k_1(W_t + k_1[cat])/(k_{in}[cat])^2 \gg 1, \quad (3)$$

then

$$[R^{\cdot}] = \sqrt{(W_t + k_1[cat])/k_1},$$

and the expression for the rate of random decomposition of polyolefins takes the form

$$V_1 = (k'_{dep} + K'_{deg})\frac{k_{in}[cat]}{k_t}\sqrt{\frac{W_t + k_1[cat]}{k_1}} +$$

$$+ (k_{dep} + k_{deg})\sqrt{\frac{W_t + K_1[cat]}{k_1}}. \quad (4)$$

In this case the rate-limiting stage of the process is the interaction of catalyst with a radical;

b) there is a considerable quantity of catalyst in the system, in other words, all of the radicals formed are converted to carbocations

$$4k_1(W_t + k_1[cat])/(k_{in}[cat])^2 \ll 1.$$

In this case the concentration of macroradicals in the system is defined by the relationship

$$[R^{\cdot}] = (W_t + k_1[cat])/(k_{in}[cat]), \quad (5)$$

and the rate of process is in the form of

$$V_1 = (k'_{dep} + k'_{deg})(W_t + 2k_1[cat])/k_t. \quad (6)$$

In the initiation of depolymerisation of PIB by the terminal group mechanism, the concentration of active sites $[R^+]$ is defined by the relationship

$$d[R^+]/dt = k_{in}[cat]C_n - k_t[R^+],$$

where $C_n = A_0/\overline{P}_n$ is the concentration of double bonds in the polymer (A_0 is the concentration of polymer, $\overline{P}_n$ is the degree of polymerisation of the polymer).

The equation for the rate of depolymerisation of PIB by the terminal group mechanism has the form

$$V_2 = k_r[R^+] = \frac{(k'_{dep} + k'_{deg})k_{in}[cat]C_n}{k_t} = \frac{(k'_{dep} + k'_{deg})k'_{in}A_0[cat]}{k_t\overline{P}_n}. \quad (7)$$

Then the rate of depolymerisation in general form is given by the equation

$$V = V_1 + V_2 = (k'_{dep} + k'_{deg}) \frac{k_{in}[cat]}{k_t} \sqrt{\frac{W_t + k_l[cat]}{k_l}} + \\ + (k_{dep} + k_{deg}) \sqrt{\frac{W_t + k_l[cat]}{k_l}} + \frac{(k'_{dep} + k'_{deg}) k'_{in} A_0[cat]}{k_t \overline{P}_n} \quad (8)$$

The equation obtained takes into account the concurrent reactions of degradation and depolymerisation on active ionic and radical sites but cannot elucidate the reasons for the difference in selectivity of the process with respect to the yield of monomer in the presence of catalysts. The selectivity of the catalyst can be determined quantitatively from the values of z (z is the length of the kinetic chain, representing the number of monomer units eliminated on average per macromolecular cleavage):

$$z = \frac{k'_{dep}[R^+] + k_{deg}[R^\cdot] + k'_{deg}[R^+] + k_{dep}[R^\cdot]}{W_t + k'[cat] + k_{ct}[R^\cdot] + k'_{ct}[R^+]}. \quad (9)$$

Table 4. Overall parameters of the catalytic degradation of polyolefins ($c_{cat} = 1 \times 10^{-3}$ mol g^{-1}; $\tau = 3.6 \times 10^3$ s).

Polyolefin	Catalyst	T, K	$z \pm 10\%$	$(k_{in} \times 10^7) \pm 5\%$, s^{-1}	E_a, kJ mol^{-1}

		623	12	1.2	
		643	19	2.7	

With an increase in activity of the catalyst in the series $LiAlCl_4$ > $NaAlCl_4$ > $KAlCl_4$, the value of z and the overall rate of degradation of polymer products increase (Table 4), while with an increase in temperature the length of the kinetic depolymerisation chain of PIB and BR on each of the selected catalysts decreases whereas the rate constant of depolymerisation increases. This is due to an increase in the contribution of the thermal component, which increases the probability of random degradation of the chain as well as chain transfer and termination. In the degradation of PE the yield of monomer is low and the concept of the length of the polymer chain should be applied to the elimination of C_4 hydrocarbons rather than monomer units. However, in contrast to PIB and BR, for PE the adopted value of z increases with an increase in temperature (Table 4), which is evidently due to the increased role of reactions involving decomposition with subsequent chain transfer which assist in increasing the yield of one of the main products of catalytic degradation of PE—isobutane. The overall energy of activation values of the catalytic degradation of polyolefins in all of the cases given are lower than for the thermal decomposition of polymers. This is attributed to a reduction in both the energy of initiation and the energy of decomposition of the polymer chain because of the cationic nature of the active site.

The kinetic scheme presented here represents the overall process of degradation of polyolefins that occurs in the presence of electrophilic catalysts. Therefore it can also be used to represent the overall kinetics of degradation of polyolefins in the presence of active and proton-donating forms of catalysts. However, at the same time it is necessary to take account of the fact that the rate constants of the interaction between catalyst and radical and the radical decomposition of polymer decrease considerably, and the rate of depolymerisation will be determined primarily by ionic processes involving initiation and chain continuation. In this case the kinetic scheme of catalytic thermal degradation of polyolefins can be represented as follows:

a) initiation (valid for initiation by both random and terminal group mechanisms)

$$P + cat \xrightarrow{k_{in}} R^+;$$

b) chain propagation

$$R_i^+ \xrightarrow{k_{dep}} R_{i-z}^+ + zM;$$

c) intermolecular chain transfer

$$R_i^+ + P_m \xrightarrow{k_{ct}} R_i + P_m^+;$$

d) destruction of active sites (chain termination)

$$R_i^+ \xrightarrow{k_t} P.$$

The rate of change in concentration of the polymer carbocations formed by the random mechanism can be given by the equation:

$$d[R^+]/dt = k'_{in}[cat][P] - k_t[R^+].$$

Assuming a steady-state concentration of active sites, we obtain

$$[R^+] = k'_{in}[P][cat]/k_t.$$

In the formation of active sites by the terminal group mechanism the expression for the rate of change in concentration of the active sites is given by the equation:

$$d[R^+]/dt = k''_{in}[cat]C_t - k_t[R^+],$$

where C_t is the concentration of terminal double bonds. Hence under steady-state conditions

$$[R^+] = k''_{in}[cat]C_t/k_t.$$

The equations for the rate of depolymerisation have the form

$$V_1 = k_{dep}[R^+] = k_{dep}k'_{in}[P][cat]/k_t \text{ (random mechanism)},$$

$$V_2 = k_{dep}[R^+] = k_{dep}k''_{in}[cat]C_t/k_t \text{ (terminal group mechanism)}.$$

Assuming that the random and terminal group processes are independent, we obtain an expression for the overall rate of degradation

$$V = k_{dep}[cat](k'_{in}P + k''_{in}C_t)/k_t.$$

Thus, the rate of the overall process of degradation of polyolefins is determined mainly by the initiation reactions, and in particular by the values of the apparent rate constants of initiation by the random and terminal group mechanisms. This makes it necessary to carry out a quantitative determination of the kinetic parameters of the initiation process.

VI. Determination of apparent kinetic parameters

Electrophilic catalytic degradation of polyolefins can be represented by a general equation that takes into account the contribution of both the random and terminal group reactions.

$$-dP/dt = z_t k_{ti} C_t + k_{ri} z_r P. \quad (10)$$

Here P is the decrease in polymer concentration (as a fraction of the original); k_{ri} and k_{ti} are the rate constants of initiation of degradation of polymer by the random and terminal group mechanisms respectively; z_r and z_t are the lengths of the kinetic chain during degradation by the random and terminal group mechanisms: C_t is the concentration of terminal double bonds. Assuming that the terminal groups which can initiate depolymerisation are consumed exponentially during degradation according to $C_t = C_{t0}\exp(-k_{ti}t)$ (C_{t0} is the initial content of terminal double bonds), which is especially typical for PIB, we obtain

$$P = \exp(-k_{ri}z_r t) + \frac{k_{ti}z_t C_{t0}}{k_{ti} - k_{ri}z_r}[\exp(-k_{ti}t) - \exp(-k_{ri}z_r t)]. \quad (11)$$

It is possible to determine the numerical values of k_{ti}, z_t, k_{ri}, and z_r at the initial stages of the process when $P \ll 1$, $t \ll 1/k_{ti}$ and $t \ll 1/k_{ri}z_r$ (experimentally this is possible when the process is carried out under low-temeprature conditions (200–300 °C) when the rates of "burning away" the chains are relatively small). Then

$$P = 1 - k_{ri}z_r t - k_{ti}z_t C_{t0} t. \quad (12)$$

The change in molecular weight of PIB can be determined from the total number of chain scissions. The number of macromolecules is given by $n = n_0 + k_{ri}t$ and their molecular weight is determined from the expression

$$\overline{M}_n = P/n \simeq \frac{1 - k_{ri}z_r t - k_{ti}z_t C_{t0} t}{n_0(1 + k_{ri}t/n_0)} \simeq \overline{M}_n^0(1 - k_{ri}z_r t - k_{ti}z_t C_{t0} t - k_{ri}t/n_0) \quad (13)$$

where $\overline{M}_n^0 = 1/n_0 = 1/C_{t0}$ (the presence of a single terminal double bond in each initial macromolecule of PIB is assumed). The relative degree of polymerisation during degradation will change in accordance with the equation

$$\overline{P}_n/\overline{P}_n^0 = 1 - k_{ri}z_r t - k_{ri}\overline{P}_n^0 t - k_{ti}z_t t/\overline{P}_n^0. \quad (14)$$

Hence it is possible to determine the change in relative degree of polymerisation in relation to the change in degree of conversion $d\alpha = \Delta P$. From Eqn. (12) we obtain

$$\Delta P = (k_{ri}z_r + k_{ti}z_t C_{t0})t.$$

As a result we obtain

$$\frac{d(\overline{P}_n/\overline{P}_n^0)}{d\alpha} = -\frac{k_{ri}z_r + k_{ri}\overline{P}_n^0 + k_{ti}z_t/\overline{P}_n^0}{k_{ri}z_r + k_{ti}z_t/\overline{P}_n^0}. \quad (15)$$

Provided that the length of the kinetic chain z_r is many times less than the degree of polymerisation $\overline{P}_n^0$, namely, $z_r \ll \overline{P}_n^0$, Eqn. (15) can be simplified.

$$\frac{d(\overline{P}_n/\overline{P}_n^0)}{d\alpha} = -\frac{k_{ri}\overline{P}_n^0 + k_{ti}z_t/\overline{P}_n^0}{k_{ri}z_r + k_{ti}z_t/\overline{P}_n^0}. \quad (16)$$

In order to simplify the calculations of the values of the kinetic parameters for each of the competing reactions we shall consider the following limiting cases:

a) when there is a small contribution from reacitons that occur on the terminal groups, i.e., when $k_{ti}z_t/\overline{P}_n^0 \ll k_{ri}z_r \ll k_{ri}\overline{P}_n^0$, the expression for the adjusted relative degree of polymerisation takes the form

$$d(\overline{P}_n/\overline{P}_n^0)/d\alpha = -\overline{P}_n^0/z_r; \quad (17)$$

b) when there is a small contribution from reactions that occur randomly, we obtain $d\alpha/dt \simeq k_{ti}z_t/\overline{P}_n^0$. The value of $\overline{P}_n^0$ in such a process for the most probable initial molecular weight distribution ($\overline{P}_w/\overline{P}_n \simeq 2$) is virtually unchanged, i.e., $d(\overline{P}_n/\overline{P}_n^0)/d\alpha \simeq 0$. This is consistent with the experimental data (Fig. 1, curves *1–3*). There is no point in using Eqn. (16) in this case since complete "burning away" of the macromolecules during depolymerisation of the polymer was not taken into account in its derivation;

c) when the main role in changing the number of chains is played by the random mechanism while the terminal group mechanism plays the main role in depolymerisation, namely when $k_{ri}\overline{P}_n^0 \gg k_{ti}z_t/\overline{P}_n^0 \gg k_{ri}z_r$, we obtain

$$d(\overline{P}_n/\overline{P}_n^0)/d\alpha = -k_{ri}(\overline{P}_n^0)^2/k_{ti}z_t. \quad (18)$$

The three variants a), b), and c) correspond to the three sections on the curve of the dependence of the calculated values of $d(\overline{P}_n/\overline{P}_n^0)/d\alpha$ on $\overline{P}_n^0$ obtained from the gradients of the corresponding experimental curves (Fig. 1). With an increase in the degree of polymerisation each of the three possible variants b), c) and a) occurs successively (Fig. 2).

It is possible to determine z_r and $k_{ri}/k_{ti}z_t$ respectively from the gradients for sections a) and c) of the curve of $d(\overline{P}_n/\overline{P}_n^0)/d\alpha$ against $\overline{P}_n^0$ (Fig. 2). The value of k_{ri} can be calculated by taking into account the fact that the random mechanism provides the main contribution to the decrease in molecular weight of the polymer. This corresponds to the relationship $d(\overline{P}_n/\overline{P}_n^0)/d\alpha = -k_{ri}\overline{P}_n^0$, from which the value of k_{ri} can be determined.

The values of z_r and k_{ri} that are obtained by treatment of the experimental data can be used to determine the numerical values of k_{ti} and z_t from Eqn. (11). The values of the kinetic parameters obtained—the rate constants of initiation and the lengths of the kinetic chain of polymer depolymerisation (given in Table 5 for the degradation of PIB in the presence of $NaAlCl_4$)—suggest that initiation of catalytic degradation by the terminal group mechanism has a predominant role under low-temperature conditions. As the temperature of degradation of the polyolefins is increased, the ratio of k_{ti} to k_{ri} decreases and at 260 °C their values become comparable.

The effect of catalysts on the degradation of polyolefins has been studied using the salts $NaCl{\cdot}AlCl_3$ and $MgCl_2{\cdot}AlCl_3$. The complex salt $MgCl_2{\cdot}AlCl_3$ has a slightly higher acidity than $NaCl{\cdot}AlCl_3$. This gives rise to an increase in activity of the $MgCl_2{\cdot}AlCl_3$ catalyst

during degradation of the polymer. It was shown in the case of the thermocatalytic destruction of PIB that in the presence of $MgCl_2 \cdot AlCl_3$ the total yield of gaseous products and the yield of just isobutylene increase considerably compared to when $NaCl \cdot AlCl_3$ is used. The change in acidity of the catalyst also has an effect on the selectivity of the process with respect to the yield of monomer. The kinetic studies on a determination of the ratio of initiation of degradation of macrochains by the random mechanism to initiation of depolymerisation by the terminal group mechanism suggest that the increase in selectivity of the process is due to an increase in the role of depolymerisation by the terminal group mechanism (Table 5). The ratio of the rate constants of random initiation to that on terminal groups during degradation in the presence of $MgCl_2 \cdot AlCl_3$ is higher than in the presence of $NaCl \cdot AlCl_3$ (Table 5), although the tendency for this ratio to decrease with an increase in temperature also remains.

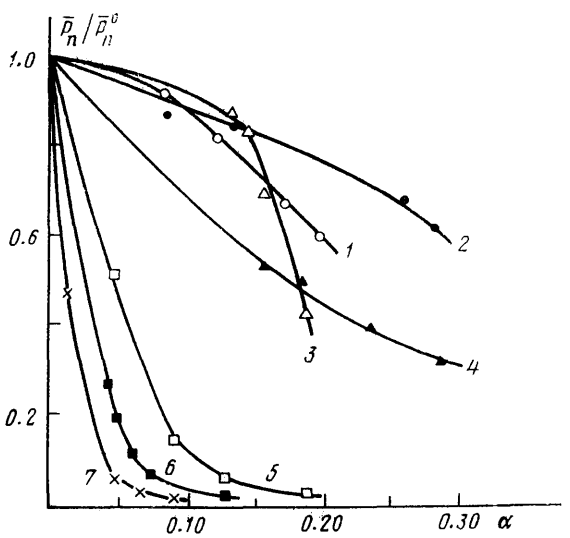

Figure 1. Dependence of relative degree of polymerisation during degradation of polyisobutylene on degree of conversion of samples of polyisobutylene. Initial degree of polymerisation: *1*, 15; *2*, 17; *3*, 20; *4*, 49; *5*, 360; *6*, 1790; *7*, 3570. Catalyst—$NaAlCl_4$, temperature—473 K.

Qualitative proof of the prevailing role of initiaiton by the random mechanism is provided by the nature of the variation in the curves of the dependence of the relative degree of polymerisation on the degree of conversion of the polymer, in particular the marked fall in $\bar{P}_n/\bar{P}_n^0$ at only small degrees of conversion of PE (Fig. 3) and the experimentally determined lack of dependence of the rate of the process on $\bar{P}_n^0$. At the same time similar results obtained using PIB suggest that there is a clearly defined dependence of the degree of conversion of the polymer on the molecular weight of the samples being degraded. Low-molecular weight polyisobutylenes (M = 800–2000) with a high content of terminal double bonds mainly undergo depolymerisation by the terminal group mechanism and the relative degree of polymerisation changes only slowly (Fig. 1, curves *1–3*). An increase in the molecular weight of PIB (Fig. 1, curve *4*) and hence a decrease in the content of C=C double bonds results in a marked increase in the proportion of initiation reactions by the random mechanism and with a very considerable increase in the initial degree of polymerisation ($\overline{M}$ = 1800–16000) (Fig. 1, curves *5–7*), when the content of terminal double bond is small, initiation by the random mechanism plays a decisive role.

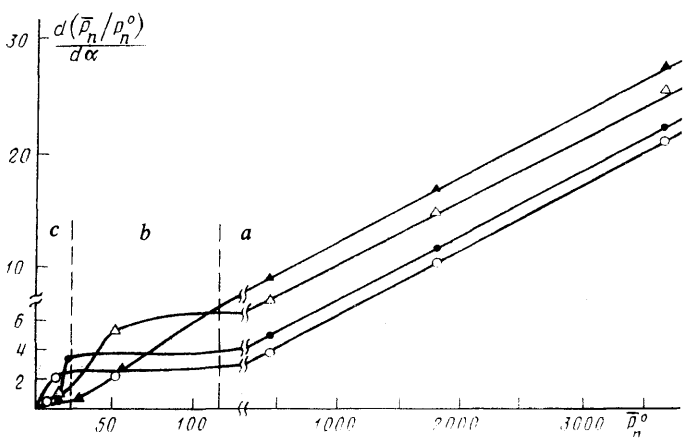

Figure 2. Change in $d(\bar{P}_n/\bar{P}_n^0)/d\alpha$ during degradation of polyisobutylene on an $NaAlCl_4$ catalyst at different temperatures: *1*, 473 K; *2*, 493 K; *3*, 513 K; *4*, 533 K.

VII. Effect of chemical structure of the polymer

For polyolefins that contain internal double bonds as well as terminal double bonds and possibly other defect groups as occurs in PE and BR, the ratio of initiation by the random mechanism to that on terminal groups varies during decomposition of the polymer.

Calculation of the kinetic parameters of catalytic degradation of PE in the presence of $NaCl \cdot AlCl_3$ shows that the values of the rate constants of initiation by the random mechanism are comparable to the rate constants of the overall process of polymer degradation (Table 6). This provides an indication of the predominance of random initiation of PE degradation and the small contribution of reactions that occur by the terminal group mechanism.

Hence, it can be maintained in general that the ratio of the number of internal labile groups (including C=C bonds) to terminal double bonds determines the nature of initiation of catalytic degradation of polyolefins and as a result has a considerable effect on the numerical values of the apparent rate constants of initiation.

VIII. Conclusion

Analysis of the currently available data on the catalytic degradation of polyolefins in the presence of different types of catalysts is able to demonstrate that acidity is one of the deciding factors in the variation in efficiency and selectivity of catalytic

degradation of polymers. However, up to the present time there has been no clear interpretation of the relationship between the acidity of the degradation catalyst and its activity and selectivity values for the majority of catalysts of polyolefin degradation (zeolites, aluminosilicates, superacids).

Table 5. Parameters of the initiation of catalytic degradation of polyisobutylene by random and terminal group mechanisms on different catalysts.

Catalyst	T, K	$k_{ti} \times 10^6$	z_t	$k_{ri} \times 10^6$	z_r	k_{ti}/k_{ri}	E_{ri}, kJ mol^{-1}	E_{ti}, kJ mol^{-1}
$NaAlCl_4$	473	1.6	–	0.2	8.1	8.1	69	47
	493	1.7	–	0.3	6.2	5.7		
	513	1.9	1.3	0.4	4.7	4.8		
	533	2.7	5.7	0.7	3.7	3.8		
$MgCl_2 \cdot AlCl_3$	473	3.35	–	0.3	8.4	10.8	70.7	45.8
	493	3.4	–	0.5	7.1	7.6		
	513	3.8	1.4	0.6	4.9	6.4		
	533	5.4	5.9	1.1	3.7	5.1		

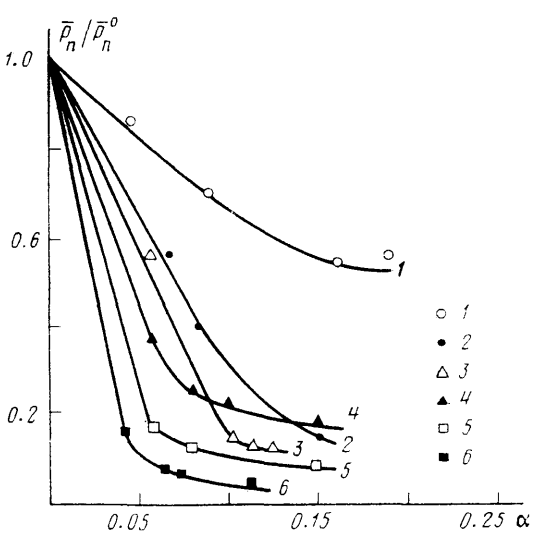

Figure 3. Dependence of change in relative degree of polymerisation on degree of conversion of samples of polyethylene with different initial molecular weights: *1*, 2 × 10^3; *2*, 2 × 10^4; *3*, 6 × 10^4; *4*, 1.45 × 10^5; *5*, 2.5 × 10^5; *6*, 2.7 × 10^5. Catalyst—$NaAlCl_4$; temperature—633 K.

It has been established that by using complex electrophilic catalysts of moderate acidity (considerably lower than the acidity of $AlCl_3$ and $HF{\cdot}SbF_5$) it is possible to increase the selectivity of the process.

The mechanism of the catalytic decomposition of polyolefins on electrophilic catalysts is based on reactions involving the formation of a polymer carbocation and its subsequent selective decomposition to form monomeric and other valuable low-molecular weight products. Initiation of the process is determined by the nature of the catalyst and the chemical structure of the macromolecules and occurs both randomly and on the terminal groups. From kinetic analysis it is possible to determine the ratio of these processes for polyolefins with different macrochain structures.

Table 6. Overall rate constants and rate constants of initiation of catalytic degradation of polyethylene by the random mechanism ($NaAlCl_4$).

T, K	$k_{ri} \times 10^7$, s^{-1}	$k_{rate} \times 10^7$, s^{-1}
573	0.25	0.93
593	0.21	1.50
613	0.95	2.80
633	1.31	6.90
653	1.71	8.70

Note: E_{ri} = 79 kJ mol^{-1}; E_a (overall reaction) = 92 kJ mol^{-1}.

CHEMISTRY AND ECOLOGY

Proceedings of the Scientific Session of the Division of General Chemistry and Chemical Engineering of the Academy of Sciences of the USSR, Moscow, 27—28 February 1989

During the last decade humanity fully recognised the necessity for thrift as regards all kinds of natural resources and for the reduction of the anthropogenic stress exerted on the environment. This recognition has been reflected in the concept of a steady development of the world community, whose elements are already being realised in countries possessing a strong economic base.

There has been a sharp growth of attention devoted to ecological problems also in our country—both in the community and at the governmental level. Serious attention is being devoted to such problems also in the activity of the Academy of Sciences of the USSR. A "program for the biosphere and ecological research by the Academy of Sciences of the USSR" was adopted in 1989 within the framework of which the "Chemistry and Ecology" section was formulated.

Ecology and its problems are connected by many links to chemistry. These involve the chemical reactions and processes in our environment, the wide variety of chemical industries with an enormous need for resources and energy and a large amount of harmful waste, the chemical pollutants arising from power engineering and transport, and the wide-scale employment in our economy and in the social sphere of a wide variety of chemical substances and products.

However, although chemistry and chemical substances and products constitute one of the principal sources of pollution of the environment, they at the same time open the most universal and effective routes leading to the overcoming of these undesirable phenomena.

The scientific session of the Division of General and Technical Chemistry of the USSR Academy of Sciences was held on 27—28 February, 1989 and the principal aspects and specific results of studies carried out within the framework of the "Chemistry and Ecology" subprogram were discussed. The proceedings of this session are published in the present issue of the journal *Uspekhi Khimii*.

The reports combined under the heading "Chemosphere and Ecology" analyse a series of important aspects of the pollution of the environment by chemicals and describe the present state of the corresponding research. In considering the problems concerning the protection of nature, it is at the same time important not to be content with merely raising the alarm but to become involved as soon as possible in the constructive solution of such problems. In this connection, interesting reports are included in the section "Introduction of Ecological Factors into Chemical Industries" and "Introduction of Ecological Factors into Power Engineering and Transport".

Overall, the proceedings of the scientific session constitute an effective base for the provision of a systematic framework and for speeding up the work of research chemists on acute modern ecological problems.

The preparation and holding in our country of the International Conference on "Chemistry and Steady Development—A Clean Environment, Waste-Free Technologies, Effective Utilisation of Energy" in September of next year should stimulate a new wide-scale employment of the advances in modern chemical science and technology for the solution of complex ecological problems and for improving the quality of the environment.

I. CHEMOSPHERE AND ECOLOGY

Translated from *Uspekhi Khimii* 3 499–506 (1991)

Protection of the environment and chemical ecology

A V Fokin
Nesmeyanov Institute of Hetero-organic Compounds, Academy of Sciences of the USSR, Moscow

A large amount of wide-ranging information on questions of ecology has appeared in the literature in recent years. Ecological problems are being debated not only by scientists pursuing various fields of research but also by journalists, writers, and workers associated with the arts.

Despite the accessibility and array of knowledge on ecology, it would nevertheless be advisable to examine these problems from the chemical standpoint if for no other reason because chemistry and the chemical industry are one of the main sources of disturbance of the equilibrium in the biosphere and because they may provide effective measures and routes for the protection of the environment from so-called anthropogenic activity.

In his studies in the first quarter of this century the eminent Russian scientist, V I Vernadskii, advanced the concept of the biosphere. He perceived the biosphere as the outer membrane of the planet. The Earth, situated within the limits of the atmosphere, hydrosphere, and lithosphere, is covered with living matter. As regards many of their properties the atmosphere, the entire hydrosphere, and a deep layer of the lithosphere are subjected to the same forces as living organisms throughout their life-span and evolution.

The air, soil and water form the totally integrated system of the biosphere, which supports all living matter, generates all energy, and despite its great vitality consists of fragile and vulnerable mechanisms. Vernadskii considered that the combined activity of all organisms on the Earth is the most powerful geochemical factor transforming the Earth's surface and an energy generating factor of planetary proportions. Having developed clear concepts on the role of the biosphere Vernadskii focussed his attention on the fact that the industrial and technological activities of man at the present time is having such a great effect on the change of the face of the Earth that they may be regarded as a "new" geological factor and that human forces have become commensurate with the forces of nature.

The interaction between the biosphere and humankind has proved to be the most important of the modern-day problems of science and technology which are present in abundance and the overall resolution of this problem is a priority for science and technology.

A feature of the modern era is the development of a society which is at variance with the limited life-supporting potential of the biosphere. While the activities of man did not interfere in the affairs of nature, nature herself created the essential conditions for her own development and equilibrium. Processes of self-regulation which balanced human activity have existed in nature. Traditionally this activity, which includes industrial production, has developed on the basis of the concept that nature's resources are unlimited and that the natural environment has limitless ability to undergo self-purification.

On account of compensation mechanisms and huge structural flexibility the biosphere's ecosystem until now has been somehow able to balance the consequences of man's activity. However, increasing human activity, the growth of energy use and technical power of society, and human interference detached from scientific forecasts have led to the contamination and transformation of the biosphere which is becoming an irreversible and frightening process. The resources of dry land and the oceans are becoming depleted, all elements of the environment are becoming contaminated, ecosystems are being degraded, and the biochemical cycles of matter are being impaired.

There are countless ways in which man can pollute the atmosphere, the seas, lakes and rivers. Wash waters from chemical plants, acids, alkalies, dyes and resins, mercury-containing compounds, cadmium, tin, and other metals, wastes from the petroleum, paper, cast-iron, and steel industries, wastes from tanneries, and automobile factories and mines, many tonnes of fertilisers and pesticides washed from the fields, icebergs of detergent foam, and waste products from municipal sewerage. The air, the earth, and the water have been unremittingly diluted and all of these poisonous discharges have been hidden. However the burden has now become inadmissible.

Humankind has finally understood that a strong barrier against the destruction of nature should be erected. A movement in support of the protection of nature is underway, the science of ecology has been created, the government have started to introduce legislation, and state and public organisations have been set up in order to protect the environment in which we live and in which our descendents will live.

The key problems related to ecology are problems of pollution and purification of the atmosphere and the oceans of the world, soil

erosion, depletion of the ozone layer, the global change in the Earth's climate, and the build-up of toxic substances in the biosphere. Most of these problems are associated with a combination of naturally occurring and extraneous chemical substances introduced into the biosphere, and this combination forms the so-called chemosphere. The undesirable changes in the chemosphere mainly on account of anthropogenic activity cause a fall in productivity of natural ecosystems, the death of hydrobionts and forests, and the disappearance of individual species and populations in the plant and animal kingdoms. These factors ultimately have a negative effect on society by retarding its development and they constitute a threat to the survival of humankind.

The increase in variety and quantity of industrial output also leads to an increase in the amount of wastes consequently generated including the so-called xenobiotics, which previously did not exist in nature and which in many ways are foreign to living organisms. Illnesses (allergic, genetic, teratogenic, endocrinal, etc.), which have become more frequent in recent years, are a consequence of such technogenic changes.

According to World Health Organisation (WHO) statistics 40 – 50% of human diseases are presently associated with an increase in ecological stress. Current forecasts indicate that anthropogenic changes in the environment are creating a real threat to the survival of humankind.

Man's interference in natural processes which causes large-scale changes is primarily manifested as the contamination of the atmosphere, the hydrosphere, and the lithosphere, and these are essentially questions of chemistry.

The vast expanse of the ocean of air leads certain people to the conclusion that there is no need to avoid contamination as in the case of water. However statistics on the growing discharge of chemicals into the atmosphere demonstrate that the conservation of pure air is becoming a major problem and that atmospheric pollution has now reached global proportions.

Industrial gases released into the atmosphere present the greatest danger. Huge metallurgical, chemical and oil refinery plants are concentrated in cities and industrial areas. Power plants, thermal power stations, gas-generating plants, and innumerable automobiles and large numbers of people are concentrated in such locations. With population growth and the expansion of industry the loading of the biosphere with gaseous and aerosol discharges has reached global proportions.

All industrial installations utilise a mineral fuel such as oil, coal, oil shale, solar oil, petrol, and kerosene. When the fuel is burned, in addition to carbon dioxide oxidation products of sulphur-containing compounds, oxides of nitrogen, carbon monoxide, and other harmful gases are formed. It has been calculated that industrial installations and chemical and metallurgical plants and other factories and heat and electric power plants release annually into the atmosphere more than 150 million tonnes of sulphur dioxide, 200 million tonnes of ash, and tens of millions of tonnes of aerosols.

By the year 2000 the discharge of sulphur dioxide could reach 450 million tonnes per annum. Sulphur dioxide is known to be harmful to human health even at a concentration of one part per million. The concentration of this gas reaches 5 parts per million or more in industrial areas. Sulphur dioxide is one of the most terrifying enemies of plants. This gas pollutes the air, sours fresh waters and the soil, and is a cause of acid rain, which annihilates entire forest areas. Depending on the moisture content of the air sulphur dioxide is usually converted into a sulphuric acid aerosol. Discharges of hyrogen sulphide, which is also a toxic gas affecting man and animals, are highly dangerous. Top of the league in this regard is the Astrakhan gas condensate factory, which in 1987 released more than one million tonnes of hydrogen sulphide into the atmosphere.

One of the most potent atmospheric pollutants is carbon monoxide, which enters the atmosphere in amounts reaching tens of millions of tonnes during the combustion of all kinds of fuels and especially automobile and engine fuel. It was previously believed that only high concentrations of carbon monoxide were harmful to man. However, studies have shown that the constant presence of even low concentrations of this gas causes cardiovascular diseases, stenocardia, lesions of coronary vessels, and atherosclerosis, and a decrease in the survival rate following infarction.

Factors associated with atmospheric pollution should also include the release of carbon dioxide which is increasing year by year. During the combustion of all kinds of fuels at least 1×10^{10} tonnes of carbon dioxide are released annually into the atmosphere and this gas absorbs a significant proportion of energy emitted by the Earth's surface.

Furthermore carbon dioxide does not impede the penetration of sunlight to the Earth and thereby creates the "greenhouse" effect. It has been suggested that as the concentration of carbon dioxide in the atmosphere increases there will be an increase in the quantity of thermal energy in the surface layers of the atmosphere and on the Earth's surface. By the year 2000 the content of carbon dioxide in the atmosphere may increase from 0.032 to 0.0375 and even to 0.040%. This global increase may cause climatic changes and other deleterious consequences. 1988 was the hottest year this century. The mean temperature in the eighties was found to be 0.34 °C higher than successive decades from 1949 to 1979.

On account of these alarming observations WHO has organised a working group for the study of climatic changes. However it is necessary to investigate and obtain evidence for the "greenhouse" theory, which was initially advanced by Soviet scientists. For example in the last century a similar warming up of the climate was recorded but this was followed by a cooling of the climate. Nevertheless, the danger of ecological changes caused by a cooling of the climate is very serious, since it may lead to a regression of the permafrost, thawing of ice, flooding of the land, and other disasters.

All forms of transport create great ecological losses. Exhaust gases, wash waters, and solid wastes from transport account for more than 30% of total pollution.

During the combustion of chemical fuel in the recovery of metals from ores and electrolysis of salts heavy metals (mercury, lead, vanadium, tin, etc.) are introduced into the environment and constitute dangerous sources of poisoning for humans, animals, and plants. For example with each tonne of caustic 600 grammes of mercury are lost. This metal in itself is a hazard and becomes especially dangerous, when this element is transformed into organomercurial compounds.

Contamination of the atmosphere with oxides of nitrogen and the Freon 11 and 12 type of propellants leads to the depletion of the ozone layer in the atmosphere which being in the upper layers of the atmosphere serves as a defence against the ultraviolet rays of the sun.

In normal operating periods nuclear power stations discharge gaseous aerosol products (krypton-85, xenon-133, radioactive iodine-131, and tritium) into the atmosphere. In addition to gases, solid radioactive fission products (promethium-147, ruthenium-106, cesium-137, strontium-90, zirconium-95, etc.) are also formed, and

the half-life period of these components varies from several months to thirty years. Almost all fission radioactive isotopes apart from the gaseous products undergo transformation into acidic waste solutions during the treatment of fuel elements. These solutions accumulate in nuclear chemical plants and present a difficult problem in regard to reprocessing and safe storage. The quantity of radioactive fission isotopes is increasing together with the increase in nuclear power engineering and burial of these products presents an exceptionally difficult problem. In fact when the Soviet Union constructs nuclear power stations abroad, it regulates the nuclear fuel and fuel elements, and they are returned with the radioactive fission products for reprocessing and burial. Thus there is a requirement to store not only Soviet radioactive wastes but also radioactive wastes from abroad. The safety of operation of the nuclear power stations themselves creates a special ecological problem as is exemplified by the Chernobyl disaster.

The amount of oil being extracted worldwide is in excess of three billion tonnes. Not taking into account accidents and catastrophes the losses of oil during transportation are equivalent to 1% of this figure. This implies that more than 30 million tonnes of oil are transferred largely into the oceans of the world. In the USSR 400 million tonnes of petroleum products are transported per annum by railroad alone. These products pollute the soil and water and other elements of the environment. In the USA petroleum products are conveyed to the consumers by a system of supply lines. A 2200 thousand kilometer network of pipelines enable losses of fuel to be sharply reduced. Of course oil is less harmful to nature than other pollutants but the huge volume produced and the corresponding volume of losses make a significant contribution to the contamination of the natural environment.

Large-scale pollution of water resources is taking place. The total quantity of water in the hydrosphere is 1400 million cubic kilometres, and 97% of this water is present in the oceans and seas, 2.14% exists in the form of ice, while only 0.29% is present in the form of fresh water on the land. In the USSR the amount of freshwater available is extremely small. Furthermore river basins including the Volga basin are being continually polluted. The ecological situation of water basins is deteriorating as a result of the multitude of chemical plants, paper and pulp mills, oil refineries, and textile factories located in areas of water. For example a single chemical plant on the banks of the Volga annually discharges forty five thousand tonnes of wastes from aniline dye manufature into the Volga.

Thousands of establishments situated along river banks in the USSR discharge annually into these rivers more than three million cubic metres of dilute acids, approximately two million cubic metres of liquid wastes including petroleum products, and millions of cubic metres of water contaminated with salts, alkalies, mineral oils, and dyes. Where do these wastes come from? Contaminated water is the result of modern-day industrial technology. The production of one tonne of synthetic fibre generates 500 cubic metres of sewage water, and this volume is increased several-fold when one takes into account the dilution of the sewage.

Present-day industrial manufacturing processes create enormous irreversible losses of fresh water leading to an increase in shortages of fresh water.

Water is also polluted at farms in which plant protection measures are adopted. We live in an age in which chemicals are extensively used in agriculture and forestry. In addition to artificial fertilisers large quantities of chemical agents are used for pest and weed control. They are of great benefit by helping to preserve the harvests of agricultural crops. For the Soviet Union alone they preserve 18–20% of the harvest.

However on account of the large-scale and at times incorrect methods of application these substances have become a serious factor in regard to the increase in ecological stress. The use of chemical products in agriculture and forestry has become the target of acute and well-founded criticism. Many negative aspects of the use of pesticides are associated with the fact that scientifically based use recommendations are abused in practice. Rates of application, use periods, and instructions for use are disregarded. However, there is another side to this problem.

In the USSR large miscalculations have been made in the elaboration of chemical systems for plant protection and the justification of their use. This situation has led to the extensive development of the production of several kinds of chemicals harmful to man and to the concentration of large quantities of dangerous chemicals and chemical plants in certain areas of the country. Underestimation of the danger of excessive production of organochlorine compounds has left its mark.

The danger of chlorine production is determined not only by the acute and chronic toxicity associated with the production of large tonnages of compounds such as hexachloran, DDT, polychlorocyclodienes and other compounds but also by polychloropolycyclic compounds (PCPC)†, which are formed as impurities in many processes involving the use of elemental chlorine and chlorine-containing substances together with aromatic organic compounds (dioxin, dibenzofuran, chlorazobenzene, and similar substances) and which are responsible for significantly more harmful and distant effects. These substances are particularly dangerous on account of their high biological activity, high chemical stability in the environment and in living organisms and their ability to be transferred from one living organism to another in nature. Even when present in negligible concentrations PCPC compounds suppress the immune system of organisms and reduce their ability to become adapted to the changing conditions of the outside world.

This type of action is accompanied by an increase in the sensitivity of the organisms to infection, particularly viral diseases, and by a decline in mental and physical working capacities. At higher concentrations (several tens of parts per trillion) PCPC compounds are found to exert a mutagenic, carcinogenic, teratogenic, and embryotoxic effect, and these compounds adversely affect the central and peripheral nervous sytem, the alimentary canal, and other organs.

Polychloropolycyclic compounds primarily 2,3,7,8-tetrachlorodibenzo-*p*-dioxin or simply dioxin inhibit all aerobic microorganisms in ecosystems, the organisms known to be responsible for the accumulation of organic substances and for the conservation and growth of the organic potential. In the human body these compounds inhibit genetically encoded mechanisms of adaptation to the natural environment, i.e. the immune system.

Intensive accumulation of PCPC compounds in nature commenced in the period in which DDT and hexachloran production unfolded. Especially large quantities of these agents began to be produced after plants were created for the production of polychlorophenols and polychlorinated biphenyls. However the manufacture and use of chlorine-containing pesticides is not the only source of PCPC compounds.

† For more detailed information see the paper by A F Kolomiitsa "Polychloropolycyclic xenobiotics" in the present issue.

These compounds are also formed in paper and pulp mills, when the paper pulp is bleached with chlorine or chlorinating agents. One cannot rule out the possibility that these xenobiotics will appear in water during chlorine disinfection procedures.

Dioxin and dienzofuran may appear in exhaust gases in non-optimised regimes for burning rubbish and wastes containing organochlorine materials. Burning articles made from polyvinyl chloride has proved to be particularly dangerous.

Exacerbation of the medical and ecological situation in cotton-growing regions of central Asia and Moldavia and the rice-growing areas in the Sea of Azov region, and the stressed state of ecosystems in the Sea of Azov and the Caspian Sea in may ways is the result of the underestimation of the effects of chlorine production and plants from which PCPC compounds are introduced into the natural environment. For example on the territory of Uzbekistan alone over the last decade approximately six thousand tonnes of chlorine-containing pesticides (in terms of active ingredient) have been used each year, despite the fact that the use of these compounds has been banned abroad.

The herbicide, propanil, which contains harmful polychlorazo-benzenes and the use of which is prohibited abroad, has been introduced and is extensively used in this country. In the USSR production of hexachloran and DDT continues. Hexachlorophene and dichloraniline, which contain harmful xenobiotics or their precursors, are also produced.

Certain pesticides which have been banned abroad have until recently been imported (for example keltan, tophos, diuron). In this country the large-scale production of polyvinyl chloride, and articles manufactured from this compound is carried out and the use and destruction of the latter are not controlled. A large number of outmoded pulp and paper mills are still in operation and in these establishments there are no facilities for the effective purification of sewage waters, and treatment of drinking water with chlorine has still not been replaced by ozonisation. It is possible to list more examples of this type.

These inconsistencies primarily arise as a result of a lack of any understanding of ecological problems and a low level of ecological awareness. Thus, so far no scientific strategies for the assessment of the ecological hazards of chemical reagents have been elaborated in the USSR. There is a lack of methodology for the prediction of ecologically acceptable routes for the advancement of chemical sciences and industry. Fully developed chemical ecology does not yet exist in this country.

Resolutions of questions concerning the control of chemical pollution reflect outdated approaches to the evaluation of the ecological hazard of chemical agents, since these approaches are based on the study of the properties of individual chemicals. Such a strategy does not take into account many associated factors. Under real life conditions a living organism in nature is exposed to the action not of a single substance but a combination of all naturally occurring and man-made chemical compounds present in the biosphere. In this case it is essential to take into acocunt the possible additive, antagonistic, and synergistic effects of the compounds in the chemosphere. For example in the presence of dioxins there is an abrupt increase in the hazard associated with the action of mycotoxins (aflatoxins and nivalenols) and carcinogen precursors (arylamines) and neurotoxic poisons on the body.

It should be emphasised that it is not the susbtances themselves but the impurities, decomposition products, and products of metabolism which may affect man and nature. One should also take into consideration the fact that, with the appearance of foreign substances in natural environments and their associated harmful effect on ecosystems, a change in the composition of the chemosphere occurs and the direction and consequences of this type of change can not yet be predicted.

The examples and facts presented indicate the importance and significance of the action of chemicals on the stressed state of the biosphere and the need to thoroughly investigate questions of chemical ecology.

It is evident from the experience gained in ecological studies carried out in the industrially developed countries that comprehensive characterisations of the ecotoxicity of chemical agents may be obtained on the basis of a fundamental knowledge of the chemosphere and its effect on ecosystems. Moreover it is surprising that the "Project of Concepts in the Programme of Biosphere and Ecology Studies by the Academy of Sciences of the USSR in the Period up to the Year 2015", which was assessed in the general assembly of the Academy of Sciences of the USSR devoted to ecology, does not include a unit concerned with the chemistry of the biosphere and chemical anthropogenic effects on nature as one of the main directions of research. Questions concerning the chemistry of the environment included in separate units of the project do not span the complete range of problems of chemical ecology but reflect an outmoded utilitarian approach to the evaluation of the ecological hazards of chemical agents.

It would be expedient to include "The Study of the Chemosphere" as a separate priority direction in this project. Fundamental studies within the framework of this unit should provide for the following sections:

—The establishment of the fundamentals of ecotoxicology as a science concerned with the effect of chemical agents on the biosphere and the development of methods of ecological normalisation. In this case it would be necessary to start from the position that, when chemical agents are used for intensive farming practices, efforts to achieve maximum bioproductivity are incompatible with the conservation of the natural environment. Thus from the ecological standpoint it is necessary to approach so-called intensive agricultural technology with great caution.

—The elaboration of scientific bases for the prediction of ecologically safe routes for advancement in the chemical industry, the creation of ecologically balanced industrial technologies and use of chemical agents. In this case the potential hazards presented by the chemical plants themselves should be assessed. Mathematical modelling of the spread of all kinds of pollution is also a necessity. At this stage it would probably be necessary to include a study of the problem of alternative fuels and studies on the sharp reduction in water consumption by industry, as for example in the "close-up" of water systems.

—The creation and organisation of essentially novel resource-saving technologies in which no wastes or very small quantities of wastes are generated.

—The elaboration of effective techniques for the purification of gaseous, liquid and solid wastes based on sorption, membrane, catalytic, and other technological processes.

—The development of pathways for the prevention of chemical and microbiological contamination of agricultural products and the environment.

—The elaboration of scientific strategies for improving the sanitation of ecosystems adversely affected by chemical agents.

—The creation of non-persistent pesticides and other chemical agents which are readily degraded and rapidly assimilated into the

natural environment and which have no harmful effect on the environment.

Information on the state of natural systems especially in regard to chemical and other kinds of contamination is of enormous importance for the protection of the environment. Most of the operative information on the biosphere is currently provided by the Earth's artificial satellites which have a resolving power of better than 10 m. However such information is suitable for "the monitoring of areas" but is inadequate for "the monitoring of the state" of natural systems. The elaboration of convenient techniques, equipment, and instruments for obtaining quantitative measurements of environmental parameters is of great importance for attaining progress in terrestrial monitoring. In this regard the design of instruments and the development of techniques which employ chemical or physicochemical principles will play an important role. The design of novel and readily obtainable instruments and techniques will improve the accuracy, validity, and range of measurable parameters in natural systems.

These are merely a few of the directions for research into the field of chemical ecology and they will undoubtedly be supplemented by new directions in the elaboration of a chemical ecology programme.

On account of the sharp increase in potential hazards to man and nature posed by the accumulation of xenobiotics in the environment, special national programmes have been organised on this aspect of chemical ecology by the industrially developed countries and through international collaboration. For example since 1980 international conferences on dioxin have been held. Of the major producers and users of chlorine products only the Soviet Union is not participating in the international collaboration on this problem and so far has no kind of programme for engaging in research into this problem. Extension of international collaboration on questions of chemical and other aspects of ecology is also an urgent necessity and should constitute a significant part of the programmes being prepared and projects targetted towards the protection of the environment.

The main objective of chemical ecology is the conservation of the vital qualities of the biosphere and the prevention of progressive pollution of the natural environment by reorganisation of anthropogenic activity which would promote the growth of industrial and agricultural output and which would exclude any unfavourable effect on nature. Ultimately the problem concerns the elaboration of conditions and measures which would promote the further development of human civilisation and the survival of humankind.

The chemical physics of the ozone layer

V L Tal'rose, I K Larin
Institute of Energy Problems of Chemical Physics,
Academy of Sciences of the USSR

The ozone layer exerts a significant effect on the properties of the middle atmosphere and creates the conditions under which the flora and fauna can exist on the Earth's surface. These features of the ozonosphere are in a sense caused by the unique physicochemical properties of ozone. The ozone molecule absorbs solar radiation intensely in the wavelength region below 290 nm, which is harmful to biological matter, and also (although less intensely) the "terrestrial" infrared radiation at a wavelength of 9–10 μm thereby enhancing by 10% the greenhouse effect caused by carbon dioxide and other radiatively-active components of the atmosphere. On the other hand ozone molecules are highly reactive on account of the low value of the energy bond between the "third" oxygen atom and the oxygen molecule. It is correct to say that the chemistry of the atmosphere and the troposphere and particularly the chemical processes associated with anthropogenic contaminants and their destruction in the atmosphere are controlled by ozone, albeit with the loss of the molecule itself.

As regards the effect of atmospheric ozone on global ecology it can be ascertained that the ozone layer is important as a factor providing a biologically safe level of ultraviolet radiation close to the Earth's surface and is involved in the conservation of the Earth's overall climate and controls the content of certain anthropogenic and natural contaminants in the atmosphere. It is noteworthy that the latter usually is under the shadow of the opposite problem, the effect of anthropogenic impurities on the ozone content. However these problems are evidently closely associated.

The stratification of the middle atmosphere caused by the change in temperature and distribution of ozone with altitude is shown in Fig. 1. The stratosphere contains the main reserves of ozone. The maximum concentration is found at an altitude of 20–25 km. At these altitudes the relative content of ozone in the atmosphere is about 1 ppm, and the total quantity of ozone in the atmosphere is equivalent to 3.3 billion tonnes. This quantity would correspond to a gas layer 3 mm in depth at normal temperature, and pressure. It should also be mentioned that ozone is not uniformly distributed over the Earth. On average there is less ozone in the tropics and more at the poles. In addition at all latitudes the total content of ozone changes with the seasons.

The above-mentioned aspects of the ecological significance of ozone will now be discussed.

I. The role of the ozone layer as a filter for biologically harmful ultraviolet radiation

This effect is caused by the fact that short-wave radiation at $\lambda < 300$ nm is harmful to many biological molecules, especially for DNA. The ozone layer which exists at present successfully fulfils a radiation protective function which may be judged according to the change in the intensity of sunlight in the 210–290 nm wavelength range with altitude. There is a distinct dip in the intensity of

natural environment and which have no harmful effect on the environment.

Information on the state of natural systems especially in regard to chemical and other kinds of contamination is of enormous importance for the protection of the environment. Most of the operative information on the biosphere is currently provided by the Earth's artificial satellites which have a resolving power of better than 10 m. However such information is suitable for "the monitoring of areas" but is inadequate for "the monitoring of the state" of natural systems. The elaboration of convenient techniques, equipment, and instruments for obtaining quantitative measurements of environmental parameters is of great importance for attaining progress in terrestrial monitoring. In this regard the design of instruments and the development of techniques which employ chemical or physicochemical principles will play an important role. The design of novel and readily obtainable instruments and techniques will improve the accuracy, validity, and range of measurable parameters in natural systems.

These are merely a few of the directions for research into the field of chemical ecology and they will undoubtedly be supplemented by new directions in the elaboration of a chemical ecology programme.

On account of the sharp increase in potential hazards to man and nature posed by the accumulation of xenobiotics in the environment, special national programmes have been organised on this aspect of chemical ecology by the industrially developed countries and through international collaboration. The chemical physics of the ozone layer

V L Tal'rose, I K Larin
Institute of Energy Problems of Chemical Physics,
Academy of Sciences of the USSR

The ozone layer exerts a significant effect on the properties of the middle atmosphere and creates the conditions under which the flora and fauna can exist on the Earth's surface. These features of the ozonosphere are in a sense caused by the unique physicochemical properties of ozone. The ozone molecule absorbs solar radiation intensely in the wavelength region below 290 nm, which is harmful to biological matter, and also (although less intensely) the "terrestrial" infrared radiation at a wavelength of 9–10 μm thereby enhancing by 10% the greenhouse effect caused by carbon dioxide and other radiatively-active components of the atmosphere. On the other hand ozone molecules are highly reactive on account of the low value of the energy bond between the "third" oxygen atom and the oxygen molecule. It is correct to say that the chemistry of the atmosphere and the troposphere and particularly the chemical processes associated with anthropogenic contaminants and their destruction in the atmosphere are controlled by ozone, albeit with the loss of the molecule itself.

As regards the effect of atmospheric ozone on global ecology it can be ascertained that the ozone layer is important as a factor providing a biologically safe level of ultraviolet radiation close to the Earth's surface and is involved in the conservation of the Earth's overall climate and controls the content of certain anthropogenic and natural contaminants in the atmosphere. It is noteworthy that the latter usually is under the shadow of the opposite problem, the effect of anthropogenic impurities on the ozone content. However these problems are evidently closely associated.

The stratification of the middle atmosphere caused by the change in temperature and distribution of ozone with altitude is shown in Fig. 1. The stratosphere contains the main reserves of ozone. The maximum concentration is found at an altitude of 20–25 km. At these altitudes the relative content of ozone in the atmosphere is about 1 ppm, and the total quantity of ozone in the atmosphere is equivalent to 3.3 billion tonnes. This quantity would correspond to a gas layer 3 mm in depth at normal temperature, and pressure. It should also be mentioned that ozone is not uniformly distributed over the Earth. On average there is less ozone in the tropics and more at the poles. In addition at all latitudes the total content of ozone changes with the seasons.

The above-mentioned aspects of the ecological significance of ozone will now be discussed.

I. The role of the ozone layer as a filter for biologically harmful ultraviolet radiation

This effect is caused by the fact that short-wave radiation at $\lambda < 300$ nm is harmful to many biological molecules, especially for DNA. The ozone layer which exists at present successfully fulfils a radiation protective function which may be judged according to the change in the intensity of sunlight in the 210–290 nm wavelength range with altitude. There is a distinct dip in the intensity of

sunlight in the above-mentioned wavelength range. However, in the 300 nm wavelength region ozone does not so effectively absorb light and the light intensity rapidly increases with increase in wavelength.

It is generally agreed that the increase in skin cancer diseases in people living at low latitudes and other biologically unfavourable consequences for the fauna and flora which have not been fully investigated is the result of a decrease in the ozone content of the atmosphere (possible also as a result of the influence of anthropogenic factors).

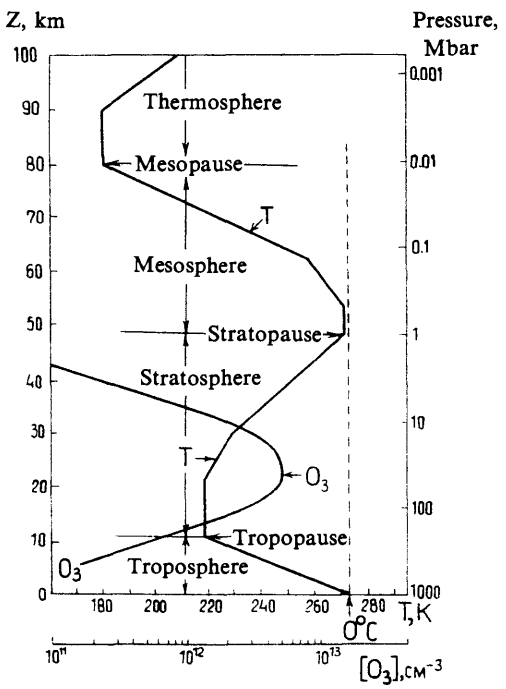

Figure 1. Stratification of the Earth's atmosphere.

II. The ozone layer as a climate-forming factor

The effect of the ozone layer on the climate is also associated with the absorption of light not only in the ultraviolet but also in the infrared region. It has already been mentioned that in absorbing infrared radiation emerging from the Earth's surface the ozone layer intensifies the greenhouse effect. However the question of the link between ozone and the climate is much more complex, because of the significantly larger number of physical and chemical factors which may affect the content of ozone in the atmosphere, since the effect of ozone on the temperature of the Earth's surface and climate is dependent on the altitude at which a change in the content of ozone occurs.

When the ozone content changes, the overall temperature effect is dependent on the absorption of short-wave and long-wave radiation. The plot in Fig. 2 illustrates how the temperature of the Earth's surface will change if the ozone content increases at different altitudes within a narrow range of altitudes when there is 3% change in temperature throughout the entire column. It is evident that up to an altitude of 30 km an increase in the content of ozone will lead to a warming of the Earth's surface and at altitudes above 30 km there will be a cooling of the Earth's surface. In this case the maximal effect will occur, when the ozone content changes in the tropopause region. At these altitudes the effect may be attributed to absorption and over-irradiation by the "terrestrial" infrared radiation at a wavelength of 9–10 μm.

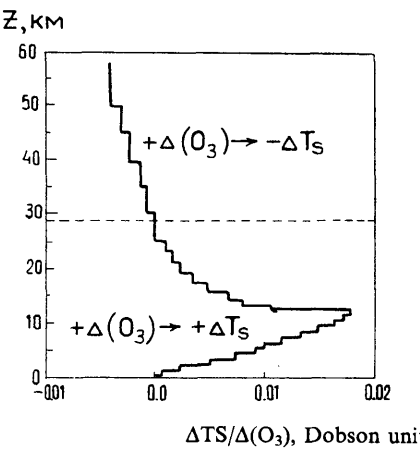

Figure 2. "Radiation" change in the temperature at the Earth's surface when the total content of ozone changes by 3% on account of the local change in ozone content at different altitudes[1] (D. U. = Dobson units).

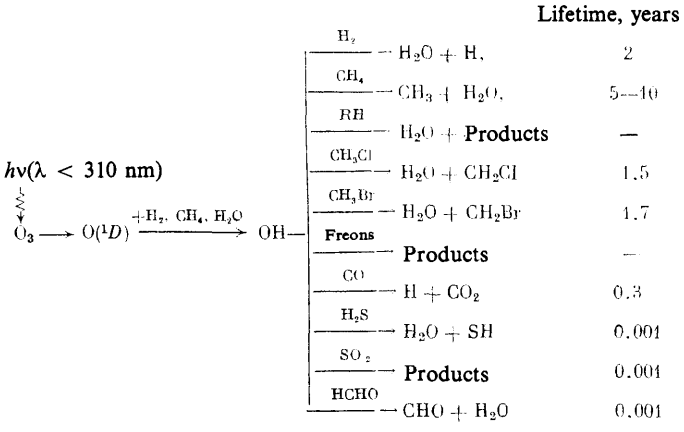

It is known that the greenhouse effect reaches a maximum at the maximal temperature contrast between absorbed and emitted radiation and that the temperature reaches the lowest values in the tropopause region.

"Cooling" as a result of the increase in content of ozone at altitudes greater than 30 km is associated with the absorption of solar radiation.

The possible change (according to data issued by the World Meteorological Organisation) in temperature of the Earth's surface within 50 years as a result of a change in the composition of microcontaminants in the atmosphere including ozone during expansion of industrial and agricultural production is shown in Fig. 3. It is apparent from assessment models that the ozone content will increase in troposphere and decrease in the stratosphere. This leads to effects acting in one direction and being additive. In this regard one should emphasise that these evaluations are not highly accurate, since it is difficult to take into account all feedbacks which arise in the system. The temperature change range for the various microcontaminants corresponds to the potential range of changes of their content within fifty years. It is evident that the maximum possible climatic effect of ozone may be even greater than that of carbon dioxide.

III. Atmospheric ozone as a factor in the chemical degradation of contaminants entering the atmosphere

It has been mentioned above that chemically active solar radiation with a wavelength shorter than 300 nm does not penetrate the troposphere and in the photochemical sense one might say that eternal night reigns. However various chemical processes occur in this short-wave "darkness" which are caused by the absorption of longer wavelength ultraviolet radiation by ozone. The mode of action of ozone towards anthropogenic and natural atmospheric components in the troposphere is presented below. The lifetimes of the atmospheric components governed by their reactions with the hydroxyl radical are also presented below. The basis of this mechanism is that photolysis

of ozone by light with a wavelength of 300—310 nm leads to the creation of metastable excited oxygen atoms in state ^1D with an energy of 1.97 eV and a radiative lifetime of 110 sec (i.e. very great in comparison with the time between collisions under tropospheric conditions). By reacting with water vapour, hydrogen and methane the $O(^1D)$ radicals form the hydroxyl radical, which in turn interacts with many anthropogenic and natural contaminants, thereby determining their lifetime in the atmosphere.

The mechanism described is an important component of the overall mechanism for the removal of contaminants from the troposphere and, as can be seen below, its actual existence may lead to the protection of the ozonosphere from certain Freons.

One should mention that similar processes also occur in the stratsophere, although in this case short-wave radiation is the main factor acting upon the Freons, and furthermore from the ecological standpoint these processes are not of such key importance as in the troposphere.

The ecological importance of the ozone layer and therefore the reason why it is essential to conserve this layer unchanged has already been mentioned.

Of all the anthropogenic factors which are potentially damaging to the ozone layer the present authors are only focussing on those Freons, which are generally considered to present the greatest hazard to the ozonosphere. This conclusion is based on results obtained by many authors over the past fifteen years from numerical modelling and from laboratory data and full-scale measurements.

An example of a model prediction of the change in content of ozone in the presence of Freons and other anthropogenic and natural contaminants is presented in Fig. 4. It is apparent from these data that the ozone content may significantly decrease with increase in the production of Freons (one has in mind mainly Freons 11 and 12).

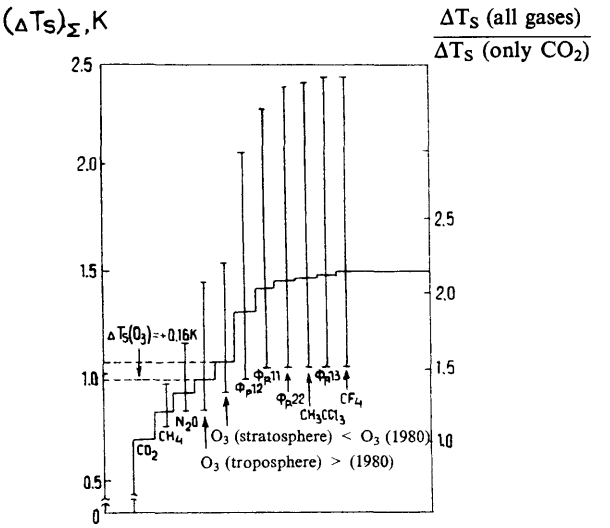

Figure 3. Change in temperature of the Earth's surface within fifty years as a result of the increase in various minor components in the atmosphere.

As regards the experimentally determined ozone trend, according to data obtained with the aid of the American satellite Nimbus-7 between 1978 and 1985 there was a 2.6 to 10% decrease in the ozone content in different latitudinal zones and an increase in the content of chlorine, and the anthropogenic proportion of the latter is nowadays one third of the total number of chlorine particles in the atmosphere.

Finally the observation in 1985 of the so-called Antarctic ozone "hole", which is characterised by a decrease of tens percent of the total content of ozone in this region in spring, supports the argument that the Freons pose a real threat to the ozonosphere.

These findings have led to the adoption of international agreements on refrigeration and the subsequent phaseout of the production of ozone-destroying Freons, which are the main source of supply of anthropogenic chloride to the stratosphere. One has in mind the Vienna convention on the protection of the ozone layer (23 May 1988) and the Montreal Protocol of the convention adopted in September 1987 and ratified by the Soviet Union in September 1988. Essentially the question concerns the prospects of renouncing the production of ozone-destroying Freons and replacing them by ozone-friendly compounds, ideally by Freons which possess the same physicochemical and biological properties but which do not destroy the ozone layer.

As a result the need arose to compare the extent of the hazard which different Freons presented to the ozonosphere and to select the less active so-called alternative compounds.

In order to meet this objective it was at first necessary to answer the question why are certain Freons harmful while others present no

hazards for the ozonosphere. In order to answer this question it was necessary to understand the mode of action of the Freons on stratosphere ozone. The mode of action is relatively well understood and in general terms all Freons, which enter the stratosphere, undergo photodissociation in the presence of solar ultraviolet radiation with emission of chlorine atoms or atoms of other halogens which destroy ozone in the following chain of reactions:

$$Cl + O_3 \rightarrow ClO + O_2,$$
$$ClO + O \rightarrow Cl + O_2.$$

In each pair of reactions of this type two particles of so-called odd oxygen, O and O_3, disappear while the chlorine atom is conserved, thereby enabling one chlorine atom to enter the stratosphere to destroy up to 100 000 ozone molecules. This "chemical amplification" is the reason for the potential hazard of Freons for the ozone layer.

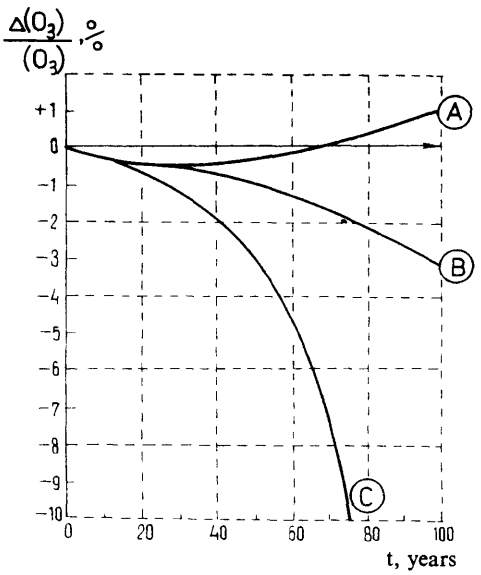

Figure 4. Change in the total content of ozone for different scenarios of increase in anthropogenic contaminants in the atmosphere[1]: A, an increase in content of CH_4 by 1% per annum; N_2O, a 0.25% increase per annum; CO_2, a 0.5% increase per annum in comparison with the level of 1980 (without any increase in content of Freons); B is A + a 1.5% increase in the content of Freons per annum in comparison with 1980; C is A + a 3% increase in the content of Freons per annum in comparison with 1980.

Thus if Freons undergo photodissociation or by some other route supply halogen atoms to the stratosphere, the ozone will be destroyed.

If the Freons underwent photodissociation or were destroyed in the troposphere, ozone-destroying particles would not appear in the stratosphere, since they may normally be rapidly washed on to the Earth's surface.

Thus a search for compounds which present no hazard for ozone would involve the identification of compounds which are destroyed in the troposphere.

It can be demonstrated that of all possible processes for the destruction of Freons in the troposphere the most important are those reactions with a hydroxyl radical and reactions involving photodissociation in the presence of light with a wavelength of more than 300 nm entering the troposphere.

The relative hazard of chlorine-containing Freons may be quantified according to the following formula:

$$\xi = W_{str}/(W_{str} + W_{trop}),$$

where W_{str} and W_{trop} is the rate of destruction of the Freon in the stratosphere and troposphere respectively. According to this formula the hazard rating of Freons 11 ($CFCl_3$) and 12 (CF_2Cl_2), which are extensively used nowadays and which are not destroyed in the troposphere, is equal to unity, while for the required ideal Freons, which undergo total degradation in the troposphere, a hazard value of zero will be obtained.

Knowing the concentration of hydroxyl radicals in the troposphere it is possible to find the minimal value of the rate constant for the reaction between the Freon and OH so that this process could have competed with the photodissociation process of Freons 11 and 12 in the stratosphere giving a lifetime of 100 years, a value typical of ozone-destroying Freons. Setting the characteristic reaction time of the Freons with OH to 100 years it is found that the required value of the rate constant should be equal to or in excess of the value of 3×10^{-16} cm^3 s^{-1}.

In fact there is a larger group of Freons with a rate constant value for the reaction with OH significantly higher than this minimal value, and the lifetime is less than 100 years. These compounds include Freons containing hydrogen atoms which can be detached by the hydroxyl radical. Freons which contain no hydrogen atoms, do not react with OH, and hence they are not degraded via this route in the troposphere. This group of compounds includes Freons 11 ($CFCl_3$), 12 (CF_2Cl_2), 113 ($C_2F_3Cl_3$), 114 ($C_2F_4Cl_2$), and 115 (C_2F_5Cl) which are extensively used in refrigeration technology and other branches of the economy and which are considered to be ozone-destroying compounds. It also follows that it could have been possible to find a substitute for these ozone-destroying compounds. However, this is not such a simple objective, because in a decomposition in which a hydrogen atom is detached from the molecule while the remaining radical can still travel around the troposphere the halogen (chlorine or bromine) remains a hazard for the ozonosphere. This reduces the problem to the chemical (with respect to the subsequent collision of the radical) or photochemical "troposphere" fate of this radical, a problem which still requires investigation.

For this reason the prediction of the extent of the hazard for ozone based on the photo-detachment of the dangerous halogen by troposphere ultraviolet radiation would be a more realistic approach.

Of those Freons which are being developed in the MGO Tekhnokhim in Leningrad as alternative compounds, three Freons are currently under investigation in the Institute of Energy Problems of Chemical Physics, Academy of Sciences of the USSR, i.e. Freons 123 ($C_2HCl_2F_3$), 134 ($C_2H_2F_4$) and 114B2 ($C_2F_4Br_2$). It has been found that with all of these compounds the rate constants of the reactions with free hydroxyl are such that for at least two of them (if these reactions would be adequate) degradation would primarily occur in the troposphere. Unfortunately the extent of

photodissociation of these two compounds by troposphere ultraviolet radiation was found to be extremely low.

The prediction in relation to the third compound, $C_2F_4Br_2$, is more realistic. The extent of light absorption in the 300 nm region was found to be low (10^{-22} cm^2) but adequate, so that $C_2F_4Br_2$ underwent photodissociation primarily in the troposphere. Nevertheless on account of the significantly greater efficiency of bromine particles in comparison with chorine particles the hazard of $C_2F_4Br_2$ was found to be greater than that of for example Freons 11 and 12.

Thus the problem of the assessment of the hazard of alternative compounds can be considered to be correctly set up but further studies are necessary in order to resolve this problem.

Mathematical modelling of the distribution of atmospheric contaminants taking account of chemical transformations

N M Bazhin, V V Penenko, A E Aloyan, G N Skubnevskaya
Institute of Chemical Kinetics and Combustion, Siberian Section of the Academy of Sciences of the USSR, Novosibirsk

The troposphere is the layer of the atmosphere adjacent to the surface of the Earth. Although the altitude of this layer is small, no more than 11 km, it plays a dominant role in the chemical processes which take place in the atmosphere. Various chemical impurities enter the troposphere, originating both from the Earth's surface as a result of natural geological, biological, chemical and physical processes, and from the upper layers of the atmosphere. In recent years, a considerable proportion of substances entering the troposphere have stemmed from anthropogenic influences, their strength being in some instances comparable to that of natural sources. A very important outcome of the anthropogenic influences is the emission into the atmosphere of substances which either do not occur in the natural state, or have until now been present in very small concentrations as, for example, freons. This may have completely unexpected and hardly foreseeable consequences.

On entering the atmosphere, the impurities become immediately involved in processes of two types:
(a) physical dilution and transport caused by different processes of diffusion and motion of air masses;
(b) chemical transformations.

The aim of the present work is to describe secondary mechanisms of atmospheric pollution, associated with the chemical transformation of impurities in the troposphere, and modelling of these mechanisms combined with hydrometeorological processes.

1. Chemical transformation of substances in the troposphere

Let us consider the possible ways of chemical transformation of substances in the troposphere. The following can be regarded as the main impurities in the troposphere: O_3, CO_2, CO, NO, NO_2, NH_3, CH_4, H_2, SO_2, CH_2O, H_2S, etc.[1] Under typical conditions (at a temperature of 25 °C) all these substances are stable enough. With few exceptions, they do not react with each other or with the main components of the atmosphere. A typical exception is apparently nitric oxide, capable of entering the reaction

$$2NO + O_2 \rightarrow 2NO_2,$$

However, the rate of this reaction, too, is insignificant as long as the NO concentration is low. Nevertheless, chemical transformations in the atmosphere do occur.

The main reason for these chemical reactions is the effect of solar radiation on constituents of the atmosphere.[2] The spectrum of solar radiation measured at the Earth's surface and in the stratosphere, is shown in Fig. 1. It is clear from it that only photons with wavelengths in excess of 300 nm reach the surface of the Earth. Thus in the troposphere photochemical dissociation of oxygen, and even to a greater extent that of nitrogen, into atoms is impossible, although some impurities may undergo photolysis. Table 1 presents some information on these components.[3]

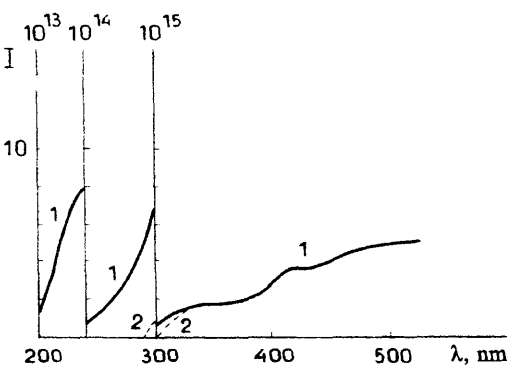

Figure 1. Spectrum of solar radiation.[3] *I* is the number of photons per second reaching an area normal to their propagation: *1*, in the stratosphere; *2*, at the Earth's surface.

