where p_o and u_o are the pressure and velocity of gas at the column outlet, p_i is the pressure at the inlet, L and d are the length and internal diameter of the column, J_2^3 is the pressure drop factor $\{J_2^3 = {}^2/_3[(p_i/p_o)^3 - 1]/[(p_i/p_o)^2 - 1]\}$. The experimental equipment comprises a system of two identical capillary columns that are connected via a valve. The pressures at the inlet and outlet of the system p_i and p_o are kept at a constant level, and the gas velocity is controlled by the valve, with readings taken from manometers between the columns before and after the valve. The authors proposed a simple graphical method for determining B_{GG}, μ_0, and α from the experimental values of the pressures and flow rate of gas. The calculated error in the determination of B_{GG} and α for compounds with a boiling point close to room temperature is not more than 1%. By varying the composition of the gas mixture, it is readily possible with this system to determine the concentration dependence of B_{GG}, μ_0, α, from which the intermolecular interaction potential in the gas phase can be calculated.[34]

4. Determination of the saturated vapour pressure of compounds with low volatility

In contrast to other methods, the gas chromatographic method of determining saturated vapour pressure does not require the compound under study to be highly pure, but on the other hand it can be used to record simultaneously the vapour pressures of several components that are present in very small quantities in mixtures. Virtually all the studies on the gas chromatographic method for determining vapour pressure on capillary columns are devoted to highly toxic materials that contaminate the environment. The method is based on the assumption that the adjusted retention time of sorbates ($t'_R = t_R - t_M$) is inversely proportional to their saturated vapour pressure. This assumption is only strictly valid for ideal solutions in which the environment of a molecule is similar to the condensed state of pure sorbate. Thus, this approximation is closer the greater the similarity between the molecules of volatile substances and the stationary phase.

It follows from the Clausius–Clapeyron equation for the vapour of substances that

$$d(\ln p_i^0) = \left(\frac{\Delta H_i}{\Delta H_{st}}\right) d(\ln p_{st}^0), \qquad (6)$$

where p_i^0 and p_{st}^0 are the saturated vapour pressures of the substance under study and a standard, ΔH_i and ΔH_{st} are their heats of evaporation. In the approximation used, the relative retention of a pair of sorbates is inversely proportional to their relative volatility:

$$k_i/k_{st} = p_{st}^0 / p_i^0, \qquad (7)$$

and

$$\ln p_i^0 = \ln p_{st}^0 - \ln(k_i/k_{st}). \qquad (8)$$

Incorporating Eqn. (6), we can write

$$\ln(k_i/k_{st}) = (1 - \Delta H_i/\Delta H_{st}) \ln p_{st}^0 - C, \qquad (9)$$

where C is a constant.

A compound which is chemically similar to the substance being studied and having a known heat of evaporation, boiling point, or saturated vapour pressure is used as the standard.[35] It is assumed in this case that $(\Delta H_i/\Delta H_{st})$ is independent of temperature over a wide range. The values of the constants $(\Delta H_i/\Delta H_{st})$ and C are determined graphically, by plotting the dependence of $\ln(k_i/k_{st})$ on $\ln p_{st}^0$ at different temperature. The required vapour pressure is calculated from the equation

$$p_i^0 = p_{st}^{0(\Delta H_i/\Delta H_{st})} \exp C, \qquad (10)$$

which follows from Eqns. (8) and (9).

The saturated vapour pressures of polychlorinated biphenyls were determined in a similar manner using a short glass CC (1 m × 0.25 mm) with an Apolane-87 phase.[36] Isobutyl 2,4,5-trichlorophenoxyacetate was used as the standard. The values of p_i^0 extrapolated to 25 °C were $2 \times 10^{-4} - 4.5 \times 10^{-6}$ mmHg. The error in determining p_i^0 was not more than 30%. However, at 25 °C the sorbates are solids, and therefore the derived vapour pressures will probably be somewhat overestimated, since all the calculations related to a gas-liquid equilibrium at the temperature of chromatographic separation (60–130 °C). The author's argument about the need to use the most nonpolar stationary phase is also questionable, since the sorbates are compounds with medium polarity. Subsequently, in order to determine the vapour pressure of organochlorine and polyaromatic compounds, Bidleman[37] used a quartz CC (1 m × 0.22 mm) with immobilised poly(dimethylsiloxane) BP-1 in addition to a column with an Apolane-87 phase. He used n-alkanes (C_{18} and C_{20}) and dibutyl phthalate as standards. However, the use of dibutyl phthalate gave values of the vapour pressure of nonpolar sorbates that were too low, so it was recommended to use $C_{14}-C_{16}$ n-alkanes when $p_i^0 = 10^{-1}-10^{-2}$ mmHg and $C_{22}-C_{24}$ n-alkanes when $p_i^0 < 10^{-6}$ mmHg as standards.

In order to assess the accuracy of the gas chromatographic determination of p_i^0, the data obtained were correlated with known values of the saturated vapour pressure. Although the temperature of separation of the components on capillary columns is considerably lower than their boiling points, it may be assumed that the experimental values of vapour pressure (p_{GC}) do in fact correspond to the vapour pressures above supercooled liquids (p_l). The equilibrium vapour pressure above a solid (p_{sol}) at 25 °C may be calculated from the entropy of fusion ΔS_f and melting point T_m of the compound respectively:[38]

$$\ln(p_l/p_s) = \frac{\Delta S_f(T_m - 298)}{298R}. \qquad (11)$$

Since the values of the entropy of sorption of a large number of compounds average out to 56.5 kJ mol^{-1} deg^{-1}, in the calculations frequent use is made of the empirical equation of MacKay:[39]

$$\ln(p_l/p_s) = 6.8(T_m - 298)/298.$$

Bideleman[37] found that the experimental vapour pressure values (p_{GC}) correlate well, but in the majority of cases they do not match the saturated vapour pressure values (p_l) determined by other methods. The correlation coefficients of the linear relationship

$$\log p_{GC} = m \log p_l + b \qquad (12)$$

for columns with Apolane-87 and BP-1 were 0.97–0.98, with the smallest deviation of p_{GC} occurring for the column with Apolane-87.[37] However, the column with BP-1 proved more convenient for a determination of the vapour pressure of chlorinated derivatives of phenol and hydroquinone.[40] The relationship between p_{GC} and p_l which was derived for chlorophenol was used in a chromatographic determination of the saturated vapour pressure of chloroguaiacols, chloroveratroles, and 4-nonylphenol.[40]

Kim et al.[41] studied the effect of different experimental factors on the accuracy of the gas chromatographic determination of the saturated vapour pressures of 20 organophosphorus pesticides with different structures. Parathion, methylparathion, diazinone, and dibutyl phthalate were used as standards. The length of the capillary columns (from 1 to 27 m) and the nature of the nonpolar stationary phases (SE-30, SE-54, RSL-100) did not have much effect on the magnitudes of the experimentally determined vapour pressures. To achieve a relative standard deviation of less than 10% it was necessary to determine the retention coefficients at five or more temperatures at 5 °C intervals or at three temperatures at 15 °C intervals. Comparison of the vapour pressures derived by the gas chromatographic method with the vapour pressures determined by the gas saturation method showed that the greatest accuracy in the gas chromatographic determination of vapour pressure is achieved when a standard that is closest in nature to the components under study is used. The lowest accuracy was recorded in the determination of saturated vapour pressures of polar compounds and components that were solids at room temperature.[41]

By using a 75 centimetre-long CC with grafted poly[dimethyl-(5%)-diphenylsiloxane] DB-5 (0.25 μm), Eitzer and Hites[42] determined the saturated vapour pressures of a number of polychlorinated dibenzo-*p*-dioxins and dibenzofurans. *p,p'*-DDT, which is eluted in a similar manner to the components being studied, was chosen as the standard. The vapour pressure of DDT was repeatedly determined by independent methods. Like the components under study, DDT is detected using a high-sensitivity electron capture detector, which makes it possible to decrease the quantity of sample to a minimum and hence exclude the possibility of overloading short CCs.[38] The authors[42] established a good correlation between the derived vapour pressure values and the retention indices of the respective dioxins and dibenzofurans determined on a CC of the same type (DB-5).[43,44] From the correlative equation obtained it is possible to predict the saturated vapour pressures of many compounds of these classes from their gas chromatographic retention indices. A comparison of the vapour pressure values determined on a column with DB-5 with the values determined by other methods showed that the gas chromatographic method gives underestimated pressure values for dibenzo-*p*-dioxins and dibenzofurans with a low chlorine content and values that a overestimated for their highly chlorinated analogues.[42]

Hinckley et al.[38] also determined the saturated vapour pressure of a number of organochlorine and organophophorus compounds and phthalate esters, using *p,p'*-DDT as a standard. The vapour pressures were 10^{-2}–10^{-4} Pa (25 °C). The authors concluded[38] that the main reasons for the lack of agreement between the vapour pressure values determined by chromatography and by other methods lie in the experimental errors in the determination and also in differences between the activity coefficients and of the compounds being studied in the stationary phase. In general, ideality of the solutions in the stationary phase is not essential for the gas chromatographic method. It is only necessary that the degree of nonideality for the compound being studied and the standard is the same. Thus, equations (7)–(9) for nonideal solutions must contain the additional terms γ_{st}/γ_i and $\ln(\gamma_{st}/\gamma_i)$ respectively, and the accuracy of this method depends on the similarity between the activity coefficients of the compound under study and the standard in the stationary phase. The authors concluded that the gas chromatographic method is of limited suitability for determining the saturated vapour pressure of polar compounds because of the difficulty in selecting a suitable polar standard due to the marked differences between the activity coefficients of polar compounds.[38]

5. Determination of activity coefficients

Lunskii and Paizanskaya[45] recently put forward a method for the determination of activity coefficients at infinite dilution from the retention indices and saturated vapour pressures of sorbates. The retention indices of hydrocarbons from the gasoline fractions of unfractionated condensates were determined on glass CCs with squalane and dinonyl phthalate. For compounds having similar activity coefficients, the dependence of the retention indices on the logarithm of the partial saturated vapour pressures comprises a series of parallel lines with the same slope, governed by the relative retention of the n-alkanes used to determine the retention indices. Points that correspond to compounds with a similar molecular structure lie on each straight line of this series. The activity coefficients are determined from the values of the intercepts on the y-axis. It is also necessary to know the saturated vapour pressure of the n-alkanes used and their activity coefficients in the stationary phases for the calculation. It was established from the data obtained that isoalkane and naphthenic hydrocarbons form athermal solutions in squalane while in dinonyl phthalate their activity coefficients decrease with increase in temperature. For aromatic hydrocarbons the reverse effect occurs when the phases are changed. Solutions of all these hydrocarbons in squalane exhibit negative deviations from Raoult's law, while in dinonyl phthalate both negative and positive deviations occur.[45]

6. Determination of the lipophilicity of volatile compounds

Lipophilicity is an important property of biologically active compounds, and it is frequently determined as the logarithm of the distribution constant ($\lg K$) of these compounds in the system octane–water. The direct determination of distribution coefficients of a very large number of chemical compounds investigated at regular intervals for biological activity is difficlt using a static method or reverse-phase liquid chromatography.

In order to make use of the extensive quantity of gas chromatographic data, Kuchar et al.[46,47] developed a method for the indirect determination of lipophilicity of homologous series of structurally similar compounds from their retention indices on nonpolar and polar capillary columns. The distribution constant in the system octanol–water can be represented as the product of the distribution constants in the systems octanol–gas and gas–water: $K_{o/w} = K_{g/w}K_{o/g}$. Unfortunately, gas chromatographic determination of distribution constants in these sytems is impossible because of the high volatility of water and octanol, so normal stationary phases (SFs) are used instead,

assuming a similarity between water and a polar SF (PSF) and between octanol and a nonpolar SF (NSF):

$$K_{o/w} \cong K_{g/PSF} K_{NSF/g},$$

$$\log K_{o/w} \cong \log(K_{NSF}/K_{PSF}) + A,$$

or

$$\log K_{o/w} = \log(V'_{R,NSF}/V'_{R,PSF}) + B,$$

where A and B are constants.

By further assuming a linear relationship between the adjusted retention volumes (V'_R) of the compounds and their retention indices ($I = \alpha \log V'_R + \beta$), it was possible to derive the relationship

$$\log K_{o/w} = CI_{NSF} - DI_{PSF} + E, \quad (13)$$

where C, D, and E are constants. By using, on the one hand, a database of Kováts indices determined on quartz CCs with SE-30 phases [poly(dimethylsiloxane)] and OV-351 (a copolymer of poly(ethylene glycol) and nitroterephthalic acid) phases[48–50] and, on the other hand, the values of lipophilicity calculated by additive methods, the authors determined the coefficients in Eqn. (13) for a large number of homolytic series of aliphatic, olefinic and aromatic esters and their chloro and nitro derivatives.[46,47] It transpired that for groups of homolytic series of structurally similar compounds the coefficients in Eqn. (13) were similar, and their lipophilicity could be calculated approximately from the common correlative equations. The high statistical significance of these equations (r = 0.921 to 0.999) is an indication of the suitability of the chosen column system for an indirect determination of lipophilicity. At the same time, the similarity between the systems SE-30–OV-351 and octanol–water is very arbitrary, and the retention volume is in fact related nonlinearity to the Kováts indices, especially for the primary members of the homolytic series.[51] Moreover, it was established that the Kováts indices on polar stationary phases cannot serve as parameters for the relative solubility of compounds since the n-alkanes used to determine them are retained to a significant extent through adsorption on the surface of the polar phase.[52–54] All these factors limit the applicability of this method to an approximate determination of lipophilicity.

The most accurate method of assessing the lipophilicity is a direct determination of the distribution constant in a static experiment. In order to determine the distribution coefficients of highly lipophilic compounds, Haky et al.[55] analysed the composition of the equilibrium water and octanol phases on a quartz CC with immobilised poly[phenyl-(5%)-methylsiloxane] DB-5. The internal standards used were anthracene and fluorene, which have well-established distribution coefficients. The recorded values of lipophilicity matched the literature data within the limits of experimental reproducibility (±0.2 units of $\log K_{o/w}$). Thus, by combining the distribution method with a quantitative analysis of the phases on a high-performance capillary column, it was possible to determine with reproducibility and accuracy the lipophilicity of compounds up to values of $\log K_{o/w} = 5.7$.[55]

7. Study of the properties of polymers

The solubility of compounds in industrial polymers is of interest in terms of its technological, hygiene and sanitation, and toxicological aspects. Capillary columns have been used to study the solubility of organic copounds in polyisobutylene, poly(vinyl acetate), poly(dimethylsiloxane),[56,57] polystyrene,[58] and poly-ethylene.[59] It was established in three studies[56,57,59] that the specific retention volumes of organic compounds in high-molecular-weight polymers deposited in capillary columns is higher than in packed columns. The specific retention volumes of 13 organic compounds, including THF, alkanes, alkenes, and arenes in a relatively thick layer (~1.4 μm) of low-density polyethylene (LDPE), dynamically deposited on a CC made of stainless steel, were measured over a wide temperature range (50–175 °C).[59] Because of the significantly nonequilibrium nature of the sorption, the retention volumes were extrapolated to zero flow of carrier gas. From the experimental finding and a considerable quantity of literature data, it was possible to derive correlative equations that related the specific retention volumes on HDPE (V_g) at different temperature with the critical parameters of the sorbates:

$$\ln(V_g p_c/100) = a + b(T_c/T)^2, \quad (14)$$

where p_c, and T_c are the critical pressure and temperature of the sorbates; a and b are constants. The correlation coefficients for equations of the type (14) are 0.991 and 0.987 for molten and rubbery LDPE. By using these equations, it is possible at given temperatures to determine the solublity of any nonpolar or medium-polar compounds in polyethylene when their critical pressure and temperature are known.

According to the results of Pawlisch et al.[58] the graphs of the dependence of exit time of the chromatographic peak maximum on the velocity of the carrier gas frequently have considerable curvature, and extrapolation to zero flow can lead to errors in the determination of true retention volumes. The same authors determined the retention volumes of benzene, toluene, and ethylbenzene on a glass CC with thick layers (7–12 μm) of polystyrene from the magnitudes of the primary peak features by means of numerical treatment of the computer signal. Subsequently the activity coefficients at infinite dilution and the Flory–Huggins interaction parameters $\chi_{1,2}$ for these compounds were calculated from the specific retention volumes.

Barrales-Rienda et al.[60] recently determined the specific retention volumes of C_9–C_{13} n-alkanes and C_6–C_{10} aliphatic alcohols in poly[*N*-(n-octadecyl)maleimide] at different temperature. The polymer was deposited on a steel CC (resulting thickness of layer 1.67 μm) using a static method. From the data obtained the authors calculated the actvity coefficients at infinite dilution, the Flory–Huggins parameters $\chi_{1,2}$, and the solubility parameters δ_1 and δ_2. Furthermore, the temperature dependences of the activity coefficients and specific retention volumes were used to determine the partial molar heats of mixing and solution, the sum of which corresponded to the heats of evaporation of the pure sorbates, as calculated from the Clausius–Clapeyron equation. In a similar manner Roth et al.,[61] using glass CCs, determined the excess molar enthalpies of solution of C_8–C_{12} n-alkanes in polysiloxanes. It was found that the values of the excess enthalpies of solution in poly(dimethylsiloxane) SE-30 were positive, while in poly[methyl-n-alkyl(C_8–C_{18})siloxanes] they were negative, which was an indication of the stronger intermolecular interaction between n-alkanes and polysiloxanes having long aliphatic side chains.

8. Study of the properties of liquid crystals

Liquid-crystalline compounds are used in gas chromatography as stationary phases that have unique selectivity towards stereoisomers. In a sense liquid-crystalline phases combine the high capacity of stationary phases with the structural selectivity of adsorbents.

Kirst et al.[62] studied the temperature dependences of the structural selectivity, capacity, and efficiency of copper CCs (40 m × 0.35 mm) with *p,p'*-methoxyethoxyazoxybenzene (MEAB), *p,p'*-azoxyphenetole (AOP), and their eutectic mixture. The

temperatures of maximum structural selectivity, determined from the ratio of the adjusted retention times of *p*- and *m*-xylenes, do not coincide with the temperatures of maximum capacity. The efficiency of the columns increases with temperature. MEAB displays the most favourable combination of these parameters on which the separation of *p*- and *m*-xylenes is dependent. The structural selectivity of the liquid-crystlline phases in capillary columns, as in packed columns, decreases with the thickness of their layers.[62]

Andronikashvili et al.[63] studied the possibility of measuring the temperatures of phase transitions of liquid crystals in steel and copper CCs (50 m × 0.25 mm). The above-mentioned MEAB and *p*-ethoxybenzylidenetoluidine (EBT) were used as the liquid-crystalline phases, It was established that the solidification temperatures of the nematic mesophases are virtually independent of the quantity of phases in the columns and the wall material. The mesomorphic–isotropic transition temperature ($T_{M\text{-}I}$) of MEAB varies by 15 °C with a change in quantity of this phase. The wall material of the columns affects the values of $T_{M\text{-}I}$ of the phases studied in different ways. Thus, on changing from steel columns to copper columns the mesomorphic–isotropic transition temperature for MEAB decreases by 8 °C while for EBT it increases by 27 °C.

The same authors determined the contribution of adsorption to the retention of organic compounds on a liquid-crystalline phase. The "internal standard" method, which assumed in particular that the surface of the walls was completely covered by the liquid-crystalline phase and that the gas–SF boundary remained unchanged on varying the proportion of the latter, was used.[28] Benzene was used as a nonadsorbing standard. It was found that the adsorption of toluene, ethylbenzene, *m*-, *p*-, and *o*-xylenes amounts to 3% of their retention values on MEAB at 95 °C. The contribution of the adsorption of n-alkanes (C_6-C_8) is an order of magnitude less.[63]

N,N' Bis(*p*-butoxybenzylidene)-α,α'-bis(*p*-toluidine) (BBBT) was treated as the stationary phase for the separation of isomeric tricyclic and tetracyclic polyaromatic hydrocarbons on stainless steel CCs.[64] The temperature dependence of the capacity of the column in the nematic mesophase region of BBBT was studied.

Russo et al.[65] recently investigated glas CCs with liquid-crystalline phases on layers of graphitised carbon and kaolin deposited on the internal walls. The phases used were *p,p'*-azoxydiphenetole (ADP) and the above-mentioned BBBT. A study was made of the stereoselectivity and efficiency of the columns in relation to the nature of the support, quantity of the phases, and temperature. It was found that on lowering the temperature, with BBBT changing from a nematic state to a smectic state, the coefficient of selectivity for separation of phenanthrene and anthracene decreased slightly, but because of the accompanying increase in viscosity of BBBT the efficiency of the columns decreased sharply. The use of kaolin has a marked stabilising effect on the efficiency of columns with BBBT and reduces the lower temperature limit by 40 °C for using columns with ADP. Thus, the use of adsorbents as supports is promising in terms of increasing the range of working temperatures and increasing the service life of capillary columns with liquid-crystalline stationary phases.

III. Application of capillary gas chromatography in chemical kinetics

1. Reaction capillary chromatography

Reaction gas chromatography has found extensive application in chemical kinetics.[1–4] Chemical reaction in the columns takes place in parallel with chromatographic separation of its products, which assists their detection and identification using sensitive and selective detectors.[66] Capillary columns are closer to the ideal model of a chromatographic reactor than packed columns, and they can be used to separate the chromatographic zones of the reaction products and the initial reactants more completely, thus assisting a study of the section of the chromatogram lying between them which characterises the reaction occurring in the column.[67]

Möller et al.[68] examined the possibility of using reaction capillary gas chromatography for a determination of thermodynamic and kinetic reaction parameters. The decomposition of dicyclopentadiene in a 60 metre-long copper CC with a Flugizon phase was studied at 189–207 °C.[69] The extent of reaction was assessed from the decrease in area of the peak due to dicyclopentadiene eluted from the column:

$$m_0/m = \exp(k_{exp} t'_R), \quad (15)$$

where m_0 and m are the quantities of dicyclopentadiene before entry and after exit from the column, k_{exp} is the experimental rate constant of reaction, t'_R is the adjusted retention time of dicyclopentadiene. Unfortunately, decomposition occurs simultaneously in both the stationary liquid phase and the carrier gas, which complicates a determination of the rate constants in each of these phases. The value of k_{exp} that is determined experimentally comprises a total rate constant in each of the phases:

$$k_{exp} = k_{SF} + (t_{CG}/t_{SF})k_{CG}, \quad (16)$$

where k_{CG} and k_{SF} are the rate constants of reaction in the carrier gas and stationary phase, t_{CG} and t_{SF} are the residence times of the reactant in the carrier gas and SF, which correspond to the hold-up time and adjusted retention time t_M and t'_R. In order to determine k_{CG} and k_{SF}, it was necessary to vary the phase ratio in the column, which was achieved by blowing off Flugizon at a high temperaure. Flugizon is a mixture of alkylnaphthalenes, so that after blowing off it is most probable that not only the phase ratio changes but also the actual composition of the stationary phase is altered. The authors calculated the rate constants for decomposition of dicyclopentadiene in Flugizon (k_{SF}) at different temperatures, but to calculate the activation energy they used hypothetical rate consant values ($\bar{k}$), which were determined by assuming that the rate constants of reaction in the carrier gas and SF were equal:

$$m / m_0 = \exp(\bar{k} t_R), \quad (17)$$

where t_R is the unadjusted retention time of dicyclopentadiene. The rate constants of reaction in the carrier gas and SF differ, and this approach results in errors. Furthermore, the kinetic data may be distorted because of the high catalytic activity of the copper surface of the capillary column.

2. Study of conformational conversions

Lai et al.[67] used quartz CCs (60 m × 0.2 mm and 25 m × 0.3 mm) with poly(dimethylsiloxanes) OV-1 and CP-Si15 to study the kinetics of conformational conversions in 9,10-bis(2,3-dimethylphenyl)phenanthrene. At 225 °C the *syn* and *anti* isomers of 9,10-bis(2,3-dimethylphenyl)phenanthrene are completely separated, while between them on the chromatogram there is a relatively long empty section of the zero line corresponding to the absence of conformational conversion between the isomers. On increasing the temperature the section between the peaks rises. The peak areas correspond to the number of molecules not participating in conformational conversions while the area of the elevated section between the peaks represents the number of molecules undergoing

conformational conversion in the column. With a decrease in velocity of the carrier gas the residence time of a sample in the hot column increases, and the number of molecules participating in conformational conversions increases. The rate constants for the forward and reverse *syn* → *anti* conversion were calculated from the decrease in peak area of the respective conformer with an increase in its residence time in the column. The values of the rate constants determined at different temperatures were used to calculate the activation energies of the forward and reverse conversions, which were 145 and 115 kJ mol^{-1} respectively. Since, in the opinion of Lai et al.,[67] the conformational conversions probably occur only in the stationary phases, it would be more appropriate to use in the calculations the adjusted retention times, corresponding to the residence of the conformers in the SF (the reaction zone), rather than the total residence time of the isomers in the columns.

The same authors recently studied the kinetics of isomerisation of acetal, butanal, and isobutanal oximes, as well as sterically hindered methylphenylanthracenes and phenanthrenes on CCs with a dimethylsiloxane phase and FFAP.[70] In order to simplify the calculations it was assumed that the rate constants of isomerisation in the carrier gas and SF were equal. The Arrhenius method was used to determine the activation energies, which constituted 100–140 kJ mol^{-1} for the rotational isomerisation of methylphenylanthracenes and phenanthrenes and about 70 kJ mol^{-1} for *syn* ⇄ *anti* conversions of oximes. Lai et al.[70] concluded that it is only possible to determine the conversion barrier in those cases where the initial concentration of a conformer in a binary mixture is not less than 5%.

3. Study of photochemical reactions

A glass capillary column is an ideal reactor for studying photochemical reactions on the surface and in thin layers. The absence of packing and the transparency of the walls permit the free access of radiation to photolabile compounds.[66] In CCs it is possible to deposit different nonvolatile supports and layers and readily batch small quantities of volatile compounds and thus study various photochemical reactions between them.

Laster et al.[66] tested the suitability of glass CCs (10 m × 0.3 to 0.5 mm) for a study of photochemical processes at the gas–solid support phase boundary in a gas adsorption form of chromatography. The photochemical demethylation of dimethylaniline adsorbed on the surface of alizarin was studied as a model. The latter was deposited on the "fluffy" internal surface of a capillary column obtained by etching the walls with 2-chloro-1,1,2-trifluoroethyl methyl ether.

Alizarin, like other anthraquinone derivatives, has strong electron-withdrawing properties in its excited triplet state. Samples of dimethylaniline vapour were introduced either in batches or continuously using a T-shaped diffusion saturator. On irradiation of the CC of the chromatograph in a thermostat with visible light from a halogen lamp, the peak due to dimethylaniline disappeared and in its place a peak due to the product of the photochemical reaction subsquently appeared, identified by chromatography–mass spectrometry as methylaniline. It was established that the frontal method with continuous introduction of sample vapour achieved a higher sensitivity and reproducibility than the development method with batched introduction of sample. In the frontal method a variant of vacancy chromatography occurs. After irradiation with light, two peaks appear at the outlet of the column—a negative vacancy peak due to decomposed dimethylaniline and a positive peak due to the reaction product. The logarithm of the dependence of the degree of reaction on the intensity and duration of column irradiation and the linear dependence on the concentration of the initial reactant indicated that the reaction was first-order with respect to dimethylaniline.[66]

IV. Study of the transport properties of different media

In order to measure diffusion coefficients in gases, liquids, and supercritical fluids, capillary columns without stationary phases are used, while for measurement of diffusion coefficients in polymers the latter are deposited as a uniform layer on the inner walls of capillary columns. The advantages derived from the methods of measuring diffusion coefficients using chromatographic equipment are the simplicity of instrumentation, high output, relatively high accuracy, and the possibility of studying diffusivity under conditions of limiting dilution.

The theory of dispersion of the zones of a nonsorbing compound in hollow cylindrical tubes was developed by Taylor[71] and Aris.[72] The height equivalent to a theoretical plate (HETP), which represents the dispersion of a zone, is defined as the sum of two components, the first of which is due to longitudinal diffusion of a compound in the mobile phase (MP) while the second results from resistance to mass transfer due to the parabolic nature of the flow profile of the MP in a cylindrical tube:

$$H = \frac{2D_{m,o}}{u_o} + \frac{d^2 u_o}{96 D_{m,o}}, \qquad (18)$$

where H is the height equivalent to a theoretical plate, $D_{m,o}$ is the diffusion coefficient in the MP at the column outlet, u_o is the velocity of the MP at the outlet, d is the internal diameter of the column. For a Gaussian elution curve the HETP is defined as

$$H = \frac{L}{N} = \frac{L}{5{,}45} \frac{(W_{0,5})^2}{t_R}, \qquad (19)$$

where L is the length of the column, N is the number of theoretical plates, t_R and $W_{0.5}$ are the exit time of the peak maximum and its width at the half-height. Having determined the value of the HETP, $D_{m,o}$ is calculated from Eqn. (18):

$$D_{m,o} = \frac{u_o}{4}(H \pm \sqrt{H^2 - d^2/12}). \qquad (20)$$

The sign in front of the square root in Eqn. (20) is usually negative, except when a gas with low flow rates is used as the MP.

1. Determination of diffusion coefficients in gases

Tubes with a diameter of 4–5 mm are mainly used to determine diffusion coefficients in gases (D_g).[73–75] When working with capillary columns both a continuous elution method[76] and a stopped flow method[77] have been used.

At the optimum flow rate of gas (u_{opt}) the values of HETP are at a minimum, and the parameter u_{opt} is simply related to the diffusion coefficient of the compound in the gas and the internal diameter of the column:

$$u_{opt} = (8\sqrt{3D_g}) / d. \qquad (21)$$

Using Eqn. (21), Knox and McLaren[78] determined d_g for ethylene in nitrogen from the value of the optimum flow rate in a capillary tube made of nylon (16.64 × 0.88 mm). The continuous elution method

has high output but at the same time it is necessary to have a precise knowledge of the internal diameter of the column and to take into account extracolumn dispersion of the zone, which in the case of using CCs may be fairly considerable.[78,79] In a subsequent study[77] the same authors put forward an alternative chromatographic method for determining D_g which avoids these difficulties. In this method, when the zone of diffusant approaches the centre of the column the flow of carrier gas is stopped and broadening of the zone occurs solely through longitudinal diffusion, which is proportional to the duration of flow stoppage (θ) and the diffusion coefficient of the component in the gas:

$$\sigma_l^2 = 2D_g\theta, \tag{22}$$

where σ_l^2 is the variance of the zone in units of length. After an interval of time θ the flow of gas is restored. The variance of the zone in time units (σ_t^2) recorded by the detector at the column outlet is made up by the extracolumn variance (σ_{ec}^2), the variance of the zone in a column by movement of gas (σ_c^2), and the variance of the zone throughout the period of flow stoppage (σ_θ^2):

$$\sigma_t^2 = \sigma_{ec}^2 + \sigma_c^2 + \sigma_\theta^2. \tag{23}$$

The variance of the peak is measured for different durations of flow stoppage (θ varies from 1 to 20 min). The σ_{ec}^2 and σ_c^2 variances do not depend on the value of θ. Thus, a graph of the variance of the peak against the duration of flow stoppage is a straight line from whose slope the diffusion coefficient is determined ($\tan\alpha = 2D_g/u_O^2$). D_g for ethylene in nitrogen was determined to an accuracy of 2% with this method using nylon tubes (8.34 m × 0.88 mm and 16.40 m × 0.88 mm).[77] A limitation of this method is the need for a small pressure drop in the tube. Thus, with a pressure difference of more than 20 mmHg the velocity of gas cannot be normalised up to the time of peak exit, which results in an overestimated value of the experimental diffusion coefficient.[77]

With a low velocity of carrier gas in a tube of small diameter the contribution of longitudinal diffusion to dispersion is much larger than that of resistance to mass transfer in the gas, and the second term in Eqn. (18) can be neglected:

$$H = 2D_{g,o}/u_o. \tag{24}$$

Taking into account the ratios of the zone variances at the outlet in units of length (σ_l^2) and time (σ_t^2) as well as the average linear rate and velocity of carrier gas at the outlet (u_o), we obtain:

$$D_{g,o} = L^2\sigma_t^2 / 2t^3J^3, \tag{25}$$

where t is the exit time of the peak maximum, J is the Martin pressure drop factor.[80] Thus, in order to determine the diffusion coefficients by a continuous elution method in capillary columns at small flow rates there is no need to have an accurate knowledge of the internal diameter of the column. Lochmüller et al.[79] derived an equation that was similar to Eqn. (25) but which did not include the J factor.

According to the law of additive variance of a chromatographic peak, the apparent dispersion is the sum of dispersions inside the column and outside it:

$$\sigma_t^2 = \sigma_{ec}^2 + \sigma_c^2. \tag{26}$$

In turn the extracolumn contribution is the sum of the variances caused by dispersion of the zone at the inlet and in the detector as well as the broadening of the signal in the detector during its amplification and recording.

When two tubes of different length are used, the extracolumn contribution can be excluded by subtracting the variance of the peak obtained on the shorter reference column from the variance of the peak obtained on the main column.[76] Lochmüller et al.[79] determined D_g for argon in helium from a graph of the linear dependence of the apparent variance of the peak on the length of the tubes employed (from 27 to 62 m):

$$\sigma_t^2 = \sigma_{ec}^2 + \frac{2D_{g,o}}{u_0^3}L. \tag{27}$$

When a microkatharometer was used as the detector the value of σ_{ec}^2 was 35 s^2. This method (subtraction of the systematic dispersion of the zone in columns with different length) is also convenient in that as a result only dispersion of the dilute "wings" of the zone are taken into account and hence the potential effect of a high concentration of diffusant in the centre of the zone is eliminated.[79]

In a recent study[81] an attempt was made to compare the 3 methods for the chromatographic determination of diffusion coefficients in a gas: 1) from Eqn. (20) without taking into account the pressure drop; 2) from Eqn. (20) including corrections for the pressure drop in the column (the J correction factor of Martin[80] and f_g correction factor of Giddings[82]

$$D_{g,o} = \frac{L}{4tJ}\left[\frac{H}{f_g} + \sqrt{\left(\frac{H}{f_g}\right)^2 - \frac{d^2}{12}}\right]$$

and 3) by the computer fitting of the van Deemter curve for a nonsorbing compound. In the latter method use was made of a HETP equation which contained, in addition to the usual terms for longitudinal diffusion and resistance to mass transfer in the gas, an additional term that was linearly dependent on the gas velocity. The latter term, according to Bemgard et al.,[81] can result from interphase resistance through friction of the gas against the walls of the CC and nonideal laminarity of its flow. However, according to the calculations of the authors,[81] the contributions from these phenomena do not make up more than 1% of the experimental values of $D_{g,o}$.

The dispersion of C_4, C_6, and C_{12} n-alkanes and toluene was studied in a quartz capillary column (100 m × 0.32 mm) without a stationary phase in relation to the flow rate of gas (H_2, 2–60 cm s^{-1}). It was established that the diffusion coefficient values determined by the first two methods depend on the gas velocity and the coefficients calculated when the pressure drop was taken into account increase with the flow rate, while they decrease when the pressure drop is ignored. Extraplation of both dependences to zero flow rate gives the same diffusion coefficient value, which agrees with the value determined by the third method, thus indicating that it is true.

A comparison of the diffusion coefficients determined in this manner with the values predicted by theory from the most accurate Fuller–Schettler–Giddings equation[83] showed that the theory gives overestimated values of D_g, which are higher the greater is the length of the n-alkane molecule. Bemgard et al.[81] did not find any correlation between the difference in predicted and experimental values of D_g and the boiling point of the products studied. In this case the geometry of the molecule evidently has a more significant effect on the magnitude of D_g, since the above-mentioned equation is based on a solid sphere model and the difference must be greater the more well-defined are the anisotropic properties of the diffusant molecules.

The gas chromatographic determination of the diffusion coefficients of compounds with low volatility presents certain difficulties, mainly because of their adsorption on the inner walls of the tubes. In order to suppress the adsorption sites on the surface of the walls during determination of D_g for polar compounds, trace amounts of these compounds were added to the carrier gas.[84]

In order to determine the diffusion coefficients of heavy n-alkanes, Vasil'ev et al.[85,86] used an even more radical method of deactivating the surface—silanisation of a glass CC with hexamethyldisilazane. There is also some difficulty in introducing the vapour of components with low volatility as a narrow zone into the column. Batched introduction systems that achieve an initial zone width in the capillary columns of the order of 10 or even 1 ms have recently been developed.[87,88] However, when low velocities of carrier gas are used, the width of the chromatographic zone in time units is so great that good results are obtained with the use of a conventional splitter inlet, which is widely used in capillary chromatography.

According to the results of Vasil'ev et al.,[85] extracolumn dispersion when an inlet with divided flow and coventional chromatographic equipment are used is about 0.5 s^2. With splitter introduction of the sample and the use of a flame ionisation detector the contribution of extracolumn dispersion was reduced to 0.1% of the peak dispersion and this eliminated the need for its compensation on reference columns.[85,86] When the flow rate of gas was 6—18 mm s^{-1} the pressure drop was negligible and the contribution from resistance to mass transfer was 0.1—0.4%, so these were ignored. Samples of pure alkanes were introduced into the splitter at the minimum level for accurate determination of the peak width to be achieved with maximum sensitivity. In order to include the sight inhibition of zone movement as a result of residual adsorption of heavy alkanes, the factor $(1 + k)^{-2}$, where k is the capacity factor ($0 \leqslant k \leqslant 0.13$), was introduced into Eqn. (25). Using this method, D_g values for C_5—C_{24} n-alkanes in helium and n-$C_{18}H_{38}$ and n-$C_{24}H_{50}$ in hydrogen, nitrogen, and argon were determined in silanised glass tubes (1.10 m × 0.25 m and 2.05 m × 0.28 mm).[85,86] It was found that the dependence of the diffusion coefficients of n-alkanes in helium at 200 °C corrected to normal atmospheric pressure on the number of carbon atoms in the molecule ($5 \leqslant n \leqslant 24$) within the limits of experimental accuracy obeyed the equation:

$$D_g^* = 0.081 + 3.553/(n + 1.083). \quad (28)$$

A similar dependence for a more restricted series of n-alkanes ($6 \leqslant n \leqslant 11$) was approximately represented by a linear equation.[89] Although the approximation was carried out on D_g values calculated from the Fuller equation,[83] the deviations of the points from a straight line were hyperbolic in nature, similar to Eqn. (28). The values of D_g calculated from Eqn. (28) for $n = 5$ and 6 were similar to the experimental values for n-pentane and n-hexane determined previously.[84] Indirect evidence for the accuracy of the D_g values determined for alkanes with low volatility may be provided by the good correspondence between the theoretical efficiency calculated from them and the experimental efficiency of the best capillary columns.[86]

2. Determination of diffusion coefficients in liquids

Capillary tubes made of stainless steel have generally been used to determine diffusion coefficients in liquids (D_l) using the disperson method of Taylor.[90—92] By combining convective dispersion with molecular diffusion in an axial direction, it was possible after a short period of time to obtain considerable dispersion of the zone. The chromatographic equipment used in this method is of simple design and allows for considerable variations in the nature of the diffusant, diffusion medium, and temperature.[93] The reproducibility of the values of D_l obtained by the Taylor method usually constitutes 1—3%.

Alizadeh et al.[94] developed a detailed theoretical basis for use of the Taylor method in determining diffusion coefficients in liquids. Analytical expressions were derived for calculation of corrections to the final volumes of a sample being introduced, recording registers of the detector and connecting tubes, and also corrections to take account of the concentration dependence of D_l. It was shown that small changes in the diameter of the column and the eccentricity of its cross-section had virtually no effect on the values of the experimental diffusion coefficients. Subsequently, Wakeham,[95] taking into account the requirements elaborated by Alizadeh et al.,[94] designed a capillary liquid chromatograph in which the error in determination of D_l did not exceed 0.5%.

Evans et al.,[90] by using a steel CC (9.14 m × 0.775 mm), studied the temperature dependence of the diffusion coefficients of spherically symmetric molecules in alcohols. The slope of lines from plots of $\ln D_l$ against $1/T$ were used to determine the activation energies of diffusion; these were 12.6 kJ mol^{-1} in methanol and 23.4 kJ mol^{-1} in octanol. In a later study,[91] in which a CC (61 m × 0.762 mm) was used, an exponential relationship between D_l for spherically symmetric molecules, the viscosity, and temperature was established. Tominaga et al.[92,96] used a column (50.0 m × 0.8 mm) to study temperature dependence of D_l for aromatic compounds in water and established that the dependence of $\ln D_l$ on the reciprocal of the absolute temperature ($1/T$) was curvilinear over a wide temperature range (8—160 °C). The calculated activation energies of diffusion were slightly dependent on the size of the diffusant molecules and decreased almost hyperbolically with an increase in temperature.[96] According to the data obtained, the diffusion coefficients of benzene in water and for self-diffusion of pure water are similar and decrease to an equally marked extent with temperature.

3. Determination of diffusion coefficients in supercritical fluids

The diffusion coefficients of compounds in supercritical fluids are approximately equal to the average values of their diffusion coefficients in gases and liquids.[97] A knowledge of diffusion coefficients under near- and super-critical conditions is necessary for supercritical fluid chromatography[98] and in the design of fluid extractors used in the food and pharmaceutical industries.[99]

Flexible quartz CCs without a stationary phase are mainly used to determine diffusion coefficients D_f in fluids. According to the assessment of Springston and Novotny,[97] D_f can be determined to an accuracy of 5% by the Taylor dispersion method. The same authors analysed the possible sources of fixed errors.[97] Thus, it was found that the secondary flow of a fluid MP in coiled columns was insignificant,[98] while the velocity of the MP was sufficiently high for the first component in Eqn. (18) to be neglected.[97] Thus, D_f could be determined from the slope of the mass exchange path of the van Deemter curve for capillary columns without a stationary phase. In the majority of cases the differentials of pressure and density of the fluid phase in the columns were small, and these were neglected.[98,100—104] Extracolumn contributions to dispersion also usually had no effect on the experimental values of D_f. In some

cases a variant of the reference column method has been used to take into account the initial dispersion of the zone during introduction.[76] The zone is recorded twice by a UV detector, before and after its passage through the main column. The first detector is placed between a short reference precolumn (1.3–1.8 m) and the main diffusion column of length 46–100 m.[102,104] The compounds are commonly introduced into the columns as solutions in organic solvents, but the dependence of the experimental values of D_f on the nature of the solvent is either only slight[100] or does not occur at all.[97,101,104] Thus, when the fluid phases (propane, CO_2) are used as solvents, the experimental diffusion coefficients of phenanthrene are similar to those obtained when solutions of phenanthrene in xylene[105] and methanol in isooctane[101] are used as samples. Adsorption of compounds on the column walls may well result in errors, so asymmetric peaks are not used to calculate D_f. It has been noted, however, that adsorption only occurs with low densities of the fluid phases.[97,101]

Springston et al.[97] and Olesik et al.[105] studied the effect of the internal diameter of the column (94–200 μm) and the sample concentrations (15 μg ml^{-1}–2.0 mg ml^{-1}) on D_f in order to test the reproducibility of the results. The highest reproducibility was achieved with columns of diameter 0.2 mm and samples with a concentration that was close to the investigated upper limit of 2.0 mg ml^{-1}. By using a chromatograph that was specially designed for physicochemical measurement under supercritical conditions, whose accuracy in the maintenance of temperature and pressure was ±0.01 °C and ±0.2 atm respectively, the authors of two studies[98,105] reduced the relative standard deviations of the experimental values of D_f to 1–2%. With this precision it was possible to detect a difference between the diffusion coefficients of polyaromatic hydrocarbons and their predeuterated analogues.

The diffusion coefficients of normal and branched symmetric C_3–C_{10} ketones, C_{18} fatty acids with a varying degree of unsaturation, liquid crystals, and squalane in fluidised CO_2 were determined with the use of a CC (46.23 mm × 0.41 mm). The values of $\ln D_f$ decreased linearly with an increase in density of the mobile phase. The authors established that for isomers or compounds with similar molecular weights, a decrease in the degree of molecular branching and an increase in their rigidity resulted in a decrease in their diffusion coefficients in fluid CO_2.[104]

CCs were used to study the temperature dependence of diffusion coefficients in fluids for the systems: benzene–CO_2 and methyl linolenate–CO_2;[100,103] anthracene–propane and phenanthrene–propane.[98] In all cases with constant densities of the fluid phases (ρ) the values of $\ln D_f$ were inversely proportional to the absolute temperature. From the slope of lines plotted on the coordinates of $\ln D_f$ against $1/T$, calculations were made of the activation energies of diffusion, which were equal to 2.4 and 5.0 kJ mol^{-1} for anthracene and phenanthrene in fluidised propane (ρ = 0.3771 g ml^{-1});[98] 4.52 kJ mol^{-1} for methyl linolenate in CO_2 (ρ = 0.8 g mg^{-1});[103] and 4.7 kJ mol^{-1} for napthalene in CO_2 (ρ = 0.6 g ml^{-1}).[106]

4. Determination of diffusion coefficients in polymers

The dispersion method of Taylor is not suitable for determining diffusion coefficients in polymers (D_p), since polymers cannot be used as mobile phases because of their high viscosity. However, by depositing polymers as a uniform layer on the inner walls of capillary columns as stationary phases, it is possible to assess their diffusion properties from the resistance to mass transfer in the layers. The resistance to mass transfer (C_l) in a uniform layer of liquid phase of thickness d_f is simply related to the diffusion coefficient:

$$C_l = 2d_f^2 / 3D_p. \quad (29)$$

Cramers et al.[107] used this approach to determine D_p for n-alkanes (C_9–C_{20}) in relatively thick films (1.06–2.35 μm) of polysiloxanes CP-Sil 5 and OV-1 immobilised on the walls of quartz CCs. Three methods for determining the resistance to mass transfer in the SF were tested. The first method was based on a determination of the difference between the experimental HETP and the calculated sum of the contributions from longitudinal and dynamic diffusion in the carrier gas as predicted by the Golay–Giddings equation.[85,108] However, a twofold increase in the thickness of polymer layers resulted in an almost twofold increase in D_p values calculated from Eqn. (29).

Better results were obtained with the second method for determining C_l, which was based on the method of "corresponding" velocities[109] corrected for the compressibility of the carrier gas.[110] The efficiency of the columns was determined by using different carrier gases (helium and nitrogen) with velocities proportional to the diffusion coefficients in each of them:

$$\bar{u}_1/\bar{u}_2 = D_{g,1}J_1/D_{g,2}J_2, \quad (30)$$

where $\bar{u}_1$ and $\bar{u}_2$ are the mean linear velocities of the gases, $D_{g,1}$ and $D_{g,2}$ are the diffusion coefficients, J_1 and J_2 are the Martin[80] pressure drop factors for the first and second carrier gases. The resistance to mass transfer in the stationary phase was defined as the ratio of the differences between the HETPs for each of the gases to the dfference in velocities of the latter:

$$C_l = [(H_1/f_1) - (H_2/f_2)]/(\bar{u}_1 - \bar{u}_2), \quad (31)$$

Here H_1 and H_2 are the HETPs, f_1 and f_2 are the Giddings[82] pressure drop factors for the first and second gases. It is clear that this method does not require a knowldge of the absolute values of $D_{g,1}$ and $D_{g,2}$; only their ratio is important, which for may diffusants is the same.[73,111] Cramers et al.[107] calculated the values of $D_{g,1}$ and $D_{g,2}$ from the Fuller equation,[83] which is recognised as the most accurate.[112] Nevertheless, the values of C_l were dependent on the absolute velocities of the gases. In order to eliminate this dependence, a correction to the ratio of the diffusion coefficients in helium and nitrogen was required. The optimum value determined for this (3.16)[107] agreed with the ratio of the experimental values of D_g for octadecane in these gases (3.15).[86]

The third method involved the computer fitting of van Deemter curves. In the opinion of Cramers et al.,[107] this method does not satisfactorily separate the contributions from resistance to mass transfer in the carrier gas and in the stationary phase. This is also supported by the results of Sandra et al.,[113,114] which estimated D_p for n-alkanes and aromatic compounds in thick films of polysiloxanes PS-255 (5 μm) and RSL-300 (3 μm) immobilised on the walls of quartz CCs. Thus, the experimental values of D_p in polyphenylsiloxane RSL-300 for the heavier homologues are higher than for the lighter alkanes whose molecules are, moreover, less bulky.

Pawlisch et al.[58] noted that when resistance to mass transfer in polymer layers predominates in the total dispersion of the zone, the shape of the peak is very sensitive to the diffusivity of the sorbates in them. A twofold decrease in D_p results in marked asymmetry of the form of tailng.

The same authors determined the diffusion coefficients of aromatic compounds in polystyrene (MW 266000) deposited as a uniform thick layer (7–12 μm) in silanised glass CCS, while the

contribution from longitudinal diffusion and resistance to mass transfer in the carrier gas was neglected. Numerical treatment of the computer signals was used to determine the primary and secondary features of the elution curves, and from them the diffusion coefficients in the polymer were calculated. It was established that an increase in temperature from 110 to 140 °C resulted in an increase in D_p values by a factor of 10^2. The graphs of $\ln D_p$ against $1/T$ were linear. The activation energies of diffusion calculated from the graphs for benzene, toluene, and ethylbenzene were 8.4, 10.0, and 10.6 kJ mol^{-1} respectively. Thus, in view of the possibility of obtaining readily controlled, highly uniform polymer layers, the use of glass capillary columns for studying the diffusion properties of polymers may have considerable future potential.

Present state of research on the sorption of inorganic compounds by oxide hydroxides from aqueous solutions

S I Pechenyuk
Institute of the Chemistry and Technology of Rare Elements and Mineral Resources, Kola Science Centre of the Russian Academy of Sciences

ABSTRACT. The general trends and methods of studying sorption from solutions on oxide hydroxide surfaces are discussed, including coprecipitation and sorption on previous activated sorbents. The models of the sorption mechanism and of the interrelation between different types of sorption are examined.

The bibliography contains 166 references.

I. Introduction

Inorganic sorbents are used in all branches of industry and in the protection of the environment. They are used when aqueous solutions must not be contaminated with when the appropriate sorbents are cheap and simple to prepare and to regenerate, and stable towards radiation.[1] Oxide hydroxides (which are also known as oxyhydrates, hydroxides, and hydrated oxides†) come closest to these requirements, offering a high sorption activity in conjunction with a relatively simple synthesis (mainly the oxide hydroxides of iron, titanium, zirconium, aluminium, and tin[1]). Iron, aluminium, and titanium are widely distributed in nature, and their use is preferred on ecological grounds. The marked variation in the properties of oxide hydroxides prepared by different methods[2–8] has stimulated extensive studies of sorption on these materials. Workers who have synthesised oxide hydroxides by different methods have obtained results which are difficult or even impossible to reconcile. A search for regularities in this stream of data should help to assess the prospects of the various trends in research, to systematise and correlate existing data, and to identify bright spots in which fundamental studies of these topics could be developed. The aim of the present review is to outline some regularities in this field of study. The discussions will be confined to work published between 1976 and 1989.

A logical analysis of existing data requires first of all a clear definition of the concepts of sorption and coprecipitation. As has been pointed out,[2,9] sorption is a process in which a substance (the sorbate) is captured by previously synthesised sorbents, whereas in coprecipitation the capture takes place during the deposition of the sorbent from a solution containing the sorbate. It follows from these definitions that coprecipitation (as compared to sorption) is a process with time limitations set by the rate of formation of the precipitate of the macrocomponent (sorbent); subsequent processes in which the microcomponent (sorbate) is captured from the solution come under the definition of sorption, which has no time limits. During the contact between the sorbent and the sorbate the deposited sorbent can undergo transformations leading to the achievement of the most stable structure for the given conditions: this occurs in all the systems but is particularly important in systems with coprecipitation. A redistribution of the sorbate between the solid and the liquid phase could take place as a consequence. The initial picture can also be blurred by changes in the state of the sorbate in solution. Furthermore the time limitation, i.e. the instant when the true coprecipitation comes to an end, is poorly defined, and therefore it is often dismissed from the discussion consciously or unconsciously.

The result of the extraction by sorption depends on the time of sorption, and therefore a knowledge of the kinetics and mechanisms of all the changes taking place in the system is a necessary condition for a correct use of the sorbent, i.e. for the best results. Sorption processes are often used to remove microcomponents in solution in the presence of macrocomponents at a concentration 3–10 orders of magnitude higher. Therefore the ratios of the sorbent and the sorbate to the macrocomponents and the participation of the latter in the sorption process should be carefully monitored.

We shall review the principal directions of the experimental studies of the sorption of inorganic compounds from aqueous solutions on oxide hydroxides, which constitute (together with studies of the sorption on carbons from the gas phase and on organic sorbents from solutions) the largest group of studies in the modern science of reactions at a phase boundary (interface science). The writer does not claim to have reviewed the topic exhaustively: he has merely collected the most interesting (or typical) results of current research.

† Hydroxides, hydrated oxides, and oxide hydroxides are different chemical compounds,[2] but in the publications reviewed here the terms are applied indiscriminately to what are essentially oxide hydroxides: the products of the reaction of oxides with H_2O, both stoichiometric and nonstoichiometric.

II. Trends in the study of sorption processes on oxide hydroxides

Studies in which the adsorbate is coprecipitated with the sorbent occupy a major place in the current work on oxide hydroxides, but most of the authors fail to distinguish between the concepts of sorption and coprecipitation and discuss their results in terms of either concept, taken at random.[10–28] The experimental foundations of most of this work consist in determining the equilibrium sorption (or coprecipitation) of the microcomponents as a function of the nature of the macrocomponent (sorbent) and of the pH of the system for a fixed composition of the ionic medium. As we have already pointed out, these quantities should be treated as quasiequilibrium quantities.

Thus, the coprecipitation of the cations of the *s*, *p*, and *d* metals and of some anions with the oxide hydroxides of Fe, Ti, Zr, La, Y, Cd, Th, Be, Mg, Sc, and Nd has been studied at pH 4–14.[10–15]

The basic conclusion most often reached in that work is that the coprecipitation of the cations increases with the acidic properties of the collector, whereas (conversely) the coprecipitation of the anions decreases. The strength of the capture of the anion decreases as its aciditiy increases. We should stress that in the whole of this work the acid–base properties of the collectors are characterised only qualitatively, and the state of complex formation of the sorbates is ignored. The need to allow for the rate of establishment of equilibrium and for the forms in which the sorbate can exist in solution has been pointed out,[10] but even in later work this rate was not determined. Some reports[11,12,22,23] draw attention to the behaviour of the sorbate in solution, but the effect of the ionic strength and of the pH on the behaviour of the sorbent is ignored, in spite of the mention of gels of freshly precipitated oxide hydroxides which undergo uncontrolled spontaneous changes over long periods under the conditions of the experiment, especially in response to changes in the pH of the suspension (pH_s).[3–8]

The results of these studies of coprecipitation in combination with sorption[10–31] consist of tabulations of pH values at which various microcomponents can be removed from a solution of given macrocomposition by coprecipitation with a stated macrocomponent.

Another approach to the study of sorption processes, which is dominant among Russian scientists, is based on the theoretical model of classical ion exchange. The methodology of the study of sorption in inorganic sorbents is the same as in studies of organic ion-exchange resins, as is clearly shown in Belinskaya's review.[32] Many typical examples can be quoted:[33–51] in most cases granulated sorbents are preferred, in spite of the known fact that the drying and heat treatment needed during the granulation can seriously degrade the sorption properties.[1] Classical methods are used, like the limited volume[34,35] and the column dynamics method.[33,37–48] Studies of the sorption kinetics of both simple and complex ions in these systems show that the rate-limiting step is usually internal diffusion within the grain).[31–35] This approach is also being used to study problems of sorption selectivity, such as the sorption of SO_4^{2-} and NO_3^- on hydrated zirconium dioxide,[33] but it leads to partial, empirical results, whereas this type of problem is already basically solved (see below).

Unfortunately, the Soviet workers whose approach we are discussing seemed unaware (judging by their lists of references) of the immense amount of information on sorption problems obtained by foreign scientists, and made no attempt to interpret their own results in terms of alternative, more fully developed approaches.

Since complex formation is a phenomenon with universal ramifications we should pay special attention to studies of the sorption of complex ions of given compositions (classical complexes). The platinum metal complexes have been studied most widely. We can distinguish two groups of studies, each devoted to the same sorbates, carried out over approximately the same period, and containing much kinetic information: references 37–54 and 55–75. The compounds studied in this work included the complexes of composition MX_4^{2-} [where M = Pd(II), Pt(II) and X = Cl^-, Br^-, CN^-, CNS^-, NO_2^-], $M'Cl_6^{n-}$ [where M′ = Pt(IV), Ir(IV), Ir(III), Os(IV), Ru(IV), Ru(III), Rh(III)], and $Ir_3O(SO_4)_6Y_3$ (where Y = H_2O, SO_4^{2-}, and HSO_4^-). Abovskaya, et al. have studied the aquo complex of Pd(II)[48] and sulphate solutions of Rh(III) containing several complex forms.[49] The sorbents used in that work[37–54] included oxide hydroxides (hydrated oxides, or oxides, in the authors' terminology) of titanium (IV), zirconium(IV), tin(IV), and aluminium(III), whereas other workers[55–75] used crystalline oxide hydroxides (oxyhydrates in the authors' terminology) of the REE and many samples of amorphous oxide hydroxide of iron(III) (ferrogels), differing in the nature of the initial iron(III) salt and in the precipitation conditions (pH, oxidiser, temperature, time, etc.).

Both groups of papers discuss the kinetics of the process, including the temperature dependence of the rate, the influence of the nature and of the concentration of the ionic medium, and the effect of the composition of the products. Some papers[55,73–75] also discuss the interaction of the sorbents with the supporting electrolytes. That work leads to the following conclusions.

The sorption of anionic complexes on the granulated oxide hydroxides of Ti, Zr, Sn, and Al is fast (equilibration time τ_{eq} = 10–60 min at 20 °C) and is characterised by diffusion-limited kinetics, i.e. the activation energy E_a of the process (kJ mol^{-1}) is 30–40 for MCl_6^{n-}, 19–25 for $PdCl_4^{2-}$,[37–48] and 22 for $PtCl_6^{2-}$ on γ-Al_2O_3.[54] On the other hand the sorption of aquo complex is very slow (τ_{eq} = 4–20 h), E_a = 18.5 kJ mol^{-1} for rhodium(III).[49] Increasing the concentrations of the components and of the supporting electrolyte slows the sorption of the complexes on the oxide hydroxides of Ti, Zr, and Sn;[37–50] furthermore increasing the ionic stength suppresses the sorption, i.e. it lowers the degree of utilisation of the sorption capacity of the sorbents, which is not large for these oxide hydroxides, reaching a maximum (30 mg metal g^{-1} of sorbent) for ZrO_2. The SO_4^{2-} ions interfere most strongly with the sorption fo MCl_6^{n-} and $PdCl_4^{2-}$ on TiO_2 and ZrO_2. Ageing the solutions of the complexes (sorbates) increases the sorption from aqueous solutions but lowers the sorption from solutions in hydrochloric acid.[37–48]

The composition of the sorbed forms immediately after the establishment of the sorption quasiequilibrium is the following: $PdCl_4^{2-}$ [51,52] and $PtCl_6^{2-}$ [54] are sorbed on γ-Al_2O_3; $PtCl_3H_2O^-$ on ZrO_2; $PtCl_6^{2-}$, $OsCl_6^{2-}$, and $OsCl_5H_2O^-$, $RhCl_6^{3-}$, $IrCl_6^{3-}$, $IrCl_6^{2-}$, and $IrCl_5H_2O^-$, and $PdCl_4^{2-}$, are sorbed on ZrO_2, TiO_2, and SnO_2.[37–48] This means that the forms predominantly present in solution are sorbed without change in composition. Upon ageing the complexes in the sorbent phase undergo a slow aquation, giving $OsCl_5H_2O^-$ and $OsCl_4(H_2O)_2^0$, $RhCl_4(H_2O)_2^-$ and $RhCl_2(H_2O)_4^+$, $IrCl_3(H_2O)_3$, and $PdCl_3H_2O^-$.[37–50]

These complexes are also sorbed undecomposed and almost instantaneously at room temperature on ferrogels from solutions not containing a supporting electrolyte,[55,57,63] and the capacity of the ferrogel can reach 2×10^{-3} mol g^{-1} of $Fe(OH)_3$, i.e. more than 400 mg of Pt, Ir, and Os on 1 g of $Fe(OH)_3$.[55] However, in the presence of a supporting electrolyte (more than 0.05 mol dm^{-3}) the

chemistry of the sorption process is radically altered.[55,57] On the surface of the ferrogels (in the presence of a supporting electrolyte) and of the REE oxide hydroxides (whether or not on ionic background is present) we observed a process which has been described in detail[55,58] and called heterogeneous hydrolysis. The rate of this process is strongly dependent on the nature of the complex, the sorbent, and the ionic background, and also on the temperature (E_a = 60–130 kJ mol^{-1}); it usually corresponds to a first-order equation in the concentration of the complex-forming metal or of the sorbate [in the latter case, except $PdCl_4^{2-}$, $OsCl_6^{2-}$, and $Pt(CNS)_4^{2-}$]. The observed rate constants K_H vary with these factors from 10^{-5} ($PtCl_4^{2-}$ [64]) to 0.2–0.5 s^{-1} ($RuH_2OCl_5^{2-}$ at 80 °C[55,65]). Heterogeneous hydrolysis takes place gradually against a background of hindered transformations of the complex sorbate in the solution, spontaneously in the pH-static regime, and not associated with oxidation–reduction or photochemical changes in the complex.[55] The products of the heterogeneous hydrolysis are the amorphous hydroxides of the central atom (CA),[55,59] strongly bound to the surface of the sorbent: the rate of detachment of the ligands from the CA is equal to the rate of transfer of the latter from the bulk of the solution to the surface of the sorbent. The rate of this process is directly proportional to the basicity of the sorbent [characterised[55] by the pH at the point of zero charge (pH_{PZC} or pH^0)] and depending in a complicated way on the concentrations of NaCl and Na_2SO_4 in the system. This dependence can be represented by the linear equation

$$K_H = a \pm bC_{el},$$

where C_{el} is the concentration of NaCl or Na_2SO_4 and the sign of the second term is determined by the nature of the sorbent and of the electrolyte.[58,62,63] It has been shown[73–75] that this is the result of the interaction of the sorbent with the supporting electrolyte, which alters the basicity of the sorbent.