It can be seen from the table that the number of substances undergoing photochemical dissociation in the atmosphere is small. Yet some of these substances, for example, HNO_2, H_2CO, NO_2, and O_3, may exhibit very high dissociation rates, their lifetimes in the troposphere being as short as a few hours. However, not all these processes play an important part in the elimination and transformation of tropospheric substances, since the path a particular substance has entered the atmosphere is also important. For example, the photolysis of nitrous acid HONO, which proceeds at a high rate, leads to the formation of OH and NO radicals, but then nitrous acid itself is formed in the atmosphere (if one excludes its anthropogenic origin) as a result of the reaction between OH and NO particles:

$$OH + NO \rightarrow HONO.$$

photodissociation of these two compounds by troposphere ultraviolet radiation was found to be extremely low.

The prediction in relation to the third compound, $C_2F_4Br_2$, is more realistic. The extent of light absorption in the 300 nm region was found to be low (10^{-22} cm^2) but adequate, so that $C_2F_4Br_2$ underwent photodissociation primarily in the troposphere. Nevertheless on account of the significantly greater efficiency of bromine particles in comparison with chorine particles the hazard of $C_2F_4Br_2$ was found to be greater than that of for example Freons 11 and 12.

Thus the problem of the assessment of the hazard of alternative compounds can be considered to be correctly set up but further studies are necessary in order to resolve this problem.

Mathematical modelling of the distribution of atmospheric contaminants taking account of chemical transformations

N M Bazhin, V V Penenko, A E Aloyan, G N Skubnevskaya
Institute of Chemical Kinetics and Combustion, Siberian Section of the Academy of Sciences of the USSR, Novosibirsk

The troposphere is the layer of the atmosphere adjacent to the surface of the Earth. Although the altitude of this layer is small, no more than 11 km, it plays a dominant role in the chemical processes which take place in the atmosphere. Various chemical impurities enter the troposphere, originating both from the Earth's surface as a result of natural geological, biological, chemical and physical processes, and from the upper layers of the atmosphere. In recent years, a considerable proportion of substances entering the troposphere have stemmed from anthropogenic influences, their strength being in some instances comparable to that of natural sources. A very important outcome of the anthropogenic influences is the emission into the atmosphere of substances which either do not occur in the natural state, or have until now been present in very small concentrations as, for example, freons. This may have completely unexpected and hardly foreseeable consequences.

On entering the atmosphere, the impurities become immediately involved in processes of two types:
(a) physical dilution and transport caused by different processes of diffusion and motion of air masses;
(b) chemical transformations.

The aim of the present work is to describe secondary mechanisms of atmospheric pollution, associated with the chemical transformation of impurities in the troposphere, and modelling of these mechanisms combined with hydrometeorological processes.

1. Chemical transformation of substances in the troposphere

Let us consider the possible ways of chemical transformation of substances in the troposphere. The following can be regarded as the main impurities in the troposphere: O_3, CO_2, CO, NO, NO_2, NH_3, CH_4, H_2, SO_2, CH_2O, H_2S, etc.[1] Under typical conditions (at a temperature of 25 °C) all these substances are stable enough. With few exceptions, they do not react with each other or with the main components of the atmosphere. A typical exception is apparently nitric oxide, capable of entering the reaction

$$2NO + O_2 \rightarrow 2NO_2,$$

However, the rate of this reaction, too, is insignificant as long as the NO concentration is low. Nevertheless, chemical transformations in the atmosphere do occur.

The main reason for these chemical reactions is the effect of solar radiation on constituents of the atmosphere.[2] The spectrum of solar radiation measured at the Earth's surface and in the stratosphere, is shown in Fig. 1. It is clear from it that only photons with wavelengths in excess of 300 nm reach the surface of the Earth. Thus in the troposphere photochemical dissociation of oxygen, and even to a greater extent that of nitrogen, into atoms is impossible, although some impurities may undergo photolysis. Table 1 presents some information on these components.[3]

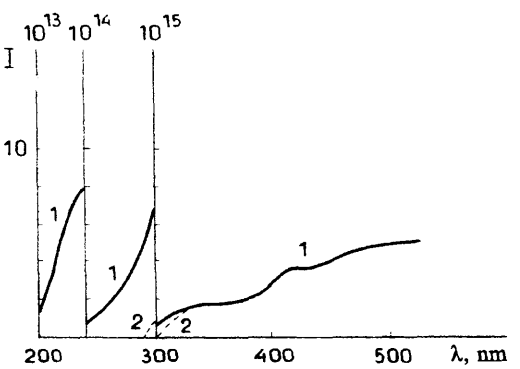

Figure 1. Spectrum of solar radiation.[3] *I* is the number of photons per second reaching an area normal to their propagation: *1*, in the stratosphere; *2*, at the Earth's surface.

It can be seen from the table that the number of substances undergoing photochemical dissociation in the atmosphere is small. Yet some of these substances, for example, HNO_2, H_2CO, NO_2, and O_3, may exhibit very high dissociation rates, their lifetimes in the troposphere being as short as a few hours. However, not all these processes play an important part in the elimination and transformation of tropospheric substances, since the path a particular substance has entered the atmosphere is also important. For example, the photolysis of nitrous acid HONO, which proceeds at a high rate, leads to the formation of OH and NO radicals, but then nitrous acid itself is formed in the atmosphere (if one excludes its anthropogenic origin) as a result of the reaction between OH and NO particles:

$$OH + NO \rightarrow HONO.$$

Therefore, the formation of HONO represents more of a sink of OH radicals than a source of them, so that a physically maintained equilibrium should exist in the troposphere

$$OH + NO \underset{h\nu}{\rightleftarrows} HONO.$$

Table 1. Chemical transformations of substances in the troposphere.

Substance	λ, nm	Photochemical reactions	Quantum yield
O_3	440÷850	$O_3 \rightarrow O(^3P) + O_2(^3\Sigma)$	~1
	300÷360	$O_3 \rightarrow O(^3P) + O_2(^1\Sigma \text{ or } ^1\Delta)$	~1
	200÷320	$O_3 \rightarrow O(^1D) + O_2(^1\Delta)$	~1
H_2CO	300÷365	$H_2CO \rightarrow H_2 + CO$	0.5÷0.6 [4]
	300÷330	$H_2CO \rightarrow H + HCO$	0.3÷0.5 [4]
NO_2	368	$NO_2 \rightarrow NO + O(^3P)$	~1 (λ = 313 nm)
HONO	370	$HONO \rightarrow OH + NO$	~1
HNO_3	300	$HNO_3 \rightarrow OH + NO_2$	~1
H_2O_2	254	$H_2O_2 \rightarrow 2OH$	~1

The situation is similar with nitric acid, hydrogen peroxide, and formaldehyde. The photodissociation of NO_2 cannot likewise result in a rapid transformation of impurities, since the former process involves the formation of an oxygen atom in the ground state $O(^3P)$. In the atmospheric conditions with a high content of oxygen, this atom reacts almost immediately with O_2 to form ozone.

The photolysis of ozone occurs in two ways. In the long-wavelength region ($\lambda > 320$ nm), photolysis brings about the formation of an oxygen atom in the ground state, $O(^3P)$, whereas at shorter wavelengths an oxygen atom in the excited state, $O(^1D)$, is formed. A feature of this atom is that it can react with water molecules, yielding two OH radicals:

$$O(^1D) + H_2O \rightarrow 2OH.$$

It is these reactions, resulting in the formation of OH radicals, that are responsible for nearly all the variety of chemical processes in the troposphere. It is worth noting that ozone enters the troposphere from the stratosphere,[1] although in the event of a high level of atmospheric pollution, one should take account of ozone sources within the troposphere.

Fig. 2 presents a scheme illustrating the general character of the chemical reactions involved. Its most characteristic feature is the occurrence of chain reactions of the type $OH \rightarrow HO_2 \rightarrow OH$. However, the chain lengths are short, being no more than several units in the layer adjacent to the surface of the Earth. Another peculiarity resides in the fact that the initial transformations of stable impurity components begin with reactions involving the OH radical. For example, the transformation of methane in the atmosphere begins with the reaction

$$OH + CH_4 \rightarrow CH_3 + H_2O,$$

followed by the reactions

$$CH_3 + O_2 \rightarrow CH_3O_2,$$

$$CH_3O_2 + NO \rightarrow NO_2 + CH_3O,$$

$$CH_3O + O_2 \rightarrow HO_2 + CH_2O,$$

$$NO_2 \xrightarrow{h\nu} NO + O,$$

$$O + O_2 \rightarrow O_3 \text{ etc.}$$

This means that substances incapable of reacting with the OH radical will have very long lifetimes, as found in the case of freons.

To describe the scheme presented in Fig. 2, one should consider approximately 40 reactions. The question is therefore often asked whether the number of reactions that need to be considered could be made smaller. As previously mentioned, the key species responsible for the transformations in the troposphere is the OH radical. The above question may be therefore worded as follows: let us assume that a reaction is important if a change in its rate by a factor of 2 results in a change in the hydroxyl concentration of 10% or more. In this case we would need to consider only 10 reactions. If the same assumption is made also to apply to all the intermediate radical species, one should consider 24 reactions.

Hence it is impossible to reduce substantially the number of reactions that need to be taken into account without a loss in the accuracy of description. It is worth noting that the validity of the kinetic description is supported by the fact that calculated concentrations of different substances agree fairly well with those obtained experimentally.[5] This allows us to formulate and solve the more complicated problem, namely simultaneous description of the processes of the transport and transformation of impurities.

2. Mathematical model of the transport and transformation of impurities

To describe the processes of the transport of impurities that would take account of chemical reactions we need mathematical models that will adequately reproduce from the physical viewpoint the motion of the atmosphere over the Earth's nonuniform surface, redistribution of various pollutants in the lower layers of the atmosphere, their transport to the upper levels, and incorporation into the system of atmospheric circulation.

One of the main 'blocks' of mathematical models developed for the solution of environmental problems is that describing the processes of the transformation of impurities. The design of such a block is governed by the fact that the atmosphere of each industrial region or city is characterised by a specific assortment of substances of natural and anthropogenic origin which may interact with each other and undergo transformations. Therefore the block describing the transformation of impurities should be specially adapted to fit the environmental conditions of the sites under investigation.

Atmospheric impurities form a multicomponent medium. The different components interact with the atmosphere and with each other. Depending on the specific physical formulation of a problem and the objectives pursued, one may describe the transformation of substances with different degrees of detail. In doing so, the 'lifetime' of each substance may be regarded as its prime characteristic. However, prior to incorporating the model of reactions into the equation of the transport of impurities, this model should be adjusted so that it does not disturb the main equilibrium conditions with respect to the mass yield of substances.

Simulation of chemical processes in the atmosphere has special features of its own. Systems of differential equations describing

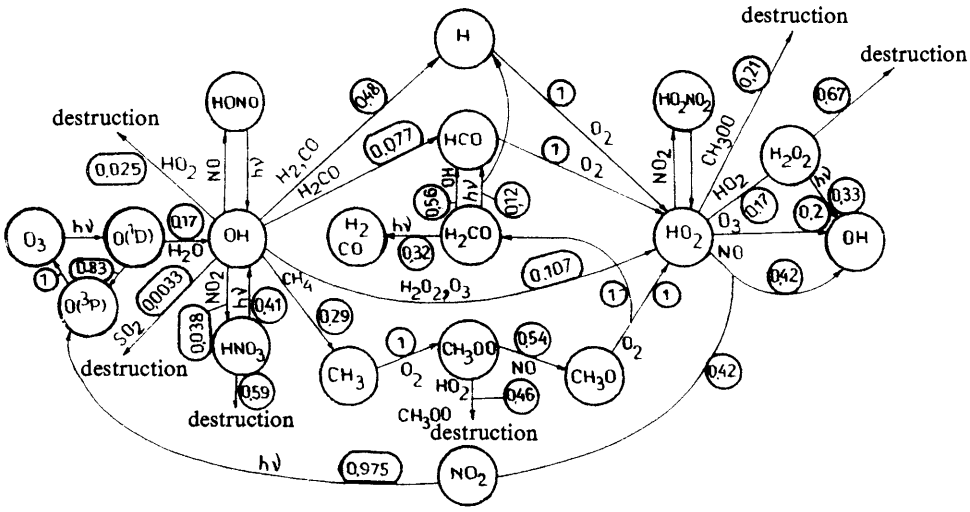

Figure 2. Scheme of chemical processes in the atmospheric layer close to the surface of the Earth; the numbers give the probability of the occurrence of particular reactions.

these processes are nonlinear. In actual problems, the number of reactions may be as great as several hundred, these reactions occurring throughout a three-dimensional domain comparatively large in size, since a typical size of an industrial region is about 100 km. Reaction rate constants differ from one another by orders of magnitude, their true values being not always precisely known. On the basis of their properties, the systems of differential equations which define the impurity transformation block may be classed as 'rigid' ones, characterised by a wide range of points within a spectrum of matrices of linearised equations. At each point of the three-dimensional space there may exist specific rigidity constraints, imposed on the system of equations, while the characteristic time scales involved in the description of chemical reactions should fit those of hydrometeorological processes. All this defines the main requirements that must be satisfied by mathematical models of the processes under study and methods of their computer-aided implementation.

The general structure of models and methods for the solution of a given class of problems, as well as examples of how to use them under specific conditions, are presented in Warneek's monograph.[6] In this paper we have therefore restricted ourselves to a brief account of the main stages of modelling.

As an example, let us consider the model of the transport and diffusion of an impurity in the atmosphere of an industrial region, these processes occurring against the background of local atmospheric events. We shall assume that all the required parameters of meteorological fields and their turbulence characteristics are given. These parameters are determined either through the use of hydrodynamic models or by measuring them in a real atmospheric environment.

Let us designate the domain as $D_t = D[0, \bar{t}]$, where D is the range of variation of spatial coordinates (x, y, z); $[0, \bar{t}]$ is the interval of time t, x and y are the coordinates in the horizontal plane and z is the altitude.

Let there be n gaseous impurities with concentrations

$$c_i = c_i(\vec{x}, t), \quad \vec{x} = (x, y, z), \quad (i = \overline{1, n}).$$

Let us designate the vector composed from these concentrations as

$$\vec{c} = \{c_i\} \quad (i = \overline{1, n})$$

and use the following system of equations to describe the processes of the transport and transformation of impurities:

$$\frac{\partial c_i}{\partial t} + \operatorname{div} \vec{u} c_i - \frac{\partial}{\partial x} \mu_x \frac{\partial c_i}{\partial x} - \frac{\partial}{\partial y} \mu_y \frac{\partial c_i}{\partial y} - \frac{\partial}{\partial z} \nu_z \frac{\partial c_i}{\partial z} +$$

$$+ B_i(\vec{c}, \theta) = F_i \quad (i = \overline{1, n}) \tag{1}$$

where

$$\operatorname{div} \vec{u} c_i \equiv \frac{\partial u c_i}{\partial x} + \frac{\partial v c_i}{\partial y} + \frac{\partial w c_i}{\partial z}; \quad \vec{F} \equiv \{F_i\} \quad (i = \overline{1, n})$$

are the sources of the impurities; $\vec{u} = (u, v, w)$ is the velocity vector; μ_x, μ_y and ν_z are respectively the coefficients of turbulent exchange of impurities in the directions x, y, and z, and θ is the air temperature. Judging by their structure, these coefficients are diagonal matrices of an order n, defined throughout the domain D_t. The coefficients of molecular diffusion are incorporated in ν_x, μ_y, and ν_z In principle, the effect of molecular diffusion may be neglected everywhere outside the lowest atmospheric layers adjacent to surface roughness. The rates of gravitational sinking or rise of impurities $w_g = \{w_i\}$ $(i = \overline{1, n})$ are incorporated in the vertical component w of the velocity vector $\boldsymbol{u}$. A matrix operator

$$B_i(\vec{c}, \theta) \equiv \{B_{ij}(\vec{x}, t, \vec{c}, \theta)\} \quad (i, j = \overline{1, n}) \tag{2}$$

defines the rates of change of the concentrations of impurities due to their transformation. Chemical reactions are nonlinear, i.e. the elements of an operator depend not only on the spatial coordinates and time, but also on the concentrations of the impurities themselves and the temperature.

A mathematical model deals with averaged fields of hydrometeorological parameters and concentrations of impurities. The scale of averaging depends on the procedure for the sampling of a model; in finite difference models this scale is characterised by the sizes of space–time cells of the lattice domain $D_t^n c D_t$. This should be taken into consideration when calculating the rates of transformation of impurities. It may be formally done through determining the average transformation rates from the average concentrations, using the same scale of averaging as that adopted in the sampling of the model. Such parametrisation procedure follows from the basic correlations of the balance of substances. Naturally, when this procedure is used, additional requirements are imposed on the choice of steps for the sampling of the model.

For the sake of simplicity, assume that contaminants do not directly influence the dynamics of the atmosphere. This assumption enables the transport and transformation processes to be considered against the background of motion of the atmosphere, the feedback from hydrothermodynamic processes being effected only through the flows of heat and moisture, and the radiation characteristics of the atmosphere.

The boundary conditions at the upper and lateral boundaries of a domain are set in such a way that the concentrations of impurities fit their background values. At the lower boundary, this condition is written in a parametric form, starting with the equation of the balance of impurities at the surface roughness level. Assuming that each impurity interacts independently with the surface of the Earth, we get

$$v_z \frac{\partial c_i}{\partial z} + \tilde{w}_i c_i = \beta_i c_i + f_{si} \quad (i = \overline{1, n}), \tag{3}$$

where β_i describes the interaction of an impurity i with the underlying surface, and f_{si} is the source of this impurity at the Earth's surface.

Different ways of parametrisation of the boundary conditions at the lower boundary of the air mass are used,[6] depending on the specific formulation of the problem.

At the initial moment, $t = 0$, the concentrations of impurities in the domain D are assumed to be known. The algorithm adopted for the solution of problems (1)–(3), is based on the splitting method. This leads to an effective and simple implementation of the model on a computer.

One usually distinguishes two stages of splitting of the equation system. The first describes the transport of impurities along the trajectories of air masses defined by the field of wind velocity $\vec{u}$, and their exchange through turbulence; the second describes the local conversions of impurities through transformation processes and takes account of their sources.

The computing algorithm is organised in such a way that, in the first stage, the equations of transport and turbulent diffusion are solved with respect to the concentrations c_i ($i = \overline{1, n}$) of each substance and independently of the others within the domain D^n and time interval $t_j \leqslant t \leqslant t_{j+1}$ with duration Δt. In the second stage, the mutual adaptation and interaction of all substances are accomplished at every point within the domain D^n independently from other points.

In practical calculations, the equation system describing the transformation of impurities need not be solved at every lattice point of the domain D^n, but only at those points where impurity concentrations reach certain threshold values, at which it becomes worthwhile to consider transformation processes. Confinement of the transformation of impurities to particular cells of the lattice domain D^n, which is a characteristic feature of the splitting method, is quite consistent with the short characteristic times of chemical reactions. Hence taking account of the transformation of impurities at an individual stage of splitting is one way of its parametrisation in numerical models. In this approach it is essential that changes in the description of particular reactions or of the mechanism of the transport of impurities as a whole are introduced at the level of separate blocks and do not affect the overall structure of the mathematical model.

The main principles of the design and implementation of models of the chemical transformation of impurities, were developed by simulating emissions which are most typical of the atmosphere of industrial cities: the emissions of sulphur-containing substances, nitrogen oxides and methane (as an illustration of the possible mechanisms of photochemical oxidiation of hydrocarbons). These individual types of transformations may occur in different combinations, depending on specific chemical conditions in the atmosphere of an industrial region. They have been incorporated in mathematical models of hydrometeorological processes and atmospheric pollution. Altogether up to 200 chemical reactions, involving 32 chemical species with different lifetimes, were included. These models were used to carry out a series of numerical trials covering a fairly wide range of possible emissions. Examples of these calculations have been reported earlier.[6–8] A model of the transport of impurities that took no account of transformation processes was also used in evaluating the impact of different anthropogenic sources of pollution on the Baikal lake area. From the analysis of results of the calculations conclusions were made as to the relative hazard to Baikal of sources located both in the lake area itself, and at greater distances in the Northern hemisphere.

Numerical trials performed with the aid of the models have demonstrated the advantages of a combined study of the conditions leading to the setting up of a hydrometeorological regime and the transport and transformation of impurities; this basic procedure makes it easier to take account of direct relations and feedbacks when estimating the influence of various natural and anthropogenic factors on the environment.

Transformation of nitrogen- and sulphur-containing compounds in the atmosphere and procedures for reducing the amounts of nitrogen and sulphur oxides in industrial waste

O M Sarkisov
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

Various nitrogen- and sulphur-containing compounds of both natural and anthropogenic origin enter the atmosphere of our planet. Examples of compounds of natural origin are reduced sulphur compounds [H_2S, CS_2, $(CH_3)_2S$, COS] and nitrogen-containing compounds (NH_3, N_2O). The principal sources of nitrogen- and sulphur-containing compounds of anthropogenic origin are nitrogen and sulphur oxides.

Various aspects of the protection of the air on our planet and in the first place the problem of "acid rain" require the knowledge of the mechanisms of the chemical transformations of nitrogen- and sulphur-containing compounds in the atmosphere. It is known that the appearance of "acid" rain may be caused by the increased content in the troposphere of the oxides NO_x and SO_2. The knowledge of the mechanisms of the formation and removal of NO_x and SO_2 from the troposphere is therefore essential. The understanding of the principles governing the self-purification of the tropsphere makes it possible to employ them for the creation of technological processes leading to a decrease in the anthropogenic NO_x and SO_2 waste ejected into the atmosphere.

The gas-phase processes relevant to the problem under consideration have been investigated for several years at the Institute of Chemical Physics of the USSR Academy of Sciences. Problems of practical importance are solved jointly with other organisations. For example, the solution of the problem of the influence of photochemical sources of sulphur and nitrogen compounds on the background level of air pollution on a regional and global scale is being sought jointly with the Laboratory for Atmospheric Monitoring. The development of methods for the purification of industrial gaseous waste is being prosecuted together with the Dzerzhinskii All-Union Thermotechnical Institute (VTI), the Southern Branch of the VTI (YuzhVTI), and the Krzhizhanovskii Energy Institute (ENIN).

Consistent study of the elementary reactions, on the basis of which the mechanisms of the chemical transformation of particular compounds in the atmosphere were devised, served as the starting point for the research being prosecuted. These studies have made a definite contribution to the understanding of the mechanisms of the oxidation of hydrogen sulphide, carbon disulphide, and ammonia in the atmosphere which has been achieved and have made it possible to propose physicochemical models for the technological developments designed to reduce the nitrogen and sulphur oxide waste ejected into the atmosphere.

$OH(v)$	N_2, O_2, O_3, CH_4, H_2	[18, 21]
$O_3(v)$	O	[22]

The majority of the gas-phase reactions in the atmosphere involve the participation of radicals. For this reason, three types of elementary processes were investigated: the reactions of radicals with the components of the atmosphere; the radical-destruction reactions on surfaces close in chemical composition to that of aerosols; elementary processes with participation of excited species (Table 1). The present day requirements are such that virtually only studies of elementary processes by direct spectroscopic methods are of practical value. For this reason, we developed new effective methods for the investigation of elementary processes based on advances in laser and computer techniques.[23]

$O_3(v)$	O	[22]

The majority of the gas-phase reactions in the atmosphere involve the participation of radicals. For this reason, three types of elementary processes were investigated: the reactions of radicals with the components of the atmosphere; the radical-destruction reactions on surfaces close in chemical composition to that of aerosols; elementary processes with participation of excited species (Table 1). The present day requirements are such that virtually only studies of elementary processes by direct spectroscopic methods are of practical value. For this reason, we developed new effective methods for the investigation of elementary processes based on advances in laser and computer techniques.[23]

It is possible to differentiate three types of methods. Intracavity laser spectroscopic (IRLS) methods[24] were developed jointly with members of the Lebedev Physical Institute. Priority on a worldwide scale has been achieved in these methods. The laser magnetic resonance (LMR) method in the IR range combined with EPR spectroscopy is the second procedure. An apparatus of this kind was first devised by Gershenzon and co-workers to investigate elementary processes.[25] The third procedure is the laser-induced fluorescence method combined with laser photolysis.[26]

These methods are highly sensitive ($\sim 10^7$ particles cm^{-2}), possess high time (10^{-7} s) and spectral (10^{-2} cm) resolutions, and make it possible to investigate various types of elementary processes.

With the aid of the above methods, we investigated the elementary reactions of the NH_2, HS, HSO, OH, HO_2, and HNO radicals with the components of the atmosphere (Table 1). On the basis of the results obtained in these studies and the available literature data, the mechanisms of the oxidation of ammonia, hydrogen sulphide, and carbon disulphide in the atmosphere were established.

It was assumed previously that minor components of the atmosphere are oxidised via the mechanism

$$M \xrightarrow{+OH} R \xrightarrow{+O_2} \ldots,$$

where M is a minor component of the atmosphere and R a radical. This mechanism involves two postulates. Firstly, as a rule the primary reaction of the minor component M is with a hydroxyl radical. Secondly, the main reaction of the R radical formed is with molecular oxygen. However, studies in recent years have shown that each minor component M can exhibit its specific features in its chemical transformation in the atmosphere and the above postulates are not general.

As suggested earlier, the mechanism of the oxidation of ammonia corresponds to the traditional mechanism

$$NH_3 \xrightarrow{+OH} NH_2 \xrightarrow{+O_2} NH_2O_2 + \ldots .$$

It has been shown[1,2] that the radical NH_2 hardly reacts with molecular oxygen at room temperature. The theoretical explanation of this finding is that the adduct NH_2O_2 has a weak N–O bond and rapidly decomposes in the reverse direction with formation of an NH_2 radical. The reactions of the NH_2 radical with the minor components of the atmosphere NO_2, NO,[3] and O_3[4] were investigated and it was shown that these reactions are fairly effective. The mechanism of the oxidation of ammonia in the atmosphere can be represented as follows:

$$NH_3 + OH \rightarrow NH_2 + H_2O, \quad (1)$$

$$NH_2 + NO_2 \rightarrow N_2O + H_2O, \quad (2)$$

$$NH_2 + NO \rightarrow N_2 + H_2O, \quad (3a)$$

$$NH_2 + NO \rightarrow N_2 + H + OH, \quad (3b)$$

$$NH_2 + O_3 \rightarrow NH_2O + O_2. \quad (4)$$

Reactions (2) and (3a) lead to the removal of nitrogen oxides, since the stable products NO_2 and N_2 are formed. A product of reaction (4) is the NH_2O radical whose reactions have not so far been investigated because of the lack of spectroscopic data for this radical. Nevertheless, our experimental data demonstrate qualitatively that the chemical transformation of this radical can lead to the formation of HNO and then NO_x, i.e.

$$NH_2O \rightarrow HNO \rightarrow NO_x.$$

There are two opposed views in the literature concerning the role of ammonia in the formation of nitrogen oxides in the atmosphere: some workers believe that the oxidation of ammonia is a major source of NO_x in the troposphere, while others believe that ammonia hardly contributes to the formation of NO_x in the troposphere. Within the framework of the mechanism established one may introduce the parameter α defined as the ratio of the rates of removal and formation of NO_x:

$$\alpha = \frac{k_2[NO_2] + k_3[NO]}{k_4[O_3]},$$

where k_2, k_3, and k_4 are the reaction rate constants and $[NO_2]$, [NO], and $[O_3]$ are the concentrations of the corresponding compounds in the troposphere.

Since the temperature dependences of the rate constants have been determined, it follows that, knowing the profiles of nitrogen oxides and ozone with respect to altitude and humidity, it is easy to calculate the influence of ammonia on the formation and elimination of NO_x. Estimates have shown that there may be regions in the lower troposphere for which α may be both greater and less than unity. However, if ammonia enters the stratosphere, then it undoubtedly removes nitrogen oxides, i.e. promotes the conservation of the ozone layer.[27]

As examples of the oxidation of reduced sulphur compounds, we shall consider the mechanisms of the oxidation of carbon disulphide and hydrogen sulphide. The mechanism of the oxidation of carbon disulphide in the troposphere can be represented as follows:

$$CS_2 + OH \longrightarrow CS_2OH \xrightarrow{O_2} COS + HSO_2.$$

According to this mechanism, the primary reaction is the association of CS_2 with the hydroxyl radical to form the adduct CS_2OH.[7] The adduct can decompose in the reverse reaction or can react with molecular oxygen.[28] It is then that further reactions of CS_2OH in the presence of oxygen lead to the formation of carbonyl sulphide and sulphur dioxide.[29] One can therefore postulate that the primary products are COS and HSO_2. The reactions of the radicals will be discussed below, but it is clear that it is in fact the reactions of HSO_2 with the components of the atmosphere which lead to the formation of sulphur dioxide.

The classical mechanism proposed previously for the oxidation of hydrogen sulphide was the reaction of hydrogen sulphide with the hydroxyl radical which affords the HS radical, which then reacts with molecular oxygen. However, it was found that the HS radicals react effectively with minor components of the atmosphere (nitrogen dioxide, ozone),[9,30] whereas the reaction with molecular oxygen is fairly slow. Although the existing estimate of the rate constant for the reaction of the HS radical with oxygen[31] still does not permit its complete exclusion, nevertheless one can assume at the present time the following sequence of principal reactions:

$$H_2S \xrightarrow{+OH} HS \xrightarrow{+NO_2,\ O_3} HSO \xrightarrow{+O_3,\ NO_2} HSO_2 \xrightarrow{O_2} SO_2.$$

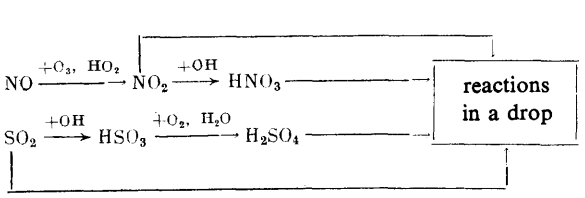
In this chain of elementary reactions,[7,9,10,30,31] virtually all the rate constants are known. We investigated the reactions of the HS and HSO radicals.[7,9]

As already stated, in the majority of the mechanisms considered, the primary oxidation reaction was assumed to be the reaction with the hydroxyl radical. This seemingly natural hypothesis was based on the fact that this radical is very reactive and its concentration in the atmosphere is adequate. However, data have been obtained recently[32] showing that the reaction of H_2S with the relatively unreactive HO_2 radical proceeds effectively:

$$HO_2 + H_2S \rightarrow HSO + H_2O. \quad (5)$$

This finding was checked both as regards the kinetics of the decrease in the HO_2 concentration and as regards the accumulation of HSO. The rate constant for this reaction is virtually the same as for the reaction of the hydroxyl radical with hydrogen sulphide. Since the concentration of the HO_2 radicals is approximately 100 times greater than the concentration of the OH radicals, we postulated a new mechanism for the oxidation of hydrogen sulphide:

$$H_2S + HO_2 \rightarrow HSO + H_2O,$$
$$HSO + NO_2 \rightarrow HSO_2 + NO,$$
$$HSO + O_3 \rightarrow HSO_2 + O_2,$$
$$HSO_2 + O_2 \rightarrow HO_2 + SO_2.$$



This is a chain mechanism of the oxidation of H_2S. The chain carriers are only two radicals—HO_2 and HSO. The rate constants for these reactions are known. The formation of HSO_2 in the reaction of HSO with ozone is tentative.

If our data for reaction (5) are correct, then the mechanism of the oxidation of carbon disulphide should also be revised. In this case, one can postulate the following mechanism:

$$HO_2 + CS_2 \rightarrow CS_2HO_2 + O_2 \rightarrow COS + HSO.$$

As regards other reduced compounds, the mechanism of their oxidation in the air has been less well investigated and therefore will not be discussed. One can only note that the principal product of the oxidation of these compounds is sulphur dioxide.

Nitrogen and sulphur oxides are removed from the atmosphere in two ways:[33] as a result of the dry deposition of SO_2 and NO_x and as a result of washing out by rain. There are in the latter case two ways in which nitrogen and sulphur oxide enter a rain drop, which can be illustrated by the following scheme:

The nitrogen dioxide and sulphur dioxide molecules can dissolve in water drops. The rate of their removal can then depend significantly on the concentrations in the drops of other substances, because if the latter react chemically with nitrogen dioxide and sulphur dioxide, then the ability of drops to absorb these gases will increase significantly compared with the level determined by Henry's law. The second channel leading to their removal involves gas-phase reactions with the formation of nitric and sulphuric acid molecules which enter the water drops.

Water drops containing nitrogen and sulphur oxides fall on the surface of our planet as rain. In certain regions, where there is much ammonia in the sinks for nitrogen oxides, the NH_2 radical can play a role analogous to that of hydroxyl radicals (its gas-phase reactions with nitrogen and sulphur dioxide):

$$NH_2 \xrightarrow{+NO_2} N_2O + H_2O,$$

$$NH_2 \xrightarrow{+SO_2} NH_2SO_2.$$

The latter reaction has been recently investigated.[34]

It follows from the foregoing that the OH and HO_2 radicals play an important role in the gas-phase atmospheric chemistry. It is therefore important to understand how the heterogeneous processes involving the destruction of these radicals on aerosols influence the nitrogen and sulphur formation and elimination processes. Processes leading to the destruction of the OH and HO_2 radicals on different surfaces, presented in Table 1, have been investigated.[13–15] The experiments were performed using surfaces whose chemical composition was close to that of the aerosols.

By generalising the experimental data obtained, the authors were able to conclude that the accommodation coefficients, i.e. the probability of the destruction of the radicals (γ) per collision with the surface, are within the following ranges for the OH and HO_2 radicals:

$$\gamma_{OH} \approx 10^{-2}—1; \quad \gamma_{HO_2} = 10^{-3}—10^{-2}.$$

Mathematical modelling based on the standard model of the atmosphere at aerosol concentrations typical for urbanised regions has shown that it is necessary to take into account the heterogeneous processes involving the destruction of both OH and HO_2 radicals.[35] The heterogeneous radical destruction reactions lead to an increase in the concentration of pollutants (for example, sulphur dioxide) in the lower atmosphere, which means that the self-purification of the troposphere is impaired with increase in the concentration of aerosols.

The calculations have also shown[36] that the heterogeneous OH radical destruction processes must be taken into account in the chemistry of the stratosphere as well. After volcanic eruptions, droplets of sulphuric acid, on which the heterogeneous destruction of OH radicals takes place very effectively, appear in the stratosphere. Allowance for the destruction of OH radicals leads to an increase in the concentration of nitrogen oxides, which leads in its turn to a decrease in the concentration of nitrogen in the ozone layer.

The third type of elementary processes investigated includes processes involving excited species, which are presented in Table 1. These studies were designed to elucidate the role of vibrationally excited species in the photochemistry of the stratosphere. As was to be expected, vibrationally excited species do not play a significant role in the troposphere.

As already stated, an appreciable amount of N_2O molecules travel from the surface of our planet to the atmosphere. These molecules are chemically inert and therefore readily reach the stratosphere, where they can participate in the formation of nitrogen oxides either under the influence of sunlight or as a result of their reaction with electronically excited oxygen atoms. The movement of NO_x to the troposphere naturally depends on the mechanism of the photochemical reactions in the stratosphere. The experimental data obtained for the deactivation processes and the reactions of excited species have made it possible to analyse the important role of the vibrationally excited species in the photochemistry of the stratosphere. Such species may be the vibrationally excited molecules of ozone $O_3(v)$ and the hydroxyl $OH(v = 9)$ (v is the

vibrational quantum number). The OH(v = 9) molecules are formed in the reaction

$$H + O_3 \rightarrow OH(v = 9) + O_2.$$

The interaction of OH(v = 9) with oxygen can lead either to the deactivation of OH(v = 9) or to the reaction

$$OH\ (v = 9) \xrightarrow{+O_2} H + O_3,$$
$$OH\ (v = 9) \xrightarrow{+O_3} OH\ (v = 8) + O_2.$$

Data obtained recently by Cheskis[37] for elementary processes involving OH(v) have shown that the rate constants for these two processes are comparable and they should therefore be taken into account in the photochemistry of the stratosphere. Allowance for these processes leads to an increase in the calculated ozone concentration in the ozone layer.

The interaction of OH(v = 9) with molecular nitrogen could also occur via two pathways:

$$OH\ (v = 9) \xrightarrow{+N_2} N_2O + H,$$
$$OH\ (v = 9) \xrightarrow{+N_2} OH\ (v = 8) + N_2.$$

Unfortunately there are no data concerning the pathway followed in the reaction of OH(v = 9) with nitrogen. However, estimates have shown that, if the rate constant for this pathway exceeds 3×10^{-15} cm^3 s^{-1}, then, when account is taken of OH(v = 9), the rate of formation of N_2O is comparable to the rate of arrival of N_2O from anthropogenic sources in the atmosphere. Ideas of this kind show that such high effectiveness of the vibrational energy in such reactions is possible.

At high altitudes (80 km), the concentration of oxygen atoms is high and vibrationally excited ozone molecules $O_3(v)$ are formed very effectively by the reaction

$$O + O_2 + M \rightarrow O_3(v) + M.$$

The $O_3(v)$ molecules can be either deactivated or they can enter into a chemical reaction with an oxygen atom:

$$O_3(v) \xrightarrow{+O} 2O_2,$$
$$O_3(v) \xrightarrow{M} O_3.$$

Experimental studies on the elementary processes with participation of $O_3(v)$ have shown[22] that the vibrational form of energy is effective in the reaction pathway. Estimates demonstrated[38] that processes with participation of $O_3(v)$ should also be taken into account in the mechanisms operating in the chemistry of the stratosphere. This process diminishes the calculated ozone concentration.

The development of methods for reducing the anthropogenic nitrogen and sulphur oxide waste ejected into the atmosphere constitutes an independent and important problem associated with the protection of the atmosphere. The understanding of the natural mechanisms of the elimination of nitrogen and sulphur oxides from the atmosphere and the study of elementary reactions made it possible to put forward chemical models for the reduction of nitrogen and sulphur oxide waste. Table 2 presents three methods for the removal of nitrogen and sulphur oxides from industrial gases. These methods are based to some extent on the principles governing natural sinks for the removal of nitrogen and sulphur oxides from the atmosphere.

The gas-phase ammoniacal purification method is based on the reactions which also occur in the atmosphere:

$$OH \xrightarrow{+NH_3} NH_2,$$
$$NH_2 \xrightarrow{+NO} N_2 + H_2O,$$
$$NH_2 \xrightarrow{+NO} N_2 + H + OH,$$
$$NH_2 \xrightarrow{+NO_2} N_2O + H_2O. \qquad (6)$$

The difference is that in the atmosphere there is a sufficiently high concentration of OH radicals (ultimately due to the effect of sunlight) and these processes can occur at room temperature. In the purification method considered, ammonia must be introduced at a fairly high temperature ($\sim$1000 K) of the effluent gases, where the branching route (6), capable of maintaining the required concentration of OH and NH_2 radicals, is significant. Studies by this method are conducted jointly with the VTI, where the technological version of this method has been applied. The method has been tested on the experimental industrial plant at the Kirovakan heat and power generating plant. However, an earthquake precluded the completion of these experiments. It has to be said that the method has not found a wide-scale development abroad hitherto, but ways of applying it at lower temperatures are being sought continuously. It is seen from the example of this method that the dry methods for the removal of nitrogen oxides must be based on the preparation of OH and NH_2 radicals at sufficiently high concentrations and low temperatures. These can be chemical, radiation, or photolytic methods.

Table 2. Methods for the removal of NO_x and SO_2 from effluent industrial gases.

Method	Reagent	Gas	Degree of purification, %	Products
Gaseous ammoniacal	NH_3	SO_2 NO_x	– 80	N_2, H_2O
Radiation-chemical	without reagents NH_3	SO_2 NO_x	90 90	HNO_3, H_2SO_4 $(NH_4)_2SO_4$, NH_4NO_3
Ozone-ammoniacal	O_3, NH_3	SO_2 NO_x	95 80	 $(NH_4)_2SO_4$, N_2, N_2O

In the radiation-chemical purification methods, the required NH_2 and OH concentrations are established by the reaction of the effluent gas with electrons. Studies conducted recently at the Institute of Chemical Physics of the USSR Academy of Sciences under the supervision of A P Shvedchikov jointly with the State Institute of Non-Ferrous Metals showed that the radiation-chemical method is promising for the purification of not only the effluent gases from heat and power generating plants containing $<0.1\%$ of carbon dioxide but also of the waste gases from industrial non-ferrous metallurgical undertakings, where the carbon dioxide content is higher. This leads to the possibility of using industrial electron accelerators not only for reducing the amount of ecologically harmful impurities (SO_2, NO_x) in waste gases but also possibly for

the creation of a new technology for the synthesis of sulphuric acid as a result of the radiation-chemical oxidation of sulphur dioxide.

The ozone-ammoniacal method is based on the principle used by nature to remove NO_x and SO_2 from the atmosphere in which a significant role is attributed to the reactions in the water drops. Ozone is needed only to convert NO into NO_2 in the gas phase:[39]

$$NO \xrightarrow{+O_3} NO_2 + O_2.$$

Next NO_2 and SO_2 enter the water drops where chemical reactions take place and the rate of removal of NO_2 and SO_2 is determined. Studies by V A Lozovskii, Yu N Kozlov, and A N Petrov (Institute of Chemical Physics of the USSR Academy of Sciences) have shown that under optimum conditions the purification process depends significantly on the interaction of NO_2 with SO_2 dissolved in the drops, which can be illustrated schematically as follows:

$$(NO_2)_{gas} \rightarrow (NO_2)_{aq} \rightarrow NO_2^- \xrightarrow{+HSO_3^-} NH_4^+,\ SO_4^{2-},\ N_2,\ N_2O.$$

This method is being developed jointly with VTI, YuzhVTI, and ENIN. It has been tested on the experimental industrial plant of the Moldavian Hydroelectric Power Station. The design of a full-scale plant for the purification of the flue gases from the heat and power generating plant in Dushanbe is now being completed.

It is noteworthy that this method has been designed in the USSR and has many advantages over foreign methods.

Systematic treatment and assessment of the risks due to superecotoxicants

A D Kuntsevich

At the dawn of his appearance 30 000–40 000 years ago, *Homo sapiens*, being a product of the overall evolution of the geosphere, depended on nature, but he soon (against the background of the 4 billion years of the existence of the planet) disturbed the essential balance of nature.

The scientific-technical revolution in the 20th century gave rise to the "explosive character" of the development of anthropogenic energy and mass exchange. As a result of the extremely rapid functioning of this process, in essence via a "chain mechanism", qualitative and quantitative changes have taken place in the geosphere of a kind such that their accumulation has been responsible for the conversion of the anthropogenic factor into a significant factor on not only a regional but also a global scale.

The long neglect of this objective consideration, the euphoria associated with gaining control of powerful types of energy, the synthesis and introduction of new substances and materials, and the "victories" over nature have in general suddenly and in an acute form faced humanity with the ecological problem as a problem of its survival.

Indeed the global climate, the ozone layer, the oceans, the forests, the biological species, and the natural resources are being increasingly considered with alarm.

A reliable answer to the question whether or not the equilibrium between the interactions in the geosphere has now been disturbed can be given on the basis of the solution of a fairly complete global model. Its main components are the dynamics of the processes, the establishment of the permissible limits to the structural, phase, and functional changes, and the estimation of the relationship between fact and norm. The development of such a model will apparently make it possible to find a satisfactory solution to the problem of the preservation of the global equilibrium. However, this requires international efforts by scientists for a long time.

At the same time, together with the development of a global model and large-scale studies within the framework of the biosphere and biological research at governmental and international levels under the auspices of the United Nations Organisation, UNESCO, and other organs, rapid assessments of signal systems in various fields, which might reveal negative trends requiring immediate action by the community, are needed without delay. One of the most important objects of such assessments should be man himself (and, by analogy, all the components of the flora, fauna, and the environment as a whole).

In the outcome of the evolution of man against the background of the manifestation of negative factors one may note undoubted positive aspects: the growth of population, the increased lifespan, development, etc. However, during the past 30 years an appreciable (severalfold) increase in congenital deformities, allergies, and other negative phenomena has been noted throughout various countries of the world. If these figures are objective, and there are no grounds for disbelieving them, then they may in fact serve as the signal indicator system indicating the exhaustion of not only the capacity for adaptation to changes in the environment inherent in man but also of the capacity of the compensating mechanisms underlying the basis of modern medicine with its system of total monitoring of persons, diagnosis, and prophylactic and therapeutic measures.

A relaxed approach to this situation is not permissible. Firstly, it is essential to estimate urgently and repeatedly the reliability of the occurrence and the growing incidence of persons with congenital deformities. The point is that, if only the growth of human lifespan is adopted as a factor measuring man's well-being and the changes in the gene stock are not analysed, then one is faced with the objective problem of the risk of the appearance after a short time of a new "destructive" population of persons, the development of which, after the attainment of a certain "critical mass", would acquire the character of a chain reaction.

It is entirely clear that it is essential and a matter of extreme urgency to alter fundamentally the general trend towards an increase in congenital deformities. After all, if even now decisive measures are adopted, the alteration of the general trend will require time and hence will involve new victims.

The solution requires the discovery of the new factor or several factors responsible for this jump in the degradation index of human gene stock. Naturally, it would be most correct to carry out research in numerous directions: the influence of the external background electromagnetic radiation, the growth of the consumption (provided that this has occurred objectively) of alcohol and drugs, as well as other negative factors.

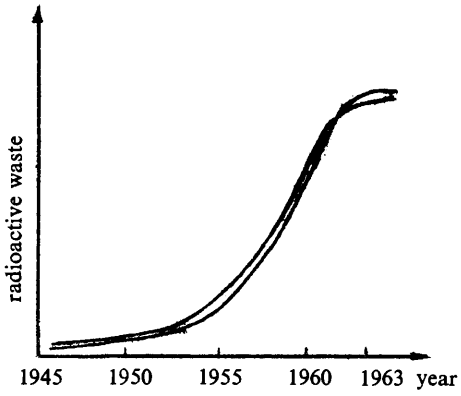

Figure 1. Approximate scale of the pollution forming the "dirty" background and exhibiting a polyfunctional biological activity. Fall-out Σ(^{90}Sr and ^{137}Cs) $\simeq 10^{18}$ Bq; amount in the stratospheric reservoir (fall-out continues) $\sim 10^{16}$ Bq.

Greenhouse effect: $\leftarrow CO_2 \rightarrow$ > 500 million tonnes (increment 0.3–0.5% annually), SO_x ~ 300 million tonnes, petroleum and petroleum products ~70 million tonnes, pesticides ~2 million tonnes, surfactants 10 million tonnes, solid waste ~4 billion tonnes, domestic waste (Moscow—2 million tonnes) ~50 million tonnes, liquid waste from animal husbandry (> 100 thousand tonnes ha^{-1}) ~13 billion m^3.

An attempt at a comparative analysis of the radiation and chemical factors has been made. Fig. 1 illustrates the approximate scale of pollution, which, in terms of its regional and global

distribution, gives rise to a kind of constant qualitative and quantitative "dirty" background which exhibits objectively, by virtue of its nature, a polyfunctional biological activity. Hence arise the anomalies in the diseases of individual regions and, as the global "dirty" background grows, the biological response to it is manifested on a planetary scale.

The understanding of this approach makes it possible to formulate at the present time the fundamentally new problem of drawing maps of the planet, state, region, town, or village based on the index of the biologically harmful activity of samples of air, soil, water, and food in terms of an integral indicator of the activity of pollutants against a very small but chronic background.

Unfortunately world practice is directed at the present time to the investigation of biological activities of individual specific substances, involving the determination of the limiting permissible concentrations (LPC) of the latter. We believe that there are at present sufficient data to transfer the estimation of the biological activity of daily air, water, and food samples also to a new polyfunctional level.

Returning to the problem of the determination of the factors responsible for the increase in the number of persons with altered heredity, one cannot fail to pay attention to the chemical factor. Among the widely distributed "chemical pollutants", mention should be made of the mutagenic polyaromatic hydrocarbons (PAH), polychlorophenols (PCP), heavy metals, and other compounds. The present author has given the term superecotoxicants (SET) to substances small doses of which exhibit a powerful activity inducing or inhibiting enzymes (Fig. 2).

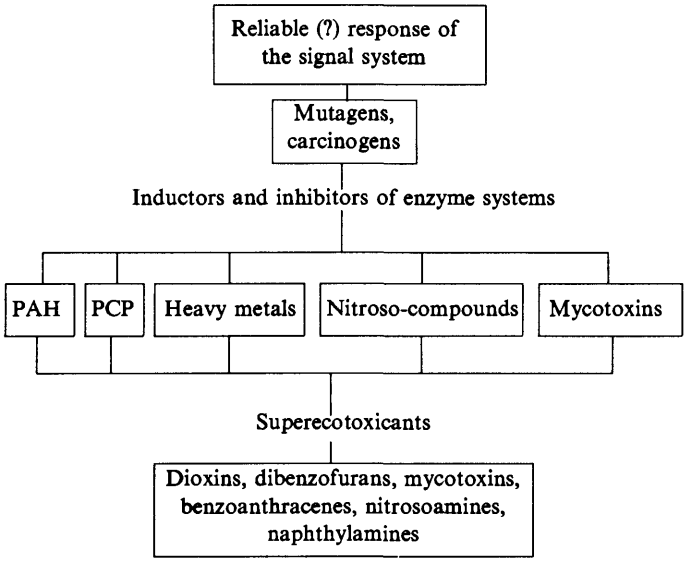

Figure 2. Chemical factors responsible for the increase in the number of persons with altered heredity.

Together with their inducing and inhibiting activities, superecotoxicants can also induce in man and animals a sharp increase in sensitivity to xenobiotics and other natural agents in the environment. It is essential to note also their natural stability and the absence of a toxicity limit (superaccumulative effect). The concept of the limiting permissible concentrations loses significance for virtually all superecotoxicants. The superecotoxicants circulate in all media and exhibit their activity through the components of the medium. Man is subject to their activity both via the aerobic pathway and perorally together with food products of plant and animal origin and water in which they accumulate from the soil and the hydrosphere. Thus yet another property is characteristic of superecotoxicants—an extremely high mobility in the ecosphere. These properties are in fact responsible for the complex toxic activity of various superecotoxicants, which can induce mutagenic, teratogenic, carcinogenic and porphyrogenic effects and can also suppress cell immunity, damage internal organs, and waste the organism.

The enormous experience gained in past toxicological studies made it possible to discover the normal logarithmic law governing the distribution of living organisms with respect to sensitivity to the action of harmful factors, including toxic substances. According to this law, the "dose–effect" relation can be in most cases fitted by monotonically increasing S-shaped curves, which are converted into straight lines when plotted on a logarithmic or a logarithmic probit grid. .

At the same time, in a number of instances experimenters have encountered significant deviations of the experimental data from the fitted S-shaped curves. The extreme case of such deviations are the so called paradoxical bimodal or two-phase effects where within a certain range an increase of dose leads not to an increase but to a decrease in the effect. The paradoxical dose relations have now been differentiated as a separate group, since they cannot be fitted by the known methods.

In our view, this shows that the methodology adopted fully takes into account all the features of the response of the organism as a complex system with numerous compensating and adaptive functions.

Theoretical treatment of the essential features of the response by living organisms to the effect of harmful factors suggests that toxic substances (superecotoxicants) act simultaneously or successively to a greater or lesser extent on virtually all the biotargets and systems of the organism, exerting their toxic action simultaneously via different mechanisms. The overall effect is then equivalent to the effect of the combined action of two or more substances involving summation (additivity), internal potentiation (synergism), and even autoantagonism.

On the basis of these features, a series of chemical substances inducing such two-phase effects have been specifically synthesised and investigated.

Analysis of experimental data on the dose relations for these compounds and of certain literature data made it possible to discover the rule governing the occurrence of "dose–effect" curves and to find a logical explanation in terms of which they can be fitted:

$$P = \frac{(D/X)^n \frac{1}{1+(D/Z)^k} + (D/Y)^m}{1 + (D/X)^n \frac{1}{1+(D/Z)^k} + (D/Y)^m},$$

where D is the dose of the substance, X and Y are the average lethal doses in the first and second phases, Z is the average effective

autoantagonistic ("antidote") dose, and n, m, and k are the corresponding coefficients for the intensity of the increase in the effect.

It has also been established that Z is a dependent quantity and can be expressed by the formula

$$\lg Z = \lg X + \frac{3.1}{m/n + k} \lg (Y/X).$$

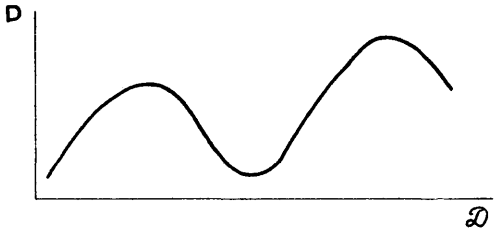

Figure 3. Two-phase dose relation.

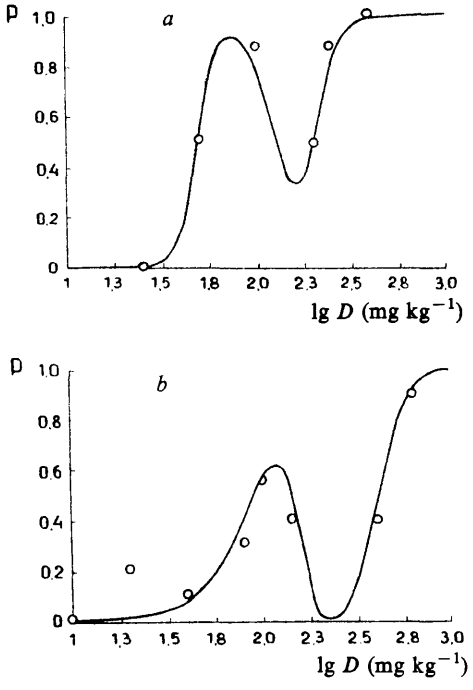

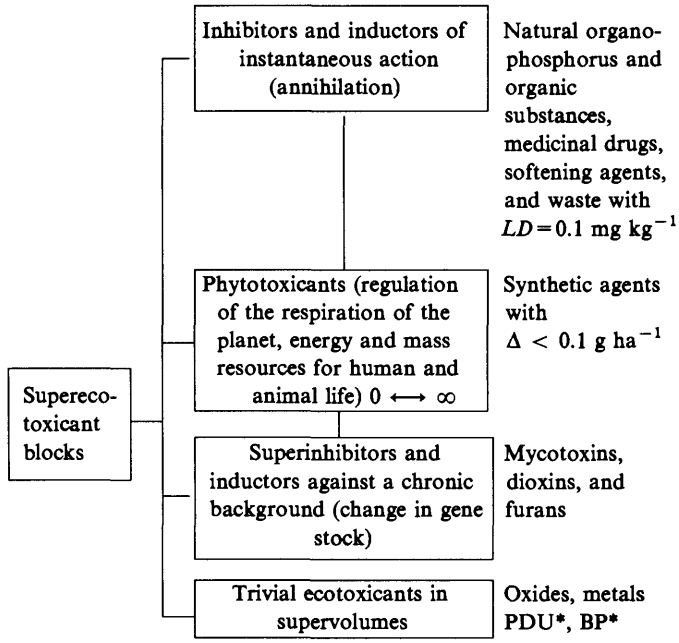

Figure 4. Experimental curves for the two-phase dose relation (composition based on dimethylbenzoanthracene) on the 45th day for white rats (*a*) and white mice (*b*).

A typical two-phase relation is presented in Fig. 3. The coefficients n, m, k, X, and Y as well as the standard deviation were determined by the multiple regression method on a computer.

An experimental confirmation of the validity of the relation is presented in Fig. 4 for dimethylbenzoanthracene (DMBA).

On the basis of the analysis carried out, it is suggested that for practical applications the superecotoxicants be treated systematically on the basis of four main blocks (they can be expanded in terms of substructures).

SCHEME

*Unidentified Russian abbreviation (Ed. of Translation).

It is striking that controls in relation to the first block have been adopted in a number of international conventions and agreements and in registers of medicinal drugs.

Controls in relation to the second block have not yet been organised although one cannot rule out the possibility that they will be included in the convention on chemical weapons.

As regards the third block, the methods of registration and control of submicro-amounts of the relevant substances and experimental estimation of their biological activity in combination with accompanying "pollutants" and "ordinary" substances require urgent tests and development on national and international levels.

The fourth block requires a more clear-cut formulation and control. Overall, the following problems come to the fore:

1. Detection, screening, systematic treatment, registration, and international control (Soviet and international systems).

2. Monitoring and local and remote control methods for chemical and express biological detection with a high sensitivity. Mapping of the planet, regions, and populated areas. Dynamics. Characteristic features. Predictions. Solutions. Practice.

3. Methods for the estimation of the integral "response" to multifactorial influences.

4. Detection, location, isolation, and abolition of sources of pollution.

5. Development of controlled cycles (waste-free technology, closed cycle manufacturing processes, absorption of absorbable gases, and the supercycle).

It is very important to note that overall, within the framework of the earlier estimate of the degree of risk associated with chemical factors, a systematic treatment and control of superecotoxicants and

the development of a methodology for their estimation should be prosecuted on a universal, international scale, since this would make it possible to obtain maps of the probable biological effects of various media (air, water, soil, food) for populated areas, regions, and the planet as a whole. This would in fact serve as a guide in the adoption of solutions.

It is necessary to go over to a new philosophy of the organisation of the life cycle of any article, any material, and any substance. This cycle must include in a unique whole the extraction of the raw material, transport, conversion of the raw material into the product, the utilisation of waste, ecologically clean employment of the product, and methods for its complete utilisation after the article has fulfilled its function (purpose). This in fact constitutes a closed "supercycle".

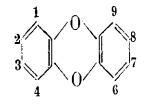
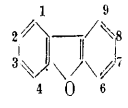
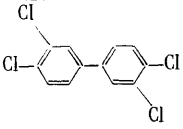
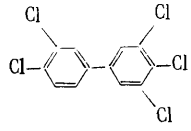
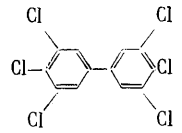
Xenobiotics from a number of polychloropolycyclic compounds (PCPC) of the dioxin type such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD), 2,3,7,8-tetrachlorodibenzofuran (2,3,7,8-TCDF), their more highly chlorinated derivatives and also 3,3',4,4'-tetra-3,3',4,4',5-penta- and 3,3',4,4',5,5'-hexachlorobiphenyls (Table 1) are some of the most dangerous ecotoxicants passed into nature from the production of the chloro-compounds and from technologies based on the use of chlorine and its compounds.











Some general properties of these xenobiotics (compiled in 1984) are given in a short review.[1] However, during the past five years the number of scientific publications on PCPC has more than doubled. Among the more than 1600 studies there are monographs, handbooks, and large reviews of the various aspects of the PCPC problem, summarising results on national and international programmes, results of national and international scientific meetings and conferences. New information, a significant part of which is presented in the proceedings of international symposia on 'Dioxin and Related Compounds',[2–5] has enabled a more ordered concept to be created of PCPC as poisons, ecotoxicants, on their influence on contemporary medicine and on the ecological situation. The most important conclusions are given below.

I. Toxic effects

Acute toxicity for warm-blooded animals is not now considered to be a criterion of the danger of PCPC for man. The primary and secondary effects of PCPC on an organism and their consequences, which depend substantially on the habitat and conditions of existence of the organism, have proved to be more important in this regard.

The primary effects of 2,3,7,8-TCDD and its analogues are linked with the high specificity of these xenobiotics towards the cytosolic A*h* receptor controlling primarily the activation of genes A1 and A2 (on the 15th human chromosome) and the set of non-specific monooxygenases, viz. cytochromes P-4501A1 and P-4501A2.[6] Recently a third locus activating the A*h* receptor has become apparent and has been investigated.[7] Participation of the complex of 2,3,7,8-TCDD with the receptor has also been shown in the suppression of a gene on the 16th human chromosome producing menadioneoxidoreductase.[8] A high affinity has been established for dioxin-type PCPC towards the nuclear thyroxine receptor and an increase in thyroxine receptor concentration has been shown in the nuclei of cells of animals poisoned with 2,3,7,8-TCDD.[9] These data suggest that the action of PCPC is directed towards a series of regulatory mechanisms of the living cell, selected in the course of evolution, started by receptor proteins with a single type of active centre. Haem, which is sterically accessible for planar PCPC, emerges as the most probable target, since of natural substances only the iron-porphyrins are capable because of their geometric and electronic parameters of interaction with all the known inducers of the dioxin type.[10]

the development of a methodology for their estimation should be prosecuted on a universal, international scale, since this would make it possible to obtain maps of the probable biological effects of various media (air, water, soil, food) for populated areas, regions, and the planet as a whole. This would in fact serve as a guide in the adoption of solutions.

It is necessary to go over to a new philosophy of the organisation of the life cycle of any article, any material, and any substance. This cycle must include in a unique whole the extraction of the raw material, transport, conversion of the raw material into the product, the utilisation of waste, ecologically clean employment of the product, and methods for its complete utilisation after the article has fulfilled its function (purpose). This in fact constitutes a closed "supercycle".

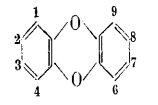
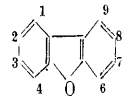
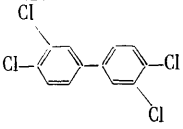
Polychloropolycyclic xenobiotics

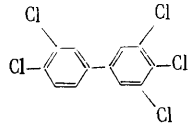
A F Kolomiets
A N Nesmeyanov Institute of Heteroorganic Compounds,
Academy of Sciences of the USSR, Moscow

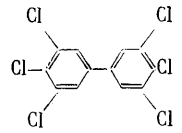
Xenobiotics from a number of polychloropolycyclic compounds (PCPC) of the dioxin type such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD), 2,3,7,8-tetrachlorodibenzofuran (2,3,7,8-TCDF), their more highly chlorinated derivatives and also 3,3',4,4'-tetra-3,3',4,4',5-penta- and 3,3',4,4',5,5'-hexachlorobiphenyls (Table 1) are some of the most dangerous ecotoxicants passed into nature from the production of the chloro-compounds and from technologies based on the use of chlorine and its compounds.











Some general properties of these xenobiotics (compiled in 1984) are given in a short review.[1] However, during the past five years the number of scientific publications on PCPC has more than doubled. Among the more than 1600 studies there are monographs, handbooks, and large reviews of the various aspects of the PCPC problem, summarising results on national and international programmes, results of national and international scientific meetings and conferences. New information, a significant part of which is presented in the proceedings of international symposia on 'Dioxin and Related Compounds',[2–5] has enabled a more ordered concept to be created of PCPC as poisons, ecotoxicants, on their influence on contemporary medicine and on the ecological situation. The most important conclusions are given below.

I. Toxic effects

Acute toxicity for warm-blooded animals is not now considered to be a criterion of the danger of PCPC for man. The primary and secondary effects of PCPC on an organism and their consequences, which depend substantially on the habitat and conditions of existence of the organism, have proved to be more important in this regard.

The primary effects of 2,3,7,8-TCDD and its analogues are linked with the high specificity of these xenobiotics towards the cytosolic A*h* receptor controlling primarily the activation of genes A1 and A2 (on the 15th human chromosome) and the set of non-specific monooxygenases, viz. cytochromes P-4501A1 and P-4501A2.[6] Recently a third locus activating the A*h* receptor has become apparent and has been investigated.[7] Participation of the complex of 2,3,7,8-TCDD with the receptor has also been shown in the suppression of a gene on the 16th human chromosome producing menadioneoxidoreductase.[8] A high affinity has been established for dioxin-type PCPC towards the nuclear thyroxine receptor and an increase in thyroxine receptor concentration has been shown in the nuclei of cells of animals poisoned with 2,3,7,8-TCDD.[9] These data suggest that the action of PCPC is directed towards a series of regulatory mechanisms of the living cell, selected in the course of evolution, started by receptor proteins with a single type of active centre. Haem, which is sterically accessible for planar PCPC, emerges as the most probable target, since of natural substances only the iron-porphyrins are capable because of their geometric and electronic parameters of interaction with all the known inducers of the dioxin type.[10]

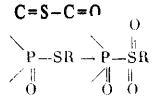
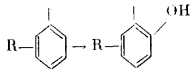
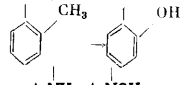
* HxCDD is hexachlorodibenzo-*p*-dioxin; HpCDD is heptachlorodibenzo-*p*-dioxin; HxCDF is hexachlorodibenzofuran; HpCDF is heptachlorodibenzofuran.

On passing into an organism PCPC act as inducers of extended false responses enabling the accumulation of a series of biocatalysts-haemoproteides in quantities dangerous for cell and organism function. Essentially, the regulatory mechanisms affected by these xenobiotics lead to a disturbance of the protective mechanisms of the

organism towards xenobiotic and toxic products of metabolism, to disturbance of hormonal metabolism and suppression of the immune system. Consequently the primary effects of PCPC are linked mainly with disturbance of the genetically controlled adaptation mechanisms of the organism to its surroundings. Thus even weak PCPC affections, manifesting as a constant discomfiture of the organism, high fatigue, reduced physical and mental ability and increased susceptibility to infection, may lead to dramatic consequences under conditions of additional, normally readily endurable, physical, chemical, biological and psychological stress.







Secondary effects of PCPC on the organism are initiated by the biocatalyst-haemoproteides induced by them, of which only cytochromes P-4501A1 and P-4501A2 have been adequately studied. Accumulation of the latter is dangerous for two reasons. In the first place complexed with PCPC they trigger the mechanism for transforming the energy resources of the cell to the conversion of O_2 into $O_2^{\cdot}$, H_2O_2 and $HO^{\cdot}$, which leads to a mutagenic effect, the biodegradation of hormones, vitamins and lipids which are sensitive to oxidation, disruption of biomembranes and disturbance of the functions of membrane-bound complexes. Immune cells are particularly susceptible to similar actions. Secondly these biocatalysts participate in the biotransformation of a great number of xenobiotics and normal metabolites by converting them into hydroxylation and epoxidation products (Table 2). As a result there is increased biodegradation of several low molecular hormones, neuromediators, vitamins, aromatic aminoacids, drugs and bioactivation of foreign substances of which precursors of aflatoxin B_1, nivalenol, carcinogens, neurotoxic substances and strong nerve poisons are particularly dangerous. All these secondary effects of PCPC aid suppression of the primary effects and, in the presence of certain xenobiotics, to the appearance of ecological illnesses.

The effect of the accumulation of nuclear thyroxine receptors stimulated by PCPC has not yet been studied. It is only possible to suppose that it is equivalent to the known effect of hyperthyroidism (activation of oxidation processes, uncoupling of oxidative phosphorylation, general emaciation of the organism), appearing at an excess of hormones of the thyroid gland. In reality the symptoms of heavy PCPC poisoning coincide with the features of hyperthyroidism.

The ecotoxicity of PCPC is caused not only by their negative action of fauna but also by the particular sensitivity to them of aerobic microorganisms, the protective mechanisms and flexible metabolism of which are controlled by a system of haem-containing monooxygenases. Anaerobes and photosynthesising organisms are significantly less sensitive to them. Consequently the accumulation of PCPC in nature and their inevitable concentration in the organic phase converts the latter into an unfavourable habitat primarily for aerobic organisms which determine the ability of ecosystems for self-restoration. The inevitable consequence of this in soil ecosystems is an expansion of habitats of anaerobes and, linked with this, biodegradation of humus and impoverishment of soils. In aqueous ecosystems PCPC extend the habitats of various algae, the accumulation of which leads to deoxygenation of the medium and acceleration of the degradation of the system.

Thus both at the level of organisms and at the level of communities of organisms PCPC destroy the most vulnerable regulatory mechanisms of living matter which determine their capability for autorestoration under aerobic conditions. A viability regulatory link weakened by PCPC endures further destruction by any other stresses. Consequently the assertion is correct that after appearing and accumulating in the biosphere PCPC of the dioxin type remain an important factor determining the increased sensitivity of man and nature to any anthropogenic influence.

Table 2. Known effects of cytochromes P-4501A1 and P-4501A2.

Biochemical effect	Reaction type	Consequence
Epoxidation of ethylenic bond, inhibition of epoxyhydrolases	C=C→C–C (O)	Bioactivation and stabilisation of mycotoxins, terpenoids, etc.
Epoxidation of arenes		Bioactivation of procarcinogens, promutagens, biodegradation of drugs
Epoxidation of thionephosphates	P=S–P=O	Bioactivation of pesticides
Epoxidation of dithiocarbamates	C=S–C=O	Biodegradation of disinfectants
Oxidation of thiol ethers		Bioactivation of neurotoxicity
ortho-Hydroxylation of substituted arenes		Bioactivation of neurotoxicity
Hydroxylation of CH_3 group		Bioactivation of neurotoxicity
N-Hydroxylation of arylamines and their derivatives	ArNH→ArNOH	Bioactivation of procarcinogens
Dealkylation of alkylaryl ethers	$ArOCH_3$→ArOH	Accumulation of phenols

II. Danger of 2,3,7,8-TCDD and its analogues to man

The danger of PCPC of the dioxin type to man is no longer the subject of discussion. It is no secret that pregnant women and children comprise a special group at risk of PCPC poisoning among people,[5] and that in regions of increased PCPC content in the environment the population and animals are characterised by increased deficiency of the immune system,[11] which may reach dramatic levels when other poisoning factors are superimposed. All the accumulated information leaves no doubt that PCPC are one of the decisive factors determining the currently observed process of reducing the geno-background of the human population in individual regions of the globe.

The subject of scientific investigations and discussions is now the problem of determining the degree of danger for man of these poisons, which is extremely important for the regulation of an effective complex of measures for health in the medical and ecological fields. Regretably there are no significant achievements in this area since mankind has proved to be unprepared to solve so important a problem.

The particular complexity of the PCPC problem is that these xenobiotics, which possess extraordinary biological activity, pass into nature as complex mixtures. The 17 main substances of this type are shown in Table 1. If one considers that many bromo-, nitro- and some methyl-substituted analogues possess a similar action their quantity grows severalfold. However even for the mixtures of

substances shown in Table 1 determination of the degree of danger is extremely complex. For this it is necessary to have reliable methods of determining the compositions of such complex mixtures qualitatively and quantitatively, to know the complete toxicological characteristics of each component and to make apparent the character of the mutual influence of substances after intake by the organism.

Up to the present time the US Environmental Protection Agency and a group of experts from the Scandinavian countries have developed the first methodology for assessing the degree of danger of PCPC to man.[12,13] It is based on the assumption that the danger of PCPC may be assessed according to carcinogenic risk, that the character of PCPC action on man and animal species is like the action of 2,3,7,8-TCDD and that the total effect of a PCPC mixture on the organism is equal to the sum of the effects of its components. Proceeding from these assumptions the dose of 2,3,7,8-TCDD considered safe on chronic administration proved to be 1 pg per kg body weight of man per day and indices of relative danger were found for all isomers relative to 2,3,7,8-TCDD (Table 1). This enabled a definite concentration of an isomer mixture to be represented by the equivalent concentration of 2,3,7,8-TCDD and its admissible quantity in various parts of the environment, in drinking water and in food to be regulated.

Results obtained using such methodology proved to be optimistic since it assumes consumption by adult man of water and food containing PCPC at concentrations up to 20–35 parts per trillion in 2,3,7,8-TCDD equivalents. Fish products and undefatted meat products are foods in which PCPC accumulates up to such concentrations. However, human milk must be considered to be dangerous for children in industrial countries since the concentration of PCPC in it exceeds that permissible by 2–10 times. In addition a mass of other information refers to such a conclusion optimistically.