Ageing the solutions of complex sorbates accelerates the heterogeneous hydrolysis; increasing the ionic strength of an electrolyte ($NaClO_4$) inert towards the sorbate and the sorbent suppresses the reaction;[66] the rate is unaffected by the charge on the complex anion.[67] A correlation has been found between the stability (or the lability) of the complex sorbate and the rate of the heterogeneous hydrolysis: the rate increases with increasing lability and with decreasing stability of the complex, and *vice versa*. The possibility of heterogeneous hydrolysis itself is determined by the stability of the complex. Thus, complexes with β = 10^{36}–10^{40} [$Pt(Cn)_4^{2-}$, $Fe(Cn)_6^{3-}$, $Fe(CN)_6^{4-}$] do not undergo heterogeneous hydrolysis.[55] The process has a pseudoequilibrium character, with sorption isotherms of the high affinity type;[76] the pseudoequilibrium capacity can reach (0.5–3.0) × 10^{-3} mol of complex g^{-1} of sorbent for the ferrogels and Ln_2O_3.[72] The reactions of these complexes with MCO_3 (M = Ca, Sr, Ba) are of the heterogeneous hydrolysis type.[68] A complex dependence exists between the rate of heterogeneous hydrolysis and the concentrations of sorbate and sorbent.[55]

We should also mention a group of papers describing sorption on previously activated oxide hydroxide sorbents [goethite, magnetite, haematite, jarosite, and amorphous hydroxides of iron(III)] at high temperatures (100–190 °C) from sulphuric-acid solutions of iridium and ruthenium in the form of sulphato or aquo hydroxo complexes of indeterminate composition.[77–81] It was shown that in these cases the sorption is irreversible, as in heterogeneous hydrolysis, and slow, that the capcity of the sorbents is low, and that the complex sorbates are fully or partially decomposed during the sorption.[81]

Lastly, we cannot fail to mention the work of Nechaev,[82–85] distinguished by an original approach to the mechanism of sorption on oxide hydroxides [for example, the sorption of $AuCl_4^-$ on the crystalline oxides of iron (III)]. Nechaev tried to relate the sorption equilibrium constants to the ionisation potentials of the oxide surfaces at pH^0.[83] He determined the composition of the sorbed forms and established that the sorption is accompanied by partial aquation of the $AuCl_4^-$.[82,84] The sorption of $AuCl_4^-$ and of its aquo derivatives was found to be described by Langmuir isotherms; the surface charge is of secondary importance in the sorption process, whereas the electronic structure of the surface plays a dominant role and determines the sorption activity of the oxides [at least, in respect of Au(III)].[85] However, the traditional (deeply "equilibrium") approach to the study of sorption and the fact that all the conclusions apply only to a single, easily hydrolysed and reduced complex ($AuCl_4^-$) detract from the value of the results.

In the foreign literature the studies of direct sorption on previously prepared sorbents greatly outnumber the studies of coprecipitation.[86,87] The vast majority of publications is based on the concept of an electrically charged oxide hydroxide surface. When in contact with H_2O or with an aqueous solution of electrolyte (sorbate) this surface can be identified with an electrode surface in contact with a solution,[88] and the appropriate definition of a potential-determining ion can be applied to it. For the oxide hydroxides these ions are H_3O^+ and OH^-;[89,90] their distribution between the bulk of the solution and the sorbent surface creates a surface charge q and a potential $\Psi(x)$ at the interface. The concepts of specific and of nonspecific sorption are also used. When the sorption energy E_s is Coulombic,

$$E = q\Psi(x),$$

i.e. when the interaction is purely electrostatic, the sorption is treated as nonspecific; in the opposite case the sorption is specific, i.e. it is accompanied by the formation of new chemical bonds. Because of the difficulty of determining $\Psi(x)$ and E_s experimentally (whereas the surface charge is easily measured[89–91]) the type of sorption is determined by using the point of zero charge PZC and the pH_{PZC} (pH^0)‡. The symbol pH^0 defines the pH of the so-called zero solution, for which the electrode has an equilibrium potential $\Psi(x)$ = 0[88] and the surface charge of the sorbent is q = 0. In the absence of specific sorption of the electrolyte ions pH^0 is independent of the concentration of electrolyte.

Simple cations and anions are mostly used as sorbates in the work of foreign scientists. Studies of sorption equilibria also seem to be predominant. Measurements of pH^0 and studies of the dependence of q on the nature and concentration of the electrolyte are a major part of most of these investigations. A specific link between the magnitude and other characteristics of the sorption and of the surface charge of the oxide hydroxide is sought, defined by the relationship between the pH^0 values of the sorbent, the pH of the suspension (pH_s) in the sorption system, and the concentration and nature of the supporting electrolyte. Since the previous review of the pH^0 and pH_{IEP} values was published[93] in 1965 it seems useful to complement the existing[93] data with information extracted from work published during the last two decades (Table 1).

‡ pH_{PZC} should be distinguished from pH_{IEP} (the pH of the isoelectric point), defined[92] as the pH of a solution in which the potential of the solid (ζ) is zero, i.e. the charge at the boundary of the diffuse layer of solution is zero.

Table 1. ph of the point of zero charge (pH^0) of some oxide hydroxides.

Oxide hydroxides	Method of preparation	Electrolyte	Concentration of electrolyte mol dm^{-3}	pH^0	Refs.

Notes. 1. The concentration of the supporting electrolyte is shown in cases of specific sorption or when the pH^0 value is quoted for specified concentrations of electrolyte. 2. pH_{IEP} is 7.9 for α-Fe_2O_3 (washed with KOH) and 6.8 for γ-Fe_2O_3 (washed with KOH).

The factual material thus obtained can be summarised as follows. In the absence (and only in the absence) of specific sorption pH^0 occurs at the intersection of all the $q = f(pH_s)$ curves for different concentrations of electrolyte,[88–92,94] and this quantity alone fully characterises the oxide (or oxide hydroxide).[94] In many cases (the oxides and oxide hydroxides of Cu, Fe, Al, Ru[95,96]) the oxide hydroxides have lower pH^0 values than the corresponding "dry" oxides, but opposite examples can also be seen in Table 1 (for Zr, Ti, and Al). The K^+, NO_3^-, and ClO_4^- ions are usually sorbed nonspecifically,[97–99] whereas the ions Ca^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}, Li^+,

Zn^{2+}, Ga^{3+}, Eu^{3+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, Pb^{2+}, SO_4^{2-}, PO_4^{3-}, SeO_3^{2-}, $P_3O_{10}^{5-}$, and F^- are specifically sorbed.[89,90,92,99,100–111]. Cl^- can be sorbed both specifically and nonspecifically.[91,112–114]

The specific sorption of cations produces a shift in pH^0 of the oxide hydroxide sorbent towards lower values, and the sorption of anions has the opposite effect. Specifically sorbed ions can displace nonspecifically sorbed ions, but not *vice versa*.[98,99] The sorption of M^{2+} and M^{3+} cations produces a change in pH_s, and is strongly dependent on this parameter if the latter is fixed and controlled. The dependence on pH_s of the equilibrium and (or) pseudo-equilibrium sorption of the cations, and the abiity of the cations to form hydroxo complexes, have a dome-like or near-exponential shape (stretched S) leading to a plateau.[29,101–106,115–117,119,120]

The first shape of this dependence is characteristic of cations which easily form stable and readily soluble hydroxo complexes, for example Zn^{2+}, Cr^{3+}, and Al^{3+}; the second is found for cations which do not possess this property, for example Co^{2+}.[115–117] The sorption of cations on oxide hydroxides is accompanied by the removal of one or two protons from one sorpton centre. At low adsorptions the sorption of M^{2+} is described by the Langmuir isotherm,[116,117] and at high adsorptions by the Freundlich[106] and Frumkin isotherms:[115] this is attributed to the energy nonuniformity of the sorption centres on the surface of oxide hydroxides.

IR spectroscopy identifies three types of surface hydroxyl groups, containing oxygen attached to the surface in mono-, bi-, and tridentate configurations.[105] At low coverages the first (and most active) type is used, and when these are occupied the energetically less favourable positions come into play. The same effect is seen in the kinetics of the process:[106] on increasing the sorbent/sorbate ratio the rate of sorption of cations (Cd^{2+}) increases because of the increased proportion of the more active centres, and *vice versa*. As reported[105,106] the rate of sorption of M^{2+} cations is quite high, and the sorption quasiequilibrium is established in 10–30 min at room temperature.

The isotherms for the sorption of anions (for example, PO_4^{3-}) on highly active oxide hydroxide sorbent samples (for example, ferrogels[109–111]) belong to the high affinity type of isotherm (H type[76]). At pH = const the sorption of the anions increases with the ionic strength of the solution. Three regions can be observed in the sorption isotherms. Ageing the ferrogels lowers their capacity towards PO_4^{3-} ions and their rate of sorption.[109–111] The sorption of PO_4^{3-} ions decreases the pH^0 value of the ferrogel.[109] Comparing data from different laboratories[55,109,111,121] shows that the properties of ferrogel surfaces are unstable and sensitive to influences from the sorbate and from the ionic medium. The sorbability of the anions increases with their acidity[122] and with decreasing pH_s.[123]

A few (but very important) studies of the effect of temperature and composition of the oxide hydroxide on its surface properties have been reported.[94,96,99,124,126,133–137] In the case of magnetite[135] and of haematite and rutile[124] it has been shown that pH^0 decreases with increase in temperature and increases when the temperature is lowered: for example, pH^0 for α-Fe_2O_3 in KNO_3 solutions is 9.5 at 5 °C, 8.6 at 20 °C, and 7.6 at 60 °C.[124] An increase in temperature also increases the slope of the $\partial q/\mathrm{q}pH$ curves slightly, and makes the branches of the $q = f(pH_s)$ curves lying in the acidic and the alkaline region respectively more asymmetric. The sorption equilibrium constants increase with temperature,[135] and the $\Delta G^0_{\mathrm{ads}\,H^+}$ values correspondingly increase somewhat; the effect of the ionic strength on the surface charge also increases only slightly with temperature.[124] On the other hand for γ-al_2O_3 pH^0 increases from 4.45 to 8.95 (even in solutions of KNO_3) when the temperature is increased from 10 to 50 °C.

Thus the response of pH^0 for an oxide hydroxide to a change in temperature depends first and foremost on its chemical nature. It is found that in the mixed oxide hydroxides RuO_2 + IrO_2 [134] and TiO_2 + Al_2O_3 [137] pH^0 is the mean of the pH^0 values of the components.[134,137] Heat treatment of the oxides also produces different effects on pH^0, depending on their chemical nature and method of preparation.[96,134] It has been established that homo- and heterodispersed sols of α-Fe_2O_3 have identical pH^0 values.[94] This is consistent with the report[134] that pH^0 is unrelated to the specific surface S_{sp} of the oxide hydroxide. Lastly we shall mention a study[138] of the kinetics of charge transfer (electrons and protons) through the interface in suspensions of α-Fe_2O_3 and α-FeOOH by the pulse radiolysis method. It was shown that the rate of charge transfer is strongly dependent on pH_s: the rate constants vary between 10^{-1} and 10^4 s^{-1} in the pH_s range 3–11.

III. Models of the sorption mechanism on oxide hydroxides

The model of the sorption mechanism should describe the distribution of the sorbate (and preferably also of the components of the supporting electrolyte) near the reactive surface (or interface) as well as the thermodynamics and the kinetics of the process. The criteria for evaluating the quality of the model were clearly formulated by Barrow and Bowden:[139] it could be useful to re-state them in their entirety. An ideal model should be effective, comprehensive, realistic, and predictive. An **effective** model should offer a detailed description of the observations: otherwise, its fundamental hypothesis is incorrect. Effectiveness is a necessary but not a sufficient quality of the model. A **comprehensive** model can be used unmodified in a wide range of conditions. A **realistic** model is consistent with generally accepted theories of the behaviour of the components of the system. A predictive model leads to a new understanding of the phenomena and offers wider prospects of exploiting them in different circumstances.

Studies of sorption processes are divided mainly into two streams, which we can call simply the western and the eastern stream. The western stream consists mainly of the Dutch–American school, to which we owe a systematic and "well equipped" theory of the sorption of ions in an electrical double layer.[89–92,94–96,100–115,119,120,124,126] This group of studies is distinguished by a very precise formulation of the problem, a strictly methodical approach, and high-grade processing of the experimental data. It is noteworthy that the research problems are considered from the standpont of preconceived ideas. While this is one of the main strengths of the approach it also introduces a certain weakness by lowering the probability of unexpectedly discovering interesting new results.

The eastern stream consists of the work of Indian and Soviet scientists (mainly the latter). It is characterised by the absence of firm preconceptions experimental results are interpreted by any suitable theory or theoretical fragment capable of explaining the experimental facts. Of course this classification of the two streams is not absolute, and a mutual "diffusion" of the two approaches and conceptions can be detected.[55,73,75,97,99,116,117,129,132]

Before proceeding to a detailed discussion of the models we should make the following comments. Whatever the actual compounds used as the sorbents (hydroxides, oxides, or even

carbonates) the effects observed in studies of sorption from aqueous solutions in real experimental systems relate to sorption on oxide hydroxides. This is suggested both by numerous studies of structure formation in oxide hydroxides[3–8,140–142] and by studies of the interaction of H_2O with oxides,[131,143–146] and has been repeatedly confirmed by the work of western scientists.

Let us begin our examination of the sorption models with the most fully developed theories. The foundations of the coordination chemical theory of sorption on oxide surfaces were laid in the 1980's.[95,147,148] The basic hypothesis of this theory is that H_2O molecules are dissociatively sorbed on the oxide surface during its contact with an aqueous solution or with a moist atmosphere: as a result the surface is covered with a layer of hydroxyl groups having a density of 2–10 OH nm^{-2},[148] which undergo fast protolytic reactions with the solution. This establishes an equilibrium distribution of the charges in advance of the other sorption processes. On a neutral surface (at the point of zero charge) the numbers of positively and of negatively charged centres are equal. At the contact with a solution of $pH < pH^0$ the surface (now in the oxide hydroxide form) becomes positively charged, whereas at pH > the surface charge is negative. As was stated above pH^0 is determined experimentally: attempts to calculate it on theoretical grounds have proved unsuccessful.[95] The sorption process is primarily electrostatic.

On a given oxide hydroxide cations are sorbed at $pH_s > pH^0$ and anions at $pH_s < pH^0$.[120,123] However, cation sorption takes place (in part) in the region of positive surface charge,[129,149] and therefore simple electrostatic models are inappropriate. A deeper understanding of the sorption can be gained from considerations of the complex formation between the cations and the OH^- groups of the boundary layer and of the replacement of these groups by anions:[148] the site binding model.[105,120] The possibility of these processes and their special features are related to the stucture of the electrical double layer (EDL) at the interface. The characteristics of the EDL are the equilibrium constants of the surface ionisation and of the surface complex formation K, the surface charge q, the capacity, and the potential $\Psi(x)$.

Barrow and Bowden[139] have constructed three models of the sorption in the EDL, composed of one, three, and four planes of ions respectively (Fig. 1). All three models give expressions for the sorption equilibrium constants.

According to the one-plane model all the adsorbed ions are accommodated in a single plane and have the same potential: the neutral $-S-OH$ surface, which joins the centres of the $-SO_3^-$, $-S-OH$, and $-S-OH_2^+$ groups. The expressions for the equilibrium constants contain the term $\exp(nF\Psi/RT)$, where n is the valency of the sorbed ion, F and F are well known constants, and T is the temperature. The surface complex is written as $-SA$.

According to the three-plane model H^+ and OH^- are located in a separate internal plane s, the electrolyte ions and the sorbate ions are in the next layer, and the expression for the equilibrium constant contains the term $\exp[-F(\Psi_\beta-\Psi_0/RT)$; the surface complex is written as $-SOH_2^+-A^-$ or $-SOH_2^+-HA$.

According to the four-plane model[150] H^+ and OH^- are again located on the innermost potential plane while the next plane contains the sorbed ions and the next the ions of electrolyte (see Fig. 1). The sorption centre is described as $-S\begin{matrix}OH\\OH_2\end{matrix}$, and the sorption complex as $-S\begin{matrix}OH\\A_1\end{matrix}$ or $-S\begin{matrix}A_1\\OH_2\end{matrix}$; the expression for the equilibrium constant contains the term $\exp(-nF\Psi_\alpha/RT)$. The sorbate can replace both the $-OH$ and the $-OH_2$ group, i.e. it can react with the surface irrespectively of its charge. From this pont of view all the surface centres are vacant, so that the sorbate reacts with centres caryring an average charge. In the case of a polyvalent sorbate this model allows interaction with all forms of ions in solution (though some are known to be preferred), i.e. it offers a choice between the particles in solution but not between the surface centres. However, even in the sorption of the PO_4^{3-}, F^-, SO_4^{2-}, and SiO_3^{2-} anions on goethite[139] none of these models is ideal. Many arbitrary assumptions are needed to produce a satisfactory agreement between calculation and experiment. Special attention must be paid to the concentration of the sorbate, the pH of the medium, and the contact time of the phases.

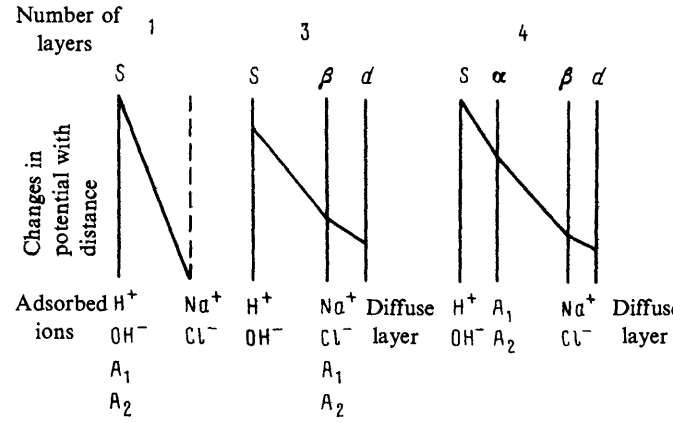

Figure 1. Three models of the interaction between the solution and the adsorption surface of the ions.[139] The bulk of the adsorbent is on the left, that of the solution is on the right; the diagrams show the proposed localisation planes of the individual classes of ions and the changes in electrical potential with distance.

These models ignore the steric factor (the size of the sorbate ions) and they treat the surface of the sorbent as uniform and nonporous, and therefore they cannot be applied to gels.[151] However, as shown by Perram,[146] a layer of oxide hydroxide gels can readily be formed on oxide surfaces in contact with water, and this observation led to the development of the EDL theory.

There have been attempts[105,106,120] to treat the surface of the oxide hydroxide sorbent as energtically nonuniform (heterogeneous) to account for the difference in sorption at low and at high coverages. The simplest two-position model[106] stipulates the formation of $-S-M(OH)_n(-Cd(OH)_2)$ from uniform $-S-OH$ centres at low coverages (i.e. low adsorption densities) through reversible reactions of the first order in the sorbate, and the use of other centres (of various types) in the region of high coverges. A more general solution of this problem is proposed by van Riemsdijk, et al.:[120] the heterogeneous surface is represented as an assembly of uniform subsurfaces, and the sorption on each of these is

described by a standard (Langmuir or Freundlich) isotherm. The heterogeneous surface is described by the symbol $-S\begin{vmatrix} O^- \\ OH^0 \\ OH_2^+ \end{vmatrix}$, and and centres with different energies are treated as subsurfaces. Models similar to the four-plane model[139] are used, and it is assumed that the form of the energy distribution function of the adsorption centres is retained when the ions are adsorbed.

Hiemstra, et al.[152] proposed a many-centre model of the adsorption on the oxide hydroxide–solution interface (multisite complexation, MUSIC) in which different OH groups are coordinated by one, two, or three metal ions; the model was thought to account for the microheterogeneity of oxide surfaces. It was tested on gibbsite, goethite, haematite, rutile, and silicon dioxide:[126] different crystallographic faces were found to make different contributions to the formation of the surface charge and to the PZC. Faces which (in general) remain uncharged over a wide range of pH were identified, and it was shown that in a crystalline oxide pH^0 is determined by the behaviour and by the presence of faces containing the greatest number of OH groups coordinated by only one metal atom from the lattice. Successful attempts to calculate the pH^0 were made.[152,126] It was shown that the binding centres model is a special case of the multisite complexation model.

Westall and Hohl[153] pointed out that the sorption energy is very difficult to divide into an electrostatic and a chemical component, though this procedure could lead to a rational choice between many possible models relying on similar law of mass action (LMA) and material balance equations but different descriptions of the EDL. Attempts to formulate a strictly quantitative description of the sorption of electrolytes on oxide hydroxide surface have also met other problems. Thus, the maximum sorption always exceeds the possible monolayer sorption,[154] and furthermore all the surface models are based on the conception of the EDL of a single particle is a large volume of electrolyte solution, though the presence in solution of a large number of dispersed particles (as is always found in real systems) shoud have a profound effect on the parameters of the EDL. The mathematical description of the EDL is very complicated even for a single particle, and for a more complex system it is quite impossible at present.[151]

Recent reports (for example, by Spitz, et al.[155]) have stressed that no quantitative descriptions of the surface–sorbate interaction based on the concept of acid–base interactions have so far been put forward. One contributor to a recent monograph,[76] Lyklema, described the sorption of ions on solid surface by rejecting all mathematical procedures and relying wholly on qualitative relationships. He defended his approach by the following argument: it is impossible at present to determine the sorption of an electrolyte, since different methods give different results; furthermore the sorption in the EDL of ions of a single type can also not be determined, and therefore it is reasonable to describe the process in terms of uncharged particles; lastly, the problem of potential-determining ions is far from clear. Evidently, a comprehensive mathematical description of sorption from solutions of electrolytes on oxide hydroxides is not likely to be available in the near future. Nevertheless it does not follow that all current attempts to produce such a description are meaningless.

Let us consider, as a typical example of the work of the eastern stream, a group of Indian and Japanese publications.[143,156–158] Venkataramani and Gupta[143] studied the sorption of H_2O on the oxides of titanium(IV), bismuth(III), and thorium(IV), and on magnetite: they measured the sorption isotherms and made pH-metric titrations of the oxide samples in a medium of $NaNO_3$. The reversibility of the sorption of H_2O was demonstrated, the effect of the preparative conditions (method of precipitation, and ageing) was studied, and the content of $-OH$ and $-ONa$ surface groups in the samples was determined. However, the results[143] cannot be used to predict the adsorption behaviour of the oxides because there is no link between the results and information on pH^0 and on the structure of the EDL, and also because no attempt has been made to determine pH^0.

Other publications in this group[156,157] discuss data on the sorption of M^{2+} and M^{3+} cations on magnetite and an amorphous iron(III) oxide from the standpoint of a typical ion exchange model. Inoue, et al.[158] treat the oxide hydroxides of tin(IV) and niobium(V) as ion exchangers with weakly acidic functional groups, interpreting the functional groups and the liquid layers near the solid surface as an exchange phase in which the electrostatic bond and the LMA have the same significance as in solutions. They correctly point out that the simplified approach in which the sorption is treated as a typical ion exchange phenomenon cannot be applied to oxide hydroxides, i.e. it does not correctly explain the effect of the experimental conditions on the sorption capacity and on the distribution coefficient. Nevertheless they make a sharp distinction between ions bound by Coulombic forces (free ions in the bulk phase) and ions attached to the functional groups by a coordinate bond ("undissociated" ions in the ion exchanger phase). They use the pH_{TEP} concept, but in fact they are operating with pH^0 since they use a nonspecifically sorbed electrolyte (NaCl) to determine this parameter. The failure to distinguish between these quantities detracts from the universality of the method, though not from its effectiveness.

We should stress the fact that complex cases are known in which none of the existing sorption models can offer a suitable explanation. For example, the sorption of UO_2 ions on the surface of the oxides of Ti(IV), Th(IV), Zr(IV), Ce(IV), and others[129,149] in the region of positive surface charge produces a shift of pH^0 towards the right. The authors put forward the concept of attack of the OH surface group by the sorbate ions without previous deprotonation: this process is energetically most favourable for dimeric and trimeric sorbate cations and their neutral molecules, and is called electrical sorption by the authors. Under these conditions the sorbate in the sorbent phase forms bridges between pairs of neighbouring surface on groups. Another example is heterogeneous hydrolysis,[55] discussed below.

The ion exchange model of this process is very widely used in the Soviet publications. It is based on the oxyacid theory of amphotericity,[159,160] according to which amphoteric oxides (hydroxides, oxide hydroxides, oxide hydrates) show cation or anion exchange properties according to the pH_s. The cation exchange properties (selectivity, capacity) of an oxide hydroxide decrease and its anion exchange properties increase. The rate of ions exchange is limited by diffusion in the boundary layer or in the sorbent grain (outer and inner diffusion), and the sorbability of the ions depends on their charge and size. The attraction towards exploiting the analogy with organic ion exchangers, which is obvious for this approach, can be seen in a group of mainly Soviet publications.[31–54] Thus, in Belinskaya's review[32] the inorganic sorbents are treated as polymeric ion exchangers with functional goroups which dissociate at the $-M-O^-$, $-M-OH$, and $-M-O-H$ bonds, though some experimental facts are admittedly incompatible with this scheme.

The discrepancy is avoided by assuming compensation of the charge on the polymeric ion exchanger skeleton (usually assumed to be negative) by mobile cations. The mathematical description of ion exchange is a well known process which can be applied to inorganic sorbents without special difficulties. In many resports[26–54] the discussion is limited to a qualitative explanation of the results in terms of the ion exchange model.

A group of papers[10–25] develops the interpretation of the sorption process (coprecipitation) as an acid–base interaction between the sorbate and the sorbent. This model is based only on static (pseudoequilibrium) experiments on the sorption of metal cations. The mechanism assumes the adsorption of hydrolysed forms of the cations with a minimum charge, i.e. $M(OH)_n^0$. It is suggested that the sorbate is attached to the sorbent by forming tin bridges between $M(OH)_n$ and the oxide hydroxide sorbent (collector).

The coprecipitation of cations begins at pH values of the system which define the onset of hydrolysis and of the formation of simple or polynuclear products in solutions of the elements being coprecipitated. The formation of coordinationally saturated complexes of the sorbate suppresses the sorption (coprecipitation) by this mechanism. Coprecipitation takes place at a pH of the medium lower than the pH for the deposition of the sorbate, suggesting a shift in the hydrolysis equilibrium of the sorbate.[16] The acid–base interaction model is qualitative and does not provide a basis for the mathematical description of the sorption equilibrium or for any prediction. The process is examined exclusively from the point of view of the behaviour of the sorbate: the behaviour of the sorbent, including the presence of charge and of an EDL on its surface, is totally ignored. As the authors themselves point out,[10–25] the observed phenomena could equally be described in terms of ion exchange, but this means using a different model to discuss the results.

An interesting analysis of this group of papers was published by Artyukhin,[30] whose conclusions are still valid. The great diversity of the points of view on the sorption mechanism and the failure to allow for the linked hydrolytic equilibria in the formulation of the sorption equilibria are stressed. It is pointed out there there is no direct proof of the sorption of both neutral and charged forms of the sorbate, and that data on the equilibrium (or quasiequilibrium) limited to pH-metric measurements are an insufficient basis for the construction of a model of the mechanism of the process. In the processing of the experimental results[29,30] an attempt was made to demonstrate the sorption of metal cations in the uncharged hydroxo form over the whole range of pH; the preferential sorption of uncharged forms implies the absence of an electrostatic barrier (which is a reasonable assumption when discussing the sorption of cations on a positively charged surface). It is concluded that all the sorptions lead to the formation of an uncharged compound in the sorbent phase. We consider this to be a special case, applicable to the aquo cations of metals, as shown by many published results.[37–54] It is assumed that any form of the sorbate, including forms present in solution in negligibly small amounts, can be responsible for the distribtion of the sorbate. Clearly, this is a problem of major importance for constructing a mechanism of the sorption on oxide hydroxides. To complete the picture we should mention (without going into details) the use of the isomorphous coprecipitation[28] and of the coordination model.[24,27]

Let us now consider the heterogeneous hydrolysis mechanism, proposed by the present writer. This is a kinetic model of a nonequilibrium process, unlike any other model used in adsorption studies. As was shown in section II, heterogeneous hydrolysis takes place with formation of uncharged hydroxo complexes as the reaction product, as in the sorption of M^{n+} cations.[10–30] The high rate of formation of these products for metals such as zinc, cobalt, nickel, and copper in noncomplexing ionic media allowed the construction of a model[16–25,29,30] of sorption involving the uncharged form $M(OH)_n^0$ as the sorbed species. However, a study of the process with sorbate in the form of stable complex ions (as in heterogeneous hydrolysis) shows that in reality the mechanism is more complex.

We should stress that not one of the sorption models previously suggested (electrostatic, ion-exchange, coordination, complex formation with the functional groups of the sorbent, acid–base, isomorphous coprecipitation) can effectively describe heterogeneous hydrolysis. The rate of the heterogeneous hydrolysis and its temperature dependence suggest first and foremost that the rate-determining step of the process is a relatively slow chemical reaction. The established participation of the electrolyte and of H_2O in the heterogeneous hydrolysis,[64,66,73,74] its uncontrollable pH-static regime,[55,60–62] the localisation of the process on the sorbent surface,[72] and its progress against a background of hindered reactions of the sorbate and of the sorbent[55] show that heterogeneous hydrolysis is a multistage chemical reaction which includes, however, an adsorption step. The uncharged form of the sorbate in heterogeneous hydrolysis is the last, and does not react. We have proposed[55] a three-stage model of the mechanism, including the fast reversible adsorption of the dominant form of the sorbate complex, the slow reversible aquation of the complex on the sorbent surface, and the fast partially reversible dissociation of the aquo complex formed on the surface of the oxide hydroxide sorbent with compensation of the additional surface charge, which defines the condition of the spontaneous pH-static regime. The observed rate constant of the heterogeneous hydrolysis can be expressed as the rate constant of a heterogeneous reaction:[161,162]

$$K_{\text{H}} = K_x k_{a_x}^{-1} k_{\partial_x}^{-1} C_x C_{\text{M}}^{-1} \left(1 + \sum_i k_{a_i} k_{\partial_i}^{-1} C_i \right)^{-1},$$

where K_d is the rate constant of the aquation of the i-th form of the complex reacting on the sorbent surface; k_{a_x}, k_{∂_x}, k_{a_i}, κ_{∂_i} are the rate constants of the adsorption and of the desorption of the reacting and of any other i form of the sorbate complex present in solution; C is the concentration of the forms; C_{M} is the total concentration of the complex-forming metal.

The rate of aquation, characterised by K_x, is several orders of magnitude greater than the rate of aquation of the sorbate complex in solution,[55] which also produces sparingly soluble uncharged hydroxo forms. Heterogeneous hydrolysis shows a similarity to the processes described in various papers,[37–54] since it includes stages of adsorption and of chemical reaction of the sorbed substances, but it differs from them in the high rate of the second stage and in the fact that the sorbate is not held on the sorbent surface in the form of the initial component. The model is effective, realistic, and comprehensive for the platinum metal group, and it has a predictive value in conjunction with quantitative data on the stability and the lability of the complex sorbates and on the basic properties of the sorbent.[55]

Data[55,58,72,75] on the pseudoequilibrium properties of the heterogeneous hydrolysis and on the interactions of the sorbents with the supporting electrolytes show that the strongly basic OH groups of the sorbent take part in the heterogeneous hydrolysis reactions, and that the presence and concentration of these groups are determined by the pH^0 value of the sorbent.

The weakness of the model lies in the impossibility of mathematically relating the rate of the process to the concentration of the basic centres of the sorbent furthermore the rate of the process cannot be calculated theoretically, since the calculation would require a knowledge of the stability constants and of the rates of aquation of the sorbate complexes, of the acid–base equilibria of the OH groups on the sorbent surface, of the rates of protolysis of the aquo forms of the sorbate in the sorbent phase, of the rate of the phase transformations of the sorbent, and of all the activity coefficients. Most of these quantities are unknown, and furthermore the form of the mathematical equations linking them to the rate is also unknown. The model also offers no information on the character of the bond between the sorbate and the sorbent during the intermediate and the final stages of the process, when the assumption of a combination of van der Waals and electrostatic bonds is not incompatible with observations.