In the first place on examining populations of persons, including volunteers, subjected to the action of PCPC, it was shown that these xenobiotics are retained significantly longer in man than in experimental animals. The time for the half-elimination of dioxin is 7 years from human lipid tissue, 1 year from monkeys and from several days to several weeks from other animal species. The absorption of dioxin is also appreciably greater in the human gastro-intenstinal tract (85% and more) compared with animals. It also turns out that highly chlorinated PCPC are retained longer than TCDD and TCDF. In animals, as in soil, they are subject to reductive dechlorination to more toxic compounds, which causes their unusual toxokinetics. Thus in animals poisoned with octa-CDD, symptoms typical of dioxin poisoning are displayed only after 13 weeks.[14] All these data cast doubt on the reliability of the methodology considered above for assessing the danger of PCPC to man. It does not consider the enhanced ability of these xenobiotics towards bioconcentration and retention by man, the inevitable result of which must be a strengthening of the long term after-effects of poisoning.

Secondly material appearing in recent years indicates the significantly higher danger of PCPC poisoning of the immune system than the carcinogenic risk. Thus in experiments on primates using food containing 5 parts dioxin per trillion for a year a strong and extended (up to 4 years) reduction was shown in the number of immune cells and in the T_4/T_8 ratio which indicates the extremely strong suppression of cellular immunity by these poisons and primarily of lymphocyte-helpers. This needs watching over since contemporary illnesses such as AIDS, T_4-leukaemia, Legionnaires' disease, etc. are linked precisely with T_4 cell activity. The extemely strong dose-dependent influence of dioxin on the immune system after oral administration (from the suppression of interleukin-1 synthesis and the sensitivity of T-lymphocytes to it, suppression of antibody formation, viability of B-lymphocytes and their bone marrow precursors to atrophy of the thymus and depletion of lymphoid tissue) is linked with the direct inflow of this xenobiotic from the gastrointestinal tract to bone marrow and subsequent migration to the thymus with poisoned cells. This must explain the excessive distribution, in regions of PCPC accumulation, of illnesses such as viral hepatitis and various intestinal infections in people and intestinal infections, viral distemper and other illnesses in animals. In such regions the status of babies and children, whose immune systems are just being formed, is particularly dramatic, the treatment of infections is greatly hindered since PCPC increase the biodegration of drugs in man and induce resistance of microorganisms to them.

The sensitivity of the immune system to substances related to dioxin is only beginning to be investigated. First results show that the danger of polychlorodibenzofurans and biphenyls for animals linked with the risk of affecting the immune system is incomparably greater than the carcinogenic risk and in this respect they are probably more dangerous than polychlorodibenzo-*p*-dioxins.[15] This correlates with the special features of their interaction with iron-porphyrin as a result of which furans and biphenyls possess high substrate specificity to a wider collection of haemoproteides than dioxins.[16]

The study of the influence of PCPC on the immune system begun in recent years is a new, significantly more difficult step in the understanding of the secrets of the actions of these xenobiotics on living matter. Chemically the main difficulty of the investigations at this step is the need to develop uniquely sensitive methods for the qantitative determination of PCPC, since the information already existing enables their danger to be considered according to the risk of affecting the immune system at concentrations of the order of tens of parts per quadrillion. Not by chance evidently, the US national programme on dioxin even in 1985 provided for the development of a method for the analysis of 2,3,7,8-TCDD with a sensitivity greater than 10^{-15} g g^{-1}.

III. Sources of dioxin-type PCPC

Investigations in recent years have led to the uncontrolled development by man of technology based on the use of chlorine and its compounds. This development has forced planning of such problems as the possibility of creating ecologically harmless chloro-compound manufacture, an ecological foundation for further large scale chlorine manufacture, the use of inorganic chlorides, in electrochemical, pyrometallurgical processes, the use of chlorine-containing oxidising agents in processes for treating material of natural origin, etc. The investigiations have stimulated searches for the rapid development of technology unconnected with the formation or use of chlorine for obtaining caustic soda, potash, oxides of alkaline earth and transition metals, etc., since PCPC are formed in dangerous quantities in a vast number of the technologies using chlorine, its organic and inorganic derivatives, in the presence of carbon and its compounds.

It has been shown in several countries that in the industrial synthesis of organochlorine compounds, the processing and use of the products introduces the maximal quantity of PCPC into the environment. Particularly dangerous are the majority of high

temperature processes for chlorinating organic substances, pyrolytic processing, combustion of organochlorine compounds and the synthesis and use of so-called PCPC precursors in nature, which include tri-, tetra-, pentachlorophenols, polychloropyrocatechols and their derivatives, 3,4-dichloroaniline and its derivatives, polychlorobenzenes and other polychloroaromatic compounds, isomeric hexachlorocyclohexanes, including Lindane, etc. All these compounds are converted into PCPC not only on pyrolysis or combustion but also on metabolism *in vivo* and on oxidation in the presence of haemoproteides. The content of PCPC in dangerous organochlorine products varies within wide limits, from fractions of a gram to tens of grams per ton. On average it may be considered that the manufacture and use of a million tons of a chloro product introduces no less than a ton of PCPC into nature.

The cellulose–paper industry is the second dangerous source of PCPC. When bleaching cellulose pulp with chlorine, oxidation and chlorination of the lignins present in the pulp occur which is accompanied by the formation of PCPC and its precursors. Replacement of chlorine by its oxide, by hypochlorites, chlorites and chlorates do not prevent the appearance of PCPC, concentrations of which reach 400 parts per trillion in waste water and up to 40 parts per trillion in bleached cellulose. The preparation of one ton of bleached cellulose by this means introduces up to 1 g PCPC and hundreds of grams of their precursors into nature. PCPC are formed by a similar route on disinfecting water containing phenolic substances and lignins with chlorine.

Significant quantities of PCPC are formed on combustion of solid domestic waste. According to existing data, operating one incinerator for a year put from 1 to 100 g PCPC into the atmosphere, the main quantity of which is evolved with the effluent gases. The quantity of PCPC formed depends on the combustion regimen and the composition of the waste burned. Their content is increased by the presence in the waste of polychlorovinyl and other polymers, and of organic and inorganic compounds of chlorine.

Sources of PCPC which are still insufficiently clarified are electrochemical processes for the manufacture of oxides of magnesium, nickel and possibly other metals from their corresponding chlorides. It is considered that these processes are comparable with the cellulose–paper industry in quantity of PCPC discharged into nature.

The smelting or initial heating of metals in electric arc furnaces is accompanied by the formation of PCPC. They are found on smelting copper and in the preparation of intermediate products for steel alloy objects. Large quantities of PCPC are emitted by motor transport using organochlorine or organobromine additives in motor fuel or in lubricants.

The list already presented indicates the extremely wide scale of poisoning of the biosphere with PCPC which has taken place in the past 30–40 years all the more so since their high stability in nature enables their constant accumulation. It may be considered roughly that during the period the manufacture and use of tens of millions of tons of organochlorine substances have introduced into the biosphere tens of tons of PCPC and several million tons of their precursors which are also partially converted into PCPC in nature. The cellulose–paper industry, metallurgy and processing of domestic refuse introduce into nature no less a quantity of PCPC than the manufacture of chlorine compounds. The total volume of PCPC fed into nature may seemingly be estimated at several hundred tons. This vast quantity of such strong poisons is sufficient to induce global disturbance of the functions of the animal life of the planet. That is why it is not remarkable that all the industrially developed nations have allotted huge resources to the exposing and elimination of technological practices emitting into the biosphere PCPC in quantities even of the order of tens of grams per year.

IV. Protection of man and nature from PCPC

Protection from PCPC is an unusual problem which is impossible to solve by traditional methods. This is due to the unusual properties of the xenobiotics considered[1] and their remarkable persistence.[17] PCPC may be destroyed in the gas phase or in solution by UV irradiation or even by sunlight. However on passing into the environment they are absorbed by inorganic materials and become insensitive to radiation. Their stability increases on passing into an organic phase and especially in living organisms where they accumulate. Only aerobic cells detoxify PCPC at a low rate. However on trying to degrade PCPC by such powerful oxidising agents as superoxide anion radicals and hydroxyl radicals, the latter destroy themselves. This guarantees the extended preservation of PCPC in nature (time for half-destruction is from 10 to 30 years or more), their ability to migrate along food chains or with water streams and transfer across borders into complexation with organic substances.

Several approaches have been studied in the search for methods of protection of man and animals from PCPC. The influence of natural antimutagens (vitamins A, B_1, E, C, etc.) on the toxic effects of dioxin has been studied in animal experiments. Competitive inhibitors of PCPC binding to bioreceptors have been studied as possible therapeutic agents. Only some reduction of dioxin effects on animals has been obtained in these cases. Evidently the formulation of a solution to the problem as the creation of a single cardinal method of protecting man from PCPC is not valid. In addition our investigations have enabled consideration of methods of prophylaxis and therapy of a series of ecological disorders arising as the fault of PCPC, primarily for groups at enhanced risk (pregnant women, babies, children).

With the aim of cleaning up the medical and ecological situation in regions of PCPC accumulation there is particular interest in the complex of programmes which, judging by available data, are being carried out in the industrially developed nations. The aim of one of them is to obtain a sharp fall in the technological burden on man and nature in affected regions. This provides:

elimination of the flow of PCPC to nature;

ecologisation of pesticides and of methods of applying them, optimisation of preparations and medicinal chemicals for living conditions and industry;

ecological standardisation of the manufacturing and agricultural industries.

Simultaneously a programme for protecting the population is being put into practice which is directed towards the partial disconnection of man from the PCPC biotransfer chain (cutting down of the consumption of dangerous food products, creation of new food sources from safe production) and the increase of man's resistance to PCPC (vitaminisation of drinks and food products, optimisation of food sources for amino acid composition, phospholipid content, etc.). Apparently the development of a complex of drugs intended for the treatment of ecological illnesses is also included.

Much attention is being paid to the ecologisation of landscapes around populated localities, in recreation zones and in plant growing areas. The aim of this programme is the creation of optimal

conditions for the development of aerobic microflora and the maintenance of constantly high activity for them. In the complex of agrotechnical and agrochemical measures developed a major role is played by a wide application of organic and microbiological fertilisers and also to growth stimulators and the development of lower and higher plants.

Significant results, obtained from putting into practice a complex of programmes in Japan, USA, Canada, FRG, and other countries in which huge quantities of PCPC have passed into the environment, indicate that mankind cannot now disregard the presence of these poisons in the biosphere and is obliged for many future decades to build up specially new conditions for his poison-free existence and cleaning of the environment. An unsafe medical situation and a multitude of regional ecological outbursts in our country are undoubtedly connected with underestimation of world-wide practice on the route and scale of using chlorine and its compounds and also of attempts to protect man and nature from the technological activity under conditions of enhanced PCPC content in the environment.

Main directions for reducing the ecological burden when using pesticides

N N Mel'nikov
All-Union Research Institute for Chemical Plant-Protection Agents

The influence of human society on the environment began in the period when people moved from gatherings in dense forests to farming and animal husbandry. The process developed particularly intensively in the period of scientific-technical revolution and the creation of various branches of industry. Each branch of modern industry makes its 'contribution' to the action on the environment. Thus combustion of coal and lignite mined at the present time leads to contamination of the environment by powerful carcinogens such as benzopyrene and benzanthracene.[1,2] Combustion of coal alone leads to the discharge of about 3000 tons of mercury into the environment[3] and a significant quantity of sulphur dioxide and other harmful products. It is sufficient to say that in the USA alone about 200 000 000 tons of various chemical compounds pass into the environment each year. Contaminants such as polychlorobiphenyls (used in the electrical industry), polychlorodibenzofurans and polychlorodibenzo-*p*-dioxins formed on combustion of municipal refuse, or when bleaching paper with chlorine and in many other cases are a serious danger. It is possible to form an opinion on the danger of this group of substances only from their acute toxicity for mammals. Thus the LD_{50} of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin for guinea pigs is 0.6–2 μg kg^{-1}, and for monkeys 70 μg kg^{-1}.[4] In addition these compounds possess carcinogenic, teratogenic and immunotoxic actions. The safe concentration of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin in drinking water is considered to be 0.000035 μg $litre^{-1}$.[5] Pesticides as contaminants of the environment amount to less than 1% of total contamination, however since they are physiologically active compounds serious attention is paid to them and there is discussion in print on the expediency of their practical use. In addition it is impossible to obtain high and consistent harvests without the application of pesticides for the protection of plants against vermin, diseases and weeds.[6,7] The application of pesticides is spreading without interruption. In 1986 a total of US$17.4 billion worth were used, in 1987 $20 billion, and according to a forecast their consumption in 1990 will rise to $21 billion.[8]

The consumption of pesticides in various countries in 1987 was as follows (in $ millions): USA 4450, Japan 3450, France 3400, USSR 1075, Brazil 875, Italy 860, FRG 855, Great Britain 760, Canada 545, India 510, Spain 485, Chinese People's Republic 465, Australia 399, Hungary 320, South Korea 280, Denmark 240, Netherlands 210, Argentina 205, Indonesia 170 and Mexico 155. The consumption of pesticides in 1987 according to preparation types was (in $ millions): herbicides 8600, insecticides 6100, fungicides 4100 and others 1200. It should be noted that the data given cover only 20 countries, the largest consumers of pesticides.[8]

The influence of pesticides and other xenobiotics depends on the following main properties: persistence, acute and chronic toxicity for various forms of living organisms, decomposability under the action of various forms of living organisms (biodecomposition) and the presence of various negative effects from small doses of preparation over an extended time. Pesticides are subdivided into six

conditions for the development of aerobic microflora and the maintenance of constantly high activity for them. In the complex of agrotechnical and agrochemical measures developed a major role is played by a wide application of organic and microbiological fertilisers and also to growth stimulators and the development of lower and higher plants.

Significant results, obtained from putting into practice a complex of programmes in Japan, USA, Canada, FRG, and other countries in which huge quantities of PCPC have passed into the environment, indicate that mankind cannot now disregard the presence of these poisons in the biosphere and is obliged for many future decades to build up specially new conditions for his poison-free existence and cleaning of the environment. An unsafe medical situation and a multitude of regional ecological outbursts in our country are undoubtedly connected with underestimation of world-wide practice on the route and scale of using chlorine and its compounds and also of attempts to protect man and nature from the technological activity under conditions of enhanced PCPC content in the environment.

Main directions for reducing the ecological burden when using pesticides

N N Mel'nikov
All-Union Research Institute for Chemical Plant-Protection Agents

The influence of human society on the environment began in the period when people moved from gatherings in dense forests to farming and animal husbandry. The process developed particularly intensively in the period of scientific-technical revolution and the creation of various branches of industry. Each branch of modern industry makes its 'contribution' to the action on the environment. Thus combustion of coal and lignite mined at the present time leads to contamination of the environment by powerful carcinogens such as benzopyrene and benzanthracene.[1,2] Combustion of coal alone leads to the discharge of about 3000 tons of mercury into the environment[3] and a significant quantity of sulphur dioxide and other harmful products. It is sufficient to say that in the USA alone about 200 000 000 tons of various chemical compounds pass into the environment each year. Contaminants such as polychlorobiphenyls (used in the electrical industry), polychlorodibenzofurans and polychlorodibenzo-*p*-dioxins formed on combustion of municipal refuse, or when bleaching paper with chlorine and in many other cases are a serious danger. It is possible to form an opinion on the danger of this group of substances only from their acute toxicity for mammals. Thus the LD_{50} of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin for guinea pigs is 0.6–2 μg kg^{-1}, and for monkeys 70 μg kg^{-1}.[4] In addition these compounds possess carcinogenic, teratogenic and immunotoxic actions. The safe concentration of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin in drinking water is considered to be 0.000035 μg $litre^{-1}$.[5] Pesticides as contaminants of the environment amount to less than 1% of total contamination, however since they are physiologically active compounds serious attention is paid to them and there is discussion in print on the expediency of their practical use. In addition it is impossible to obtain high and consistent harvests without the application of pesticides for the protection of plants against vermin, diseases and weeds.[6,7] The application of pesticides is spreading without interruption. In 1986 a total of US$17.4 billion worth were used, in 1987 $20 billion, and according to a forecast their consumption in 1990 will rise to $21 billion.[8]

The consumption of pesticides in various countries in 1987 was as follows (in $ millions): USA 4450, Japan 3450, France 3400, USSR 1075, Brazil 875, Italy 860, FRG 855, Great Britain 760, Canada 545, India 510, Spain 485, Chinese People's Republic 465, Australia 399, Hungary 320, South Korea 280, Denmark 240, Netherlands 210, Argentina 205, Indonesia 170 and Mexico 155. The consumption of pesticides in 1987 according to preparation types was (in $ millions): herbicides 8600, insecticides 6100, fungicides 4100 and others 1200. It should be noted that the data given cover only 20 countries, the largest consumers of pesticides.[8]

The influence of pesticides and other xenobiotics depends on the following main properties: persistence, acute and chronic toxicity for various forms of living organisms, decomposability under the action of various forms of living organisms (biodecomposition) and the presence of various negative effects from small doses of preparation over an extended time. Pesticides are subdivided into six

groups according to persistence: 1) preparations with a retention time in the environment of more than 18 months, preparations with a retention time of 2) 18 months, 3) 12 months, 4) 6 months, 5) 3 months and 6) less than 3 months. It is quite evident that depending on climatic conditions the retention time of any xenobiotic in the environment may vary within fairly wide limits. However it is possible to use the following formula to compare individual preparations for persistence and overall ecological burden on the environment:

$$EB = \frac{C}{LD_{50}} P,$$

where EB is the ecological burden per hectare, C the standard consumption of the preparation per hectare in g, P the persistence of the preparation in weeks (half life) and LD_{50} is the standard acute toxicity in mg kg^{-1}.[9] Finally, the formula shown does not give absolute values but enables comparison of the relative danger from one preparation to another.

Table 1. Persistence, acute toxicity and standard consumption of pesticides of various generations.

Pesticide generation	Persistence group	LD_{50}, mg kg^{-1}	Standard consumption, kg $hectare^{-1}$
Insecticides			
First generation:			
arsenic compounds	1	1.8–5	4–10
Second generation:			
organochlorine	1–2	25–1000	0.1–2
organophosphorus	5–6	1–3000	0.5–5
carbamates	5–6	25–1000	0.5–2
Third generation:			
pyrethroids	5–6	40–2000	0.006–0.1
hormonal	5–6	1000–2000	0.05–0.3
Fungicides			
First generation	1–3	5–450	5–9
Second generation (disinfectants)	5–6	18–200	0.003–0.2
Third generation (dithiocarbamates)	5–6	400–6000	1.8–3
Fourth generation (azoles)	5–6	400–4000	0.025–0.15
Herbicides for monocotyledonous weeds			
First generation (TCAN, Dalapon)	4–5	3000–4000	4–20
Second generation (thiocarbamates)	5–6	400–1400	1–2
Third generation (hydroquinone derivatives)	5–6	800–3000	0.25–1
Herbicides for dicotyledonous weeds			
First generation:			
dinitrophenols	5	40–100	2–4
ammonium sulphate, chlorates	4–5	100–500	200–600
Second generation (aryloxyalkanecarboxylic acids, benzoic acid derivatives)	2–4	300–1000	0.2–2
Third generation (sulphonylureas)	1–6	1000–5000	0.01–0.05

It should be noted that in the last decade pesticides have undergone profound changes both in persistence and in ecological burden on the environment and in danger to animals and man. Data are shown in Table 1 on some properties of pesticides of various generations. As is evident from Table 1 a sharp change has occurred in the persistence, toxicity and standard consumption per hectare of the preparations under consideration. For example the standard consumption of insecticides has been reduced from several kilograms to several grams per hectare, the acute toxicity has also changed. Preparations may be selected with different duration of action and the same toxicity for mammals. Earlier compounds, chiefly of arsenic, were used which had a practically absolute persistence but at the present time there are preparations which are decomposed into the simplest substances during one or two days, weeks or months. Such preparations may not damage the environment.

There is a completely analogous picture for fungicides the standard consumption of which is up to 25–100 g $hectare^{-1}$. At such standards of consumption it is difficult to visualise contamination of the environment, since two tons of soil will carry 2.5–10 mg preparation. Results on the design of new herbicides are particularly prominent both for control of monocotyledonous and dicotyledonous weeds.

Regarding persistence it is also possible to select herbicides the rate of decomposition of which does not exceed one vegetation cycle.

It should also be noted that fairly weakly toxic preparations may be selected according to their mammalian toxicity, in many cases not exceeding the acute toxicity of sodium chloride. It is pertinent here to recall the hypothesis of Paracelsus, that all substances are poisonous but only the dose makes them a poison. This hypothesis is also true for establishing maximum tolerated levels (MTL) for such effects as teratogenic and carcinogenic action. For example on feeding animals with food containing more than 120 g kg^{-1} ethylenethiourea, the appearance of malignant tumours is observed while at a lower content of this substance in food no carcinogenic action was recorded. Furthermore it is necessary to study the possible remote consequences of the action of small doses of preparations over an extended time in certain animal species and in three generations of experimental animal. Adequate guarantees of the safety of a preparation will emerge in such a study.

An important problem in the study of new preparations is their biodegradation by various species. With this aim the metabolism of pesticides has been studied in mammals, plants and microorganisms with isolation and identification of all the pesticide decomposition products and also with determination of the rate of metabolism and the dynamics of residues at harvest. Determination of the dynamics of decomposition of pesticides in plants enabled establishment of the expected time after treatment necessary to obtain products free of pesticide. In many countries the expected time is the chief criterion for the quality of products treated with pesticides (in addition to analytical determination of residues of them at harvest). Finally the expected time, which is determined for each region separately, may not be the same under different climatic conditions and in different cultures. The expected time is linked to a significant extent with temperature, residues and the metabolic rate in a given culture. For example chlorosulphone metabolises rapidly in wheat and is practically not decomposed at all in sugar beet.

Prior to permitting a new preparation for practical use in agriculture it is carefully studied in all the aspects enumerated above including the mutagenic, carcinogenic action and the teratogenic effect in animals. However data obtained in one animal species may not always be transferable to another animal species or man. Consequently a 'safety margin' is taken which in the majority of cases is two orders of magnitude less than the safe level for animals.

Pesticides intended for the treatment of animals and their food are studied in a given species of animal. Not only is their content determined in animal husbandry products going into human food but also the dynamics of their elimination from animals and the character and content of the metabolic products. Such a study guarantees to a fair degree the safety of using animal husbandry products in human food. It is noted that preparations which give residues in animal husbandry products, are not used at the present time in the majority of countries. However it is necessary to note that after use fairly significant quantities of DDT, toxafen and other similar substances were retained in the environment, hence residues of the substances indicated are frequently found in water although in insignificant quantities.[10] It is noted that significant quantities of polychlorobiphenyls are found in many living organisms as is seen from Table 2.

Table 2. Content of polychlorobiphenyls in various forms of animal.

Organism	Year	PCB content mg kg^{-1}*	Region
Pike	1980	2.4	Baltic
Guillemot	1981	100	Sweden
Cormorant	1975	130	Sweden
Eider	1980	2.6	Spitzbergen
Osprey, eggs	1978	200	North Sweden
Marsh harrier, eggs	1977	150	North Sweden
White tailed eagle	1982	340	Lapland
Grey seal	1976–1978	38	Baltic
Ringed seal	1981	85	—
Greenland seal	1982	4.5	—
Caspian seal	1977	1.5	Caspian

*Calculated in lipids.

As is known polychlorobiphenyls are not used as pesticides but are extremely stable compounds being metabolised slowly by various living organisms. Even more stable is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin which may be retained in Californian soil for more than 14 years.

It is noted that extremely poisonous compounds, products of the metabolism of phytopathogenic fungi, such as mycotoxins, may accumulate in the environment. The toxicity of some of them is given in Table 3. The use of pesticides enables elimination of mycotoxins which possess carcinogenic and mutagenic action as well as high toxicity.

Analysis of grain cereals for nivalenol content (500 samples from 19 countries) showed that mycotoxins may be contained in grain in extremely significant quantities.[11] Results are shown in Table 4 on the determination of nivalenol in several grain crops from 19 countries. It shows that the nivalenol content of same samples reached fractions of one percent. Fungi of the fusarium, verticillium and some other genera are producers of many toxins.

In addition to the toxins produced by microorganisms there are a large number of poisonous plants in nature by which people used to be poisoned with lethal outcome. In Central Asia over 30 years there was a large number of poisonings by trichodesma seeds which contaminated wheat and entered flour, as a result of which many cases of poisoning were recorded. After the application of herbicides of the aryloxyalkanecarboxylic acid type this weed was successfully eliminated and poisoning of people ceased. Toxicities for mice of certain peptides isolated from plants are given in Table 5.[12] As is seen such peptides are extremely toxic and are close in potency to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, which is the most poisonous xenobiotic.

Table 3. Acute toxicity of some mycotoxins in rats.

Mycotoxin	LD_{50}, mg kg^{-1}
Aflatoxin B_1	7.2
Toxin T	3.6
Nivalenol	7.4
Fusarenone X	4.4
Maloformin	4.0
Strychnine (for comparison)	7.5

Table 4. Content of the mycotoxin nivalenol in various cultures.

Culture	Nivalenol content, mg kg^{-1}
Wheat	127
Barley	101
Maize	766
Rye	47
Oats	438
Rice	22
Sorghum	90

Table 5. Acute toxicity of some peptides of vegetable origin.

Name	Plant	LD_{50}, mg kg^{-1}
Abrin	*Abrus precatorius*	0.6
Viscotoxin	*Viscum album*	2.4
Volkensine	*Adenia volkensii*	1.4
Modecin	*Adenia degitata*	2.1
Ricin	*Ricinuscommunis*	2.6

The 17-year experiment of Polish investigators on the influence of pesticides in crop rotation on the environment is of interest.[13] It was carried out from 1963 to 1980 in an area of more than 500 hectares. In all of this period 11 846.3 kg pesticides were applied to the area mentioned. This included 804.2 kg DDT, 376.26 kg Lindane, 170.28 kg Methoxychlor, 476.626 kg organophosphorus and carbamate insecticides, 697.975 kg fungicides (including 9.02 kg mercury compounds) and 9315.302 kg herbicides. All products grown on the area mentioned were analysed each year as well as the wild animals, birds, water and soil. As a result of the work the

authors concluded that contamination of plants by pesticides, Lindane, DDT, or organophosphorus compounds was not observed. They were not detected in the parts of plants near the ground nor in roots. It is particularly interesting that they were not detected in potato tubers or in sugar beet in spite of their presence in the soil. The best test object for determining soil contamination by organochlorine preparations is the earthworm, in which bioconcentration of DDT and Lindane occurs, and is linked with their constant living in soil and feeding specifically on organic residues. Ground beetles and field mice are also capable of accumulating organochlorine preparations and carbamates but do not accumulate organophosphorus compounds.

The observations of the Polish investigators correlate to a definite extent with results of the work of scientists of other countries, including the Soviet Union.

The dynamics of growth of the numbers of wild animals and birds are of interest. In Hungary in 1967 roe deer, boar, deer, grey partridges, pheasants and hares were recorded at 107.8, 12.2, 21.8, 588, 889.0 and 101.76 thousands respectively at a pesticide consumption of less than 3 kg hectare^{-1}. In 1974 when the consumption of pesticides per hectare of seeding and planting land had grown to 4.6 kg the numbers of animals indicated above increased to 173.0 17.0, 38.0, 860.0, 2360.0 and 1100.0 thousands respectively.[14] A similar picture was observed in North Rhine Westphalia.

The influence of pesticides on aquatic flora and fauna has great significance and in this connection their toxicity for water organisms, including various fish species, has been studied in an extremely detailed manner. It was established that organochlorine compounds are capable of accumulating in fish, from which they are eliminated comparatively slowly and as a result they may pass with the fish into the human food chain. However, the use of such a type of compound has either been sharply reduced or stopped completely in the majority of countries, including the Soviet Union. Organophosphorus pesticides themselves do not as a rule accumulate in fish and are rapidly eliminated. For example Carbofos is eliminated from fish in one day and other phosphorus pesticides in a week.

It is necessary to record that the use of insecticides in agriculture may be reduced by 30–50% by using sex pheromones for determining numbers of the most dangerous pests and determining thresholds for their noxiousness. Pheromones are ecologically clean and may not damage the environment or useful insects. It is expedient to use insect pheromones as widely as possible. Pheromones may replace insecticides to a significant extent in the disorientation of insects.

Cutting down the consumption of fungicides may occur only through the removal of stable sorts of plants, which however lose their resistance to a given form of disease after 2–3 years. In this connection it is doubtful whether it will be possible to give up fungicides in the next decade. There is no reasonable alternative to herbicides. In addition, in the majority of cases residues of herbicides are not found in the harvest. However in all cases it is most expedient to use a combined system of plant protection with intensive farming technologies. An integrated system of plant protection when considering harm thresholds and a well tuned monitoring of harmful organisms helps appreciably to reduce the ecological burden arising from the use of pesticides.

It is necessary to set up a state plant protection service of the type of the veterinary service which will secure correct and intelligent use of pesticides and the observance of a standard plant health situation. Special self-supporting teams must be set up for plant protection for tenants, which should use pesticides in a skilled manner and guarantee purity of the resulting products.

Possible approaches to ecologically sparing insecticides

A V Kamernitskii, I G Reshetova
N D Zelinskii Institute of Organic Chemistry,
Academy of Sciences of the USSR, Moscow

The main danger of using synthetic insecticides is their toxic action on warm-blooded animals and man, linked with the fact that the preparations used until now act on the life-guaranteeing systems common to the living world. There are two possible ways to reduce this danger, either to reduce the stability of preparations or to increase the selectivity of their action. The first is a palliative since it, in the final consideration, leads to accumulation in nature of only secondary conversion products of the labile preparation. Solution of the selectivity of action problem may in our view be found in diverting interest to that region of insect physiology which is most removed from the physiology of vertebrates, viz. the insect endocrine system, the functional principles of which differ markedly from those of vertebrates. Thus compounds replacing or blocking juvenile hormones or shedding (ecdysteroids) and capable of causing sudden or irreversible changes in insect activity may prove to be completely neutral or even useful for all remaining living beings.

The possibility of such an approach has been verified in our laboratory using synthesised compounds of the polyhydroxysteroid series as examples.

These compounds were represented by derivatives of 20-keto-21,24-dinorcholane with an open side chain or tetrahydropyran ring E and with Δ^5,5αH,5αOH-6-keto grouping in rings A/B, with derivatives of 20-acetoxy-21,24-dinorcholane with increasing number of oxygen-containing substituents in ring E and with the same substituents in rings A/B, with derivatives of Δ^5,5αH,5αOH-6-keto-steroids with a δ-lactone ring E, with analogues of the natural chiogralactone with various degrees of saturation and oxidation state of ring E or derivatives of 21,24-dinorcholan-23-oic acids.

It was shown that compounds of the types investigated may actually intrude in the process of metamorphosis of insects, inhibiting it. At the same time, as was established in other experiments, compounds of the same type are synergists of the binding of glucocorticoids with cytosol receptors in the heart of warm-blooded animals, i.e. they display adaptogenic properties. Such a combination of actions on insects and warm-blooded animals is at least extremely promising. Naturally the direct use of complex steroidal preparations as insecticides is unsuitable because of their low availability, however determination of the parameters of groups strengthening their interaction with those and other receptors, may lead to simpler analogues.

New trends in the creation of pesticides with a low ecological stress

V G Kartsev
Division of the Institute of Chemical Physics, USSR Academy of Sciences, Chernogolovka

Modern farming cannot do without effective protecting agents against pests, disease, and weeds. The use of pesticides makes it possible to reduce the labour expended in agriculture on the care of seedlings and makes it possible to proceed to the growing of the most important cultures by an industrial technology which ensures high and stable crops.

At the same time the use of pesticides poses a series of most important ecological problems because of their negative side effects on the ecosphere, accumulation in objects within the environment, etc. World science—chemical, biological, and ecological—is therefore faced by the important and urgent problem of creating a new generation of ecologically safe chemical plant protecting agents.

The use of the ideas suggested by nature appears the most promising, in particular the creation of compounds analogous to natural chemical plant protecting agents, as well as their chemical modification. Such compounds act as a rule at low and ultralow concentrations, are highly selective, and do not persist for a long time. They include, for example, phytoalexins (substances of endogenic origin synthesised in plants in response to the action of various factors, including pathogenic microorganisms, in order to combat them), allelopathic agents (minor metabolites of higher plants which suppress the development of other plant species, i.e. which exhibit herbicidal properties), phytocides, cytokinins, and auxins of natural origin, etc.

The procedures for the chemical modification of natural biologically active compounds are similar to the approaches used in the modification of natural chrysanthemic acid (secondary metabolite of camomile), which led to a whole new branch in the field of synthetic metabolites—pyrethroids.

Ecologically clean biotechnological processes for the preparation of pesticides have been developed vigorously in recent years, for example, the advances by Japanese investigators in the biotechnological synthesis of avermectins—ionoform antibiotics exceptionally active against a number of vicious pests (ticks, phytophages, and nematodes). These studies were noted in 1986 as the greatest worldwide achievement in the field of pesticides.

A series of other aspects of the creation of highly selective and relatively ecologically safe pesticides are also noteworthy. These include photodecomposable pesticides, herbicides with photodynamic activity (PDH), and propesticides.

Possible approaches to ecologically sparing insecticides

A V Kamernitskii, I G Reshetova
N D Zelinskii Institute of Organic Chemistry,
Academy of Sciences of the USSR, Moscow

The main danger of using synthetic insecticides is their toxic action on warm-blooded animals and man, linked with the fact that the preparations used until now act on the life-guaranteeing systems common to the living world. There are two possible ways to reduce this danger, either to reduce the stability of preparations or to increase the selectivity of their action. The first is a palliative since it, in the final consideration, leads to accumulation in nature of only secondary conversion products of the labile preparation. Solution of the selectivity of action problem may in our view be found in diverting interest to that region of insect physiology which is most removed from the physiology of vertebrates, viz. the insect endocrine system, the functional principles of which differ markedly from those of vertebrates. Thus compounds replacing or blocking juvenile hormones or shedding (ecdysteroids) and capable of causing sudden or irreversible changes in insect activity may prove to be completely neutral or even useful for all remaining living beings.

The possibility of such an approach has been verified in our laboratory using synthesised compounds of the polyhydroxysteroid series as examples.

These compounds were represented by derivatives of 20-keto-21,24-dinorcholane with an open side chain or tetrahydropyran ring E and with Δ^5,5αH,5αOH-6-keto grouping in rings A/B, with derivatives of 20-acetoxy-21,24-dinorcholane with increasing number of oxygen-containing substituents in ring E and with the same substituents in rings A/B, with derivatives of Δ^5,5αH,5αOH-6-keto-steroids with a δ-lactone ring E, with analogues of the natural chiogralactone with various degrees of saturation and oxidation state of ring E or derivatives of 21,24-dinorcholan-23-oic acids.

It was shown that compounds of the types investigated may actually intrude in the process of metamorphosis of insects, inhibiting it. At the same time, as was established in other experiments, compounds of the same type are synergists of the binding of glucocorticoids with cytosol receptors in the heart of warm-blooded animals, i.e. they display adaptogenic properties. Such a combination of actions on insects and warm-blooded animals is at least extremely promising. Naturally the direct use of complex steroidal preparations as insecticides is unsuitable because of their low availability, however determination of the parameters of groups strengthening their interaction with those and other receptors, may lead to simpler analogues.

New trends in the creation of pesticides with a low ecological stress

V G Kartsev
Division of the Institute of Chemical Physics, USSR Academy of Sciences, Chernogolovka

Modern farming cannot do without effective protecting agents against pests, disease, and weeds. The use of pesticides makes it possible to reduce the labour expended in agriculture on the care of seedlings and makes it possible to proceed to the growing of the most important cultures by an industrial technology which ensures high and stable crops.

At the same time the use of pesticides poses a series of most important ecological problems because of their negative side effects on the ecosphere, accumulation in objects within the environment, etc. World science—chemical, biological, and ecological—is therefore faced by the important and urgent problem of creating a new generation of ecologically safe chemical plant protecting agents.

The use of the ideas suggested by nature appears the most promising, in particular the creation of compounds analogous to natural chemical plant protecting agents, as well as their chemical modification. Such compounds act as a rule at low and ultralow concentrations, are highly selective, and do not persist for a long time. They include, for example, phytoalexins (substances of endogenic origin synthesised in plants in response to the action of various factors, including pathogenic microorganisms, in order to combat them), allelopathic agents (minor metabolites of higher plants which suppress the development of other plant species, i.e. which exhibit herbicidal properties), phytocides, cytokinins, and auxins of natural origin, etc.

The procedures for the chemical modification of natural biologically active compounds are similar to the approaches used in the modification of natural chrysanthemic acid (secondary metabolite of camomile), which led to a whole new branch in the field of synthetic metabolites—pyrethroids.

Ecologically clean biotechnological processes for the preparation of pesticides have been developed vigorously in recent years, for example, the advances by Japanese investigators in the biotechnological synthesis of avermectins—ionoform antibiotics exceptionally active against a number of vicious pests (ticks, phytophages, and nematodes). These studies were noted in 1986 as the greatest worldwide achievement in the field of pesticides.

A series of other aspects of the creation of highly selective and relatively ecologically safe pesticides are also noteworthy. These include photodecomposable pesticides, herbicides with photodynamic activity (PDH), and propesticides.

The photodecomposable pesticides include compounds which exhibit fungicidal and herbicidal effects in the dark and which are converted into inactive and non-toxic compounds in the light. The first representatives of these compounds have been synthesised in the

Division of the Institute of Chemical Physics of the USSR Academy of Sciences.

The activity of the PDH is based on the use of natural regulators of intracellular biochemical processes. This suggests a comparatively high ecological cleanliness of preparations with photodynamic activity. Among the advantages of the PDH, one may include the high selectivity of their toxic activity based on the photodependent biological effect, achieved in plant organisms, and the impossibility of their photoactivation in the organisms of warm-blooded animals. In addition, one should note that the outcome of the effect of the PDH on the cell is the activation of radical oxidation reactions of various intercellular components and in the first place membrane components. The quantum yield of these processes can significantly exceed unity. By virtue of this feature of photodynamic processes, one may hope that it will be possible to reduce sharply the active concentrations of the preparations, which is important from the ecological and economical points of view. Furthermore, one should postulate that the non-specificity of the activity in the photodependent stage rules out the possibility of the development of plant species resistant to the PDH.

The action of propesticides (compounds which do not exhibit a pesticidal activity from the beginning) is based on the biochemical activation of the molecules by the enzyme systems of plants, as a result of which the pesticide molecules are generated in the plant cells. The species specificity of such preparations is based on the differences in the activities of enzymes in cultivated plants and weeds. For example, the difference between the activities of alcohol dehydrogenase in various plants served as a basis for the creation of selective propesticides of the chlorophenoxyethanol series (phenteracol — Hungary).

The study designed to create herbicides of this type as well as PDH necessitates the development of a biochemical base for the investigation of the principles governing the species specificity and selective toxicity. Here it is possible to distinguish three most important problems:

The study of the characteristic features of the transport of pesticides through biological membranes, the establishment of relations between their transport characteristics and their structure, and the determination of the characteristic features of the interaction of pesticides with biological membranes, including the molecular mechanisms of the influence of pesticides on the structure and function of membranes.

The study of the differences in the biochemical homeostasis of cells of useful and harmful organisms and in pathological states. The determination of the molecular mechanisms of the response reactions to the action of xenobiotics.

The study of the characteristic features and pathways in the metabolism of pesticides in the cells of living beings and in objects within the environment in order to elucidate the mechanisms of the pesticide effect and also the routes to their metabolic activation and the characteristics of the latter.

Biologically active substances of ecological importance and methodological aspects of the estimation of the biological activity of pollutants

S A Ostroumov
Lomonosov Moscow State University

The study of natural ecological chemoregulators and chemomediators is important for the development of new ecologically safe pesticides and chemical plant and crop protecting agents.

Substances of this kind include phytoalexins and other antifungal substances in plants, phage repellants, antifeedants, toxins, antiovipositants, phytoecdysones, juvenile hormone substances, and various attractants and pheromones. One of the problems associated with the chemical pollution of the biosphere is that of the estimation of the biological activity of pollutants. In order to discover the optimum methods of estimating pollutants and xenobiotics, to investigate the possibility of a correspondence between data obtained by various methods and for various objects, and also with the aim of securing new information about the biological activity of anthropogenic substances, the author carried out biotests on certain pesticides and surfactants as well as certain industrial preparations on various biological objects. The substances investigated included pesticides (DNOK and lontrel), surfactants (sulphonol, sodium dodecanesulphonate [sodium dodecyl sulphate?], Triton X-100, ethonium, and TDTMA), and surfactant-containing preparations "Kashtan" (chestnut), "Verbena" (vervain), "Vil'va" [?], and others. The seedlings of a number of plants, including macrophytes, were used as the test objects. It has been shown in the latest experiments that sulphonol (0.5 ml litre^{-1}) almost completely suppresses the growth of the roots of *Oryza sativa*. It is proposed that the adopted modifications of biotesting methods be used on a wider scale for the estimation of the biological activity and ecological danger of substances.

Social-ecological aspects of the use of plant protecting agents in Uzbekistan

I N Ruban, N L Voropaeva, S Sh Rashidova
Institute of the Chemistry and Physics of Polymers, Academy of Sciences of the Uzbek SSR, Tashkent

Since the 1970s, the problem of dangerous xenobiotics among polyhalogenated polycyclic compounds capable of exhibiting mutagenic, carcinogenic, teratogenic, and embryotoxic activities and of damaging the liver and the immune and central nervous systems as well as the blood forming organs at very low concentrations has been widely discussed in the world press. One of such compounds is dioxin, which forms part of the composition of copper

trichlorophenoxide and other numerous plant protecting agents. This communication deals with the problem of dangerous xenobiotics in relation to Uzbekistan and an attempt is made to develop a strategy for the replacement of copper trichlorophenoxide by non-trivial preparations, which make plants resistant to bacterial diseases.

In order to solve the problem of the replacement of copper trichlorophenoxide by non-toxic preparations, it is essential in our view to develop the following measures: to eliminate the use of waste from cotton fields as fuel; to rethink the solution to problems concerning the preparation of the soil in regions where subterranean water is in close proximity; to eliminate the ploughing in of the stems, branches, and other parts of the cotton plant after raw cotton has been harvested; to develop measures for the stabilisation of light soils; to develop methods for the attachment of preparations to the surfaces of seeds during their treatment, which will make it possible to reduce the dispersion of the preparations and their accumulation within the preserving areas in cotton cleaning workshops; to go over to an improved automated technology for the pre-sowing preparation of seeds; to replace phenthiurams and copper trichlorophenoxide by highly effective preserving agents which are non-toxic to warm-blooded animals; to carry out preserving only under stationary conditions, during periods which do not coincide with the flowering of fruit trees; to abandon procedures involving the enzymic treatment of the waste from cotton fields (cotton stems and branches after harvesting raw cotton) in order to obtain additives to the main diet of cattle.

All this can be achieved with the aid of polymer systems for the stabilisation of sand and soil, which makes it possible to prevent the migration of sand and light soils and this in turn will tend to reduce the horizontal migration of preparations incorporating dioxin and other toxic admixtures, with the aid of polymer compositions for the encapsulation of cotton seeds whereby one can eliminate the friability of the preserving agent in the treatment of seeds, storage, transport, and sowing, and by discovering the physicochemical properties of polymer systems and the biological principles on the basis of which it is possible to achieve the specific synthesis of fungicides and bactericides and to create polymer compositions with a high adhesive strength.

In order to solve the social problem, it is desirable to reconstruct the technological process of the presowing preparation of seeds by the following measures: to devise systems for the remote control of the preserving-encapsulation process which would eliminate contact between man and toxic preparations; to develop machines for the encapsulation of cotton seeds and the seeds of other agricultural cultures, which would differ from the existing analogous devices by social advantages combined with a comparatively high productivity; to develop measures for the replacement of traditional preserving agents by compounds of both chemical and biological origin which are non-toxic to warm-blooded animals.

For the solution of the problems formulated, an experimental-industrial specimen of an ecologically closed device "Kapsula-1" was created. It rules out, on the one hand, contact between man and preserving agents and, on the other hand, their tendency to slide off the surfaces of seeds after the additional introduction of water-soluble polymers into the suspension of preserving agents. A satisfactory social effect is achieved by constructing a device for the high-quality coating of seeds by virtue of the high strength of the adhesion of polymer coatings to the surfaces of seeds.

We have now developed together with the VNIIKhSZR polymeric forms of a series of seed preserving agents based on polyvinylpyrrolidinone, the sodium salt of carboxymethylcellulose, methylcellulose, and their mixtures manufactured both in the Soviet Union and abroad. The choice of the polymer matrices is dictated by the characteristic features of the dissolution in the temperature range coinciding with the temperatures at which the seeds of various agricultural cultures germinate. Familiar preparations with systemic and contact activities are used as preserving agents—bronocot, sandopan, alett, tigan, ridomil, and their combinations. However, the majority of these preparations exhibit a definite toxicity to warm-blooded animals and we shall therefore consider in greater detail the alett + polymer binder system.

The treatment of cotton seeds by this system does not exert a significant influence on the capacity of the seeds to germinate in the field compared with the control (phenthiuram) and does not affect the crop of raw cotton. Bearing in mind that alett is based on aluminium and the aluminium compound of triethyl phosphate, whose toxicity is low, and that the toxicity indices are not comparable with those of copper trichlorophenoxide, the data obtained in the field experiments can satisfy the high requirements of the agroindustrial complex of the region. However, the high norms for the consumption of the preparation undoubtedly cannot fail to influence the ecological system in the case of its universal use for a long time. This is why we have devoted much attention to the search for alternative plant protecting agents, which fully rule out a negative effect on the environment and which subsequently determine the ecological strategy concerning the important problem of the protection of agricultural cultures against pathogens and pests.

The complex preparation biopolan, consisting of green microalgae, an antibiotic of the polyene series, and polyvinylpyrrolidinone and systems based on chitin-chitosan derivatives are in our view most promising. Without exerting a negative influence on the capacity of the cotton plant to germinate in the field, grow, and develop as well as the cotton crop, biopolan restores the balance between various species of microorganisms in the soil, creating ultimately highly fertile ecological areas. The introduction of the antibiotic into the composition of biopolan significantly expands the methods for combating the pathogenic fungal species inducing root rot in agricultural plants. The mechanism of the action of systems of this kind has been fairly thoroughly investigated. The role of the chitin-chitosan derivatives in the plant protecting system and in the disinfection of soils has not been investigated thoroughly enough to be able to infer with a high degree of probability their effectiveness let alone recommend their introduction into agriculture. In the study of these systems, it is necessary to investigate the mechanisms of the action of such preparations and to carry out screening and field tests against different backgrounds of infection of soils by pathogenic forms of microorganisms and of pollution by dioxin and its decomposition products.

Thus the solution of problems associated with the use of plant protecting agents at the present time and in the future should follow the route involving the creation and application of a very precise and ecologically closed technology, careful selection of plant protecting agents, and the selection of the method of application, taking into account the ecological crisis situation in the region.

Division of the Institute of Chemical Physics of the USSR Academy of Sciences.

The activity of the PDH is based on the use of natural regulators of intracellular biochemical processes. This suggests a comparatively high ecological cleanliness of preparations with photodynamic activity. Among the advantages of the PDH, one may include the high selectivity of their toxic activity based on the photodependent biological effect, achieved in plant organisms, and the impossibility of their photoactivation in the organisms of warm-blooded animals. In addition, one should note that the outcome of the effect of the PDH on the cell is the activation of radical oxidation reactions of various intercellular components and in the first place membrane components. The quantum yield of these processes can significantly exceed unity. By virtue of this feature of photodynamic processes, one may hope that it will be possible to reduce sharply the active concentrations of the preparations, which is important from the ecological and economical points of view. Furthermore, one should postulate that the non-specificity of the activity in the photodependent stage rules out the possibility of the development of plant species resistant to the PDH.

The action of propesticides (compounds which do not exhibit a pesticidal activity from the beginning) is based on the biochemical activation of the molecules by the enzyme systems of plants, as a result of which the pesticide molecules are generated in the plant cells. The species specificity of such preparations is based on the differences in the activities of enzymes in cultivated plants and weeds. Ecological aspects of the technology for the application of pesticides

K P Kutsenogii
Institute of Chemical Kinetics and Combustion, Siberian Division of the USSR Academy of Sciences, Novosibirsk

Studies on the problem of reducing the amount of pesticides in order to diminish the pesticide stress on the environment have been prosecuted for many years at the Institute of Chemical Kinetics and Combustion of the Siberian Division of the USSR Academy of Sciences.

It is believed that, for the effective use of pesticides, it is essential to achieve a certain density of the pesticide deposit and to distribute uniformly its particles on the surfaces of plants with which insects come into contact. If this postulate is always valid, then estimates show that in this case the amounts used are minimal. However, our investigations showed that this is not always true. We demonstrated that the size of the particles influences significantly the efficiency of the pesticide and that there is an optimum particle size for which the consumption of the pesticide is minimal. This size depends on the type of plant, the insect species, the meteorological conditions, and the height of the source (depending on the technology of the application). Together with the Computer Centre of the Siberian Division of the USSR Academy of Sciences, theoretical models have now been developed, which, when executed on a computer, make it possible to determine the optimum particle size. Using this generator, experimental-industrial tests have been carried out in various regions of the country, on different cultures, and with different classes of pesticides. Overall, the experimental-industrial treatment was performed on an area in excess of 200 000 hectares. It was confirmed that the application of the optimum aerosol technology makes it possible to reduce the consumption of the pesticide by a factor of 2 to 10 compared with the traditional technologies. The levels of pollution of the vegetation are reduced by a factor of 10 and more and those of the soil by a factor amounting to tens and hundreds. Aerosol treatments exert a milder influence on biocenoses. The harmful consequences to animals and man are diminished. Labour productivity becomes tens of times higher, while the expanditure of labour and materials diminishes severalfold. Six self-financing enterprises have already been organised in various regions of the country. Our main activity is nowadays concentrated on the study of remote ecological and sanitary-hygienic consequences, on the expansion of the application of the optimum technology to other classes of physiologically active substances, on the training of cadres, on the development of specific technological regulations, and on further improvement of the aerosol technique itself.

Ecological applications of the results of studies designed to assess the regulation and prediction of the stability of polymeric materials

O M Karpukhin
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

I should like to draw attention to a topic, not yet touched upon, which has a bearing on ecology and chemistry. The influence of chemistry on ecology should be manifested on at least three levels: the manufacture of chemicals, their exploitation, and their utilisation.

The matters discussed today in the Session concerned mainly problems of manufacture and the processes related to them. Very little has been said about the other two aspects, and yet this is a very important problem and certain approaches to its solution exist.

At the Institute of Chemical Physics, there exists a group of laboratories concerned with the problem of the regulation of the operational stability of a wide range of materials and not only polymeric materials.

The problem of prolonging the useful life of a material is in fact equivalent to increasing the scale of its manufacture and is therefore the problem of an ecologically clean method of increasing such manufacture.

However, it is not always necessary that the material should have the longest possible operational life. Very frequently a definite limited operational period is required after which the material should leave the system in an ecologically clean way. This is the second important problem on which studies are being conducted at the Institute of Chemical Physics of the USSR Academy of Sciences.

Ecological aspects of the technology for the application of pesticides

K P Kutsenogii
Institute of Chemical Kinetics and Combustion, Siberian Division of the USSR Academy of Sciences, Novosibirsk

Studies on the problem of reducing the amount of pesticides in order to diminish the pesticide stress on the environment have been prosecuted for many years at the Institute of Chemical Kinetics and Combustion of the Siberian Division of the USSR Academy of Sciences.

It is believed that, for the effective use of pesticides, it is essential to achieve a certain density of the pesticide deposit and to distribute uniformly its particles on the surfaces of plants with which insects come into contact. If this postulate is always valid, then estimates show that in this case the amounts used are minimal. However, our investigations showed that this is not always true. We demonstrated that the size of the particles influences significantly the efficiency of the pesticide and that there is an optimum particle size for which the consumption of the pesticide is minimal. This size depends on the type of plant, the insect species, the meteorological conditions, and the height of the source (depending on the technology of the application). Together with the Computer Centre of the Siberian Division of the USSR Academy of Sciences, theoretical models have now been developed, which, when executed on a computer, make it possible to determine the optimum particle size. Using this generator, experimental-industrial tests have been carried out in various regions of the country, on different cultures, and with different classes of pesticides. Overall, the experimental-industrial treatment was performed on an area in excess of 200 000 hectares. It was confirmed that the application of the optimum aerosol technology makes it possible to reduce the consumption of the pesticide by a factor of 2 to 10 compared with the traditional technologies. The levels of pollution of the vegetation are reduced by a factor of 10 and more and those of the soil by a factor amounting to tens and hundreds. Aerosol treatments exert a milder influence on biocenoses. The harmful consequences to animals and man are diminished. Labour productivity becomes tens of times higher, while the expanditure of labour and materials diminishes severalfold. Six self-financing enterprises have already been organised in various regions of the country. Our main activity is nowadays concentrated on the study of remote ecological and sanitary-hygienic consequences, on the expansion of the application of the optimum technology to other classes of physiologically active substances, on the training of cadres, on the development of specific technological regulations, and on further improvement of the aerosol technique itself.

Ecological applications of the results of studies designed to assess the regulation and prediction of the stability of polymeric materials

O M Karpukhin
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

I should like to draw attention to a topic, not yet touched upon, which has a bearing on ecology and chemistry. The influence of chemistry on ecology should be manifested on at least three levels: the manufacture of chemicals, their exploitation, and their utilisation.

The matters discussed today in the Session concerned mainly problems of manufacture and the processes related to them. Very little has been said about the other two aspects, and yet this is a very important problem and certain approaches to its solution exist.

At the Institute of Chemical Physics, there exists a group of laboratories concerned with the problem of the regulation of the operational stability of a wide range of materials and not only polymeric materials.

The problem of prolonging the useful life of a material is in fact equivalent to increasing the scale of its manufacture and is therefore the problem of an ecologically clean method of increasing such manufacture.

However, it is not always necessary that the material should have the longest possible operational life. Very frequently a definite limited operational period is required after which the material should leave the system in an ecologically clean way. This is the second important problem on which studies are being conducted at the Institute of Chemical Physics of the USSR Academy of Sciences.

II. INTRODUCTION OF ECOLOGICAL CONSIDERATIONS INTO CHEMICAL AND OTHER INDUSTRIES

Translated from *Uspekhi Khimii* **60** 559–564 (1991)

Certain possibilities of gas-separating membranes for the creation of ecologically clean industries

N A Plate, V V Teplyakov, V S Khotimskii, Yu P Yampol'skii
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

The problems of the separation or purification of natural, technological, and exhaust gases have now become especially acute (particularly due to the imperfection of the existing technologies). Certain problems of industrial technology can be solved with the aid of the membrane separation of gases, which constitutes in essence an ecologically clean method.

The assortment of industrial gas-separating membranes, elements, and devices available throughout the world is not as yet very great but, bearing in mind certain advantages of membrane processes, many firms (chemical companies, manufacturers of membranes, suppliers of gases, and engineering firms) have expanded wide-scale research into the membrane separation of gases. According to the prediction by the Day Chemical Company, the scale of the manufacture of gas-separating modules has increased from ten million dollars in 1985 to 145 million dollars in 1990. The separation of gases with the aid of membranes is based on the different rates of transport of gaseous components through polymer membranes due to the [different?] gradients of their partial pressures (concentrations).

A characteristic feature of membrane gas separation processes is the flow regime of their operation. A readily permeable component, for example, a harmful component, can be "removed" from the stream of gaseous raw material entering the membrane module, obtaining at one outlet from the membrane module an ecologically cleaner mixture and at the other outlet (beyond the membrane) a stream enriched in the harmful component to be utilised further or used in recycling. The degrees of extraction and sampling of the components can be varied within wide limits, but, when account is taken of the driving force of the process (partial pressure), it is most convenient to use membranes for the depletion or enrichment of gaseous mixtures with a high content of the components to be separated. At the same time, thorough single-stage purification of gas mixtures by membrane methods cannot as yet compete with alternative methods, for example, the reagent procedures.

It appears that the membrane separation of gases can be used in the solution of ecological problems in the following versions: the isolation and removal of harmful components from gaseous waste; the incorporation of membrane processes in the technology for the prevention of the formation of side products; the application of autonomous membrane devices in processes for the intensification of purification stages.

Table 1. The permeability and selectivity of certain industrial gas-separating membranes.

Type of membrane	Q, litres $m^2\ h^{-1}\ atm^{-1}$					
	H_2	O_2	N_2	CH_4	CO_2	CO
Asymmetric planar polyvinyltrimethylsilane membrane (Institute of Petrochemical Synthesis of the USSR Academy of Sciences, "Plastmassy" Scientific-Industrial Association, 1975)	2500	580	160	260	2000	160
Composite polysulphone hollow fibre (Monsanto Corporation, USA, 1979)	151	22.7	3.8	6.3	104	6.6
Composite planar membrane based on a ternary copolymer comprising fluorinated polymers (Asahi Glass Company, Japan, 1982)	1900	560	140	220	2300	–
Composite planar membrane based on cross-linked polysiloxanes (Asahi Glass Company, Japan, 1980)	4100	3400	1800	5200	13000	–

In the construction of devices, these versions are achieved by inserting membrane devices (modules) in the gaseous "tails" of exhausts from technological processes, or by incorporating membrane modules in the technological scheme for the process, or by using gas mixtures prepared autonomously by membrane methods with intensification of the stages involving the purification of solid and liquid waste. The main gas separating polymer membranes used in industry are described above (Table 1).

The asymmetric planar polyvinyltrimethylsilane (PVTMS) has been developed at the Topchiev Institute of Petrochemical Synthesis (IPS) of the USSR Academy of Sciences and has been manufactured since 1975 by the "Plastmassy" (Plastics) Scientific-Industrial Association. The membrane has been used in processes designed to enrich air in oxygen, in the isolation of hydrogen from its mixtures with nitrogen, methane, and carbon monoxide, and for the separation of mixtures of carbon dioxide and methane. Certain parameters of its permeability are presented in Table 1.

The Monsanto Corporation (USA) manufactures an asymmetric composite polysulphone hollow fibre designed for the industrial separation of water-containing gas mixtures. The membrane modules of this firm are partly used also for the enrichment of oxygen in air.

The anisotropic composite planar membranes of the Asahi Glass Company (Japan) are used mainly for the enrichment of oxygen in air and in processes designed to regulate the composition of a gaseous medium.

New polymer materials for gas-separating membranes are being vigorously investigated in world laboratories. These are, for example, silane-containing block copolymers, polytrimethylsilylpropyne (it has the most effective gas-permeability parameters among the known polymers), and siloxane-containing and other polymeric materials (Table 2). It is noteworthy that the mixtures to be separated consist, with rare exceptions, of permanent gases the diffusion of which in the membrane does not entail specific interactions. On the other hand the separation of, for example, acid gases requires the creation of materials which operate stably under severe chemical conditions. This problem is at present in the development stage (see polyamidoimides in Table 2).

Table 2. Certain experimental specimens of gas-separating membranes tested in world laboratories.

Polymeric materials	Mixtures separated
Silane-containing copolymers (Institute of Petrochemical Synthesis of the USSR Academy of Sciences)	Permanent gases, hydrocarbons
Polytrimethylsilylpropyne (Sanyo Chemical Industry, Japan; Air Products, USA; Institute of Petrochemical Synthesis of the USSR Academy of Sciences)	Air, biogas
Siloxane-containing and other polymers (General Electric Corporation, USA; Polimersintez Scientific-Industrial Association, Mendeleev Moscow Institute of Chemical Engineering, USSR)	Oxygen, nitrogen, carbon dioxide
Poly-4-methylpent-1-ene (Khimvolokno Scientific-Industrial Association, USSR: Torei Company, Japan)	Oxygen, nitrogen, carbon dioxide
Poly(phenylene oxide) (General Electric Corporation, USA)	Air
Polyamidoimides (Ube Company, Japan; Institute of Macromolecular Compounds of the USSR Academy of Sciences)	Hydrogen, acid gases

One of the examples of the membrane separation of gaseous waste is the separation of biogas (Fig. 1). This problem is particularly urgent in large cities where giant plants for the processing of waste are being built. Biogas is obtained in the biodegradation processes involving the waste from animal husbandry, the manufacture of feed, and municipal waste and is formed in enormous amounts—0.5 nm^3† per kilogram of the processed raw material. Fig. 1 shows that the liquid bioprocessing products are utilised as organic fertilisers and biogas, partly used to maintain the biofermenter in the working state, is ejected as waste. Studies on the membrane separation of biogas have been initiated at the Institute of Petrochemical Synthesis of the USSR Academy of Sciences jointly with the Institute of Microbiology of the Academy of Sciences of the Latvian SSR. Preliminary estimates (Table 3) have shown that the membrane purification of biogas will make it possible to obtain a high calorie fuel, freed from hydrogen sulphide locally, for the autonomous provision of energy without any special ecological consequences. Furthermore, it is possible to obtain technical carbon dioxide.

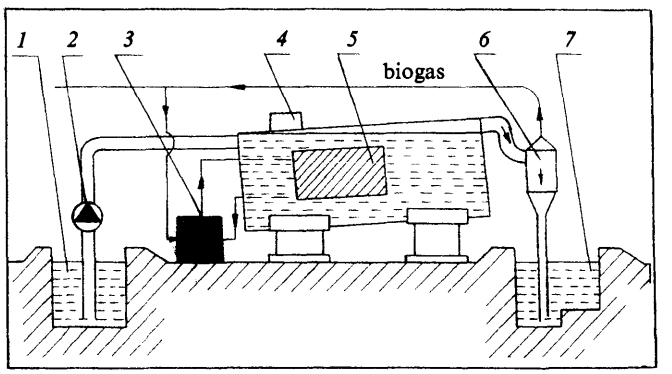

Figure 1. The biogas apparatus (Institute of Microbiology of the Academy of Sciences of the Latvian SSR): (*1*) manure storage compartment; (*2*) pump; (*3*) heat generator; (*4*) service hatch; (*5*) heat exchanger; (*6*) gas–liquid separator; (*7*) organic fertiliser storage compartment.

Table 3. Composition of biogas.

Main components	Initial biogas	After membrane purification
Methane, %	60	95
Carbon dioxide, %	40	5
Accompanying gases (H_2S, H_2, etc.), %	Up to 1	—

The heat generation by the initial biogas and the biogas after membrane purification is indicated below:

	Initial biogas	After membrane purification
Heat generation	50000 kcal nm^{-3}†	8500 kcal nm^{-3}†
	5.8 kW h nm^{-3}†	9.9 kW h nm^{-3}†

*The unit of volume is probably m^3, not nm^3 (Ed. of Translation).

One of the important ecological problems which it will be essential to solve in the next few years with the aid of membrane separation methods is that of reducing the amount of organic solvent vapours or the vapours of petroleum products ejected as waste in the form of mixtures with air. Here a typical source of pollution is not large-scale chemical plants but a multiplicity of small and medium sources—storage depots for motor fuel and filling stations, car body painting workshops in the automobile industry, furnaces for the preparation of sand moulds, etc. In the scheme applied by the Mercedes Company (Federal Republic of Germany), the organic solvent vapours are not only removed from the gaseous medium in such chambers but are also extracted for subsequent use.

Membranes based on cross-linked elastomers are usually employed for processes of this kind. For example, the separation of chloromethanes (methylene chloride, chloroform, and carbon tetrachloride) from nitrogen can be achieved with the aid of membranes based on polychloroprene rubber and its copolymers as a result of the high selectivity of the vapours in relation to nitrogen. The selectivity for gas-separating membranes usually amounts to several tens. As can be seen in Fig. 2, higher selectivities are achieved in this instance, which is extremely important since the typical concentrations of the impurities isolated from air are low.

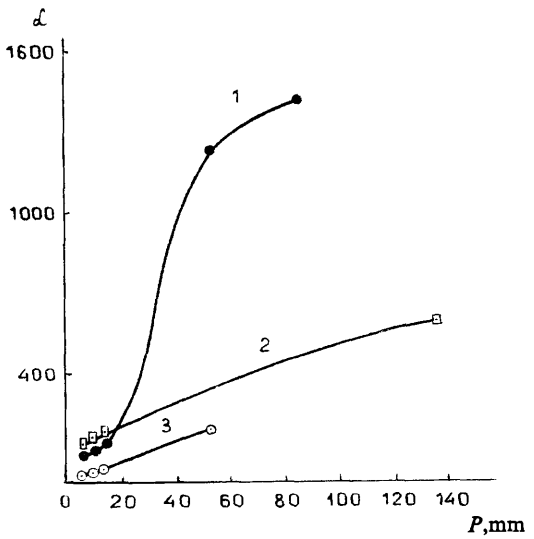

Figure 2. Dependence of the selectivity α (the ratio of the permeability of the organic solvent vapour to the permeability of nitrogen) in the separation of solvent vapours from nitrogen on the partial pressure of the vapour: (*1*) $CHCl_3$; (*2*) CH_2Cl_2; (*3*) CCl_4.

The development of membrane purification methods for gases in order to remove harmful impurities now requires the creation of highly selective and highly permeable membranes with the aid of which it would be possible to solve also the problem of the removal of acid gases from air mixtures.

As an example of the second aspect of the application of membrane processes for ecological purposes, one may consider the oxo synthesis process, i.e. the preparation of secondary alcohols and carbonyl compounds in reactions with participation of synthesis gas. In particular, in the manufacture of butyl alcohols from 2-ethylhexanol, whose output in the USSR amounts to hundreds of thousands of tonnes, the $H_2:CO = 1:1$ synthesis gas is used. On the other hand, in the steam conversion [water gas] reactions, the $H_2:CO = 3:1$ synthesis gas is obtained. Therefore, in order to obtain the synthesis gas with the required composition, one has to apply the complex technology of the copper–ammonia extraction of carbon monoxide from the stream with its subsequent injection into the initial synthesis gas in order to obtain a mixture having the required composition, for example, in the current manufacture of butyl alcohols by the "Perm'nefteorgsintez" Industrial Association.

Part of the gas resulting from the steam conversion of methane (with the composition $H_2:CO = 3:1$) is directed to the carbon monoxide isolation unit with the aid of the copper–ammonia purification. According to the specification, there should be no losses of the copper–ammonia solution, but in reality they occur and are not small. In only one industrial manufacture of the synthesis gas by the "Perm'nefteorgsintez" Industrial Association they amount to 15 tonnes annually when recalculated as metallic copper, i.e. one is dealing with waste comprising a highly toxic metal. Furthermore, ammonia compounds forming part of the composition of the copper–ammonia complex also have an ecologically harmful effect. The replacement of the absorption purification by the membrane process will not only greatly simplify the technological scheme of the process (here there is a possibility of both single- and two-stage versions with intermediate compression of the process product—hydrogen) but also fully eliminates the harmful stage involving washing with the copper–ammonia solution. Bearing in mind that similar and larger plants exist also at other sites (Angarsk, Salavat), the development of a membrane process for controlling the composition of the synthesis gas, which is now being initiated at the Topchiev Institute of Petrochemical Synthesis of the USSR Academy of Sciences in collaboration with the All-Union Institute of Petrochemical Processes, can be important both as regards the community and the protection of the environment.

As regards the third field of application of membranes, nowadays this can concern devices for the preparation of air enriched in oxygen and for the intensification of various biopurification processes. The manufacture of gas-separating devices for the enrichment of air in oxygen based on the Soviet PVTMS gas-separating membrane, the first of its kind in the world, has been initiated in the USSR (Table 4). The "Kriogenmash" Scientific-Industrial Association manufactures also MVK [MAO?—membrane air–oxygen] apparatus of this kind with a productivity of 12.5 to 300 nm^3 of air per hour, the air being enriched in oxygen up to 35%. Such autonomous sources of oxygen are designed to increase the efficiency of the aerobic biopurification of waste; they improve the parameters of other oxidation processes.

One can also imagine that membrane gas-separating devices can play a definite role in the creation of ecologically clean internal combustion engines. Estimates have shown that for this purpose it is necessary to ensure, under room conditions, streams with a flow rate amounting to tens of cubic metres per hour with an oxygen concentration up to 30%. The existing industrial membranes do not possess such capacities. Among laboratory specimens, the greatest hopes are concentrated on polytrimethylsilylpropyne which occupies an unusually high place even in the leading group of organosilicon polymeric membrane materials. Table 5 shows that its permeability is higher by an order of magnitude than the permeabilities of other

materials. If the problem of the manufacture of such a membrane can be solved, then, apart from improving the technical-economical parameters of the operation of the engine, by increasing the oxygen content and reducing the nitrogen level in the air mixture it will be possible also to reduce the ejection into the surrounding atmosphere of the combustion products in the form of hydrocarbons, nitrogen oxides, and solid carbon. The same situation arises also in fuel–energy plants.

Table 4. Membrane gas-separating devices of the MVK series designed for the preparation of air enriched in oxygen directly from the atmosphere.

Principal characteristics	MVK 0.0125	MVK 0.025	MVK 0.3
Productivity, $nm^3 h^{-1}$*	12.5	25.0	300
O_2 concentration, %, not less than	35	35	35
Specific energy consumption, kW h m^{-3}	0.35	0.25	0.14
Starting time, min	1–2	1–2	2–3

*Probably $m^3 h^{-1}$ (Ed. of Translation).

Table 5. Gas permeability coefficients (P) for organosilicon polymers.

Polymer	$10^9 P$, cm^3 cm $cm^{-2} s^{-1}$ $cmHg^{-1}$			
	hydrogen	methane	oxygen	nitrogen
Polyvinyltrimethylsilane	20	1.8	4.4	1.1
Polydimethylsiloxane	65	95	60	28
Polytrimethylsilylpropyne:				
Japan Institute of Petrochemical	690	720	400	200
Synthesis of the USSR Academy of Sciences	700	–	590	280

Thus the possibilities of ecologically clean membrane gas separation processes are associated primarily with the creation of new polymeric materials and membranes with an exceptionally high productivity and selectivity and also with the creation of membrane methods and devices in which the membrane would play not only the role of a separating element but would also be actively involved in the chemical reactions of the substances, i.e. would play the role of a membrane reactor.

Chemical aspects of a circulating water supply

M I Kabachnik, N M Dyatlova
Nesmeyanov Institute of Organoelement Compounds,
USSR Academy of Sciences, Moscow
All-Union Institute of Chemical Reagents and Specially Pure Chemicals, Moscow

One of the most important ecological problems is that of water. Using water from various natural sources in enormous amounts, the human population partly wastes it by evaporation but most of it is returned to nature in the liquid but contaminated form. In the USSR the overall water resources amount on average to 4500 km^3 per year (4/5 corresponds to surface waters and 1/5 to subsoil waters). It is believed that a little more than 110 km^3 of water can be used annually for industrial and agricultural needs and for utilities without harming the water balance in the country. The industrial consumption of water in the USSR runs to many tens of cubic kilometres (from 40 to 60 km^3 according to different data). Approximately the same amount of water is consumed domestically by the population. The manufacture of one tonne of nickel requires on average 800–850 tonnes of water. The bleaching of 1 tonne of cotton requires 280 tonnes of water. One tonne of caustic soda requires 250–300 tonnes of water, etc. Naturally, even in related undertakings, these consumptions differ markedly. Nevertheless they are very large. A similar situation has been observed also in other industrially developed countries. For this reason, the saving of water and the fight against the exhaustion of the water resources of our planet and the contamination of water have now become one of the most important problems facing humanity.

One of the aspects of the solution of this problem involves the conversion of industrial undertakings and heating systems to a circulating water supply. Trends of this kind are characteristic of many branches of industry, but they are perhaps most characteristic of ferrous metallurgy—a large consumer of water.

The water economy in metallurgical undertakings has developed rapidly during the last decades towards the creation of a circulating water supply system.

More than one thousand circulating water supply systems have now been created in the undertakings of the Ministry of Ferrous Metallurgy of the USSR; the fraction of the circulating water supply in the overall water consumption of this branch of industry has exceeded 85%.

The conversion of the water economy of any industry to circulating schemes leads to a gradual impairment of the quality of water in the systems. As a result of the repeated employment of limited volumes of water (with a necessary external supply to make good the losses) in such systems, salts accumulate and dense salt deposits are formed on the equipment.

The formation of salt deposits in circulating water supply systems is now occurring on a wide scale. Industrial undertakings suffer annual additional costs and losses running altogether to several hundreds of millions of roubles. The removal of part of the circulating water to water reservoirs in order to reduce the content of sparingly soluble salts and thus diminish the rate of formation of deposits is used as a palliative solution. It is then necessary to

materials. If the problem of the manufacture of such a membrane can be solved, then, apart from improving the technical-economical parameters of the operation of the engine, by increasing the oxygen content and reducing the nitrogen level in the air mixture it will be possible also to reduce the ejection into the surrounding atmosphere of the combustion products in the form of hydrocarbons, nitrogen oxides, and solid carbon. The same situation arises also in fuel–energy plants.

Table 4. Membrane gas-separating devices of the MVK series designed for the preparation of air enriched in oxygen directly from the atmosphere.

Chemical aspects of a circulating water supply

M I Kabachnik, N M Dyatlova
Nesmeyanov Institute of Organoelement Compounds,
USSR Academy of Sciences, Moscow
All-Union Institute of Chemical Reagents and Specially Pure Chemicals, Moscow

One of the most important ecological problems is that of water. Using water from various natural sources in enormous amounts, the human population partly wastes it by evaporation but most of it is returned to nature in the liquid but contaminated form. In the USSR the overall water resources amount on average to 4500 km^3 per year (4/5 corresponds to surface waters and 1/5 to subsoil waters). It is believed that a little more than 110 km^3 of water can be used annually for industrial and agricultural needs and for utilities without harming the water balance in the country. The industrial consumption of water in the USSR runs to many tens of cubic kilometres (from 40 to 60 km^3 according to different data). Approximately the same amount of water is consumed domestically by the population. The manufacture of one tonne of nickel requires on average 800–850 tonnes of water. The bleaching of 1 tonne of cotton requires 280 tonnes of water. One tonne of caustic soda requires 250–300 tonnes of water, etc. Naturally, even in related undertakings, these consumptions differ markedly. Nevertheless they are very large. A similar situation has been observed also in other industrially developed countries. For this reason, the saving of water and the fight against the exhaustion of the water resources of our planet and the contamination of water have now become one of the most important problems facing humanity.

One of the aspects of the solution of this problem involves the conversion of industrial undertakings and heating systems to a circulating water supply. Trends of this kind are characteristic of many branches of industry, but they are perhaps most characteristic of ferrous metallurgy—a large consumer of water.

The water economy in metallurgical undertakings has developed rapidly during the last decades towards the creation of a circulating water supply system.

More than one thousand circulating water supply systems have now been created in the undertakings of the Ministry of Ferrous Metallurgy of the USSR; the fraction of the circulating water supply in the overall water consumption of this branch of industry has exceeded 85%.

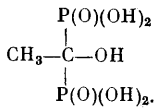
The conversion of the water economy of any industry to circulating schemes leads to a gradual impairment of the quality of water in the systems. As a result of the repeated employment of limited volumes of water (with a necessary external supply to make good the losses) in such systems, salts accumulate and dense salt deposits are formed on the equipment.

The formation of salt deposits in circulating water supply systems is now occurring on a wide scale. Industrial undertakings suffer annual additional costs and losses running altogether to several hundreds of millions of roubles. The removal of part of the circulating water to water reservoirs in order to reduce the content of sparingly soluble salts and thus diminish the rate of formation of deposits is used as a palliative solution. It is then necessary to

make good this loss by supplying fresh water to the system, which leads to partial return to open water supply systems. As industrial undertakings are converted into loss-free water utilisation schemes, it becomes urgently necessary to solve the problem of the stabilisation of the possible precipitation of deposits of salts responsible for the hardness of water, i.e. the creation of inhibitors of salt deposition and corrosion.

A similar situation has arisen in non-ferrous metallurgy, in the chemical and petroleum industry, in the systems employed in thermal electric power stations, in heat and power plants, and in other branches of industry. In all cases the organisation of an ecologically favourable circulating or closed water supply is inhibited by the abundant formation of salt deposits, whose periodic removal involves much labour and time. Hence arises the problem of preventing salt deposits, which although difficult is entirely soluble. Thus the solution of a major, one may say global, ecological problem is based on the solution of the more specific problem of inhibiting salt deposition.

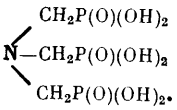
The main component of salt deposits is usually carbonates (mostly calcium carbonate), formed from the hydrogen carbonates responsible for the temporary hardness of water. Procedures for the chemical prevention of salt deposition and for washing the equipment clean have been proposed at different times—for example, the acidification of water and the use of a series of polymeric inhibitors, but best results have been obtained by employing polyphosphates, which form complexes with the cations of the deposited salts. However, polyphosphates are effective only when the content of salts in water does not exceed 3 mequiv. litre^{-1} (however, many waters, especially those from artesian wells, contain a greater amount of salts). Furthermore, in all cases the effective action of polyphosphates is comparatively brief—so long as the content of salts in the circulating water does not rise to the limit indicated above (as a result of the supply of fresh water and evaporation). Finally, polyphosphates gradually hydrolyse. Thus the use of polyphosphates does not exclude measures for the removal of salt deposits. Naturally, in their presence this can be done more rarely but it is nevertheless frequent enough.



An effective procedure for combating salt deposition involves the binding of metal cations into water-soluble complexes with the aid of complexones. The disodium salt of ethylenediamine-*N,N,N'N'*-tetra-acetic acid (EDTA) (Trilon B) was used initially as a reagent of this kind. Other carboxylic acid complexones have also been proposed. However, subsequently, following the appearance of organophosphorus complexones, they were all to a large extent displaced by the latter, since these are more effective and at the present time organophosphorus complexones are in fact widely employed to inhibit salt formation in circulating and closed water supply systems.

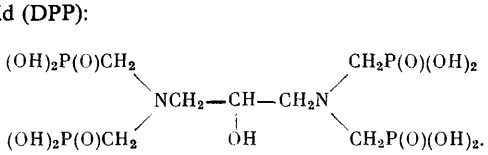
The effectiveness of organophosphorus complexones is based not only on their ability to form stable water-soluble complexes with the majority of cations present in water, but also, and this is particularly important, on their ability to effect inhibition in substoichiometric amounts, the amount of the complexone required being significantly smaller than the amount necessary for the stoichiometric formation of stable complexes. Studies have shown that this is a consequence of the adsorption of complexones on the crystallisation nuclei of the salt, which prevents the growth of the nuclei and the formation of crystals. A supersaturated solution incapable of giving rise to a deposit is formed.

Numerous organophosphorus complexones have been tested. It was found that the most effective complexones are those whose molecules contain several (three or more) phosphonic acid groups.



At the present time our industry produces the following organophosphorus compounds for the inhibition of salt deposition.

1. Hydroxyethylidenediphosphonic acid (HEDP):



HEDP is obtained from acetic acid and phosphorus trichloride. We investigated its complex forming properties and the methods for its industrial synthesis. HEDP can be used as a salt deposition inhibitor both in a pure form and in different compositions.

2. Nitrilotrimethylphosphonic acid (NTP):

NTP is obtained from ammonium chloride, formaldehyde, and phosphorus trichloride. The extremely effective IOMS combined inhibitor of salt deposition and corrosion has been developed. This preparation contains about 80% NTP, but, since ammonium chloride (a waste product in the manufacture of polyethylenepolyamines) containing an admixture of polyethylenepolyamines is used as the nitrogen-containing starting material, the preparation contains, apart from NTP, also phosphorylated polyethylenepolyamines which have a synergistic effect on NTP. The phosphorus-containing starting material used under these conditions is phosphorous acid (a waste product in the manufacture of lauryl peroxide). This results in the preparation of an extremely cheap and extremely effective salt deposition inhibitor—IOMS.

3. 2-Hydroxypropylene-1,3-diamine-*N,N,N'N'*-tetramethylphosphonic acid (DPP):

DPP is obtained from epichlorohydrin, ammonia, formaldehyde, and phosphorus trichloride. A technical product, obtained from a crude mixture consisting of 80% of 1,3-diamino-2-propanol and 20% of polymeric products of the interaction of ammonia with epichlorohydrin, is manufactured on the basis of DPP. The phosphorylation of such a mixture yields DPP and polycomplexones. This mixture is manufactured under the name DPP-1 or FOSFANOL (a neutral form of DPP-1). The effectiveness of the technical product is higher than that of pure DPP.

Each of the proposed salt deposition inhibitors has its "speciality"—the type of salt deposits which it prevents most effectively.

The use of recipes which include, apart from organophosphorus complexones, also corrosion inhibitors, surfactants, and other ingredients has become very important.

The overall volume of manufacture of organophosphorus complexones used as salt deposition inhibitors amounts at present to several thousand tonnes annually (10 commercial brands are produced). Much experience has accumulated in industry as regards the preparation of organophosphorus complexones for the inhibition of salt deposition, in particular for the stabilisation of water by complexones in circulating gas purification cycles in blast furnaces. Complexone stabilisation of water is used nowadays in the

metallurgical plants in Chelyabinsk, Novolipetsk, Magnitogorsk, and Makeevka. Use of complexones has made the extent of the formation of carbonate deposits many times smaller.

Under the influence of complexones, the previously formed deposits, consisting mainly of calcium carbonate, undergo a change in structure, soften, and are gradually washed out of the system. It has been noted that the combination of IOMS and HEDP gives rise to a positive result even for a high carbonate hardness of the circulating water (35 mequiv. litre^{-1}).

The prevention of salt deposition permitted a reduction of the cost of maintenance by a factor of several tens. Salt deposition and corrosion inhibitors have been introduced in more than 20 metallurgical undertakings.

A second example is provided by the water supply to the gas purification equipment in ferroalloy furnaces. Provision has been made for a circulating water supply. The cooling and purification of the circulating water after gas purification are carried out in the sludge accumulator. During warm seasons, the system is operated continuously. As the temperature of ambient air is reduced during winter an intense increase in salt deposition begins on the impellers of the pumping equipment supplying water to consumers. The water pressure falls and after 5–7 days the pumps have to be switched off to clean the impellers. The cleaning is carried out mechanically by hand. The use of 1 g m^{-3} of FOSFANOL makes it possible to continue the operation without stopping for the removal of the salt deposits.

Mention should also be made of the application of HEDP in chemical factories, in heat exchange systems employing artesian water with a temporary hardness of 5–7 mequiv. litre^{-1}. The employment of polyphosphates to prevent salt deposition proved ineffective. Experience gained in the operation of the water circulation cycle with the cooling water heated to 50 °C and using HEDP demonstrated the high stabilising effect of the reagent and made it possible to abandon frequent stopping of the equipment for cleaning.

It is possible to quote many more examples. Effective results have been obtained using organophosphorus complexones in the water circulating systems of non-ferrous metallurgy, in the coal industry, in the mineral fertiliser industry, in medium- and high-pressure boiler plant, in particular, in more than 20 combined heat and power generating plants, hydroelectric power stations, and atomic power stations, in the water heating boilers of central heating systems, in cooling systems with cooling towers, in hydrotransport apparatus, etc.

The consumption of the organophosphorus complexone in circulating water supply systems is usually approximately 1–3 g m^{-3}. It is noteworthy that sometimes, together with the inhibition of the salt deposition, a diminution in the corrosion of metallic surfaces is also observed. To achieve this effect, anticorrosion additives are usually introduced into the composition.

The effect of organophosphorus complexes and salt deposition inhibitors is normally considered from the standpoint of economic results attained under these conditions: a significant diminution of the cost of prophylactic maintenance, the shortening of the periods during which the equipment remains idle, and the saving of labour, metal, water, etc. The economic effect can then run into tens and hundreds of millions of roubles. However, economy is not the only concern. The use of salt deposition inhibitors permits a very wide scale employment of circulating water supply systems and its ecological effect is hard to overestimate: the saving of water, whose resources are extremely limited, is achieved and the ejection of contaminated and mineralised waters into the environment is prevented.

Naturally, the inhibition of the formation of salts in circulating water supply systems has so far been only initiated. Although a fairly wide range of phosphorus-containing complexones have been created, on the basis of which inhibiting compositions have been developed, much work still remains to be done on the introduction into numerous water consuming industries of circulating water supply systems employing salt deposition and corrosion inhibitors, which may make a major contribution to the solution of ecological problems in our country.

Biological purification of sewage from chemical plants

V N Koren'kov, B P Zhukov
Scientific-Industrial Combine "Soyuz", Lyubertsy

Sewage from chemical plants contains substances both in solution and in the form of suspensions including compounds which constitute explosion hazards. These substances may be present at concentrations many times higher than the maximum permissible concentration for reservoirs, and therefore it is unacceptable for sewage to be discharged without purification. The most satisfactory solution would be to utilise the substances present in the water and the purified water itself in the chemical plant thereby transforming the processes in the plants into operations generating a low level or even no effluent. In the scientific-industrial combine "Soyuz" at Lyubertsy a procedure for the treatment and purification of water and the recycling of water from industrial sewage has been developed and includes the following elements (Fig. 1):

1) Local installations for the purification and recycling of water from industrial sewage in each phase of the manufacturing process as a result of which 70% of the water and up to 90% of useful substances can be returned to the plants (such substances would otherwise have been irreversibly lost and it would have been necessary to purify 100% of the industrial waste waters containing a high concentration of toxic materials);

2) A facility for the purification of industrial sewage in plants in which suspended substances are mechanically removed leaving 30% of the effluents formed by washing of equipment, premises, and pipework, etc.;

3) Biological sewage works in which industrial and domestic waste waters are purified concomitantly so that all toxic components are rendered completely harmless;

4) Secondary purification plant and where necessary the exhaustive purification of biologically purified effluents with the return of this water to the process water of chemical and other plants.

State-of-the-art techniques and modern water purification equipment are used, for example ultra- and hyper-filtration, membrane electrolysers and electrolysers with a three-dimensional cathode, continuously operating self-washing filters, and compact sedimentation tanks.

Biological purification of sewage from chemical plants

V N Koren'kov, B P Zhukov
Scientific-Industrial Combine "Soyuz", Lyubertsy

Sewage from chemical plants contains substances both in solution and in the form of suspensions including compounds which constitute explosion hazards. These substances may be present at concentrations many times higher than the maximum permissible concentration for reservoirs, and therefore it is unacceptable for sewage to be discharged without purification. The most satisfactory solution would be to utilise the substances present in the water and the purified water itself in the chemical plant thereby transforming the processes in the plants into operations generating a low level or even no effluent. In the scientific-industrial combine "Soyuz" at Lyubertsy a procedure for the treatment and purification of water and the recycling of water from industrial sewage has been developed and includes the following elements (Fig. 1):

1) Local installations for the purification and recycling of water from industrial sewage in each phase of the manufacturing process as a result of which 70% of the water and up to 90% of useful substances can be returned to the plants (such substances would otherwise have been irreversibly lost and it would have been necessary to purify 100% of the industrial waste waters containing a high concentration of toxic materials);

2) A facility for the purification of industrial sewage in plants in which suspended substances are mechanically removed leaving 30% of the effluents formed by washing of equipment, premises, and pipework, etc.;

3) Biological sewage works in which industrial and domestic waste waters are purified concomitantly so that all toxic components are rendered completely harmless;

4) Secondary purification plant and where necessary the exhaustive purification of biologically purified effluents with the return of this water to the process water of chemical and other plants.

State-of-the-art techniques and modern water purification equipment are used, for example ultra- and hyper-filtration, membrane electrolysers and electrolysers with a three-dimensional cathode, continuously operating self-washing filters, and compact sedimentation tanks.

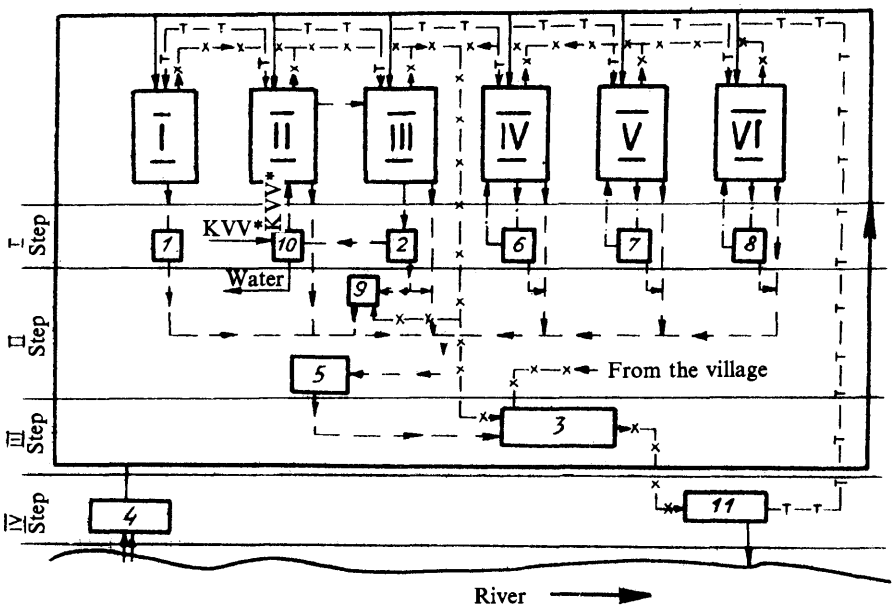

Figure 1. A four-step schematic representation of the treatment and purification of water and the recycling of water from industrial effluents: I–VI, production phases; *1, 2, 6, 7, 8, 10*, local installations for the purification and recycling of industrial wastewaters; *9*, installation for the biological purification of oxygen-containing inorganic compounds; *5*, installation for the mechnical purification of the total sewage from the plant; *3*, biological sewage works; *11*, installation for the secondary purification and exhaustive purification of sewage; *4*, water intake.

*The meaning of this abbreviation is not clear; it may refer to aluminium treatment (Ed. of Translation).

Biofilters with plastic packing, air tanks with a porous aggregate, and also a unique method involving biological reduction of oxygen-containing inorganic compounds including highly toxic hexavalent chromium and the separation of chromium as a precipitate in the form of the hydroxide, Cr(III), are used for biological purification. The latter method has been devised in collaboration with the Institute of Biology of Water Reservoirs, Academy of Sciences of the USSR. Other oxygen-containing inorganic salts of perchloric, nitric, and nitrous acids are converted into harmless chlorides and free nitrogen. This process is achieved with the aid of microorganisms isolated in the Institute of Biology of Water Reservoirs, Academy of Sciences of the USSR. This method is protected by eighteen patents published in the USA, England, France, the Federal Republic of Germany, and Italy, etc.

Heavy-duty vertical filters with a rubble packing are used for secondary purification of the biologically purified mixture of industrial and domestic effluents. Active charcoal is incorporated into the free space between the packing grains in order to achieve a high degree of purification, and the charcoal is regenerated *in situ* by a chemical treatment without the need to unload the filter. After this type of treatment the water quality meets the specifications for the water of fish-farming reservoirs (Five-day biological oxygen demand (BOD_5), 2; quantity of suspended matter, 5; nitrate nitrogen, 0.02; nitrates, 9; petroleum derivatives, 0.05 mg/litre.

The specially designed high-performance and continuously operating filters and equipment for the biological purification of water used in chemical plants have formed the basis for the creation of facilities for intensive fish farming in an enclosed recycling system. These facilities may be operated both in fish farms (for breeding young fish) and in large-scale establishmnents (for fish breeding on a commercial scale). A schematic representation of the installation is shown in Fig. 2.

The installation has a fish production capacity of 200 kg of carp per cubic metre of the reservoir per annum, whereas in fish breeding ponds the value of this parameter is no greater than 200 g/m^3 per annum, i.e. 1000-fold less productive. The installations devised are superior to the best foreign equivalents in regard to quality of recycled water, compactness, and fish production efficiency. These devices are patented in Comecon countries. More than seventeen agreements have been reached for acquiring the intensive fish farming technology designed in the scientific-industrial combine "Soyuz" in Lyubertsy. Thermal power stations have shown a particular interest in these installations.

An essentially novel and ecologically safe method for rendering waste waters harmless by the reduction of oxygen-containing inorganic compounds with open cultures of microorganisms has aroused great interest in regard to the purification of effluents from chemical plants. Waste waters from certain plants are polluted with toxic inorganic salts which are readily soluble in water and which contain bound oxygen in the molecule, for example salts of perchloric, chlorous, nitric and nitrous acids. The maximum permissible concentrations for domestic (in the numerator) and fish farming (in the denominator) reservoirs are as follows: perchlorates, 5/0.08; chlorates, 20/0.35; nitrates, 45/40; nitrites, 3.3/0.08; hexavalent chromium, 0.05/0.001.

Biochemical reduction could be the most straightforward and economical method for purification of water by removal of oxygen-containing inorganic compounds. However this type of process is

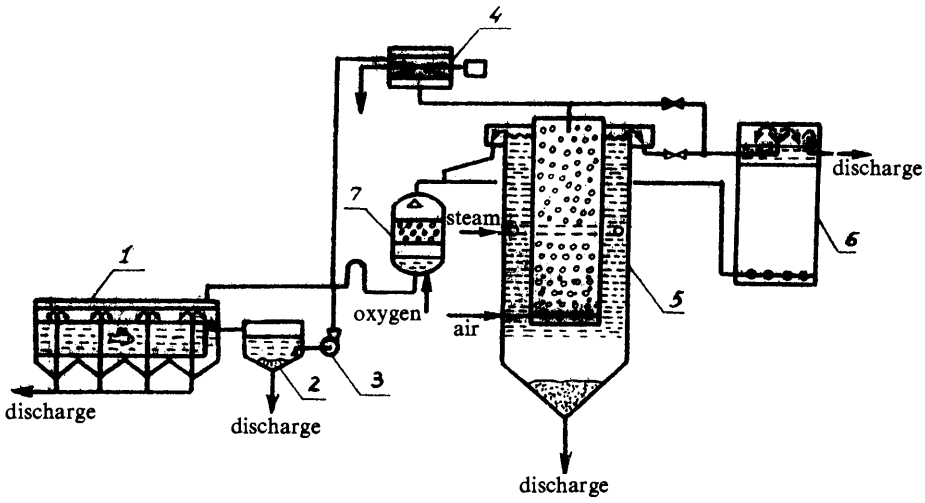

Figure 2. A schematic representation of an installation for intensive fish farming: *1*, fish tank; *2*, dirty water container; *3*, pump; *4*, continuously operating self-washing filter; *5*, aeration tank/sedimentation tank; *6*, denitrifier; *7*, oxygenator.

available for only three classes of compounds, i.e. nitrates (nitrate reduction), sulphates (sulphate reduction), and carbon dioxide (methanogenesis). Each class of compound is reduced only by a specific unique microbial culture under strictly defined conditions essential for the growth and metabolism of the microorganisms. Foreign scientists have been unable to identify microorganisms which have the ability to reduce other oxygen-containing inorganic compounds.

In order to assess the possibility of achieving the biochemical reduction of oxygen-containing anions of perchloric, chromic and other acids, the present authors have made a thermodynamic calculation of the change in the isobar-isothermal potential of the biochemical reactions occurring during the oxidation of organic substances.

It has been shown that in these reactions a whole series of oxygen-containing substances generate energy and they may be ranked in the following order of decreasing energy yield:

$$ClO_4^-,\ ClO_3^-,\ NO_3^-,\ NO_2^-,\ Cr_2O_7^{2-},\ Cr_2O_4^{2-},\ \text{and}\ SO_4^{2-}.$$

However, this does not imply that in addition to the denitrifiers and sulphate reducers there are microorganisms with the ability to reduce other anions of interest.

Nevertheless Soviet scientists in the Institute of Biology of Water Reservoirs, Academy of Sciences of the USSR, have isolated microorganisms, which have the ability to utilise the bound oxygen in salts of perchloric acid (i.e. *Vibrio dechloraticans Kusnezovi*) and also chromates and bichromates [*Bacterium dechromaticans (Rom)*][1,2].

Processes, equipment and installations for the purification of waste waters to remove these compounds with the aid of these unique strains have been developed (Fig. 3).

Optimal media have been developed for the strains discovered by V I Romanenko[3] and the morphological, cultural, and biological characteristics and sugar relationships have been studied, and the conditions required for maximum viability have been determined. The present authors have been able not only to elaborate a process but also to enhance the process in which water is rendered safe by removal of these compounds.[4]

The profile of the biochemical reduction of oxy-anions and the effect of physicochemical factors (temperature, redox potential, pH, organic substrates, etc.) on these processes have been studied in laboratory, semi-industrial and pilot-plant devices.

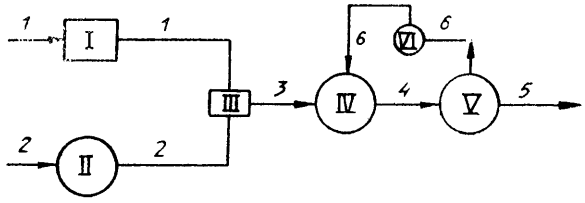

Figure 3. A schematic representation of the removal of hexavalent chromium from effluents; I, neutraliser; II, V, sedimentation tanks; III, mixer; IV, biological regenerator; VI, pump; *1*, chromium-containing waste waters; *2*, domestic waters; *3*, a mixture of chromium-containing and domestic waters; *4*, purified waters with a specific sludge and chromium hydroxide; *5*, purified effluent; *6*, specific sludge.

The process of biochemical reduction of oxy-anions can be described by a system consisting of three differential equations characterising the relationship between the rate of utilisation of the nutrient substrate, $dZ/d\tau$, the kinetics of the utilisation of chemically bound oxygen, $dE/d\tau$, and the rate of increase (or decrease) in viable specific bacteria, $dX\delta/d\tau$. By resolving this system of equations and taking into account the material balance for continuous cultivation and batch cultivation devices it was possible to obtain an equation

for the technical calculations for the installations in which salts of perchloric acid could be rendered harmless (converted to harmless chlorides) and nitrites and nitrates could be converted to free nitrogen. The nutrient substrate consisted of readily oxidisable organic substrates present in domestic effluents, surplus activated sludge, processed biofilm from normal biological sewage works, effluents from meat-packing plants, and others.

The biological method for the purification of effluents by removal of Cr(VI) devised in the scientific-industrial combine Soyuz in Lyubertsy is now being used in various branches of the national economy, since waste waters containing this harmful toxicant occur extensively not only in the chemical industry but also in a wide range of other industries (especially in the electroplating industry).

With the aid of the method recommended for the purification of chromium-containing effluents it is possible to achieve a three-five-fold reduction in expenditure on the construction of installations and engineering equipment and a five-seven-fold reduction in operating costs depends on the flow-rate of the effluents, the chromium concentration, and the required degree of purification (for each cubic metre of chromium-containing water which may be decontaminated) in comparison with the less expensive installations for the chemical removal of Cr(VI) from effluents. The cost of purifying one cubic metre of chromium-containing industrial effluent in a mixture with domestic waste water is no greater than 5–10 kopeks.

It has been confirmed by reliable medical sources that the microorganisms, which reduce Cr(VI) to Cr(III), are harmless and are not causative agents of diseases. An installation for the biological purification of water to remove Cr(VI) by a batch process has been operating trouble-free since 1974 in the scientific-industrial combine Soyuz in Lyubertsy. A facility for the continuous purification of effluents to remove Cr(VI) has been in operation for ten years in the metal-coating workshop at the "Kommunar" automobile factory in Zaporozhe providing a cost savings of 65,000 roubles. An installation for the continuous purification of ground water in order to remove Cr(VI) operating at an efficiency of 8000 cubic metres per day is now in the second year of operation in the Aktyubinsk Chromium Compound Plant (ACCP). The purified water and the chromium hydroxide obtained are used in industrial processes. A cost savings of 4.4 million roubles has been achieved. A batch process facility is being installed in the Moscow factory "Frezer". It is intended to introduce additional facilities for the removal of Cr(VI) from effluents in the automobile factory "Kommunar" and ACCP. Work will be carried out within the guide-lines of the All-Union programme "Biotekhnika" (Biotechnology) in collaboration with the Institute of Biology of Water Reservoirs, Academy of Sciences of the USSR, on the development of techniques for the removal of Cr(VI) from effluents in different branches of industry and for the reprocessing of chromium-containing dumps in ACCP which amount to five million tonnes.

An economical justification study for constructing installations in the Lyubertsy aeration station for decontaminating treated chromium-containing solutions by a biological method for 900 factories in Moscow and the Moscow district and utilising the extracted chromium is currently being carried out. The anticipated cost savings is 30 million roubles per annum. In 1988 an agreement was reached with the Italian firm Olivetti to introduce the method for biological removal of Cr(VI) in Italy. Three Italian firms are currently expressing an interest in acquiring a license.

The determining role of the redox process in the formation of the quality of the aqueous environment

Yu I Skurlatov
Institute of Chemical Physics, Academy of Sciences of the USSR, Moscow

One of the factors determining the adverse effect of man on the environment is the imbalance of redox processes in water reservoirs involving oxygen and hydrogen peroxide, agents which play a key role in the determination of water quality in the natural environment.

In recent years numerous articles have appeared in the literature on the determination of the content of hydrogen peroxide in different water systems, seas, and oceans[2,3] rivers and lakes,[4–7] and in rain and snow[8,9] and even in mineral ice samples in Greenland and in Antarctica.[10] All authors arrive at the same conclusion. Hydrogen peroxide is an inherent component of the natural aqueous environment. It can even be demonstrated that before the intervention of man the evolution of aerobic life on Earth occurred not only in the presence of oxygen and water but also in the presence of hydrogen peroxide.

Hydrogen peroxide in an aqueous environment may arise from four main sources: 1) entry from the atmosphere; 2) formation as a result of catalytic processes for oxidation involving oxygen; 3) formation as a result of photochemical reactions in the presence of sunlight, and 4) formation as a result of biological emission.

When the atmosphere becomes polluted there is an abrupt curtailment of the influx of hydrogen peroxide "from the sky" to the Earth's surface. In environmentally clean regions snow and rain contain $10^{-5}-10^{-4}$ M hydrogen peroxide, whereas according to the data obtained by the present author and co-workers hydrogen peroxide may be totally absent from regions subjected to atmospheric pollution. In turn this leads to a deterioration in the condition of soil ecosystems.

The present author has shown that the presence of hydrogen peroxide in moisture in the soil (in irrigation water) significantly enhances seed germination and plant growth, shortens the duration of the vegetative period, and increases the yield of agricultural crops.

The determining role of the redox process in the formation of the quality of the aqueous environment

Yu I Skurlatov
Institute of Chemical Physics, Academy of Sciences of the USSR, Moscow

One of the factors determining the adverse effect of man on the environment is the imbalance of redox processes in water reservoirs involving oxygen and hydrogen peroxide, agents which play a key role in the determination of water quality in the natural environment.

In recent years numerous articles have appeared in the literature on the determination of the content of hydrogen peroxide in different water systems, seas, and oceans[2,3] rivers and lakes,[4–7] and in rain and snow[8,9] and even in mineral ice samples in Greenland and in Antarctica.[10] All authors arrive at the same conclusion. Hydrogen peroxide is an inherent component of the natural aqueous environment. It can even be demonstrated that before the intervention of man the evolution of aerobic life on Earth occurred not only in the presence of oxygen and water but also in the presence of hydrogen peroxide.

Hydrogen peroxide in an aqueous environment may arise from four main sources: 1) entry from the atmosphere; 2) formation as a result of catalytic processes for oxidation involving oxygen; 3) formation as a result of photochemical reactions in the presence of sunlight, and 4) formation as a result of biological emission.

When the atmosphere becomes polluted there is an abrupt curtailment of the influx of hydrogen peroxide "from the sky" to the Earth's surface. In environmentally clean regions snow and rain contain $10^{-5}-10^{-4}$ M hydrogen peroxide, whereas according to the data obtained by the present author and co-workers hydrogen peroxide may be totally absent from regions subjected to atmospheric pollution. In turn this leads to a deterioration in the condition of soil ecosystems.

The present author has shown that the presence of hydrogen peroxide in moisture in the soil (in irrigation water) significantly enhances seed germination and plant growth, shortens the duration of the vegetative period, and increases the yield of agricultural crops.

An ecologically safe method for stimulating plant growth devised by the present author is being introduced in Moldova for glasshouse and field cultivation. Results obtained from trials with soya-bean and tomato plants indicate that an increase in yield equivalent to 500–700 roubles/hectare is being achieved.

Catalytic and photochemical processes involving oxygen are of great importance in the formation of hydrogen peroxide within reservoirs.

In the catalytic processes hydrogen peroxide accumulates during the oxidation of reducing substrates which are more reactive with oxygen than with hydrogen peroxide. An increase in the hydrogen peroxide content is usually found in areas in which untreated municipal sewage is discharged.

Sunlight is a determining factor in processes in which hydrogen peroxide is formed in surface waters and in summertime photochemical processes involving microscopic algae resulting in the formation of hydrogen peroxide are most important.[11] Examples in which hydrogen peroxide is formed as a secondary product of photosynthesis have been described in the literature.[12] With the aid of various microscopic algae the author has observed and characterised another effective channel through which the ultraviolet component of sunlight exerts an effect on algae.

The manner in which the hydrogen peroxide content in the natural aqueous environment changes over a 24-hour period is shown in Fig. 1. With the aid of a technique devised by the present author and co-workers[12] for the determination of hydrogen peroxide it is possible to make measurements with an accuracy of 10^{-7} M.

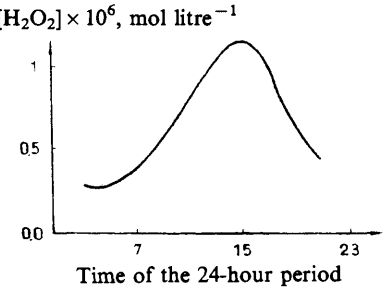

Figure 1. Diurnal course of the hydrogen peroxide content in a natural water.

The fact that the hydrogen peroxide content of natural waters is dependent on solar activity indicates that this molecule is present at a quasi-stationary level in the aqueous environment, i.e. in addition to hydrogen peroxide formation processes exist for the decomposition of hydrogen peroxide.

It has been found that both of these processes, the formation and decomposition of hydrogen peroxide, are accompanied by the efficient generation of reactive particles in the natural water and that these particles are involved in self-purification of the aqueous environment (O_2 and OH radicals and metal complexes in anomalously high oxidation states). Studies carried out by the present author and co-workers have shown that algae involved in the formation and decomposition of hydrogen peroxide promote radical and peroxidase oxidation of contaminating substances. In the summer period of the year an effective channel exists in the natural aqueous environment for the biogenic initiation of self-purification processes (Fig. 2).

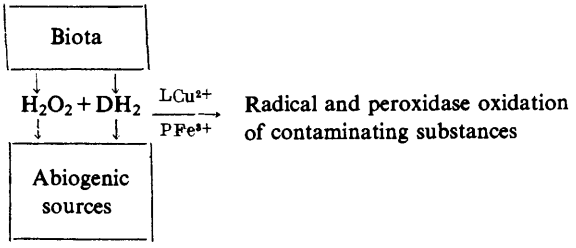

Figure 2. A chemico-biological model for the self-purification of a natural aqueous environment.

The efficiency of radical and peroxidase oxidation of contaminating substances is determined by the rate of photochemical formation of hydrogen peroxide. The present author has calculated that 10–50% of the hydrogen peroxide is decomposed in natural waters with the formation of free OH-radicals and other reactive particles.

A feature of the kinetics of hydrogen peroxide decomposition by microscopic algae is that the process is of zero or first order with respect to the hydrogen peroxide concentration, and in both cases the rate of the reaction is proportional to the algal biomass.[14]

The first-order reactions include the decomposition of hydrogen peroxide by catalase, whereas the zero-order reactions include the peroxidation of reducing substances formed in dehydrogenase reactions. The rate of the zero-order reactions is determined by the rate of formation of these substances acting as reducing agents. Under quasi-stationary conditions the rates of formation and decomposition of hydrogen peroxide are equal to:

$$W_f = k_{f,1} + k_{f,2}\,[\mathrm{B}],$$
$$W_d = (k_{d,1} + k_{d,2}\,[\mathrm{H_2O_2}])\,[\mathrm{B}],$$

so that the quasi-stationary concentration of hydrogen peroxide in the natural aqueous environment is determined by the relationship:

$$[\mathrm{H_2O_2}] = \frac{k_{f,1} + (k_{f,2} - k_{d,1})\,[\mathrm{B}]}{k_{d,2}\,[\mathrm{B}]} \approx \frac{k_{f,2} - k_{d,1}}{k_{d,2}},$$

where $k_{f,1}$ and $k_{f,2}$ are the effective rate constants for hydrogen peroxide formation, and $k_{d,1}$ and $k_{d,2}$ are the rate constants for hydrogen peroxide decomposition.

The main conclusion from this simplified picture is that two situations may arise in the aqueous environment depending on whether the flow of hydrogen peroxide or reducing substances is predominant.

The redox state exhibits a diurnal or seasonal course in accordance with the change in solar activity and water temperature. It has been found that the transition of the environment from a state in which hydrogen peroxide is present in the water to a state in which reducing substances (which readily interact with hydrogen peroxide) are present is of great significance for aqueous ecosystems. When quasi-reducing conditions are formed in the water, the water

becomes toxic for organisms which undergo intensive water exchange with the environment.

Fish larvae in the early stages of development obtained from artificially breeding sturgeons (Chondrostei) and phytophagous fish serve as a bio-assay of the change in redox state of the aqueous environment (Fig. 3).

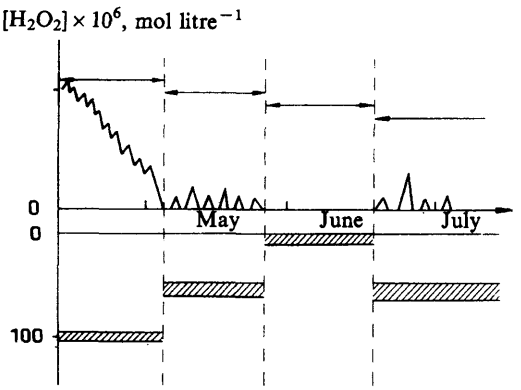

Figure 3. Seasonal time-course of the redox-state and toxicity of the aqueous environment in reservoirs in which blooms of blue-green algae have developed.

Under conditions in which toxic reducing conditions have been formed in the water, addition of hydrogen peroxide to the water leads to the normalisation of larval development. The present author and co-workers have developed and introduced into VORZe Fish Breeding Stations a method for breeding larvae of sturgeons which is based on the addition of further quantities of hydrogen peroxide to the water in which toxic reducing conditions have arisen.

By comparing the results obtained from the determination of the content of hydrogen peroxide in the Volga water with data on the death rate of larvae in Fish Breeding Stations it was possible to conclude that the seasonal changes in the redox state in the Volga began in 1976. Prior to this data the factory produced more than twelve million sturgeon fry per annum, whereas after this data this figure was less than eight million. By addition of hydrogen peroxide to the water it has been possible to breed more than five million additional physiologically sound Caspian sturgeon fry (an increase of more than one million fish above the previous maximum value).

Evidently a change in the redox state of the aqueous environment is a decisive factor in the reduction of the breeding potential for fish which spawn in the summer period of the year.

Two years ago a new problem arose with sturgeons. Stratification of muscle tissue in sexually mature fish and egg resorption was observed. Apparently this phenomenon was also associated with the disruption of the redox state in the Volga which occurred in 1976, since the commercial returns on the fish (catches) begin precisely within 10–12 years. In fact now the results of those impairments in the physiological development of the fish larvae which occurred in the larval stage can be seen.

The blue-green algae act as generators of reducing substances which leads to a change in the redox state of the natural environment.[15] Under conditions of interspecies competition they release into the environment certain substances which readily interact with hydrogen peroxide (Fig. 4).

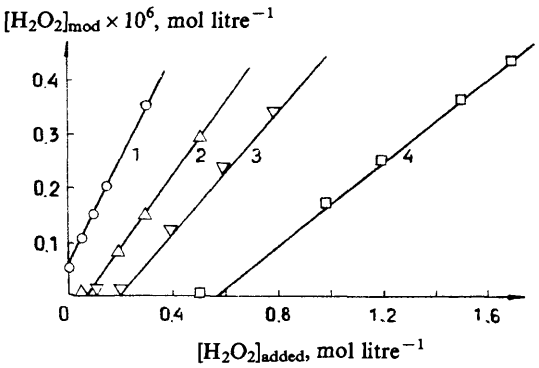

Figure 4. Interaction between hydrogen peroxide and substances acting as reducing agents which were released by blue-green algae (dark conditions).

Note. The key to the numbered plots are not given in the original manuscript (Ed of Translation).

The rate of generation of the reducing substances is determined by the ecological factors, temperature and illumination.

Although the formation of reducing conditions in the water is not accompanied by any significant changes in hydrochemical parameters, several adverse consequences immediately arise.

1. The hydrogen peroxide disappears, the hydrogen peroxide which is essential for the normal operation of physiological processes in organisms with an intensive water-exchange mechanism (the same fish larvae in the early stages of development).

2. There is a transition of copper into the biologically unavailable non-reactive reduced form, apparently in the form of a complex with sulphydryl compounds. Consequently respiratory apoenzymes may be synthesised and these apoenzymes contain no copper in the active centre in the early stages of development of the aquatic organisms. Such cases have been described in the literature in regard to plant cells.[16] It is of great interest that when the biosynthesis is terminated the appearance of copper in the medium does not lead to the activation of the apo-enzyme.

3. It is possible that the reducing agents themselves, which are involved in the formation of the reducing state of the aqueous environment, have a toxic action. One cannot rule out the possibility that substances released by blue-green algae into the environment constitute one variety of the so-called algotoxins.[17] Research workers in many countries throughout the world have studied the algal toxins, which appear in reservoirs in which blooms of blue-green algae have arisen. Cases in which large numbers of birds and animals have perished are known and there have been instances of human food poisoning when water from "blooming" reservoirs has been consumed.

4. There is a sharp decline in the self-purifying capacity of the aqueous environment. Under these conditions toxic compounds of natural or anthropogenic origin may accumulate in the water.

5. The development of a pathogenic microflora is found, and the reducing environment favours the development of these organisms. Cases of large-scale outbreaks of human diseases such as heptatitis, cholera, amoeboid meningitis, etc. have been reported. It has been suggested that the death of large numbers of Baltic seals from distemper was associated with the blue-green algal blooms in the Baltic Sea. One should note that even in small quantities hydrogen peroxide inhibits photosynthesis in blue-green algae and suppresses the mass development of the algae. Thus the control of processes which determine the content of hydrogen peroxide in the natural environment is an urgent problem.

The present author considers that one of the factors which promote an imbalance of reservoir redox processes, in addition to the regulation of river discharge and contamination of waters with nitrogen- and phosphorus-containing mineral compounds, is the fact that the possible effect of the redox state of the municipal effluents purified by biological methods has not been taken into account.

The studies carried out by the present author on the municipal sewage works in Belgorod showed that under oxygen deficient conditions before transfer to the aeration taken reducing substances appear in the effluents which are toxic to aerobic organisms and which can be titrated with hydrogen peroxide. Furthermore these toxic substances partially pass through the biochemical sewage purification plant. At the same time the readily oxidisable compounds are retained in the aeration tank and on entry into a reservoir these compounds would promote the formation of hydrogen peroxide and detoxify the reducing toxins. This implies that the sewage plant for the biological purification of municipal effluents may act as a kind of filter which inhibits the entry of hydrogen peroxide into the water thereby exerting a pronounced effect on the redox processes within the reservoir.

This suggestion is not without foundation. One may recall that sturgeons began to perish in the Volga in 1976. In the same year sewage plants for the biochemical purification of effluents of large cities in the Volga basin came into operation.

A new consequence of the imbalance of redox processes within the reservoirs and the associated radical-mediated processes in natural waters was the appearance of the super-oxidising state of the aqueous environment in a number of reservoirs. This was most pronounced in the Pripyat and Dnepr rivers after the Chernobyl disaster. The super-oxidising state apparently arises during extreme intensification of radical-associated oxidation processes. The carriers of superoxidised equivalents are sorbed on to suspended particles. The nature of these components has not been precisely determined but EPR data indicate that they could be microcolloidal particles of manganese in mixed oxidation states (+3, +4).

During the formation of the superoxidised state of the environment in the water adult breeding fish {phytophagous and fish caught in a fine-mesh [sic. A type of fish? (Ed. of Translation)] net} begin to perish in fish farms and in natural reservoirs. The addition of reducing agents, for example ascorbic acid, to fish farming ponds in which the superoxidised state has been formed, leads to the normalisation of the situation.

Thus redox processes and the associated radical processes play an exceptionally important role in the formation of the quality of the natural aqueous environment and in the resolution of problems of nature conservancy. The latter is associated with the intensification of purification of effluents, the regulation of water quality in fish farms, the improvement of water quality in irrigation farming, the development of water-monitoring systems, and prevention of blooming in reservoirs used as sources of drinking water, etc. The increasing ecological pressures in many regions of the USSR dictates the need for a further extension of studies in the field of hydrochemical processes. Hopefully a real key for the control of the quality of natural waters will be found.

Problems of risk and safety in the chemical-forestry complex†

B V Gidaspov
The "State Institute of Applied Chemistry" Scientific-Industrial Association, MGO Tekhnokhim, Leningrad

Undertakings of the chemical-forestry complex in our country constitute a serious potential threat to the lives of the service personnel and the population in the adjoining regions. The principal trend in the development of such undertakings involves an increase in output from different plants, an improvement in technological parameters (temperature, pressure, and concentration), the processing of a large amount of materials, and the accumulation in technological areas of an appreciable amount of inflammable, explosive, and toxic chemicals.

This fact requires a serious analytical approach to the development of technological processes and of equipment used in the latter and also to the planning of industrial developments taking into account the consequences which may arise in incidents of various degrees of seriousness, starting from slight leakages, failure of hermetic seals in the reaction equipment, and going as far as large scale explosions and fires.

It is noteworthy that, unfortunately, in the Soviet Union there have been in this respect virtually no systematic studies based on unique scientifically well-founded principles and the results of incidents occurring in different undertakings are not considered as a whole. At best they are retained in the subdivisions of various ministries and are inaccessible. On the other hand, one cannot fail to note that in the industrially developed countries very much attention has been devoted to the problem of risk and safety, including the ecological safety of chemical undertakings— programmes are being developed at the governmental level, being financed both by the government and individual firms. For example, in the EEC countries alone three programmes have been realised recently and the fourth, concerned with problems of the safety of chemical industries and the prevention of accidents, is being carried out. A series of centres for the study and prediction of catastrophes have been created in the USA at well known universities and in major companies. Specialist journals are being published and specialists are being trained. The importance and urgency of this problem were emphasised at a conference held in 1987 in Rome, where more than 140 reports representing virtually all the industrially developed countries were delivered.

It is important to emphasise that the relevant research is based on a systematic approach to ensuring safety at all stages of planning and exploitation: in the normal, pre-accident, and accident regimes with localisation of the consequences of the accident including its organisational aspects.

The estimation of risk and the adoption of appropriate measures designed to diminish it constitute one of the main aspects of the procedures for ensuring the safety of the control of processes in devising plans for coping with accidents and in planning new industries. The stages in the assessment of risk are as follows:

1. Identification of the danger in which one usually employs "denial tree" and "events tree" methods or denials type analysis. The necessity to examine the entire spectrum of the possible types of danger (from minor frequently occurring breakdowns to major and rare accidents).

2. Analysis of the consequences of accident situations based on the mathematical models devised taking into account the severity, danger, and type of incident.

3. Analysis of the frequency of incidents in which "denials or events trees" are also used.

4. Estimation of the degree of risk as a combination of the frequency of the event and the severity of its consequences. Naturally, all the studies are being prosecuted with a wide-scale employment of computer systems.

More than 60 data banks concerning incidents in chemical undertakings as well as 120 data banks concerning dangerous chemicals are known to exist abroad at the present time. Programs for the abolition of major incidents in chemical plants for the manufacture of herbicides, in petrochemical complexes, etc. have been developed in detail. In individual instances the expenditure on the application of methods for the analysis of the risk in technological processes and industries reaches 20–25% of the total cost and yet it pays for itself in the course of a short period (5–6 years) of operation.

Unfortunately, the trends which can be clearly traced in the activities of the research organisations in the world are much less pronounced in the activities of the corresponding organisations of the Soviet Union, although the general trends in the development of the technosphere in chemical industries are approximately the same in our country. As an example, one can show that the proportion of factories and their output have been increasing in the petrochemical complexes of developed countries: in the USA, Canada, and the Soviet Union (Fig. 1).

It has to be said that petrochemical complexes constitute a very serious risk. For example, the petrochemical complex located close to Leningrad in the town of Kirishi contains approximately 500 000 tonnes of combustible petroleum products in an area of approximately 1.5 km^2. If one admits the theoretical possibility that these petroleum products can form a gas–air mixture, then the power of its overall explosion will be approximately equivalent to the explosion of a 3–5 megatonne nuclear device. Naturally, the consequences of such an accident would be felt over distances running into many tens of kilometres.

At the same time one cannot fail to note that experience gained in the work of organisations associated with the creation of specialist engineering techniques in our country and in the first place in space rocket engineering (much experience has been accumulated in a series of organisations associated with the creation of the space rocket technology in our country including the safe exploitation of both the rocket themselves and of the launching equipment) merits continuous attention specially under the conditions of the developing changes. It is now appropriate and necessary to pose the question concerning the use of this experience for reducing the degree of risk and increasing the safety of chemical industries. For example, at the State Institute of Applied Chemistry Scientific-Industrial Association (SIAC SIA‡) and also in the organisations working in cooperation with the latter, extensive researches have been conducted and are

†This seems to be a euphemism for the rocket fuel industry (Ed. of Translation).

‡Russian abbreviation NPO GIPKh (Ed. of Translation).

being conducted, including large-scale experiments, into the potential danger of chemical compounds used in specialist technology (rocket fuel, etc.). A broad spectrum of inflammable and explosive properties of various metallic and non-metallic materials is being investigated; systems have been created whereby one can analyse the possibility of the development of a thermal explosion as the most typical cause of many accidents; programs have been developed whereby it is possible to create mathematical models which effectively reproduce the real situations frequently observed in reality. Thus, detailed fundamental studies on the interaction of self-inflammable components with nitrate oxidants made it possible to demonstrate clearly the impossibility of the detonation of this system even when the components are mixed rapidly. This in turn led to a multibillion economic gain in the creation of a whole series of launching systems.

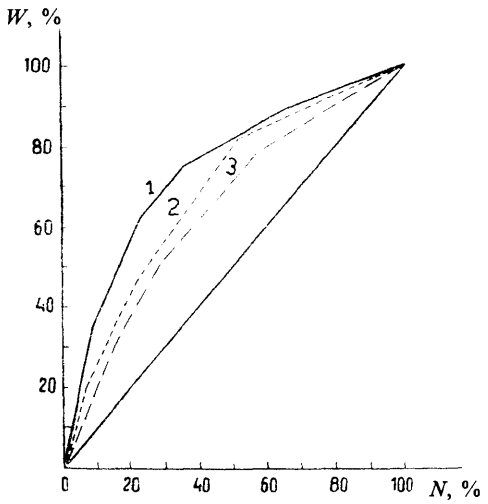

Figure 1. The increase in the power (W) and the fraction of factories (N) in petrochemical industries throughout the world: (*1*) USA, 1985; (*2*) Canada, 1984; (*3*) USSR, 1985.

In many accidents which have occurred in our country on military firing ranges and in the course of special large-scale experiments (for example, in the simulation of the break up of a rocket in the tube of a submarine) a virtually complete agreement between prediction and the real consequences of accidents of this kind was demonstrated. Detailed investigation of the transient processes in the combustion and detonation of liquid and gaseous oxygen and hydrogen led to the creation of reliable fire and explosion warning systems in the "Energy"–"Storm" complex known throughout the world.

As regards considerations with a direct bearing on chemical industries, one should note that the most typical cause of accidents is inadequate knowledge of the relevant chemistry and also of the physical processes in various stages of potentially dangerous industries. For example, in the manufacture of hydrogen peroxide by the isopropyl method (Kuibyshev) there have been several accidents of various degrees of severity associated with the fact that in the various stages of the study of this process the side products arising from the oxidation of isopropyl alcohol by hydrogen peroxide were undetected. These peroxide compounds are typical initiating explosives as regards their characteristics and their accumulation in the stagnant zones of any kind of apparatus, starting with columns and extending to pumps, inevitably leads to an accident. The understanding of the mechanism of this phenomenon made it possible to take necessary technical measures which reduced the risk and danger in this industry and in recent years we have fortunately not had any such incidents.

A similar typical error, made in the research stage, consists in the fact that sometimes no account is taken of the possibility of the formation of explosives in other systems. For example, in 1988 an explosion occurred at the Kropotkin chemical factory. Studies conducted at the SIAC SIA showed that, apart from the target reaction designed to produce polyfurite, a polyfurite–sodium perchlorate explosive mixture is also formed. Perchlorates accumulated and, in combination with the combustible substances, generated an explosive substance which was the cause of the explosion. The use of perchloric acid in this industry is the main source of risk.

The second cause of accidents is that the probability of the occurrence and thermodynamics of reactions leading to side products, whose heats are sometimes greater than that of the main reaction, are not always accurately calculated. We again refer to the experience gained at the SIAC SIA: a serious explosion with the breakup of the apparatus and of the building in the manufacture of perfluoro-oenanthic acid occurred in October, 1986 at the experimental factory in Dzerzhinsk. The heat of the main reaction, for which the apparatus was designed and in relation to which the entire technological process had been tested, did not exceed 6 kcal mol^{-1}:

$$2CF_3(CF_2)_5COOCH_3 + KBH_4 + 2CH_3OH \rightarrow$$
$$2CF_3(CF_2)_5CH_2OH + KBO_2 + 2C_2H_5OH + 6 \text{ kcal mol}^{-1}.$$

It has now been established that, together with the main reaction, there is a possibility of a side reaction between methyl perfluoro-oenanthate and potassium perborate in the presence of methanol, whose heat is 50 kcal mol^{-1}:

$$2CF_3(CF_2)_5COOCH_3 + KBH_4 + 3CH_3OH \rightarrow KF + BF_3 +$$
$$+ C_6F_{14} + C_3F_8 + H_2O + 6CO + 4CH_4 + 2H_2 + 50 \text{ kcal mol}^{-1}.$$

The reaction takes place when the synthetic process is carried out in a reactor whose size differs significantly from that of the analogous reactor used in the laboratory method and leads to a thermal explosion in air of the products of the synthesis.

In research and particularly in planning studies, very little account is taken of secondary factors in accidents. In particular, the failure of the hermetic seal in a 50 m^3 vessel (and this is still a very small volume) filled with a combustible gas, for example, natural gas or any other hydrocarbon, leads to burns and damage felt over a distance of approximately 3 km.

Fig. 2 presents curves for the variation of pressure in the shock wave front on detonation and the explosive pulse in this case. Here no account was taken of the fact that many factors — temperature inversion, wind, accidental ground features, secondary fragments, etc. — make an additional "contribution" and intensify the effect of the explosion and hence must be taken into account in assessing the risk of a real accident of this kind.

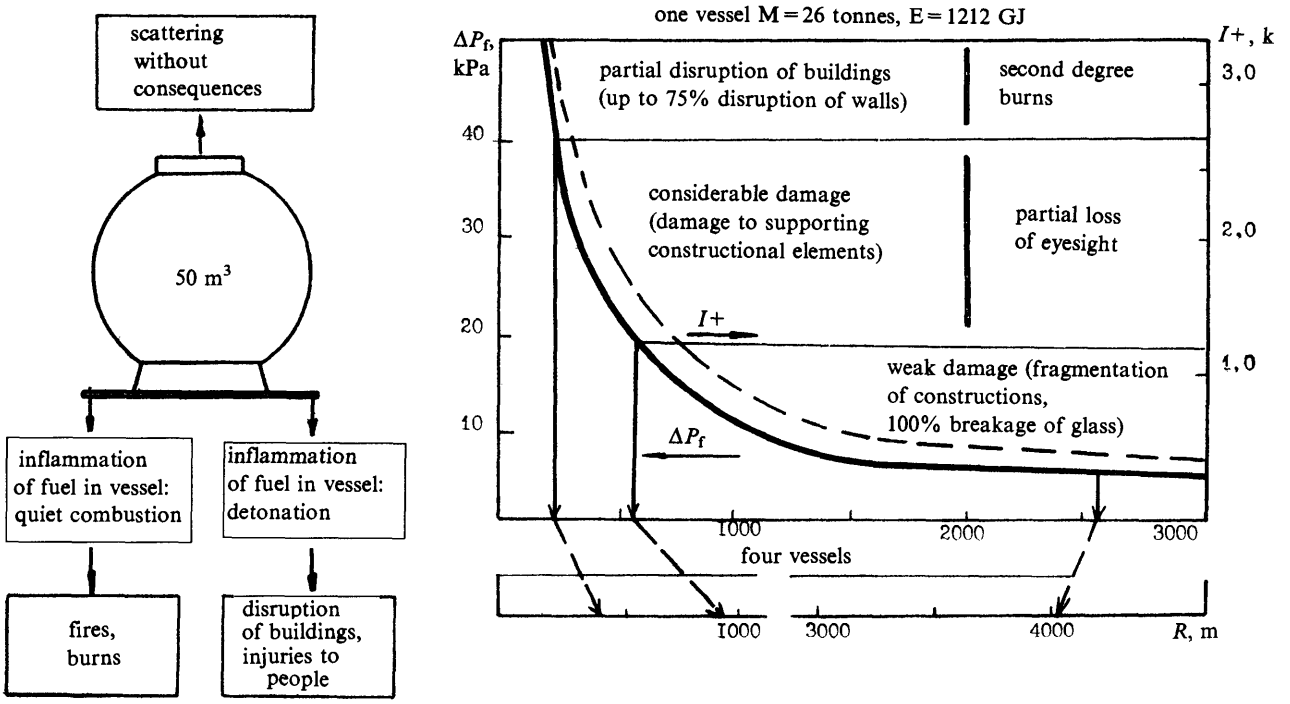

Figure 2. Danger of failure of the hermetic seal and explosion of a container (V = 50 m^3); Δ_{p_f}, change in pressure in shock wave front; I, explosion pulse; R, radius of action.

The pollution of the environment by chemical products during various accidents is also a serious risk factor and requires continuous study.

The most important field of research, which in our country also lags in its development, involves the creation of systems for the automated control of processes which would make it possible to assess not only the occurrence of a process "post factum" but also the onset of a pre-accident situation and on a time scale such that it would be possible to localise these accident situations by altering the technical parameters.

Thus one is dealing with the creation of not simply automated control systems but systems for the early identification of processes, especially in those stages where they are potentially dangerous. It is noteworthy that, for the solution of the set of problems listed above, concerning the questions of safety of industry, including chemical industries, it will be desirable to make use of the existing experience in the organisation of similar studies already gained abroad.

Such experience also exists in the Soviet Union. In particular, methods for dealing with leakages of rocket fuels have been developed in the course of many years at the SIAC SIA. These methods included both technical aspects for the abolition of the consequences of such leakages and provided for all the organisational measures. It has to be said that the many breakdowns which have occurred, for example, as a result of railway accidents, were made good fairly rapidly and without human casualties. Such experience should be transferred also to chemical undertakings.

Here it is useful to point to the relationship between the conditions governing the occurence of modern accidents and the structure and expenditure on their prevention. We may note that the present expenditure does not yield the required effect because it is concentrated on technical systems and there has been virtually no expenditure on the training of directing personnel to take control of safety measures. The tragic events in Chernobyl and the earthquake in Armenia showed how important it is, in the initial stages of the development of catastrophes, to establish control by means of a set of measures and to control large masses of people in a state of psychological stress in order to diminish the consequences of the catastrophe.

Thus it is evident that we are faced by the necessity to develop significantly the studies in the field of risk and safety in the industries of the chemical-forestry complex. Such studies should be given priority by the government. One may propose the following subdivisions of research of this kind:

1. The construction of computational-theoretical models and the determination of risk factors in accident situations in chemical industries.

2. The creation of a data bank of starting materials, intermediates, and final products designed to ensure the construction of a safety system.

3. The improvement of existing methods and means and creation of new ones for the determination of the characteristics of the danger associated with chemicals.

4. The creation of a single methodology for the localisation and abolition of the consequences of explosions and emissions of toxic substances.

5. Estimation of the economic effectiveness of the measures designed to ensure the safety of chemical industries.

6. Analysis and expert assessment of measures designed to improve the ecological aspects and safety of the existing chemical undertakings. Events of recent years — numerous accidents and even catastrophes — which we have witnessed and in which we have participated, demonstrate that the development of this priority field of research can not be put off.

Solid phase chemical reactions and new technologies

N S Enikolopov
Institute of Synthetic Polymeric Materials, Academy of Sciences of the USSR, Moscow

Principles for carrying out chemical reactions in solid bodies are considered in this paper as is the design of new technologies and materials based on the previously unknown phenomena which we discovered when studying reactions in the solid phase.

Modern chemical science has developed in the last 200–300 years on the basis of experiments performed while observing natural phenomena and appropriate special experiments. This knowledge became the basis of modern chemistry. However all the reactions which were observed in nature and studied under laboratory conditions proceeded mainly either in the gas or liquid phases or in solution, in melts or on the surface of a solid body. As a rule chemical reactions do not proceed or proceed extremely slowly in the bulk of a solid body because of the absence of diffusion of reactants to one another and diffusion of the reaction products. Alchemists even said that a solid body was death for chemistry since it had no motion. Several years ago we showed successfully that if a shear deformation was brought about in a solid body then at the point of shear deformation chemical reactions took place in it at extremely high rates. As is shown in Fig. 1, together with the shear stress τ there is also a certain pressure p applied to the substance being investigated in order that the system is not destroyed at the time of shear deformation. Before passing to a systematic presentation of the results of these experiments it is necessary to check that a shear deformation can be brought about in solid bodies in industry as under laboratory conditions.

Bridgman's anvil is shown in Fig. 2. The test sample (1), a substance or mixture of substances in which a chemical reaction is to be effected, is clamped between two anvils (2) of tempered steel. One of them (in the given case the lower) is rotated about its axis generating a shear deformation. This laboratory machine permits work with gram quantities. A similar shear deformation may be effected by pressing the solid test substance through a cone under high pressure (Fig. 3). Depending on the relationship $\lambda = S_1/S_2$ it is possible to vary the size of the shear deformation but the applied pressure p determines the rate of deformation. In this case it is possible to work with tens of grams of substance. There is also a series of other devices enabling experiments to be carried out under laboratory conditions. Industrial machines have been developed capable of processing tons of substance per hour. Extruders are such machines (Fig. 4). The rotating screw generates the required pressure and passes the substance into the gap formed between the stationary body of the extruder and the rotating bit of the screw. Two- and multiscrew extruders also exist where special 'cogs' effect shear deformation. At present tens of machines have been constructed in which solid phase chemical reactions can be effected under laboratory and industrial conditions.

The basic rules for carrying out solid phase chemical reactions are now considered. It has been shown that almost all reactions known in inorganic and organic chemistry will proceed under conditions of shear deformation in solid bodies. We have successfully studied hundreds of reactions such as polymerisation processes, addition, substitution and decomposition reactions, etc.

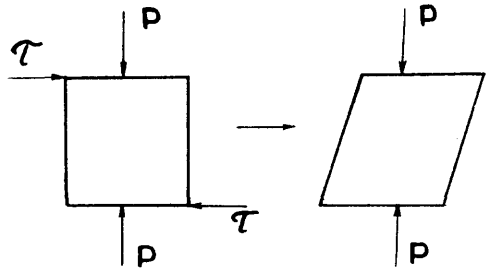

Figure 1. Schematic representation of the combined influence of pressure and shear deformation.

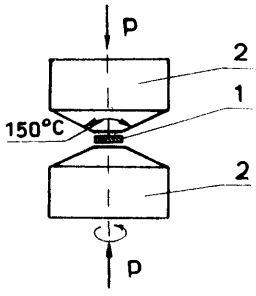

Figure 2. Bridgman's anvils.

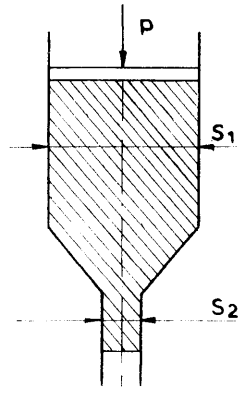

Figure 3. Outline of cone extruder.

A typical 'kinetic' curve of a solid phase reaction occurring under the action of shear deformation is shown in Fig. 5. In contrast to classical chemical kinetics the angle of rotation of the anvil and not

time is disposed on the abscissa, i.e. a value proportional to the shear deformation. The yield of product is on the ordinate as usual. All the chemical reactions studied by us proceed in accordance with the typical 'kinetic' curve.

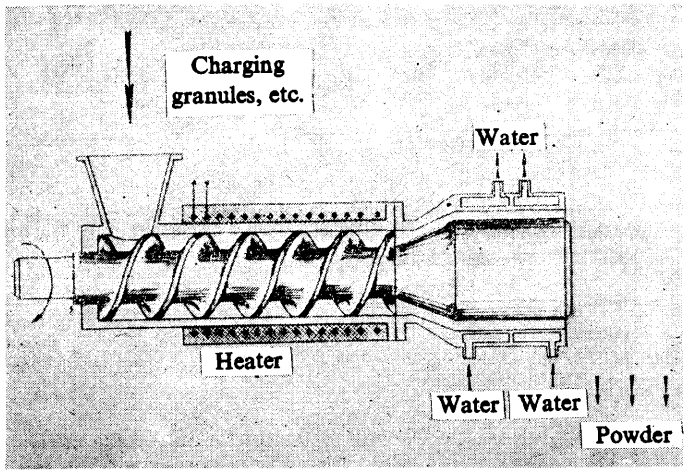

Figure 4. Extruder.

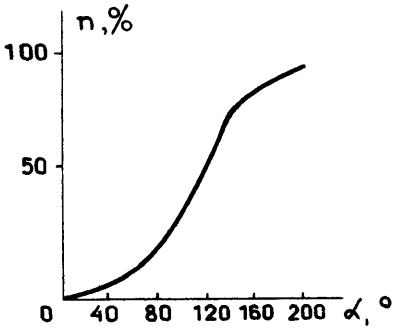

Figure 5. Dependence of polymer yield on the angle of rotation of the anvil (t = 20 °C, P = 10 kBar).

The most characteristic features of solid phase chemical reactions are as follows.

1. Simple compression of the sample by extremely high pressure does not induce a chemical reaction. After removing the shear deformation a long stay under high pressure also does not lead to an increase in product yield, i.e. there is no poste-effect. The direction of the deformation also does not influence the size of the yield. At a given value of deformation the yield will be the same independent of the rotation of the anvil to left or right or after many changes in the direction of rotation.

2. The rate of chemical conversion in solid bodies on shear deformation is extremely high in comparsion with the reaction rate in liquid and even more so than in the gas phase. Under isothermal conditions the reaction rate in a solid body is 3–8 orders of magnitude greater than in the liquid phase.

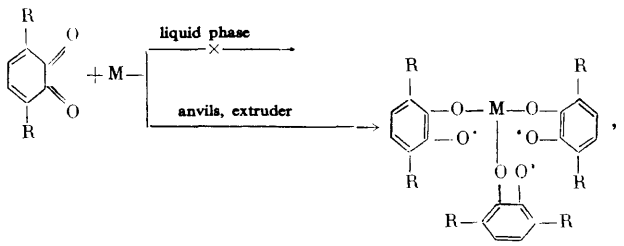
3. Under the conditions indicated the usual concept of 'catalysis' and 'catalyst' lose their classical sense. Reactions proceed without a catalyst although some special additives may influence the course of the process but this is an action on the mechanism.

4. The extent of chemical reaction is proportional only to the size of the shear deformation.

$$W = \frac{c_0 - c}{c_0} \sim \alpha,$$

where W is the extent of the reaction, α is the shear deformation, c_0 and c are the initial and running concentrations respectively.

The chemical reaction rate is proportional to the deformation rate.



$$V \sim \frac{d\alpha}{dt}.$$

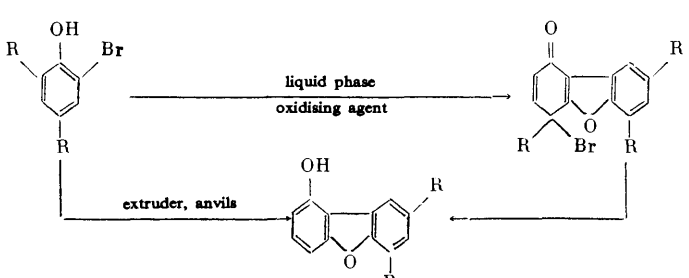
5. Mass transfer processes under the conditions indicated also have special features which are impossible to explain within the framework of the usual diffusion of molecules and atoms in solid bodies. Consequently it is impossible to use the generally accepted concept of a diffusion coefficient for the quantitative characterisation of the rate of mass transfer. Nonetheless using the concept of 'reduced diffusion coefficient' it is possible to compare the rate of mass transfer in a solid body at the point of shear deformation with the usual diffusion coefficient. It turned out that the value of the reduced diffusion 'coefficient' was 8–10 orders of magnitude greater than the diffusion coefficient in the same solid body without shear deformation and 3–5 orders of magnitude greater than the diffusion coefficient of the same molecules at the same temperature in the liquid phase.

The values given for the relative reaction rates and diffusion 'coefficients' were determined qualitatively and consequently are characterised by lower values. They may in fact be much greater. The reaction rate is determined as the total quantity of substance resulting from unit volume in unit time. However as was shown above the reaction rate is determined by the deformation rate and in the sample (tablet) being investigated the deformation rate varies from the centre to the periphery when rotating one of the anvils from zero to a maximum at the edge of the sample. Furthermore a large gradient in deformation rate is displayed across the thickness of the sample. Consequently the values given for the chemical reaction rate and the mass transfer rate represent only the lower limit of these values.

6. One of the main problems of chemical science is the determination of the course of a chemical reaction. Consequently it comprises many strictly established chemical rules specified thermodynamically or kinetically by the features of the chemical process. Numerous experiments by us have shown that these laws and empirical rules of conducting chemical reactions, which have been discovered when investigating processes in liquid and gaseous phases, are very frequently also displayed in the solid phase. There are several cases when a reaction does not proceed in a solid body as predicted by classical chemistry. For example quinone reacts with

powdered metals (aluminium, chromium, iron, etc.) and forms a free radical with three unpaired electrons:

where R = $C(CH_3)_3$; M = Al, Cr, V, Mo, etc. Evidently the analogous reaction does not proceed in the liquid phase by virtue of the fact that an aluminium atom is not able to lose 3 electrons sequentially and quadrimolecular reactions are never observed in chemical kinetics.



7. In solid phase chemical reactions, as a rule, there are few intermediate reaction products (the final product is generally formed straight away). In the liquid phase

$$A \xrightarrow{K_1} B \xrightarrow{K_2} C \ldots \xrightarrow{K_n} X,$$

and in the solid phase A → X where K_i is the rate constant.

This is linked with the fact that the time for carrying out a chemical experiment is comparable with the time characteristics of the sequential intermediate reactions ($\tau = 1/K_i$). It is evident that in the liquid phase all the intermediate products (B, C, etc.) disappear after a long time and only the final product remains in the system.

8. In the solid phase the reaction rate constant is several orders of magnitude greater than in the liquid phase. Consequently in the latter case the characteristic reaction time becomes much less than the time of the experiment and the formation of only the final reaction product is observed. One of such cases is shown below when the formation of an intermediate was not observed on carrying out the reaction in the solid phase.

where R = t-Bu.

9. The rates of chemical, metallurgical, biological, enzymic and other processes depend on temperature and as a rule the reaction rate grows as the temperature is increased (Arrhenius rule):

$$V \sim e^{-E/kT},$$

where E is the energy of activation.

The size of the energy of activation (it may have a value of a few to tens of kilojoules per mole) characterises the rate of increase of reaction rate with rise in temperature. That is why some processes accelerate rapidly and others less so with increase in temperature. As a rule however all accelerate.