IV. Interrelation between the properties of the sorbate, of the sorbent, and of the ionic medium and the sorption mechanism

In his analysis of the status of research on sorption by inorganic compounds and of coprecipitation Melikhov[9] observed that very little published information is available on the relationship between the sorption and the states of the surface region of the sorbent and of the sorbate in this region and (we add) in the solvent, and that insufficient attention is being paid to this problem. Workers in the eastern stream are specially prone to ignore the interrelation of three aspects of the sorption process: the structure formation in the sorbents (in our case, the oxide hydroxides), their surface properties (which depend directly on the previous aspect), and the sorption itself. On the other hand, as was shown by Khvostova and Pichugina[163] (for the platinum metals, though their conclusions apply also to other metals), the real composition, i.e. the nature and the relative amounts of the complex forms in solution, determine the degree of removal of an element by extraction, electrode position, cementation, etc., and obviously also by sorption. The addition of any other reagent, including the solvent, produces a shift of the equilibrium aquation, hydrolysis, and of other reactions (substitution, polymerisation, complexation of the ions, etc.) in the solution, and thus affects the sorption process to the extent of inducing a change in the mechanism.[37–75] However, this obvious consideration is often ignored, and in many cases even the initial complex forms of the sorbed element are not established.[15,25,27,28]

Let us now examine the few disconnected data on this topic and establish possible interrelationships between the three aspects of the sorption process defined above.

The following propositions can be considered to be established beyond dispute. I. Crystalline oxides (and oxide hydroxides) have a much lower sorption activity than their corresponding amorphous phases; their capacity is lower,[55,72,78,82–84,99,106,156] their kinetics are more sluggish,[60,65,77–80] and their selectivity is lower, i.e. they have sorption isotherms of the Langmuir or Freundlich type instead of "high affinity" isotherms.[72,106,116,117,156] 2. The presence of ligands in the solution, and their nature, have a strong influence on the magnitude and on the kinetics of the sorption;[22,23,25,47–49,55,77,87,164] metal ions bound in complexes are much less sorbable than unbound ions. 3. Ions in the sorbed state undergo chemical reactions, especially hydrolysis, much more readily than free ions in solution.[55,101–106,115–118] 4. The supporting electrolyte interacts with the sorbent[73–75,90–92] (see also Table 1) and with the sorbate,[55] strongly influencing both the kinetic and the (pseudo)equilibrium characteristics of the sorption process.

We shall consider, as a specific example of the establishment of interrelations between the properties of the sorbate, of the sorbent, and of the ionic medium and the sorption mechanism, a group of papers on the sorption of complex anions of the platinum metals on the oxide hydroxides of titanium(IV) and zirconium(IV),[37–50] on ferrogels, and on the oxide hydroxides of the REE.[55–75] These studies are specially suitable for our analysis because they include kinetic data, which allow various effects of the properties of the components to be displayed though they remain constant during equilibrium measurements.

The analysis of these studies[37–50,55–75] shows first of all that at least two stages are needed for the sorption process; the adsorption stage itself and a preliminary chemical interaction of the sorbate with H_2O, the supporting electrolyte, and the sorbent surface. The composition of the sorption complex and the rate of transformation of the sorbate in the sorbent phase depend on the nature of the sorbate and of the sorbent, but the participation of the ionic medium is very substantial in both cases. In the first stage this effect is seen as a competing interraction between the sorbate and the background ions, which lowers the extent of sorption (say) of the complex anions when the concentration of NaCl or of Na_2SO_4 is increased.[37–50] In the second stage the effect is seen in the form of the interaction of the supporting ions with the sorbate and the sorbent, as shown most clearly by the dependence of the rate of heterogeneous hydrolysis on the concentration of the ligand in solution and by the change in the sorption properties of the REE oxide hydroxides and of the ferrogels[55–75] under the influence of the ionic medium.

Obviously, the slow changes in the chloro complexes sorbed on the surface of the titanium(IV) and zirconium(IV) oxides[37–47] bear some similarity to heterogeneous hydrolysis, but the rates of these reactions are so small that the authors[37–47,50] could not detect the complete detachment of the ligands. This process can be represented as the second stage of the heterogeneous hydrolysis infinitely stretched out in time, whereas the sorption of the complexes on the surface of the titanium(IV) and zirconium(IV) oxide hydroxide surfaces is interpreted as the fixed first stage of the proposed[55] three-stage mechanism of heterogeneous hydrolysis. The difference in mechanism between the first[37–50] and the second group of studies[55–75] is due to a difference in the characteristic properties of the sorbent surface: its size and its energy nonuniformity, but the property of the sorbent mainly responsible for the change from the ion exchange to the heterogeneous hydrolysis mechanism is probably its basicity.[55]

The basicity of the sorbents has been characterised[55] by the pH^0 values, which are well correlated with other quantities determined by the basicity (the Cartledge ionic potential and the pH of the saturated solutions of hydroxides, calculated from the solubility products,[165] Fig. 2). This allows us to compare oxide hydroxides of different structure groups, arbitrarily assuming them to have equal basicities. The correlation can also be made in terms of data obtained[166] by characterising the acid–base properties of oxides through the heats and the isotherms of the sorption of NH_3 and CO_2 from the gas phase. According to that work[166] the basicity of the oxides increases in the series

$$BeO, TiO_2, ZrO_2, Nb_2O_5, Ga_2O_3 < ThO_2,$$

$$MgO, ZnO, Al_2O_3 << CaO, Nd_2O_3, La_2O_3,$$

whereas by using the Table 1 we obtain

$Al_2O_3, TiO_2,$

$ZrO_2 < \alpha\text{-}Cr_2O_3 < Fe_3O_4 < CeO_2 < Yb_2O_3 < Sm_2O_3 < ThO_2.$

The two sequences are satisfactorily consistent.

It is also clear that pH^0 is strongly dependent on the method of preparation of the oxide hydroxide. According to the pH^0 values (see Table 1) the bulk (or surface) positive charge of the metal oxide hydroxides produced at the contact with aqueous solutions of electrolytes decreases in the sequence

Fe^{3+} hydrogels (with $pH_{bas} > 8-9$)$Ln_2O_3.nH_2O > Cr_2O_3 > Al_2O_3 >$

$>$ FeOOH(goethite, akaganeite, lepidocrocite) $> ZrO_2 > TiO_2$.

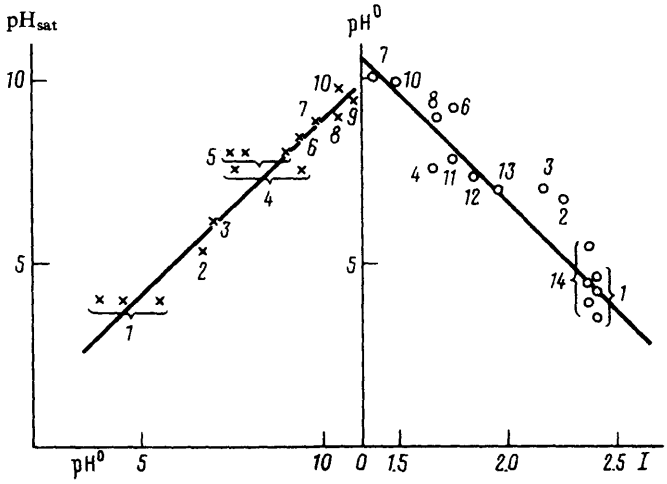

Figure 2. Correlation between pH^0, the ionic potential *i*, and the pH of a saturated solution of oxide hydroxides:[55] *1*, $TiO(OH)_2$; *2*, $ZrO(OH)_2$; *3*, $Cr(OH)_3$; *4*, $Cu(OH)_2$; *5*, $Y(OH)_3$; *6*, $Zn(OH)_2$; *7*, $Pb(OH)_2$; *8*, $La(OH)_3$; *9*, $Ni(OH)_2$; *10*, $Cd(OH)_2$; *11*, $Sn_2O_3.nH_2O$; *12*, $Y_2O_3.nH_2O$; *13*, $Yb_2O_3.nH_2O$; *14*, $Sn(OH)_4$.

The easy replacement of sorbed complex anions by simple anions (for example, SO_4^{2-}) [37–48] is characteristic of nonspecific, electrostatic bonds (see Section III). The strength of the electrostatic bond to a protonated oxide hydroxide surface is determined by the density of surface charge. At low surface charges the electrostatically bound sorbed groups experience negligibly small interactions from the weakly electrophilic sorbent surface (TiO_2, ZrO_2), and therefore the rate and the extent of transformation of the sorbed complex ions on the crystalline oxide hydroxides of Ti, Zr, Sn, and Fe are small, the sorption is reversible,[37–50] and these sorbents are not suitable for removing metals (typical complex formers) from media containing complexing salts.

As the density of surface charge and the basicity of the surface are increased the ratio of the rates of the adsorption stage and of the transformation of the sorbate in the sorbent phase is altered: though the rates of adsorption and desorption remain high, the rate of the second stage increases. Thus, in the hydration and protonation of the dry REE oxides the surface becomes saturated with basic hydroxyl groups which are not removed from the surface into the bulk of the solution when the acid content of the system is limited. Therefore the matrix of the Ln_2O_3 oxide has a decreased affinity for electrons and for hydroxyl groups, even when the surface has a positive charge. This nucleophilicity weakens the metal–anionic ligand bonds in the sorbed complex, and facilitates its transformations (aquation, in the case of heterogeneous hydrolysis). The ferrogels and the carbonates of the alkaline-earth metals show a similar behaviour.[55]

Thus the basicity of the oxide hydroxide sorbent determines the sorption mechanism and the changes in basicity define the boundary between "ion exchange" and heterogeneous hydrolysis. These considerations are convincingly confirmed by the observation that lowering the basicity of a ferrogel by removing the excess of OH groups during cryogranulation while retaining its large specific surface and amorphous structure alters the character of the sorption process and converts the heterogeneous hydrolysis into "ion exchange".[55]

By using the pH^0 as a characteristic of the basicity of the oxide hydroxide, the stability constants of the complex sorbate, and data on the interaction of the ionic medium with the sorbate and the sorbent we have formulated the group of principles which should guide the choice of conditions for the sorption extraction of complex-forming metals from complex-forming media.[55]

1. The complete sorptional removal of complex-forming metals form complex-forming media containing high concentrations of electrolytes without changing the composition of the solution is possible only under conditions of fast and exhaustive transformations of the sorbate in the sorbent phase.

2. The process which ensures this condition is heterogeneous hydrolysis.

3. Metals can be effectively precipitated from complex-forming media by heterogeneous hydrolysis if the stability constant of the complex does not exceed $10^{38}-10^{40}$; the process is completed in practically convenient times if the half-life of the ligand in the sorbate complex is less than 2–3 days at temperatures between 20 and 100 °C.

4. Sorbents suitable for heterogeneous hydrolysis in salt media include the crystalline (or gel) oxide hydroxides with $pH^0 \geqslant 6.5$ [i.e. the oxide hydroxides and the carbonates of Cu(II), Ni(II), Cd, Pb(II), Zn, etc.].

5. To remove metals which form labile but stable complexes in the presence of high concentrations of ligand we must use neutral or weakly alkaline gel sorbents; for systems with low concentrations of ligand and (or) inert complexes in salt media the most effective sorbents are crystalline oxide hydroxides of the Ln_2O_3 type.

V. Conclusions

The great majority of studies of sorption on oxide hydroxides deals with sorption equilibria (or pseudoequilibria): little attention has been paid to its kinetics, in spite of the reported observation[106] of very strong energy nonuniformity of the sorbent surface. Fairly simple cases of sorption of aquo cations and acid anions are usually considered; the mathematical description of the sorption is very complex, and is based on many more or less arbitrary assumptions. The treatment of the results often reduces to the traditional models of Langmuir sorption and ion exchange. Most of the publications are aimed primarily at the behaviour of either the sorbent or the

sorbate. Sorption experiments are carried out either in the absence of an ionic background or in solutions of electrolytes indifferent to the sorbate. Crystalline phases are predominant among the sorbents. Studies of the EDL do not resolve the contradiction in the effects of pH_s on the sorption process. There is no information on the effect of interactions of the electrolyte with oxide hydroxide gels on the sorption properties of the latter (except the ferrogels[55]), and very little has been published on the composition and distribution of the sorption products on the sorbent surfaces, on the changes in structure and properties of the sorbent during the sorption, and on the effect of the temperature, composition, and concentration of the ionic medium on the rate and the mechanism of the sorption process. Very diverse partial models of the sorption mechanism have been put forward. We are therefore unable to formulate the general principles to be followed in the selection of practical sorption conditions and to propose a comprehensive predictive model.

Unfortunately, work based on the so-called equilibrium measurements of sorption during coprecipitation contains little information and is non-predictive because the coprecipitation with metal oxide hydroxides [usually of Fe(III), Ti(IV), Zn(IV), Sn(IV), Al(III), etc.] usually produces gel-like deposits with a very high sorption capacity (the corresponding crystalline phases have a much lower activity[72,75,78,79]). Flynn[6] has stressed that gel phases are nonequilibrium systems containing an excess of free energy. Therefore equilibrium measurements during coprecipitation are, in reality, nonequilibrium measurements, and in the case of complex sorbates they depart from equilibrium in respect of both the sorbent and the sorbate. These data are points on a kinetic curve of very long duration. An important contribution to the understanding of the behaviour of these sytems was made by Egorov,[2] but unfortunately his book has not received the attention which it deserved. Only by combining data on the phase formation in gels, which are plentifully available,[3–8,141,142] with data on the interactions between gels and electrolytes, of which very few are available at present, will a convincing explanation be found for the results of a large group of investigations.[10–30,86,87,101,103]

Concerning the potential application of sorptional extraction in practice we note that the prejudice of many workers in favour of crystalline granulated oxide hydroxide sorbents (in preference to gel sorbents) is based on the widespread belief that the former are more convenient and can be use repeatedly (see, for example, Simanova and Boichinova[50]), whereas the latter cannot, and also on considerations of cost and ecological effects. Both arguments are largely misconceptions. As regards convenience, one thinks of the use of sorbents in columns in automated industrial processes, ignoring the stringent requirements of stable dynamic regimes and absence of impurities in the solution, which do not apply to the use of gel-like sorbents in a static regime. The gel sorbents can be used with simpler apparatus. As regards cost and ecological considerations we should consider the whole cycle of operations involved in the synthesis of granulated oxide hydroxides; precipitation from a salt solution, washing formation, drying, and heat treatment. Though the cost of this overall process is lower than the cost of synthesising organic sorbents (resins) it is quite considerable. The volume of water needed to wash the precipitated gel should also be compared with the volume of water which can be purified by the sorbent thus produced. The synthesis of the gel sorbents includes only the first (or the first and second) stage of this synthetic cycle. In view of the much higher sorption activity of the gels we recommend their use in many practical applications.

The capacity and the selectivity of a sorbent do not vary in the same sense; repeated use of the sorbent assumes a stable structure and stable properties. A careful analysis shows that these advantages of the sorbents always occur in pairs, i.e. two of them exclude the third. But are all three always required?

The following situations are met in practical cases of sorptional concentration.

1. The extraction (recovery) of a valuable microcomponent from a very large volume of solution (for example, gold from sea water). This requires stability of the sorption properties and a high capacity, whereas the selectivity (extent of removal) is less important since the process is repeated until the sorbent is saturated. In this case the granulated sorbent is definitely preferable.

2. The intensive purification of large volumes of very dilute solutions from trace impurities (for example, the purification of drinking water from heavy metals). Here selectivity is important, a high capacity is desirable, but the possibility of repeated use is less important. A gel sorbent could be preferred.

3. The extraction (recovery) of valuable microcomponents from small volumes of solutions, usually technological and containing high concentrations of electrolytes (for example, platinum metals from electrochemical production solutions) in order to minimise the loss of valuable materials in the technological cycle. In this case selectivity is important; the use of the total capacity and the repeated use of the sorbent are effectively excluded. A gel sorbent is preferred.

4. The concentration of trace components in analytical chemistry: in this case selectivity is the only requirement.

We should also note that in the second and the third case the kinetics of the sorption are very important, whereas in the first and the fourth case they are of secondary importance.

Thus the crystalline, granular, and gel sorbents all have a place in the practical exploitation of the method, but for different purposes.

This analysis of published data on sorption on oxide hydroxides has identified the main gaps in this area and has shown the need to fill these gaps, to systematise experimental facts more fully, and to unify the procedures and the terminology used in the research. The range of materials under study must be expanded further, and relationships between the properties of the sorbates and of the sorbents and between the sorption mechanism and the prospects of practical application of the sorption methods of concentrating components must be established.

Electrochemistry of transition metal single crystals with well defined surfaces

G V Khaldeev, T A Syur
Gor'kii Perm' State University

ABSTRACT. The effect of extended defects of the surface of metallic single crystals on the electrochemical processes of dissolution and formation of a new phase has been analysed. Theoretical ideas on the rearrangement of a crystal surface (phase transitions of the second kind) during the adsorption of surface-active substances are presented. The reconstruction (faceting) of the surface under the influence of electrochemical processes and the adsorption of nucleophilic species (hydrogen, oxygen, halogen ions) from the gas phase and from electrolytes on a well defined metal single crystal surface have been evaluated.

The bibliography contains 94 references.

I. Introduction

Expermental studies of the electrochemistry of well defined metal single crystal surfaces have stimulated the development of new theoretical models. The use of methods having a local resolution better than 0.1 nm provides information on the reconstruction of near-surface layers of the crystal, which usually have a stepped structure with a range of surface-active centres.

The flat condenser model (the boundary between an infinite defect-free crystal and an isotropic liquid medium) does not give a strictly quantitative description of the mechanism of the electrochemical corrosion process. The metal surface (M) contains surface defects which create adsorption centres of various types and which have different energy levels. These centres generate fields associated with deformation displacements. The description of the discrete structure of the interface must allow for the formation of complex electrical double layers (EDL) on both the metal and the electrolyte side: electrons from the metal penetrate into the active part of the fixed EDL forming electron tails. The components of the electrolyte adsorbed on the metal experience the action of the electron tails; this produces long-range order in the film, which acquires a quasi-crystalline structure.[1]

In this review we shall examine recently published data on the effect of the reconstruction of the first few near-surface layers by the adsorption-chemical interaction with the electrolyte particles upon the conditions of formation of a new phase during an electrochemical process. Often the interaction on an M/electrolyte interface does not produce a phase transition of the first kind (corrosion) but is limited to a transition of the second kind which changes the short-range order of the hierarchical structures of the EDL both in the electrolyte and in the metal. Unfortunately only a few electrochemists have paid sufficient attention to the characterisation of the surface and to the analysis of changes in the structure of near-surface layers of monocrystalline samples. Our analysis of experimental information on crystal surfaces must therefore be limited to data for surfaces having reliably determined crystallographic characteristics.

II. Surface defects. The discrete metal lattice model

The first model to succeed the parallel plate condenser model was the "jelly" model, in which the near-surface layer consists of an ensemble of uniformly charged spherically symmetrical atoms. Each pair of atoms in the first near-surface layer was characterised by a defined binding energy E_b, decreasing with increasing distance (r_{ij}) between the atoms. Because of the periodicity of the structure of a metallic crystal the E_b values are crystallographically related, and periodic bond chains (PBC) can be delineated in the first near-surface layers.

According to the generally adopted Franck–Cabrera classification[2] solid surfaces are divided into singular, near-singular (vicinal), and non-singular (diffuse), usually called *F*, *S*, and *K* faces. The *F* faces are the surfaces parallel to the two PBC systems with the largest E_b. Atomically smooth singular surfaces coincide with the low-index crystallographic planes and have a different packing density S_{hkl} of the surface atoms. The atomically rough (slightly inclined to the *F* faces) vicinal *S* faces deviate by a small angle from the singular orientation and have a stepped structure (Table 1): the length *L* exceeds the height *h* of the steps (low-index planes). The vicinal *S* faces can be stabilised by the reconstruction of the terraces between the steps. This has been observed expermentally for planes close to (100) and (111) in Au.[4] At certain "magic" angles, defining the deviation of (*khl*) from the low-index face, and for which the distances between steps are multiples of the period of the superstructure, the energy of the surface is substantially decreased.[5] Surfaces with different orientations, characterised by large step heights (β_0), are non-singular *K* faces (in which the step length *L* is

commensurate with the step height h). Examples of stepped surfaces of the $n(110)-(0\bar{1}1)-(0\bar{1}1)$, $n(110)-(1\bar{1}0)$, and $n(110)-(001)$ type are shown in Fig. 1 (where n is the number of rows of atoms in the terrace).

Table 1. Types of stepped surface (S faces) in the cubic system.[8]

Symbol of the stepped face	Miller indices	Angles between flat terraces and steps
$n(111)-(111)$	$(n, n, n-2)$	$\mathrm{tg}^{-1}(\frac{2\sqrt{2}}{3n-2})$
Sample: 9(111)–(111)	(997)	6.45°
$n(111)-(100)$	$(n+1, n-1, n-1)$	$\mathrm{tg}^{-1}(\frac{2\sqrt{2}}{3n-1})$
Sample: 10(111)–(100)	(11, 9, 9)	5.57°
$n(100)-(111)$	$(2n-1, 1, 1)$	$\mathrm{tg}^{-1}(\frac{\sqrt{2}}{2n-1})$
Sample: 10(100)–(111)	(19, 1, 1)	4.25°
$n(100)-(110)$	$(n, 1, 0)$	$\mathrm{tg}^{-1}(\frac{1}{n})$
Sample: 9(100)–(110)	(910)	6.34°
$n(110)-(111)$	$(2n-1, 2n-1, 1)$	$\mathrm{tg}^{-1}(\frac{\sqrt{2}}{2(2n-1)})$
Sample: 5(110)–(111)	(991)	4.49°
$n(110)-(100)$	$(n, n-1, 0)$	$\mathrm{tg}^{-1}(\frac{1}{2n-1})$
Sample: 9(110)–(100)	(980)	3.37°

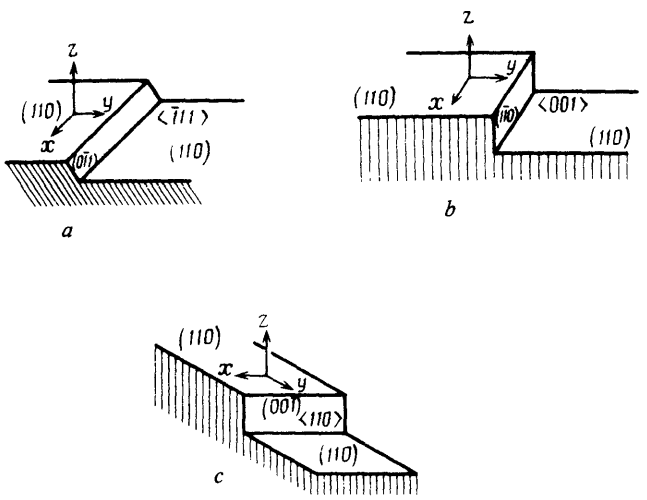

Figure 1. Geometry of the stepped surfaces; *a*, $n(110)-(0\bar{1}1)$; *b*, $n(110)-(1\bar{1}0)$; *c*, $n(110)-(001)$; n is the number of atomic rows in the terrace.

Singular surfaces have sites of a single type for capturing adsorbed species, but both one-centre adsorption and stronger multicentre adsorption can take place. According to Horiuti[6] the latter are called s states and the one-centre adsorption centres are called r states. For cubic crystals the width (r_{hkl}) and the depth (h_{hkl}) of the strong adsorption centres (s states) are calculated by the formula

$$r_{110} = a/2 - R_M,\ h_{110} = a\sqrt{2}/2 - R_M, \quad (1)$$

$$r_{100} = a\sqrt{2}/2 - R_M,\ h_{100} = a/2 - R_M, \quad (2)$$

$$r_{111} = (a/\sqrt{2})/2 \cos 30° - R_M,\ h_{111} = a\cos(\widehat{[100][111]}) - R_M, \quad (3)$$

where a is the lattice parameter of M, and R_M is the radius of the M atom, which corresponds most closely to the Zacharaisen radius $R_{M,z}$. The latter is calculated by the model of the ideal h.c.p. structure constructed from spherically symmetrical elements of radius $R_{M,z} = \Omega^{1/3}/2^{5/6}$, where Ω is the atomic volume of M at room temperature.[7]

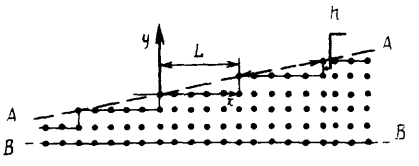

Figure 2. Square lattice with an $[lk]$ ($k = 5$) surface;[8] L is the length of the step, h is its height.

Atomically flat ideal singular F faces of M contain regular defects of the broken bond type having densities (for example, in the diamond lattice) of $\sqrt{3}/4a^2$ for the (111) face, $3/4a_2$ for the (001) face, and $3\sqrt{2}/8a^2$ for the (011) face. A simple square lattice with a single index [like the $\{lk\}$, $k = 5$ lattice surface shown in Fig. 2] is usually stepped with a step height h. Planes with the smallest number of broken bonds are energetially the most favourable for the formation of the equilibrium forms of crystals during dissolution (or corrosion). Therefore the morphology of the surface corresponds to the direction of the corrosion process which lowers the total surface energy of the system.[8]

The packing densities of the atoms are different for different S_{hkl} surfaces. Thus, the low-index (111), (001), and (011) faces of nickel crystals contain the following numbers of surface atoms (N_s) per 1 m^2 of surface area; 1.87×10^{19}, 1.61×10^{19}, and 1.14×10^{19}, and those of silver monocrystals 1.38×10^{19}, 1.20×10^{19}, and 0.84×10^{19}. Calculations of the packing densities show that the nonsingular terraced faces have the loosest surfaces. These faces, with a well defined angle of deviation from the low-index faces, are most often met in the surfaces of polycrystals.

III. Orientation dependence of the dissolution of a metal during phase transitions of the first kind (corrosion, electrocrystallisation)

Unfortunately, reliable experimental data are few, because in most cases experimental electrochemists have used monocrystals with S faces while claiming them to be singular low-index F faces. Working

surfaces are usually prepared by cutting the monocrystal by the spark erosion method, which produces the required *hkl* orientation to within 1–3°: the working surfaces are therefore invariably stepped. The best surfaces, closest to the low-index *F* faces, have a deviation of ~1° in the noble meals. A slight improvement can be achieved[9] by including a final ion etching stage (Ar^+) in the surface preparation programme (mechanical polishing with diamond pastes, electropolishing, chemical polishing). Clavilier and co-workers[10] used a special sample preparation programme in their electrochemical investigation, including a surface cleaning stage by vacuum annealing and cooling, and they claim a precision of 1–3′ in their control of *hkl*.

Another weakness of many experimental studies is a casual approach to the preparation of the electrode and to the general experimental technique; oxides, adsorbed particles, and other contaminants are removed carelessly from the surface, and mechanical lapping and polishing methods are used though they are known to perturb the structure of the near-surface layer. The most reliable electrochemical data were obtained on the equilibrium faces of single-crystal whiskers, whose working *F* faces are very close to singular surfaces.

The physical methods used to characterise and to control experimentally the surface *ex situ* and *in situ* include X-ray diffraction (XRD), high-energy and low-energy electron diffraction (HEED and LEED), secondary ion mass spectroscopy (SIMS), Auger electron spectroscopy (AES), X-ray and ultraviolet photoelectron spectroscopy (XPS and UPS), elastic and inelastic neutron scattering (ENS and INS), elastic and inelastic scattering of helium atoms (EHS and IHS), and electron beam microanalysis (EBMA),[11] as well as other methods. Further developments in high-resolution electron microscopy (0.1–0.3 nm) have been achieved, with chemical analysis of the near-surface layer and new methods of exploiting the resonant scattering of X-rays[12] in interpreting the fine structure of the extended X-ray absorption spectra (EXAFS). By using these methods the distance between the absorbing atom and the atoms of the first coordination sphere can be determined to within 0.001 nm, and to within 0.01 nm for the next three spheres. Information on the local chemical composition and on the atomic and electronic structure of the surface is important for determining the electrochemical characteristics of metals. Auger electron spectroscopy can be used to calculate (from the energy of the Auger electrons) the local density of states in the valence band for the M surface. Several of the methods listed above are usually combined within the same experiment. The analytical possibilities of the methods are summarised in Table 2.

The interactive combination of these methods with electrochemical methods, which allow the degree of excitation of the particles in the near-surface layers of the metal and of the electrolyte to be controlled, makes it possible to re-examine the phase transitions of the first and second kind in the metal corrosion process and in the deposition of a new phase on the surface. The phase transition of the first kind during the dissolution of the crystal is preceded by a relaxation and rearrangement of the surface layers (phase transition of the second kind).

The dissolution of the crystal leads to the disappearance of some faces and the retention of others; in the surface layers of polycrystals the grains contacting the solution in given orientations dissolve fastest. The crystal in the solvent medium behaves so as to retain its mass by rearrangement of the near-surface layer, and the surface tension γ_{ji}^0 decreases according to the expression

$$\partial\gamma_{ij}^0/\partial r_{ij} = 0, \quad (4)$$

where r_{ij} is the distance between interacting particles.

The positions of the individual atoms in the near-surface layer of M are jointly described by the index (*hkl*). Sites for the adsorption of surface-active substances are considered to be equivalent. The expression (4) reflects the decrease in the area of the solid surface, which must be accompanied by an increased chemical resistance of the metallic crystal in the liquid medium. The decrease in the true area of the electrode surface is reflected by the decrease in the rate of corrosion (K) as the dissolution time increases. K can be increased by special methods (stirring, the application of an anodic potential), but the maximum rate (observed at the beginning of the dissolution

Table 2. Characteristics of the different methods of studying the surface and near-surface layers of metals.[11]

process) cannot be re-established without changing the nature of the solution.

A description of the effect of the roughness (or curvature) of the surface K_M on the chemical activity of its different regions is implicit in the well known Gibbs–Thomson equation, according to which the difference $\Delta\mu$ between the chemical potentials of the particles in the solid located on a projection or in a groove is proportional to the curvature K_M of the surface:

$$\Delta\mu = \gamma^0_{ij}\Omega K_M.$$

The curvature can be defined as

$$K_M \simeq d^2y/dx^2$$

where x, y are the coordinates. For $x \to 0$ the difference $\Delta\mu$ is a maximum, and therefore atoms tend to be transferred from projections to the flat surface. In this way the surface tension γ^0_{ij} of the crystal grain can minimise its surface area.

The kinetics of the dissolution of M are described by the Arrhenius expression[13]

$$i = k\theta\exp(-E_a/RT),$$

where k is the rate constant, θ is the coverage of the surface by the products of the dissolution reaction E_a is the activation energy of the dissolution, R is the gas constant, and T is the absolute temperature. In practice the ratio of the rates of dissolution (i) on portions of the surface of types r and s is the most useful parameter. The rate of dissolution of projections (i_p) on the M surface is greater than the rate of dissolution of hollows (i_h). If the projections and the hollows are approximated by hemispheres of atomic dimensions ($\sim$0.01 nm) the ratio of i_p to i_h can be written

$$i_p/i_h = \exp(2\gamma^0_{ij}\Omega/R_S RT), \quad (5)$$

where $R_S = K_M^{-1}$ is the radius of curvature of the surface ($R_S > 0$ for a projection, $R_S < 0$ for a hollow).