It turns out that in solid phase chemical reactions occurring under the action of shear deformation the activation energy is zero. Reaction rates do not depend on temperature in the temperature range from −196 to +200 °C. This is a characteristic of numerous reactions, such as addition, dissociation, substitution, polymerisation, etc. It is necessary to record specially that in solid phase chemical reactions the energies of activation are zero not only in exothermic but also in endothermic processes. The absence of activation energy in exothermic reactions is explained by the reacting molecules being deformed in the pliable deformation of a solid body. These deformed molecules or combinations of deformed molecules already have sufficient energy to surmount the kinetic barrier (ε) (Fig. 6). But in the case of endothermic processes, in addition to the kinetic barrier, a barrier exists linked with the size of the dissociation energy (Q). The overall energy equation is

$$E = \varepsilon + Q.$$

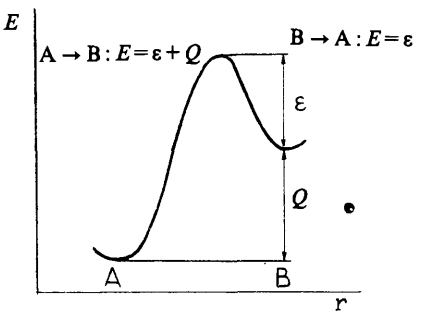


Figure 6. Dependence of the potential energy of the system along the reaction coordinate.

In solid phase endothermic reactions the energy of activation is also zero. This indicates unequivocally that among the deformed molecules (excited as a result of elastic deformation) or combination of molecules there are some in which the accumulation of total energy is greater than ε + Q. It is evident that the number of these molecules is not great since it is difficult to accumulate a large quantity of energy in the system because of the incompressibility of solid bodies at moderate pressures (tens of kilobars). That is why the extent of reaction in endothermic processes is insignificant.

It is therefore seen that the absence of an energy of activation in solid phase chemical reactions is a very important feature. It was shown by special experiment that this phenomenon is not linked with local heating in a friable solid body at the time of deformation. The portion of the volume being heated is too small to explain the absence of an energy of activation within the framework of these concepts.

As has been shown the rate of a solid phase chemical reaction is proportional to the deformation rate. Industrial machinery and laboratory equipment have upper limits for rates of deformation consequently they also have an upper limit for reaction rate. As indicated these rates are 5−8 orders of magnitude greater than the rates of these reactions in the liquid phase. It is evident that if the deformation rate can be successfully increased it should be possible to bring about solid phase chemical reactions at even greater rates than those indicated above.

About 50 years ago Bridgman showed that if a solid body or powder is pressed between two anvils then the system loses mechanical stability above a certain critical pressure and is destroyed with scattering of the solid particles. Our investigation showed that the critical pressure for bursting depends on many factors particularly on the thickness of the tablet being tested (h) (Fig. 7). It turned out that a minimum value of h_{cr} exists below which the system does not burst even at very high pressures (maximum pressure was 30 GPa in the case in question). However h_{cr} is not a strictly limiting value. If there is shear deformation as well as pressure then the system loses mechanical stability at a thickness lower than h_{cr}. In this case a thickness (h_{cr}^{o}) exists at which even a shear deformation does not lead to bursting. It turns out that the critical bursting pressure also depends on the diameter and mass of a tablet, the rate of loading the system, the nature of the substance, small additions and many other factors apart from the tablet thickness. Thus above the continuous curve (Fig. 7) the system is mechanically extremely unstable and leads to bursting, but below the curve it is stable.

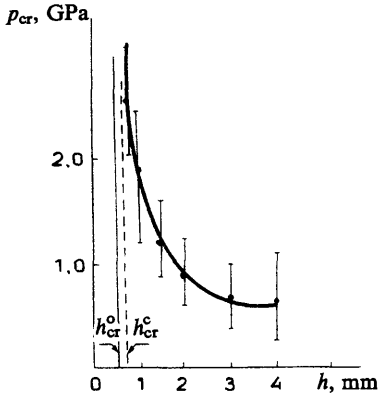

Figure 7. Dependence of critical explosion pressure p_{cr} on tablet thickness.

Our qualitative investigations showed that the duration of these bursts was much less than 10^{-5} to 10^{-6} sec (it is possible that the real time was less than 10^{-8} and 10^{-9} sec).

The investigations showed that under the indicated conditions the same reactions take place as under the action of shear deformation but their time course was not seconds or tens of seconds but less than 10^{-6} sec. This is like the so-called detonation reactions when the rate of propagation of the chemical reaction is greater than or equal to the rate of propagation of sound in the same solid body. Evidently simple long term compression without mechanical bursting (below the lower continuous curve in Fig. 7) does not lead to chemical reaction.

Endothermic reactions occur on mechanical bursting because mechanical energy accumulates in a solid body on compression (possibly in the experimental equipment generally) and this mechanical energy is transformed directly into chemical energy. As is seen from Table 1 the limit (critical bursting pressure p_{cr}) does not depend on temperature in the range −78 to +80 °C.

The reaction yield also does not vary. As was shown above the yield in endothermic reactions is naturally so low because the energy stored in the system is also little. So long as a reaction is weakly exothermic, such as hydrolysis and neutralisation reactions (see below), then after the same time of bursting (10^{-6} sec) the yield is almost 100%. This is linked with the fact that there is no need to put additional energy into the system while carrying out the reaction, on the other hand energy, although little, is evolved. It is only necessary to overcome the kinetic barrier which, as has been shown, does not exist in solid phase reactions.

Table 1. Bursting reactions.

Substance	Bursting pressure, 10^2 MPa		
	−78° C	room temperature	80° C
$CuSO_4 \cdot 5H_2O$	7.5	7.5	7.0
$CuCl_2 \cdot 2H_2O$	15	8	7.5
$Na_2SO_4 \cdot 10H_2O$	3	3	− *
$Na_2CO_3 \cdot 10H_2O$	4	4	− *
$MnSO_4 \cdot 5H_2O$	7	7	7
$ZnSO_4 \cdot 7H_2O$	11	9	6
$NiSO_4 \cdot 7H_2O$	9	10	5.5
$CoSO_4 \cdot 7H_2O$	7	6	4.5
$FeSO_4 \cdot 7H_2O$	11	13	15
$MgSO_4 \cdot 7H_2O$	7.5	9.5	− **
$Al(NO_3)_3 \cdot 9H_2O$	8.5	3.5	− *
$KAl(SO_4)_2 \cdot 12H_2O$	7	6.5	5
$Cr_2(SO_4)_3 \cdot 6H_2O$	17	17	−***
$KCr(SO_4)_2 \cdot 12H_2O$	13	17	8
$(NH_3)_2Fe(SO_4)_2 \cdot 6H_2O$	8	5	5

* No burst, sample was irrigated.
** Two sequential bursts at pressures of 3 and $15 \cdot 10^2$ MPa.
*** Burst occurs only on dropping pressure.

In the case of strongly exothermic reactions (a heat effect for the reaction amounting to hundreds or thousands of kilojoules) in addition to a detonation rate for the course of the reaction the formation is observed of a shock wave leading to destruction of the anvils and most of the experimental equipment. Metallothermic reactions are such reactions when one metal by virtue of its own high reactivity reacts with oxides, sulphides or sulphates of another metal and replaces it.

$$M^1 + M^2(X) - M^1(X) + M^2,$$

where X is $(O)_n$, $(S)_m$ or $(SO_4^{2-})_u$, etc. (n, m, u are integers).

An enormous quantity of non-ferrous and rare elements are produced by means of metallothermy at the present time. This industry has developed successfully at home and abroad for more than ten years. The mechanism and kinetics of these reactions are consequently well known.

The characteristic feature of metallothermic reactions is that they are, as a rule, strongly exothermic. The reactions shown below are also extremely exothermic.

$$CuSO_4 + Al \rightarrow ?$$
$$CuSO_4 + Mg \rightarrow ?$$
$$Fe_2O_3 + Al \rightarrow ?$$
$$Fe_2O_3 + Mg \rightarrow ?$$

The composition and quantities of the reaction products are still not strictly established.

Under uniaxial compression of mixtures of these powders (particle size from 0.1 to 1 mm) at room temperature the system loses mechanical stability (explosion) at the point of reaching a pressure equal to p_{cr} and as a result of the vigorous reaction a detonation occurs with destruction not only of the anvils but also of most of the equipment. It must be noted that each detonation leads to the destruction and scattering of reaction products which markedly hinders investigation of them.

Metallothermic reactions have been studied in a detailed manner by scientists all over the world for over a hundred years. It has been established that under the usual conditions the reaction is initiated at 1100–1200 °C and spreads at a rate of millimetres per second. The temperature at the spreading front of an exothermic reaction is 2000–2500 °C.

In the present case reaction is initiated at room temperature and is complete after less than 10^{-6} sec, consequently the propagation rate is kilometres per second. It must be noted particularly that although the dimensions of the reacting solid particles are comparatively large (diameter ~1 mm) the reaction successfully reaches an advanced stage of completion after so short a time.

Combination of the results obtained indicates that in the given case the detonation course of the chemical reactions occurs not as a result of high temperatures with subsequent heating of the unreacted layer as happens on thermal spreading but isothermally at low temperature like the usual solid phase chemical reaction, a significant portion of the thermal energy is evolved after completion of the reaction.

In the case of strongly exothermic reactions (metallothermic for example) the time for completion of the process is less than 10^{-5} to 10^{-6} sec. The propagation rate will be of the order of kilometres per second (anvil diameter 1 cm) and not millimetres per second as in thermal propagation. On the other hand the proceeding of a solid phase chemical reaction at detonation rate, isothermally, at low temperatures shows unequivocally that in solid phase reactions a mechanism exists for an ultra high speed process without initial heating up of the system, i.e. not linked with the Arrhenius rule. This is also indicated by the fact that in the reactions investigated the sizes of the reacting particles were of the order of 1 mm but the reaction went to completion. Complete conversion of the system at the molecular level had occurred after a time of less than 10^{-5} to 10^{-6} sec.

The detonation course of metallothermic reactions in solid bodies is accompanied by destruction of the anvils and of the equipment generally. This indicates that under the given conditions a mechanism exists for the transformation of chemical energy (reaction thermal effect) directly into mechanical energy without high temperatures and without the formation of a gaseous phase.

The conversion of the chemical energy of a reaction into mechanical is usually effected in the following manner. In a closed volume in the gas phase or under conditions when a gas phase is formed, the thermal energy evolved as a result of a chemical reaction heats the system, the pressure in the system rises enabling mechanical work to be carried out. In the case of solid phase chemical reactions it is seemingly necessary to assume formation of a shock wave directly at the time of the process. As was shown above in the case of decomposition (endothermic process) the reverse process occurs, mechanical energy is converted directly into chemical energy without initial heating of the system.

Let us consider the possibility of using the results obtained from investigating solid phase chemical reactions such as the higher mixing rate (diffusion 'coefficient') in comparison with liquid phase reactions, the independence of the rate of chemical conversion on temperature, the absence of catalysts, etc., in the technology of manufacture of useful substances and materials.

In modern industry (chemical, metallurgical, building materials, cellulose–paper, etc.) enormous quantities of solvent and catalyst are used for the optimum conduct of a process in the liquid phase and processes are carried out at extremely high temperatures. The need to use solvents, catalysts and high temperatures becomes superfluous for a solid phase process.

Investigations have shown that the known industrial processes may be carried out at room temperature without using solvents. The manufacture of soap has been known to man from ancient times. The process reduces to the addition of water to solid fat and solid ash and the mixture is boiled to form soap. Soap is manufactured by this technology up to the present the only difference being that solid alkali is used in place of ash. We have developed an industrial method of soap manufacture in a solid phase without solvent. At the present time a dry method of making paper from wood pulp has been developed similarly.

On the basis of the ideas described above a new physical elastic deformation method of crushing has been developed. It must be noted that contemporary crushing machines (ball mills, vibration mills, disintegrators, etc.) have an extremely low performance. When crushing synthetic and natural polymers (resins, wood, polymers, cellulose, etc.) by the elastic deformation method performance is increased by more than an order of magnitude.

Mixtures rather than individual polymers are widely used in industry at the present time to obtain new materials and articles made of them. Usually two basic methods are used. These are fusing and mixing or precipitation from a common solvent. Both methods have several technical, economic and qualitative drawbacks.

As has been shown the rate of mixing is sharply increased in the solid state on shear deformation. The very same occurs with macromolecules. Consequently a new technology for obtaining polymeric mixtures has been successfully created.

The use of solid phase chemical processes in industry may therefore lead to the creation of new, ecologically clean and energetically advantageous processes.

Polyelectrolytes in the solution of ecological problems

V A Kabanov, A B Zezin, V A Kasaikin, A A Yaroslavov, D A Topchiev
Lomonosov Moscow State University
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

Polyelectrolytes have been used traditionally for the decomposition of colloidally disperse systems and for structure formation in the latter. We have shown in recent years that the use for such purposes of polymeric complexes formed by the interaction of two oppositely charged elecrolytes—polyelectrolyte complexes (PEC)—leads to qualitatively new possibilities in this field.

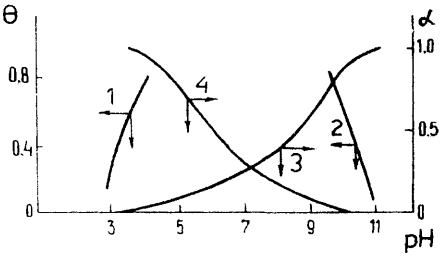
The interaction of linear polyelectrolytes bearing unlike charges is due to the occurrence of reversible reactions involving the formation of new bonds between chemically complementary units of the reacting molecules. The reaction between polyacrylic acid (PAA) and polyvinylamine (PVA) is illustrated schematically below:

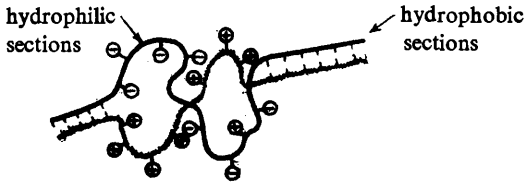
(1)

Fig. 1 (curves *1* and *2*) illustrates the dependence of the degree θ of the interpolyelectrolyte reaction (1) on the pH of the reaction medium. The degree of reaction (1) is understood as the fraction of the units of the polymeric acid or base which have formed salt linkages with the units of the oppositely charged macromolecule, i. e.

$$\theta = c_k c_0,$$

where c_k = [$-COO^-H_3N^+-$] is the concentration of the interpolyelectrolyte salt bonds and c_0 the concentration of the units of the polymeric acid or base in the reaction system. Evidently the degree of reaction (1) increases and reaches the high value θ = 0.8 within a narrow pH range (1–2) (curves *1* and *2*), while the degree of ionisation α of the corresponding weak polyelectrolytes (curves *3* and *4*) increases monotonically over a wide range of the pH of the reaction medium. This demonstrates the cooperative character of the interpolyelectrolyte reaction and the anticooperative character of the charging process involving free polymeric acids and bases. The cooperative nature of the interpolyelectrolyte reaction is responsible for the exceptionally high stability of the polyelectrolyte complexes within certain pH and ionic strength ranges. In such media, polyelectrolyte complexes are capable of swelling to only a limited extent and give rise to a kind of plastic hydrogel. At the same time, at salt, acid, or alkali concentrations exceeding critical values, the equilibrium in reaction (1) shifts to the left, the interpolyelectrolyte salt linkages holding together the polyions break, and the polyelectrolyte complexes are converted into a soluble state.





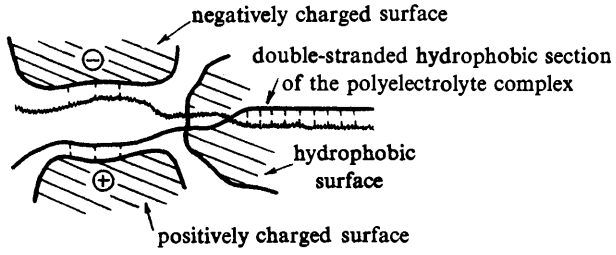


Figure 1. Dependence of the degree of the interpolyelectrolyte reaction θ between equimolar amounts of high-molecular-weight polyacrylic acid and polyvinylamine hydrochloride (curve *1*) and between sodium polyacrylate and polyvinylamine (curve *2*) on the pH. Dependence of the degree of dissociation α of polyacrylic acid (curve *3*) and polyvinylamine (curve *4*) on the pH. Concentration of polyelectrolytes 0.02 M; c_{NaOH} = 0.2 M; c = 0.1 M; t = 20 °C.

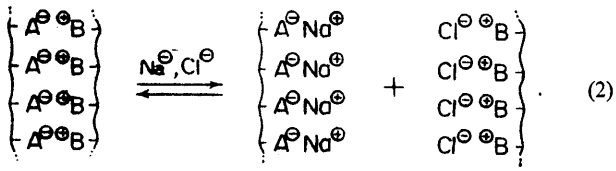
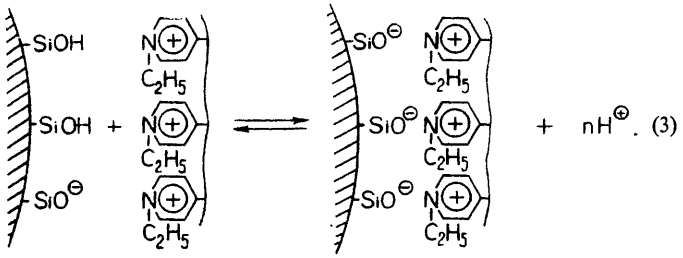


The polyelectrolyte complexes contain hydrophobic regions made up of paired sections of the complementary chains and hydrophilic sequences of ionogenic groups formed by disconnected sections of oppositely charged polyions. A fragment of a polyelectrolyte complex molecule is illustrated schematically below:

Sections of different nature in the swollen polyelectrolyte complex are capable of changing places with one another at a high rate. These structural features of polymeric complexes impart to the latter the unique capacity to be adsorbed on surfaces of different nature and to become adapted to varying external conditions in the contact zone. A fragment of a polyelectrolyte complex in contact with different particles of the disperse phase may be represented as follows:

The technology of the preparation and application of polymeric complex binders is extremely simple. It can be reduced to the preparation of dilute aqueous solutions of a mixture of polyelectrolytes in which the electrostatic interaction between oppositely charged polyions is prevented by shielding due to low-molecular-weight salts, for example, mineral fertilisers. The binder is then introduced into the disperse system, the solution being sprayed onto the surface of the soil or ground by means of any spraying technique. On subsequent washing of the treated layer with water, for example, by spraying or by rainfall, the shielding electrolyte is diluted and removed from the sphere of reaction (2):

(2)



The equilibrium in reaction (2) is then displaced to the left, i.e. towards the formation of the polyelectrolyte complex. The resulting polyelectrolyte complex gel is capable of repeatedly drying out and becoming moist without impairment of adhesion properties, i.e. of the quality of the reinforced layer. Various low-molecular-weight organic and inorganic substances, for example, fertilisers, plant growth stimulators, herbicides, and other physiologically active compounds, can also be incorporated in the polyelectrolyte complex gels. For this purpose, it is sufficient to simply add them to the initial solution. The substances immobilised in the polyelectrolyte complex are then capable of being transferred from the polyelectrolyte complexes to the surrounding medium at a controlled rate.

By virtue of these properties, the polyelectrolyte complexes have been used successfully as structure-forming agents for soils to prevent their erosion by water and wind and to achieve a simultaneous increase in fertility. In the soil-polymer crust, the particles of the disperse phase are linked to one another by thin layers of the polyelectrolyte complex. Such crusts are not broken up by strong winds and rain. The procedures described have been applied successfully, for example, to grass over the sloping sides of earth channels. Polymeric complexes introduced onto the surface of the ground prevent its wind and water erosion during the period necessary for the growth and development of the grass cover. This makes it possible to tidy up reclamation systems incomparably more economically and effectively than can be done by traditional procedures. Polymeric complexes have also been widely tested as agents for the prevention of the washing away of soils and the subsequent crust formation on cotton seedlings and also as agents preventing the blowing away of the protecting banks in vineyards by hurricane force winds (up to 30–40 m s^{-1}).

It is significant that all these antierosion measures can be applied with a very low consumption of polymers (from 20 to 100 kg ha^{-1}). Simultaneously with the main effect, a marked stimulation of planned growth and development is observed. Treatment of cotton fields with polymeric complexes after sowing enhances the development of the root system and improves the capacity of the cotton plant for germination. This favourable effect of the polyelectrolyte complexes on germination can be to a large extent explained by the greenhouse effect of the soil-polymer crust, which retards the evaporation of moisture from the surface of the soil.

In the solution of ecological problems, one can use as polyelectrolytes both synthetic industrial polymers, for example poly(diallyldimethylammonium chloride) (commercial name—VPK-402), poly(dimethylaminoethyl methacrylate), hydrolysed polyacrylonitrile (HYPAN), as well as the products of the modification of natural polymers, for example, cellulose. The use of the waste from major industries for such purposes is especially attractive. For example, oxidised ligands, which are the products of the treatment of wood, can be used as polyanions. These water-soluble polymers, which pollute the environment, can be extracted quantitatively from the waste of the cellulose-paper plants in the form of an insoluble complex which can be used, in its turn, as a structure-forming agent.

Linear polyelectrolytes are capable of reacting effectively with oppositely charged colloid particles. We established that this interaction is described satisfactorily within the framework of the idea that there is cooperative electrostatic attraction between the units of the linear polyelectrolyte and the oppositely charged ionogenic groups distributed on the surface of the colloid particles. A reaction of this type between polysilicic acid (PSA) and the linear poly(*N*-ethyl-4-vinylpyridinium bromide) (QPVB) polycation is illustrated in Scheme 3. Reaction (3) results in the formation of polymer-colloidal polyelectrolyte complexes, whose composition is determined by the state of ionisation of the units of the linear polyelectrolytes and of the ionogenic groups distributed on the surface of the colloid particle:

(3)

Fig. 2 illustrates the dependence of the degree of the polymer-colloid reaction between the polyelectrolyte complex and QVPB on the pH (curve *1*). Evidently, as in the case of interpolyelectrolyte reactions, the formation of the polymer-colloid polyelectrolyte complex is accompanied by an appreciable increase in the degree of ionisation of the surface silanol groups of polysilicic acid (cf. curves *2* and *3*). It is seen from the above figure that the degree of reaction (3) in terms of the linear polymer (curve *1*) increases with increase in pH to the higher value (QPVB) = 0.7 at pH 9. This means that in alkaline media most of the units of the linear polycation are linked by salt bonds with the surface of the colloid particles. The relatively small steepness of the θ–pH curves, i.e. the low cooperativity of the polymer-colloid reactions is a consequence of the conformational non-complementarity of the interacting components—linear macromolecules and compact colloid particles. The conformation of the linear macromolecule, incorporated in the particles of the polymer-colloid polyelectrolyte complex, is characterised by the presence of a large number of loops. In other words, the set of its conformations is appreciably depleted compared with the set of conformations of a similar macromolecule in a dilute solution. A natural consequence of this is the tendency of the particles of the polymer-colloid polyelectrolyte complex to aggregate and form larger particles—floccules. Thus the flocculation of the colloid systems when the latter interacts with linear polyelectrolytes is in fact caused by the impairment of the thermodynamic quality of the solvent in relation to the chains linked to the surfaces of the colloid particles and hence by the spontaneous segregation of the adsorbed macromolecules as a concentrated phase. In the large

associated species (floccules) formed under these conditions, the colloid particles are separated from one another by polymer layers swollen to the maximum extent and formed by sections of the adsorbed polymer chains which on adsorption failed to come into contact with the surfaces of the colloid particles.

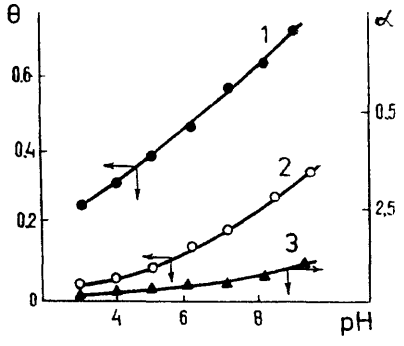


Figure 2. Dependence of the degree of the polymer-colloid reaction between QPVP and the polysilicic acid sol [*1*, θ(QPVP); *2*, θ(PSA)] and of the degree of dissociation of the surface silanol groups of the polysilicic acid sol (curve *3*) on the pH; c(QPVP) = 0.0025 M; degree of polymerisation of QPVP = 2500; sol particle radius = 56 Å; t = 20 °C.

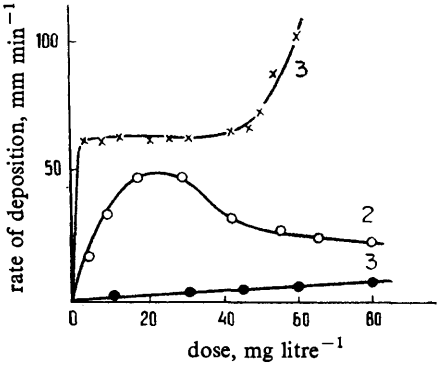
note that the high rate of deposition of the disperse particles and the quality of the clarification of the colloid systems persist over a wide range of variation of the concentrations of a polycomplex flocculant of this kind. In addition, this makes it possible to avoid the undesirable effects due to the partial stabilisation of dispersions on exceeding the dose of the flocculant.



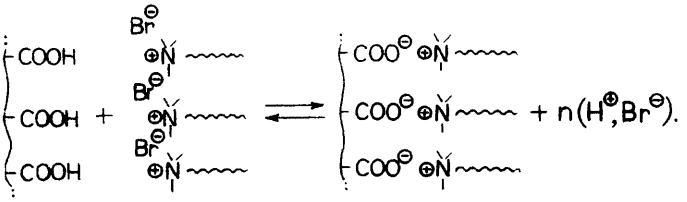


Figure 3. Flocculation of the sludge from the elutriation crust of the lanthanide ores from the Belozimsk deposit; sludge concentration 10 wt.%; particle size 70 μm: *1*, HYPAN; *2*, VPK-402; *3*, HYPAN; VPK-402 = 1:1.

By virtue of the ability of linear electrolytes to react with colloid particles, they are used as flocculants for the intensification of the processes involving the separation of highly disperse suspensions and emulsions. This is required, in the first place, for the creation of closed water circulation systems in undertakings of the mining industry. As an example, one may quote the successful use of the Soviet-produced industrial polycation VPK-402 in the Lovozersk mining-enrichment plant as a flocculant in connection with the establishment of a closed water circulation. The joint use of oppositely charged polyelectrolytes proved to be particularly effective. This makes it possible to reduce by an order of magnitude the consumption of polymer-flocculants with the simultaneous appreciable increase in the rate and quality of the clarification of dispersions. This was demonstrated in relation to the thickening of the highly disperse fraction of the ore from the Beloziminsk deposit (Fig. 3). Fig. 3 shows that the introduction of polymeric anions, for example HYPAN, hardly alters the rate of deposition of colloid particles (curve *1*). On the other hand, linear polycations play the role of flocculants (curve *2*). However, an increase in the content of VPK-402 above a certain optimum amount is again accompanied by a decrease in the rate of deposition and also in the quality of the clarification of the colloid system, i.e. under these conditions the polycation functions as a stabiliser of the disperse system. A qualitatively different flocculation picture is observed when linear polyelectrolytes bearing unlike charges are introduced jointly (curve *3*). In this case the rate of separation of the disperse phase is much higher than in the case where only the polycation is used and the effect indicated is attained with appreciably lower consumptions of the jointly applied oppositely charged polyelectrolytes compared with the cationic flocculant (cf. curves *2* and *3*). It is important to

Linear polyelectrolytes are able to interact cooperatively with oppositely charged micelle-forming surfactants. Such a reaction between polyacrylic acid and dodecyltrimethylammonium bromide (DDTMAB) is presented below:

(4)

As in the case of reactions between chemically complementary linear macromolecules, the polyelectrolyte—surfactant reaction is characterised by a high cooperativity (Fig. 4). The degree of such reaction increases sharply within a narrow range of the pH of the reaction mixture. The degree of dissociation of the polymeric acid incorporated in the polyelectrolyte complex particle then exceeds the degree of dissociation of the free polymeric acid at the same pH (cf. curves *1* and *2*). This results in the formation of stable polymeric polyelectrolyte—surfactant complexes stabilised by the hydrophobic interactions of the alkyl substituents in the surfactant with one another and with the hydrophobic sections of the chain in addition to the salt bonds formed between the ionogenic groups of the linear macromolecule and the diphilic surfactant ions. Such polymeric complexes are formed at a surfactant concentration in the solution lower by two and more orders of magnitude than the critical concentration for a micelle formation (CCM) for the same surfactant. This makes it possible to employ polyelectrolytes for the

effective extraction of surfactants from spent waters. The polymeric complexes isolated under these conditions are in their turn highly effective flocculants capable of decomposing simultaneously mineral dispersions and emulsions of organic substances. This has been demonstrated in experiments on the purification of spent waters in the rolling mills of the Moscow "Serp i molot" (Hammer and sickle) factory.

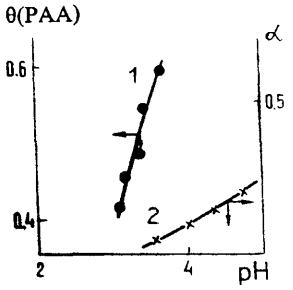

Figure 4. Dependence of the degree of reaction θ between equimolar amounts of polyacrylic acid and dodecyltrimethylammonium bromide (DDTMAB) (curve *1*) (polyacrylic acid and DDTMAB concentrations 0.03 M) on the pH; dependence of the degree of dissociation α of polyacrylic acid (curve *2*) on the pH; c_{NaOH} = 0.1 M; *1*, 20 °C.

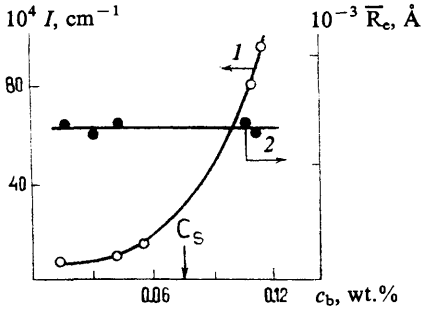

Figure 5. Dependence of the integral intensity of the scattered light *I* (curve *1*) and of the microemulsion drop size ($\bar{R}_e$) (curve *2*) on the amount of emulsified benzene (c_b); composition of the polyelectrolyte complex [PMANa]/[DDTMAB] = 0.2; [PMANa] = 0.03 M; [DDTMAB] = 0.03 M; pH 5.7; t = 20 °C.

The diphilic surfactant ions in the particles of such polymeric complexes are segregated into intramolecular micelles whose size and morphology are determined by the composition of the polymeric complex and the degree of polymerisation of the linear polyelectrolyte. By virtue of the presence of the intramolecular micellar phase, the polyelectrolyte–surfactant polymeric complexes effectively solubilise organic substances which are sparingly soluble in aqueous media, with formation of thermodynamically stable microemulsions of the "oil–water" type. Fig. 5 presents the dependence of the integral intensity of scattered light (curve *1*) and the drop size of microemulsions (curve *2*) on the amount of emulsified benzene. Eviently the size of the drops of the benzene microemulsion in water, stabilised by the complex of sodium polymethacrylate (PMANa) and the surfactant, is independent of the amount of emulsified benzene, while the integral light scattering intensity increases with increase in the amount of emulsified hydrocarbon. It is noteworthy that microemulsions are formed at a hydrocarbon concentration appreciably lower than that of the saturated solution of the hydrocarbon in water (c_s). This means that the drops of the microemulsion consist of a solution in the hydrocarbon of fragments of the polymeric acid bound to the aliphatic groups of the surfactant. The microemulsion particles can be readily separated from the aqueous medium, for example, by adding small amounts of polycations to the system. Thus the polymeric complexes of linear polyelectrolytes with micelle forming surfactants can be used to extract sparingly soluble organic compounds from aqueous media.

Polyelectrolytes have been used successfully also for the extraction of metal ions from aqueous media. Cross-linked polymers, capable of forming complexes with transition metal ions, including heavy metals, are widely used for this purpose. It has been found that the degree and rate of extraction of the metal can be increased by an order of magnitude by using a simple but effective method of "adjusting" the polymeric sorbent to a particular ion. This procedure consists in the fixation of the optimum conformations of the sections of the chains which arise in the polymer-metal complex formed by the linear polyelectrolyte. The complex is then cross-linked. The resulting complex-forming cross-linked polymer "remembers" the optimum structure and in subsequent cycles behave as an "adjusted" highly effective polymeric sorbent.

New metal- and carbon-containing catalysts for the catalytic removal of harmful impurities from industrial gaseous waste

E I Bagrii, V T Popov, D I Slovatskii, V G Lipovich
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

The intensification of economic activity has led in recent years to dangerous ecological complications in many regions of our country. Emission into the atmosphere of gaseous waste comprising nitrogen and carbon oxides, carbon disulphide, organic sulphides, hydrogen cyanide, ammonia, and acetylene, which are present in the industrial waste from chemical, petrochemical, gas, and metallurgical industries, in automobile exhausts, in the exhausts from thermal power stations, etc., has given rise to especially great fears.

The incorporation in the processing treatment and the increase in the degree of utilisation of new types of petroleum, gas condensites, and accompanying gases with a high content of hydrogen sulphide and mercaptants are characteristic of the petroleum processing and gas industries in the USSR. For example,

effective extraction of surfactants from spent waters. The polymeric complexes isolated under these conditions are in their turn highly effective flocculants capable of decomposing simultaneously mineral dispersions and emulsions of organic substances. This has been demonstrated in experiments on the purification of spent waters in the rolling mills of the Moscow "Serp i molot" (Hammer and sickle) factory.

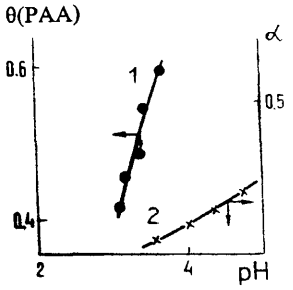

Figure 4. Dependence of the degree of reaction θ between equimolar amounts of polyacrylic acid and dodecyltrimethylammonium bromide (DDTMAB) (curve *1*) (polyacrylic acid and DDTMAB concentrations 0.03 M) on the pH; dependence of the degree of dissociation α of polyacrylic acid (curve *2*) on the pH; c_{NaOH} = 0.1 M; *1*, 20 °C.

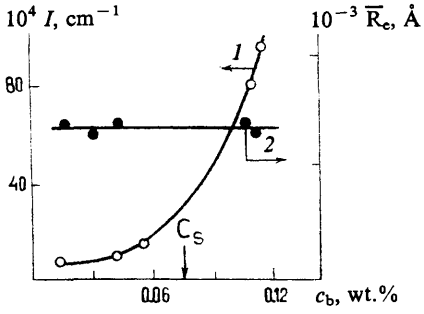

Figure 5. Dependence of the integral intensity of the scattered light *I* (curve *1*) and of the microemulsion drop size ($\bar{R}_e$) (curve *2*) on the amount of emulsified benzene (c_b); composition of the polyelectrolyte complex [PMANa]/[DDTMAB] = 0.2; [PMANa] = 0.03 M; [DDTMAB] = 0.03 M; pH 5.7; t = 20 °C.

The diphilic surfactant ions in the particles of such polymeric complexes are segregated into intramolecular micelles whose size and morphology are determined by the composition of the polymeric complex and the degree of polymerisation of the linear polyelectrolyte. By virtue of the presence of the intramolecular micellar phase, the polyelectrolyte–surfactant polymeric complexes effectively solubilise organic substances which are sparingly soluble in aqueous media, with formation of thermodynamically stable microemulsions of the "oil–water" type. Fig. 5 presents the dependence of the integral intensity of scattered light (curve *1*) and the drop size of microemulsions (curve *2*) on the amount of emulsified benzene. Eviently the size of the drops of the benzene microemulsion in water, stabilised by the complex of sodium polymethacrylate (PMANa) and the surfactant, is independent of the amount of emulsified benzene, while the integral light scattering intensity increases with increase in the amount of emulsified hydrocarbon. It is noteworthy that microemulsions are formed at a hydrocarbon concentration appreciably lower than that of the saturated solution of the hydrocarbon in water (c_s). This means that the drops of the microemulsion consist of a solution in the hydrocarbon of fragments of the polymeric acid bound to the aliphatic groups of the surfactant. The microemulsion particles can be readily separated from the aqueous medium, for example, by adding small amounts of polycations to the system. Thus the polymeric complexes of linear polyelectrolytes with micelle forming surfactants can be used to extract sparingly soluble organic compounds from aqueous media.

Polyelectrolytes have been used successfully also for the extraction of metal ions from aqueous media. Cross-linked polymers, capable of forming complexes with transition metal ions, including heavy metals, are widely used for this purpose. It has been found that the degree and rate of extraction of the metal can be increased by an order of magnitude by using a simple but effective method of "adjusting" the polymeric sorbent to a particular ion. This procedure consists in the fixation of the optimum conformations of the sections of the chains which arise in the polymer-metal complex formed by the linear polyelectrolyte. The complex is then cross-linked. The resulting complex-forming cross-linked polymer "remembers" the optimum structure and in subsequent cycles behave as an "adjusted" highly effective polymeric sorbent.

New metal- and carbon-containing catalysts for the catalytic removal of harmful impurities from industrial gaseous waste

E I Bagrii, V T Popov, D I Slovatskii, V G Lipovich
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

The intensification of economic activity has led in recent years to dangerous ecological complications in many regions of our country. Emission into the atmosphere of gaseous waste comprising nitrogen and carbon oxides, carbon disulphide, organic sulphides, hydrogen cyanide, ammonia, and acetylene, which are present in the industrial waste from chemical, petrochemical, gas, and metallurgical industries, in automobile exhausts, in the exhausts from thermal power stations, etc., has given rise to especially great fears.

The incorporation in the processing treatment and the increase in the degree of utilisation of new types of petroleum, gas condensites, and accompanying gases with a high content of hydrogen sulphide and mercaptants are characteristic of the petroleum processing and gas industries in the USSR. For example,

promising petroleum deposits (Tengiz, Zhanazholsk) and gas condensate deposits (Karachanak, Astrakhan, and Orenburg deposits and the adjoining petroleum deposits), characterised by great depths of deposition (3500–5500 m), high pressure at the outlet from the well (50–90 MPa) and an elevated temperature (80–125 °C) as well as a high gas factor (600–900 m^3 $tonne^{-1}$), contain between 5 and 30 wt.% of hydrogen sulphide and 2–15 wt.% of carbon dioxide together with methanethiol, carbon disulphide, and other harmful substances.

The effluent and blast gases in the majority of chemical industries, coke-chemical factories, and other industrial objects also contain considerable concentrations of impurities comprising carbon disulphide, mercaptans, nitrogen oxides, etc. The existing methods of extraction, storage, transport, and processing do not ensure the maintenance of an ecologically safe situation in regions where these products are extracted and processed.

The exhaust gases from internal combustion engines and thermoelectric power stations also make a considerable contribution to the contamination of large cities, especially Moscow, by gases. Nitrogen oxides, formed on combustion of diesel fuel, masoute, and especially natural gas constitute a specially great risk to the health of the population. Thus the change in the fuel used by thermoelectric power stations to natural gas increased almost by an order of magnitude the concentration of nitrogen oxides; their concentration in the centre of Moscow exceeds severalfold the limiting permissible concentration (LPC). It is sufficient to say that one thermal power station with a power output of 300 MW releases annually 194 tonnes of nitrogen oxides, 497 tonnes of sulphur dioxide, and 630 tonnes of carbon monoxide. Polycyclic aromatic hydrocarbons, also formed on incomplete combustion of diesel fuel, are no less dangerous. The limiting permissible concentrations of these compounds are 10^{-6} mg m^{-3}, which is smaller by six orders of magnitude than the concentration of, for example, carbon monoxide and nitrogen oxides.

Several versions of catalytic systems based on precious metals have now been developed abroad; all the automobiles produced must be fitted with them. Unfortunately our country lags appreciably in this respect.

A characteristic feature of the majority of industrial gaseous waste in modern industries is their multicomponent nature, which complicates the solution of the problem of their chemical deactivation by means of a series of different chemical reactions leading to the formation of both harmless and new dangerous substances. For example, when the gas contains components such as sulphur dioxide, hydrogen sulphide, carbon dust (C), and carbon monoxide at the usual process temperatures (200–500 °C), there is a possibility of the occurrence of tens of reactions of this type. Some of them are presented in Table 1.

The picture becomes even more complicated if nitrogen oxides or ammonia are present. In the general case, the situation reduces to the occurrence of a whole sequence of oxidation-reduction reactions, where the compositions of the intermediate and final products are fairly complex or cannot be predicted beforehand. In order to determine the final mixture composition, it is insufficient to know only the initial concentration; the concentrations of the substances are a function of time, local temperature gradients, and the specific features of the action of the catalysts. And yet ecological problems require the virtually complete neutralisation of harmful components; the concentrations of most of them should not exceed tenths or even hundredths of a milligram per cubic metre. A certain polyfunctionality is therefore required from the catalysts employed, including a combination of catalytic and adsorption activities.

Such properties are possessed, in particular, by activated charcoals, but their availability and cost preclude their wide scale employment for the purification of large volumes of industrial gaseous waste.

Table 1. Certain possible reactions of the components of ecologically harmful gas mixtures.

Reaction	Heat change, kcal	Free energy change ΔF^0, kcal mol^{-1}
$2H_2S+SO_2 \rightarrow 2H_2+^3/_8S_8$	–	−16.5
$H_2S+^1/_2O_2 \rightarrow S+H_2O$	+53	–
$H_2S+^3/_2O_2 \rightarrow H_2O+SO_2$	+124	–
$2H_2S+O_2 \rightarrow 2H_2O+S_2$	+106	–
$2H_2S+SO_2 \rightarrow 2H_2O+^3/_2S_2$	−11.45	−3.52
$SO_2+2CO \rightarrow 2CO_2+^1/_2S_2$	–	−41.09
$CO+^1/_2S_2 \rightarrow COS$	–	−17.25
$C+S_2 \rightarrow CS_2$	–	−3.75
$CO_2+C \rightarrow 2CO$	–	ΔH^0=40.79
$2SO_2+2C \rightarrow 2CO_2+S_2$	–	–

We suggested that synthetic metals and carbon-containing catalysts with adsorption and polyfunctional catalytic activities be used for these purposes. They are formed in the catalytic decomposition of hydrocarbons on *d* metals within a certain temperature range. In essence, this phenomenon takes place in virtually each industrial process involving the catalytic processing of a hydrocarbon-containing raw material (catalytic cracking processes, dehydrogenation, reforming, etc.) and is well known as an extremely undesirable process leading to the saturation of catalysts by coke; it entails the loss of their activity and necessitates the regeneration of the catalysts. Systematic studies on this process, carried out by numerous investigators,[1–4] showed that the formation of carbon is a process which takes place in accordance with definite rules and can be fully controlled. The structure of the carbon formed then depends both on the nature of the metal and on the carbon deposition conditions.

A typical dependence of the degree of conversion of hydrocarbons into activated charcoal on temperature passes through an extremum (Fig. 1). The optimum temperatures for a number of oxides (Fig. 1*a*) and hydrocarbons (Fig. 1*b*) are described by general relations in terms of the variables optimum temperature–logarithm of the heat of formation of acetylene from the given raw material (Fig. 2). The optimum temperatures also differ for the same raw material and different metals. We obtained general criterial relations for a multiparameter system of this kind, from which it is possible to find the conditions governing the preparation of the activated charcoal. This makes it possible to predict the process and to control it. It was shown that, for example, in the case of C_8H_{10} the optimum calculated temperature is 757 K, while the experimental temperature is 768 K.

The activated charcoal obtained was studied by various physicochemical methods. The elemental composition, the specific surface, the valence state of the metal, and the X-ray diffraction characteristics of the carbon were investigated.

It was established that metals are present as a rule in the finished catalyst in the zerovalent (reduced) state but have a distorted crystal lattice (Table 2). In the case of iron and cobalt, the formation of carbides and cementides was observed, which does not happen in the case of nickel. The metal particles are distributed throughout the catalyst bed with formation of 100–250 Å clusters. The following structural characteristics were determined from the X-ray diffraction patterns for catalytic carbon: the interplanar spacings d_{002}, the size of the coherent scattering regions (CSR), the size of the pseudocrystallites L_c and L_a, and the diffraction coefficient M characterising the degree of organisation of the carbon atoms to form a graphite-like structure. Table 2 shows that no appreciable correlation is observed between these characteristics and the nickel content in the catalytic carbon.

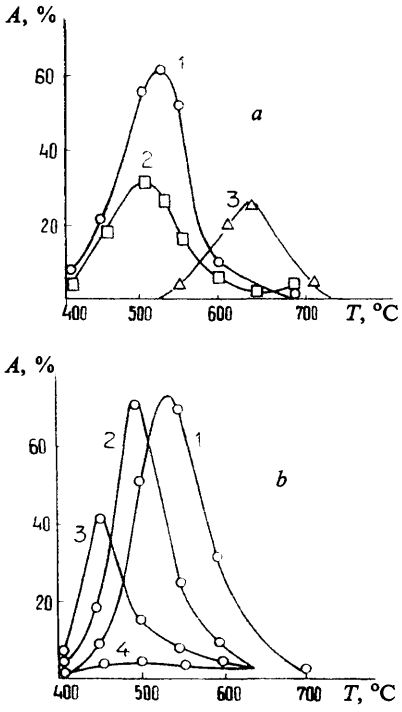

Figure 1. Temperature dependence of the yield of the activated carbon: *a*, for metal oxides (*1*, NiO; *2*, Co_2O_3; *3*, Fe_2O_3); *b*, for hydrocarbons (*1*, C_6H_6; *2*, cyclo-C_6H_{12}; *3*, C_7H_{16}; *4*, $C_3H_5CH_3$).

We shall now consider the principal results obtained in the study of the activities of catalysts both in model mixtures under laboratory conditions using a pulse method and in industrial gaseous waste (Table 3).

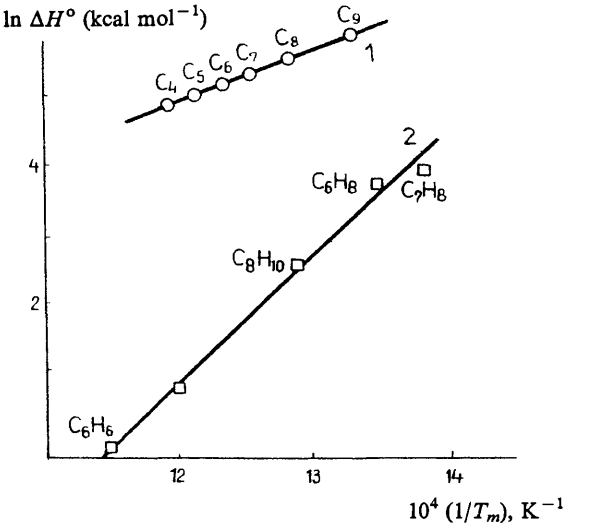

Figure 2. Dependence of the heat of formation of the carbon material ($\Delta H°$) on the optimum process temperature (T_m) for various hydrocarbons: *1*, paraffin; *2*, cyclic (aromatic and unsaturated) hydrocarbons.

Table 2. X-Ray phase analysis of catalytic carbon (DRON-2, Cu K_α line).

c_{Ni}, wt.%	S_{sp}, $m^2 g^{-1}$	d_{002}, Å	L_c, Å	L_a, Å	M, %	Ni	
						CSR, Å	d, Å
0.9	166	3.45	88	94	92.5	–	2.037
2	161	3.46	87	100	91.0	360	2.041
2.8	156	3.41	103	95	92.0	210	2.034
4.5	146	3.41	116	95	87.0	275	2.033
6.0	135	3.42	100	100	91.7	290	2.035
10.0	74	3.40	110	90	82.5	200	2.032
100	–	–	–	–	–	–	2.03

It is also seen from the data presented that, as the hydrocarbon accumulates, the specific adsorption surface increases and the concentration of the metal diminishes, the metal being highly dispersed by the growing carbon.

The specific surface of the catalyst depends on the matrix employed, but it does not as a rule exceed 240–260 $m^2 g^{-1}$ (according to low-temperature nitrogen adsorption data), i.e. is significantly lower than the specific surface of activated charcoal (600–800 $m^2 g^{-1}$). The electron photomicrograph in Fig. 3 shows metal-containing carbon fibres.

Oxygen is absorbed at temperatures in the range 300–350 °C. When the catalyst specimen is treated with oxygen at 300 °C, the evolution of carbon dioxide is not, however, observed. Oxygen is consumed in the oxidation of the nickel reduction centres. At higher temperatures, oxygen is also consumed in the oxidation of the carbon of the catalyst, which results in the evolution of carbon dioxide.

Carbon monoxide is absorbed at temperatures in the range 200–550 °C. Under these conditions, the main reaction product (carbon dioxide) begins to evolve from 300 °C upwards.

Carbon dioxide is absorbed by the catalyst in the temperature range from 20° to 250 °C, the maximum corresponding to 50 °C (1.22 $cm^3\ g^{-1}$). At a temperature above 200 °C, carbon dioxide may be removed by thermal desorption.

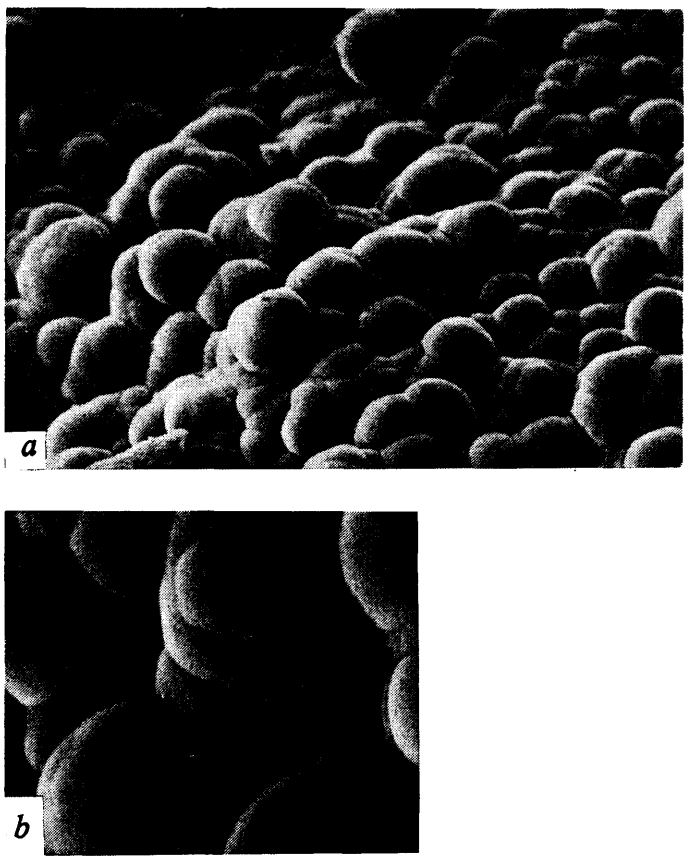

Figure 3. Photomicrographs of the catalyst (on a γ-Al_2O_3 carrier); magnification $\times 350$ (*a*) and 1400 (*b*).

Nitric oxide is absorbed in the temperature range 50–250 °C, the maximum degree of absorption being observed at 150 °C (1.54 $cm^3\ g^{-1}$). Molecular nitrogen is evolved in the same temperature, its amount diminishing with increase in temperature (from 5.0×10^{-2} cm^3 at 50 °C to 0.6×10^{-2} cm^3 at 250 °C). Nitrogen and carbon monoxide and dioxide are evolved on thermal desorption (in the temperature range from 150 °C to 500 °C).

It is of interest to note that the absorption of nitric oxide on activated charcoal does not begin until 200 °C (also with evolution of nitrogen).

In the absence of an oxidant, hydrogen sulphide is poorly adsorbed on the various catalysts tested and does not decompose. In the presence of various oxidants (air, sulphur dioxide), the decomposition of hydrogen sulphide is observed even at room temperature with formation of elemental sulphur (mainly S_8). The amount of adsorbed hydrogen sulphide on the treated catalyst does not exceed 6%. The most active of the catalysts investigated (carbon-saturated γ-Al_2O_3 containing 4.5% of nickel) converted (before breakthrough) 3000 volumes of gas.

Table 3. The activities of catalysts in relation to certain gases.

Gas	Absorption temperature, °C	Chemical reaction temperature, °C	Main product
Oxygen	300–350	>300	Carbon dioxide
Carbon monoxide	200–250	>300	Carbon dioxide
Carbon dioxide	20–250	—	—
Nitric oxide	50–250	>50	Nitrogen
Hydrogen sulphide	20 (pore)	>20*	Sulphur (S_8)
Ammonia	20–450	>20*	Nitrogen
Methane	450–600	>450	Carbon monoxide, carbon dioxide, water
Carbon disulphide, hydrogen cyanide	20	—	Carbon disulphide, hydrogen cyanide

*In the presence of oxidants.

Table 4. Composition of gaseous waste (temperature 350–1100 °C).

Substance	Content, mg m^{-3}
Hydrogen sulphide	360
Sulphur dioxide	60
Carbon monoxide	7.3
Nitrogen oxides	306
Ammonia	197
Benzene	474
Hydrogen cyanide	4
Benzopyrene	0.21
Oxygen and nitrogen	residue

Ammonia is absorbed over the entire experimental temperature range (the maximum is at about 100 °C). Ammonia is an effective reducing agent, which reduces the metal, carbon oxides, and nitrogen oxides. Thermal desorption begins at 450 °C with evolution of nitrogen into the gas phase.

Methane is absorbed at fairly high temperatures (450–600 °C), carbon monoxide and dioxide being evolved into the gas phase. The same products are also formed on thermal desorption. The same temperature range is characteristic of the activity in relation to the methane–nitric oxide mixture.

A catalytic effect was not observed in relation to mercaptans, carbon disulphide, and hydrogen cyanide. Mercaptans, using butanethiol as an example, are not absorbed, while carbon disulphide and hydrogen cyanide remain on the catalyst in the adsorbed form. Aliphatic and aromatic alkyl-substituted hydrocarbons are also effectively adsorbed. The strength of adsorption of hydrogen cyanide is confirmed by the fact that it is desorbed at a temperature above 200 °C. However, these compounds can interact on contact with oxidising gases.

The results obtained in preliminary tests on catalysts in industrial gaseous waste from the Moscow Coke–Gas Factory (MCGF), the Kashirsk Thermoelectric Power Station, and the Cellulose Industry in Krasnoyarsk are presented below. Table 4 gives the composition of the effluent gases from the MCGF.

As a result of the application of the catalyst, hydrogen sulphide, hydrogen cyanide, and nitric oxide are eliminated from the gases (Table 5).

Table 5. Results of tests on new catalytic systems (MCGF).

Source of waste	Ecologically harmful impurity	Catalyst operating conditions		Impurity concentration, mg m^{-1}		Duration of operation before breakthrough	Efficiency of purification, %
		space velocity, h^{-1}	temperature, °C	before purifcation	after purification		
Straight run coke gas	Hydrogen sulphide	300	20	3000	0	312	100.0
Reverse run coke gas	"	470	20	30	0	816	100.0
Straight run coke gas	Hydrogen cyanide, hydrogen	300	20	1000	2.8	1440	99.7

	"	1000	20	500	9	1	98.2

The advantages of the catalysts described above are as follows:

availability and the possibility of obtaining them directly in the factory, since this requires only a carrier, a hydrocarbon gas, a metal salt, and plant of suitable size and of a relatively simple design;

a lower cost than that of activated charcoal, which makes it possible to organise a large scale industrial production without a large capital expenditure;

the possibility of using spent catalysts, already containing metals, as carriers;

the use of catalysts makes it possible to combine adsorption and catalytic purification processes;

The solution of the problem of the elimination of ecologically harmful impurities from gaseous waste can be reduced (in view of the multifunctional nature of the catalyst) to setting up a balance between oxidative and reductive components. This provides a simple and effective lever for controlling the process, can guarantee the reliability and quality of the purification, and creates conditions for automating the purification processes and the monitoring of the chemical composition of the waste.

The large scale employment of the systems developed requires the creation and organisation of the production of standard apparatus for coating inorganic materials with carbon. At the present time, there exists only laboratory apparatus as well as the plant at the MCGF, which has made it possible to produce one tonne of the catalyst. It is necessary to solve a series of technological problems (in particular, the problem of the additional aerodynamic resistance to the effluent gases) and to develop methods for the regeneration of the catalysts. Furthermore, it is essential to develop apparatus for the rapid analysis of the effluent gases before and after purification, a computer technique, and a module for the automatic control of the purification processes.

Membrane technology in the resolution of nature conservancy problems

S F Timashev
Karpov Research Institute of Physical Chemistry, Moscow

1. The potential of membrane technology and certain examples

In future membrane technology could provide the basis for resolving a number of ecological problems in many branches of industry and agriculture. Practical experience throughout the world has highlighted examples of how membrane technology may be used on the industrial scale in order to resolve ecological problems.

First of all there is the project in the USA now in its final stages in which the salinity of the Colorado river has been reduced from 1.5 g^{-1} to approximately 0.7 g^{-1} (i.e. in regard to salt content the water has been converted to drinking water). A similar water processing facility is now under construction in the town of Hume (Arizona state) close to the border with Mexico. In this case part of the river discharge will be channelled through the desalination plant where blocks of membrane assemblies for reverse osmosis are located and have an operating efficiency of 400 thousand cubic metres per day. Under these conditions the solvent (water) is forced through the membranes in the presence of a high osmotic pressure (the operating pressure is usually approximately 3–5 MPa) while salts

The results obtained in preliminary tests on catalysts in industrial gaseous waste from the Moscow Coke–Gas Factory (MCGF), the Kashirsk Thermoelectric Power Station, and the Cellulose Industry in Krasnoyarsk are presented below. Table 4 gives the composition of the effluent gases from the MCGF.

As a result of the application of the catalyst, hydrogen sulphide, hydrogen cyanide, and nitric oxide are eliminated from the gases (Table 5).

Membrane technology in the resolution of nature conservancy problems

S F Timashev
Karpov Research Institute of Physical Chemistry, Moscow

1. The potential of membrane technology and certain examples

In future membrane technology could provide the basis for resolving a number of ecological problems in many branches of industry and agriculture. Practical experience throughout the world has highlighted examples of how membrane technology may be used on the industrial scale in order to resolve ecological problems.

First of all there is the project in the USA now in its final stages in which the salinity of the Colorado river has been reduced from 1.5 g^{-1} to approximately 0.7 g^{-1} (i.e. in regard to salt content the water has been converted to drinking water). A similar water processing facility is now under construction in the town of Hume (Arizona state) close to the border with Mexico. In this case part of the river discharge will be channelled through the desalination plant where blocks of membrane assemblies for reverse osmosis are located and have an operating efficiency of 400 thousand cubic metres per day. Under these conditions the solvent (water) is forced through the membranes in the presence of a high osmotic pressure (the operating pressure is usually approximately 3–5 MPa) while salts

are retained. The flow of desalinated water will be mixed with the untreated portion of the Colorado river discharge so that the river water in Mexico has an acceptable salt content.

The future possibility of combining complexone (based on organophosphorus compounds) stabilisation (prevention of salt deposition) of water† with membrane treatment of water in circulating water supply systems by means of ultrafiltration, electrodialysis, and reverse osmosis should be considered. This approach would be even more attractive, since in the case of water stabilisation by complexones part of the circulating discharge would inevitably have to be replenished and the organophosphorus compounds would remain outside the water circulating system.

Reverse osmosis installations are also used for generating large volumes of drinking water, and this process is carried out in Saudi Arabia in plants for the distillation of briny waters in which approximately 10^4 m^3 of water are produced each day. There is a clear awareness of the severity of problems associated with water supplies in the USSR especially in Southern regions. Adequately large reserves of brackish water (approximately 3–6 g l^{-1}) have been located, so that attention may be focused on the supply of water to rural areas which would be ecologically safe as a result of the use of membrane techniques. The success of the respective developments will apparently be determined not only by the availability of high performance membranes (with respect to operating efficiency, selectivity, chemical and thermal output, stability, mechanical properties) but also by the creation of high-capacity membrane devices and by the supply of essential equipment including heavy duty pumps.

It is noteworthy that progress has already been made in the USSR in resolving water supply problems. In Tambov the Rodnik type of electrodialysers fitted with ion-exchange membranes MK-40 and MA-40 and with an operating efficiency of 1–4 m^3 h^{-1} (a product of the scientific-industrial complex Plastmassy, Scientific Research Institute of Plastics) have been in full-scale production since 1974. These facilities provide a reliable supply of drinking and household water produced from brackish waters of artesian boreholes for more than one million inhabitants of rural localities in Kazakhstan, the land along the Volga, the Ukraine, Kalmykin, and Central Asia.

The main electrodialysis installations for demineralisation of water for the requirements of the Prikumskii plastic factory are currently operating. These facilities (operating efficiency is approximately 50 m^3 h^{-1}) reduce the salt content from 0.75–0.8 g l^{-1} to 0.1 g l^{-1}. In this case a certain portion of the demineralised water is used in low pressure steam boilers, while the remaining portion of the water after secondary purification by ion-exchange is utilised for the industrial manufacture of ethylene oxide. The significant reduction in the amount of waste waters attained with the aid of this type of water treatment technology has a favourable ecological effect.

Academician A V Fokin‡ has already indicated in an earlier report that losses of mercury in Soviet plants during the production of one tonne of caustic soda (a total quantity of more than 0.5 million tonnes per annum) reaches 600 g, whereas in foreign countries the loss of mercury during the production of caustic soda is more than an order of magnitude lower. Apparently the only answer to this problem would be to convert to the production of caustic soda under clean conditions with the aid of membrane techniques. By adopting such a strategy there would still be many problems to surmount, despite the purchase of perforated carboxyl-containing membranes and electrolysers from the Japanese firm, Asaki Glass. It is noteworthy that the world-wide production of "membrane" caustic reached approximately 4.5 million tonnes per annum in 1988. [1]

In a number of major chemical and petrochemical plants membrane techniques are now being introduced for the extraction of exploitable components from process gas mixtures which, in addition to saving resources, enables harmful gaseous discharges to the atmosphere to be reduced or eliminated. The American firm Monsanto uses membrane assemblies with an operating efficiency of up to 2.8 × 10^4 m^3 h^{-1} as a result of which up to 9% of the hydrogen not utilised in the chemical transformations can be returned to the manufacturing process and up to 99% of the hydrogen may be concentrated and subsequently utilised for the synthesis of ammonia and methanol and for hydrorefining and hydrogenolysis. A high order of cost savings is being attained in Saudi Arabia where the firm "Chieda" has built an air separation plant for generating high purity oxygen (1200 tonnes per day) and nitrogen (10^4 m^3 h^{-1}) in a petroleum chemistry complex (plants for the production of ethylene, ethylene glycol, and low density polyethylene). In this regard certain achievements in the Soviet Union are noteworthy. Gas separation membranes made of polyvinyltrimethylsilane and gas-separating membrane devices have been developed§. Assemblies, which are commercially available from the scientific-industrial complex "Kriogenmash", are used for the biological purification of waste waters, oxygenation of water for the artificial breeding of fish and other living organisms, for medicinal purposes, and for the generation of a controlled gas phase during the storage of different kinds of agricultural produce and for other purposes. Other examples in which membrane technology may be effectively employed could be given.

2. Resolution of fundamental problems in membrane separation. The basis of the development and extensive exploitation of membrane technology for a wide range of practical purposes

Advances in membrane technology will only be possible as a result of a comprehensive study of a broad range of scientific problems, and the wide experience of many foreign firms supports this view. The main problems will be briefly listed.

1. Problems associated with the production of materials (organic polymers, inorganic material particularly ceramics) for membranes. In this case one has in mind a broad range of problems concerning membrane material science which relate to the selection of conditions for the synthesis and treatment of materials and to the formation of membranes and their modification (volume, surface).[2,3].

† See the paper by M I Kabachnik and N M Dyatlova "Chemical Aspects of a Circulating Water Supply" in the present issue.

‡ See the article by A V Fokin "Protection of the Environment and Chemical Ecology" in the present issue.

§ See the article by N A Plate, V V Teplyakov, V S Khotimskii, and Yu P Yampol'skii "Certain Possibilities with Gas-separating Membranes for the Creation of Ecologically Friendly Plants" in the present issue.

2. Problems associated with the physical chemistry of membrane separation. This group of questions includes attempts to determine the nature of the selectivity of the transport of a given component through the membrane and the determination of the structure of membranes in various three-dimensional scales (beginning with nanometres) and relationships between the structure and functional characteristics of the membranes.[4,5] The mechanisms of transport of ions and molecules within different types of synthetic membranes vary. "Particle size" effects play a major role in microfiltration (particles in the 0.02 μm – 10 μm range are retained) and ultrafiltration (particles typically with a mass of 500 daltons to 0.1 μm in size[5]) processes. However even in the case of ultrafiltration surface force fields, the interaction (Coulomb, dispersion, and "structural"[6]) between particles passing through the membrane pores and the surface of the pore have a significant effect on the efficiency of the separation process. Therefore modification of the surface of the pores (for example by grafting of charged and polar functional groups) may significantly alter the retention effect.

Fields of surface forces are exerted in a particular way in reverse osmosis processes, when under the influence of high osmotic pressures the solvent or individual components of a complex solvent are pressed through the submicropore or subchannel system. In this case the efficiency of the separation (when specifications are met in regard to chemical and mechanical stability of the selective layer in the membranes) is dependent on the topology of paths along which the solvent flows and on the fields of surface forces created by the functional groups within the material used.

In a large proportion of currently available processes for electrodialysis, electrolysis, gas separation, and pervaporation (evaporation through non-porous "diffusion" layers) drift diffusion transport through membranes occurs, so that the effect of membrane separation is determined for various components in the mixtures by the differences in the permeability constants (P) of the material from which the membrane is made. These values are obtained as the product of two factors, a thermodynamic factor (the solubility constant of a component in the given material, the Henry constant) and a kinetic factor (diffusion coefficient, electrical mobility, etc.). In a number of cases the mutual action of the penetrating components have a significant effect, for example on account of the plasticisation of the polymeric matrix, when one of the components dissolves in the latter.

Even at this level of factual description of cross-membrane transport many problems arise which are associated with the need to have an adequate understanding of the technological parameters of the membranes and with the determination of routes for increasing the efficiency of membrane separation, mainly on account of the selection of materials for membranes. The problems increase immeasurably on transition to regimes of intensive mass-transfer through the membrane (high current densities flowing through the membrane, high operating pressures), when the above-mentioned quasi-equilibrium representations are found to be inadequate. Under these conditions the selectivity of the separation may be determined entirely by kinetic factors and may be dependent to a greater extent on the membrane structure in different spatial scales, and on the condition of the membrane surface and the interphase boundaries in the body of the membranes.[4] By gaining an understanding of the nature of the above-mentioned features of the transport process the membrane material and the surface of the membranes can be realistically modified with the objective of obtaining membranes with specified characteristics.

New qualitative relationships and hence new advances in research in the development of new-generation membranes may be elaborated, when barrier membrane structures are used for the separation of mixtures, i.e. ultrathin layers of submicroscopical thickness (10 – 100 nm) made from organic or inorganic materials formed on ultrafiltration and microfiltration supports. In this case the permeability of the membrane layer to a particular type of particle is dependent on the ratio of two spatial scales: the minimal length of a_0, the average distance between centres of localisation of the particle moving in the membrane and also the correlation length, ξ, the characteristic degree of the structural heterogeneity of the barrier layer within the limits of which "coherence" is realised. On scales greater than ξ the system is homogeneous, and therefore the permeability constant P of membranes with a thickness $d \gg \xi$ has the normal meaning. However, when $d < \xi$, the parameter P is not a constant value, since the flow of particles through the membrane under stationary conditions is dependent on the value d according to the non-traditional method (the fractal mode of transport). On account of the difference in the values of the probabilities of the elementary jumps for the various particles, the local heterogeneity of the layer structure is "felt" in different ways by the different types of particles passing through the membrane. Thus the barrier layer may for example consist of a homogeneous system for certain particles, $i (d \gg \xi_i)$, but may constitute a fractal system for other particles, $j (d < \xi_j)$. Thus one might conclude that there is possibly a relationship between the selective permeability of the different types of particles and the thickness of the barrier layers. This may serve as a basis for the targetted search for barrier structures, which are highly permeable and highly selective with respect to specific components and which have different chemical properties and a different three-dimensional structure.

3. Questions concerning the optimisation of separation processes. The advantages of membrane techniques for resolving specific problems concerning the isolation or concentration of the required components from a gas or liquid mixture may be totally realised only when the process as a whole is optimised. In this case combined (integrated) process diagrams may be obtained specifying the use of other process units (distillation, rectification, etc.) in addition to membrane blocks (in general with membrane cascades including recycling[7]).

These complex strategies may be fulfilled by means of mathematical modelling of the processes and the creation of a bank of models for membrane-sorption processes and cross-membrane transport of components in the mixtures. All of the advantages of membrane technology can be exploited only when the process flows, equipment construction, types of membranes, and process arrangements are optimised with the aid of the mathematical models derived.

3. Prospects for the use of membrane technology to resolve ecological problems

Academician I V Petryanov-Sokolov commented on the essential strategic direction for scientific studies against a background of imminent ecological calamities. "There is no process which does not require continual monitoring..." One might anticipate that through the extensive use of membrane separation techniques it should be possible to come close to confirming this principle in real-life situations. Several Soviet developments, which could form the basis of ecologically acceptable processes, are indicated below.

A) The elaboration of basic membrane technology processes for the extraction of utilisation of ammonia from gasous and liquid discharges from chemical and metallurgical plants

In present-day manufacture of ammonia (plants for the synthesis at an output of approximately 450 tonnes of ammonia per annum are used) there are no closed-up material cycles in relation to ammonia. A certain proportion of the circulating gas mixture, the so-called blow-off gases (approximately 7–8 thousand $nm^3\ h^{-1}$) are led out of the synthetic cycle in order to prevent the accumulation of secondary gases above a particular level (approximately 10%) and tank gases are released from the storage tank (approximately 2.5 thousand $nm^3\ h^{-1}$). After the ammonia has been condensed (by cooling to 243–248 K), the ammonia content in the blow-off and storage tank gases is 1.4 and 10.7 vol.%, respectively. The ammonia is either burned in the jets of tube furnaces for natural gas conversion, which leads to further losses of the original raw material and to marked contamination of the environment with oxides of nitrogen¶, or is washed with water with the formation of ammonia water (approximately 3–6 vol.% ammonia) which in many cases is regarded as liquid sewage.

In this regard the close-up of material cycles with respect to ammonia is a key priority from the ecological standpoint (with an unquestionable saving of resources) and could be achieved if highly selective membranes were used for the extraction of ammonia from tank and blow-off gases and also from the ammonia, liquid sewage of the plant.

Ecologically important problems are associated with the operation of gaseous nitration processes which are still used, i.e. the chemico-thermal treatment of steel items, in order to increase their strength, corrosion resistance, and durability by saturation of the surface layer with the nitrogen formed during the thermal dissociation of ammonia, which is present among the operating gases used. An important defect of nitration technology is the partial (approximately 50%) thermal dissociation of ammonia, as a result of which the remaining portion of ammonia is burned with the formation of oxides of nitrogen. There is obviously a need for close-up of the ammonia cycle in this case also, since the annual demand for ammonia is $3-4 \times 10^6\ m^3$ on the premises of the Ministry of Automobile and Agricultural Engineering alone. The need to isolate ammonia from gas mixtures also arises in a number of biotechnology processes.

Membrane technology may be used for the separation of mixtures containing ammonia, in order to surmount this complex of problems. The membrane used for this purpose could be formed from hollow fibre, which has anomalously high permeability and selectivity parameters with respect to ammonia ($P_{NH_3} \approx 5\ m^3/(m^2\ h\ atm.)$, $\alpha = P_{NH_3}/P_{H_2} \approx 10^3$). This type of membrane is under development at present in the Karpov Scientific-Research Institute of Physical Chemistry in collaboration with a number of other organisations, i.e. the Kiev Branch of the All-Union Scientific-Research and Design Institute of Synthetic Fibre, the "Khimvolokno" scientific-industrial complex, the Okhtinsk scientific-industrial complex "Plastopolimer", the State Scientific-Research and Design Institute of the Nitrogen Industry and Products of Organic Synthesis, the Moscow Engineering and Physics Institute, and the Institute of Chemical Physics, Academy of Sciences of the USSR. [8,9] The membranes are based on a perfluorinated sulpho-containing copolymer with a high thermal and chemical stability. Effective methods for modifying the copolymer have been found, adhesive fillers have been developed for gas separation membrane elements, and processes have been designed in which gases are separated in hollow fibre membrane modules using different flow diagram arrangements for organisation of the process. In contrast to known membranes based on polyfluoroethylene resin[10] this membrane is not susceptible to the marked effects of plasticisation and its properties are not altered, when the composition of the ammonia-containing mixture is changed. Trials performed on membranes and gas-separating elements based on these materials have shown that in principle it is possible to surmount the above-mentioned problems on the industrial scale in regard to resource saving and the prevention of harmful wastes from entering the environment.