It has been pointed out[14] that hollows and projections (of curvature $K_{M,h}$ and $K_{M,p}$ respectively) will function as microanodes and microcathodes with a potential difference

$$\Delta E = (2\gamma^0_{ij}\Omega/zF)(K_{M,p} + K_{M,h}). \quad (6)$$

where F is the Faraday and z is the valency of the electrode reaction.

ΔE decreases with the square of the distance from the projection to the hollow, and the energy term (the dependence of ΔE on R_S) becomes a curve with a minimum at the distance $0.5\,R_S$.

For a flat boundary at $R_S \to \infty$ the Gibbs absorpton equation becomes

$$d\gamma^0_{ij} = -q_{S,0}dE_0 - \sum_i \Gamma_i d\mu_i\,, \quad (7)$$

where $q_{S,0}$ is the surface charge for an electrode potential E_0, $\Gamma_i = N_i/A_S$ is the number of adsorbed i particles (the Gibbs adsorption), N_i is the number of moles of the i-th component, and A_S is the surface area of the crystal. This equation cannot be used, since for T = const the system is invariant. However, when $K_M \neq 0$ we can write

$$d\gamma^0_{ij}/dR_S = -\Gamma_i(d\mu/dR_S) \quad (8)$$

and after some substitutions arrive at the Tolman equation[15]

$$\gamma^0_{ij}/\gamma^0_{ij\infty} = (1 + 2\delta/R_S)^{-1}\,. \quad (9)$$

For a flat surface $\delta/R_S \to 0$ and $\Gamma_i/\Delta\rho \to \delta$ (the distance from the interface); $\Delta\rho$ is the difference between the densities of the crystal and of the liquid phase. It is clear that the increase in Γ_i (i.e. the decrease in γ^0_{ij}) depends on the curvature of the corroding surface.

In a macroscopic analysis of the increments $\Delta\gamma^0_{ij}/\gamma^0_{ij}$ we must allow for a possible increase (as well as a decrease) in the surface area A_S. Gokhshtein[16] introduced the differential factor

$$\beta = \Delta A_S/A_S = \Delta\gamma^0_{ij}/\gamma^0_{ij},$$

related to the curvature of the surface K_M by the expression

$$\beta = 1/2[(1 - \nu)K_M + (1 + \nu)K_M^{-1},$$

where ν is the Poisson ratio for the metal ($\nu \cong 0.25$). The curvature of the surface K_M can be altered by the adsorption of species from the solution (with charge transfer) at the electrochemical contact. Faceting of the surface (to give S and K faces) is possible, including, as a first stage, the rearrangement of the near-surface layers of the crystal. The coherence of the coupling of the EDL with the metal and the electrolyte plays an essential role in the rearrangement of the first few surface layers of the crystal.

IV. Adsorption of chalcophilic particles and phase transitions of the second kind in the near-surface layers of monocrystals

An ideal crystal surface has the unique property of a stretched skin, i.e. an elastic surface tension γ_{ij} which compresses the inner part of the crystal. When a metallic crystal is cut to produce a new surface in transition metals, which contain electronic surface states of the Tamm or of the Shockley type, the atoms in the first near-surface layers are regrouped (rearranged, reconstructed), and γ_{ij} decreases. The radii of the first, second, and third coordination spheres on the newly formed surface of transition metals are greater than in the bulk (for example, for Fe the increase is $> 3\%$).

A strict thermodynamic description of the reconstruction of the near-surface layers can be based on Landau's theory of phase transitions.[17] Large displacements (Δd) of the atoms in the metal lattice are characterised by a nonlinear function for the deviation of the atoms from the given equilibrium positions (the nonlinear order parameter) in this theory. This function is exactly equivalent to a density wave in the metallic crystal.[18]

In the surface layers of very pure monocrystals the distance between the first and the second layer (Δd_{12}) at right angles to the surface is less than the corresponding distances in the bulk (Table 3), i.e. we observe a perturbation of the translational invariance and an alternation of the sign (with decreasing amplitude), which is more marked for the stepped nonsingular K faces [for example, (997), (991), (311), see Table 1]. This change in Δd, not related to the adsorption of particles from the solution, is a fundamental property of the first few near-surface layers of metallic crytals.

The reconstruction of the near-surface layer of a crystal was first described in terms of the charge model. The infringement of the translational invariance produces effectively localised electronic states

which give rise to surface energy bands from closely placed energy levels. The formation of surface charge and of an EDL of thickness comparable to that of the Debeye screening radius leads to the filling of the conduction band. An electric field normal to the surface and a bending of the energy bands are produced. A relaxation (a change in the displacement Δd) takes place under the influence of the surface tension forces, and the surface layer is reconstructed as a result of the difference in energy between the electronic states produced by small deformations of the surface structure. In diamond-like structures [for example, (111)Si] the relaxation can be as high as 30%.[19]

During the reconstruction of the surface layers of the crystal we observe transverse and longitudinal displacements in the first rows of atoms in addition to the displacements Δd normal to the surface. Transverse relaxation is found on singular, low-index F faces, such as the (111), (110), and (100) faces of b.c.c. crystals of the transition metals. Both longitudinal and transverse displacements of the atoms in the first layers of atoms are possible on nonsingular S faces [for example (210), (310), and (211)].[20]

The compressive stresses in the first near-surface layers of crystals are always replaced in the deeper layers by compensating expansion stresses produced by the action of the *sp* electron gas and by the short-range repulsive pair interactions between the atoms. The tangential displacements (Δd_r) of the atoms in the first layers are expressed[26] as

$$\Delta d_r = -\frac{1}{2G_c}\int_0^\infty f_1(tr)[\nu t^2\varphi + (1-\nu)\frac{\partial^2\varphi}{\partial z^2}]dt, \qquad (10)$$

where G_c is Young's modulus, φ and r are the spherical coordinates, f_1 is a Bessel function, and the z axis is directed towards the bulk of the crystal.

A test of formula (10) by computer calculations shows that these stresses have a variable sign. The adsorption of particles from the solution produces a rearrangement which stabilises the surface layer: a phase transition of the second kind takes place in a thin layer of the crystal. Obviously, two mechanisms can be suggested for the effect of adsorbed SAS on the reconstruction of the surface:[27] (*i*) in some metals the symmetry of the atomic arrangement is modified by the adsorption of SAS, approaching the symmetry found in the bulk, and (*ii*) the adsorption of the SAS produces a reconstruction of the surface which stabilises it. These are usually the least close packed F faces in the f.c.c. (011) and the b.c.c. lattices [(001) and (111)].

According to Benneman and Tomanek[28] the reconstruction of the surface is the result of the minimisation of the surface free energy (which at $T = 0$ K is the half-sum of E_b for the two free surfaces) associated with the surface tension:

$$\gamma_{ij}^0 = \frac{1}{N_S}\sum_{i=1}^{N_A}(E_{b,k} - E_{b,i}), \qquad (11)$$

where $E_{b,k}$ and $E_{b,i}$ are the binding energies of the atoms in the bulk and on the surface of the crystal, and N_A is Avogadro's number. Acording to Rusanov[29] the tangential forces Δd_r act in a near-surface layer of thickness l, and therefore Eqn. (11) should be re-written

$$\gamma_{ij}^0 = \int_0^l(\sigma(z) - \sigma^0)dz,$$

where $\sigma(z)$ and σ^0 are the stress tensors in the bulk and on the surface of the crystal.

The heat of reconstruction of the clean surface $\Delta\gamma_R^0$ is the difference between the surface tensions of the rearranged (γ_R^0) and the nonrearranged surfaces (γ_u^0):

$$\Delta\gamma_R^0 = \gamma_R^0 - \gamma_u^0. \qquad (12)$$

The changes in d produced by the reconstruction of the surface are entirely different in the presence of an adsorbed SAS. There are a few crystals whose clean surfaces do not become reconstructed, and also some crystals in which the amplitude of the atomic vibrations in the first layers is comparable with the amplitude of the vibration of the adsorbed SAS particles, and the rearrangement proceeds as a cooperative resonance process. When SAS species are adsorbed the heat of reconstruction [according to (12)] becomes:

$$\Delta\gamma_R = \Delta\gamma_R^0 - \Delta\gamma_{ads}. \qquad (13)$$

In this expression

$$\Delta\gamma_{ads} = \theta_{SAS}(E_{ads,R} - E_{ads,u}), \quad (14)$$

where E_{ads} is the energy of the adsorbate–adsorbent bond and the difference $E_{ads,R} - E_{ads,u}$ is determined by calculation or experimentally. From Eqn (14) we obtain the main diagnostic criterion for the supression or the initiation of the reconstruction:

$$\Delta\gamma_R = \Delta\gamma_R^0 - \Delta\gamma_{ads} < 0, \quad (15)$$

which can be determined by a simple method (Fig. 3).

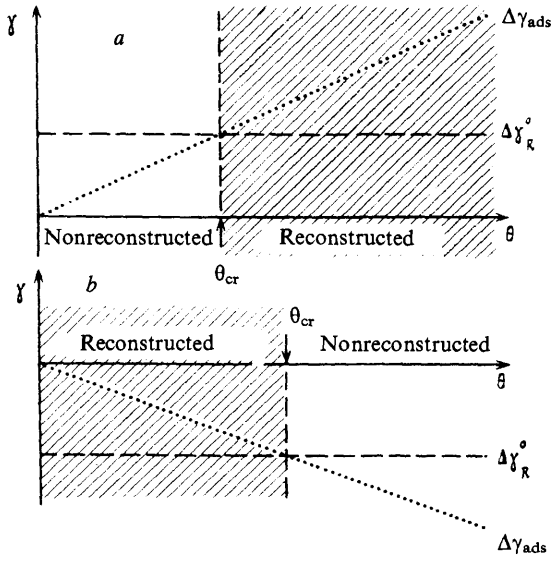

Figure 3. Changes in surface energy during the reconstruction of the near-surface layer of the metal:[24] *a*, onset of reconstruction; *b*, suppression of reconstruction.

In order to obtain the surface tension γ_{ij}^0 by Eqn. (11) we must expand $E_{b,i}$ into two terms:

$$E_L(x) = \Delta E_{rep}(z) + \Delta E_b(z), \quad (16)$$

where $\Delta E_{rep}(z)$ is the Born–Mayer phenomenological short-range repulsive potential: $\Delta E_{rep} = \Sigma A_S exp(-pR_{a,i})$, $R_{a,i}$ is the length of the bond along the z axis between the adsorbed particle and the M(i) surface atom, p is the damping coefficint, and $\Delta E_b(z)$ is the contribution from the adsorbate–adsorbent interaction. Eqn. (16) shows that the driving forces of the rearrangement are the elastic forces in the near-surface layer. The rearrangement induces a change in the chemical composition of alloys. A LEED study of the enrichment of the first surface layer in the close-packed (111) face of a monocrystal of the $Pt_{0.1}Ni_{0.9}$ alloy by platinum atoms[30] showed that the degree of enrichment can reach 30 ± 4% while the second layer is depleted of platinum by 5 ± 3%. Therefore we must allow for the ennobling of the surface even before the contact with the electrolyte when calculating the corrosion resistance of binary alloys containing a noble metal component. The ennobling of the surface layer is a well known phenomenon in corrosion or anodic dissolution studies, but it is usually attributed to the transport of alloy components into the solution and their subsequent reprecipitation.

In electrochemical dissolution processes of M taking place at low speed the rearrangement of the surface layer is undoubtedly an active factor. The ionisation of the metal during dissolution $M^0 \rightarrow M^{+n} + ne^-$, produced by the breaking of the M–M bond followed by charge transfer, should lead to periodic pulsations of the atoms in the first layer associated with the formation of metastable states. This effect will be reflected in the magnitude of the current flowing through the electrochemical system. Instability of the surface structure is mainly seen in the *d* metals with a half-filled *d* band. The mechanical instability (reconstruction) stimulates a rearrangement of the force and energy distributions on the surface, leading to electrical instability.

This type of electrical instability, accompanied by current pulsations (oscillations), is often observed in electrochemical processes on solid electrodes under conditions of pre-phase (adsorptional) evolution of material on the surface at relatively low overvoltages (η = 0.02–0.03 V) in the cathodic or the anodic region. Current oscillations may result in periodic mechanical vibrations in the M/electrolyte system, whose amplitude depends on the shape of the electrode and on the electrolysis parameters.[31]

V. Reconstruction of monocrystal surfaces during the adsorption of hydrogen, oxygen, and halogens

The adsorption of light chalcophilic species (hydrogen, oxygen, haloens) produces the highest activity in the reconstruction of the near-surface layers of metals.

Hydrogen

An analysis of the interaction of hydrogen with the near-surface layers of transition metal monocrystals is of practical value in the chemistry of catalysis and in the assessment of corrosion and brittleness in constructional materials. The reversible absorption of hydrogen in a metal plays an important role in hydrogen energetics. We shall discuss the structural effects resulting from the adsorption of hydrogen on the surface of the transition metals of Groups IB, VIB, and VIII of the Periodic Table, beginning with the adsorption of hydrogen from the gas phase, because this information is invariably used in the analysis of the contact between a metal and an electrolyte. The studies were carried out by LEED, AES, IRS, and other methods.

Adsorption from the gas phase. Most of the experimental work was done with well characterised nickel monocrystal surfaces. The adsorption parameters depend on (*hkl*), but it has been shown that the nickel (100) and (111) faces are affected similarly by the adsorption of hydrogen.[22] There are two sequentially filled β states, with activation energies for desorption of ~0.84 (β_1) and 1.00 eV (β_2). The number of hydrogen atoms in the adsorbed monolayer (*ML*) varies between $\sim 3 \times 10^{18}$ and 1.5×10^{19} atoms m^{-2}, i.e. it is slightly lower than N_S for these faces. The work function of the electron (Φ_M) from the surface of the metal M increases in proportion to the filling of the nickel surface by hydrogen (θ_H) up to saturation (state β_2), reaching ~0.2 eV at saturation (θ_H = 1 *ML*,

5×10^{-2} Pa, 298 K). LEED measurements indicate the formation of a disordered adsorbed layer of hydrogen on nickel at 298 K.

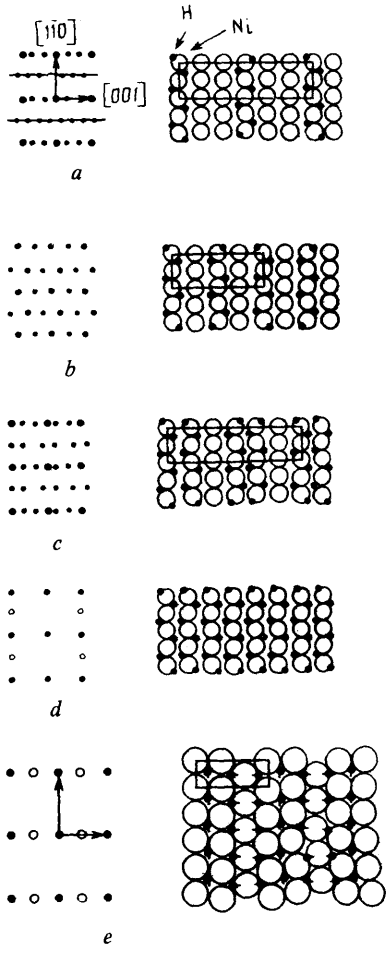

Figure 4. Superstructures formed on the (110)Ni face for different θ_H (*ML*): *a*, 0.33; *b*, 0.50; *c*, 0.67; *d*, 1.00; *e*, 1.50; on the left, LEED diffraction pattern, on the right, model.[32]

The adsorption of hydrogen on the least close packed (110) face of nickel shows some special features.[32–35] In particular, it has been shown that at the θ_H values for which $\Phi_m \cong 0.06$ eV a one-dimensional structure with the same periodicity (1×2) as the nickel lattice is formed as a result of the attraction of the adsorbed hydrogen atoms in the [1$\bar{1}$0] direction along the rows of nickel atoms of the first near-surface layer. This phase transition of the second kind is accompanied by an increase in the binding energy of the hydrogen to the nickel E_{Ni-H}, but the interactions of the adsorbed atoms in the [001] direction, across the above rows, are much weaker. The periodicity of the structures produced by the adsorption are strongly dependent on θ_H:[32] at $\theta_H = 0.33$ *ML* the first disordered (2×6) superstructure is formed, the (2×4) superstructure at $\theta_H = 0.5$ *ML*, a second (2×6) at $\theta_H = 0.67$ *ML*, and at still higher coverages we find the (2×1)–2H at $\theta_H = 1.0$ *ML* and finally the (1×2)–3H at $\theta_H = 1.5$ *ML* (i.e. at saturation) (Fig. 4). Hydrogenation of the (110) nickel face ($T \geqslant 220$ K) produces "stripes" with a (1×2)–3H structure in the [001] direction. The surface is reconstructed and consists of paired and of extended rows of nickel atoms. The hydrogen aotms are adsorbed on two (*r* and *s*) positions with a low and a high Ni–H bond energy respectively,[33] i.e. in the triple vacancies between the first two nickel layers parallel to the paired rows of the first layer in the [1$\bar{1}$0] direction, forming saw-like chains, and in the triple vacancies normal to the rows of nickel atoms in the [001] direction. The length of the Ni–H bond becomes 1.72 ± 0.01 nm, and the nickel atoms of the second layer are displaced alternately and mutually at right angles by ± 0.02 nm. The density of the adsorbed hydrogen atoms is 1.71×10^{19} atoms m^{-2}, and $E_{Ni-h} \simeq 2.75$ eV. There are reports[34,35] that at $T = 298$ K the chemisorption of hydrogen on (110)Ni–(1×1)H rearranges the surface into (110)Ni–(5×2)H, so that the nickel atoms of the first layer are shifted by 0.05 nm in the direction of dimerisation (Fig. 5), forming tetramers, which can also be interpreted as a combination of paired and extended rows (every fifth row in the [001] direction is extended).

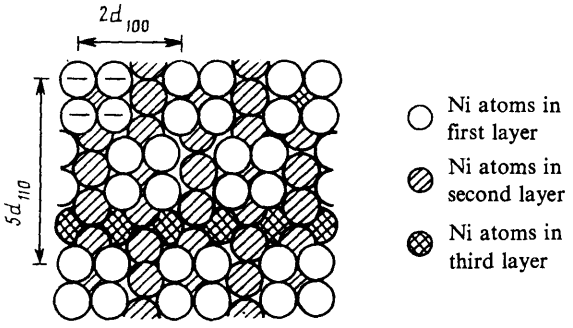

Figure 5. (5×2) Superstructure formed on (110)Ni by the adsorption of 0.5 *ML* of hydrogen at $T = 298$ K.[34]

In the high-index nickel *S* faces [for example, (997)Ni, (510)Ni, etc.] the presence of steps and terraces plays an important role, as was pointed out above. Thus, on the (510)Ni face at $T \simeq 100$K and coverages up to $\theta_H \leqslant 0.9$ *ML* hydrogen is adsorbed both on the terraces and on the steps (with preferential coverage of the steps),[36] and at $\theta_H > 0.9$ *ML* even molecular hydrogen is adsorbed, but only on the step edges.

The stepped (997)Ni *S* face, which is a combination of monoatomic (111) steps and nine-atom (111) terraces (Table 1), has a hydrogen capture probability at $T = 298$ K 10 times higher than the singular (111)Ni *F* face.[37] At low temperatures ($T \leqslant 250$ K) hydrogen adsorption takes place mainly on the step edges, but at high temperatures it extends over the terraces (according to LEED and HEED studies). The predominant adsorption of hydrogen on the steps can be demonstrated by the dependence of the sticking coefficient on the angle of incidence (Fig. 6). We can see that at $T = 90$ K the function $s_0(\theta_H)$ is determined exclusively by the presence of steps. Conversely, at $T = 800$ K only the terraces affect the kinetics of adsorption, and the plot of the $s_0(\theta_H)$ function is identical to that obtained for the (111) plane, inclined at 6.4° to the (997) plane.

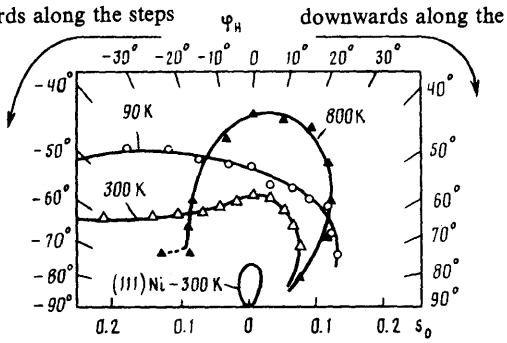

Figure 6. Dependence of the sticking coefficient s_0 on the angle of incidence of the molecular beam of hydrogen φ_H on the (997) and (111) nickel faces at different temperatures.[36]

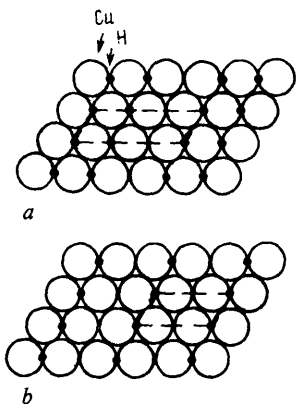

Figure 7. Superstructures formed on the (111)Cu face:[39] *a*, (3 × 1); *b*, (2 × 1).

Copper

On the (110)Cu face the adsorption of hydrogen is mainly in the atomic form,[32] with low values of E_a (0.18–0.20 eV), denoting a low probability of attachment of hydrogen molecules. It has been shown by LEED measurements that subsurface reconstruction with formation of a specific (1 ×2)* phase takes place at 300 K. The octahedral surface position of the hydrogen atoms is more favourable than the interstitial position in the bulk of the metal, but it is less stable (by 0.3 eV) than the normal chemisorption position.[38] Under these conditions a substantial contribution to the stabilisation is provided by the change in the relaxation of the near-surface layer of atoms (Δd_{12} = 4–9.6% at θ_h = 0.5 *ML*). Of course, so far we have no definite model of the resulting structure, because of the difficulty of correlating the LEED results variously obtained for the (110)Cu surface covered with hydrogen.

A study of the temperature dependence of the adsorption of hydrogen on the (111)Cu surface by IR spectroscopy has shown[39] the presence of two superstructures (3 × 3) at 150 K and (2 × 2), into which the (3 × 3) phase is converted when heated to 186 K (Fig. 7). The structures are combinations of domains with (3 × 1) and (2 × 1) orientations. The adsorbed hydrogen atoms are accommodated in (111)Cu double vacancies parallel to the rows, so that every third row is extended for the (3 × 1) structure and every second for the (2 × 1) structure. The filling with hydrogen of the double vacancies is confirmed by studies of the electron energy loss spectra (ν_1 = 1040 cm^{-1}, whereas a ν_1 frequency of 1000 cm^{-1} is calculated for the filling of triple vacancies).

Ruthenium

Like the (110)Ni–H system, the (100)Ru–H system forms a wide spectrum of superstructures at low temperatures, depending on θ_H. At θ_H = 2.0 *ML* we find the (1 × 1)–2H structure (Fig. 8), in which the chains of adsorbed hydrogen atoms are arranged only in the [$\bar{1}$20] direction, unlike the (1 × 2) structure obtained for nickel.[32] A reversible surface reconstruction takes place at θ_H = 1.5 *ML*: in this state alternate ruthenium atoms are raised above the plane of the surface, and form a (2 × 2) structure. The density of adsorbed hydrogen atoms at θ_H = 2.0 *ML* is 1.73 × 10^{19} atoms m^{-2}, with E_{Ru-h} = 2.7 eV, which is comparable with the N–H bond energy. According to the desorption spectra hydrogen can be adsorbed in the α_1, β_1, and β_3 states, which exist at 220, 260, and 350 K respectively. The α_1 state corresponds to the formation of a (1 × 1)–2h structure (θ_H = 2.0 *ML*), the β_1 (probably) to the formation of a (2 × 2) structure (θ_H = 1.5 *ML*), and the β_3 state to the (1 × 2) structure. As in the case of nickel the sticking coefficient s_0 initially has very high values ($s_0 \simeq 1$), so that a coverage of only 0.3–0.4 *ML* of hydrogen is sufficient to saturate this state. However, s_0 rapidly falls to ~0.1 for the filling of the β_1 state at θ_H = 1.5 *ML*, and the rate of adsorption also falls.

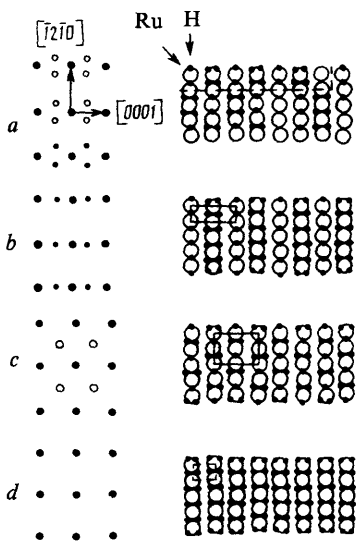

Figure 8. Superstructures formed on the (100)Ru face for different θ_H (*ML*):[32] *a*, 1.0; *b*, 1.4; *c*, 1.5; *d*, 2.0.

Rhodium

The structures obtained in the adsorption of hydrogen on the (110)Rh face (Fig. 9) are similar to those found on ruthenium.[32] At θ_H = 2.0 *ML* a structure with a periodicity of (1 × 1) is formed,

with two hydrogen atoms in the unit cell. The hydrogen occupies triple vacancies, forming linear chains in the [1$\bar{1}$0] direction, but in this arrangement it produces stronger changes in the surface relaxation of the rhodium atoms than it does in ruthenium.[40] As in other *d* metals, we find a compression at right angles to the surface (a decrease in Δd, Table 3). The distance between the layers is 0.132 nm, and the length of the Rh–H bond is 0.184 nm.

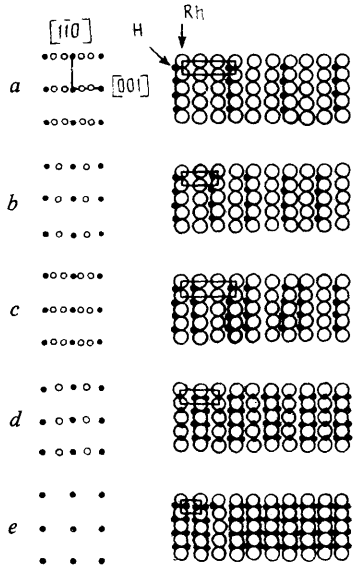

Figure 9. Superstructures formed on the (110)Rh face for different θ_H (*ML*):[32] *a*, 0.33; *b*, 0.50; *c*, 0.67; *d*, 1.60; *e*, 2.00.

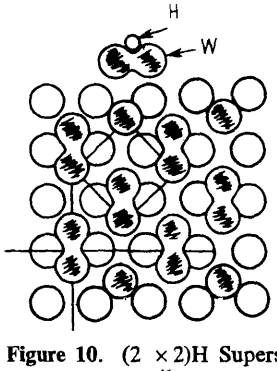

Figure 10. (2 × 2)H Superstructure formed on the (100)W face for θ_H = 0.25 *ML*.[41]

Under these conditions the density of the hydrogen atoms is ~2 × 10^{19} atoms m^{-2}. The high bond energy E_{Rh-H} = 5.7 eV [unlike E_{Ni-H} = 2.7 eV for (110)Ni] can account for the lack of surface reconstruction in rhodium even after the adsorption of large amounts of hydrogen. The hydrogen desorption spectra show that two states are being filled: α_1 (at 138 K), corresponding to the (1 × 1)–2H structure (θ_H = 2.0 *ML*), and α_2 ($T \simeq$ 250 K), corresponding to the (1 × 2) structure (θ_H = 1.5 *ML*). As was subsequently pointed out,[25] at θ_H = 0.5 *ML* a reconstruction takes place, yielding a (1 × 2)–2H structure in which the hydrogen atoms occupy three-coordinated positions between two atoms of the upper layer and one atom of the second layer, and are arranged along rows of rhodium atoms in the [1$\bar{1}$0] direction. The surface relaxation changes so as to maintain a distance of 0.127 nm between the first and the second layer, which is comparable with the results obtained for the (1 × 1) structure. The electronic work function Φ_M reaches 0.930 eV for $\theta_H \to 1$ *ML*, but the increase in Φ_H is not affected by an increase in p_{H_2}.[42] This effect is attributed[42] to the preferred orientation of the hydrogen dipole with its negative end towards the gas phase.

Tungsten

At $T \simeq$ 300 K and low surface coverages of the (100)W surface flash desorption reveals one adsorbed β_2 state whose formation is completed at θ_H = 0.16–0.25 *ML*. At higher surface loadings we observe a second (β_1) state in which the density of adsorbate is 2.0 × 10^{18} molecules m^{-2}.[22] The ratio of the concentrations corresponding to saturation in each of the states is σ_1/σ_2 = 2. The adsorption of hydrogen in the β_1 state producs a diffraction pattern corresponding to the (2 × 2) structure, which reduces to the ordered (1 × 1) structure at θ_H = 1 *ML* (Fig. 10), with molecules and atoms accommodated in tetrapores. The adsorption of hydrogen on the (100)W *F* face at θ_H < 0.25 *ML* produces a reconstruction with the surface tungsten atoms in pairs in the [100] direction, forming dimers, and the adsorbed hydrogen atoms are accommodated on the surface atoms as saw-tooth chains.[41]

Flash desorption studies of the (100) and (110) tungsten faces gave similar results.[22] When the adsorption has taken place at 300 K we observe two peaks for β_1 and β_2 states with E_{W-H} bond energies of 1.2 and 1.4 eV respectively. When saturated these states contain approximately the same number of particles, formed by dissociative adsorption; at θ_H = 0.5 *ML*, when the β_2 state is filled, a (2 × 1) structure is formed and the hydrogen is again accommodated in tetrapores. the density of adsorbate in the β_2 state is 1.42 × 10^{19} atoms m^{-2}. The electronic work function decreases with increasing coverage during the adsorption in this state, reaching Φ_M = 0–(–0.5) eV at θ_H = 1.0 *ML*. There are reports that multilayer coverage (θ_H = 8 *ML*, 300 K) produces a reconstruction of the less closely packed (110)W face in which the tungsten atoms are shifted relative to each other in a [1$\bar{1}$0] direction and the hydrogen atoms occupy triple vacancies.[43]

In the b.c.c. tungsten lattice the (211)W is the simplest *S* face, containing atoms having two coordinations: in close-packed rows, forming the first or the surface layer respectively, or in the channels between rows.[9] Though the latter are in the second layer they are accessible to adsorption. This nonuniformity of the face is reflected by the hydrogen adsorption. We observe two adsorption states, β_1 and β_2, which are filled sequentially at $T \simeq$ 100 K. They correspond to atomic states with approximately equal contents of adsorbate at saturation. The sticking probability is $s_0 \simeq 1$, and the decrease in s_0 produced by an increase in Φ_H is proportional to $(1-\theta_H)$. The LEED method failed to detect the formation of a structure with a (1 × 1) periodicity. The electronic work function Φ_M increases by ~0.6 eV for β_2 but falls when the β_1 state is filled. This is explained by the structual properties of the (211)W face towards the adsorbed hydrogen (the adsorbed β_1 state is above the

plane of the surface, and the β_2 state is below it). If a hydrogen atom is adsorbed in a β_1 state (in the uppermost close-packed rows) its dipole is oriented with its positive end towards the metal, resulting in a decrease of Φ_M.