B) Elaboration of membrane technologies for the extraction and concentration of "acid" components from gas mixtures

In recent years serious ecological problems have arisen in regard to the processing of certain gas-bearing formations mainly in the Orenberg and Astrakhan regions. The main cause of the ecological hazard is the low standard of technology employed for recovery of the gas and also the equipment used which results in the discharge of hydrogen sulphide, sulphur dioxide and carbon dioxide into the atmosphere. Sulphur dioxide is also released into the atmosphere from many industrial plants. Discharge of this gas by thermoelectrical power stations amounts to more than eight million tonnes in the USSR [11] and integrated mining and metallurgical works (Norilsk and others)† discharge several million tonnes. The problems of extraction and concentration of acid gas are especially acute in ferrous metallurgy sites, for example sulphur dioxide in coke chemical plants and carbon dioxide in blast furnaces. Gaseous discharges from motor transport are also known to present a serious hazard to the natural environment.

The release of ecologically harmful components, including acid gases, into the atmosphere has serious consequences. The hazards are mainly acid rain, which is a threat to soil bacteria and causes degradation of the topsoil, and also the greenhouse effect as a result of the release of carbon dioxide.

Apparently it will be possible to eliminate some of these problems in future[12–14] with the aid of membrane technology (it is hoped that in this regard the major successes will be associated with the use of catalytic methods for the recovery of acid gases). Although at present there are essentially no large-scale industrial installations in operation for the entrapment and concentration of the components in aggressive acid gases (sulphur dioxide, hydrogen sulphide, oxides of nitrogen), intensive research in underway in many parts of the world in the search for high-efficiency membranes for acid gases, and line diagrams are in preparation for membrane processes and membrane-sorption and other combined installations.

Of the membranes developed in the USSR for extraction of aggressive acid gases and gas mixtures generated by the various plants, and "Seragel" type membranes are noteworthy.[15] These membranes are highly selective for sulphur dioxide and hydrogen sulphide. In addition membranes for hydrogen sulphide and carbon

¶ Apparently discharges of oxides of nitrogen together with emergency discharges of ammonia in the Shchekin industrial complex "Azot" caused irreparable damage to Tolstoy's farm in Yasnaya Polyana.

† See the article by K I Zamaraev, "Development and Introduction of Catalytic Methods for the Detoxification of Discharges from Industry and Motor Transport" in the present issue.

dioxide which are based on aromatic polyamidoimides obtained from solutions of polymers in N-methylpyrrolidone are of interest.[16]

The American firm Bend Research has designed a membrane, which is highly selective for hydrogen sulphide ($P_{H_2S}/P_{CO_2} \approx 30$) [17] and which consists of a gelatinoid layer containing an alkylpyrrolidone or an alkyl phosphate carried on an asymmetrical cellulose support. In earlier reports[18,19] it has been shown that membranes based on heat-resistant and chemically stable perfluorinated copolymers ("Nafion") are highly efficient in regard to the extraction of acid gases. These copolymers contain sulphonic acid groups with carriers containing amino groups and anion-exchange groups with quaternary ammonium bases. In these cases[18] difficulties are encountered in the determination of specific pathways for the modification of these types of materials and the elaboration of thin-layer (< 50 μm) membrane technology. Thus there would appear to be great potential in the use of hollow fibre modules with membranes based on perfluorinated ionomers for the extraction of acid gas and also for the extraction of ammonia. In these types of materials the gas molecules are transported through a system of submicroscopic canals[4] and the diffusing molecules undergo reversible binding with functional groups or the carriers. In this case certain components may be selectively controlled by altering the moisture content of the membranes.[20] One might suggest that, in addition to the above-mentioned aggressive components (hydrogen sulphide, sulphur dioxide, and ammonia) and carbon dioxide, membranes based on perfluorinated ionomers, which constitute a class of relatively heat resistant and chemically stable polymeric membranes, may (with certain modifications) also be used for the extraction of oxides of nitrogen and carbon monoxide (in the presence of nitrogen) from gas mixtures, for the separation and concentration of certain hydrocarbons, and for drying gases. The above-mentioned studies emphasise the interest in perfluorinated materials containing functional groups as membranes which may be used for the separation of the most aggressive and ecologically harmful components from gaseous media. Apparently in future in addition to hollow fibre membranes flat composite membranes with a selective layer formed from solutions of perfluorinated ionomers will be manufactured (for roll modules).

C) Design of a process of membrane electrolysis in alumina production

A membrane electrolysis process in which the recuperation of alkali is a major component of the technology for the recovery of industrial products in alumina production is being developed by the State Scientific-Research and Design Institute of the Rare Metals Industry, the Institute of Metallurgy and Enrichment, Academy of Sciences of the Kazakh SSR, and alumina plants within the Ministry of Metallurgy of the USSR.

In addition to the question of resource savings the treatment of soda-sulphate mixtures, which are formed during the recovery of sulphide-containing bauxites in a number of aluminium plants in which alkali is completely regenerated (ten–twelve thousand tonnes in terms of 100% caustic on average in each factory), has a very marked ecological impact. Trials with electrolysis using perfluorinated ion-exchange membranes in an installation at an alumina works in the Urals aluminium factory have shown that in principle it is possible to attain almost total regeneration of alkali with the concomitant production of gypsum. Broader objectives have been set for the use of membrane electrolysis for reprocessing carbonate-sulphate, chloride-carbonate, and chloride-sulphate mixtures and also alkaline aluminate solutions.

D) Replacement of ion-exchange cycles by continuous membrane processes in the production of riboxine

A preliminary analysis of the existing technologies for the production of riboxine in plants in which medicinal preparations are manufactured has shown that the use of electrodialysis may significantly reduce losses (reaching almost 50%) of the main product and significantly reduce the ecological hazard presented by the plant on account of the elimination of discharges of water used for the regeneration of ion-exchange columns. The technology of demineralisation by electrodialysis may provide the basis for this and a number of other biotechnological processes.

E) Processes for the treatment of industrial waste waters involving the extraction of valuable components

It is noteworthy that among many plants of this type in existence throughout the world including those in which electrodialysis is employed (see for example Ref. 21) processes are being designed involving the use of impregnated liquid membranes, which contain a solution of a complex-forming agent and an ionophore in an organic solvent, which is injected into the pores of the membrane support. By creating in these systems a counter (antiport) flow of ions of like sign (for example M^{n+} and nH^+) or a unidirectional flow (symport) of ions of opposite sign (M^{n+} and nOH^-) it is possible to achieve a high degree of extraction of the required component (Cu^{2+}, Cr^{3+}, VO_2^{2+}, etc.) from the original solution. In this way copper has been extracted from wash waters in electroplating shops.[22] Porous hollow fibres made from polypropylene have been used as a hydrophobic matrix, the impregnated phase being a solution of di(2-ethylhexyl)-phosphoric acid in n-dodecane. A pH value of 3–5 was maintained in the feeder solution. When sulphuric acid is used in the recipient solution, up to 99% extraction of copper, a toxic component of waste waters, was attained, which corresponded to a residual copper concentration at the normal BOD level. In this case a saturated solution of copper sulphate was obtained in the recipient solution. The demineralised water from which the copper had been removed was returned for use as the wash water and the saturated solution of copper sulphate was used for the periodic adjustment of the composition of the electroplating baths. There is an obvious need to employ this type of technology in industry in the USSR from the standpoint of resource saving and ecology.

One should note two additional general factors.

1. Attainment of ecological objectives is impossible in the absence of any novel techniques and equipment for the continuous monitoring (analytical chemical) of the composition of the environment (atmosphere, reservoirs, land) which permit rapid determinations, and which are reliable and simple to operate. One is essentially concerned with the design and production of a new generation of analytical facilities, i.e. chemical membrane sensors, miniature, highly sensitive devices for the direct, selective, and fully automated determination of chemical compounds in industrial systems and natural specimens. In these devices film (membrane) coatings made from organic and inorganic materials with increased permeability constants with respect to particular environmental components (molecules, ions) are used as barriers separating the environment under analysis from the recording system (semiconducting oxide films, field-effect transistors, etc.). With the aid of these systems it will be possible to monitor rapidly and continuously the chemical composition of liquid and gaseous natural media and industrial discharges down to trace concentrations. Unfortunately studies and developments of this nature are not in

progress in the institutes of the Section of General and Industrial Chemistry, Academy of Sciences of the USSR.

2. As regards solving ecological problems we have no right to procrastinate. It is our duty to our fellow-countrymen and to the world community to exploit to the maximum all available means for construction plants which discharge little or no wastes, in order to reduce the concentration of harmful and toxic components in the environment. This is a very complex problem, which is compounded by the fact that the Soviet authorities at present have no effective mechanisms which help industrial enterprises and factories to become interested in exploiting the achievements of science which are targetted towards the resolution of acute ecological problems. It would seems that, if there are no such mechanisms available, they must be created or at least their creation must be encouraged.

In a present-day assessment of the economic efficiency of technological processes the actual damage which they inflict upon the natural environment (in the mining of exploitable minerals, during the disposal of industrial wastes, at water intakes, etc.) and the expenses which the complete restoration of the environment would demand are not taken into consideration. If in future the objective (by introduction of appropriate laws by the Supreme Soviet of the USSR) will be to take into account this hazard in an adequate manner‡ during the planning of the various technological projects and to weigh the economic advantages against the effects of such projects, the economic advantages of fulfilling many technological plans will be viewed in a completely different light. The need to uphold a way of life with resource-, material- and energy-saving and environmentally acceptable technologies (in particular membrane technology) is undoubtedly becoming a vitally important issue for factories and industrial enterprises. It is precisely this type of revaluation of the technical level of a diverse range of manufacturing processes under Soviet conditions which may open up a route to new technologies.

Development of ecologically balanced industrial technology for obtaining chlorine-containing monomers

G A Tolstikov, S S Shavanov
Institute of Chemistry, Bashkir Scientific Centre,
Urals Division of the Academy of Sciences of the USSR, Ufa

Plans for the development of the national economy foresee the promise of a radical upheaval of technological processes based on the more progressive achievements of the work of fundamental and applied scientific investigators. Chemical technologies occupy an important place when putting this programme into effect, and safeguard practically all regions of society. Halogen-containing compounds play an important role in industrial manufacture. This is particularly so for organochlorine compounds which are involved in a number of the largest multitonnage products. It is also known that their manufacture yields many ecological problems which are difficult to resolve. Thus the manufacture of polyvinyl chloride, which reaches a world volume of more than 20 million tons per year, yields up to 9% practically unusuable waste products. It is possible to regard as ecologically unbalanced the current manufacture of several other organochlorine substances, particularly chloroprene, the monomer for obtaining rubbers possessing several desirable properties (oil stability, ozone-stability, incombustibility, elasticity).

A set of studies has been carried out in the Institute of Chemistry of the Bashkir Scientific Centre, Urals Division of the Academy of Sciences of the USSR which were directed towards the creation of technological processes for obtaining chlorine-containing products allowing for modern ecological requirements.

As the basis of our concept we rejected gas phase or other high temperature reactions which are not as a rule capable of high selectivity. It is clear that under conditions of effecting multitonnage technology each percentage point of selectivity causes either the appearance of an enormous quantity of waste products or their abrupt curtailment. We included within our interests the technology of making unsaturated chlorohydrocarbons of composition C_2-C_4 which have high practical value.

Since the selectivity of these chemical processes is determined by the elimination of hydrogen halide from compounds obtained by the previous chlorination of the corresponding organic compounds, attention was paid mainly to the development of catalysts guaranteeing high yields of the desired products. At the same time serious attention was paid to the technological aspects having no less important value in the creation of ecologically safe manufacture. We therefore started from the premise assumed by us of the priority of liquid phase methods effected under mild conditions. The use of the closed cycle principle was an important concept. Thus sodium chloride was formed on alkaline dehydrochlorination and does not usually find regular use. In our scheme high purity sodium chloride is obtained, it may be used for electrolysis, for making sodium carbonate by the Solvay process and even in the food industry.

High efficiency catalysts guaranteeing practically complete selectivity for the alkaline dehydrohalogenation reaction have been developed by us based on new concepts in interphase catalysis. This unique phenomenon of organic synthesis discovered in the seventies immediately attracted the attention of numerous investigators who directed their work both to its use in the synthesis of various organic compounds and to establishing the mechanism for carrying out the catalytic process.[1–3] It is known that various quaternary compounds such as crown ethers, polyethyleneglycol, etc. display catalytic activity in interphase reactions and are widely used. Analysis of the known work on the theoretical aspects of catalysis of interphase reactions shows that there is no unequivocal understanding of the role of catalysts at present.

In our view the generally accepted concept, according to which anion exchange is the initial catalytic act in interphase processes catalysed by quaternary compounds, particularly quaternary ammonium salts, has not been argued sufficiently. Confirmation of the formation of the corresponding ion pairs in the organic phase by deprotonation of the substrate has not been confirmed by reliable proof. On the contrary there are ideas on the formation of alkoxides from the corresponding quaternary ammonium salts and alcohols in the presence of concentrated aqueous solutions of alkali metal hydroxides. All this indicates the absence up to the present of a theory explaining reliably the rules of interphase catalysis.

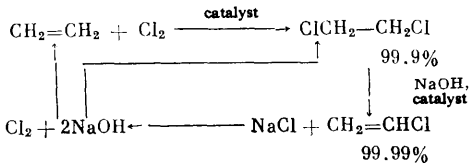
Since quaternary ammonium salts are widely used in practice as catalysts because of their availability and fairly high catalytic activity, our attention was concentrated on these compounds during the investigation.

The known high catalytic effect of tetraalkyl(trialkylbenzyl)-ammonium alkoxides in the dehydrohalogenation reaction of polyhaloalkanes under the action of concentrated aqueous solutions of NaOH served for a while as the reason for the direction of our investigations.[4]

Some data obtained on dehydrochlorinating 1,2-dichloroethane are shown for illustration (Table 1).

Table 1. The effect of anion structure on the rate (W) of formation of vinyl chloride (temperature 50–55 °C, molar ratio C_2H_4 : NaOH = 1 : 2, NaOH — 50%, reaction time 30 min, quantity of catalyst 0.3 mol%).

Catalyst	10^4 W, mol litre^{-1} sec^{-1}	Dichloroethane conversion, %
$(C_2H_5)_3NCH_2C_6H_5{+}Cl^-$	8.6	28.5
$(C_2H_5)_3NCH_2C_6H_5{+}CH_3O^-$	13.9	45.7
$(C_2H_5)_3NCH_2C_6H_5{+}C_2H_5O^-$	16.8	56.3
$(C_2H_5)_3NCH_2C_6H_5{+}C_4H_9O^-$	20.7	68.1
$(C_2H_5)_3NCH_2C_6H_5{+}C_7H_{15}O^-$	21.7	71.6
$(C_2H_5)_3NCH_2C_6H_5{+}C_6H_5CH_2O^-$	31.6	99.5
$(C_2H_5)_3NCH_2C_6H_5{+}ClC_6H_4CH_2O^-$	37.9	99.7 *
$(C_4H_9)_4N^+OH^-$	9.3	30.8
$(C_4H_9)_4N^+Cl^-$	9.2	30.6
$(C_4H_9)_4N^+Br^-$	9.6	31.8



* Reaction time 24 min.

As is seen from the data of Table 1 tetraalkyl(trialkylbenzyl)-ammonium alkoxides display significantly higher catalytic activity compared with other quaternary ammonium salts. It was natural to study this phenomenon deeply in competing β-elimination and

nucleophilic substitution reactions having in mind the constantly increasing ecological requirements for the manufacture of unsaturated C_2-C_4 chlorohydrocarbons. Absolute priority was given to a fundamental investigation of the mechanism of the catalysts found since according to our concept it must have a general character independent of the type of interphase reaction. In addition a true understanding of the catalytic process creates a basis for its control. The conclusion drawn from our investigations was that the catalysis of β-elimination is effected not by the individual quaternary ammonium salts but by the formation of complexes by them.[5-8]

The reaction occurs synchronously in the organic phase and on the surface separating the phases. The principal complex is an associate of the quaternary ammonium salt and proton-donating compounds. Associates are solvated in the organic phase with the organohalogen substrate and interact with organic base on the phase separation surface. The mechanism proposed excludes anion exchange of the catalyst as the initial catalytic act. It is also important that the catalytic activity of the complex is determined both by the basicity of the proton-donating component and by the charge on the nitrogen atom in the tetraalkyl(trialkylbenzyl)-ammonium cation. The presence of an allyl substituent increases catalytic activity appreciably (allyl effect). On this basis a series of highly effective and readily available catalysts for β-elimination in polyhaloalkanes has been developed. The application of these catalysts to the process of obtaining vinyl chloride by the alkaline liquid phase dehydrochlorination of 1,2-dichloroethane affords virtually the first ecologically clean technology.

We are proposing a new strategy for industrial establishments making polyvinyl chloride based on closed cycles with complete chlorine consumption at the place of manufacture. One such cycle comprises the preparation of chlorine and sodium hydroxide by electrolysis, the selective chlorination of ethylene and the dehydrochlorination of 1,2-dichloroethane, and preparation of polymer by ecologically pure technology and, finally, the return of sodium chloride to electrolysis. The efficiency of the process may be judged from the stage of synthesising vinyl chloride. A reactor with a working volume of 1 m^3 has a throughput of 20 000 to 40 000 tons per year. Since the monomer is obtained with a purity never previously achieved in industry the waste products are reduced to a fraction of a percent. The manufacture of polyvinyl chloride resin suitable for making articles of the highest quality and a long use period may be developed from the high purity monomer. The preparation of articles for medicinal techniques, including single-use syringes, is a particularly important use for high purity polyvinyl chloride. The ecologically balance cycle developed for obtaining vinyl chloride may be depicted schematically in the following manner.

Two equivalents of sodium hydroxide are formed at the electrolysis stage for each equivalent of vinyl chloride. This is one of the positive factors in the organisation of the manufacture of unsaturated organochlorine monomers with complete consumption of chlorine. In this case half of the quantity of sodium hydroxide obtained becomes a commercial product. Comparative data are given in Table 2 which characterise the features of vinyl chloride manufacture by the gas method and by the liquid dehydrochlorination of dichloroethane.

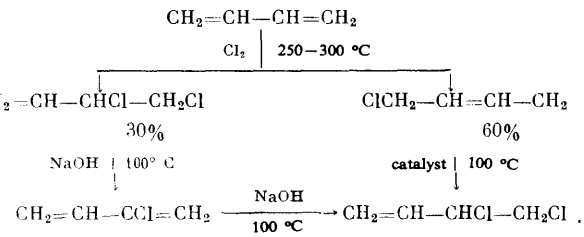
$$CH_2Cl—CH_2Cl \begin{cases} \longrightarrow CH_2=CHCl + HCl, \\ \longrightarrow CH_2=CHCl + NaCl. \end{cases}$$

Table 2. Technological process for obtaining vinyl chloride.

Main features of manufacture	Gas phase method	Liquid phase dehydrochlorination of dichloroethane
Reaction selectivity, %	95–98	99.99
Dichloroethane conversion, %	50–60	99.5–99.6
Conditions:		
Temperature, °C	500–550	55–60
Pressure, atm	20–30	without pressure
Unutilisable waste products, thousands of tons per 10 million tons	500–110	1–2

Such features of existing processes as the incomplete conversion of the initial dichloroethane and the high temperature and pressure, are some of the factors raising the price of the final product and complicating the overall maintenance of the technological process. The large quantity of waste products also compels critical treatment of this technology. The structure and composition of the waste products are such that the problem of their utilisation has not been solved and it is doubtful whether it may be solved in a forseeable time. There are harmful organochlorine products, spent sulphuric acid and 'sooty-resinous pulp' (according to the terminology of the production workers) among the waste products. Special areas are separated off for the burial of similar 'gifts'. Consequently the start-up of pilot-plant equipment to operate at the Kaustik Sterlitamaksk Industrial Company is an urgent requirement. The putting into operation of new technology is impossible without its careful analysis under factory conditions. Here it is necessary to add that the unit cost of vinyl chloride obtained by the technology proposed allowing for capital outlay and profit rate will be several percent lower than by the gas phase method. From the ecological point of view the technology proposed by us is preferable.

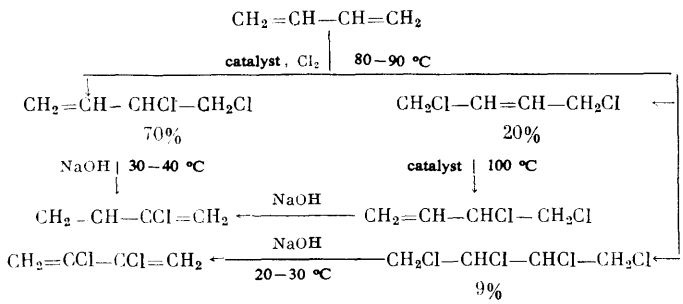
The closed cycle concept proposed by us has also been suggested for the manufacture of chloroprene rubber. We are convinced that the adoption of our proposal will loosen the stiff ecological knots tying the technology used at present.



Data from operating a pilot-plant indicate that technology giving almost 10 times less chlorine-containing waste products and leading to practically zero quantities of waste water may be possible. It is extremely important to simplify the technological process, to miniaturise the devices and to replace alloy by more available materials. In addition provision is made in the proposed process for the preparation of dichlorobutane, which is not manufactured in the USSR.

Our principle of operation has replaced the high temperature vapour phase by liquid phase processes taking place under mild conditions which we have applied to the chlorination of butadiene. This step in the existing industrial synthesis of chloroprene, which yields an extremely large quantity of waste products and direct losses (the recurrent result of being out of order due to corrosion of expensive imported compressors and other equipment), is converted

by our proposed catalytic liquid phase method into a step clearly moving the ecological characteristics of the whole technology in a better direction. It therefore turned out to be important that the products of more extended chlorination resulting without fail in the gas phase chlorination of butadiene, were completely absent. As a result of this the need to create special places for burial was reduced.



The features of the process for obtaining chlorine-containing monomers by the existing manufacture and by the method developed by us are shown below.

Existing technology

Unutilisable waste products are 7–9% on chlorination, the total quantity of waste products is 250 kg per ton of chloroprene.

Method developed by us

Unutilisable waste products are 0.5–1% on chlorination. Total quantity of waste products are 20–30 kg per ton of chloroprene.

New catalysts have enabled the development of ecologically clean technology for the synthesis of Triallate, an effective herbicide against wild oats. The process is characterised by little waste and a high quality product. The key problem in this technological process is the synthesis of 1,1,2,3-tetrachloropropene from 1,2,3-trichloropropane. This is a four-step process [reactions (1)–(4)], the step selectivity is low, which gives a large quantity of unutilisable chlorine-containing waste products. To this it is necessary to add a large volume of waste water containing harmful and as yet unidentified contaminants.

$$CH_2Cl-CHCl-CH_2Cl \xrightarrow[90\ ^\circ C]{NaOH} \underset{70\%}{CH_2=CCl-CH_2Cl}, \quad (1)$$

$$CH_2=CCl-CH_2Cl \xrightarrow{Cl_2} \underset{25\%}{CH_2Cl-CCl_2-CH_2Cl}, \quad (2)$$

$$CH_2Cl-CCl_2-CH_2Cl \xrightarrow{Cl_2} \underset{35\%}{CH_2Cl-CCl_2-CHCl_2} + HCl(?), \quad (3)$$

$$CH_2Cl-CCl_2-CHCl_2 \xrightarrow[90\ ^\circ C]{NaOH} \underset{71\%}{CH_2Cl-CCl=CCl_2}, \quad (4)$$

$$(iso\text{-}C_3H_7)_2NH + COS + NaOH \rightarrow (iso\text{-}C_3H_7)_2N-\overset{\overset{O}{\|}}{C}-SNa \xrightarrow{CH_2Cl-CCl=CCl_2} \rightarrow \underset{85\%}{(iso\text{-}C_3H_7)_2N-\overset{\overset{O}{\|}}{C}-S-CH_2-CCl=CCl_2}. \quad (5)$$

In addition the final step is characterised as unstable due to the lability of the intermediate product, which also reduces the manufacturing efficiency.

The new technology developed by us and tested in laboratory and pilot-plant equipment possesses high selectivity at all steps and is illustrated in the scheme shown below. It must be stressed that the catalysts found proved to be extremely effective particularly at the step of obtaining Triallate.

$$CH_2Cl-CHCl-CH_2Cl \xrightarrow[catalyst]{NaOH} \underset{98-99\%}{CH_2=CCl-CH_2Cl}, \quad (6)$$

$$CH_2=CCl-CH_2Cl \xrightarrow{Cl_2} \underset{92\%}{CH_2Cl-CCl_2-CH_2Cl}, \quad (7)$$

$$CH_2Cl-CCl_2-CH_2Cl \xrightarrow[catalyst]{NaOH} \underset{96\%}{CH_2Cl-CCl=CHCl},$$

$$CH_2Cl-CCl=CHCl \xrightarrow{Cl_2} \underset{98-99\%}{CH_2Cl-CCl_2-CHCl_2}, \quad (9)$$

$$CH_2Cl-CCl_2-CHCl_2 \xrightarrow[catalyst]{NaOH} \underset{100\%}{CH_2Cl-CCl=CCl_2}, \quad (10)$$

$$(iso\text{-}C_3H_7)_2NH + COS + CH_2Cl-CCl=CCl_2 \xrightarrow[0-10\ ^\circ C]{catalyst} \rightarrow \underset{98-99\%}{(iso\text{-}C_3H_7)_2N-\overset{\overset{O}{\|}}{C}-S-CH_2-CCl=CCl_2}. \quad (11)$$

The advantage of the developed technology is a sharp drop in waste products and also an appreciable reduction (6–7 times) in the quantity of waste water. The process achieves an ecological balance previously inaccessable.

The examples given graphically demonstrate the unlimited possibilities for chemistry to solve ecological problems in practice. It is necessary to carry out an analysis of the existing technology, to develop processes absolutely acceptable from the point of view of preserving the environment and to develop, together with ministries, a long-term plan of fundamental and applied investigations directed towards the creation of chemical processes new in principle. A fairly radical reconstruction of the chemical industry must be expected in line with trends in the development of modern science and chemical technology and the urgently dictated requirements of ecology.

Catalytic systems for the purification of industrial effluent gases

S P Kiperman, T Yu Sergeeva, A S Dryakhlov, V M Kisarov
Zelinskii Institute of Organic Chemistry,
USSR Academy of Sciences, Moscow
NIIOGAZ Branch, Dzerzhinsk

The elimination of toxic impurities from industrial effluent gases constitutes an important ecological problem which has hitherto been solved to only a slight extent in our country. Such purification is desirable when the concentration of impurities in air exceeds the limiting permissible concentration (LPC) but is not sufficiently high to make their trapping economically viable. One of the most rational ways of removing such impurities involves, in the given instance, extensive catalytic oxidation.

The specific features of the catalytic purification under industrial conditions consists in the fact that the composition of the impurities removed is in general extremely complex and varied. The extensive oxidation of the effluent gases of different composition can be most effectively achieved with the aid of platinum and palladium catalysts containing the active metal, at a concentration amounting to a fraction percent, on porous and metallic carriers. These catalysts are capable of effecting a stable acceleration of the reaction at low temperatures with conversion of the impurities to give concentrations of the latter corresponding to the LPC and with conversion of functional compounds into non-toxic substances. Some of the effective catalysts are reforming catalysts (AP-56 and its later analogues) extracted from industrial apparatus after deactivation. They retain a high stable activity in extensive oxidation processes. The use of catalysts on a metallic support instead of porous carriers is more useful, since it rules out the blocking of the pores by industrial dust and increases the period of the operation of the catalyst.

Systematic studies on the separate and joint oxidation of toxic impurities under stationary and non-stationary conditions on industrial catalysts have been carried out in recent years at the Zelinskii Institute of Organic Chemistry of the USSR Academy of Sciences jointly with the Dzerzhinsk branch of the NIIOGAZ. These investigations made it possible to establish kinetic models of the extensive oxidation of various classes of compounds (paraffins, aromatic hydrocarbons, aldehydes, alcohols, acids, esters, and organic nitrogen compounds), to discover their common features and significant differences, and to develop a theory of the kinetics of catalytic reactions of mixtures of organic compounds. The latter permits the prediction, on the basis of experimental data for the reactions of individual compounds, of kinetic models for the reactions of mixtures of these substances with the aid of the idea that there is a simple mutual influence in the surface layer of the catalyst.

On the basis of the kinetic models obtained, the Dzerzhinsk branch of the NIIOGAZ together with the Institute of Organic Chemistry of the USSR Academy of Sciences achieved the catalytic purification of the effluent streams of air in the manufacture of synthetic aliphatic acids at the Novokuibyshevsk petroleum processing factory (with a turnover of 240 000 roubles annually) and also additional purification on horizontal and vertical machines for the enamelling of cable at the Moldavkabel' and Moskabel' factories with a turnover of 30 000 – 50 000 roubles annually).

Water-soluble polymers for the purification of waste water

E F Panarin
Institute of Macromolecular Compounds,
USSR Academy of Sciences, Leningrad

The high anthropogenic stress arising from large cities, industrial undertakings, and large animal husbandry complexes has led to an unsatisfactory state of the water system in many regions of the USSR. An unsatisfactory ecological situation has arisen in the Lake Ladoga – the Neva – Bay of Finland system. The natural capacity of the water system for adaptation has reached its limit.

The question of the purification of large volumes of waste water has arisen. The situation is aggravated by the necessity to disinfect these waters to remove the pathogenic microflora and to achieve its detoxification by removing heavy metal salts which enter the water mainly from industrial undertakings.

The most acute problem is that of the processing and utilisation of deposits from urban purification plant, hundreds of tons of which are carried away to waste dumps because they cannot be converted into fertilisers owing to their high content of heavy metals and pathogenic microorganisms.

One of the most important stages in the processing of deposits from purification plant is their conditioning and dehydration, which is achieved with the aid of high-molecular-weight water-soluble polymers — flocculants, ensuring the rapid coagulation and precipitation of suspended particles and promoting thereby the dehydration of the deposits. The efficiency of the flocculant is determined by its molecular weight and also by its charge. The higher the molecular weight of the flocculant, the lower its amount required for the conditioning of the deposit and for the shortening of the duration of the process. Cationic polyelectrolytes with a molecular weight of at least $10^6 \times (6-10)$ proved to be the most effective.

Bearing in mind the marked variations in the composition of the contaminants and in the properties of the deposits as a function of the waste ejected into water, flocculants of different types are widely used abroad. Despite the fact that the requirement for them runs to tens of thousands of tonnes, high-molecular-weight flocculants are

Water-soluble polymers for the purification of waste water

E F Panarin
Institute of Macromolecular Compounds,
USSR Academy of Sciences, Leningrad

The high anthropogenic stress arising from large cities, industrial undertakings, and large animal husbandry complexes has led to an unsatisfactory state of the water system in many regions of the USSR. An unsatisfactory ecological situation has arisen in the Lake Ladoga – the Neva – Bay of Finland system. The natural capacity of the water system for adaptation has reached its limit.

The question of the purification of large volumes of waste water has arisen. The situation is aggravated by the necessity to disinfect these waters to remove the pathogenic microflora and to achieve its detoxification by removing heavy metal salts which enter the water mainly from industrial undertakings.

The most acute problem is that of the processing and utilisation of deposits from urban purification plant, hundreds of tons of which are carried away to waste dumps because they cannot be converted into fertilisers owing to their high content of heavy metals and pathogenic microorganisms.

One of the most important stages in the processing of deposits from purification plant is their conditioning and dehydration, which is achieved with the aid of high-molecular-weight water-soluble polymers — flocculants, ensuring the rapid coagulation and precipitation of suspended particles and promoting thereby the dehydration of the deposits. The efficiency of the flocculant is determined by its molecular weight and also by its charge. The higher the molecular weight of the flocculant, the lower its amount required for the conditioning of the deposit and for the shortening of the duration of the process. Cationic polyelectrolytes with a molecular weight of at least $10^6 \times (6-10)$ proved to be the most effective.

Bearing in mind the marked variations in the composition of the contaminants and in the properties of the deposits as a function of the waste ejected into water, flocculants of different types are widely used abroad. Despite the fact that the requirement for them runs to tens of thousands of tonnes, high-molecular-weight flocculants are

not manufactured in the USSR. In the purification of drinking and waste water, imported flocculants are mainly employed, a large amount of foreign currency being expended annually for their purchase.

Ultra-high-molecular-weight neutral, cationic, and anionic polymers, which proved to be effective flocculants for the conditioning of waste water deposits in Leningrad, the waste waters from animal husbandry complexes, and also from a number of paper and aluminium-magnesium industries, have been synthesised by novel methods at the Institute of Macromolecular Compounds of the USSR Academy of Sciences. The foundation for the development of a broad assortment of flocculants for different purposes was thereby laid at the Institute.

The "Akromidan-LK" flocculant, which is not inferior to foreign products in its efficiency and in a number of characteristics is superior to them, was most widely tested under different conditions. At the present time a technology for the manufacture of this flocculant is being developed and an experimental plant is being designed in which it is proposed to develop an industrial technology and to produce experimental batches of flocculants for wide scale testing.

In order to organise a wide scale industrial manufacture of new highly effective flocculants, it is essential in the first place to initiate the commercial manufacture of the starting material—amino-acrylates, the plants for the manufacture of which are at present moth-balled. This will make it possible to achieve the industrial production of Soviet highly effective flocculants and to solve the problem of providing flocculants for the existing technology for the dehydration of deposits both on urban purification plants and on purification plants of animal husbandry complexes and paper industrial undertakings.

A new chemical technology—the basis of technological processes for the protection of nature

I K Grigor'yants
Moscow Automobile Construction Institute

The dramatic situation as regards the pollution of soil, water containing areas, and air caused by the industrial and agricultural activities and the ejection into the domestic environment of an enormous amount of organic and inorganic substances, various types of dust and gaseous, liquid, and solid products have made it urgently necessary to create fundamentally new technologies designed to protect nature and in many cases to save it.

Such a new technology, which may serve as a foundation for nature-protecting technological processes, is the controlled release technology (CRT). The physicochemical basis of the TRC is spontaneous processes—diffusion, osmosis, and dissolution, described by thermodynamic, Fick, and van't Hoff laws.

The control of the above processes using for this purpose the specific properties of high-molecular-weight compounds (matrix, transport, and constructional) will make it possible to construct entropic macromolecular chemical engines for the long-term and controlled metered injection of chemically and biologically active substances into any medium involving activity (the organism, soil, water-containing area, reactor, etc.). Macromolecular chemical engines (MCE) function without external energy sources as a result of the difference between the chemical potentials in the medium and in the MCE and by virtue of the increase in entropy in the "MCE—disposal medium" macrosystem.

The controlled release technology and macromolecular chemical engines can find and are finding applications in various branches of engineering and the national economy: plant cultivation, animal husbandry, the fishing industry, veterinary science, the health service, the food industry, in chemical engineering processes, in long term food storage, in protection against corrosion, and in autonomous systems, i.e. systems where prolonged controlled injection of various preparations is required: medicinal drugs, fertilizers, pesticides, biostimulators, inhibitors, catalysts, insecticides, herbicides, etc.

The use of the CRT in any of the fields listed above leads to the creation of new technological processes with the following features: ecological cleanliness—by virtue of the possibility of injecting the useful substance at a specified point in a strictly defined amount in the course of a specified period; the saving of resources—as a consequence of the elimination of the non-productive consumption of useful substances involving a balance between the rate of consumption and injection of the required components (for example, fertilizers); energy saving—as a consequence of the absence of the need for external energy sources to permit the functioning of controlled release polymer systems.

In support of the above postulates, three developments concerning the protection of soil, animals, and water containing area may be briefly described: the study and the cultivation of vegetables (cucumbers, tomatoes) by a non-traditional procedure, prophylaxis of strongyloidosis in cattle, and the development of polymeric devices for the measured microinjection of biologically and chemically active substances into water-containing areas.

It was shown in relation to the examples quoted that, in the growing of tomatoes and cucumbers on APION devices (devices for the metering of fertilisers), the consumption of fertilisers is reduced to the biologically necessary level (by a factor of 5–15), the crop is increased, the quality of the produce is improved, and the ecological cleanliness of the technological process is radically improved.

In the therapeutic and prophylactic treatment of cattle with the aid of LAUS devices (devices for the metered release of an antihelminthic preparation in the animal's stomach), the weight increment in the animals fed on pastures increases, and the quality of the pastures is improved by the faeces containing the antiparasitic preparation.

By ensuring prolonged metered injections at a specified rate of molluscocidal preparations into water-containing areas or flowing water systems with the aid of supercharged polymer pumps, one prevents the spreading of severe infective diseases of animals and humans without damaging the aquatic and terrestrial inhabitants of the ecosystem.

Overall, on the basis of the controlled release technology, it is possible to develop radically new technological processes, generating significant ecological, social, technical and economic effects and being directly designed to perform nature protecting functions, the husbanding of resources, and the maximum improvement of the human environment.

Development of new ecologically clean technologies in the manufacture of nitric and sulphuric acids

S A Zhukov
Institute of Chemical Physics,
USSR Academy of Sciences

Studies on ecologically clean manufacturing processes are being developed in several directions in the Laboratory of Macrokinetics of the Division of the Institute of Chemical Physics of the USSR Academy of Sciences. The first concerns the creation of new technologies in the manufacture of sulphuric acid. Using a special reactor and a stoichiometric mixture of sulphur dioxide, oxygen, and water vapour as the reaction mixture, it has been possible to organise the process in such a way that the sulphur dioxide [trioxide?] formed in the reaction combines with water and condenses on the cold walls of the reactor. As a result, it is removed from the reaction, leads to no aftereffect, and does not inhibit the reaction. The advantages of this method are evident. Firstly, it has been possible to raise the concentration of sulphur trioxide from 10 to 66% and to reduce significantly the dimensions of all the gas connecting tubes. Furthermore, such a technology makes it possible to organise a closed cycle and hence to go over a completely waste-free manufacturing process.

Yet another way of obtaining sulphuric acid is undergoing laboratory tests at the present time and consists of the following steps: if a stoichiometric SO_2+O_2 mixture is frozen until solid, is irradiated with a light flux, and is then rapidly warmed, a reaction takes place at a high rate and with a high yield as a result. This procedure for the synthesis of H_2SO_4 has been tried in several laboratories.

Finally, yet another aspect of such investigations is associated with the safety of the operation of chemical reactors and of power engineering.

During the last decade, we have been actively concerned with the study of ebullition, which is a field seemingly very remote from chemistry. However, it was found that ebullition crises are surprisingly analogous to processes such as combustion and detonation, i.e. the traditional objects of study at the Institute of Chemical Physics.

The latest results achieved in this field suggest that in the immediate future we shall apparently be able to describe and understand the physics of the dangerous phenomenon of the vapour-phase explosion.

III. INTRODUCTION OF ECOLOGICAL CONSIDERATIONS INTO POWER ENGINEERING AND TRANSPORT

Problems of the development of catalytic after-burners for the exhaust gases from automobiles and of alternative ecologically clean fuels

O V Krylov, Kh M Minachev, V I Panchishnyi
Institute of Chemical Physics, USSR Academy of Sciences

The exhaust gases from internal combustion engines are the principal source of harmful pollutants in the atmosphere. Unfortunately, our Press has devoted little attention to this factor. The main bulk of publications objecting to the pollution of the atmosphere refer to the chemical industry and electric power stations. However, in reality the pollution of the atmosphere by automobiles is incomparable in terms of scale to the harmful effects of the chemical industry. In the chemical industry, pollution is more local and can be more readily detected by smell and colour than the automobile exhausts and for this reason is more likely to attract the attention of journalists.

The approximate composition of the spent gases from petrol engines is presented in Table 1. The composition of the gases naturally varies as a function of the type of engine and, in particular, the nature of the fuel. After catalytic cracking, petrol contains more paraffins and, after reforming it contains more aromatic compounds, etc. Most of the gases listed in Table 1 have no colour or smell.

According to an estimate,[1] in the USA there are 5.5 times more motor cars (110 million) than in the USSR (20 million). However, as a result of measures taken for the strict control of exhaust gases each automobile in the USA emits at least four times less harmful substances than in the USSR. The damage to human health in the USSR due to the pollution of the atmosphere caused by the exhaust gases from engines is estimated to cost 60 million roubles annually. It has been suggested that the overall scale of pollution of the atmosphere in 1990 will amount to 242 million tonnes, including 172 million tonnes due to motor cars. The exhaust gases from internal combustion engines are responsible for more than 70% of diseases among children. The incident of lung cancer and also the number of spontaneous miscarriages have increased. It is believed[1] that 68% of all the human diseases are induced by breathing poisoned air.

The interaction of nitrogen oxides NO_x with hydrocarbons under the influence of solar radiation induces the appearance of the so-called photochemical smog. Thus the exhaust gases from automobiles are particularly harmful in poorly ventiliated cities with a large amount of solar radiation such as Log Angeles, Alma-Ata, and Tbilisi. We emphasise yet again that smog is caused not so much by chemical or power industry as by motor cars.

I. Norms for the emission of toxic products

The principal methods for reducing the toxicity of autombile exhaust gases involve the improvement of engine design, the introduction of electronic devices for regulating the composition of gases, the improvement of the composition of fuel, and catalytic purification. The first studies on catalytic purification date back to the 1920s and systematic studies in this field were initiated in 1949 by E Houdry (USA).[2] However, the widescale incorporation of the results of these studies did not begin until the end of the 1970s after the U.S. government introduced controls for the emission of toxic substances and reduced the permitted norm (limit) for the latter.[2] Since then the norms for the emission of toxic substances have been continuously made more strict (Table 2).

The reason for this process has been the sharp impairment of the state of the atmosphere in cities with heavy motor traffic. The adoption of clean air laws and the stage by stage increase in the rigour of standards have led to serious steps being taken in the USA as regards the problem of the purification of motor car exhaust gases. In the course of an approximately 20 year period of observations, the level of emitted incomplete combustion products from newly produced motor cars has been reduced by a factor of ~ 10 and the level of nitrogen oxides has been reduced by a factor of 3–4.

Even more strict standards as regards nitrogen oxides have been adopted in Japan (Table 2). In Western Europe the 1988 norm is less rigorous but since that year newly produced automobiles in Europe began to be fitted with catalytic after-burners. There has been a corresponding diminution in the use of ethylated petrol and in 1990–1991 it should cease altogether. The norms for emitted gases in Western Europe gradually approach the American and Japanese ones. Application of norms to emissions has also been introduced in the USSR (Table 3).

It is essential to note that, owing to the complexity of the procedure for the determination of the exhaust gases (special equipment, driving cycles, etc.), the certification of a given model as regards toxicity and the issue of a special certificate guaranteeing that the automobile meets the specified ecological parameters at least

in the course of a guaranteed distance (80–160 km) have come to be generally adopted. Since the renewal of car fleets and models in Western markets takes on average 3–5 years, this specifiction of norms ensures the maintenance and in many cases the improvement of the ecological situation.

Table 1. Spent gases from petrol engines.

Components	c_{max}, vol.%	Toxicity
N_2	74–77	Non-toxic
H_2O	3.0–5.5	»
O_2	0.2–5.0	»
CO_2	0.5–12	»
CO	0.2–5.0	Toxic
NO_x	0–0.8	»
SO_2	0.02–0.1	»
Paraffins	0–1.2	»
Olefins	0–1.6	»
Aromatic compounds	0–0.4	»
Soot	0–0.4 *	»
Benzopyrene	up to 20*	Carcinogenic

* The concentration is expressed in g m^{-3}.

Table 2. The norms for the emission of toxic products in the USA, Japan, and Western Europe.

Country	year	Norm, g km^{-1}		
		hydrocarbons	CO	NO_x
USA*	up to 1975	6.2	52	3.4
	1975	0.93	9	1.9
	1980	0.25	4.3	1.2
	1985	0.23	2.1	0.62
Japan	1988	0.25	2.1	0.25
Western Europe	1988	0.86	6.17	1.63

* In 1990, George Bush signed the law concerning the further increase in the strictness of emission norms (including that for CH_2O).

One should also note the well tried procedure for the introduction of standards in the West, the combined approach to their application, and also the provision for legal and economic sanctions as regards the quality of fuels and oils, the system of financial incentives for the low toxicity of exhausts, etc.

The adoption in the USSR of sufficiently strict standards has unfortunately not led to a significant improvement of the atmosphere, as regards risks to health, in large cities for a number of reasons. In the first place, one should note the considerable gap between the quality of the exhaust from an automobile leaving the conveyer belt and an autombile in normal use—the extremely low quality of technical servicing and the long operating life lead to a toxicity several times greater than the specified parameters. The norms are simply not fulfilled. There exist considerable reserves also in the design and in the technology of the manufacture of the engine and of the means of transportation—random tests have shown that even on delivery a considerable percentage of Soviet automobiles do not meet the requirements of the standards.

Table 3. The norms for the emission of toxic products in the USSR.

Year of introduction	Weight category of automobiles	Norms, g m^{-1}		
		hydrocarbons	CO	NO_x
Actual standard OST 37.001.054–86	1250 kg	5.06	14.8	–
	1450 kg	5.43	16.8	–
For engines with catalytic converters				
1991	h=1.4–2.0 litres	1.97	7.4	–
1988	h > 2.0 litres	1.97	7.4	–
1990	h > 2.0 litres	1.63	6.17	0.86
For engines without catalytic converters				
1991	h=1.4–2.0 litres	3.7	11.1	1.48
1990	h > 2.0 litres	4.19	11.1	1.48

Note. h = volume of cylinders.

Another cause is the structure of the standards in the USSR, which have separate norms for automobiles without converters and for automobiles with converters [the latter are close to Western European norms]. However, when there are two norms, nobody tries to satisfy the stricter one. In view of the fairly liberal interpretation of standards, it is difficult to expect a serious effort by industry and operating organisations to achieve a radical decrease in the toxicity of spent gases.

Finally one should emphasise that extremely strict norms as regards toxicity can be satisfied only by a combined approach to the problem, which presupposes a high level of organisation of the fuel combustion process in the engine cylinders, electronic control of the engine, the availability of lead-free fuel, and the appropriate level in the industrial manufacturing process, servicing, and the application of extremely effective devices such as catalytic converters.

II. Catalysts

In the practice followed in the leading foreign countries, the exhaust gases from internal combustion engines are purified in catalytic converters. A large number of catalytic reactions take place

on the detoxificiation catalysts for the exhaust gases from automobiles, for example:

$$CO + {}^1/_2O_2 \rightarrow CO_2, \quad (1)$$

$$C_nH_m + (n + m/4)O_2 \rightarrow nCO_2 + (m/2)H_2O, \quad (2)$$

$$H_2 + {}^1/_2O_2 \rightarrow H_2O, \quad (3)$$

$$CO + NO \rightarrow {}^1/_2N_2 + CO_2, \quad (4)$$

$$C_nH_m + 2\,(n + m/\Delta)NO \rightarrow (n + m/\Delta)N_2 + m/2H_2O + nCO_2, \quad (5)$$

$$H_2 + NO \rightarrow {}^1/_2N_2 + H_2O, \quad (6)$$

$${}^5/_2H_2 + NO \rightarrow NH_3 + H_2O, \quad (7)$$

$$2NO + 5CO + 3H_2O \rightarrow 2NH_3 + 5CO_2, \quad (8)$$

$$2NO + CO \rightarrow N_2O + CO_2, \quad (9)$$

$$CO + H_2O \rightarrow CO_2 + H_2, \quad (10)$$

$$CH_4 + 2H_2O \rightarrow CO_2 + 2H_2. \quad (11)$$

The key reactions among the processes listed above are the oxidation of CO [reaction (1)] and of hydrocarbons [reaction (2)] to CO_2 and the reduction of nitrogen oxides by carbon monoxide to molecular nitrogen [reaction (4)]. Under non-stationary conditions, where the temperature of the exhaust gases varies from 200 to 1000 °C and the mixture composition varies from an oxidising mixture (with an excess of O_2) to a reducing mixture (with a deficiency of O_2), the best and virtually the only catalysts available, despite their high cost, are noble metals: platinum, palladium, ruthenium, and rhodium. In terms of their activities in the three main reactions, they can be arranged in the following way:[3]

Reaction	Catalysts
$CO+O_2$	$Pd \approx Rh > Pt > Ru$
$C_nH_m+O_2$	$Pt > Pd,\ Rh > Ru,$
$NO+CO$	$Ru > Rh > Pt > Pd.$

In terms of the complete set of catalytic properties, rhodium occupies the first place. However, it is very expensive—not more than 2.5 tonnes of rhodium are produced annually throughout the world. For this reason, the main component of catalytic converters (after-burners) is platinum, more rarely palladium, their overall production exceeding 100 tonnes. For the majority of reactions, platinum is more active than palladium but it is approximately twice as expensive. The main exporters of platinum metals on the world market are the USSR and the Republic of South Africa.[2]

The active component (a noble metal) is deposited on the oxidant (aluminium oxide), while the latter is deposited on a ceramic block in an amount of approximately 0.1%. For an overall weight of the catalyst of about 1–2 kg in one converter, this entails the consumption of 1–2 g of platinum.

There are two main types of converters: the straight-flow converter in which the exhaust gas passes through thin (0.5–1 mm) straight channels in a catalytic block with the deposited catalyst and a Z-shaped converter in which the catalyst, in the form of spherical pellets coated by the active mass, is exposed to the exhaust gases. Catalysts of the first time are being developed, for example, by the Engelhard Company and are used by the Ford Automobile Company. Catalysts of the second type are manufactured by the UOP Company and are used by the General Motors autombobiles.

The overall cost of the catalysts used in automobile after-burners is at present about one-third of the total cost of the catalysts manufactured throughout the world. The sharp increase in the cost of catalysts for the purification of automobile exhaust gases which occurred in 1988 is noteworthy. New stricter norms for the emission of harmful waste were introduced in Western Europe in that year.

Cost of catalysts manufactured throughout the world

	1987	1988
Petrochemical industry	620 million dollars	650 million dollars
Chemical industry	570 million dollars	600 million dollars
Automobile industry	330 million dollars	485 million dollars
Total	1520 million dollars	1735 million dollars

About 4 billion dollars have been spent on the development of catalytic converters by U.S. firms. At the same time, in the USSR controversy has continued as to the desirability of using converters, which are fitted throughout the world to more than 100 million automobiles with appropriate systems, about half of the world's consumption of noble metals being consumed in their provision.

In the development of catalysts during the 1970s, attention was concentrated on the possibility of eliminating hydrocarbons and carbon monoxide from exhaust gases with their aid. To ensure the complete combustion of these impurities, the catalysts must operate in the presence of a slight excess of air in the so-called "lean" mixtures with the stoichiometric coefficient $\alpha = [O_2]/[\Sigma C_nH_m] = 1.0-1.05$. In "rich" mixtures ($\alpha < 1$), the degree of conversion of hydrocarbons and carbon monoxide is sharply reduced.

A similar study of the kinetics of the reduction of NO_x by carbon monoxide, carried out, in particular, at the Institute of Chemical Physics of the USSR Academy of Sciences[4] on platinum and rhodium catalysts, showed that the opposite behaviour is observed for reaction (4); complete conversion is ensured in "rich" mixtures with $\alpha < 1$, while with increase in the oxygen content in the mixture it falls sharply. Only within a narrow concentration range (near stoichiometry) is there a "window" in the vicinity of which it is possible to achieve with a high degree of completion both the oxidation of carbon monoxide and hydrocarbons and the reduction of nitric oxide. The width of the "window" has come to be characterised by the quantity Δ (Δ is the range of variation of the oxygen content in the products resulting from the mixture in which all three reactions can occur with a high degree of convesion). Data[5] for the width of the "window" for different catalysts are presented below:

Catalyst	Ru	Pd	Pd–Ru	Pt	Pt–Rh	Pt–Pd–Rh
Δ, %	0.08	0.1	0.13	0.20–0.26	0.32–0.4	0.44–0.5

As can be seen from these data, binary and ternary catalysts are more effective in the elimination of all impurities than monometallic catalysts. In practice Pt–Rh catalysts are most often employed. However, owing to the high cost of rhodium, attempts have been made to reduce its content, i.e. to create compositions made up of platinum and rhodium in which rhodium would continue to exhibit its promoting effect even though its amount has been reduced. It has been possible to obtain effective catalysts with the ratio Pt : Rh = 15 : 1.

The study of the mechanism of the NO + CO reaction by spectroscopic-kinetic methods *in situ* (during catalysis), carried out at the Institute of Chemical Physics of the USSR Academy of Sciences,[4,5] showed that CO_2 and NCO groups can be identified on the catalyst surface under the conditions of the catalytic reaction.

On the basis of these investigations, the following mechanism of the NO + CO reaction was proposed:

$$NO + M_1 \rightleftarrows M_1{-}NO,$$
$$CO + M_1 \rightleftarrows M_1{-}CO,$$
$$CO + M_2 \rightleftarrows M_2 - CO,$$
$$NO + M_2 \rightleftarrows M_2{-}NO,$$
$$M_2 + M_2{-}NO \rightarrow M_2{-}N + M_2{-}O,$$
$$M_2{-}N + M_2{-}CO \rightarrow M_2{-}NCO + M_2,$$
$$M_1 + M_2{-}NCO \rightleftarrows M_1{-}NCO + M_2,$$
$$M_1{-}NCO + M_1{-}NO \rightarrow M_1{-}CO + N_2 + M_1,$$
$$M_1{-}CO + M_2{-}O \rightarrow M_2{-}CO_2 + M_1,$$
$$M_2{-}CO_2 \rightarrow CO_2 + M_2,$$

where M_1 are metallic centres on which NO molecules are adsorbed in the undissociated form and M_2 are similar centres on which NO molecules are adsorbed in the dissociated form. The key intermediate species is in this instance apparently the isocyanate NCO which can be adsorbed both on the metal (2240 cm^{-1} IR band) and on the carrier (2260 cm^{-1} band). The NCO groups can diffuse from the metal to the carrier and back again. The decomposition of NCO results in the formation of N_2. In the steady (stationary) state, the concentration of NCO adsorbed on the carrier does not enter into the kinetic equation. However, the real process in catalytic after-burners is markedly non-stationary. In a non-stationary process it is in fact important to have reserves of NCO stored on the carrier, which diffuses to the active centres of the metal and ensures the continuous reduction of NO to N_2.

Catalysts ensuring the removal of all harmful impurities (CO, C_nH_m, and NO) are referred to as three-component catalysts (it would be more correct to call them three-pathway catalysts) or bifunctional catalysts. Their composition is as a rule more complex than that of the catalysts designed solely for oxidation. Furthermore, in automobiles fitted with catalytic converters there are special electronic devices regulating the composition of gases so that they are close to stoichiometry.

After a time, the efficiency of the catalyst falls. The principal causes of the deactivation of platinum and rhodium catalysts are as follows:

(1) sintering after prolonged operation whereupon the size of the platinum and rhodium single crystals increases from 10–50 to 1000–5000 Å.

(2) the formation of higher oxides in an oxidising atmosphere, for example of Rh_2O_3, which reacts with the carrier to form $RhAlO_3$;

(3) the separation of the catalyst into layers, which leads, in particular, to the concentration of rhodium in the surface layer;

(4) poisoning (Pb, S, Zn, and P poisons).

The most important factor in the USSR is de-activation as a result of poisoning by lead, which is present in ethylated petrol. Non-ethylated petrol is used only in several large cities (Moscow, Leningrad, Kiev, and Alma-Ata). However, even in these cities it is difficult to avoid filling car fuel tanks with ethylated petrol anywhere outside the cities and this results in the deposition of lead on the catalyst surface and puts the converter out of order.

As a result of much research carried out by a number of firms, it has been possible to reduce appreciably the content of noble metals in catalysts for the purification of exhaust gases by introducing various additives, in some cases up to 0.1–0.2 g. The following are the main stabilising additives: SiO_2, CeO_2, SnO_2, BaO, and Cr_2O_3, whose role is to prevent the sintering of metal particles, and also additives which provide oxygen (CeO_2, MoO_3, WO_3, etc.). It appears that additives of this type are especially important for the operation of the catalyst under non-stationary conditions. It has been shown at the Institute of Chemical Physics of the USSR Academy of Sciences[6] that, when the $Pt + V_2O_5$ system is used, it is possible to reduce appreciably the temperature of the onset of the oxidation of methane. Under these conditions, the non-equilibrium V_2O_5 oxide phase is produced and on it oxygen is rapidly transported to the hydrocarbon oxidation centres. Such systems are very important for initiating the operation of the catalyst at a low temperature. The composition of one of the catalysts used by the Ford Company is as follows: 19% Al_2O_3, 1.6% NiO, 0.7% CeO_2, 0.15 Pt, an 0.015% Rh. Here CeO_2 is apparently both a stabiliser and an oxygen supplying agent.

Silicate systems are usually employed as carriers in the catalyst: cordierite $Al_4Mg_2Si_5O_{18}$, mullite $3Al_2O_3.2SiO_2$, and spodumene $LiAl(SiO_3)_2$. Cordierite is most common. Aluminium oxide (corundum — α-Al_2O_3) is sometimes used directly without decomposition on a silicate support.

The ShPK-2, ShPAK-0,5, and other catalysts, developed at the Karpov Physicochemical Institute and the Institute of Organic Catalysis and Electrochemistry (IOCE) of the Academy of Sciences of the Kazakh SSR jointly with NAMI, are used in the Soviet Union. The active component of the catalyst is platinum and palladium deposited on Al_2O_3 spherical pellets thermostabilised by added silicon, calcium, lanthanum etc. oxides. Experimental-industrial batches of the catalysts are produced by the Redkinsk factory.

Catalysts on metallic block carriers with a honeycomb structure are also being developed. Work on catalysts of this group has been carried on at the IOKE of the Academy of Sciences of the Kazakh SSR. The production of laboratory batches of metalic block carriers has been initiated at this institute and methods for depositing the support on the walls of the block channels (to increase the specific surface) and of depositing the active component on the carriers prepared in this way have been developed.

At the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences, catalysts on ceramic block carriers (made of spodumene, cordierite, and silicon nitride) are being developed jointly with other organisations. The blocks have a high mechanical strength (resistance to wear) and a reduced hydrodynamic resistance.

Catalytic converters are being developed and are being tested in the USSR by the Central Institute of Motor Construction Engineering (for diesel engines) and by the Automobile Engine Research Institute (NAMI) for petrol engines. The tests are performed on engine stands, stands with revolving drums, and under operating conditions on automobiles themselves.

The mass production of catalytic converters in the USSR has not yet been initiated. Several years ago, an experiment was carried out in Moscow: 600 taxicabs were fitted with catalytic converters. The experiment failed completely; firstly, it was not possible to prevent the introduction of ethylated petrol into the fuel tanks, which resulted in the poisoning of the catalyst, and, secondly, fires were started because in a number of engines the ignition did not work properly. For this reason, the uncombusted fuel entered the after-burner, was ignited on the catalyst, spoilt the after-burner, and sometimes set the engine on fire as well.

Thus the necessary conditions for the successful operation of catalytic converters is a thoroughly tuned engine with properly functioning ignition and non-ethylated lead free petrol.

3. Diesel fuel

Despite the widely held view that the toxicity of the spent gases from diesel engines is low, the problem of the protection of the environment from this source of emission should apparently be assessed as at least comparable to the problem of the pollution of the atmosphere by the spent gases from carburettor (petrol) engines, and, as transport fleets are increasingly provided with diesel engines and the study of the composition of the products of the combustion of diesel fuel intensifies, the urgency of the problem of their detoxification is becoming increasingly more acute and self-evident. Indeed, the amount of waste comprising the incomplete combustion products for which norms have been specified—carbon monoxide and hydrocarbons—generated by diesel fuels is smaller by a factor of 5–10 than that generated by carburettor engines, while the amount of waste comprising nitrogen oxides is similar. However, diesel engines eject into the atmosphere considerable amounts (on average 0.3–0.5 g m^{-3}) of soot—disperse particles which contain biologically active and toxic components, among which there is a group of carcinogens (benzopyrene, fluoranthene, chrysene, etc.), aldehydes, sulphur, nitrogen-containing organic compounds, inorganic sulphur compounds, etc.[7]

Despite the ambiguity of the results obtained in the study of the emission of these compounds by engines of different types, the leading role of diesel engines in polluting the atmosphere by disperse particles is noteworthy. Thus, according to an estimate,[8] the contribution of diesel engines to the 24.6 million kg of disperse particles ejected annually into the atmosphere in Western Europe by automobile exhaust gases is 21.3 million kg. In addition to the enhanced biological activity and toxicity, the presence of suspended disperse particles in the atmosphere impairs visibility on motor roads, pollutes the regions adjoining the roads, etc. In estimating the overall balance in the pollution of the atmosphere by the exhaust gases from diesel engines, one should naturally take into account also the presence in the exhausts of components for which norms have been laid down—carbon monoxide and especially hydrocarbons. Finally, the increased emission by diesel engines of nitrogen oxides constitutes a serious danger to the environment and human health especially if one bears in mind the increased biological activity of carbon monoxide in the presence of nitric oxide. These considerations, combined with the well known tendency towards an increase in the fleet of diesel-engined motor cars, show that the purification of the exhaust gases from diesel engines constitutes a serious and extremely urgent problem whose solution would make it possible to improve significantly the ecological situation not only in sites with limited exchange of air—mine shafts, quarries, stores, ships' holds, etc.—but also in cities with intense motor traffic, where the fraction of automobiles and buses with engines of this type has been increasing steadily.

Neutralisation (conversion) in diesel engines can be achieved by catalytic oxidation, filtration, or a combination of both methods. In addition, the application of these processes to the diesel engine is complicated by a number of factors due to the specific features of the operation of the antitoxic devices in the exhaust tract of the diesel engine. Among them the following should be included:

the relatively low temperature of the spent gases, which usually does not exceed 300–400 °C even under supercharged conditions;

the presence in the gas stream of fairly high (0.2–0.6 vol.%) concentrations of sulphur oxide compounds (mainly sulphur dioxide) and nitric oxide (0.1–0.2 vol.%), which are comparable or actually higher than the concentration of carbon monoxide;

a very considerable (up to 0.5 g m^{-3}) content of disperse particles of diesel soot in a number of instances (when the quality of the tuning of the fuel injection is inadequate) supplemented by aerosols comprising uncombusted fuel;

an increased emission of the degradation products of motor fuels, including the additives introduced into the fuel (the loss of oil in diesel engines is about 0.5% of the consumption of the diesel fuel, which is approximately 1.5–2.0 times greater than in carburettor engines);

strict requirements as regards the resistance of the exhaust system in modern and especially turbocharged diesel engines (the pressure drop in the exhaust system is limited to 500 mm of water).

These features of the design and of the working process in diesel engines have a significant influence on oxidation catalytic processes as well as filtration processes and must be taken into account in selecting and assessing the components, especially catalysts, used to purify the exhaust gases from a diesel engine.

As regards the operating conditions of diesel engines in the USSR, sulphur creates the greatest problems. Here we may note that almost the entire petroleum extracted in the USSR contain considerable amounts of sulphur and our industry (as well as science) is concerned with the catalytic hydrodesulphurisation, which appreciably lags behind foreign countries. Admittedly, one should note that the sulphur dioxide emitted with fuel combustion products in diesel engines makes a relatively small contribution (1–3%) to the overall pollution of the atmosphere by sulphur dioxide (thermal electric power stations make the main contribution). However, the oxidation of sulphur dioxide on a catalyst results in the formation of the appreciably more toxic sulphur trioxide, whose reaction with Al_2O_3 converts the latter into the sulphate, which leads to rapid breakdown of the catalyst.

A large series of studies on the selection of active oxide catalysts for catalytic converters has been carried out at the Azizbekov Azerbaijan Petrochemical Institute.[9] Studies are also being prosecuted at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences and at the Institute of Chemical Physics of the USSR Academy of Sciences. Sulphates leading to the breakdown of the catalyst are formed in almost all the oxide compositions. The development of oxide catalysts in Bulgaria has been reported.

It is noteworthy that the attempts to replace noble metals in converters in both petrol and diesel engines for the removal of harmful gases by a system comprising the oxides of transition metals or other elements have so far proved unsuccessful, mainly because of their being poisoned by the components of the exhaust gases and because of their low activity at low temperatures. The results in this field cannot nowadays be regarded as even hopeful to any extent.

In the USSR, catalytic converters for diesel engines are manufactured in small numbers using platinum and palladium catalysts (of the type ShPK and ShPAK). However, the Al_2O_3 forming part of their composition is rapidly converted into $Al_2(SO_4)_3$, which can be washed away by water on regeneration. After 2–3 regenerations, the converter becomes unsuitable. Despite their short lifetime, such converters are nevertheless used in highly gas-saturated closed spaces and in deep quarries.

There are certain prospects of being able to use aluminosilicates to create carriers with an increased resistance to sulphur oxides, but the choice of the optimum ratio of SiO_2 and Al_2O_3 makes it necessary to take into account, apart from the minimum capacity for conversion into sulphate, a number of other properties: strength, surface, resistance to water vapour, etc. It is possible to use other compounds, which do not interact with sulphur trioxide—phosphates, oxygen-free silicon compounds, etc.

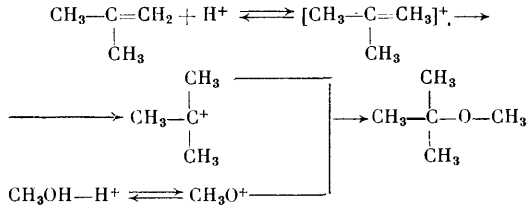
The removal of soot is also a difficult problem. The planned standards for the emission of disperse soot particles are 0.16 g km^{-1} in 1989 and 0.12 g km^{-1} in 1992 for light automobiles and 0.6 g kW^{-1} h^{-1} in 1988 and 0.14 g kW^{-1} h^{-1} in 1994 for goods vehicles and buses with diesel engines.[10]

Taking into account the extremely high sensitivity of diesel engines to the resistance of the exhaust system and also the fairly strict requirements which must be met by the weight and size characteristics of the antitoxic devices, the creation of soot filtering systems for the latter presupposes the solution of a set of problems, including those concerning materials and catalysis:

(1) the choice of a material and of a technology for the construction of a filter from it subject to the permissible resistances, temperature, resistance to the action of the components of the spent gases, strength characteristics, porous structure, soot trapping efficiency, etc.;

(2) the search for catalysts capable of reducing by 200–300 °C the temperature of the combustion of the soot accumulated by the filter, ensuring thereby the regenation of the filter by means of the heat of the spent gases;

(3) the development of filter-catalytic devices ensuring in a single space the after-burning of the incomplete combustion products as well as the trapping of the soot.



Apart from the problem of creating a filtering material, it is in this instance necessary to solve the problem of depositing a support (meeting the requirements as regards the pressure drop on the filter) and of the regulation of the soot regeneration (combustion) process in order to eliminate the superheating of the catalyst. It is also necessary to develop methods for increasing the useful lifetime of the catalyst and the filter in which provision is made for protection against the ash products of the combustion of soot.

4. Alternative fuels

Tetraethyl-lead, used as the antiknock additive, is a highly toxic component of petrol. One of the versions of the causes of the destruction of the Roman Empire is the poisoning by lead of its inhabitants who used water from lead pipes. This led to apathy of the inhabitants and the consequent destruction of the empire under the onslaught of barbarians. Lead acts on the human nervous system and is not eliminated from the organism. Furthermore, lead compounds have a destructive effect on nature in territories adjoining motor highways.

There exist two main ways of creating metal-free high-octane fuels: (1) by increasing the degree of catalytic processing of the products of the primary distillation of petroleum: cracking, reforming, etc.; (2) by using metal-free antiknock additives. In the USA, studies are being prosecuted mainly via the first route, whilst in Europe the second route is followed. Certain firms (for example, ENI—Italy) have carried out a wide scale screening of newly synthesised organic compounds as antiknock agents. In the USSR, studies on such a scale have not been performed.

The most widely used antiknock agent in the West is t-butyl methyl ether (TBME). It is synthesised using acid catalysts:

The side reactions accompanying the synthesis of TBME are as follows:

$$\text{iso-}C_4H_8 + H_2O \rightleftharpoons (CH_3)_3COH,$$
$$2CH_3OH \rightleftharpoons H_2O + CH_3OCH_3,$$
$$2\text{iso-}C_4H_8 \rightleftharpoons C_8H_{18} \longrightarrow \text{polyisobutenes},$$
$$CH_3OH + \text{iso-}C_4H_8 \rightleftharpoons CH_3OC_4H_9.$$

Catalysts of the synthesis of TBME include gel cation exchangers (KQ-2, FPP), heteropolyacids ($H_3PW_{12}O_{40}$/activated charcoal), H-acids [sulphonic acids, H_2SO_4, HCl, and HNO_3 (70–150 °C)], zeolites, Al_2O_3, $Al_2O_3.SiO_2$, and P_2O_5/Al_2O_3 (60–250 °C). In the presence of some of them, it is possible to achieve a selectivity close to 100%. Methods for the continuous catalytic synthesis of TBME using zeolites (Tseokar-2) or toluene-*p*-sulphonic acid have been developed at the Institute of Chemical Physics and at the Institute of Organic Chemistry at the USSR Academy of Sciences. Methods for the synthesis of TBME are being developed at the Institute of the Ministry of Petrochemical Industry. However, the large scale manufacture of TBME in the USSR is not planned to start until 2000–2005.

The decrease of the octane number of petrol, induced by the decrease in the content of lead and aromatic hydrocarbons, is fully compensated by the addition of 5–15% of TBME. The use of TBME also constitutes a very rational procedure for the indirect introduction of methanol into petrol. The problems of phase separation, occurring in petrol–methanol mixtures, do not then arise.

The manufacture of TBME in the USSR requires an increase in the manufacture of methanol. This can be achieved by using a new productive method of synthesis of methanol developed at the Institute of Petrochemical Synthesis of the USSR Academy of Sciences.[12]

Using a procedure similar to that for the synthesis of TBME, it is possible to obtain from tertiary C_5 olefins the tertiary methyl pentyl ether, which has certain advantages over TBME as an antiknock agent.

A disadvantage of such antiknock agents is the presence of oxygen atoms in their molecules. The combustion of the ethers results in the formation of toxic aldehydes.[13,14] In the norms for the emission of toxic products, aldehydes are so far in no way regulated and this also applies to carcinogens of the type of benzopyrene. This problem requires special study.

We are unable to consider here the problems of the toxicity of all types of automobile fuels. We may note that, whereas from the standpoint of economics this problem continues to be discussed, the systematic studies on fuels from the standpoint of ecology are clearly inadequate.

Studies on the use of light hydrocarbons as a petrol-substitute fuel have been expanded in recent years in many countries including the USSR. Thus an attempt has been made to use

propane–butane mixtures as a fuel. In recent press publications, it has been reported that the drivers and passengers of automobiles operating on the propane–butane mixture have been poisoned. This can apparently be accounted for by design faults and not by the higher toxicity of the combustion products. On combustion of the propane–butane fuel, the exhaust gases contain much less carbon monoxide and hydrocarbons, but the amount of NO_x is approximately the same as in the combustion of petrol.[13] However, it is hardly possible to supply the automobile fleet by large amounts of the propane–butane fuel. The situation is different as regards methane, the potential amount of which in the USSR is very great. At the present time methane is regarded as the No. 1 alternative fuel.

The combustion of light hydrocarbons in internal combustion engines is being investigated at the Institute of Chemical Physics of the USSR Academy of Sciences. It has been found that the emission of toxic products can be reduced by a suitable organisation of the combustion process in the engine.