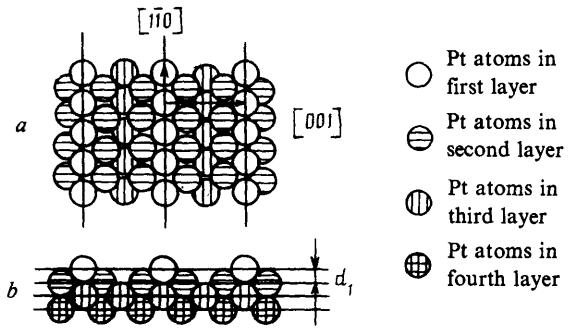

Figure 11. (110)−(1 × 2)Pt Superstructure formed after treating the (110)Pt surface in ultra-high vacuum:[32] *a*, plan view; *b*, side view.

Platinum

As we know, the clean surface of the "loose" (110)Pt face (unlike that of nickel or rhodium) is unstable and is spontaneously reconstructed into a (1 × 2) structure when treated in a high vacuum, so that each row is extended in the [001] direction.[32] In this way the third layer of platinum atoms becomes accessible to the adsorption of hydrogen as well as the second. The surface of the (110)Pt face can be represented as an assembly of (110) micro-facets inclined at 109.5° relative to each other, containing various types of triple or double vacancies between the first and the second layer. The hydrogen adsorbed on these sites does not affect the initial reconstruction (Fig. 11). Of course, the faceted (110)Pt surface is relatively rough and therefore can hold more hydrogen atoms than other faces [$\theta_H = (2.2 \pm 0.2) \times 10^{19}$ atoms m^{-2}]. The hydrogen is adsorbed in two states [β_1 and β_2, for $\theta_H = (0.4-0.6)$ *ML*, 300 K].

The β_1 state formed at $T \simeq 200$ K requires longer exposures to reach saturation. Initially the sticking probability is $s_0 \simeq 1$, but during the filling of the β_1 state $s_0 = 0.022$ and $E_{Pt-H} \simeq 2.8$ eV. The electronic work function initially increases with the coverage ($\Phi_M = 0.170$ eV for $\theta_H = 0.3$ *ML*), but at $\theta_H = 1$ *ML* Φ_M falls to 0.05 eV (Fig. 12). This is explained by the difference between the dipole moments of the β_1 and the β_2 state ($\mu_2 = +0.12$ D for β_2 and $\mu_1 = -0.17$ D for β_1, where 1 D = 10^{-2} C m[44]), which depend on the topology of the adsorbed hydrogen. The filling of the β_1 state corresponds to the adsorption of hydrogen on the (111) micro-facets, when the negative ends of the dipoles of the hydrogen adatoms are directed towards the upper row of platinum atoms. The adatoms themselves lie below the plane of the image charge, i.e. in the triple vacancies, and this lowers the dipole moment of the metal.

Two adsorption states have been observed by the thermal desorption of hydrogen from the close packed (111)Pt face, but at 300 K the β_1 state is absent because of the low energy of the Pt−H bond, and the β_2 state is only partially filled.[9] It has been shown that in the β_1 and the β_2 state the hydrogen is atomically bound to the platinum and that at $\theta_H = 1$ *ML* the amounts of these two states are approximately equal. The hydrogen is adsorbed in triple vacancies between the atoms of the first and the second platinum layer without perturbing the ordered (1 × 1) structure, so that the length of the Pt−H bond is 0.058 nm,[45,46] and $E_{Pt-H} \simeq 2.6$ eV.

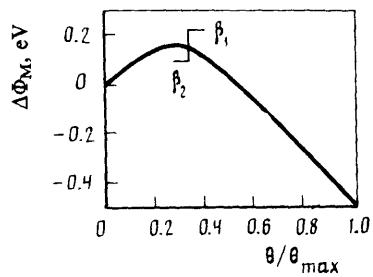

Figure 12. Dependence of the electronic work function Φ_M on the surface coverage θ_H for the (110)Pt face;[44] β_1 and β_2 are the adsorption states.

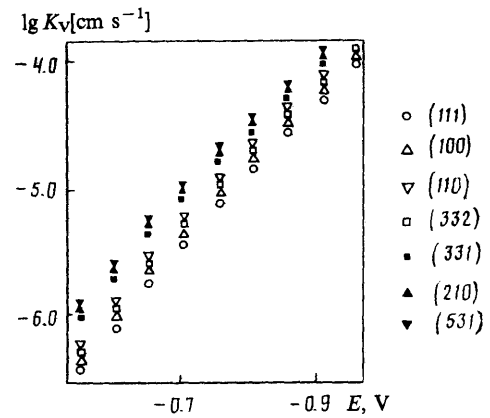

Figure 13. Dependence of the rate of the hydrogen evolution reaction on the potential for different *F* and *S* faces of a gold monocrystal (0.1 M $HClO_4$).[47]

Interesting results have been obtained on the stepped (997)Pt face [a combination of monoatomic steps and nine-atom terraces, oriented in the [111] direction]. As on the (997)Ni face, the sticking probability s_0 was found to be very high [~4 times greater than on the singular (111)Pt face.[32,34]]. At high coverages $\theta \geqslant ML$ the s_0 values for (997)Pt (like the Φ_M values) are comparable with those obtained for (111)Ni. However, at low saturations the "loose" steps of the (997)Pt *S* face act as centres on which the hydrogen is adsorbed most rapidly, is held most strongly, and has a dipole of opposite sign to that of hydrogen adsorbed on (111)Pt. There is evidence of the presence of a second break in the dependence of s_0 and $\Delta\Phi_M$ on θ_H at $\theta_H = 0.15$ *ML*: 9 hydrogen atoms are adsorbed

on each terrace at saturation. Therefore the two centres at the ends of each terrace have a stronger Pt–H bond energy than the others, and are the first to be filled. It is experimentally established that these centres are geometrically different from the others, and that the hydrogen atoms adsorbed on them have dipoles different from the rest.

Adsorption in solutions of electrolytes

The adsorption of electrochemically reduced hydrogen (during which the pressure of the gas on the metal surface is much higher than p_{H_2} = 1 GPa) has been adequately studied on well characterised faces of gold, platinum, nickel, and niobium monocrystals.[47–60]

Thus the hydrogen evolution reaction (HER) has been studied not only on the low-index gold faces, but also on the (311), (210), (332), and (531) *S* faces, consisting of sets of steps and terraces.[47] It was found that both in $HClO_4$ solutions and in electrolytes with specifically adsorbed halogen ions (Hal^- = F^-, Cl^-, Br^-, I^-) the HER is slower on the close-packed faces, but faster when the faces contain steps and breaks. The rate of the HER increased with the concentration β_0 of monoatomic steps; for example, in a solution of NaF the rate of the HER on the (210) gold face was ~3.5 times higher than on the (111) face (Fig. 13). This is due mainly to the decrease of Φ_M on the atomically rough *S* and *K* faces. Obviously, the low-coordinated *r* states on the crystal surface have a catalytic effect on the adsorption of hydrogen. When in contact with the surface the hydrogen fills the tetrapores on the steps, forming bonds.

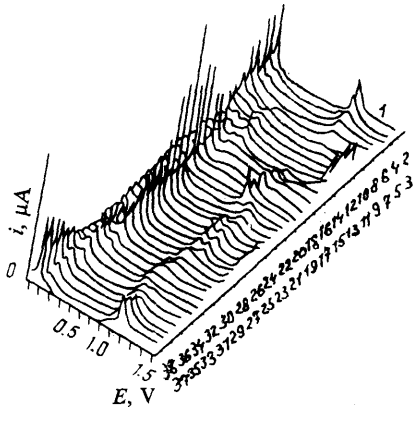

Figure 14. Current–voltage diagrams for Pt faces of different crystalline orientation.[49] Face indices: *1*, (110); *2*, (551); *3*, (331); *4*, (227); *5*, (332); *6*, (554); *7*, (10109); *8*, (202019); *9*, (111); *10*, (201919); *11*, (1099); *12*, (544); *13*, (355); *14*, (322); *15*, (513); *16*, (211); *17*, (311); *18*, (511); *19*, (211); *20*, (911); *21*, (1711); *22*, (3111); *23*, (100); *24*, (2110); *25*, (1510); *26*, (1210); *27*, (910); *28*, (610); *29*, (510); *30*, (410); *31*, (310); *32*, (210); *33*, (530); *34*, (320); *35*, (430); *36*, (620); *37*, (12110); *38*, (110).

These pores offer strong bond positions (*s* state) which are energetically more favourable to adsorption. The difference in E_{M-H} energies between the weakly bound (*r*) and the strongly bound states (*s*) is determined essentially by the crystallographic parameters of the hydrogen adsorption. This has been experimentally demonstrated, for example, for the (881), (771), and (661) *k* faces of an Fe + 3% Si crystal,[48] which are combinations of 8-, 7-, and 6-atom terraces, consisting of (110) planes and of loose monoatomic (100) steps. The radii of the tetrapores (*s* state) on the (110)Fe and (100)Fe faces are r_{110} = 0.00173 and r_{100} = 0.0766 nm. Therefore, since the radius of a hydrogen atom is r_h = 0.046 nm, the adsorbed hydrogen can easily penetrate into the pores in the steps afer being discharged, but the process is suppressed in the close-packed terraces.

The form of the cyclic potentiodynamic potential–current curves depends on the density of β_0 and (*hkl*) steps in the platinum *S* faces.[49] As β_0 decreases, i.e. as the packing density S_{hkl} is increased, the characteristic hydrogen adsorption peak moves into the region of positive potentials (Fig. 14), due to the increase in Φ_M and to the corresponding shift of the zero charge potential $E_{q=0}$. it can also be seen that, as the less densely packed steps become saturated, hydrogen begins to be evolved on the terraces and the intensity of the corresponding peak is increased. Cyclic potentiodynamic curves can be used for a quantitative as well as a qualitative assessment of the adsorption on the *K* faces of monocrytals, and in particular for determining the structural characteristics of these faces, as was demonstrated[50] for the [*n*(111) × (100)] platinum surfaces (*n* = 2–9, 12, 14, 20, 26, and 40).

High-sensitivity optical methods[51] are now widely used to determine the changes in structure of monocrystal surface at the contact with electrolytes. We know that the form of the electroreflectance (ER) spectra depends on the crystallographic orientation of the faces; the $\Delta R/R$ effect (where *R* is the Fresnel reflection coefficient) is smaller when the lattice is most closely packd [for an f.c.c. lattice, of copper (say), the sharpest peaks are found in the spectrum of the (311) *S* faces, and the weakest in the spectrum of the (111) face[52]]. Furthermore the presence of steps and of terraces with different crystallographic orientations is also reflected by the shape of the spectral lines.

The structure of the interface between monocrystalline gold [(111), (100), (110), and (210) faces] or silver electrodes [(111) and (100) faces] and an aqueous solution of 0.01 M NaF has been studied ellipsometrically.[53] As before, a strong dependence of the optical spectra near $E_{q=0}$ on the crystallographic orientation of the electrodes was noted [though the spectra of the reconstructed and of the nonreconstructed (100)Au faces do not differ very markedly]. The effect of the charge density *q* on the polarisation angle Δ depends on the sign of the charge; for $q < 0$ only a small $q = f(\Delta)$ response is observed. This is consistent with the assumption of a weak metal–solvent interaction. The sharp change in the level of the optical signals for $q > 0$, largely determined by the crystallographic orientation of the sample, can be attributed to the onset of specific adsorption of the anions and to a strong $M-H_2O$ interaction. Information on the surface structure was obtained by calculating the relaxation time of the free electrons τ: the greater is τ, the smaller is the difference in structure between the surface and the bulk. As expected, the highest value of τ was found for the most closely packed (111)Au face.

Subsurface defects (dislocations, vacancies, and their combinations) have a marked influence on the electrochemical characteristics of a monocrystal suface. The walls of the etch pits formed on defects can be described as a combination of terraces (*F* faces) and steps with breaks (*k* faces). This produces new adsorption–desorption peaks, not seen on the potential–current curves of well ordered surfaces of perfect monocrystals.[54] The application of a relatively small number of oxidation–reduction

cycles, or of a high-temperature anneal, eliminates the defect portions of the electrochemical process and finally yields an improved potential–current curve.

However, it hs been reported[55] that extending the range of applied potentials can produce irreversible changes in the potential–current curve as a result of a far-reaching breakdown in the initial structure of the metal. The same situation is found when the scan rate of the potential is increased (>0.1 V s^{-1}); fast cycling "strikes" the metal atoms in the near-surface layer from their equilibrium positions. This results in microfaceting, i.e. in a change in surface structure accompanied by the formation of highly coordinated adsorption s states. Fig. 15 shows, as an example, the cyclic potentiodynamic E, i curves for the (111)Au and (111)Pt faces for different scan rates and different ranges of the applied potential. The structure of the (111)Pt and (100)Pt surfaces has been studied by transmission electron microscopy (TEM) after various cycles of electrochemical treatment.[56,57]

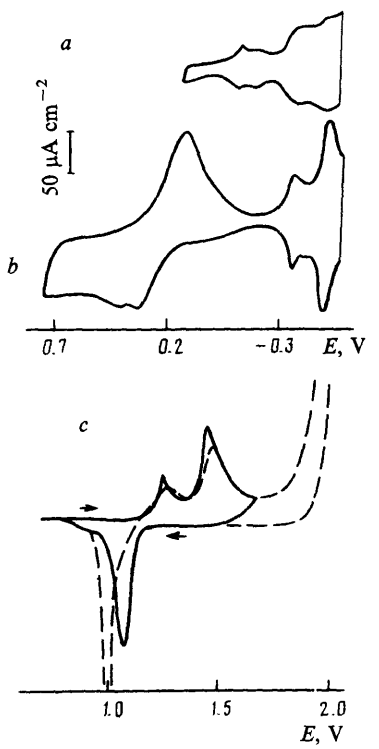

Figure 15. Current–voltage curves of the (111)Pt and (111)Au faces for different potential scan rates and different applied potentials: *a*, (111)Pt, 0.5 M H_2SO_4, V_E = 0.5 V s^{-1}, E = 0.15–(–0.48) V; *b* (111)Pt, 0.5 M H_2SO_4, V_E = 0.2 v s^{-1}, E = 0.70–(–0.5) V;[58] *c*, (111)Au, 0.1 M $HClO_4$, V_E = 0.02 V s^{-1}, E = 0.7–1.7 V (full line), E = 0.7–2.0 V (broken line).[93]

Let us examine more closely the electrochemical faceting process. The (111)Pt and (100)Pt faces were subjected to the so-called (100) treatment in a solution of 0.5 M H_2SO_4, consisting in the application of rectangular potential pulses (0.23–1.23 V) at a frequency of 3.5 kHz. Under these conditions the potential E varied cyclically between the hydrogen evolution region and the oxide formation region (–0.5–0.7 V) for a short time (0.5–5 s). This treatment had a radical influence on the morphology of the (111)Pt face [while the (100)Pt face was not significantly affected], and the results were comparable with the application of several hundred single pulses of the potential. After 5 s of this treatment the (111)Pt face showed an increased roughness K_M, the steps became flat and well defined, and the outline of the terraces was markedly altered by the formation of K faces (with atomic projections and hollows), seen in the TEM pictures as small kinks on the terrace surfaces. The monocrystallinity of the (111)Pt steps after the electrochemical treatment is explained by the ability of the steps to act as recesses for Pt adatoms, leading to cluster formation and thus being self-perpetuating. After 50 cycles of applied potential (0.77–0.53 V) with a scan rate of 0.2 V s^{-1} less than 10% of the surface has escaped the phase transition of the second kind (faceting).[58] In this case the shape of the E, i curve is similar to that obtained for polycrystalline platinum. Thus the parameters of the electrochemical treatment (E and V_E values, frequency of the applied pulses, etc.) have a strong influence on the morphology and on the crystallographic orientation of the experimenal faces. These effects explain the large differences in the published results.[59]

In the electrochemical reactions, as in the adsorption of hydrogen from the gas phase, the surface of metal monocrystals becomes reconstructed.[60] Homa, et al.[61] described the transition of the (100)–(5 × 20)Pt structure into the (100)–(1 × 1)Pt structure after contact with the 0.1 M HF + CO electrolyte while cycling E between 0.05 and 0.50 V or without an applied potential. These workers conclude[61] that the instability of the surface is due to the adsorption of small quantities of CO during the preparation of the electrode for the experiment, which suppresses the reconstruction. The reverse transition from the (100)–(1 × 1)Pt to the (100)–(5 × 20)Pt structure during the contact of platinum monocrytals with 0.5 M H_2SO_4 + 0.1 M $H_2C_2O_4$ was observed by Orts, et al.[62] This reconstruction is typical not only of the (100)Pt surface but also of the (310), (610), and (211) platinum K faces, which contain terraces with a (100) orientation. As suggested,[62] the reconstruction process is due to the specific adsorption of the $HC_2O_4^-$ ions. There are reports[63] of the reconstruction of the (110)Pt surface at the contact with 1 M H_3PO_4 [transition of the (1 × 1) into the (1 × 2) superstructure by cycling E between 0.065 and 0.750 V with V_E = 0.05 s^{-1}]. The reconstruction of the (111)Au surface in a dilute solution of HF and $HClO_4$ has also been studied.[64] The (111)Au surface was pretreated in ultra-high vacuum by Ar^+ ion bombardment followed by heat treatment. The two-dimensional (111)–($\sqrt{3}$ × 22)Au structure, unstable at any applied potential, was formed on the close packed (111)Au surface. This was followed by the structural transition of (111)–($\sqrt{3}$ × 22)Au into the ordered (111)–(1 × 1)Au structure, which survived 10 cycles of potential scanning (0.2–1.75 V, V_E = 0.05 V s^{-1}).

Reports on the stability of the (100)Au face reconstructed by a similar vacuum treatment are contradictory. Thus, it was shown[52] that the resulting (100)–(5 × 20)Au structure (a hexagonal close packed upper layer on a square sublattice) is stabilised by immersion in 0.01 M solutions of $HClO_4$ and H_2SO_4 over the whole range of applied potential, which excludes specific adsorption (up to 0.31 V in $HClO_4$ and up to 0.11 V in H_2SO_4). This reconstruction is suppressed only by the adsorption of ClO_4^- and SO_4^{2-} anions. However, other works[64,65] find that the (100)–(5 × 20)Au structure, like the (111)–($\sqrt{3}$ × 22)Au structure, is converted into the

ordered (111)−(1 × 1)Au structure at any applied poential. The difference in surface tension $\Delta\gamma_{ij}$ between these structures is only 0.06−0.09 eV, and therefore a phase transition of the second kind can take place even in the physisorption region with $E_b \simeq 0.1$ eV. The stability of the (100)−(5 × 20)Au structure in contact with an electrolyte is attributed[65] to contamination of the surface during the preparation of the gold monocrystals by silicon and alkali metals, which stabilise the reconstructed surfaces of the 3*d* transition elements.

The (110)Au surface is reconstructed after being annealed and cleaned in an ultra-high vacuum. It forms a (1 × 2) superstructure which survive cyclic changes in potential (−0.35−0.45 V) when immersed in 0.01 M $HClO_4$. Contamination of the clean (110)Au surface by small quantities of calcium induced the formation of a (1 × 3) structure, which was again transformed into a (1 × 2) structure by the application of a variable potential in the same electrolyte.[66] This is inconsistent with Hamelin's results.[65]

The reconstruction of the (100)Au face in 0.005 M H_2SO_4 during cyclic changes in E (−0.1−1.3 V) was studied by electroreflectance spectroscopy.[67] The difference between the optical spectra of reconstructed and of nonreconstructed surfaces was attributed[67] to the presence of surface Tamm states, suppressed by the adsorption of SAS during phase transitions of the second kind. From the increase (or decease) in the height of the characteristic peaks for the optical transitions from the *d* band to the empty surface states in the ER spectrum the kinetics of the reconstruction of the (100)Au face were determined.

Oxygen

In an electrochemical corrosion process it is important to allow for the surface relaxation of the oxygen adsorbed on the metal surface, which has a high chemical affinity for the transition metals. The chemisorption of oxygen (like the chemisorption of halide ions) at 298−2300 k increases the distance between the uppermost near-surface layers: $\Delta d_{12} = 2.0 \pm 1.0\%$ in the case of the $p(2 \times 2)$ surface structure observed for coverages $\theta_0 < 0.4$ *ML*, and $\Delta d_{12} = 5.2 \pm 1.5\%$ in the case of the $c(2 \times 2)$ for 0.4 *ML* $< \theta_0 <$ 0.46 *ML* (*p* and *c* refer to the cell types: *p* for primitive and *c* for centred). The particles adsorbed from the solution usually stabilise (freeze) both the normal and the tangential vibrations of the atoms in the surface layer of the metal.

The study of these vibrations was begun by Germer, et al.,[68] who examined the "loose" (110)Ni faces. In the first two layers the amplitudes of the vibrations in the mutually perpendicular <001> and <110> directions differed by a factor of ~1.5, and in the deeper layer (beyond the sixth) the amplitudes were comparable. The amplitude of the vibration of the surface layers normal to the surface (0.0117−0.0001 nm) is much greater than the amplitude of the atomic vibrations in the bulk (0.0080 nm); this ratio of the amplitudes, which is very important in corrosion studies, is not affected by the adsorption of oxygen. An important structural feature of the oxidation is the negligibly small effect of the relaxation of the surface layer of the crystal on the Coulombic barrier opposing the penetration of the adsorbed oxygen into the metal. Thus, for the (111)Cu face Bauschicher[69] showed that the reconstruction of the near-surface layer, which begins after the adsorption of the first three oxygen atoms (at $\theta_0 = 0.5$ *ML*), lowers the energy barrier to the penetration of additional oxygen atoms from 8.2 to 5.3 eV. This process initiates the reconstruction of the surface, since the chemical bond for the incorporation of additional oxygen atoms is strengthened.[70]

The reconstruction of the low-index faces of monocrystals as θ_0 is increased has long been recognised.[71] The work function Φ_M increases at first during the adsorption of the first portions of oxygen on the (001)Ni surface, and then decreases (due to the reconstruction of the first layer of the crystal). The kinetics of the reconstruction of the (2 × 4) into the (2 × 1) structure on the (011)Ni face during the adsorption of oxygen are described by the well known Avrami−Kolmogorov equation, which assumes an initial induction period:

$$V_t/V = 1 - \exp(-K_t t^m), \tag{17}$$

where V and V_t are the rate of reconstruction of the surface without and with oxygen respectively, K_t and m are coefficients and $m \simeq 0.3$. The height of the activation energy barrier is 0.23 eV. On the (001)Ni and (011)Ni faces the charge transfer from the nickel to the oxygen atoms increases with θ_0, and the energy of the Ni−O bond decreases,[70] as does also the number of holes in the 3*d* sub-band (as a result of the hybridisation of the 3*d* states of nickel and of the 2*p* states of the adsorbed oxygen).[72] The "fit" of the oxygen on the ideal surface of the *F* crystal face is improved by a decrease in Φ_M (and therefore also in S_{hkl}).[73]

The adsorption of oxygen on the metal surface is followed by the formation of oxide (which usually has semiconductor properties). For layer thicknesses smaller than the Debye length $l_D = [2\varepsilon_{D,Ox}\varepsilon_{D,V}(\Phi_M - \Phi_{ox})/e^2 n_{Ox}]^{1/2}$ the band bending in the oxide (the shift by E_0 from the Fermi level E_F) is described by the equation[74]

$$E_F - E_C = E_{C0} \pm [en^2_{Ox}(\Phi_M - \Phi_{Ox})(l_{Ox} - l_D)2\varepsilon_{D,Ox}\varepsilon_{D,V}], \tag{18}$$

where Φ_{Ox} is the electronic work function of the oxide, l_{Ox} is the thickness of the oxide layer, $\bar{n}_{Ox}$ is the average concentration of free electrons in the oxide, E_C is the energy of the bottom of the conduction band, E_{C_0} is the position of the bottom of the conduction band of the oxide for $l_{ox} > l_D$; $\varepsilon_{D,Ox}$ is the dielectric permittivity of the medium and $\varepsilon_{D,C}$ is the dielectric permittivity of free space ($\varepsilon_V = 8.854 \times 10^{-12}$ F m^{-1}). According to Eqn. (18) $E_F - E_C$ varies as the oxide thickness l_{ox} increases. The surface energy E_C is determined by the ratio of Φ_m to Φ_{Ox}, decreasing steeply at first when the adsorption layer of oxygen is formed and then stabilising as l_{ox} continues to increase. A decrease in γ^0_{ij} [and therefore also in ΔE, see Eqn. (6)] suppresses the electrochemical dissolution of the metal.

The ionic conductivity of the oxide films is exponentially dependent on the electric field within the oxide E_{Ox}, and can be calculated by the Günterschultz−Betz equation

$$i_+ = A_+ \exp(B_+ E_{Ox}), \tag{19}$$

where A_+ and B_+ are empirical constants of dimensions A m^{-2} and m V^{-1} respectively. The formation of these films on the *d* metals is made possible by the reconstruction of the first few layers of the crystals. Thus, in the $p(2 \times 2)0/(111)$Ni surface structure the length of the Ni−Ni bonds is increased by ~1.5 nm (sic., Ed. of Translation),[75] which helps the fitting of the next portions of oxygen and their clustering. According to LEED and AES data[76] at surface coverages of the (001)Ni surface by adsorbed oxygen $\theta_0 \leqslant 0.25$ *ML* ($T = 500$ K) we observe a $p(2 \times 2)$ structure, at 0.25 *ML* $\leqslant \theta_0 \leqslant$ 0.35 *ML* a $c(2 \times 2)$ as well as the $p(2 \times 20$ structure, and at $\theta_0 \geqslant$ 0.35 *ML* only the $c(2 \times 2)$ structure. Reiudle, et al.[76] assume that a $p(1 \times 1)$ structure is also possible. The most stable is the $p(2 \times 2)$

structure, in which the oxygen atom is in a highly coordinated state in the tetrapore.

In the least densely packed (110)Ni plane (as shown by some early experiments[77]) the oxygen successively forms the (3 × 1), (2 × 1), and (3 × 1) surface structures at $\theta_0 \leqslant 0.3$ *ML*. The oxygen occupies long bridging positions in a strongly coordinated state with a 3 nm Ni–O distance, forming rows in the [001] direction (Fig. 16). A decrease in the activation energy of 0.03–0.05 eV (at θ_0 = 0.5 *ML*) is produced by the rearrangement (faceting) of only the first three near-surface layers (Fig. 16*d*).

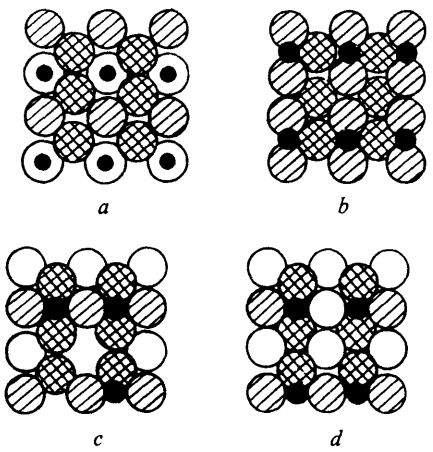

Figure 16. Structure of the (2 × 1) oxygen adsorption phase on the (110)Ni face: *a*, weakly coordinated adsorption of oxygen without reconstruction of the near-surface layer; *b*, reconstruction of the face through the replacement of Ni by O atoms; *c*, reconstruction of the face with displacement of the Ni atoms; *d*, faceting of the face during the adsorption of O ("tooth separation" model[77]).

Comparing the chemical compositions of oxygen layers prepared from the gas phase (10^{-4} Pa, 500 nm) and by electrochemical oxidation at a constant potential *E* (0.01 M $HClO_4$, 1.05 V) shows that in the latter case the NiO layer (l_{Ox} = 85 nm) is covered with a hydroxide layer (l_{HOx} = 25 nm).[78] The structures of the oxide layers are also different: the (100)NiO face is formed from the gas phase and a disordered phase with local inclusions of (111)NiO from the electrolyte.

The energy of the M–O bond is quite high (4.0–14.0 eV), and the dissolution of the oxide at the corrosion potential E_{cor} in pure water according to Purbaix' data[79] seems thermodynamically improbable for many *d* metals. The breakdown of the oxide in aqueous media is accompanied by the penetration of anions (A^-) into the oxide with simultaneous adsorption of water molecules. Some comments by Vijh on these processes[80] are based on the relative values of the dielectric constants of water (ε_{D,H_2O}) and of the oxide ($\varepsilon_{D,Ox}$), and of the electric fields E_{H_2O}, E_{ox}. For an anodic potential of 1 V a field $E_V = 10^{10}\,\varepsilon_{D,V}$ V m^{-1} normal to the electrode surface is produced, in a vacuum, in an oxide layer 10 nm thick.

Table 4. Dielectric constants of the oxides.

Oxide	$10^8 E_{Ox}$, V m^{-1}	ε_{Ox}	$10^{10} D$, V m^{-1}	$10^3(1/\varepsilon_{Ox})$	l_D, nm
Bi_2O_3	2.2	40	0.88	25.0	30.0
UO_3	3.6	25(UO_2)	0.90	40.0	11.9
Y_2O_3	4.4	18	0.79	55.5	23.9
Nb_2O_5	4.6	41	1.92	24.1	11.8
ZrO_2	5.1	22–25	1.02–1.35	40.0	16.0
TiO_2	5.0	15–40	0.75–2.00	25.0	6.4
WO_3	5.5	42(WO_2)	2.31	23.8	5.5
Ta_2O_5	6.2	27	1.71	36.2	7.3
Al_2O_3	7.9	8–10	6.32–8.29	95.2	12.7
SiO_2	26.0	3	0.91	285.7	4.2

In an aqueous solution (unlike a vacuum) we must allow for the adsorption of water and for the formation of an electrical double layer. The normal field at the anode–electrolyte contact is $E_{H_2O} = E_V/\varepsilon_{D,H_2O}$; for an anodic oxide it is $E_{ox} = E_V/\varepsilon_{D,Ox}$. Therefore we can write $E_V = E_{H_2O}\varepsilon_{D,H_2O} = E_{Ox}\varepsilon_{D,Ox} = 1 \times 10^{10}$ V m^{-1} and characterise the changes in the oxide in terms of the dielectric displacement vector. Indeed, for many oxides we find that $E_V \equiv D$ = const (Table 4). By using the universal constant *D* we can explain the formation of thick layers on the valve metals and of thin layers on the noble metals. The width of the tunnelling barrier l_D of the oxides is smaller in the metals which have a high chemical resistance. We can lower l_D and improve the electronic conductivity of the oxides of the valve metals (Nb, Ti, Zr) by anodic treatment in very concentrated alkaline solutions with anodic current densities $i_a = (2.5–4.0) \times 10^4$ A m^{-2}, E = 35 v, T = 303 K, t = 10–20 s.[81]

The thermodynamic description of the simultaneous adsorption of A^- anions and of water molecules on the metal surface:

$$A^-(H_2O)_n + (H_2O)_{ads}(M) \rightleftarrows A^-(M) + (H_2O)_{n+1},$$

requires a knowledge of the hydrophilicity or hydrophobicity ΔG°_{hydr} of the adsorbent.[82] The change in Gibbs free energy is

$$\Delta G^\circ_{ads} = \Delta G^\circ_{hydr} + \Delta G^\circ_{M-A^-} - \Delta G^\circ_{M-H_2O}, \qquad (20)$$

where $\Delta G^\circ_{M-A^-}$ and $\Delta G^\circ_{M-H_2O}$ are the parts of the free energy responsible for the adsorption of the anion and of water, and $\Delta G^\circ_{hydr} = \Delta G^\circ_{A^--H_2O}$ is the chemical energy of hydration of the anion. According to Trasatti's calculations[82] the linear increase in the zero-charge potential $E_{q=0}$ with increasing reticular density of

the monocrystal surface S_{hkl} is responsible for a decrease in ΔG°_{ads}. For two corroding metals in contact with the solution Eqn. (20) becomes

$$\Delta(\Delta G^\circ_{ads}) = -\Delta(\Delta G^\circ_{M-H_2O}). \quad (21)$$

Halide ions

Experimental determinations of ΔG° have been carried out for systems composed of halide ions and well characterised low-index faces of noble metals.[83] Depending on the reticular density S_{hkl} the values of the second term in Eqn. (20) can be arranged in the sequence

$$-\Delta G^\circ[(111)M\text{–}Hal^-] > -\Delta G^\circ[(001)M\text{–}Hal^-] > -\Delta G^\circ[(011)M\text{–}Hal^-].$$

The specifically adsorbed Hal^- anions weaken the bond in the $M-H_2O$ complex. In crystals with a covalent bond and *s, p* metals (Cd, Sn, Bi) the relationship (21) was tested by studying the adsorption of aliphatic alcohols,[84] assuming that the interactions of $R-OH$ (where $R \equiv nCH_2$ denotes the methyl groups in the SAS) with the surface are negligible (for $nCH_2 = 0$, $\Delta G^\circ = 0$), i.e. the change in free energy per methyl group should be zero. The ability of the SAS to become adsorbed on two corroding metals in ohmic contact (often met in practice) is determined by the properties of the water in the EDL and in the bulk of the solution:

$$\frac{\Delta(\Delta G^\circ_0)}{\Delta n} = \frac{\Delta(\Delta G_S)}{\Delta n} - \frac{\Delta(\Delta G_V)}{\Delta n}. \quad (22)$$

The change in the energy of hydrophobic hydration in the bulk (ΔG_V) and in the EDL (ΔG_S) for aliphatic alcohols, calculated by Eqn (21), shows that the contribution of the interaction energy of the water molecules to the energy of adsorpion is insignificant and approximately the same for different *s, p* metals.[84]

Water on a metal surface has a low-entropy structure; the entropy factor is determined by the *(hkl)* of the surface. In the case of chemisorbed halide ions incorporated in the interstitial sites between the surface metal atoms the energy term is characterised, as for $H_{ads}(M)$ and $O_{ads}(M)$, by two maxima, i.e. we have states of strong and of weak specific adsorption. It is believed that the transfer of charge from the halide ion to the metal is accompanied by a change in the orientation of the water molecules in the $Hal(H_2O)_6^-$ cluster being discharged (from the orientation with the oxygen atoms towards the surface to the orientation with the hydrogen atoms towards the surface[85]). The formation of adsorption cluster structures on the metal surface strengthens the charge transfer as compared with the single atom: the charge transfer coefficient (the Esin–Markov coefficient K_{EM}) is greater for the cluster than for the single Hal atom.