The study of the ignition limits of ballast-containing hydrocarbon mixtures (containing combustion products and inert gases) demonstrated a distinct shift of the ignition region for hydrocarbons heavier than propane to richer compositions, while the ignition region for the only hydrocarbon lighter than oxygen (methane) was displaced towards leaner mixtures (although their composition is closer to stoichiometry). The study of the operation of a one-cylinder petrol engine with low filling (in reality the engine operates most of the time partial load conditions with low filling) also showed that stable operation with low filling (minimum scatter in pressure diagrams and the absence of missing in ignition) is recorded in the region of rich mixtures. These experiments indicate the influence of diffusion-thermal phenomena (roughly speaking the "selective" diffusion of the lighter, deficient mixture component) on the combustion process and that attempts to shift the range of stable operation to leaner composition in engines operating on petrol by increasing the energy of the discharge are doubtful. Studies prosecuted at the Institute of Chemical Physics of the USSR Academy of Sciences, using a discharge with additional charging, with plasma ignition, and using a "magnetic" spark plug led to the same result. Furthermore, the energy required to ignite rich propane mixtures is much lower than that required for the ignition of lean mixtures. Conversely, the energy is minimal for methane in lean mixtures. All this indicates the special role of methane as an engine fule. Methane has an octane number in excess of 100 and can be used for higher compressions (12–13 and above) and smaller cylinder diameters.

The possibility of the operation of engines on methane in lean mixtures eliminates the problem of the ignition of carbon monoxide and hydrocarbons. The problem of NO_x naturally remains. An important problem is the filling of cylinders and the storage of methane. The storage of methane in the compressed form in cylinders requires a large capital expenditure associated with the conversion of petrol filling stations into gas filling compressor stations. The use of compressed methane naturally limits the transportation distance. Experiments on the possibility of filling with methane cylinders containing an adsorbent—silica gel or activated charcoal—have been carried out at the Institute of Chemical Physics of the USSR Academy of Sciences.

The problem of the use of methane in internal combustion engines involves a number of questions associated directly with the engine. It is necessary to create an engine which operates on methane at a high compression. For this reason, it is impossible to employ the usual petrol engines. The use of methane at a low compression (7–8) is pointless. One can be satisfied with an intermediate version of the engine in which the compression is reduced from 12–13 to 7–8. It is possible to create a gas-diesel cycle at high compressions (>15–17) with injection of an igniting dose of fuel with a high octane number.

The opposite process is one involving the pre-chamber ignition of methane (a single fuel engine containing an injection apparatus only in the ignition system). It is also possible to introduce petrol and even heavy fuels (for example, with post-injection into a very lean methane–air mixture (for a coefficient of the excess of air of 5 and above, i.e. for a low consumption of methane).

Engines with precombustion chamber ignition, constructed at the Gorky Automobile Factory on the basis of designs developed at the Institute of Chemical Physics of the USSR Academy of Sciences, are used in the Volga motor cars. They achieve an appreciable reduction of the emission of carbon monoxide and hydrocarbons. For the wide scale introduction of high-octane fuels and catalytic converters, the manufacture of automobiles with precombustion chamber ignition may be a palliative solution. For this purpose, it is essential to continue the work at the Gorky Automobile Factory and the Institute of Chemical Physics of the USSR Academy of Sciences.

Hydrogen is an ecologically clean fuel. It can ignite over a wide range of concentrations and burns in very lean mixtures in the presence of a large excess of air. The maximum temperature developed in the engine and determining the formation of nitrogen oxides is therefore much lower than in the combustion of petrol and the oxides NO_x are hardly formed.[14] The exhaust gases contain no hydrocarbons and carbon monoxide. The only combustion product is water vapour.

The problem of hydrogen as a fuel for internal combustion engines has been widely discussed. At the end of the 1988, an international conference on hydrogen power engineering was held in Moscow.[15] At the present time, the remaining problem is the high cost of hydrogen and the difficulty of storing it. However, in the XXIst century the cost of hydrogen will be such that its use will become justified not only from the ecological but also from the economic point of view, especially bearing in mind the high cost of cleaning the environment when other fuels are employed. Together with the gasification of coal, the promising processes for the preparation of hydrogen are apparently those where hydrogen is produced from the biomass.[15] An interesting method is the preparation of hydrogen by decomposing hydrogen sulphide. Before the industrial development of such a process, one should abandon the development of the Astrakhan deposit of natural gas and other hydrogen-containing gases.

Hydrogen for use in internal combustion engines may be stored in compressed and liquefied forms and as part of hydrides. At the present time, liquid hydrogen is most promising, but there is as yet no final technical and economical solution.

In the USSR, the problem of using hydrogen as a fuel for internal combustion engines is a major concern of the Institute of the Problems of Machine Construction of the Academy of Sciences of the Ukrainian SSR (Kharkov). The involvement of specialists in catalysis in the problem of hydrogen power engineering is clearly inadequate.

A version of the use of hydrogen in internal combustion engines may involve the employment of fuels generating hydrogen on decomposition. For example, methanol produces the $CO+2H_2$ mixture on catalytic decomposition. This mixture burns at high rates for very lean compositions (the diffusion-thermal phenomena in hydrogen are especially pronounced for lean compositions) and for

this reason this version is also ecologically interesting. A catalytic reactor for the decomposition of methanol may be placed before the combustion chamber and can be heated by the combustion products.

An alternative to the proposed variants may be the abandonment of the automobile as a means of transport in the XXIst century.

For the successful prosecution of the relevant studies in the USSR, the following steps are necessary:

1. The creation of a qualifying commission made up of scientists and engineers of the USSR Academy of Sciences and government departments for the systematic examination of the prospects for the manufacture of automobile fuels from the standpint of ecology.

2. An appreciable expansion of theoretical studies at the Institutes of the USSR Academy of Sciences on catalytic conversion, particular attention being devoted to the mathematical modelling of non-stationary catalytic processes in engines, the study of elementary processes in the conversion of carbon monoxide, hydrocarbons, nitrogen oxides, and ammonia by physicochemical methods *in situ*, and the development of conversion processes in the presence of oxygen. It is necesary to devise a theory of the effect of additives increasing the efficiency of noble metals as oxidation catalysts.

3. The development of longer-lived catalysts resistant to the action of poisoning impurities (sulphur dioxide, lead, etc.) and further studies designed to reduce the content of noble metals in catalysts and their complete or partial replacement by oxide systems whilst retaining the required level of efficiency and useful life.

4. The development of catalyst carriers (monolithic and granular) with a required level of hydrodynamic, mechanical, and physico-chemical characteristics and resistant to the action of catalytic poisons. Their production in the USSR should be initiated.

5. The development of methods for the regeneration of catalysts containing noble metals.

6. The organisation of the industrial manufacture of catalysts to provide catalytic converters for petrol and diesel engines.

7. The improvement of the design of internal combustion engines and the introduction of oxygen sensors and electronic systems for the control and regulation of fuel compositions.

8. The provision of the promoter of catalysts with the necessary amount of compounds of precious metals. The limitations to the use of platinum should be removed.

9. The development of methods for the removal of disperse particles from exhaust gases, including catalytic methods for the after-burning of soot on filter elements.

10. An increase in the number and accessibility of tests of catalytic converters on automachines, including comparative tests; the provision of foreign currency for the purchase of the best foreign designs.

11. The creation of a program of toxicological tests on the products of the combustion of various fuels, including oxygen-containing fuels.

12. The achievement of the strict fulfilment of the standard norms of the UNO and the USSR as regards the emission of toxic substances. Economic measures stimulating the use of antitoxic devices (for example, penalities for harmful emissions, and conversely, a decrease in the price of automobiles fitted with a catalytic converter) should be introduced. The question of the introduction of norms for the emission of aldehydes and carcinogenic hydrocarbons should be raised.

13. The submission to the government of the USSR of the proposal to accelerate the large scale manufacture of methanol and TBME.

14. The organisation of the mass screening of organic compounds for the antiknock properties in order to replace tetraethyl-lead in petrol.

15. The expansion of theoretical studies on the combustion of various fuels in automobile engines. A well equipped centre for problems of combustion should be created.

16. The examination of the problem of the need to create a high-compression methane engine.

17. The expansion of the manufacture of engines with precombustion chamber flame ignition for the rapid solution of the problem of reducing harmful exhausts in the immediate future.

18. Theoretical and experimental study of the use of adsorbents to concentrate methane in cylinders.

19. An appreciable intensification of research into the combustion of hydrogen in engines and on catalytic, photochemical, electrochemical, thermal, and biological methods for the production of hydrogen and its storage in a liquefied or bound form. The prospects for using hydrogen in internal combustion engines should be widely discussed and the participation of catalytic laboratories in the solution of this problem should be increased.

Development and introduction of catalytic methods for the detoxification of industrial and automobile transport waste emissions

K I Zamaraev
Institute of Catalysis, Siberian Division of the
USSR Academy of Sciences, Novosibirsk

New technologies based on the use of chemical catalysis should play an important role in the solution of acute ecological problems. Firstly, these are the catalytic technologies for the detoxification of the largest amounts of waste emissions from industry and automobile transport. Secondly, these are new technologies, producing little waste, for the manufacture of chemical products and based on the use of more selective catalysts.

The catalytic technologies for the detoxification of gases and liquid waste from various branches of industry and automobile transport, developed by the "Katalizator" Interbranch Scientific-Technical Complex, will be examined below. Their wide scale employment in the existing undertakings and in transport could even today improve significantly the ecological situation in our country.,

1. Elimination of sulphur dioxide from the waste gases in non-ferrous metallurgy

The emission of sulphur dioxide by non-ferrous metallurgical industries is one of the principal sources of the formation of acid rain. The "Katalizator" Scientific-Technical Complex is developing, jointly with the organisations of Ministry of Metallurgy of the USSR, several technologies for the removal of sulphur dioxide from such gaseous emissions with the simultaneous manufacture of valuable products—sulphuric acid or elemental sulphur. Some of these developments are significantly superior to those abroad as regards the level of their sophistication.

A non-stationary method (the flow reversal process) for the removal of sulphur dioxide with the simultaneous manufacture of sulphuric acid has been developed. This new technology is suitable for the majority of regions in the USSR. It is applied on an industrial scale in a number of factories. With the aid of this technology, more than 300 000 tonnes of sulphuric acid annually is already being produced† and is finding useful applications in the national economy. Licences for the flow reversal process for the oxidation of sulphur dioxide have been taken up by firms in Japan and Bulgaria.

Catalysts and processes for the conversion of sulphur dioxide into sulphur are being developed for the detoxification of the waste gases from the Noril'sk Mining-Metallurgical Industrial Unit. The conversion of sulphur dioxide into sulphuric acid under the conditions of the Noril'sk establishment is not appropriate because of the difficulties in transporting it away. Sulphur can be obtained by the partial reduction of sulphur dioxide to hydrogen sulphide, after which the catalytic Claus process is carried out. This process can be achieved in the presence of both heterogeneous and homogeneous catalysts. Both heterogeneous and homogeneous catalysts of the Claus process, specially developed for the Noril'sk Mining-Metallurgical Industrial Unit, have already been tested experimentally in the latter. The characteristic features of the new heterogeneous catalyst are improved activity (as a result of this, it is possible to reduce significantly the size of the catalytic apparatus) and also resistance to the oxygen present in the waste gases from the unit. The manufacture of a large batch of this catalyst for experimental-industrial tests is being prepared.

A method for the removal of sulphur dioxide from waste gases is being developed on the basis of the new homogeneous catalyst—the so called LES‡ (liquid-phase elimination of sulphur) process. At the present time this method is being tested on a large scale experimental apparatus in Noril'sk.

2. Elimination of nitrogen oxides from the waste gases from chemical industries and thermal electric power stations

A new catalytic method is being developed for the reduction of nitrogen oxides by ammonia under artificially created non-stationary conditions (a variant of the flow reversal process). An experimental-industrial apparatus with an output of 10 000 $m^3\ h^{-1}$ has been constructed and has been working successfully.

A variant of the flow reversal process for the selective catalytic reduction by ammonia of nitrogen oxides in the waste gases from thermal electric power stations is being developed.

3. Elimination of hydrogen sulphide from natural gas

The natural gas from a number of large deposits in the USSR contains considerable admixtures of hydrogen sulphide. The method for its elimination used at present is fairly complex. It is based on the partial oxidation of hydrogen sulphide to sulphur oxides followed by the multistage Claus process. The "Katalizator" Interbranch Scientific-Technical Complex has been developing jointly with the organisations of the Ministry of the Gas Industry of the USSR a fundamentally new single-stage purification technology involving the catalytic oxidation of hydrogen sulphide to elemental sulphur. The method has passed an experimental test in the detoxification of the so called blow-off gases from bore holes.

4. Elimination of carbon monoxide and organic substances from industrial waste gases

An appreciable amount of carbon monoxide and a wide variety of organic compounds is present in the waste gases from ferrous metallurgical and chemical industries. Harmful organic substances

Development and introduction of catalytic methods for the detoxification of industrial and automobile transport waste emissions

K I Zamaraev
Institute of Catalysis, Siberian Division of the
USSR Academy of Sciences, Novosibirsk

New technologies based on the use of chemical catalysis should play an important role in the solution of acute ecological problems. Firstly, these are the catalytic technologies for the detoxification of the largest amounts of waste emissions from industry and automobile transport. Secondly, these are new technologies, producing little waste, for the manufacture of chemical products and based on the use of more selective catalysts.

The catalytic technologies for the detoxification of gases and liquid waste from various branches of industry and automobile transport, developed by the "Katalizator" Interbranch Scientific-Technical Complex, will be examined below. Their wide scale employment in the existing undertakings and in transport could even today improve significantly the ecological situation in our country.,

1. Elimination of sulphur dioxide from the waste gases in non-ferrous metallurgy

The emission of sulphur dioxide by non-ferrous metallurgical industries is one of the principal sources of the formation of acid rain. The "Katalizator" Scientific-Technical Complex is developing, jointly with the organisations of Ministry of Metallurgy of the USSR, several technologies for the removal of sulphur dioxide from such gaseous emissions with the simultaneous manufacture of valuable products—sulphuric acid or elemental sulphur. Some of these developments are significantly superior to those abroad as regards the level of their sophistication.

A non-stationary method (the flow reversal process) for the removal of sulphur dioxide with the simultaneous manufacture of sulphuric acid has been developed. This new technology is suitable for the majority of regions in the USSR. It is applied on an industrial scale in a number of factories. With the aid of this technology, more than 300 000 tonnes of sulphuric acid annually is already being produced† and is finding useful applications in the national economy. Licences for the flow reversal process for the oxidation of sulphur dioxide have been taken up by firms in Japan and Bulgaria.

Catalysts and processes for the conversion of sulphur dioxide into sulphur are being developed for the detoxification of the waste gases from the Noril'sk Mining-Metallurgical Industrial Unit. The conversion of sulphur dioxide into sulphuric acid under the conditions of the Noril'sk establishment is not appropriate because of the difficulties in transporting it away. Sulphur can be obtained by the partial reduction of sulphur dioxide to hydrogen sulphide, after which the catalytic Claus process is carried out. This process can be achieved in the presence of both heterogeneous and homogeneous catalysts. Both heterogeneous and homogeneous catalysts of the Claus process, specially developed for the Noril'sk Mining-Metallurgical Industrial Unit, have already been tested experimentally in the latter. The characteristic features of the new heterogeneous catalyst are improved activity (as a result of this, it is possible to reduce significantly the size of the catalytic apparatus) and also resistance to the oxygen present in the waste gases from the unit. The manufacture of a large batch of this catalyst for experimental-industrial tests is being prepared.

A method for the removal of sulphur dioxide from waste gases is being developed on the basis of the new homogeneous catalyst—the so called LES‡ (liquid-phase elimination of sulphur) process. At the present time this method is being tested on a large scale experimental apparatus in Noril'sk.

2. Elimination of nitrogen oxides from the waste gases from chemical industries and thermal electric power stations

A new catalytic method is being developed for the reduction of nitrogen oxides by ammonia under artificially created non-stationary conditions (a variant of the flow reversal process). An experimental-industrial apparatus with an output of 10 000 $m^3\ h^{-1}$ has been constructed and has been working successfully.

A variant of the flow reversal process for the selective catalytic reduction by ammonia of nitrogen oxides in the waste gases from thermal electric power stations is being developed.

3. Elimination of hydrogen sulphide from natural gas

The natural gas from a number of large deposits in the USSR contains considerable admixtures of hydrogen sulphide. The method for its elimination used at present is fairly complex. It is based on the partial oxidation of hydrogen sulphide to sulphur oxides followed by the multistage Claus process. The "Katalizator" Interbranch Scientific-Technical Complex has been developing jointly with the organisations of the Ministry of the Gas Industry of the USSR a fundamentally new single-stage purification technology involving the catalytic oxidation of hydrogen sulphide to elemental sulphur. The method has passed an experimental test in the detoxification of the so called blow-off gases from bore holes.

4. Elimination of carbon monoxide and organic substances from industrial waste gases

An appreciable amount of carbon monoxide and a wide variety of organic compounds is present in the waste gases from ferrous metallurgical and chemical industries. Harmful organic substances

† February, 1989.

‡ SOZh in Russian (Ed. of Translation).

are also present in the emissions from a number of other undertakings employing solvents, varnishes, etc.

In order to achieve the detoxification of such emissions, the "Katalizator" Scientific-Technical Complex has proposed several technologies based on catalytic extensive oxidation reactions. The usefulness of a particular technology is determined by the nature and concentration of harmful impurities, the degree of saturation of the emission with dust, etc. For high concentrations of the substances being oxidised, one can employ the oxidation method in additional reactors with a stationary catalyst bed. At lower concentrations (down to 0.5–0.8 g m^{-3}), the flow reversal process is effective. This new energy-saving method has already been introduced in seven§ undertakings in different cities. At still lower concentrations, it is possible to use the adsorption-catalytic method. Finally, the method involving oxidation in a fluidised catalyst bed is promising for the detoxification of dust–gas mixtures. In particular, studies are being prosecuted on the introduction of this method for the purification of gaseous emissions from the Coke-Chemical Industry and plants for the dry quenching of coke.

5. Catalytic combustion of liquid organic waste

A method has been developed for the combustion of liquid organic waste in compact reactors with a fluidised catalyst bed (catalytic heat generators). The procedure makes it possible to burn the waste at comparatively low tempereatures, i.e. under conditions which rule out the formation of toxic nitrogen oxides, and at the same time it permits the utilisation of the heat evolved.

6. A catalytic method for the detoxification of waste water

This technology is also based on the use of catalytic heat generators. It has passed an experimental-industrial test and is applicable to the purification of salt-free waste waters containing organic substances at concentrations sufficient to vaporise water by the heat of their combustion.

A similar technology is being developed also for the detoxification of the solid waste present as admixtures in waste waters.

7. Block catalysts for the purification of the exhaust gases from internal combustion petrol engines

The exhaust gases from automobile transport constitute one of the main sources of the pollution of the atmosphere by carbon and nitrogen oxides. Specimens of block and granulated catalysts of different kinds have been produced for the elimination of these oxides from the exhaust gases. Experimental tests of catalysts based on metallic blocks and alumina grains have been carried out with positive results.

The data presented below concerning the catalytic technologies for the detoxification of the gaseous and liquid emissions from industry and automobile transport, being developed at the "Katalizator" Interbranch Scientific-Technical Complex, are summarised in Table 1, which also indicates the level (i.e. the degree of completion) of each development. About half of them have been introduced into industry or are at the stage of experimental-industrial tests.

Table 1. Catalytic technologies for the detoxification of the waste emissions from industry and automobile transport developed at the "Katalizator" Interbranch Scientific-Technical Complex.

Type of pollutant	Source of pollution	Type of development	Level of development
Sulphur dioxide	Waste gases from metallurgical and chemical industries; natural gases; concomitant gases in petroleum processes; gaseous emissions from heat and power generating plant	Non-stationary method for the processing of sulphur oxides with formation of sulphuric acid	Industrial apparatus
		Liquid-phase purification method with formation of commercial sulphur	Experimental-industrial apparatus
		New catalysts of the Claus process	Experimental apparatus
		Claus method in a non-stationary regime	Research stage
		Catalytic procedure for the purification of waste gases from the Claus process	Experimental apparatus
Hydrogen sulphide	Waste gases from metallurgical and chemical industries; concomitant gases in petroleum processing	Liquid-phase purification method with formation of commercial sulphur	Experimental-industrial apparatus
		New catalysts of the Claus process	Experimental apparatus
		Claus method in a non-stationary regime	Research stage
		Catalytic procedure for the purification of waste gases in the Claus process	Experimental apparatus
		Plants for the detoxification in a fluidised bed of the hydrogen sulphide-containing blow-off gases from bore holes	Experimental apparatus
Nitrogen oxides	Technological gases and gaseous emissions from industrial undertakings; spent gases from internal combustion engines; gaseous emissions from heat and power generating plant	Non-stationary purification method	Experimental-industrial apparatus
		Development of block catalysts for converters	Experimental-industrial apparatus
		Development of granulated catalysts for converters	Experimental-industrial apparatus
		Method of involving selective catalytic reduction by ammonia	Research stage
Carbon monoxide	Technological gases and gaseous emissions from industrial undertakings; spent gases from internal combustion engines	Non-stationary purification method	Experimental-industrial apparatus
		A fluidised bed catalytic purification method	Experimental apparatus
		Adsorption-catalytic purification method	Experimental-industrial apparatus
		Development of block catalysts for converters	Experimental apparatus
Organic compounds	Technological gases and gaseous emissions from industrial undertakings; waste water; products of the incomplete combustion of organic fuels	Non-stationary purification method	Industrial apparatus
		A fluidised bed catalytic purification method	Experimental apparatus
		Detoxification plant used on catalytic heat generators	Experimental-industrial apparatus
		The use of mixed catalytic air heaters for combustion	Experimental-industrial apparatus

However, the rate of introduction of the new developments is clearly unsatisfactory. They have been applied in a comparatively small number of undertakings and have not so far led to a

§ By February, 1989.

significant alteration of the ecological situation in our country. The main reason for this unsatisfactory situation is inadequate interest in industrial undertakings in measures for the protection of nature. In my view, there is only one solution to the problem which has arisen: the universal introduction of fines for exceeding the level of harmful emissions above the permitted limit. A reasonable approach is necessary both to the selection of the initial magnitude of the fines and to the dynamics of their increase as a function of time. Both these parameters must be chosen so that industrial undertakings are encouraged to introduce more rapidly nature-protecting technologies without going at the same time beyond the limits of realistic possibilities.

From statements made by the leaders of the State commission on Nature in the USSR, we known that the inevitable introduction of fines is expected at the beginning of the next five year plan and that proposals for the appropriate resolutions are being prepared. They suggest that it would be right to publish these proposals as quickly as possible, so that they can be discussed in good time and also to make sure that workers of the industrial undertakings and in transport should be convinced of the reality of the coming fines.

Ecological aspects of the production and consumption of hydrogen

K N Semenenko
M V Lomonosov Moscow State University

The world annual production of hydrogen is about 50–60 million tonnes, including that of the USSR which is about 6 million tonnes. Natural gas is the major raw material for the production of commercial hydrogen; the amount of hydrogen obtained by electrochemical methods is not greater than 1–2% of the total.

Virtually all hydrogen produced is consumed within the chemical industry, in particular for the production of ammonia and nitrogeneous fertilisers. In the decades ahead, it is expected that not only will hydrogen production increase (to 80–100 million tonnes annually), but also the structure of its consumption will change. It is also predicted that the use of hydrogen in the national economy will increase in an effort to create ecologically clean power generation and fuel technology for transportation facilities, to increase substantially the efficiency of oil refining and to use coal as the raw material for the production of synthetic fuel. Even nowadays, a small admixture of hydrogen to motor fuels would assist in overcoming a number of regional environmental problems, primarily those of increasing pollution of the atmosphere by carbon monoxide and carcinogenic products from the combustion of organic fuels, prevalent in large cities and opencast mines, which produce ore, coal, and other minerals.

Hydrogen is assuming special importance in low-volume high-technology branches of industry, such as electronic and pharmaceutical, in the production of high-purity metals and alloys, composite materials, chemically highly active substances, catalysts, and the like.

In the mid-1970's, the possibilities of the widespread use of hydrogen in the national economy as an alternative fuel or energy carrier were considered in the context of the so-called "energy crisis". At that time, however, various approaches to energy problems, based on the concept of hydrogen energy system, despite its apparent logic and attraction, were not supported by the necessary volume of research and development work. What is more, in engineering and economical respects the above approaches lost the competition with alternative ideas for the development of power engineering complexes based on high-performance energy-saving technologies.

At present, owing to the worldwide deterioration of the ecological situation, hydrogen is again actively considered as an alternative fuel and hopes are being placed on it. This feeling was expressed by the US participant at the 7th International Conference on Hydrogen Energy Systems, held in Moscow in October 1988. The use of hydrogen "gives humanity a unique change to survive in the world, rescued from ecological and social disasters", he said in his concluding remarks.

It is worth quoting some figures which illustrate how acute is the ecological problem associated with the combustion of organic fuel. In recent years, the industrial emission of carbon dioxide has been in excess of 5 billion tonnes annually, while that of carbon monoxide was in the range of 100–200 million tonnes annually. The emissions increased by a factor of 3.5 compared with their level in the 1950's and the tendency to increase is continuing: by the year 2000, the amount of carbon dioxide entering the atmosphere will rise to 6.0–6.5 billion tonnes annually, whilst that of carbon monoxide will rise to 250–300 million tonnes annually. Motor transport is responsible for up to 20% of CO_2 and (depending on the region) for 60–90% of CO emissions. For example, during the period 1985–1988, 800 000 trucks and diesel buses, which formed part of the Moscow fleet, ejected into the atmosphere about 200–250 thousand tonnes of carbon monoxide annually, excluding carcinogenic smoke resulting from incomplete combustion and pyrolysis of organic fuels.

However, in order to pave the way for hydrogen energy systems, including ecologically clear transport, we must solve a number of complex technical problems, relating to chemistry and to hydrogen technology, or at least in the next few years get this process going.

The first problem is due to the fact that hydrogen is currently too expensive as a fuel and is produced in amounts that are too small to satisfy the demand for it in the new branches of the national economy, which include not only power generation, but also chemical technology and materials science applications mentioned earlier.

Furthermore, current production of hydrogen from natural gas is itself not ecologically clean and not only leads to the consumption of nonrenewable resources of this valuable raw material, but is also accompanied by the generation of a considerable amount of carbon dioxide as a by-product. In the USSR alone, the emission of carbon dioxide into the atmosphere caused by hydrogen production, is about 18–20 million tonnes annually.

In view of this, improvement of the existing processes for electrochemical production of hydrogen by the electrolysis of water and water vapour is acquiring paramount importance along with the reduction in the associated energy consumption which may be achieved through the use of radically new materials and nonconventional chemical processes, primarily those based on renewable energy sources, such as solar energy, wind power, geothermal and hydrothermal processes, etc.

In the late 1970's a concept was promoted which is currently acquiring practical importance, namely that not only water and

significant alteration of the ecological situation in our country. The main reason for this unsatisfactory situation is inadequate interest in industrial undertakings in measures for the protection of nature. In my view, there is only one solution to the problem which has arisen: the universal introduction of fines for exceeding the level of harmful emissions above the permitted limit. A reasonable approach is necessary both to the selection of the initial magnitude of the fines and to the dynamics of their increase as a function of time. Both these parameters must be chosen so that industrial undertakings are encouraged to introduce more rapidly nature-protecting technologies without going at the same time beyond the limits of realistic possibilities.

From statements made by the leaders of the State commission on Nature in the USSR, we known that the inevitable introduction of fines is expected at the beginning of the next five year plan and that proposals for the appropriate resolutions are being prepared. They suggest that it would be right to publish these proposals as quickly as possible, so that they can be discussed in good time and also to make sure that workers of the industrial undertakings and in transport should be convinced of the reality of the coming fines.

Ecological aspects of the production and consumption of hydrogen

K N Semenenko
M V Lomonosov Moscow State University

The world annual production of hydrogen is about 50–60 million tonnes, including that of the USSR which is about 6 million tonnes. Natural gas is the major raw material for the production of commercial hydrogen; the amount of hydrogen obtained by electrochemical methods is not greater than 1–2% of the total.

Virtually all hydrogen produced is consumed within the chemical industry, in particular for the production of ammonia and nitrogeneous fertilisers. In the decades ahead, it is expected that not only will hydrogen production increase (to 80–100 million tonnes annually), but also the structure of its consumption will change. It is also predicted that the use of hydrogen in the national economy will increase in an effort to create ecologically clean power generation and fuel technology for transportation facilities, to increase substantially the efficiency of oil refining and to use coal as the raw material for the production of synthetic fuel. Even nowadays, a small admixture of hydrogen to motor fuels would assist in overcoming a number of regional environmental problems, primarily those of increasing pollution of the atmosphere by carbon monoxide and carcinogenic products from the combustion of organic fuels, prevalent in large cities and opencast mines, which produce ore, coal, and other minerals.

Hydrogen is assuming special importance in low-volume high-technology branches of industry, such as electronic and pharmaceutical, in the production of high-purity metals and alloys, composite materials, chemically highly active substances, catalysts, and the like.

In the mid-1970's, the possibilities of the widespread use of hydrogen in the national economy as an alternative fuel or energy carrier were considered in the context of the so-called "energy crisis". At that time, however, various approaches to energy problems, based on the concept of hydrogen energy system, despite its apparent logic and attraction, were not supported by the necessary volume of research and development work. What is more, in engineering and economical respects the above approaches lost the competition with alternative ideas for the development of power engineering complexes based on high-performance energy-saving technologies.

At present, owing to the worldwide deterioration of the ecological situation, hydrogen is again actively considered as an alternative fuel and hopes are being placed on it. This feeling was expressed by the US participant at the 7th International Conference on Hydrogen Energy Systems, held in Moscow in October 1988. The use of hydrogen "gives humanity a unique change to survive in the world, rescued from ecological and social disasters", he said in his concluding remarks.

It is worth quoting some figures which illustrate how acute is the ecological problem associated with the combustion of organic fuel. In recent years, the industrial emission of carbon dioxide has been in excess of 5 billion tonnes annually, while that of carbon monoxide was in the range of 100–200 million tonnes annually. The emissions increased by a factor of 3.5 compared with their level in the 1950's and the tendency to increase is continuing: by the year 2000, the amount of carbon dioxide entering the atmosphere will rise to 6.0–6.5 billion tonnes annually, whilst that of carbon monoxide will rise to 250–300 million tonnes annually. Motor transport is responsible for up to 20% of CO_2 and (depending on the region) for 60–90% of CO emissions. For example, during the period 1985–1988, 800 000 trucks and diesel buses, which formed part of the Moscow fleet, ejected into the atmosphere about 200–250 thousand tonnes of carbon monoxide annually, excluding carcinogenic smoke resulting from incomplete combustion and pyrolysis of organic fuels.

However, in order to pave the way for hydrogen energy systems, including ecologically clear transport, we must solve a number of complex technical problems, relating to chemistry and to hydrogen technology, or at least in the next few years get this process going.

The first problem is due to the fact that hydrogen is currently too expensive as a fuel and is produced in amounts that are too small to satisfy the demand for it in the new branches of the national economy, which include not only power generation, but also chemical technology and materials science applications mentioned earlier.

Furthermore, current production of hydrogen from natural gas is itself not ecologically clean and not only leads to the consumption of nonrenewable resources of this valuable raw material, but is also accompanied by the generation of a considerable amount of carbon dioxide as a by-product. In the USSR alone, the emission of carbon dioxide into the atmosphere caused by hydrogen production, is about 18–20 million tonnes annually.

In view of this, improvement of the existing processes for electrochemical production of hydrogen by the electrolysis of water and water vapour is acquiring paramount importance along with the reduction in the associated energy consumption which may be achieved through the use of radically new materials and nonconventional chemical processes, primarily those based on renewable energy sources, such as solar energy, wind power, geothermal and hydrothermal processes, etc.

In the late 1970's a concept was promoted which is currently acquiring practical importance, namely that not only water and

water vapour can be used as raw materials for the production of hydrogen, but also hydrogen sulphide, at first glance an exotic chemical compound. Its natural resources are very large and may in principle serve as the basis for the development of industrial technologies. A solution to this scientific and technological problem would increase the availability of raw materials for hydrogen energy systems and hydrogen technology. In actual fact, the above concept has more general ecological and economical character, since in the first place it involves purification of natural hydrocarbon raw materials from highly toxic hydrogen sulphide and the use of the latter in the production of hydrogen and such a valuable chemical product as free sulphur.

Another problem with hydrogen energy systems is that, even with abundant cheap fuels or energy carriers, any branch of power generation (including that based on hydrogen) will flourish only if facilities are available for the effective use of chemical energy contained in the fuel and its conversion into electrical energy, thermal energy, etc.

For hydrogen, considering its unique physicochemical properties, such as calorific value which exceeds that of organic fuels by a factor of 3.5 and its low activation energy barrier with respect to catalytic oxidation, one can regard electrochemical power generators, which have 2–2.5 times greater efficiency than heat engines, as such facilities.

However, as opposed to heat engines which can in principle run on 'dirty' commercial hydrogen containing carbon oxides, water vapour, hydrocarbons and other impurities, electrochemical power generators are "capricious" and can use only high-purity hydrogen with no contaminants, which cause poisoning of catalytic contacts and reduce the efficiency of electrochemical oxidation. The above-mentioned high-technology branches both of chemical industry and of materials science place equally stringent requirements upon the purity of hydrogen.

Therefore, industrial hydrogen technology that would be appropriate for hydrogen energy systems would consist not only of ecologically clean technology for hydrogen production, based on the renewable sources of initial materials and energy, but would also involve a technology for the separation of industrial gas mixtures containing hydrogen and a high degree of purification of the latter that would reduce the content of impurities to $10^{-3}-10^{-4}$ vol.%.

At present, the most effective procedure for the production of high-purity hydrogen from industrial gases involves their preliminary separation and enrichment with hydrogen as the main component followed by the use of membrane technology, with palladium alloys acting as the materials for the selective filtration of hydrogen.

As long as the use of high-purity hydrogen is confined to certain special branches of metallurgy and the production of materials for the microelectronics and pharmaceutical industries, and does not exceed several thousand tonnes annually, this need may well be met on the basis of the existing technology. However, the situation will drastically change when hydrogen will be looked at as a basis for the creation of ecologically clean power systems for the 21st century. In this case the required annual production of low-cost high-purity hydrogen will amount to hundreds of thousands rather than thousands of tonnes. This task cannot be fulfilled with filters, using palladium alloys, simply because the required amount of palladium is not and will never be available. Alternative materials are required, which would act in a way similar to palladium alloys but would essentially differ in cost and suitability for mass production and consumption.

The second of the above problems is formulated in much the same manner, i.e. the creation of catalysts for the oxidation of hydrogen in electrochemical power generators. Materials containing platinum and platinum group metals serve as catalysts in contemporary fuel cells which are widely used in space and other special applications†. The consumption of platinum for each fuel cell with an output of 1 kW is about 100–200 mg. Even if this amount were to come down by a factor of 100 through improvements in the technology of production of electrode materials, the consumption of platinum metals required to furnish a fleet of, say, 50 million vehicles with an average power of 100–150 kW, woud nevertheless amount to approximately 500–600 tonnes, which is substantially more than the world annual extraction of platinum (not counting the USSR) of about 80 tonnes. Therefore, the creation of an ecologically clean electric car is in principle highly improbable, unless platinum-free catalysts for 'cold' electrochemical oxidation of hydrogen which would be competitive or at least comparable to platinum-based ones, are produced.

Fundamental studies on the chemistry of the interaction of hydrogen with metals and intermetallic compounds, conducted in the USSR and abroad[1–5] since 1968, offer real prospects for a successful search for and creation of catalysts that could replace palladium and the metals of the platinum family.

The "hydride dispersion" technology, which emerged in 1980–1982 on the basis of the above studies, allows dispersed metallic powders to be produced that are functionally similar to palladium and platinum group metals.

This technology is based on the ability of a large group of alloys of rare-earth elements, titanium, zirconium calcium, and magnesium, with transition metals which possess appropriate crystalline and electronic structures to reversibly absorb up to 1000–1200 times their volume of hydrogen, with a relatively small thermal effect (~5000 kcal per 1 kg of H_2). This process is accompanied by spontaneous comminution and formation of fine powders without resource to any mechanical processing. The resulting powders are characterised by a narrow particle size distribution, which depends on the number of sorption–desorption cycles, and "sterile" unoxidised surfaces. The sorption of hydrogen is also accompanied by a 15–25% increase in the volume of the metallic phase, its structure remaining unaltered and having a very low activation energy barrier. It is remarkable that the density of hydrogen nuclei in the hydride phase exceeds that of liquid hydrogen by a factor of 1.5–2.0.

A sponge which can be used an unlimited number of times for soaking up and squeezing out a liquid may serve as a model for these alloys. In our case hydrogen takes the place of the liquid, being sorbed on cooling and released on heating. Technological potentialities of these alloys are very high, being in the range of 10–15 thousand cycles.

It is important that hydrogen can also be sorbed from gas mixtures that contain as much as 80–90% of nitrogen, methane, inert gases, water vapour, oxygen, and carbon dioxide.

Another interesting feature of this process is its high selectivity, i.e. only hydrogen is sorbed. Therefore, the purity of hydrogen desorbed during the thermal decomposition of the hydride phase, i.e. on 'squeezing out the sponge', is very high, in excess of 99.999%.

† We are referring here to 'low-temperature' fuel cells. In the USSR, the USA and a number of other countries, strenuous efforts are currently under way to create prototypes of industrial 'high-temperature' fuel cells based on ceramic oxide materials.

Table 1 also shows various areas of application of metallic powders produced by the hydride dispersion technique. One should take special note of two processes, directly related to the ecological aspects of hydrogen technology and power engineering.

Table 1. Applications of dispersed metallic powders produced by the chemical dispersion technique. The powders are characterised by "sterile" unoxidised surfaces; absence of cold hardening and mechanical contamination; and narrow particle size distribution, controllable over a required range.

1.	Absorbents of hydrogen from industrial gas mixtures.
2.	Components of platinum-free catalysts for the oxidation of hydrogen in electrochemical fuel cells.
3.	Reversible sources of high-purity hydrogen, containing up to 1200 volumes of hydrogen per unit volume of a solid phase.
4.	Magnetic materials produced by compacting dispersed powders with the composition RCO_5, R_2CO_{17}, where R = Fe, B, etc.
5.	"Working media" in thermalsorption equipment and mechanisms.
6.	Components of mateirals with a high density of hydrogen nuclei.
7.	Highly efficient catalysts for processes involving activation of molecular hydrogen.

Problems involved in producing high-purity hydrogen, including its extraction from gas mixtures with low hydrogen content, may be resolved through the creation of absorption units, wherein a mass of a dispersed powder, or compacted material produced from it, kept together by an organic or metallic binder, performs sequentially in a sorption–desorption mode. The gas mixtures may be quite poor in hydrogen, containing as little as 10–15 vol.%.

The viability analysis of the sorption method carried out independently by several organisations, showed its high efficiency: the cost of obtaining 1 tonne of high-purity hydrogen from industrial hydrogen-bearing gases was found to be 1000–1500 roubles, which is approximately 2–3 times less than the current price.

A more promising, although technologically more complicated technique, involves the use of filters produced from dispersed powders containing rare-earth metals and metals of the iron group, these powders having been obtained by the hydride dispersion method. Judging from preliminary data (referring to 1988), such materials may well compete with palladium–silver alloys.

The second task is to create new catalysts for the oxidation of hydrogen, based on dispersed powders containing nickel, manganese, zirconium, etc. Studies along these lines are being conducted in the Soviet Union—the Electrochemistry Institute of the USSR Academy of Sciences, the Moscow State University and other organisations—and abroad, and are particularly actively pursued in Japan, USA, and EEC countries. Considerable progress has already been made in this direction. Current densities in electrodes, manufactured from compressed powders are now as high as 200–300 mA cm^{-2}, comparable to those in contemporary small fuel cells in which platinum-containing catalytic contacts are used.

Abroad, the hydride dispersion technique forms the basis for one of the fastest developing high-technology branches of industry.

In the USA, Japan, and EEC countries the envisaged annual production of hydrogen-absorbing alloys is about 1000 tonnes. Production of such alloys is apparently carried on an industrial scale in China, where hydride technology is being actively applied in the electronic industry, in the chemical industry, and for the production of high-quality magnetic materials. The world market prices for dispersed powders capable of reversibly absorbing hydrogen are currently about 400–500 US dollars per kg. Japanese experts estimate that by the year 2000 the internal market alone for the materials and articles involving the use of hydride technology will reach about 500 million US dollars.

Let us take a brief look at the model of the interaction of hydrogen with alloys of rare-earth metals, titanium, zirconium, and magnesium with transition metals (iron, cobalt, nickel, copper, chromium and vanadium) which is used as the basis for predicting the nature of such interaction in relation to the crystalline structure, chemical composition, and thermodynamic properties of the alloys.[6–8]

If an alloy capable of absorbing hydrogen is regarded as a 'sponge', reversible sorption of hydrogen should be possible under the following conditions:

1. The energy of activation of chemisorption of hydrogen at active centres on the surface of the metallic phase should be small. This surface can be modified by introducing into the alloy small admixtures of other metals so as to influence the physicochemical properties of the hydride phase in the desired direction.

2. The structure of the alloy should have a crystal-chemical 'predisposition' to the sorption of hydrogen, this predisposition being characterised by the presence of cavities or voids of definite size and configuration.

3. For virtually all alloys that are potential hydrogen sorbents, a reaction alternative to the sorption of hydrogen is thermodynamically possible, for example, a chemical reaction of destruction yielding binary hydrides and free transition metals which do not absorb hydrogen. The probability or possibility of a reaction of this kind at a certain temperature and hydrogen pressure is predictable, given the main thermodynamic properties of the initial alloy. On this basis chemists may design and produce any alloy whose sorption parameters would be optimised to meet specific technical conditions required by chemical engineers and designs of equipment for various purposes.

This allows us to be optimistic about prospects of using the hydride technology for creating in the near future ecologically clean power engineering complexes, based on a wide use of hydrogen as the chemical raw material, energy carrier, and medium for conducting technological operations in sterile conditions.

Prospects and current problems in the reduction of emission from automobile transport

V Z Makhov
Moscow Motor Highway Institute

The contribution to atmospheric pollution by automobile transport, which amounts to 15–25% relative to the overall pollution, increases to 75–80% (with respect to CO) when pollution in cities is considered.

Real tests have shown that the limiting permissible concentrations have been exceeded by a factor of 7–16 with respect to components for which norms have been laid down in relation to automobile transport, the factor increasing to 20–50 with respect to the overall emissions subject to norms let alone the presence of indirectly normalised and non-normalised components (lead and sulphur compounds, aldehydes, etc.) as well as the "background" (inadequate purification of water, contamination of food products). A similar situation is characteristic of at least 116 cities in the USSR. The possible measures for the planned reduction of emissions from transport, in Moscow for example, could actually prove ineffective because of the growth of the transport fleet and its long renewal cycle (up to 20 years).

The USSR tends to adopt the normalisation level established by the EEC and UNO rules, although the majority of the European countries are going over to the stricter U.S. norms. However, even the EEC and UNO norms presupposes the use of only non-ethylated (unleaded) petrol as the fuel and hence the catalytic purification of spent gases. In our country, the presence of norms for automobiles with catalytic converters (production for export with imported converters) is combined with "milder" norms for automobiles without converters (for internal use). Such "dual" normalisation reflects the situation in which there is a lack of material means for the fulfilment of stricter norms. Thus acording to EEC estimates, the changeover by 1991 to non-ethylated fuels will require 2.7–3.5 billion dollars in capital investment. One must recognise that, as a result, there has been no reduction in automobile transport emission in our cities. Therefore in the general prospective programme for the reduction of emissions from means of transportation, it is essential to concentrate on the rapid improvement of the ecological situation in cities.

The problem of developing promising means of transportation with improved economic parameters includes the search for ecologically acceptable energy carriers. The most promising of these (hydrogen) cannot be regarded as an "ecologically clean" fuel because of the formation, on its combustion in air, of NO and the thermal pollution common to all energy consuming devices. A real effect can be achieved even at the present time by using liquified and compressed gaseous fuels.

The use of gaseous fuels in engines with a homogeneous mixture makes it possible to go over to the combustion of leaner mixtures, taking into account the effect of the diffusional enrichment of the flame front in the lighter component. In diesel engines, the use of gaseous fuel involves the solution of the problem of the reliable ignition of the gaseous fuel stream.

The most effective and realistic procedure is the employment of soot filters in diesel engines and of controlled catalytic converters in petrol engines. However, such converters require an oxygen sensor, an electronic system for the control of fuel injection, and the use of a fuel without a lead antiknock agent. The same measures can be taken in the solution of urgent ecological problems in cities, including Moscow. Here one can assume that purely technical problems are not of decisive importance. In the first place, it is essential to solve the following main problems:

The specification of norms for harmful emissions by legal organs with an expert assessment by an independent competent organisation (the USSR Academy of Sciences) instead of normalisation by what is in fact a government department.

The establishment of the magnitude of fines on the grounds that it is preferable to finance nature-protecting measures rather than pay for the pollution of the atmosphere under conditions where industrial undertakings are economically truly independent.

Transition from financing the research programmes set up by the researchers themselves to the creation of a scientific-industrial association with target financing and the rights of the director (or general constructor) concerning its utilisation.

A combined approach to decreasing the contamination of a city with gases, the reconstruction of the network of highways, and the development of green zones and plantations (including for this purpose financial means received from the increased expenditure on transport).

Thus the current task of reducing sharply the level of contamination of cities by gases is organisational rather than technical in character, which should be taken into account in the development of an ecological programme.

IV. ANALYSIS OF CHEMICAL CONTAMINANTS

Translated from *Uspekhi Khimii* **60** 661–666 (1991)

Physicochemical analysis of organic toxic substances in natural waters

V S Petrosyan, V I Bogdashkina, P I Dem'yanov, A T Lebedev, M P Khimenes, N S Yashina
M V Lomonosov Moscow State University

One of the most important problems in preserving the environment is the identification and quantitative determination of the contaminating substances passing into it. Upwards of 1000 organic compounds are included in the list of priority contaminants of the biosphere.[1] The main organic contaminating substances of natural waters are recognised to be phenols, lignins, pesticides and petrochemicals.

Investigations have been carried out by us recently with the aim of developing procedures for the qualitative and quantitative analysis of the various classes of contaminating substances, primarily hydrocarbons and phenols, using physicochemical methods such as capillary gas chromatography (CGC), gas chromatography-mass spectrometry (GCMS) and nuclear magnetic resonance spectroscopy (NMR).

Petrochemical hydrocarbons are some of the main and stable contaminants of aqueous media. As a result of human activity more than a million tons of petrochemicals pass into the oceans of the world every year, 90% entering with fresh water.[2] Such contamination of the oceans leads to a disturbance of the ecological balance, accumulation of petrochemicals in aqueous organisms and correspondingly in man.[3]

CGC and GCMS are universal methods of analysis of oil and petrochemicals in the environment. This is linked with the ability of chromatographic methods to resolve complex mixtures and with the high sensitivity of chromatographic and mass spectrometric detectors.

CGC was used for the determination of contamination by paraffin hydrocarbons of the western waters of the Black Sea.[4] Water was sampled at 25 points of the coastal waters to the west of longitude 32° E in April 1981. Samples of water were extracted with chloroform and the paraffin hydrocarbon fraction was separated from the extracts. The concentration of n-alkanes containing from 14 to 44 carbon atoms was determined by GLC.

In the region investigated the overall concentration of n-alkanes varied from 2 to 400 μg litre^{-1}. The coastal zone and also all the navigable region was characterised by an increased content of hydrocarbons (see Fig. 1). This may be explained by contamination of the Black Sea both by carry down from rivers and by means of transport.

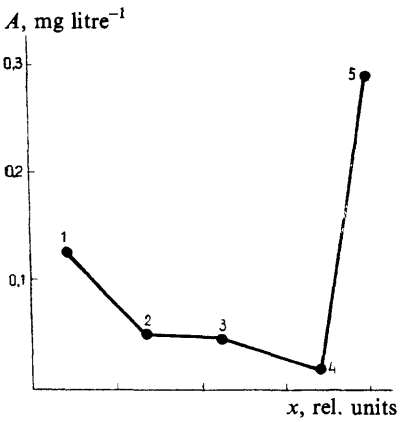

Figure 1. Dependence of the total content of n-alkanes (A) in water from the Black Sea on distance (x) from the coast: *1*, station 36; *2*, station 35; *3*, station 34; *4*, station 33; *5*, station 31.

An important question linked with contamination of the world's oceans by petrochemicals is the solution of the arbitrary problem of the search for the culprits of petroleum contamination.

A complex approach to the solution of this problem was used by us in several cases when determining culprits for the catastrophic oil spills in the Baltic Sea. In this case CGC was used for determining the ratios of quantities of isoprenoid and normal hydrocarbons Ph/C_n and Pr/Ph, where $n > 18$, Ph is phytane and Pr is pristane, from which the culprits of the spills were identified.

It was established previously,[5-7] that NMR spectroscopy enables analysis of both crude petroleum and its refined products including heavy fractions not yielding to chromatography. This method is used together with other physicochemical methods for the estimation of structure-group parameters of petroleum. The main parameters determined by NMR are the relative content of aromatic protons H_a (contribution of the integrated intensity of signals for aromatic protons in the ^1H NMR spectrum to the total integrated signal intensity) and the relative content of aromatic hydrocarbons C_a (contribution of the integrated intensity of signals for aromatic carbons in the ^{13}C NMR spectrum to the total integrated signal intensity). It was shown that it was necessary to use a relaxant such as chromium(III) acetylacetonate for the quantitive determination of the C_a parameter and a method for decoupling the spin-spin interaction of ^{13}C nuclei with protons. The decoupling unit was switched on during the time for sensing the impulse of the radiofrequency field and was switched off during the time for sensing the free induction signal. This led to the quenching of the nuclear Overhauser effect.

Analysis of specimens of petroleum spills showed that depending on the weathering of the petrochemicals, H_a may vary several fold while the C_a parameter was practically unchanged. In addition data from the analysis of numerous oilfields of the Soviet Union showed[7] that the range of change of C_a was wider than that of H_a and was 9–23%. Consequently the C_a parameter, together with the overall shape of the ^{13}C NMR spectrum, which enabled determination of the oil type, paraffinic or napthenic, was used to determine the source of origin of the oil spill into the sea.

Table 1. Results of analyses of contamination of the Baltic Sea by hydrocarbons.

Parameter	Sample				
	Control oil		Oil I, weathered	Contamination samples taken from the sea	
	I	II		I	II
H_a, %	4.0	0	2.2	2.3	1.5
C_a, %	18	14	20	18	19
Pr/C_{17}	0.59	0.98	0.50	0.49	0.52
Ph/C_{18}	0.78	0.56	0.72	0.71	0.72
Pr/Ph	0.75	1.75	0.70	0.69	0.72

Data shown in Table 1 of CGC and NMR which were used for determining the culprit for a catastrophic oil spill in the Baltic Sea. Samples presented for analysis were from two assumed sources of the spill (oils I and II), an oil sample subjected to 40 days weathering under laboratory conditions (oil I, weathered) and samples of contamination taken from the sea (I and II). NMR data and the ratios of isoprenoid hydrocarbons Pr/Ph showed that oil from the first source had spilled into the sea.

The procedure for determining the culprit for the contamination by GCMS was based on the detection of aromatic compounds of the homologous series benzene, naphthalene, anthracene and phenanthrene. Since polynuclear aromatic hydrocarbons are less subject to weathering and biodegradation in water in comparison with aliphatic hydrocarbons for example[8,9] the probability of correctly identifying the culprit of a spill by detection of these compounds is high. It appeared possible to analyse petrochemicals which had been in the sea for several days (their composition was very different from that initially).

In the case of water with little contamination, i.e. when the sensitivity of the gas chromatograph-mass spectrometer was inadequate to carry out an analysis in the field scanning mode, monitoring of definite ions from aromatic hydrocarbons of the series indicated was used. To detect homologues of benzene the instrument was adjusted to record ions of mass m/z 77, 91 and 105, of naphthalene 127, 141 and 155 and of anthracene and phenanthrene 177, 191 and 205. Such a procedure enabled the sensitivity of determining aromatic hydrocarbons to be increase 100–1000 times. The culprit of the contamination was determined fairly simply from the chromatogram drawn from the current of the indicated ions.

Table 2. Content of some organic contaminants in test samples of snow and water in Kemerovo.

Compound	Concentration (μg litre^{-1})	
	snow	water
Hexadecane	112.0	2.9
Pentadecane	151.0	2.8
Octadecane	75.4	3.9
Nonadecane	70.0	9.0
Tricosane	98.0	4.4
Octacosane	98.0	2.0
Nonacosane	279.0	traces (<0.5)

Contamination of surface waters may also occur from the atmosphere since[10] on going from alkanes to a polynuclear aromatic hydrocarbon the size of the contribution of this contamination to the total contamination of water increases from 1–2 to 25%. Gas chromatographic analysis of samples of snow taken in March 1988 near Kemerovo showed that alkanes and aromatic hydrocarbons

were the principal organic contaminants of snow. For example, the content of individual n-alkanes was 100–200 μg litre^{-1} and their total content exceeded 3 mg litre^{-1} which was approximately 10–100 times greater than their content in water samples from the same region. An analogous result was observed for aromatic hydrocarbons. On the other hand phenols, widely represented in water, were practically absent from snow samples with the exception of phenol itself and dimethylphenols. Data on the content of certain organic compounds present at the highest concentrations in snow and water samples are given in Table 2.

It is possible to explain the similar character of the distribution of contamination in the given region by the theory of the adsorption of organic compounds by dust particles suspended in the atmosphere.[10] The process for the transfer of organochlorine pesticides, polychlorinated biphenyls and polynucler aromatic hydrocarbons, which occurs in this way, has been studied previously.[10] Carbon dust, present in the atmosphere of Kemerovo, adsorbs organic compounds to a significant extent, having higher values of adsorption coefficients than activated carbon k_c. The value of $\lg k_c$ for higher alkanes and aromatic hydrocarbons is appreciably greater than for phenols, alcohols and ethers.[1]

Phenols, like hydrocarbons, belong to the group of widely distributed and highly toxic contaminants of natural waters. Chlorophenols are formed on chlorination of water, and their toxicity and ability to accumulate in organisms grows with increasing content of chlorine atoms in the aromatic ring.[1,11] Many phenols are detected in water by taste and smell at concentrations less than 0.1 μg litre^{-1}.[1]

From our data the detection limit for phenols when using CGC with a flame-ionisation detector was from 0.4–1.8 μg litre^{-1}, and by HPLC was several μg litre^{-1}, which frequently does not meet modern nature conservation requirements. It is possible to increase the sensitivity and selectivity of determining phenols by chromatographic methods if phenols are converted into various derivatives.[12] Thus the combined use of acetylation and pentafluorobenzoylation of chlorophenols and the use of an electron capture detector enables the quantitative determination of phenol in water at concentrations of 0.2–0.4 μg litre^{-1}.[13] With the aim of improving and clarifying the actual possibilities of the highly sensitive quantitative analysis of phenols in natural waters at the background level by CGC and HPLC, we have carried out a qualitative and quantitative determination of phenols as pentafluorobenzyl ethers (I), pentafluorobenzoyl (II) and dabsyl (III) esters.

$$C_6F_5CH_2Br + ArOH \longrightarrow C_6F_5CH_2OAr, \quad (I)$$

$$C_6F_5COCl + ArOH \longrightarrow C_6F_5COOAr, \quad (II)$$

(III)

Various esters and ethers of types (I)–(III) were synthesised and obtained in the pure state for the first time for this purpose. Their structures were demonstrated by elemental analysis, IR and NMR spectroscopy and mass spectroscopy.

It was established that the limits of detection of derivatives of types (I) and (II) by CGC using an electron capture detector were 1–2 mg and of derivatives (III) by HPLC 1–2 ng. For the quantitative determination of phenols as derivatives (I)–(III) we determined values of the relative factors for the detector signal in relation to the phenol derivatives and also established the so-called degree of detectability of phenols (i.e. the degree of conversion of phenols by the method). Limits of detection of phenols in natural waters were 10–100 ng litre^{-1}.

For the qualitative determination of phenols as derivatives (I)–(III) we studied their mass spectral decomposition by electron impact and for derivatives (I) by chemical ionisation with isobutane recording both the positive and negative ions. It was established that mass spectrometry enabled identification of phenols in nautral waters with a high degree of reliability.

The method of determining phenols as ethers of type (I) was tested by us when investigating water from the Moscow River in the spring of 1987 for the presence of phenols (Table 3).

Table 3. Content of phenols in water samples from the Moscow River.

Compound	LPC, μg litre^{-1}	Concentration in water, μg litre^{-1}
Phenol	1	2.9
4-Chlorophenol	1	7.7
4-Nitrophenol	20	1.4
Pentachlorophenol	10	103.9
2,4-Dinitrophenol	30	10.7

Identification of derivatives of phenols was carried out by comparing retention times of standards (pentafluorobenzyl ethers of phenols) at various temperature modes of chromatography and was confirmed by gas chromatography-mass spectrometry. As follows from the data of Table 3 the content of chlorophenols in the Moscow River exceeded the values of the limiting permissible concentrations (LPC) by 3–10 times. The contents of nitrophenols were somewhat lower than the LPC values.

Problems of the development of ecological instrument making

M A Grachev, A V Avrorin
The Limnological Institute, Siberian Division
of the USSR Academy of Sciences, Irkutsk

The attention devoted to the development of new analytical methods and instruments for ecology has been aroused by the appearance in the waste from economic activity of a large amount of highly toxic pollutants, which are dangerous to man and the environment even in very small amounts. The detection of these substances at the level of limiting permissible concentrations against the background of interfering substances is a very complex scientific and technical task. Bearing in mind that about 70 000 organic compounds are being used throughout the world and are therefore present in the environment and that their number increases by 1–2000 annually,[1] the necessity for newer modern approaches to ecological analyses becomes evident. For such studies, it is essential to have at one's disposal a set of fairly universal methods and instruments with a high sensitivity and selectivity. The results should be interpreted on a computer. Furthermore, it is essential to possess a data bank for the identification of substances.

The development of analytical methods in ecology has been stimulated by a series of accidents in chemical undertakings and by the results of their investigation. The results of a study of the accident in Seveso (Italy) in 1976,[2,3] where the latest advances in chromatography and mass spectrometry had to be used in order to detect traces of dioxins, which poison human beings and pollute the locality, have appeared in print to the greatest extent. The consequences of the agricultural pollution and of the use of chemicals (herbicides) during most recent wars have also served as stimuli.[4] All these major catastrophic pollutions have led to a sharp increase in the number of scientific publications on the development of analytical methods using the latest instruments: highly effective gas and liquid chromatograph and mass spectrometers, which are used in more than half the instances where analytical methods are needed.[5]

The increasing complexity of the ecological situation and frequent accidents in chemical undertakings have induced a rapid growth of the industrial manufacture of analytical apparatus in various countries. The quality of the apparatus has been increasing significantly as a result of a large number of service devices: devices for sampling and preparation of samples and a sophisticated system for the interpretation of data on computers with extensive program libraries, data bands, and systems for the identification of substances.

The achievements in instrument making and electronics enabled a number of firms to develop mobile laboratories equipped with chromatographs and mass spectrometers. The best known of these is the TAGA-3000 Laboratory (Canada). It uses as the detector a mass spectrometer with a device for the automatic injection of samples from the atmosphere, which ensures a high sensitivity (10^{-15} g cm^{-3}). The presence of a navigating device makes it possible to plot maps of contamination in the given locality. The MM-1 mobile laboratory of the Bruker Company (Federal Republic of Germany) has effective analytical characteristics. It uses as the detector a quadrupole mass spectrometer with sample injection through a capillary column and with heating at the sampling site. This laboratory is designed for the rapid identification and estimation of the amount of organic substances in water, air, and on the surface. It can be used to analyse the distribution of dioxins.[6]

The use of modern analytical methods and apparatus combined with well thought out organisational measures is undoubtedly the most promising trend in ecology, which has already frequently led to positive results, and not only in the case of industrial accidents already mentioned. The significant improvement of the ecological situation in the region of the Greak Lakes (USA) and the Mississippi River may serve as an example. The combination of modern physicochemical and biological analytical methods and international cooperation has made it possible to investigate fairly rapidly the causes of the death of seals in Lake Baikal.[7]

The use in ecology of the majority of analytical instruments is limited by their high cost, the need for special accommodation, and the unduly laboratory-oriented design of the instruments as well as the need for highly qualified specialists to carry out the analyses. For the mass application of analytical instruments in ecology, the designers must significantly reduce the cost of the apparatus without loss of their quality, reduce their weight and size, and expand their operating conditions.

The small batches of chromatographs and mass spectrometers produced by Soviet industry do not satisfy the requirements of ecologists either as regards their functional possibilities or their operating characteristics. Essential instruments such as chromatograph-linked mass spectrometers and quadrupole mass spectrometers are not produced at all. There is a particularly serious lack in the field of assembly and interpretation of data on the basis of modern advances in computer techniques. Devices for continuous monitoring based on laser techniques and small cheap and selective sensors of different types are completely lacking.

One of the main reasons why Soviet industry lags behind in ecological instrument making is the absence of a scientific-technical base and of permanent specific organisational stimuli, which, on the one hand, would stimulate the demand for ecological instruments because of the need to carry out measures to protect nature and, on the other hand, would stimulate the manufacture and improvement of their quality.

The Siberian Division of the USSR Academy of Sciences prepared the program "Development of Methods, Instruments, and Mobile Laboratories for the Analysis of the Pollution of the Environment", which can be regarded as the first stage of work designed to create a

Problems of the development of ecological instrument making

M A Grachev, A V Avrorin
The Limnological Institute, Siberian Division
of the USSR Academy of Sciences, Irkutsk

The attention devoted to the development of new analytical methods and instruments for ecology has been aroused by the appearance in the waste from economic activity of a large amount of highly toxic pollutants, which are dangerous to man and the environment even in very small amounts. The detection of these substances at the level of limiting permissible concentrations against the background of interfering substances is a very complex scientific and technical task. Bearing in mind that about 70 000 organic compounds are being used throughout the world and are therefore present in the environment and that their number increases by 1–2000 annually,[1] the necessity for newer modern approaches to ecological analyses becomes evident. For such studies, it is essential to have at one's disposal a set of fairly universal methods and instruments with a high sensitivity and selectivity. The results should be interpreted on a computer. Furthermore, it is essential to possess a data bank for the identification of substances.

The development of analytical methods in ecology has been stimulated by a series of accidents in chemical undertakings and by the results of their investigation. The results of a study of the accident in Seveso (Italy) in 1976,[2,3] where the latest advances in chromatography and mass spectrometry had to be used in order to detect traces of dioxins, which poison human beings and pollute the locality, have appeared in print to the greatest extent. The consequences of the agricultural pollution and of the use of chemicals (herbicides) during most recent wars have also served as stimuli.[4] All these major catastrophic pollutions have led to a sharp increase in the number of scientific publications on the development of analytical methods using the latest instruments: highly effective gas and liquid chromatograph and mass spectrometers, which are used in more than half the instances where analytical methods are needed.[5]

The increasing complexity of the ecological situation and frequent accidents in chemical undertakings have induced a rapid growth of the industrial manufacture of analytical apparatus in various countries. The quality of the apparatus has been increasing significantly as a result of a large number of service devices: devices for sampling and preparation of samples and a sophisticated system for the interpretation of data on computers with extensive program libraries, data bands, and systems for the identification of substances.

The achievements in instrument making and electronics enabled a number of firms to develop mobile laboratories equipped with chromatographs and mass spectrometers. The best known of these is the TAGA-3000 Laboratory (Canada). It uses as the detector a mass spectrometer with a device for the automatic injection of samples from the atmosphere, which ensures a high sensitivity (10^{-15} g cm^{-3}). The presence of a navigating device makes it possible to plot maps of contamination in the given locality. The MM-1 mobile laboratory of the Bruker Company (Federal Republic of Germany) has effective analytical characteristics. It uses as the detector a quadrupole mass spectrometer with sample injection through a capillary column and with heating at the sampling site. This laboratory is designed for the rapid identification and estimation of the amount of organic substances in water, air, and on the surface. It can be used to analyse the distribution of dioxins.[6]

The use of modern analytical methods and apparatus combined with well thought out organisational measures is undoubtedly the most promising trend in ecology, which has already frequently led to positive results, and not only in the case of industrial accidents already mentioned. The significant improvement of the ecological situation in the region of the Greak Lakes (USA) and the Mississippi River may serve as an example. The combination of modern physicochemical and biological analytical methods and international cooperation has made it possible to investigate fairly rapidly the causes of the death of seals in Lake Baikal.[7]

The use in ecology of the majority of analytical instruments is limited by their high cost, the need for special accommodation, and the unduly laboratory-oriented design of the instruments as well as the need for highly qualified specialists to carry out the analyses. For the mass application of analytical instruments in ecology, the designers must significantly reduce the cost of the apparatus without loss of their quality, reduce their weight and size, and expand their operating conditions.

The small batches of chromatographs and mass spectrometers produced by Soviet industry do not satisfy the requirements of ecologists either as regards their functional possibilities or their operating characteristics. Essential instruments such as chromatograph-linked mass spectrometers and quadrupole mass spectrometers are not produced at all. There is a particularly serious lack in the field of assembly and interpretation of data on the basis of modern advances in computer techniques. Devices for continuous monitoring based on laser techniques and small cheap and selective sensors of different types are completely lacking.

One of the main reasons why Soviet industry lags behind in ecological instrument making is the absence of a scientific-technical base and of permanent specific organisational stimuli, which, on the one hand, would stimulate the demand for ecological instruments because of the need to carry out measures to protect nature and, on the other hand, would stimulate the manufacture and improvement of their quality.

The Siberian Division of the USSR Academy of Sciences prepared the program "Development of Methods, Instruments, and Mobile Laboratories for the Analysis of the Pollution of the Environment", which can be regarded as the first stage of work designed to create a

base for ecological instrument making. The program included 34 research and experimental-design studies which are planned for 1989–1991. The program of the development of studies in the subsequent period will be prepared in 1990 using the experience gained.

The main executor of the program is the Limnological Institute of the Siberian Division of the USSR Academy of Sciences. The overall cost of the studies is 23 million roubles (7.7 million roubles annually). The main bulk of the studies are being performed by members of the Institute of the Siberian Division of the USSR Academy of Sciences, the Geophysical Instrument Making Division of the Tochnash Design Bureau at the Institute of Geology and Geophysics of the Siberian Division of the USSR Academy of Sciences, the EKOTEK Company, and the experimental factory of the Irkutsk Scientific Centre.

It is proposed initially to set up and standardise a limited list of toxicants, each of which will represent a specific group of ecological toxicants of prime importance, classified in relation to the analytical methods and instruments. Such a list is necessary for laboratory tests of instruments and should be reduced to a minimum in order to diminish the cost of the development of the metrological aspect of the work.

In addition, it is necessary to set up an information data bank for the study of the advances in the field of ecological instrument making and for the refinement of different aspects of the research. In the course of the studies, it is proposed to develop a packet of programs for personal computers, to carry out bibliographic and patent searches, and to introduce the information into the data base and analyse it.

The next group of studies is designed to create instruments for the analysis and monitoring of prime toxicants in the gas phase.

In order to construct the gas chromatographs, it is essential to employ the experience gained in the development of the "Ekho" gas analyser-identifier, whose design is so advanced that it can become the basis for a series of universal an specialised chromatographs which are not inferior to the best devices throughout the world. The design of the "Ekho" gas analyser is protected by a patent.[8] The instrument employs novel units: a device for sample injection from a concentrator, polycapillary columns, an improved electron capture microdetector, and a microprocessor device for controlling the apparatus and for interpretation of data, which are also protected by patents. Further improvements to the design of the apparatus will make it possible to extend the range of substances analysed and to improve the sensitivity of the determination of impurities in the atmosphere to 10^{-15} g cm^{-3} (combined with a resolving capacity ranging from thousands of plates in portable versions of the apparatus to tens of thousands of plates in stationary designs). The detector being developed on the basis of molecular condensation nuclei possesses unique sensitivity and is capable of detecting a wide range of substances. The set of existing technical solutions, the degree of elaboration of the components of the apparatus, and the design as a whole make it possible to create an instrument which will not be inferior to the best devices available throughout the world as regards its characteristics.

Rapid performance (a fraction of a second for the entire range of substances detected) and a high sensitivity (10^{-13} g cm^{-3}) are combined in the novel instrument called "drift spectrometer", where the substances are separated on the basis of the non-linear dependence of the mobilities of their ions in specially generated electric field pulses.[9,10] The instrument operates with air being continuously pumped through it and is designed to analyse the composition of the air on board moving carriers. The studies being performed should lead to the construction and tests of a prototype of the instrument. The instrument has no analogues abroad.

For remote-control analyses, it is proposed to construct a batch of atomic-absorption mercury Zeeman analysers in air which have proved very satisfactory in a whole series of tests on the detection of mercury vapour in the atmosphere performed on an aeroplane (developed by the Institute of the Optics of the Atmosphere, Siberian Division of the USSR Academy of Sciences, Tomsk).

Members of the Krasnoyarsk Scientific Centre of the Siberian Division of the USSR Academy of Sciences have been investigating new principles of the analysis of air and liquid media using the resonance effects in laser spectroscopy and microwave spectroscopy. It is proposed to construct analysers with a very simple design and easy to operate.

It is proposed to construct several prototypes of a lidar for remote-control measurements of the amounts of sulphur dioxide, nitrogen oxides, and aerosols in the atmosphere and to test them in Tomsk, Novosibirsk, and Irkutsk. The instrument has been developed by the Institute of the Optics of the Atmosphere of the Siberian Division of the USSR Academy of Sciences and is designed to monitor the state of the atmosphere in the vicinity of major industrial undertakings, heat and power generating plant and urban regions.

Yet another group of studies has been devoted to the development of means for the analysis of liquids. These studies should result in the modernisation of the electronic units of the "Milikhrom" liquid chromatograph, the development of which led to the award of the USSR State Prize. The novel units and blocks of the chromatograph, patented in major capitalist countries[12–18] and protected by USSR patents, ensure effective characteristics of the instrument: sensitivity down to 10^{-9} g with respect to nucleotides, duration of analysis from 2 to 20 min, and selectivity equivalent to 4000 plates.[11] After modernisation, the instrument should be produced commercially.

It is also proposed to use the best advances in the development of the units of the "Milikhrom" chromatograph to improve the efficiency of the ionic chromatograph in a flow-injection analyser. By virtue of the employment of the principle of microcolumn chromtography, a tenfold saving has been achieved in the reagents and sorbents in the ionic chromatograph compared with the best foreign analogues. The flow-injection analyser is based on the detector of the "Milikhrom" chromatograph incorporating a 2:μl cell and a small-size system for the supply of the solution of the solvent and for injection.

An attempt has been made to devise an apparatus for the neutron-activation analysis of admixtures of chemical elements in water under field operating conditions. For this purpose, one uses small neutron generators with a flux $>10^8$ neutron s^{-1}. Similar generators are used for the neutron bore hole logging. In the above study a novel design of a generator with a gas-filled tube was employed. The study led to the creation of a mock-up of the apparatus.

The most complex problems have to be solved in the studies designed to devise different types of mass spectrometers. The principal difficulties arise in the creation of transportable versions of the apparatus for mobile ecological laboratories and in the development of devices for the introduction of samples. It is proposed that both direct sample injection from the atmosphere and sample injection via chromatographic columns be employed, as well

as a novel hydrodynamic procedure for the introduction of liquid samples into the mass spectrometer.

The possibility of devising a Soviet-produced transportable quadrupole mass spectrometer has been investigated. The MM-1 mass spectrometer, developed by the Bruker Company (Federal Republic of Germany), may serve as a model.

It is proposed to develop an analytical system based on a static mass spectrometer with a samarium magnet, which is equipped with a device for the introduction of samples from the atmosphere, a line of receivers for the simultaneous recording of the mass spectra, a device for coupling to a personal computer in order to interpret the information and identify the substances, and a vacuum system capable of working as a part of the equipment of a mobile ecological laboratory. The study should be completed by the construction and test of the system as part of an ecological laboratory. The system is designed for the analysis of toxicants of prime importance in the gas and liquid phases.