In the strong specific adsorption the Hal^- ion is accommodated in a many-centre adsorption site on the metal surface, but if the adsorption is weak and the transfer of charge is only partial the reconstruction of the hydration shell of the ion is not substantial. Crystallographic factors have a large influence on the standard thermodynamic parameters of the adsorption of halide ions. On platinum electrodes, and on electrodes of the other *d* metals, we observe an increase in the entropy of adsorpion and a decrease in the Gibbs free energy and in the enthalpy. The standard thermodynamic parameters for the adsorption of Cl^- ions on Pt and on Hg (kJ mol^{-1}) are:[86]

	ΔG	ΔH	$T\Delta S$
Hg	–2.06	–10	7.9
Pt	–6.10	–30	23.8

The "charging" of the metal surface by halide ions suppresses the formation of passivating oxygen compound: the thickness of the passivating layer l_{Ox} decreases with increasing concentration c_{Hal^-} in the solution and with increasing time of immersion of the electrode in the medium containing halogen. The halide ions can be arranged in the following series with respect to their effectiveness in the dissolution of the 3*d* transition metals: $F^- > Cl^- > Br^- > I^-$. The electrically negative halide ions adsorbed on the metal surface weaken the $d-\pi^*$ interaction with the passivating chalcophilic particles, and they assist the desorption of adsorbed hydrogen from the surface of the transition metals. The desorbing action of the halide ions can be adequately explained in terms of formal kinetics. For the Volmer–Heyrovsky mechanism of the hydrogen evolution reaction (HER), realised as two consecutive one-electron transfers to the M_k active centres:

$$H_9O_4^+ + M_k + e^- \rightarrow M_kH_{ads} + 4H_2O, \quad (23)$$

$$M_kH_{ads} + H_9O_4^+ + e^- \rightarrow M_k + 4H_2O + H_2, \quad (24)$$

the conjugated competing process

$$Hal^- + M_k \rightarrow M_kHal_{ads} + e^-, \quad (25)$$

$$M_kHal_{ads} + Hal^- \rightarrow M_k + Hal_2 + e^-, \quad (26)$$

leads to the generation of very mobile charge carriers which are free to tunnel. Reactions (23)–(26) on metal surfaces completely or partially covered with an oxide phase improve the electronic conduction in the solid phase and lower the chemical resistance of the metal.

Data on the coherence of the contacting phases and on the structure of halogen ad-layers on the well characterised surfaces of noble-metal monocrystals have been obtained in recent years.

Platinum

Structural studies by LEED and AES methods of the (111)Pt face in contact with aqueous solutions of KBr or $CaBr_2$ at different pH have shown that the adsorbed halide ion forms an ordered (111)Pt–(3 × 3)Br structure on the metal surface,[87] similar to the structure obtained by exposing platinum to HBr vapour in a vacuum.[88] This structure can exist at positive potentials, but it is reconstructed by the incipient reduction (with desorption) of the bromine atoms at –0.1 V by the scheme

$$(111)Pt\text{–}(3\times3)Br[\theta_{Br} = 4/9ML] + $$

$$+ xe^- \rightleftarrows (111)Pt(4\times4)[\theta_{Br} = 7/16ML] + xBr^-,$$

where x corresponds to only $4/9 - 7/16 = 0.007$ electron per Br^- anion on one surface Pt atom. This means that the adsorption of bromide (like that of other halide ions) is a redox process with partial charge transfer. The adsorption of halide ions is more marked in acid solutions than in alkaline solutions, mainly because

of the competition with adsorbates containing oxygen [see Eqn. (20)], which interact strongly with the surface. The ordered (1 × 1) structure and the diffuse oxygen surface layer with $\theta_0 = 0.5$ *ML* are retained during the initial stages of oxidation of the platinum, but in the second stage (as was pointed out above) the ordering is perturbed in both the platinum and the oxygen.

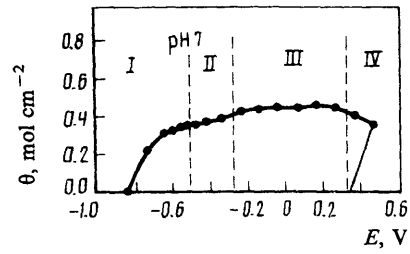

Figure 17. Dependence of the packing density of the iodine atoms on the (111)Pt face upon the electrode potential:[87] *I*, region of existence of the $(\sqrt{3} \times \sqrt{3})R30°-I$ superstructure; *II*, region of simultaneous existence of the $(\sqrt{3} \times \sqrt{3})R30°-I$ and $(\sqrt{7} \times \sqrt{7})R19°-I$ superstructures; *III*, region of existence of the $(\sqrt{7} \times \sqrt{7})R19°-I$ superstructure; *IV*, region of existence of the (3 × 3)−I superstructure.

Immersing the (111)Pt face in aqueous solutions containing iodine produces an ordered ad-layer of iodine atoms[87] whose packing density and structure depend on the potential (Fig. 17). The (111)Pt−(3 × 3)I[θ_I = 4.9 *ML*] structure exists at moderately high positive potentials (~0.5 V), the (111)Pt−$(\sqrt{7} \times \sqrt{7})R19°$−I[$\theta_i$ = 3/7 *ML*] at intermediate potentials (~0.1 V), and the (111)Pt−$(\sqrt{3} \times \sqrt{3})R30°$−I[$\theta_I$ = 1/3 *ML*] at negative potentials (< −0.5 V).

The reductive desorption of I^- anions takes place at very high negative potentials (< −0.8 V). All these structures are observed also after treating (111)Pt with HI and I_2 vapour in a vacuum.[89] The adsorption of iodine vapour on the stepped [6(111) × (111)]Pt(*s*) platinum surface failed to reveal even a partial affinity of the iodine atoms for the stepped formations on the surface.[90] Instead, the presence of steps (kinks) produced several phase domains with a local (3 × 3) or $(\sqrt{3} \times \sqrt{3})R30°$ geometry, and a structural correspondence of the adjoining terraces [6(111) × (111)]Pt−(3 × 1*T*)−I, [6(111) × (111)]Pt−(8 × 1*T*)−I, and [6(111) × (111)]Pt−(20 × 2*T*)−I.

As could have been expected, the chemosorption of chlorine anions on a platinum electrode is much weaker than the chemisorption of bromide or iodide. HCl species in a vacuum do not form an ordered layer on the (111)Pt face.[87] The peak on the *E*, *i* curve produced by the adsorption and desorption of chlorine can be distinguished from the hydrogen peak only because the former process [see reaction (25)] is independent of pH.[91] For $c_{HCl} \leqslant 0.01$ mol dm^{-3} the adsorption of chlorine becomes stronger, and produces an ordered (111)Pt−(3 × 3)Cl (τ_{Cl} = 0.33 *ML*) layer. The packing density of the chlorine is close to 0.5, which corresponds to the h.c.p. lattice.

Silver

The adsorption of halide ions on the (111)Ag face is an active process of the oxidation−reduction type,[87] as in the case of platinum. The reductive desorption of chlorine and bromine takes place almost entirely at negative potentials (< −0.8 V), and the iodine remains adsorbed over a wide range of potential (−0.6 to + 0.6 V). Chlorine and bromine atoms form simple (111)Ag−$(\sqrt{3} \times \sqrt{3})R30°-x$ structures, with θ_x = 1/3 *ML*, whereas iodine gives the structures which are also obtained in the electrodeposition of the silver on a (111)Pt face previously treated with iodine (Fig. 18). Thus the silver surface is reconstructed in solutions containing iodine.

Studies of the adsorption of halide ions by thermal desorption and UPS have shown that the adsorption−desorption characteristics are independent of the nature of the halogen.[92] Comparing the results for (110)Ag and (111)Ag confirms the strong topological dependence of the adsorpion of the halogens.

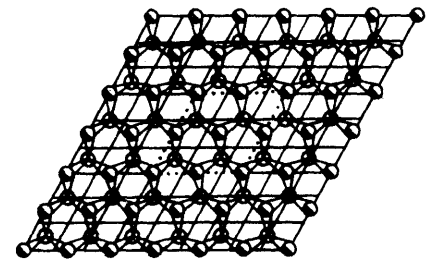

Figure 18. Structure of the (111)Pt−(3 × 3)Ag, I face; (θ_{Ag} = θ_I) = 4/9 *ML*.[87]

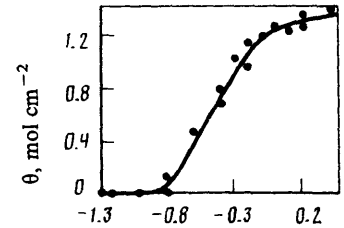

Figure 19. Dependence of the packing density of the bromine atoms on the (100)Au face upon the electrode potential.[93]

Gold

For the other noble metals only a few data on adsorption and surface reconstruction are available so far. The adsorption of bromine on the (100)Au face from aqueous solutions produces the (5 × 20)→(1 × 1) structural transition.[93] The dependence of the bromine packing density on the electrode potential (Fig. 19) can be described by the Avrami−Kolmogorov equation (17) with a long induction period and a potential < −0.5 V.

Copper

Chlorine adsorbed from a 10^{-3} M solution of HCl on the (100)Cu face forms the (100)Cu$-(\sqrt{2} \times \sqrt{2})R45°-$Cl structure with $\theta_{Cl} = 0.5$ *ML*, almost irrespective of the applied potential and of the concentration of chloride ions.[94] Desorption of the adsorbed chlorine is observed by immersing the electrode in 10^{-3} M H_2SO_4 at $E < -0.11$ V.

VI. Conclusions

Our analysis of the metastable states of the near-surface layer of metallic crystals in contact with a condensed (liquid) or a noncondensed (gas) medium suggests new approaches to corrosion-electrochemical processes (phase transitions of the first kind, accompanied by the evolution of adsorbed gases and by the adsorption and penetration of light chalcophilic species). Unique properties are found in the hydrogenated metal–electrolyte system. since hydrogen has an anomalously high diffusion coefficient in metals it is easly redistributed in the lattice and interacts with surface and subsurface defects, altering their concentration, topology, and energy state. Other outstanding aspects of the behaviour of hydrogen in condensed media are the ease with which it can lose (or gain) an electron, the ability of protons to generate heavier species dissolved in the metal, the contribution of H^- and H^+ to the deprotonation of adsorbed water structures, and the formation of new compounds in the adsorbed layers.

A new topic in electrochemistry has been created: the electrochemistry of monocrystals with well characterised surfaces. The possibility of analysing surface rearrangements by a whole group of high-resolution physical methods not only creates a new situation in this field of knowledge but also forces us to reconsider the traditional electrochemical approaches, which relied exclusively on an analysis of integral kinetic information on the transfer of charge across the metal–electrolyte interface

Mechanism of the interaction between Group VIII metals and oxides of transition elements

O S Alekseev, Yu A Ryndin
Institute of Catalysis, Siberian Branch of the Russian Academy of Sciences, Novosibirsk

ABSTRACT. The results of research into the chemisorptive and catalytic properties of Group VIII metals supported on oxides of transition elements are reviewed. The mechanisms put forward to account for the effects of a strong interaction between metal and support are discussed. The causes of the strong interaction between metal and support are analysed using the results of studies on the properties of $(M + E^{IV})/SiO_2$ model systems.

The bibliography includes 187 references.

I. Introduction

Supported metal catalysts are being used to an increasing extent in large-tonnage industrial processes involving the chemical treatment of hydrocarbon raw materials (reforming, hydrogenation, dehydrogenation, etc.), and in the future they may also be used for the synthesis of a wide range of hydrocarbons and oxygen-containing compounds from CO and H_2. Therefore, extending the range of control over their catalytic properties is a vital task. Variation of the dispersity, the use of promoters, and varying the nature of the support constitute effective methods of controlling the activity and selectivity of a supported metal.

In the 1960s Schwab and Solymosi[1,2] called into question the generally held view at the time that an oxide support that prevented the sintering of a metal was inert. In 1978 Tauster et al.[3] discovered the effects of a strong metal–support interaction (SMSI) for metals that were supported on oxides of transition elements (TE). After publication of this pioneering work the number of studies in this area started to increase at an exponential rate (Fig. 1), and in 1982 an international conference devoted to the effect of supports and additives on the catalytic properties of metals was organised. It is worth noting that even at that time there was an intuitive understanding of the common nature of the mechanisms of the action of TE oxides as supports and promoters of active metals (also reflected in the name of the conference). To date more than 1000 studies on the problem of SMI have appeared in the literature. In correlating these studies it may be noted that the consequences of SMSI are: a) a reduction in specific chemisorption of CO and H_2 on a metal; b) a sharp decrease in specific catalytic activity of the metal in reactions involving hydrocarbons; c) an increase in specific catalytic activity and a change in selectivity in the hydrogenation of CO; d) an intensification of these effects with an increase in the temperature of reduction of the catalyst and their reversible disappearance after oxidation followed by treatment with hydrogen at a moderate temperature.

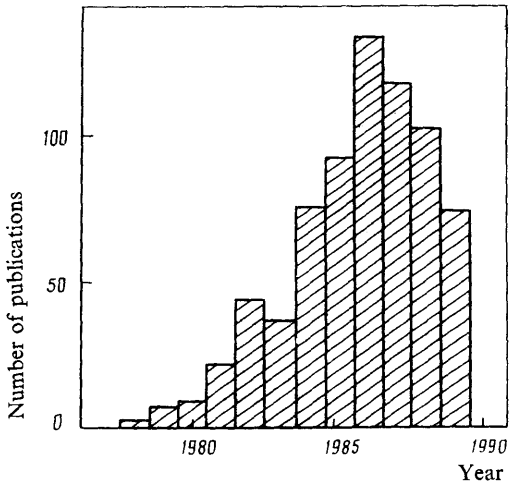

Figure 1. Growth trend for the number of publications on the problem of SMSI.[179]

It should be noted that effects similar to those of SMSI had previously been detected by Ermakov et al.[4–8] in catalysts prepared by fixing highly dispersed particles of Pd and Pt on low-valent surface Mo, W, or Re ions. In these studies the idea that the effect of the addition of an element that is difficult to reduce on the properties of Pd and Pt is caused by an interaction between the metal clusters and the surface ions of the promoter was first developed and confirmed experimentally. This interaction increases the stability of the dispersed metal towards sintering and is responsible for a change in its electronic properties, resulting in a change in its chemisorptive and hence its catalytic properties.

Despite the fact that at the present time a very large amount of experimental material on research into the properties of catalysts with SMSI has been collected, reviews concerned with classification

of the accumulated data are virtually absent from the literature. In the present review there is the task of analysing the results obtained by different research workers in the field of SMSI. At the same time particular attention is given to an analysis of models put forward to explain the effects of SMSI.

II. Properties of Group VIII metals supported on oxides of transition elements

1. Chemisorptive properties

The first systematic study of the adsorption of CO and H_2 on different Group VIII metals supported on TiO_2 was undertaken by Tauster et al.[3] It was as a result of this investigation that the unusual phenomenon known as "a strong metal–support interaction" was observed. In fact, the reduction of Group VIII metals supported on TiO_2 at a low temperature (473 K) results in the formation of dispersed catalysts that are capable of the chemisorption of considerable quantities of CO and H_2. At the same time when the reduction temperature is increased to 773 K the quantity of chemisorbed CO and H_2 on all systems decreases almost to zero, while according to the data of electron microscopy and X-ray phase analysis such a significant change in the chemisorptive properties as this is not due to sintering of the supported metal.[3]

The range of supports on which the chemisorptive properties of metals are altered was considerably extended in subsequent studies.[9–12] Thus, on increasing the reduction temperature to 773 K for Ir supported on Nb_2O_5, V_2O_3, Ta_2O_5, almost complete suppression of the chemisorptive properties towards CO and H_2 was observed. It should be noted that treatment with oxygen followed by reduction at a moderate temperature (573 K) almost completely restores the chemisorptive capacity of the supported metals.

Water has a similar influence on the SMSI effect. It was shown by Duprez and Miloudi[13] that treatment of Pt, Ni, and Rh supported on TiO_2 with water vapour at 773 K completely eliminates the phenomenon of a decrease in chemisorption of H_2. At the same time, on a number of supports such as SiO_2, Al_2O_3, Se_2O_3, MgO, ZrO_2, V_2O_3, no perceptible changes in the chemisorptive properties of supported metals were observed over a wide range of reduction temperatures. On the basis of these results the authors[9–12] assumed that the SMSI effect is characteristic of readily reducible oxides of transition elements. In fact, it was demonstrated by Loye et al.[14] in a study of the chemisorption of H_2 on Ni/Ti_nO_{2n-1} that the ratio of H : Ni decreases substantially on increasing the degree of reduction of the support. Beringhelli et al.[15] reported a decrease in chemisorption of H_2 on Rh/ZrO_2, although this had not previously been found for Ir/ZrO_2.[9] The patterns of variation in chemisorptive properties of Group VIII metals found by Tauster et al.[3] were confirmed in the studies of other authors.[16–22]

An interesting correlation between the chemisorptive properties of Pt and the heats of adsorption of H_2 and CO was found by Vannice et al.[23–25] It was shown that the heats of adsorption of CO and H_2 on Pt deposited on different supports (SiO_2, Al_2O_3, TiO_2) with low-temperature reduction of the catalysts did not depend on the nature of the oxide but were governed by the dispersity of the supported metal, being equal to 28 and 30 kcal mol^{-1} for CO and H_2 respectively. However, the high-temperature reduction of Pt/TiO_2 in hydrogen (773 K) resulted in a substantial decrease in the heats of adsorption for CO to 10 kcal mol^{-1} and for H_2 to 6–10 kcal mol^{-1}. Thus, for Pt/TiO_2 when the degree of covering the surface of Pt with CO and H_2 decreases, there is a reduction in the heats of chemisorption of these gases. Apart from that for Pt/TiO_2 no other similar correlations were found.[22] Despite the contradictory nature of the results of Vannice et al.,[22–25] a decrease in the heats of adsorption of CO and H_2 on the surface of the metal, resulting in a decrease in strength of the metal–adsorbate bond may be regarded as one of the causes of a reduction in the degree of covering the surface of the supported metal with a high reduction temperature.

2. Catalytic properties

a) Conversions of hydrocarbons

A change in the chemisorptive properties of metals supported on oxides of transition elements at high reduction temperatures must have a considerable effect on the properties of M/E_xO_y systems. Thus, the activity of Pt/TiO_2 in the hydrogenation of benzene decreases after high-temperature reduction (793 K) by a factor of $10^{1.5}$ compared with a catalyst reduced at 473 K.[26] In the dehydrogenation of cyclohexane and the hydrogenation of ethylene the activity of Pt/TiO_2 decreases by a factor of 10. After reduction of Ir/TiO_2 and Rh/TiO_2 at 793 K a similar dependence occurs: in the hydrogenation of benzene the activity decreases by a factor of 10–100, in the dehydrogenation of cyclohexane it decreases by a factor of 5, and in the hydrogenation of ethylene it decreases by a factor of 10–100.[26] Oxidative treatment followed by reduction at a low temperature restores 80% of the original activity of these catalysts. A similar decrease in activity in the hydrogenation of benzene at a high reduction temperature (773 K) was observed for Pt/TiO_2,[27] (Ni, Pd, Ir)$/TiO_2$,[16] Pt/TiO_2,[28] and Rh/TiO_2 and Pt/TiO_2.[29]

In the hydrogenolysis of paraffins the activity of the catalysts is significantly affected by the temperature of their initial treatment in hydrogen. On increasing the reduction temperature from 523 to 773 K, Burch[30] observed a thousandfold decrease in the specific catalytic activity of Ni/TiO_2 in the hydrogenolysis of n-hexane. A similar dependence was found for (Ni, Pt, Pd/TiO_2) [16,31] and for Rh/TiO_2 [28] in the hydrogenolysis of ethane. At a reduction temperature of 773 K complete deactivation of the catalyst occurred in the same reaction for Ir/TiO_2.[26] Data on the effect of the reduction temperature on the properties of M/TiO_2 are given in five studies.[32–36] For all the Group VIII metals, except for Ru, when the reduction temperature is increased in the hydrogenolysis of ethane there is a sharp decrease in specific catalytic activity. At the same time, as for the hydrogenation of hydrocarbons, oxidative treatment followed by reduction under mild conditions restores the initial activity of the catalysts.[18,26,28,33,35]

It is interesting to note that the effect of the temperature of treatment does not manifest itself to an equal extent for all oxides of transition elements. Thus, in the hydrogenation of benzene on Pt/CeO_2 the activity decreases by a factor of 5 when the reduction temperature is increased, while in the hydrogenolysis of n-hexane there is no decrease in activity at all,[37] although the activity of Pt/TiO_2 in these reactions decreases by a factor of $10^{1.5}$–10^2.

b) Hydrogenation of carbon monoxide

An indication of the effect of the nature of the support on the properties of Group VIII metals in the hydogenation of CO was first given by Ichikawa et al.[38–40] In studying the synthesis of CH_3OH on Rh, Pd, Ir, and Pt catalysts at atmospheric pressure, the authors[38–40] showed that the activity and selectivity of the catalysts

depended not only on the nature of the metal itself but also on the composition of the supported compound and the acid-base properties of the support. Thus, in the hydrogenation of CO on oxides with weakly defined basic properties such as MgO, La_2O_3, and V_2O_3, methanol is mainly formed, while on oxides with pronounced basic or acidic properties (Li_2O, SiO_2, TiO_2), methane is formed. A similar effect from the support on the properties of supported palladium in the hydrogenation of CO at a high pressure was observed by Ryndin et al.[41] However, in these studies[38–41] there is no analysis of the effect of dispersity on the activity and selectivity of the process. At the same time the dispersity of supported metal particles plays a significant role in this reaction. Thus, it was shown in two studies[42,43] that the specific catalytic activity of Pd/SiO_2 in the hydrogenation of CO to methane increases with an increase in dispersity of Pd, but it was found by Hicks and Bell[44] that the specific catalytic activity of Pd/SiO_2 in the synthesis of methane does not depend on the dispersity of Pd while the specific catalytic activity of Pd/La_2O_3 decreases with an increase in dispersity of Pd. In two other studies[45,46] it was shown that in the synthesis of methanol from CO the specific catalytic activity of Pd/SiO_2 and Pd/La_2O_3 catalysts increases with a decrease in dispersity of the supported metal. It was shown by Arkawa et al.[47] that for Rh catalysts the selectivity of the reaction with respect to oxygen-containing products increases with an increase in dispersity of Rh. On the whole the results given in the literature concerning the effect of dispersity on the activity of supported metals in the hydogenation of CO are quite contradictory.

The nature of the support affects the properties of a supported metal more significantly than a change in its dispersity.[48] It was shown in several studies[16,30,49–53] that at a reduction temperature of 723 K the specific catalytic activity of Ni/TiO_2 is higher than that of Ni/SiO_2, Ni/Al_2O_3, and Ni/C by a factor of 10–100. At the same time there was an increase in selectivity towards the formation of higher hydrocarbons.

Similar trends were found for other Group VIII metals.[54,55] Thus, Vannice[56,57] showed that the specific catalytic activity of platinum catalysts in the synthesis of methane was unchanged over a wide range of particle size (from 12 to 1000 Å), while the nature of the support had a considerable effect on their specific activity, which in Pt/TiO_2 was 10 times higher than in Pt/Al_2O_3 and $Pt/(SiO_2-Al_2O_3)$ and 100 times higher than in Pt/SiO_2. A constant value of the specific catalytic activity over a wide range of change in particle size of Pd in the hydrogenation of CO to CH_4 was established by Vannice et al.[58] However, as for Pt, the specific catalytic activity of Pd changed by a factor of 100 on varying the support (at the same time the activation energy of the reaction does not depend on the nature of the oxide).

An increase in activity of the supported metal also takes place on changing from SiO_2 and Al_2O_3 to oxides of transition elements. For example, the activity of Ni/Nb_2O_5 and Ni/ZrO_2 is considerably higher than the activity of Ni/SiO_2 and Ni/Al_2O_3,[59,60] and at the same time the selectivity towards higher hydrocarbons reaches 55%. It was shown by Szymanski et al.[61] that the specific catalytic activity of Pt/ZrO_2 in the synthesis of methanol at atmospheric pressure is higher than that of Pt/SiO_2 and Pt/C by a factor of $10^{1.5}$, and the selectivity with respect to CH_3OH reaches 50%.

The effect of the reduction temperature on the properties of nickel catalysts in the synthesis of CH_4 from CO and H_2 was investigated in two studies.[59,62] When the reduction temperature of Ni/ZrO_2 and Ni/TiO_2 was increased from 543 to 973 K the activity per unit weight of nickel decreased more than ten times while the dispersity of the nickel did not alter significantly.[59] Fang[62] showed that on increasing the reduction temperature from 523 to 723 K the specific catalytic activity of Ni/TiO_2 decreased by a factor of 2, which was due to a decrease in strength of the Ni–CO bond, since there is a direct correlation between the decrease in activity and the reduction in strength of the Ni–CO bond. The reverse dependence occurs for Pt and Pd supported on TiO_2. At a reduction temperature of 773 K the specific catalytic activity of Pd/TiO_2 and Pt/TiO_2 is higher than at 573 K.[56,58,63]

An increase in the reduction temperature of M/E_xO_y has only a slight effect on the selectivity for hydrogenation of CO to methane. It was shown by Turlier et al.[59] that the selectivity towards CH_4 for Ni/TiO_2 and Ni/ZrO_2 when the reduction temperature is changed from 523 to 923 K is virtually unchanged. It was shown by Anderson et al.[16] that the selectivity of a Pd/TiO_2 catalyst in the synthesis of CH_4 is virtually independent of the reduction temperature, but it is 20% higher than the selectivity of Pd/SiO_2.

Interesting results were reported by Kunimori et al.[21] in a comparison of the catalytic properties of Pd and Rh supported on TiO_2 and Nb_2O_5. When the reduction temperature for Rh/Nb_2O_5 and Pd/Nb_2O_5 was increased from 573 to 773 K, in addition to a decrease in chemisorption of CO by a factor of more than 10, there was a decrease in the specific catalytic activity of these catalysts in the synthesis of CH_4—by a factor of 100 for Rh/Nb_2O_5 and by a factor of 10 for Pd/Nb_2O_5. At the same time the activity of Rh/TiO_2 and Pd/TiO_2 remained constant on increasing the reduction temperature. However, prolonged experiments on the hydrogenation of CO on Rh/Nb_2O_5 and Pd/Nb_2O_5 catalysts showed that with the passage of time their activity increases to a value that is typical for samples reduced at 573 K. In the opinion of Kunimori et al.,[21] the increase in activity of M/Nb_2O_5 is due to disruption of SMSI by oxygen formed through dissociation of CO or by water formed as a result of reaction. At the same time the higher activity of M/TiO_2 catalysts compared to M/Nb_2O_5 (whatever the reduction temperature) is due to the readier disruption of the interaction between metal and support.[21] The true activity of M/TiO_2 catalysts at high reduction temperatures, according to Kunimori et al.,[21] must be lower than the observed value by a factor of 10–100.

It was found by Jackson et al.[64] that the specific catalytic activity of Ru/TiO_2 catalysts prepared from supported Ru carbonyl clusters decreased with an increase in reduction temperature, while raising the reduction temperature from 523 to 873 K had no effect on the activity of Rh/ZrO_2 catalysts.[65]

Thus, the data reported in the literature concerning the effect of the reduction temperature on the activity of Group VIII metals supported on TiO_2 and other oxides of transition elements in the hydrogenation of CO are contradictory in nature. However, the increase in specific catalytic activity of metals supported on TiO_2 or other oxides of transition elements compared to that of the same metals supported on SiO_2 or Al_2O_3 is not in doubt.[66]

III. Models of the interaction between metals and oxides of transition elements

1. Direct interaction between metal atoms and low-valent ions of a support

A model which assumes direct interaction between the atoms of a supported metal and low-valent ions of the support was put forward by Horsley.[67] This model was based on theoretic calculations using

the method of the self-consistent field of dispersed waves of models of molecular clusters for a Pt/TiO_2 catalyst. Two different models were considered (Fig. 2). According to model (A) (Fig. 2*A*) a platinum atom interacts with an octahedral $(TiO_6)^{8-}$ cluster, while the metal atom is situated outside the octahedron. Model (B) (Fig. 2*B*) assumes that there is an oxygen vacancy in the $(TiO_6)^{8-}$ cluster that is occupied by a Pt atom. While in model (A) the closest neighbours of the Pt atom are oxygen ions, in model (B) direct coordination between the Pt atom and the titanium cation is assumed.