The problems concerning the testing and calibration of instruments for the analysis of traces of substances in the gas phase are being solved. Generators of standard concentrations of prime toxicants, based on the constancy of the concentration of the vapour of a solution at a given temperature, are being developed for the purpose of the tests. The solution is deposited on a large surface,[19] in the given instance on the channels of a polycapillary plate. The generators are first calibrated against a radioactive label. A calibration table, indicating the concentration of the toxicant vapour at a specified temperature to within $\pm 10\%$, is assigned to each generator. It is possible to construct in this way generators for the determination of the concentrations of substances down to 10^{-14} g cm^{-3} in air. Sets of such generators, designed for different concentrations, make it possible to test the linearity and sensitivity of instruments over a wide dynamic range.

Fluorine-graphite matrices, maintaining a constant flux of an evaporating substance for up to 6 months, are prepared by a special technology and are used for the sorption of volatile substances. The advantages of the sorption generators of standard concentrations are their small size and ease of operation, which makes it possible to incorporate them directly into the automatic calibration apparatus.

In the course of these studies, measures will be taken to ensure the metrological certification of the generators and sets of generators in the required numbers will be constructed.

A large series of studies is being performed on the creation of chromatographic phases and different types of capillary and polycapillary columns for gas chromatography. The results obtained at the Institute of Organic Chemistry of the Siberian Division of the USSR Academy of Sciences in the synthesis of polysiloxane liquid phases, reagents in the deactivation of the surfaces of glass and quartz using a specially developed technology for the deposition and stabilisation of phases, made it possible to set up the manufacture of columns which are not inferior to the best foreign examples either as regards selectivity or as regards the range of working temperatures (from -60 to 320 °C). The principal task at the present stage is to ensure the provision of highly effective chromatographic columns in all the developments involved in the given programme.

In order to improve the characteristics of a traditional analytical instrument—the emission spectrometer—a study has been undertaken to construct a mock-up of such a spectrometer in which all the latest advances in this field are employed: holographic grids, a recorder with a line of photodiodes for the simultaneous recording of the MASI spectra, and the assembly and interpretation of information with the aid of microprocessor computers. The size of the apparatus is significantly reduced and the requirements as regards vibration stability are less stringent, which makes it possible to employ the device in mobile laboratories.

A large series of studies has to be carried out on the development of methods for the analysis of toxicants of prime importance (it is proposed to involve in this investigation a large team of members of the Institutes of the Novosibirsk, Krasnoyarsk, and Tomsk Scientific Centres). The analytical methods should be based on the devices developed in accordance with the given programme and should employ the latest advances in the computer interpretation of information. A data bank should be set up for use in personal computers in order to identify the substances analysed. In the first stage of the investigation, it is proposed to create data banks and systems for the identification of substances against the background of impurities.

Two studies are designed to develop hydroacoustic devices for hydrobiological studies and for the estimation of the stock of fish and the state of water-containing areas.

The development of a mobile ecological laboratory is the most complex component among those planned in the programme "development of methods, instruments, and mobile laboratories for the analysis and monitoring of pollutants in the environment". The laboratory should be placed in a specially equipped automobile (bus). In the first stage of the development, it is proposed that the laboratory should incorporate (after structural modification) the following instruments: a modernised Ekho-M gas chromatograph, a modernised Millikhrom liquid chromatograph, a drift spectrometer, a mass spectrometer with sample injection from the atmosphere, a bioluminometer, an aerosol counter, devices for the selection and preparation of samples, and a set of personal computers within the automobile. The laboratory is designed for the operational analysis of the state of the environment. In the first stage of these studies, it is also necessary to revise the necessary set of apparatus, to specify the unsolved problems, and to formulate the task for the next stage.

The programme is completed by a series of studies designed to prepare for the construction of a scientific-industrial base for ecological instrument making at the Irkutsk Scientific Centre. In accordance with the resolutions of the Praesidium of the Siberian Division of the USSR Academy of Sciences, it is proposed to create the Irkutsk Engineering-Ecological Centre, in which the total number of engineers and other workers employed will be up to 1000. The tasks in the Centre are the development of modern methods for the analysis and monitoring of the state of the environment, the coordination of the work of the organisations participating in the execution of the programmes, the construction and testing of prototypes of the apparatus, the incorporation in commercial production of the developments achieved at the Centre, and cooperation in the practical employment of such developments by the monitoring organisations.

Chromatography in ecology

O G Larionov
Institute of Physical Chemistry, USSR Academy of Sciences, Moscow

The solution of the problem of ecology in all countries, namely the creation of waste-free technologies the utilisation of the materials obtained, the study of their metabolism under operating conditions, their regeneration, and their disposal, is impossible without chemical analysis of complex organic mixtures, which permits not only the determination of the overall content of the organic substance but also the establishment of the presence and the determination of the concentrations of specific mixture components. Chromatography combined with mass spectrometry, IR Fourier spectroscopy, UV spectroscopy, etc. has become such an analytical procedure.

Chromatography makes possible the selective determination of microimpurities at virtually any level, which is especially important in the solution of ecological problems. As a result of the chromatography of a mixture, the separated individual components pass to the instrument for their determination (mass spectrometer, IR Fourier spectrometer, etc.) and are then identified by spectroscopic methods. At the present time, all the leading and the majority of ordinary analytical laboratories abroad, engaged in the analysis of objects in the environment, are equipped with chromatograph-linked mass spectrometers and a large number of gas and liquid chromatographs.

The state of organic analysis in our country is extremely unsatisfactory: thus only one of each ten sanitary-epidemiological stations, i.e. the principal organ for the monitoring of the environment, is at present equipped with gas chromatographs and the number of liquid chromatographs is even smaller. We lag behind the USA by a factor of 5–6 as regards the manufacture of gas chromatographs and by a factor of 50–60 as regards liquid chromatographs. Chromatograph-linked mass spectrometers of modern design are not manufactured in the USSR and, according to our information, IR Fourier spectrometers, which might be used in combination with chromatographs, are not being developed either.

The foregoing shows that, for the successful solution of ecological problems, it is necessary to develop analysis and especially organic analysis on the basis of primarily chromatographic methods combined with mass spectrometry. For a rapid rectification of the existing situation, it is desirable to organise a methodological centre and regional analytical centres provided with modern equipment purchased abroad.

Electrochemistry and protection of the environment

V E Kazarinov
Frumkin Institute of Electrochemistry, USSR Academy of Sciences

There are many electrochemical aspects of the solution of ecological problems. In the first place, these include the creation of new industrial technologies, procedures for the purification of waste waters, and the development of sensors for the monitoring of the environment. Electrochemistry can also make a serious contribution to the creation of ecologically clean transport and power engineering.

A series of studies designed to protect the environment has been carried out in recent years at the Institute of Electrochemistry of the USSR Academy of Sciences. A procedure has been developed for the ultilisation of gas-absorption hydrochloric acid, which is a waste product of the large scale organochlorine synthesis in the electrochemical chlorination of ethylene to dichloroethane. This procedure is protected by patents. An experimental-industrial 5 kA apparatus has been constructed and tested jointly with the undertakings of the Ministry of Chemical Industry at the "Orgsintz" factory in Sumgaite. A technical requisition for a plan of an experimental works designed to produce 10000 tonnes of dichloroethane annually has been made. Unfortunately, the works has not so far been constructed and the contamination of the Caspian Sea continues.

Electrochemistry and protection of the environment

V E Kazarinov
Frumkin Institute of Electrochemistry, USSR Academy of Sciences

There are many electrochemical aspects of the solution of ecological problems. In the first place, these include the creation of new industrial technologies, procedures for the purification of waste waters, and the development of sensors for the monitoring of the environment. Electrochemistry can also make a serious contribution to the creation of ecologically clean transport and power engineering.

A series of studies designed to protect the environment has been carried out in recent years at the Institute of Electrochemistry of the USSR Academy of Sciences. A procedure has been developed for the ultilisation of gas-absorption hydrochloric acid, which is a waste product of the large scale organochlorine synthesis in the electrochemical chlorination of ethylene to dichloroethane. This procedure is protected by patents. An experimental-industrial 5 kA apparatus has been constructed and tested jointly with the undertakings of the Ministry of Chemical Industry at the "Orgsintz" factory in Sumgaite. A technical requisition for a plan of an experimental works designed to produce 10000 tonnes of dichloroethane annually has been made. Unfortunately, the works has not so far been constructed and the contamination of the Caspian Sea continues.

The scientific principles of a low-waste industrial technology for the electrosynthesis of chemical additives to polymers are being developed. In particular, processes for the electrochchemical synthesis of sulphenamide M (a thiazole vulcanisation accelerator) and benazole P (a benzotriazole photostabiliser for polymers) have been developed. These make it possible to obtain high-quality products, to abandon the use of chemical oxidants, and to reduce sharply the amount of industrial waste. Both developments are being tested on an experimental-industrial plant at NIIKhIMPOLIMER (in Tambov).

On the basis of the results of fundamental research into electrocatalysis, a highly sensitive and rapid method for the analysis of organic impurities and heavy metals in water, which has no analogues in world practice, has been devised. The method is protected by USSR and Swiss patents. On the basis of this method, our Institute devised and constructed jointly with NIIKhIMMASh a series of analysers (AKVEL) which have been highly approved by specialists at International and All-Union Expositions. Their sensitivity is 0.01 mg litre^{-1} with respect to total organic carbon and 0.001 mg litre^{-1} with respect to heavy metals. The duration of analysis is 3–15 min. The weight of the apparatus is 1.5 kg and its size is 19 × 28 × 20 cm. the AKVEL analyser is not inferior to the best western analysers for total organic carbon as regards sensitivity and speed of action. At the same time, it is distinguished by simplicity of design, small size, and low cost.

An experimental batch of AKVEL analysers, used for the monitoring of especially pure deionised water and for the analysis of natural waters, has been produced recently. Studies are being prosecuted on the creation of a sensor for organic impurities which is extremely small and works in a stream of water using an ion-exchange membrane as the electrolyte.

Sensors for oxygen in liquid media, carbon dioxide, hydrogen sulphide, carbon monoxide, and hydrogen have been developed. The electrochemical sensors designed to determine the concentrations of sulphur dioxide and hydrogen sulphide, constructed jointly with the Automation Experimental Design Bureau "Khimavtomatika", have no analogues in world practice as regards electrochemical instrument making. Models of sensors for low and high concentrations have been developed. The nominal time for the establishment of readings is 30–40 s. The sensors are distinguished by a low level of the background signal and a high stability of the output signal and contain no precious metals. It is proposed that the sensors be used to monitor the atmosphere in sulphuric acid and other industries.

Several types of sensors for oxygen have been developed: amperometric sensors of the Clark type and sensors based on a new adsorption kinetic principle. The Clark type sensor with a membrane, for artificial blood circulation apparatus, is distinguished by the rapidity of response, high stability of readings, and very small size (miniaturisation). An experimental batch of such sensors has been produced recently by the Institute of Experimental and Clinical Surgery of the Ministry of Health of the Georgian SSR. Clinical tests have been carried out under operating conditions and permission for clinical application has been received. These sensors can be used successfully also for ecological purposes.

Studies are being prosecuted on an oxygen sensor of the open type (without a membrane) for use in liquid and gaseous media with a carbon material as the indicator electrode. The response requires several seconds. The range of pressures determined is 0–760 mmHg.

The sensor based on the adsorption kinetic principle has a number of advantages over those available previously. High speed of response (4 s), high sensitivity (10 mV per 1% of O_2), accuracy at the level of the best foreign devices (0.1–0.2%), and a significant reduction of the consumption of oxygen during analysis. The sensor can be used in gaseous, liquid, and biological media.

A selective catalyst for a carbon monoxide sensor, permitting the determination of CO concentrations in the presence of hydrogen, has been developed. The sensors, with an improved selectivity, have been constructed jointly with the Chirchiksk Automation Experimental Design Bureau and have been introduced at the Novo-Dzhambul'sk Phosphorus Works.

It is noteworthy that the electrochmeical methods are extremely effective in the creation of sensors for different individual substances. They are highly sensitive, respond rapidly, and can be used in automatic monitoring systems.

Local monitoring. Organic materials — new possibilities for ecological monitoring

A A Ovchinnikov, L M Khidekel', V N Spektor
Insitute of Chemical Physics, USSR Academy of Sciences, Moscow

The principal argument used by opponents of giving immediate priority to ecological problems is the lack of reliable quantitative data on the state and quality of the environment and about the immediate and remote ecological consequences (including man) of deviations from the ecological norm and concerning the very concept of the ecological norm. The primary aspect of the answers to all these questions is provided by the measurement of the set of parameters of the environment which is as complete as possible.

Ecological monitoring is divided into global, regional (at the level of continents, sub-continents, and countries and the trans-border transport of pollutants), territorial (industrial regions, cities, large agricultural-industrial complexes, dissipation of pollutants), and local (the vicinity of individual undertakings, emissions, waste, discharges, and the technosphere).

Each of the above types of monitoring has its own main task and its own set of measuring devices. However, the optimum provision of information-gathering devices for the control system at all the hierarchical levels can be achieved only by employing the entire set of data obtained by all types of monitoring, i.e. by means of a systemic approach.

Global, regional and territorial monitoring are carried out mainly by remote control methods — aerocosmic, laser, etc. The main limitation of the remote control methods is the generation of averaged information and appreciable difficulties in establishing a specific source of pollution of the environment or, more precisely, the determination of the centres of ecological breakdowns. However, the devices for remote control monitoring have been thoroughly developed during the last decades, a system of exchange of information within the limits of individual countries has been set up, and a system of international links is being gradually established.

The principal cause of the breakdown of ecological equilibrium is human activity, as a result of which local monitoring comes to the fore in the solution of problems of the rational control of ecological processes. However, local monitoring is in fact least adequately

The scientific principles of a low-waste industrial technology for the electrosynthesis of chemical additives to polymers are being developed. Local monitoring. Organic materials — new possibilities for ecological monitoring

A A Ovchinnikov, L M Khidekel', V N Spektor
Insitute of Chemical Physics, USSR Academy of Sciences, Moscow

The principal argument used by opponents of giving immediate priority to ecological problems is the lack of reliable quantitative data on the state and quality of the environment and about the immediate and remote ecological consequences (including man) of deviations from the ecological norm and concerning the very concept of the ecological norm. The primary aspect of the answers to all these questions is provided by the measurement of the set of parameters of the environment which is as complete as possible.

Ecological monitoring is divided into global, regional (at the level of continents, sub-continents, and countries and the trans-border transport of pollutants), territorial (industrial regions, cities, large agricultural-industrial complexes, dissipation of pollutants), and local (the vicinity of individual undertakings, emissions, waste, discharges, and the technosphere).

Each of the above types of monitoring has its own main task and its own set of measuring devices. However, the optimum provision of information-gathering devices for the control system at all the hierarchical levels can be achieved only by employing the entire set of data obtained by all types of monitoring, i.e. by means of a systemic approach.

Global, regional and territorial monitoring are carried out mainly by remote control methods — aerocosmic, laser, etc. The main limitation of the remote control methods is the generation of averaged information and appreciable difficulties in establishing a specific source of pollution of the environment or, more precisely, the determination of the centres of ecological breakdowns. However, the devices for remote control monitoring have been thoroughly developed during the last decades, a system of exchange of information within the limits of individual countries has been set up, and a system of international links is being gradually established.

The principal cause of the breakdown of ecological equilibrium is human activity, as a result of which local monitoring comes to the fore in the solution of problems of the rational control of ecological processes. However, local monitoring is in fact least adequately

provided with measuring devices. The existing measuring devices and sensors, mainly from the range of analytical instruments which were not initially designed for ecological purposes, are too cumbersome, expensive, and insufficiently selective for wide scale employment in practice. Furthermore, it is virtually impossible to achieve their unification as regards the output signal and thus to create an information-measuring system on their basis.

The creation of monitoring-measuring apparatus for local monitoring of the environment requires the involvement of devices produced by microelectronic instrument making, involving the use of adequate materials for the sensitive elements of sensors.

During the last decade, data have appeared in the scientific and patent literature concerning the effective use of organic semiconductors as materials for the sensitive elements of sensors designed to determine the composition of complex gas mixtures, including the real atmosphere.

The advantages of organic semiconductors are their high sensitivity and selectivity combined with a high resistance to breakdown including the poisoning effect of the accompanying impurities. Sensors for ammonia, phosphine, arsine, hydrogen sulphide, oxygen, and sulphur dioxide have already been developed on the basis of organic semiconductors (molecular charge-transfer complexes and conducting polymers as materials of the sensitive elements) and the possibility of constructing sensors for a number of other gaseous atmospheric pollutants has been investigated. The use of metal-containing phthalocyanines for the detection of hydrogen sulphide yielded best results, superior to the current world level.

These sensors, which operate even in a direct resistive regime, are distinguished by their small size, reliability, stability of operation under natural conditions, and the possibility of being manufactured by means of a standard planar microelectronic technology. Their main disadvantage is an inadequately rapid cyclic response in the interrogatory (discrete) regime of the operation of information-measuring systems incorporating such sensors. A further increase in the rapidity of response, the expansion of the range of measurement using a single sensor, miniaturisation, and the generation of a voltage signal without an intermediate amplifier involve the use of integrated hybrid sensitive elements combining in a single planar structure a transistor based on the traditional semiconductors and a sensor based on organic semiconductors.

One of the important conclusions reached in a theoretical study of the relation between the sensitivity and selectivity of the sensitive elements and the electronic structure of organic materials has been the conclusion that extensive purification or purification with subsequent deliberate doping of the materials of the detecting media is necessary, since the presence of non-controlled impurities makes the semiconductor non-intrinsic and always reduces the sensitivity and the threshold of the determination and frequently also the selectivity of the material of the sensitive element. Methods for the purification of organic semiconductors have now been developed at the Gorky State University. For the practical purpose of constructing information-measuring systems for local atmospheric monitoring, one of the consequences of this systemic approach is most important, namely, when two sensitive elements based on organic semiconductors have comparable but different sensitivities with respect to two atmospheric components being determined, the concentration and temperature dependences of their sensitivities are different for the two elements, which makes it possible to increase their selectivity appreciably by purely computer methods. This property of the sensitive elements in the sensors of the multiparameter system permits a reduction of the requirements which must be met by the material of each element and an increase in their effectiveness in the system. The earlier sensors are amplitude-modulated detectors. Their great advantage is their low intrinsic cost and ready susceptibility to technological operations, while their disadvantage is the need for additional schematic and technical solutions in computer systems for the collection and processing of information.

The enormous advantages of large information-measuring systems constructed using modern facilities provided by the computer technique arise from the application of frequency-modulated sensors. Thus an instrument for the measurement of the concentrations of atmospheric and technological oxygen has been developed on the basis of the long-lived diphenylpicrylhydrazyl radical in the core of a superheterodyne receiver exposed to the stream of gas.

Thus the materials developed within the framework of studies on the electronics of organic materials can provide a new elementary base for ecological instrument making, which will in its turn make it possible to create an effective local monitoring system. The creation of such a system will permit the adoption of well-founded solutions in controlling the operation of undertakings in order to rule out the pollution of the environment, and in the first place the atmosphere, on the state of which depends human health and man's very life.

Strong metal–carrier interaction and its role in catalysis

L V Ermolov, A A Slinkin
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The present state of the problem of the strong interaction of a metal with the carrier is analysed and the main causes responsible for the appearance of this effect are considered. Data demonstrating the influence of the strong interaction of a metal with the carrier on the absorption and catalytic properties of deposited metallic catalysts are presented.

The bibliography includes 175 references.

Contents

I. Introduction 331
II. The sources of the effect of the strong interaction of a metal with the carrier 331
III. Manifestations of the effect in deposited metallic catalysts 335
IV. The apparent effects of the strong interaction of a metal with the carrier 340

I. Introduction

The term "strong metal–carrier interaction", which is so widely used nowadays to describe a wide variety of effects in reduced deposited metallic catalysts, was introduced by Tauster[1] to designate interactions whose essential feature involves the formation of a covalent bond between the atoms of the deposited metal and the cations of carriers such as TiO_2 [1] and vanadium, manganese, niobium, and tantalum oxides.[2]

A classification of metal–carrier interactions has been proposed;[3,4] a weak interaction (on non-reducible oxides of the type SiO_2, Al_2O_3, etc.), a moderately strong interaction (in zeolites), and a strong interaction (on oxides capable of being reduced at elevated temperatures). Without going into the details of the mechanisms, one can give the following phenomenological definition of the effect of the strong interaction of a metal with the carrier (SIMC): the SIMC effect is the term applied to the group of phenomena leading to the alteration of the electronic and structural properties of deposited metallic particles, which is accompanied by the corresponding changes in the absorption and catalytic (rate of reaction, selectivity) properties.

During the years which have elapsed since the publication of Tauster's study, a large number of studies devoted to the nature of the SIMC effect have been published. It was found that the phenomenon is much more complex than was suggested in the first investigations and the aim of the present review is therefore to compare the earlier data with the results published recently in order to understand more clearly the nature of the effect and the direction which will be taken by further studies.

II. Sources of the effect of the strong interaction of a metal with the carrier

In modern literature, the following sources of the SIMC effect have been specified:[3,5–10] electronic (collective and local) interactions, migration of the carrier on to the surface of the metallic particles and encapsulation of the metal in the carrier, the formation of alloys and intermetallic compounds, and thermodynamic factors.

1. Electronic interactions

The explanation of the SIMC effect in terms of collective electronic phenomena is based on Schwab's idea[11] that the Schottky theory is applicable to the metal–carrier interface in catalytic systems. If the catalyst contains an *n*-type semiconductor with an electron work function φ_n (on reduction, TiO_2 actually becomes precisely such a semiconductor) and a metal with a work function φ_m, where $\varphi_n < \varphi_m$, then electrons will migrate from the semiconductor to the metal until the chemical potentials of both solids (Fermi levels) are equalised. Under these conditions, the layer of the semiconductor adjoining the metal is depleted in current carriers and becomes positively charged, while the layer of the metal becomes negatively charged. A potential barrier, called the Schottky barrier, arises at the interface. If the Schottky theory is applicable to deposited metallic catalysts, then the change in the concentration of conductivity electrons does indeed influence the catalytic and adsorption properties, and this constitutes one way of explaining the SIMC effect, which has in fact been used in some studies.[12] However, the question arises of the meaning of the change in the concentration of conductivity electrons in the metal if their number in the latter is 10^{23} per cm^3. In order to determine from experimental data[13] the real concentration of electrons migrating from the carrier to the metal in conformity with the Schottky theory, the potential difference at the nickel–germanium interface was calculated. It was found that one electron is transferred from the conductivity band of germanium per 10^4 atoms. Evidently such a transition cannot alter in any way significantly either the concentration of conductivity electrons or the nature of the filling of the *d* band and it cannot influence greatly the adsorption and catalytic properties [of the metal]. This proof has been quoted also in other communications[14,15] in which deposited palladium catalysts were considered. Many investigators altogether cast doubt on such an approach, in which conductivity electrons are regarded as being responsible for the catalytic and adsorption properties of the metal. Furthermore, there is no certainty that the Schottky theory is applicable to the metal–carrier interface in real catalysts, because the potential jump at the interface may be due to the presence of extraneous poorly conducting layers between the metal and the semiconductors, for example layers of oxides as well as chemical impurities or lattice defects on the surface. Nevertheless, despite the clear deficiencies of the collective approach, some investigators[16,17] attempted in recent

years to use it to account for the mechanism of the influence of the carrier on the catalytic and adsorption properties of the deposited metal. For platinum deposited on TiO_2 to which Ta^{5+}, Sb^{5+}, or W^{6+} had been added to increase the electronic conductivity of the carrier, a model has been proposed,[18] according to which a platinum particle 20 Å in diameter creates on the carrier an electron-depleted semispherical zone with the radius r = 640 Å (Fig. 1). The authors suggest that electron transfer to platinum reaches an extent sufficient to alter the properties of the deposited metal compared with platinum on a non-doped TiO_2 after reduction at 473 K.

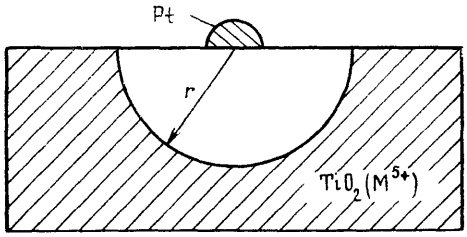

Figure 1. Model of the location of platinum crystals on the surface of modified TiO_2.[18]

Explanations associated with the local interaction of the metal atoms with a definite centre on the carrier surface are better founded.

TiO_2, which is reduced, losing O_2 on heating *in vacuo*, is the most typical carrier for the SIMC effect.[5] Hydrogen, dissociatively adsorbed on the deposited metal is capable of reducing TiO_2 at elevated temperatures. According to EPR spectroscopic data,[19] the deposited Ti/TiO_2 catalyst contains about 0.3% of Ti^{3+} ions after reduction in H_2 at 573 K. The ions are formed by the reaction

$$Ti^{4+} + O^{2-} + H = Ti^{3+} + OH^-.$$

Four different forms of Ti^{3+} have been observed for the same system,[20] two of which are on the surface and are sensitive to the adsorption of CO and H_2 and one form, with $g_\perp$ = 1.969 and $g_\parallel$ = 1.936, is present only on Pt/TiO_2 and is absent from reduced TiO_2. Reduction at 773 K leads also to the formation of anionic vacancies (Y) on the carrier surface:

$$2Ti^{4+} + 2O^{2-} + 2H = 2Ti^{3+} + O^{2-} + H_2O + Y.$$

Further, it has been noted in a review[5] and in a later study[20] that it is by no means always possible to detect the signal due to Ti^{3+} in the EPR spectra. Moreover, the ease of the migration of the anionic vacancies from the surface into the bulk of the carrier has been emphasised.[21] Thus reduced TiO_2 constitutes a mobile system with surface and bulk-phase anionic vacancies, OH^- anions, and Ti^{3+} cations in a state of dynamic equilibrium. We may note that, apart from isolated Ti^{3+}, the appearance of conducting Magneli phases (Ti_nO_{2n-1}) has been observed in deposited metallic catalysts reduced at 743 and 773 K.[22,23] The deposition of the metal (in the given instance Pd) reduces the electron work function of the Magneli phases and prevents their oxidation in O_2 at 300 K.[22]

Experiments using XPS, ^1H NMR, EPR, and the adsorption of H_2 demonstrated that at temperatures above 573 K the hydrogen adsorbed on the metal (Ni, Pt, Rh) spills over into the oxygen vacancies of the reduced TiO_2 with formation of the hydride-like forms $Ti-H^{3+}$.[24]

It is noteworthy that the relation between the SIMC effect and the anatase–rutile transition in deposited metallic catalysts reduced at 643–873 K has been emphasised in a number of recent studies.[25–27]

In the definition of the term SIMC,[1] it was postulated that a covalent bond is formed between the metal atom and the Ti^{3+} cation formed on reduction of the carrier. Quantum-chemical calculations for the interaction of platinum and TiO_2 using two cluster models (Fig. 2)[28] confirmed the validity of this hypothesis. The model (II) in which platinum atoms are inserted in the oxygen vacancies of the carrier with formation of a bond between Pt and Ti^{3+}, is more convenient. Not only a covalent interaction but also an ionic interaction involving the transfer of an electron from Ti^{3+} to a Pt atom takes place in this model. The disposition of the metal atoms outside the TiO_6 octahedron gives rise to only weak interaction as a consequence of the repulsion between Pt and the nearest O^{2-} ions. Indirect evidence for the metal–carrier interaction in highly disperse metallic systems has been obtained by spectroscopic methods. Thus it has been shown by the XPS method[29] that, after the reduction in H_2 at 773 K, the binding energy of the $4f_{7/2}$ level of Pt in the 5% Pt/TiO_2 system diminishes by 9.4 eV compared with the same specimen reduced at 473 K. Electron transfer from TiO_2 to Ni atoms has been observed by the XPS and AES methods in the Ni/TiO_2 system in which nickel was deposited in a thin layer on TiO_2 subjected to a preliminary vacuum treatment at 673 K.[30] The degree of electron transfer is 0.1 of an electron per Ni atom.[30] An increase in electron density on the Rh and Pt clusters as a result of their interaction with Ti^{3+} cations after high-temperature reduction has been observed by the XPS, AES, SIMS, and ISS methods.[31] Within the framework of this model, it is easy to explain the disruption of the SIMC effect by O_2, which leads to the disappearance of oxygen vacancies in the carrier and hence of Ti^{3+} cations.

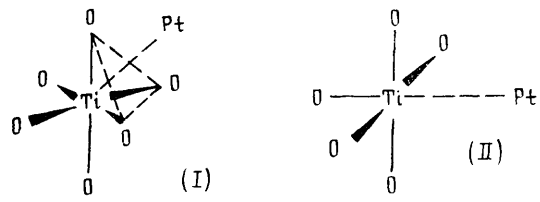

Figure 2. Cluster models for quantum-chemical calculations for the local interaction of a Pt atom with TiO_2.[28]

Direct evidence for the formation of a direct $Rh-Ti^{n+}$ chemical bond in the Rh/TiO_2 catalyst after reduction at 773 K[32] and of the $Rh-Ta^{n+}$ bond in the Rh/Ta_2O_5 catalyst after reduction at 858 K[33] has been obtained recently by the EXAFS method, the cation of the carrier being located in the first coordination sphere of Rh with a radius of 2.55 Å (2.68 Å in the Rh–Ti alloy) and about 1.7 Å

(2.73 Å in the Rh–Ta alloy) respectively. On the other hand, if the Rh/TiO_2 catalyst is obtained not by impregnation with a $RhCl_3$ solution but by the reaction of $Rh(\eta^3\text{-}C_3H_5)_3$ with the OH groups on the TiO_2 surface and subsequent reduction, then according to the EXAFS and electron microscopic data, thin three-layer positively charged Rh clusters are formed on the TiO_2 surface (Fig. 3) and interact strongly with the surface oxygen which remains in the catalyst even after reduction in H_2 at 773 K.[34]

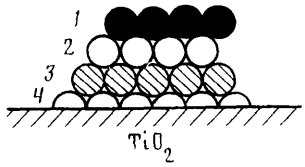

Figure 3. The structure of a Rh cluster fixed on the surface of TiO_2: *1–3*, upper, second, and first layers of rhodium atoms respectively; *4*, layer of oxygen ions of the carrier.[34]

An interesting approach to demonstrating the interaction of the Ni clusters with Ti^{3+} in the Ni/TiO_2 system has been used in a study[35] where the properties of the nickel deposited on the SiO_2 surface, modified by Ti^{3+} cations as a result of the attachment of $Ti(BH_4)_3$ and subsequent removal of the ligands *in vacuo* at 423 K, proved to be close to those of the Ni/TiO_2 catalyst reduced at 773 K. A similar result was obtained for palladium deposited on the SiO_2 surface and the surface of carbon doped with Pr^{3+} cations via organometallic precursors.[36] However, the SIMC mechanism examined above is not apparently the only one.

The possibility of a strong interaction of the deposited metal with the acid centres of the carrier has been frequently pointed out in the literature. For example, Zur Loye et al.[37] investigated the magnetic properties of the 1% Ni/TiO_2 catalyst prepared in different ways. It was then found that extrapolation to zero field of the specific magnetisation (σ) of the catalyst obtained by ion exchange and reduced at 773 K yields a value close to σ for the metallic nickel powder, while σ for the catalyst obtained by the impregnation method is diminished after reduction under the same conditions and corresponds to the reaction of 36% of the nickel with TiO_2. It has been suggested that the difference in the behaviour of the given system is due to the difference in the concentration of the surface OH groups, which is greatly reduced in the specimen obtained by ion exchange.

If one postulates the interaction of the metal with the acid centres, then the SIMC effect should be manifested on zeolites, aluminosilicates, Al_2O_3, ZrO_2, modified SiO_2, and other carriers with acid properties. The occurrence of electronic interaction between Ru clusters and Lewis and Brønsted acid centres has been demonstrated by IR spectroscopy and the thermoprogrammed reduction method in a study[38] of a series of ruthenium catalysts deposited on SiO_2, Al_2O_3, $SiO_2.Al_2O_3$, and an HY zeolite. The increase in acidity in the sequence $SiO_2 < Al_2O_3 < SiO_2.Al_2O_3 < HY$ is correlated with the increase in the electron deficiency on the Ru centres for the adsorption of CO. An XPS study of Ni, Pd, Re, Rh, Ru, and Pt, deposited on SiO_2, $\gamma\text{-}Al_2O_3$, and zeolites established that the metals interact to the maximum extent with zeolites, which is probably due to the presence in the latter of the strongest acid centres.[39] According to XPS, EXFAS, and electron microscopic data, the 6–7 and 11–13 Å Pt_{18} and Pt_{45} clusters located within the structure of the H-ZSM-5 zeolite are coordinated to the skeletal oxygen even after reduction at 773 K and exhibit an appreciable electron deficiency.[40] The interactions of platinum with the acid centres of L-zeolites modified by alkali and alkaline earth metal cations, after reduction at 623 K as a result of charge transfer, have been reported in a study[41] where the catalytic activity of the Pt/L-zeolite system was investigated in the hydrogenation of benzene and toluene.

Another example of the interaction of a metal with definite centres on the carrier is provided by the formation of paramagnetic Pt^{3+} cations on heating in O_2 of ammineplatinum deposited on Al_2O_3, which apparently takes place in the presence of a Lewis acid centre on the carrier surface:[42]

$$O^{2-}\text{—}Pt^{4+}\text{—}O^{2-} \xrightarrow{\text{reduction}} \square\, Pt^{2+}\text{—}O^{2-} + {}^1/_2O_2,$$
$$\square\, Pt^{2+}\text{—}O^{2-} + L\text{—}Al_2O_3 \xrightarrow{\text{heating}} \square\, Pt^{3+}\text{—}O^{2-} + L^-\text{—}Al_2O_3.$$

In general, the question of the relation between the SIMC and the acid properties requires a serious systematic study, which may yield interesting results when the acid carriers investigated in recent years (such as TiO_2, modified Al^{3+},[43] $\gamma\text{-}Al_2O_3$ treated with $SiCl_4$ [44] and tetraethoxysilane[45] vapours, the chemically mixed $TiO_2\text{–}SiO_2$, $TiO_2\text{–}Al_2O_3$, $Al_2O_3\text{–}SiO_2$, and $ZrO_2\text{–}SiO_2$ carriers,[46–48] and SiO_2 modified by the Sc^{3+}, Mg^{2+}, Fe^{2+}, Zn^{2+}, Al^{3+}, and Ga^{3+} cations[49]) are used for the preparation of deposited metallic catalysts.

Thus the explanations of the SIMC effect within the framework of local ideas reduce to a change in the electronic state of the metal atom and hence of the catalytic and adsorption properties under the influence of some kind of centre on the carrier surface. This is apparently true of an atomically disperse metal and small two-dimensional crystals and also of the atoms in larger metallic particles at the metal–carrier interface.[8]

2. Migration of the carrier onto the surface of metallic particles and encapsulation of the metal in the carrier

The appreciable changes in the properties of metallic particles whose size is 50 Å and more after high-temperature reduction cannot be explained solely by electronic effects. Several groups of investigators[50,51] put forward a hypothesis according to which part of the surface of metallic crystallites is shielded by the partially reduced TiO_2. A series of careful experiments carried out in 1984 confirmed the validity of this hypothesis.[52–54] It was found that TiO_x (where $x < 2$) has the surprising ability to migrate over considerable distances in a short time. For example, in an H_2 atmosphere at 698 K, TiO_x fragments appear on the surface of 120 Å thick nickel film deposited on TiO_2 after only 10 min, including the time necessary for the reduction of the TiO_2 surface.[54] The surface of platinum or rhodium film 30 Å thick on TiO_2 reduced beforehand are half-coated by a TiO_x monolayer after keeping the specimens in H_2 at 673 K for 2 min.[9] The mechanism of the migration of TiO_x is nevertheless not clear. On the one hand, in certain studies[54,55] the diffusion of TiO_x within the crystallites of the deposited metal has been demonstrated and, on the other, since the migration is frequently rapid it is logical to postulate that the carrier penetrates between the grains of the metal.[56] At any rate, the migration requires the dissociation of bonds in the crystal lattice of the carrier

and this can occur when the loss of the Madelung energy is made good by the stronger TiO_x–metal interaction. Thus the appearance of a TiO_x layer on the surfae of the metal supports the SIMC. We may note that not only the TiO_x phase can shield the surface of the deposited metallic particles. On the basis of the results of studies of the adsorption of H_2 and O_2, XPS, and electrical conductivity of the Ni/TiO_2 catalysts reduced at 623 and 773 K and having a nickel particle size of 100–200 Å, the following picture of the phase distribution has been put forward[57] (Fig. 4). Depending on the NiO content, on the surface of the initial catalyst there is either the nickel titanate phase (at a NiO concentration $\leqslant$ 35 mol%) or a mixture of nickel titanate and the NiO phase (at a NiO concentration > 35 mol%).[58] The reduction of 623 K is accompanied by the appearance of Ni crystals stabilised on the surface layer of the $Ni_\delta Ti_{1-\delta}O_2$ solid solution, which partly shields the Ni surface, and of the TiO_x bulk phase. The increase in temperature to 773 K leads to the decomposition of the $Ni_\delta Ti_{1-\delta}O_2$ solid solution and the formation on the surface of the conducting TiO_x of large nickel crystals, whose surface is shielded by the same TiO_x phase.

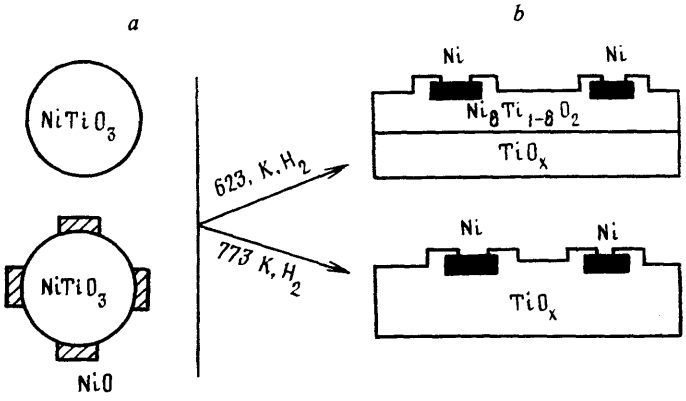

Figure 4. Distribution of the phases on the surfaces of initial (*a*) and reduced (*b*) nickel catalysts deposited on TiO_2.[57,58]

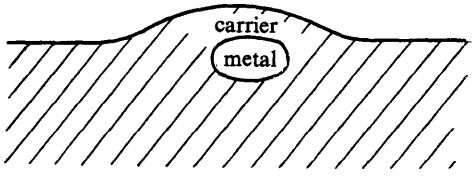

Figure 5. Model of a fully encapsulated metal particle.

The effect involving the spreading of the carrier on the metal surface during reduction is observed not only in metal–TiO_2 catalysts but also in the systems Ni/Nb_2O_5 at 773 K,[59] Ni/CeO_2 at 673 K,[60] and Pt and Rh/V_2O_3 at 773 K [61] and also for carriers which are difficult to reduce such as La_2O_3 in the Pd/La_2O_3 catalysts at 573 K,[29] ZrO_2 in the Rh/ZrO_2 catalysts at 873 K,[62] and SiO_2 modified with WO_3 in the Pt/WO_3–SiO_2 catalysts at 673 K.[29] In the last instances, the spill-over of hydrogen plays a major role in the reduction of the carriers to ZrO_x (with $x < 2$) and WO_2. Apparently even SiO_2 and Al_2O_3 exhibit some mobility in H_2 at high temperatures (about 1200–1300 K) and are capable of partially shielding the surface of the deposited metal.[4] On the other hand, there are carriers which migrate at an even higher rate than TiO_x. Thus an appreciable amount of MnO_x has been detected after heating for only 100 s *in vacuo* at 503 K on nickel films 150 Å thick deposited on MnO.[63]

We may note that the term "encapsulation", which means the immersion of the metallic particle in the carrier, is used fairly frequently in the literature.[64,65] Ultimately, the total encapsulation of the metal (Fig. 5) differs from the total shielding of the metal surface by the carrier perhaps only by the fact that the encapsulated metal does not recover its properties after oxidative treatment,[66] while in the case of the shielded metal in O_2 the carrier film becomes segregated and the metal surface is significantly freed with partial or complete removal of the SIMC effect after further mild reduction (Fig. 6).

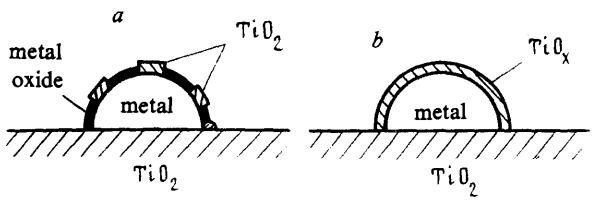

Figure 6. Model of the shielding of the metal surface by the carrier for different types of treatment: *a*, O_2, 673 K; *b*, H_2, 773 K.

Tauster, Vannice, Haller, Dumesic and over investigators,[9,24,29,31,67,68] who studied in detail the SIMC effect, frequently drew attention to the fact that often the carrier does not simply creep mechanically onto the metal, diminishing its surface area, but enters into electronic interactions with it, altering its properties. This can be seen particularly clearly in the study of metals coated by an incomplete TiO_x monolayer.[53,67]

The shielding of the metal surface by TiO_x combined with the electronic interaction is also observed when the metal is deposited on a support modified by TiO_2. Thus the study by XPS and Auger spectroscopic methods of platinum deposited on SiO_2 coated by 1–2 monolayers of TiO_2 showed that, apart from the partial shielding of the metal surface by the TiO_x oxide at high reduction temperatures, anionic vacancies and Ti^{3+} ions are formed and the platinum atoms interact with Ti^{3+}.[69] Admittedly, in contrast to the Pt/TiO_2 catalysts, in the Pt–TiO_2–NiO_2 system the TiO_2 phase exhibits a lower mobility and is more difficult to reduce as a consequence of the formation of strong linkages of the type Si–O–Ti.

3. Thermodynamic factors

In this section we shall consider the thermodynamic aspect of the SIMC effect. Theoretical calculations for the interaction of platinum with TiO_2 have led to the conclusion that, on strong interaction after the high-temperature reduction, the platinum crystallites should become lamellar.[16] This was indeed observed in an electron microscopic study of the Pt/TiO_2 catalyst in an H_2 atmosphere at 1075 K (Fig. 7), TiO_2 being reduced under these conditions to

Ti_4O_7, while the platinum particles on SiO_2 have a spherical shape.[70] Baker[71] showed that in H_2 at 875 K the spreading of platinum takes place after 10 s. Subsequent treatment in O_2 at 875 K of the Pt/TiO_2 catalyst reduced at a high temperature alters reversibly the morphology of the platinum crystals to the spherical form (Fig. 7).[71] From the thermodynamic point of view, this effect can be explained by the fact that platinum wets the surface of the reduced carrier phase more effectively than platinum oxide wets the TiO_2 surface.

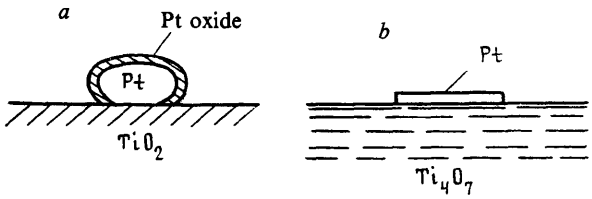

Figure 7. The change in the form of the Pt crystals deposited on TiO_2 and treated in a O_2 atmosphere at 875 K (*a*) and in a H_2 atmosphere at 1075 K (*b*).[70,71]

The spreading of the metal on the surface of the reduced TiO_2 has also been observed for nickel[72] and iron[73] but not for palladium[74] and rhodium.[75]

The existence of lamellar metal crystals is not an unambiguous demonstration of the SIMC. Firstly, this is associated with the experimental difficulty of identifying low-contrast images and, secondly, lamellar crystals have been observed on Ni/SiO_2,[76] Ru/SiO_2,[77] and Ru/Al_2O_3 [78] catalysts where there is apparently no SIMC effect. Evidently in certain systems weak physical forces are insufficient to alter the degree of wetting of the oxide surface by the metal.

The thermodynamic approach can explain also the high mobility of certain carriers coating the metal surface. Ko and Gorte[79] showed that TiO_x and NbO_x wet the platinum surface 5 times more effectively than Al_2O_3 and SiO_2. A comparative study of sorbed TiO_2 and Al_2O_3 layers on nickel yielded similar results. Under these conditions, the TiO_x monolayer occupying 0.1 of the nickel surface alters the catalytic and adsorption properties of the metal to the same extent as for coating by 0.7 of a Al_2O_3 monolayer.[67]

Finally, a thermodynamic model has also been developed for the encapsulation of the metal, according to which the free energy of the deposited system diminishes when the metallic particle is immersed in the carrier provided that the surface energy of the metal exceeds significantly the energy at the metal–carrier interface.[65]

4. The formation of alloys and intermetallic compounds

It was already noted above that the SIMC effect can be manifested also when a metal is deposited on SiO_2 and Al_2O_3. The reduction of the Pt/Al_2O_3 catalyst can be represented by Eqns. (1) and (2). It has been suggested[80] that the formation of a surface alloy via reaction (2) is a more realistic process:

$$Pt + Al_2O_3 \underset{\frac{1}{2}O_2,\ 723\ K}{\overset{H_2,\ 773\ K}{\rightleftharpoons}} Pt \cdot Al_2O_3, \qquad (1)$$

$$Pt + {}^1/_3Al_2O_3 \underset{\frac{1}{2}O_2,\ 723\ K}{\overset{H_2,\ 773\ K}{\rightleftharpoons}} Pt \cdot Al_{2/3}. \qquad (2)$$

The formation of the intermetallic compounds Pt_xAl_y has been observed for a platinum film 200 nm thick deposited on Al_2O_3 after reduction in H_2 at 1200 K [81] and also in a study of the Pt/Al_2O_3 catalyst under an electron microscope at a high temperature under the influence of an electron beam.[82] Magnetic measurements for the Ni/SiO_2 catalyst reduced at about 1180 K demonstrated the presence of the Ni–Si alloy.[83] If such surface alloys and compounds are formed, they can indeed explain the change in the adsorption and catalytic properties of deposited metals.

The change in the properties of the Pt/TiO_2 system can also be due to the formation of surface intermetallic compounds because the reaction

$$TiO_2 + 2H_2 + 3Pt \rightarrow TiPt_3 + 2H_2O$$

is thermodynamically feasible at 773 K.[84] However, in this case it is not possible to observe a shift of the binding energy of the $4d_{5/2}$ level of platinum.[80] The formation of an alloy between a metal and titanium has been observed[1] at temperatures above 1120 K. In general, for metals deposited on TiO_2 the SIMC state is induced by reduction at lower temperatures than are required for the formation of intermetallic compounds such as Pt_3Ti, Ir_3Ti, and Ni_3Ti and, furthermore, metallic titanium could not be identified under any conditions.[85,86] Nevertheless, the presence of two types of Ni–Ti(Ni–Nb) distances has been established by the EXAFS method for the Ni/TiO_2 and Ni/Nb_2O_5 catalysts reduced at 773 K, the shorter distance of 2.62 Å (2.65 Å) being comparable to the distance characteristic of the corresponding alloys.[87] The structure of the carrier is apparently reorganised in the vicinity of the nickel particles. In a recent study[88] using high-resolution electron microscopy and Pt/TiO_2 and Pt/ZnO catalysts reduced at 773 K and above, the intermetallic compounds Pt_3Ti, PtTi, and PtZn were detected. Direct evidence for the formation of RhTi and especially Rh_3Ti after the reduction of Rh/TiO_2 catalysts at temperatures above 623 K has been obtained by the XANES method.[89]

Thus the question of the formation of alloys and intermetallic compounds and of their influence on catalytic and adsorption properties, especially at reduction temperatures in the range 700 to 900 K, remains controversial. However, for certain catalytic systems one must consider the possibility of the extensive reduction of the carrier. For example, the reduction of the Pt/GeO_2 catalyst even at 573 K is accompanied by the formation of the intermetallic compounds Pt_5Ge,[90] while in the case of the Pt–ZnO system, the compound PtZn appears at the metal–carrier interface after treatment in H_2 above 573 K.[91]

III. Manifestations of the effect in deposited metallic catalysts

1. The influence of the SIMC on chemisorption properties

A typical external manifestation of the SIMC effect is the suppression of the chemisorption of H_2 and CO after the high-temperature reduction of metallic catalysts deposited on TiO_2 with retention of the dissociative character of the chemisorption of H_2. Table 1 presents the literature data for the chemisorption of H_2 and O on various metals deposited on TiO_2. After reduction at 473 K, the ratio of the adsorbed H atoms or CO molecules to the total number of metal atoms characterises the dispersity of the metal on the carrier for Ir, Pt, Ru, Rh, and Pd. This ratio decreases sharply

by a factor of 4–7 and more if the catalysts are reduced in H_2 at 773 K. In the latter case, the metal particle size, calculated from the degree of chemisorption of H_2 or CO, does not correspond to the real particle size determined by the X-ray diffraction and electron microscopic methods. Consequently, the decrease in the degree of chemisorption of H_2 and CO is not associated with the increase in the size of the metal crystals during the high-temperature treatment.

Table 1. Chemisorption of H_2 and CO on metals (M) deposited on TiO_2 (50 $m^2\ g^{-1}$).

Metal	T_{red}, K	H/M	CO/M	Refs.

* T_{red} = reduction temperature.

Similar effects have been observed also for Ni, Fe, and Co deposited on TiO_2. However, a number of features should be noted. Firstly the dispersity of these metals on TiO_2 is usually low (5–10%). Secondly, the extent to which the degree of chemisorption of H_2 diminishes (by a factor of 1.5–2) after the high-temperature reduction is smaller. The clear effect for the 15% Ni/TiO_2 catalyst after reduction at 1023 K (Table 1) is evidently associated with the encapsulation of nickel in the carrier.

The adsorption of H_2 is suppressed after the high-temperature reduction of metals, which may also be deposited on carriers other than TiO_2. The chemisorption of H_2 on iridium-containing catalysts has been investigated.[2] The results are compiled in Table 2.

Tauster emphasised the correlation between the reduction temperature required for the appearance of the SIMC effect and the susceptibility of the oxide carriers to reduction. For the iridium systems, the following series of carriers can be formulated in terms of the decrease in the reduction temperature required to suppress the chemisorption of H_2: $ZrO_2 > Ta_2O_5 > TiO_2, V_2O_3 > Nb_2O_5$,[2,92] although the H/Ir ratios after reduction at 774 K are similar for all the catalysts, except Ir/ZrO_2, and are in the range 0.06–0.01.

Table 2. Chemisorption of H_2 on deposited Ir catalysts.[2]

* S_{sp} = specific surface.

It is possible to quote examples also of other deposited metals. Thus the chemisorption of H_2 on 7.5% Ni/CeO_2 diminishes by a factor of 20 on raising the reduction temperature from 523 to 673 K, on the 3% Rh/Ta_2O_5 catalyst the decrease is by a factor greater than 15 after reduction of 858 K,[33] and on the 15% $Ni/TaO_2–ZrO_2$ catalyst the decrease is by a factor of approximately 8 after raising the reduction temperature from 573 to 793 K.[96]

The decrease in the capacity for chemisorption is frequently accompanied by qualitative changes. The decrease in the initial heats of adsorption of H_2 on the Pt/TiO_2 catalyst from 22.2 to 19.1 kcal mol^{-1} and in the average heats of adsorption from 14.9 to 12.9 kcal mol^{-1} on raising the reduction temperature from 523 to 773 K has been reported.[97] Using the thermoprogrammed desorption method and IR spectroscopy, Raupp and Dumesic[67] showed that, when TiO_x flows onto the nickel surface, the strong centres for the adsorption of CO (apical nickel atoms) with a desorption activation energy of about 134 kJ mol^{-1} are blocked and CO is then sorbed on weaker centres which are not occupied in adsorption on a clean nickel surface owing to the appreciable repulsion between the CO molecules. The long-range electronic influence of TiO_x is believed to be responsible for the decrease by 6 kJ mol^{-1} in the strength of the bonding CO for a degree of surface coverage of nickel by TiO_x of 0.1. The slow absorption of H_2 after the high-temperature reduction of the Ni/TiO_2 and Pt/TiO_2 catalysts, accompanied by a decrease in the strength of adsorption, has been observed.[98] The authors explain this by the slow binding of hydrogen at the metal–carrier interface or on the TiO_x coating of the surface of the metallic particles.

In a study of the states of adsorbed CO on the Ni/TiO_2 surface (film 120 Å thick on a thin layer of TiO_2), reduced at 700 K, and on the surface of nickel single crystals, the high-resolution spectra of the

electron energy losses for the deposited nickel showed a faster decrease in the intensity of the 1910 cm^{-1} band (bridging form of CO) as a function of the duration of the treatment of the specimen in H_2 compared with the intensity of the 2020 cm^{-1} band (linear form) owing to the blocking of the surface nickel centres by the TiO_x phase similar to the cluster effect in the alloys.[54] A similar blocking of the nickel centres by the oxide MnO_x (where $x = 0.2-0.5$), whereupon the amount of chemisorbed CO decreases linearly with increase in the area of the shielded metal surface, has been observed after the reduction of Ni(III) single crystals coated by MnO_2.[99] In addition, the appearance of new forms of CO adsorbed at the sites of contact between the nickel particles and the MnO_x "islands", to which corresponds a peak at 305 K in the thermal desorption spectrum and a 1620 cm^{-1} band in the high-resolution electron energy loss spectra has been noted. Vannice et al.[68] state that the band in the IR spectra of CO adsorbed on the Pt/TiO_2 catalyst shifts from 2050 cm^{-1} to 2070 or 2080 cm^{-1} after high-temperature reduction and explains this by the weakening of the Pt–C bond as a consequence of the increase in the filling of the *d* orbitals of platinum in the SIMC state.

As a rule, in the SIMC state the CO/H ratio increases for platinum group metals approximately from 1 to 2 –3,[5] while for Ni, Fe, and CO the ratio CO/H usually changes to a lesser extent.

In the joint adsorption of H_2 and CO on the nickel surface partly coated by TiO_x, the bond between CO and nickel is weakened and the concentration of the strongly bound hydrogen increases by 1–2 orders of magnitude compared with the clean nickel surface, i.e. in this case hydrogen competes successfully with CO for the adsorption centres on nickel.[72]

One of the features of the SIMC effect is its partial or complete reversibility after treatment in O_2 at 673 K [100,101] and after the adsorption of O_2 at 298 K [5] with subsequent mild reduction in H_2 (Fig. 5), which leads to the recovery by the deposited metal of its normal adsorption capacity in relation to H_2 and CO.

At the end of the 1970s, it was believed that the chemisorption of H_2 and CO is not suppressed on metals deposited on SiO_2, Al_2O_3, and certain other non-reducible carriers. However, subsequent experiments showed a decrease in the degree of chemisorption of H_2 on Ni/SiO_2 (reduction temperature 1120–1180 K) by a factor of 3–7 compared with Ni/SiO_2 (920 K) [83] and on Pt/Al_2O_3 reduced at 773 K (the extent to which the degree of chemisorption diminishes depends on the form of Al_2O_3).[102] For the Ni/Al_2O_3 catalyst (873 K), the nickel particle size, determined from the degree of chemisorption of H_2, is greater than the value estimated from electron microscopic data and the strength of the adsorption of H_2 on nickel is diminished owing to the interaction of the metal with the carrier, while the CO/H ratio reaches 4.4.[103]

The introduction into SiO_2 of the TiO_2 or Nb_2O_5 additives in an amount corresponding to one monolayer leads to the SIMC effect in the Ni/TiO_2 (Nb_2O_5)–SiO_2 catalysts reduced at 673 K. In this case, the catalysts can be arranged in the following sequence in terms of the degree of suppression of the chemisorption of H_2: Ni/TiO_2 (Ni/Nb_2O_5) > Ni/TiO_2-SiO_2 ($Ni/Nb_2O_5-SiO_2$) > Ni/SiO_2.[104,105] A similar result has been observed of 1% Pt/Al_2O_3 after the introduction of 4% of Ti into the carrier.[106] In contrast to CO and H_2, the chemisorption of O_2 on deposited metallic catalysts, calculated per m^2 of the metal surface, does not change on raising the reduction temperature of the catalyst, while the size of the metal particles, determined from the degree of chemisorption of O_2 and X-ray diffraction and electron microscopic data, remains unaltered. A change in the stoichiometry of the adsorption of O_2 at room temperature on the Ni/TiO_2 catalyst prepared by impregnating TiO_2 with nickel(II) chloride (O/Ni_{surf} = 1),† compared with Ni/SiO_2 and Ni/Al_2O_3 (O/Ni_{surf} = 2) reduced as 773 and 573 K, and also on the Ni/TiO_2 obtained by impregnating TiO_2 with nickel(II) nitrate, has been noted[107] on raising the reduction temperature from 573 K (O/Ni_{surf} = 2) to 773 and 973 K (O/Ni_{sur} = 1). This conclusion is based on the comparison of the nickel particle sizes estimated from the degree of chemisorption of O_2 and X-ray and magnetic measurements. For the stoichiometries presented above, these dimensions agree satisfactorily. It is noteworthy that the nature of the carrier can influence not only the stoichiometry of the adsorption of O_2 but also the strength of its bond with the deposited metal. For example, the Ir–O bond strength is greater when iridium is deposited on the highly basic MgO surface than on deposition on $Al_2O_3-SiO_2$.[108]

Additional information about the SIMC states can be extracted with the aid of the adsorption of N_2. Resasco and Haller[109] reported that, on reducing the reduction temperature of the 2% Rh/TiO_2 catalyst, the degree of adsorption of N_2 at 523 K increases, while the degree of adsorption of CO at 298 K is suppressed (Table 3). These effects were not observed on the 2% Rh/Al_2O_3 catalyst.

Table 3. The influence of the catalyst reduction temperature on the adsorption of N_2 at 523 K and of CO at 298 K on the 2% Rh/TiO_2 catalyst.[109]

773*	0.01	0.024	0.034

* Repeated reduction after treatment in O_2 at 673 K.

Although Burch and Flambard[110] did observe an increase in the degree of adsorption of N_2 at 273 K on the 1% Ni/TiO_2 and 5% Ni/TiO_2 catalysts reduced at 723 K compared with the 1% Ni/SiO_2 and 5% Ni/SiO_2 catalysts, they concluded that the adsorption centres are the Ti^{3+} cations located next to the oxygen vacancies because reduced TiO_2 adsorbed more N_2 per unit carrier surface than the Ni/SiO_2 catalysts, while non-reduced TiO_2 altogether failed to adsorb N_2. In the presence of nickel, the adsorption capacity of TiO_2 increased by virtue of the ready reduction of TiO_2 by the atomic hydrogen formed on nickel. Thus the increase in the amount of N_2 adsorbed on deposited metallic catalysts with increase in the preliminary reduction temperature can be regarded as one of the signs of the occurrence of the SIMC, although its interpretation is controversial.

† Ni_{surf} represents nickel atoms on the surface.

2. Catalytic properties and the strong interaction of metal with the carrier

The SIMC effect is manifested not only in the adsorption properties but also in the catalytic properties of deposited systems. With increase in the temperature of the reduction of metals deposited on TiO_2, a decrease in their activity is observed in the hydrogenolysis of hydrocarbons, the hydrogenation of benzene, the dehydrogenation of cyclohexane, and the isomerisation of methylpentanes. On the other hand, an increase in activity in the D_2-H_2O exchange and in the H_2 + CO and NO + CO reactions as well as the change in selectivity in the CO + H_2 reaction had been observed compared with metals deposited on SiO_2 and Al_2O_3 or on non-deposited metals.

We shall consider initially the structure-sensitive (in terms of Boudart's classification[111]) reactions of hydrocarbons such as hydrogenation, dehydrogenation, and isomerisation.

The experimental data for the benzene hydrogenation and cyclohexane dehydrogenation reactions on Rh, Ir, and Pt deposited on TiO_2 (Table 4) indicate a decrease in the activity of the Ir and Pt catalysts by an order of magnitude with increase in their reduction temperature.

Table 4. The influence of the reduction temperature of the metals deposited on TiO_2 on their activity in hydrogenation and dehydrogenation reactions.

* W is the catalyst activity.

** Relative to the activity of the specimen reduced at 473 K.

For the hydrogenation of benzene at 403 K, the activity of the 9.8% Ni/TiO_2 catalyst, reduced at 723 K, is 44 × 10^3 molecules s^{-1} Ni^{-1}, which is smaller by a factor of 4.75 than the activity of the same catalyst reduced at 523 K and by a factor of 3.61 than the activity of the 9.8% Ni/SiO_2 catalyst reduced at 723 K.[114] The decrease in the degree of conversion of benzene in hydrogenation at 393 K from 83 to 30% with increase in the catalyst reduction temperature from 673 to 793 K respectively has been observed on a catalyst containing 15% of nickel and deposited on a TiO_2-ZrO_2 mixed carrier (TiO_2/ZrO_2 = 1/1),[96] the SIMC state being abolished after the subsquent oxidation and reduction of the specimen at 573 K.

The relative probabilities of desorption and hydrogenation in the reaction of ethylene with deuterium have been determined.[115] It was found that the probability of the desorption of ethylene from Pt/TiO_2 is six times greater than from Pt/SiO_2. The authors explain this by the decrease in the strength in the absorption of ethylene on Pt/TiO_2 as a result of electron transfer from the carrier to the metal, although one should note that the catalyst was reduced at 573 K.

In the isomerisation of methylpentanes on the Pt/TiO_2 catalyst, the specific activity was smaller by a factor of 50 than on the Pt/Al_2O_3 catalyst, while the adsorption of hydrogen was suppressed slightly.[116] The isomers are formed mainly via the mechanism involving the migration of bonds in intermediate compounds.

The structure-sensitive hydrogenolysis reactions of saturated hydrocarbons and the interactions in the CO + H_2 reaction constitute a good test of the change in catalytic properties under the influence of the SIMC.

Table 5 presents data obtained[117] for the hydrogenolysis of ethane at 478 K on metals deposited on TiO_2 and SiO_2, reduced at 773 K for 16 h. It is noteworthy that the specific activity was calculated assuming 100% dispersity of the metal on TiO_2, which does not introduce serious errors for noble metals. However, this hypothesis is incorrect for Fe, Ni, and Co, because their dispersity is usually in the range 5–10%. Thus the real relative decrease in activity is greater by a factor of 10–20 than the values quoted in Table 5. Furthermore, iron in the SIMC state is almost inactive probably owing to the encapsulation effect. In terms of the decrease in the activity of the metal by the SIMC in the hydrogenolysis of ethane compared with the activity in the state of a weak interaction (M/SiO_2), the Group VIII noble metals can be arranged in the following sequence: Pt > Pd > Os, Ir > Rh > Ru, the activity of Ru remaining unchanged.

Table 5. The activities of deposited Group VIII metals, reduced at 773 K, in the hydrogenolysis of ethane at 478 K.[117]

M	W, mol h^{-1} m^{-2}		Relative specific activity of SiO_2/TiO_2
	SiO_2	TiO_2	
Fe	$1.2\cdot10^{-5}$	$<10^{-13}$	$>10^8$
Co	$3.4\cdot10^{-5}$	$1.0\cdot10^{-9}$	$3.4\cdot10^4$
Ni	$8.0\cdot10^{-4}$	$8.0\cdot10^{-7}$	10^3
Ru	$1.8\cdot10^{-3}$	$1.4\cdot10^{-3}$	1.3
Rh	$2.2\cdot10^{-4}$	$2.9\cdot10^{-5}$	7.6
Pd	$6.7\cdot10^{-10}$	$2.6\cdot10^{-13}$	$2.6\cdot10^3$
Os	$4.2\cdot10^{-2}$	$9.6\cdot10^{-5}$	$4.4\cdot10^2$
Ir	$1.1\cdot10^{-4}$	$3.0\cdot10^{-7}$	$3.7\cdot10^2$
Pt	$7.2\cdot10^{-10}$	$<10^{-13}$	$>7\cdot10^3$

A sharp decrease in the activity in the hydrogenolysis of n-butane and neopentane in the presence of Ir/TiO_2 in the SIMC state,[118] in the hydrogenolysis of n-hexane in the presence of Pt/TiO_2 [90] and Ni/TiO_2,[114] and in the hydrogenolysis of n-heptane in the presence of Ru/TiO_2 [119] has been noted.

On deposition of 9% of nickel on SiO_2 coated by a monolayer of TiO_2, the activity of nickel in the hydrogenolysis of ethane falls by 2–3 orders of magnitude compared with its activity on SiO_2.[104] A decrease in the activity of the 9% Ni/SiO_2-TiO_2 system from 5.6 × 10^{-5} to 9.5 × 10^{-6} molecules s^{-1} Ni_{surf}^{-1} with increase in the

specimen reduction temperature from 573 to 773 K has also been noted.

Such effects are not characteristic of catalysts with a TiO_2 carrier alone. Thus, on raising the reduction temperature of the 10% Ni/Nb_2O_5 system from 573 to 773 K, its activity in the hydrogenolysis of ethane falls by a factor of 35,[120] while the activity of the 9% $Ni/Nb_2O_5-SiO_2$ catalyst (Nb_2O_5 monolayer on a SiO_2 surface) diminishes under similar conditions by a factor of 14.[105]

The catalytic properties of deposited metals in the SIMC state have been studied in greatest detail in the CO + H_2 reaction, their activity being significantly higher than that of the metal single crystals and metals deposited on Al_2O_3 and SiO_2. Table 6 presents the activities for the Ru, Rh, Pt, and Ir catalysts.

Table 6. Specific activities of deposited Group VIII noble metals in the CO + H_2 reaction at 548 K and for the ratio CO/H_2 = 3.

M, %	T_{red}, K	$10^3 W$, $M_{surf}^{-1} s^{-1}$	Relative activity		Refs.

2% Ir	723	45	17	45	[95]

Evidently the specific activity of the M/Al_2O_3 catalyst is higher than that of the M/SiO_2 catalyst (the activity of the latter is comparable to that of the non-deposited metals). This is usually explained by the greater extent of the interaction of the metal with the carrier for the M/Al_2O_3 systems.[5] A strong interaction of the metal with the carrier does not affect the activity of Ru, which is correlated with the ease of the spreading of Ru on the surfaces of different carriers.[77,78] However, the selectivity of Ru/TiO_2 in relation to C_2 hydrocarbons and hydrocarbons with higher molecular weights is appreciably higher.[123] The specific activity of Rh, Ir, and Pt deposited on TiO_2 is higher approximately by 1 and 2 orders of magnitude than the corresponding values for catalysts deposited on Al_2O_3 and SiO_2, the fact that the activity of Rh/TiO_2 is highest being correlated with the highest reactivity of the CO adsorbed on it.[124] As regards selectivity, the latter does not change appreciably for Ir and Pt, whereas on Rh/TiO_2 and Rh/Al_2O_3 the main reaction product is methane and on Rh/SiO_2 it is methanol.[121,125] The data obtained by Japanese workers for the Rh/TiO_2 and Ir/TiO_2 catalysts[126] conflict with the above results, since the rate constants for the conversion of CO into methane hardly change on transition to the SIMC state. On the other hand, for Pt and Pd in the SIMC state, the rate constant is 10 times smaller than in the "normal" state.[127]

Deposited Fe, Co, and Ni apparently behave differently in the CO + H_2 reaction. Owing to the Fe encapsulation effect, it is difficult to observe the changes in catalytic properties on different carriers. Cobalt deposited on TiO_2, SiO_2, and Al_2O_3 has comparable activities.[4] On the other hand, the SIMC exerts an appreciable influence on the catalytic properties of the Ni/TiO_2 system. This system therefore merits greater attention.

Vannice[95] noted that the activities of various Ni/TiO_2 catalyst specimens, reduced at 723 K, in the CO + H_2 reaction at 548 K exceeds by a factor of 2–37 the activity of Ni/Al_2O_3 and Ni/SiO_2. In another study,[128] the ratio of the activities of the 5% Ni/TiO_2 and 5% Ni/SiO_2 catalysts, reduced at 723 K, was 33.8 at a reaction temperature of 553 K. The change in the activity of Ti in the SIMC state is as a rule accompanied by an improvement of selectivity in relation to higher hydrocarbons. Thus, whereas the selectivity of 9.8% Ni/SiO_2 (reduction temperature 723 K) was 9.3%, for 9.8% Ni/TiO_2 (723 K) it amounted to 27.7%.[114] At a reaction temperature of 600 K, the selectivity in relation to methane reached 99.82% for 9% Ni/Al_2O_3 (700 K), 54.6% for 13% Ni/TiO_2, and 68.1% for 12.5% Ni/Nb_2O_5 (700 K) (reaction temperature 503 K).[129]

The rate-limiting stage in the CO + H_2 reaction in the presence of deposited nickel catalysts is known to be either the dissociation of the adsorbed CO [130] or the hydrogenation of surface carbon.[131] A series of kinetic models have been proposed for the Ni/TiO_2 catalysts in the SIMC state,[132,133] according to which an increase in the fraction of hydrogen adsorbed on the surface, the weakening of the bond between CO and the metal, and other factors examined in detail above increase the rate of the rate-limiting stage. These conclusions have been confirmed by kinetic experiments on the hydrogenation of atomic carbon and the dissociation of CO on nickel-containing catalysts reduced in H_2 at 723 K. It was found that, while the activation energy remains unchanged, the specific rates of hydrogenation of carbon in the presence of nickel on different carriers differ by more than an order of magnitude, diminishing in the sequence Ni/TiO_2 > Ni/Al_2O_3 > Ni/SiO_2.[134] In addition, the order of the reaction with respect to H_2 is twice as great for Ni/TiO_2 as for other catalysts. The dissociation of CO on Ni/TiO_2 is also much faster.

A model has been proposed[114] for the Ni/TiO_2 system containing large nickel particles in which the specific influence of the carrier is restricted to the interface between the metal and the carrier. The increased activity of Ni/TiO_2 in the CO + H_2 reaction can be explained by the appearance of specific centres at the interface on which CO molecules are activated (Fig. 8*a*).

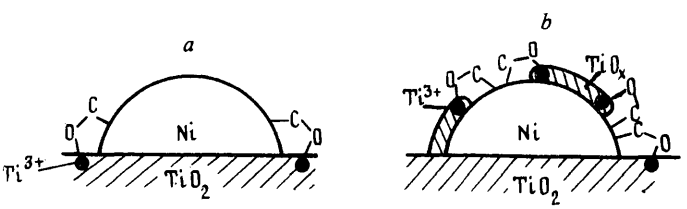

Figure 8. Model of the active centre in the CO + H_2 reaction at the interface between the Ni particle and the surface of the carrier after reduction at 573 K (*a*) and 773 K (*b*).[114]

Ponec[8] and Takatani and Chung[54] hold a similar view. In later investigations,[135] where an increase in activity in the CO + H_2 reaction was not observed for Ni, Pd, and Ir (deposited on TiO_2) in the SIMC state (suppression of the chemisorption of H_2 and of

activity in the hydrogenolysis of ethane), the model taking into account the phenomena at the interface was developed further (Fig. 8*b*). According to the authors,[135] the reduction of the catalyst at temperatures of about 723 K leads to the migration of TiO_2 onto the surfaces of metallic particles and the creation of new superactive centres at the interface. A significant proportion of the less active metallic centres are then shielded and ultimately the overall activity remains almost unaltered.

Chung et al.[136] rejected the model of Burch and Flambard on the grounds of data obtained for sputtered Ni/TiO_2 (100) specimens and for Ni (111) partly coated by TiO_2. They were treated in H_2 at 773 K. The authors believe that, if the active centres were located on the periphery of the nickel "islands", then the maximum concentration of such centres and hence their activity would have been observed for coverages corresponding to 0.6 of a nickel monolayer on TiO_2 or 0.6 of a TiO_2 monolayer on nickel. On the other hand, the highest experimental activity was shown by specimens containing three nickel monolayers on TiO_2 (100) and 8% TiO_x on Ni (111). Furthermore, their catalytic properties proved to be similar. It was concluded that the TiO_x diffusing onto the catalyst surface exerts a decisive influence on the activity of nickel. Similar conclusions (diffusion of CeO_x) have been reported[60] for the Ni/CeO_2 system.