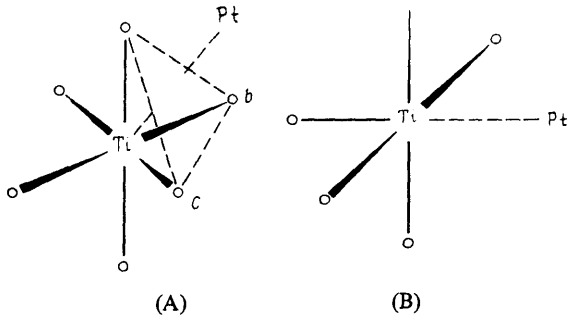

Figure 2. Models of clusters in a Pt/TiO_2 catalyst.[67]

Theoretical calculations show that for model (A) the platinum atom cannot lie sufficiently close to the $(TiO_6)^{8-}$ cluster because of strong repulsion between the Pt atoms and the adjacent oxygen ions, and the formation of a Pt–Ti bond is impossible.[67] For model (B) the Pt atom and Ti cation can lie sufficiently close to each other and the formation of a $Pt-Ti^{3+}$ bond is possible.[67] This bond is probably partly ionic with electron transfer from Ti^{3+} to the platinum atom. According to the authors,[67–69] even a small transfer of electron density to platinum will produce a change in hybridisation of the metal–metal bonds, which assumes considerable changes in metal–metal distances. This may affect the population or change in symmetry of *d* orbitals in such a manner that they will not be able to interact with the molecular orbitals of H_2 and CO. As a result, a decrease in chemisorption and strength of the bond between metal and CO and H_2 will occur. It is clear that the interaction between metal atoms and Ti^{3+} atoms is of a specific type and only occurs at the metal–support phase boundary, since the metal atoms and cations of the support are restricted in movement at the limits of the crystal lattice.[70]

The hypothesis put forward by Horsley was later supported experimentally in a number of studies. For example, Golodets et al.[71–73] observed a reduction in strength of the Ni–CO and Ni–H bonds on a Ni/TiO_2 catalyst as a result of the electronic interaction of $Ni-Ti^{3+}$. A similar trend was observed for a Pd/La_2O_3 catalyst.[74] However, the data from studies on the electronic state of metals are contradictory. Thus, in two studies[17,75] no significant changes occurred in E_{bind} of the core levels of Rh and Pt supported on TiO_2 (X-ray photoelectron spectroscopy method), so the authors were able to conclude that electron transfer from Ti^{3+} to the Rh and Pt atoms was negligible. At the same time, it was shown in several other studies[28,69,76–82] that reduction of (Rh, Ni, Pt)/TiO_2 catalysts with hydrogen at 873 K results in a decrease in E_{bind} of the core levels of the metals, which suggests an increase in electron density on the metal atoms.

Experimental confirmation of an interaction occurring between Ti^{3+} cations and Group VIII metals constituted important evidence in favour of the Horsley mechanism. A series of phyiscal methods (X-ray photoelectron spectroscopy, high-resolution electron energy loss spectroscopy, and UV photoelectron spectroscopy) were used to establish that when Ni,[76,83] Pt,[84] Pd,[85] and Rh [70] are deposited on the surface of a support containing Ti^{3+} cations, the spectroscopic parameters that are characteristic of Ti^{3+} cations either decrease or disappear. It was shown by means of Auger spectroscopy[70] that deposition of Rh on TiO_2 is accompanied by oxidation of the surface, and the changes in the UV photoelectron spectra are similar to those that occur when oxygen is adsorbed.

Direct experimental confirmation of the existence of a Rh–Ti bond was first obtained by Shpiro.[28,79] In a study of a Rh/TiO_2 catalyst reduced at 773 K using secondary ion mass spectrometry, mixed $RhTi^+$ clusters were detected together with Rh^+ and Ti^+, while at reduction temperatures of 473 and 573 K no $RhTi^+$ clusters were observed.

At the same time there is virtually no information in the literature about detection of a metal–Ti^{n+} bond by means of the extended X-ray absorption fine structure (EXAFS). Only two examples of the detection of such bonds using the EXAFS method are known. Thus, Konigsberger[86] found the Rh–Ti^{n+} distance to be 3.4 Å in length in a Rh/TiO_2 catalyst reduced at 773 K. However, this distance is too great for the formation of a chemical bond.[70] For a similar catalyst, Haller[87,88] demonstrated the existence of a Rh–Ti^{n+} bond of length 2.55 Å, which is somewhat shorter than the length of the Rh–Ti bond in the majority of stable intermetallic compounds (2.68 Å). However, in more recent studies of Rh/TiO_2 catalysts using EXAFS it was not possible to detect a Rh–Ti^{n+} bond.[68] The difficulties in attempting direct detection of a M–Ti^{n+} bond arise because it is of a special type and is only formed at the metal–support interface. It is therefore to be expected that the coordination numbers for titanium may be low and lie outside the limit of sensitivity of this method.

2. Change in morphology of supported metal particles

The formation of flat metal particles (with a "pill-box" or "raft-like" structure) on the surface of partially reduced TiO_2 were first introduced by Baker[89] to explain the existence of SMSI. In a study of the sintering of Pt on different supports using high-resolution electron microscopy over a temperature range of 425–1075 K it was shown that the dispersity of Pt deposited on TiO_2 is higher than that on other supports. At the same time the Pt particles have a flat hexagonal form with uniform thickness, which indicates the formation of flat structures. Moreover, in the presence of Pt, TiO_2 was reduced to Ti_4O_7, being accompanied by a change in the lattice parameter (5.6 Å). In fact, Prins[90] showed by means of EPR that Pt catalyses the reduction of TiO_2. After treatment of a Pt/TiO_2 catalyst with hydrogen even at 573 K, the concentration of Ti^{3+} ions is 30 times less than in the pure support.

It was shown by Baker et al.[91] that the formation of flat metal particles in an M/TiO_2 system is reversible. Thus, high-temperature treatment of Pt/TiO_2 with water vapour or O_2 results in the formation of globular Pt crystallites, while repeated reduction leads to the formation of flat structures.

A comprehensive scheme of the formation of flat particles is depicted in Fig. 3. As a result of high-temperature reduction, hydrogen atoms, diffusing from the surface of the metal to the support, reduce the Ti^{4+} ions to Ti^{3+}. At the same time oxygen vacancies are formed in the surface layer through the elimination of lattice oxygen in the form of H_2O. The resulting oxygen vacancies can be compensated by the formation of a bond between the metal atoms and Ti^{3+} cations. In fact, it was shown by Gingerich et al.[92] that the Pt–Ti bond is stronger than Pt–Pt. Thus, in their tendency to form a $M-Ti^{n+}$ bond, the metal atoms enter oxygen vacancies, and flat structures are formed on the surface, which was recorded by means of electron microscopy.[91] On oxidation by oxygen or H_2O the $M-Ti^{n+}$ bonds are broken and Ti_4O_7 is oxidised to TiO_2. At the same time the metal particles change their structure, adopting an energetically more favourable spherical form. The metal acquires its normal chemisorptive and catalytic properties through cleavage of the $M-Ti^{3+}$ bonds.[90,91]

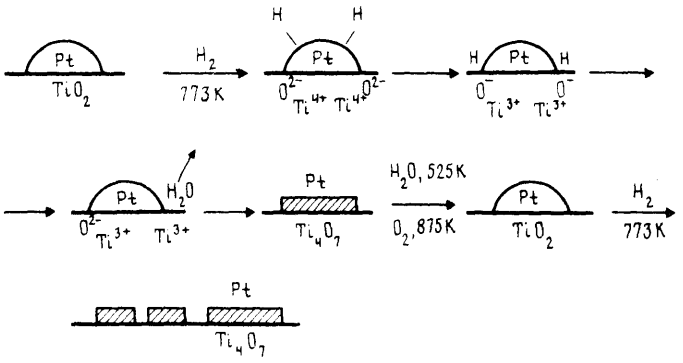

Figure 3. Scheme for the formation of flat metal structures in the system Pt/TiO_2.[90,91]

It should be noted that the unique flat structure of the Pt particles was not observed on oxides of nontransition elements (SiO_2, Al_2O_3) or on carbon. However, it was shown by Yates et al.[93] that flat Rh particles may also be obtained on Al_2O_3, while the shape of the particles does not affect the chemisorptive properties of Rh. Thus, the change in chemisorptive and catalytic properties of the metals in an SMSI state cannot be explained solely by a change in shape of the particles.

We should note that the existence of flat structures in other metals has not been clearly demonstrated. For example, the formation of flat particles of Ni in a Ni/TiO_2 catalyst was demonstrated by Mustard et al.[94] using electron microscopy, while flat structures were not detected by Baker et al.[95–97] in studies on similar catalysts. The formation of flat structures in Pd/TiO_2 was also not detected in another study.[98]

The results which suggest that partial reduction of TiO_2 occurs in the presence of Group VIII metals are not in doubt. The fact that the supported metal is localised on the reduced forms of TiO_2, namely, Ti_4O_7, suggests that the metal atoms form a chemical bond with the surface Ti^{3+} cations. A change in the chemisorptive and catalytic properties of a supported metal also occurs because of the interaction between the metal atoms and the Ti^{3+} cations.[89] The mechanism discussed in this section reiterates the assumptions made by Horsley.[67]

3. Formation of intermetallic compounds

The formation of intermetallic compounds was first proposed by Tauster as one of the mechanisms for interaction between a supported metal and a transition element oxide.[3] Experimental support for this hypothesis was obtained in two studies,[99,100] in which it was demonstrated that $Pt_{1-x}Zr_x$ intermetallic compounds are formed during the high-temperature reduction of Pt/ZrO_2 according to the reaction:

$$(1-x)Pt + xZrO_2 + 2xH_2 \longrightarrow Pt_{1-x}Zr_x + 2xH_2O.$$

In the case of $Pt/ZrO_2/C$ catalysts, intermetallic compounds are formed according to the reaction:

$$(1-x)Pt + xZrO_2 + 2xC \longrightarrow Pt_{1-x}Zr_x + 2xCO,$$

where C acts simultaneously both as a reducing agent and support. Appreciable formation of $Pt_{1-x}Zr_x$ compounds occurred at temperatures above 873 K. With an increase in temperature x increases and reaches a maximum value ($x = 0.25$) at 1273 K.

In three studies[96,101,102] the formation of compounds of the type M_3Ti was observed at 973 K for (Ni, Pt)/TiO_2. However, in two other studies[26,103] for Ni/TiO_2 there is no possibility of intermetallic compounds being formed even at 1073 K, since at this temperature TiO_2 cannot be reduced to metallic titanium.

A decrease in specific chemisorption of CO on Ni_xZr_y was observed by Tomanek et al.,[104] and it was established that above 300 K carbon monoxide is mainly adsorbed in a dissociative form. It should be noted that after treatment of the Pt_3Ti catalyst with hydrogen, the thermally programmed desorption (TPD) spectra indicated that desorption of H_2 did not occur. In the opinion of Bardi et al.,[105,106] either H_2 is not adsorbed at all on the surface or it is adsorbed sufficiently strongly for desorption not to occur up to 900 K. However, it is widely known that intermetallic compounds can form hydrides. Thus, it was shown in three studies[107–109] that Zn–Ni, Zr–Co, and Zr–Ni–Mo intermetallic compounds can dissociatively adsorb H_2 and contain it in bulk in the form of monoatomic species, which assumes that there is a high concentration of active hydrogen on the surface.

In the hydrogenolysis of ethane the activity of $Pt_{1-x}Zr_x/(ZrO_2, C)$ is 15–20 times lower than that of Pt/ZrO_2 and Pt/C catalysts.[99,100] It was shown in three studies[61,99,100] that in the hydrogenation of CO the specific catalytic activity of $Pt_{1-x}Zr_x$/support catalysts does not depend on the nature of the support, but their activity is higher than that of Pt/support catalysts by a factor of 10, and their selectivity towards CH_3OH reaches 80%.

It should be noted that intermetallic compounds are stable towards oxygen and do not decompose at room temperature.[26,110,111] However, oxidation at temperature above 573 K results in segregation of the components and a decrease in the observed changes in chemisorptive and catalytic properties.[107,109–114]

4. Electronic interaction between a metal and transition element oxide

Schwab[1] and Solymosi[2] attempted to explain the change in catalytic properties of metals on varying the nature of the support in terms of an electronic interaction between the deposited metal and

support. Interest in these ideas grew again at the end of the 1980s. For example, it was shown in two studies[115,116] that electron transfer between the metal and support can play a substantial role in the catalytic reaction. It was first suggested by Meriaudeau[26] that electron transfer between metal and support is the main cause of the change in chemisorptive and catalytic properties of metals in an SMSI state. The model put forward by Meriaudeau[26] is based on the theory of semiconductors and is depicted schematically in Fig. 4.

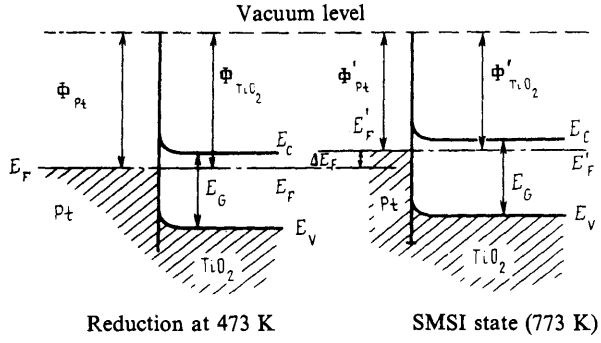

Figure 4. Schematic depiction of energy diagram for the system Pt/TiO_2.[26] E_F is Fermi level, Φ is electronic work function, E_V is top of valence band, E_C is bottom of conduction band, E_G is width of forbidden band, ΔE_F is increase in Fermi level in the SMSI state.

Since at a low reduction temperature the electronic work function (Φ) for TiO_2 is 5.5 eV while for Pt it is 5.6 eV,[26] the Fermi level (E_F) of TiO_2 lies near E_F for platinum. At high reduction temperatures, as a result of the high concentration of defects in TiO_2 (oxygen vacancies and Ti^{3+}) the electronic work function decreases to 4.6 eV, while the value of E_F becomes higher than in Pt. At the points of contact between platinum and TiO_2 the values of E_F equal out through the flow of electron density from support to platinum. The excess electron density on Pt will cause a modification of its electronic structure through a progressive filling of the d orbitals and there is a transition from a d^9 configuration to d^{10}, i.e., to the same as in gold. Gold is known not to exhibit the chemisorption of H_2 and does not catalyse reactions involving the dissociative chemisorption of hydrogen.

When oxygen is added TiO_2 undergoes reoxidation. In this case the support becomes electron-deficient, which assist a flow of electron density from platinum to support. As a result Pt acquires a normal d^9 configuration and at the same time its normal chemisorptive properties restored.

The hypothesis put forward by Meriaudeau[26] has been supported experimentally in four studies.[117–120] Thus, it was shown by Herrmann et al.[118,119] that on reduction of TiO_2 in the presence of platinum, the electrical conductivity of TiO_2 increases by a factor of 100, which suggests that platinum plays a catalytic role in the reduction of TiO_2 and it confirms the results of Huizinga and Prins.[90] It was established[119] that evacuation of TiO_2 at 673 K increases the electrical conductivity by a factor of 100, and the subsequent deposition of Pt leads to a decrease in electrical conductivity of TiO_2 by a factor of 2. A decrease in the electrical conductivity of TiO and Ti_2O_3 on deposition of Pt was also observed by Chen and White.[117] These phenomena are due to the simultaneous occurrence of two processes:[117,119] 1) formation of anion vacancies through removal of lattice oxygen and the generation of free electrons; 2) migration of the free electrons from the bulk of the support to the metal, resulting in a decrease in electron density on the support and a decrease in its electrical conductivity. As a result of the latter process the chemisorptive properties of the metal must change, according to Meriaudeau et al.[26] In fact, it was shown by Loye et al.[14] for Ni/Ti_nO_{2n-1} that with an increase in the degree of reduction of the support, a decrease in chemisorption of H_2 occurs. The change in chemisorptive properties of Ni through a change in electronic structure is supported by Longe and Stacy.[121] At the same time in a study by Fang et al.[62] on similar systems it was shown that an increase in bulk concentration of Ti^{3+} has no effect on the catalytic properties of Ni in the hydogenation of CO. Using X-ray photoelectron spectroscopy, Huizinga and Prins[122] did not detect any change in the electronic state of Pt when the reduction temperature for Pt/TiO_2 was changed from 483 to 823 K.

An alternative explanation to that put forward by Baker et al.[89] concerning the formation of flat metal particles follows from the mechanism proposed by Meriaudeau.[26] Chen and White[117] assume that when transfer of electron density occurs from the bulk of TiO_2 to the metal, the negatively charged metal particle will tend to increase its surface area in order to reduce the surface charge density. Consequently, when electron transfer occurs the formation of particles with a flat shape becomes energetically more favourable.

Despite the fact that the mechanism proposed by Meriaudeau[26] accounts for the change in chemisorptive and catalytic properties of platinum, which has a d^9 configuration, it cannot be recognised as a fundamental principle since it does not explain why Ir and Rh, which have d^7 and d^8 electron configurations respectively, when supported on oxides of transition elements exhibit properties that are characteristic of systems with SMSI.

5. Interaction at the metal–support interface

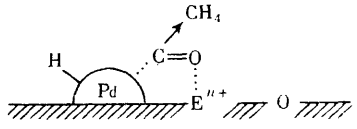
The existence of an interaction at a metal–support interface was first demonstrated by Burch and Flambard.[50] According to the model put forward by them, the formation of anion vacancies and Ti^{3+} ions at the phase boundary can produce a change in the catalytic properties of a supported metal through direct and indirect participation of the support in the catalytic process. For example, Ti^{3+} cations that are formed at the phase boundary can participate in the activation of CO molecules which undergo dissociative hydrogenation by hydrogen adsorbed on the surface. Furthermore, the support can form part of a heteroatomic adsorption site involving metal atoms and Ti^{3+} cations on the surface of the support. It has been suggested that during adsorption to these sites a CO molecule forms a bond via its carbon atom with a metal atom while the oxygen atom binds to a surface Ti^{3+} cation, resulting in a considerable loosening of the bond in the CO molecule and assisting its hydrogenation. Burch and Flambard[49,50] assume that in the interaction of metal atoms with Ti^{3+} cations through the transfer of electron density to the metal atoms the electronic properties of the supported metal are modified. When excess electron density occurs on the metal it is to be expected, on the one hand, that there will be a decrease in the activity of the catalysts in reactions involving the conversion of hydrocarbons because of a reduction in the strength of chemisorption of reactants on the surface of the metal, while on the

other hand, an increase in activity is to be expected in the hydrogenation of CO through an increase in the rate of dissociation of a CO molecule or an increase in the rate of desorption of reaction products.[49,50]

The idea that the support participates in the catalytic process and that specific active sites are formed at the phase boundary has found further confirmation in several studies.[123–128] For example, it was shown by means of angular resolved X-ray photoelectron spectroscopy[125] that on treatment of Pt/TiO_2 with hydrogen, the resulting Ti^{2+} and Ti^{3+} cation sare localised at the metal–support interface. Stadler et al.[126] found that the high activity of a Pd/TiO_2 catalyst in the hydrogenation of 1,5-hexadiene is due to coordination of the olefin on the surface Ti^3 cations and to hydrogenation of the resulting complex by hydrogen that is dissociatively adsorbed on the surface of palladium.

It was established[127] that on addition of Sb^{5+}, Ta^{5+}, W^{6+} ions to Pt/TiO_2 and Pt/Nb_2O_5, there is a decrease in chemisorption of hydrogen because of an electronic interaction at the interface between Pt and the introduced ions. When Na^+ ions were added to Ni/TiO_2, the selectivity of the catalyst increased and higher alcohols were formed from synthesis gas, which is attributed by Hayasaka et al.[128] to the participation of the Na^+ ions in the activation of CO.

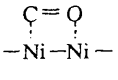
The high activity of Pd/TiO_2 and Pd/La_2O_3 catalysts in the hydrogenation of CO is attributed to participation of supports in hydrogenation.[21,45] In this case, as was suggested by Burch and Flambard,[49,50] the authors assume[21,45] that cations of the support can form part of a mixed adsorption site and participate in the activation of a CO molecule:



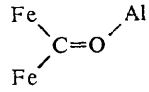
(I)

or take part in the adsorption of reaction intermediates.

Thus, the existence of active sites at the metal–support interface assumes that an unusual form of CO adsorption occurs parallel to the surface. The possibility of the planar coordination of CO simultaneously on Pt and Ti atoms was calculated theoretically by Mehandru et al.[129] According to Rice and Haller,[130] vibrations of the planar-coordinated form of CO should appear in the region below 1800 cm^{-1} in the IR spectra. In fact, it was shown in two studies[131,132] by means of IR spectroscopy that when manganese, titanium, or zirconium ions are added to a Rh/SiO_2 catalyst, a new absorption band due to CO appears in the region 1800–1600 cm^{-1}. In this case its position depends on the metal–promoter ratio. We should note that in 1965 Garland,[133] when studying the adsorption of CO on Ni films, first detected an unusual absorption band of adsorbed CO at 1620 cm^{-1}, which was provisionally attributed to the coordination of CO on two nickel atoms:



It was only progress in the chemistry of cluster compounds that demonstrated the validity of assigning the absorption bands in the region below 1700 cm^{-1} to vibrations of CO coordinated simultaneously through its carbon and oxygen atoms on metal atoms. For example, Nelson et al.[134] established the presence of



residues with a CO vibration frequency of 1527 cm^{-1} for different Fe carbonyl clusters. It was shown by Sachtler et al.[135] that for different heteronuclear Mo, Fe, and Ru complexes the absorption bands of CO in M–C–O–M residues are in the region of 1700–1500 cm^{-1}.

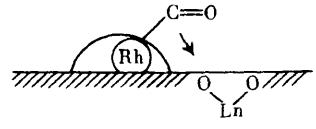
A considerable contribution towards proving that complexes exist at the metal–support interface in catalysts of the type M/E_xO_y was made by Bredikhin et al.,[136–139] who demonstrated by means of IR spectroscopy that in the adsorption of CO, complexes are only formed at the metal–support interface for catalysts prepared by deposition of metals on oxides of transition elements (TiO_2, ZrO_2, HfO_2, V_2O_5, La_2O_3). At the same time for metals supported on oxides of *p*-elements (Al, Zn, Cd, Ga, Bi) and also for bulk metals or supports without metals, the formation of these complexes does not occur. Moreover, a systematic study of the chemical and spectroscopic properties of complexes formed at the metal–support interface was undertaken by Bredikhin et al.[136–139] It was shown in this case that they have a number of characteristics:

1) a broad absorption band in the region of 1800–1600 cm^{-1}, whereby its position depends on the nature of the metal and support used;

2) a low value of the isotopic shift ($^{12}CO \rightarrow {}^{13}CO$) and a lower value of the high-frequency shift with an increase in the degree of filling the surface compared to surface carbonyls, and the heat of adsorption of CO is similar to the corresponding value for carbonyl complexes;

3) they are oxidised by oxygen, in the same way as surface carbonyls.

At the same time the question concerning the type of CO adsorption at the sites formed at the metal–support boundary remains open. While Bredikhin et al.[136] give preference to complexes of the type

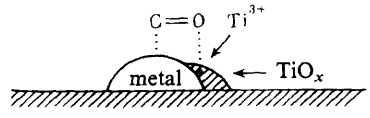


in several other studies[20,49,50,130,131,135] the authors assume that an adsorbed CO molecule forms a complex of the type (I).

Despite the difference in proposed forms for the coordination of CO at the metal–support interface, it may be assumed that the hydrogenation of CO on M/E_xO_y catalysts occurs with the participation of novel complexes of adsorbed CO, which accounts for the unusual nature of their catalytic properties in the hydrogenation of CO. There is no doubt that further studies need to be carried out in order to verify this hypothesis, but the results already reported in the literature indicate the necessity for admitting the funadmental possibility of the coordination of molecules at the metal–support interface in representing the mechanisms of the catalytic reactions.[138]

6. Diffusion of TiO_x to the surface of the metal

According to a number of published studies, one of the most widely recognised mechanisms introduced to account for the unusual properties of metals on oxides of transition elements is the diffusion of partially reduced residues of the support to the surface of the metal particles. This mechanism was first suggested by Meriaudeau et al.[37] and was further developed in three studies.[16,140,141] This mechanism essentially involves partial reduction of TiO_2 around the perimeter of the metal particles followed by migration of the TiO_x residues to the surface of the particle. As a result the surface of the metal particle is obstructed by small islets of TiO_x, resulting in a decrease in the available surface of the metal for chemisorption of hydrocarbons and hydrogen, and hence to a decrease in activity of the catalysts in the conversion of hydrocarbons.[37,140] Furthermore, the total metal–support interface increases as a result of the migration of TiO_x to the surface of a metal particle. At the same time, according to Anderson et al.,[16] there is an increase in the number of adsorption sites consisting of metal atoms and E^{n+} cations that can participate in the coordination of a CO molecule according to the scheme:



Thus, on the basis of this mechanism participation of the support in the activation of CO explains the increase in activity of M/TiO_x catalysts in the hydrogenation of CO.[16,142]

Experimental support for the mechanism involving decoration of the metal surface is provided in a number of studies.[143–160] At the same time the question regarding the migration mechanism of TiO_x to the surface of the metal remains open. For example, in two studies[16,162] distortion of the crystal lattice of platinum was observed on reduction of Pt/TiO_2 above 673 K, which was attributed to diffusion of TiO_x into the bulk of Pt. Diffusion of TiO_x into the bulk of Pt over the temperature range 700–900 K was recorded in two other studies.[163,164]

It has also been thought possible that transport of TiO_x to the surface of the metal occurs through the intermediate formation of metastable $M-TiO_x$ compounds which segregate on reduction to form TiO_x residues on the surface of the metal. For example, the formation of $Ni-TiO_x$ structures was recorded in two studies.[121,165] The formation of $LaPd_xO$ structures on reduction of a Pd/La_2O_3 catalyst was demonstrated by Fleisch et al.,[166] and at the same time an increase in electron density on Pd was detected by X-ray photoelectron spectroscopy. On addition of K^+ ions to a Pt/TiO_2 catalyst, a decrease in chemisorption of H_2 occurred, which Spencer[167] related to the participation of potassium ions in the form of K_2TiO_3 in the transport of TiO_x to the surface of Pt.

Furthermore, the counter-diffusion of metal atoms and resulting TiO_x residues at the metal–support interface is not excluded. According to Spencer,[168] the mobility of the metal atoms is governed by the Hüttig temperature (T_H), which is equal to one third of the melting point of the metal. For example, T_H = 700 K for Pt, 750 K for Rh, and 700 K for TiO_2 and TiO. It is to be expected that at reduction temperatures above 700 K the mechanism for transport of TiO_x to the surface of the metal through the mutual diffusion of metal atoms and TiO_x residues predominates.[97,168]

In order to confirm the hypothesis about decoration of the metal surface, a study was made of model systems obtained by depositing TiO_2 on the surface of different metals. It was shown by Gorte et al.[163,169] that when the content of TiO_x on the surface of Pt foil is increased, the chemisorption of CO and H_2 is almost completely suppressed. The activity of TiO_x/Pt catalysts in the synthesis of CH_4 from CO and H_2 is similar to that of Pt/TiO_2, while at the same time there is a decrease in the activation energy of reaction by 12 kcal mol^{-1}.

An increase in the activity of model TiO_x/Rh catalysts in the hydrogenation of CO with an increase in the extent of surface coverage of Rh foil with TiO_x particles was observed by Levin et al.[170] The maximum increase in activity in the synthesis of CH_4 occurred when the extent of surface coverage of the metal with TiO_x was 15%, which is attriubted to an optimum number of Rh atoms being located along the TiO_x boundary.[170]

The maximum activity for model TiO_x/Ni catalysts in the synthesis of CH_4 occurred at 8% covering.[171] It was shown[172] that the chemisorption of CO on the surface of Ni(III) decreases in the presence of MnO_x, and the quantity of chemisorbed CO decreases linearly with an increase in coverage of the nickel with MnO_x particles. Moreover, in the presence of MnO_x a novel form of adsorbed CO occurs on the surface of Ni(III) with vibration frequency 1620 cm^{-1}, the intensity of this form reaching a maximum for average degrees of coverage with MnO_x.

Thus, investigation of model TiO_x/M catalysts shows that blocking the metal surface with partially reduced residues of support (TiO_x) and modification of the electronic properties of the metal through the interaction of metal atoms with TiO_x results in a considerable loss of chemisorptive properties of these catalysts. However, the presence of residues of support on the surface of the metal leads to an expansion in the metal–support interface and an increase in the number of active sites consisting of metal atoms and support, which may be the cause of the increased activity of catalysts in the hydogenation of CO. We should note in conclusion that the model for decoration of the surface of the metal with TiO_x residues is generalised model and incorporates the models put forward by Horsley, Baker, and Burch.

IV. Study of the mechanism of the interaction between Group VIII metals and oxides of transition elements using $(M + E^{IV})/SiO_2$ model systems

It may be concluded from an analysis of the results given above that six basic mechanisms to account for the unusual properties of metals supported on transition element oxides have been discussed in the literature. However, the experimental data supporting a given mechanism are usually contradictory, and not one of these hypotheses has so far received conclusive experimental confirmation. We should note that research into the problems of SMSI is mainly being conducted in the following areas:

a) a study of real M/E_xO_y catalysts using a range of physical methods;

b) the development and study of model systems (mainly catalysts obtained by covering the metal surface with TiO_x residues);

c) theoretical calculations of the active sites in catalysts with SMSI.

It would appear that significant progress in solving the problem of SMSI could be achieved either by conducting more precise experimental studies of M/E_xO_y catalysts using a range of physical methods or by developing fundamentally new model systems. In this regard the results of studies by Ryndin et al.,[173–184] in which the directed synthesis of $M-E^{n+}$ heteroatomic active sites similar to the active sites supposedly existing in real M/E_xO_y catalysts on the surface of an inert matrix has been carried out using organometallic chemical methods, are of interest. The ideas developed by Ermakov[4–8] form the basis of the synthesis of the $(M + E^{IV})/SiO_2$ catalysts. As a result of a reaction between Group IV organometallic compounds with SiO_2, bonding of the surface hydroxide groups occurs, while treatment in H_2 results in the formation of fixed, coordinatively unsaturated E^{IV} ions. When organometallic compounds of Group VIII metals are subsequently deposited, they interact with the coordinatively unsaturated E^{IV} ions to form $M-E^{n+}$ bonds. With this method it is possible to obtain active sites directly by synthesis rather than as a result of high-temperature reduction as in the case of M/E_xO_y catalysts.

We shall briefly summarise the results obtained from the studies on model $(M + E^{IV})/SiO_2$ systems.

1. Information about the state of surface E^{IV} ions

a) State of E^{IV} before deposition of a Group VIII metal

It follows from the chemisorption and TPD data of Ryndin et al.[180] that treatment of fixed Ti and Zr organometallic complexes with hydrogen either gives surface hydride complexes or leads to the formation of low-valent ions that are not bound to hydrogen. The composition of the surface compounds depends on the treatment conditions of the samples, principally on the temperature of treatment (Table 1). The presence of low-valent ions in E^{IV}/SiO_2 samples is confirmed by the X-ray photoelectron spectroscopy data.[180]

Table 1. Composition of the surface compounds for the system 1.1% Ti/SiO_2.[180]

Activation conditions	Average degree of oxidation	H/Ti	Surface compounds
No treatment	4.0	–	H_2, 423 K	3.4	2.3	H_2, 573 K	3.0	1.2	H_2, 873 K	2.7	0.1	O_2, 673 K	4.0	–	
According to the electron microscopy data, disperse oxide phases or extended two-dimensional formations of E^{IV} compounds are not formed in reduced E^{IV}/SiO_2 samples.[180] It follows from the data of EXAFS that the reduced Zr/SiO_2 catalysts mainly contain isolated Zr ions bound to oxygen of SiO_2.[179,180]

b) State of E^{IV} in the presence of M

This information may be obtained from data on the quantity of O_2 consumed in the oxidation of $(M-E^{IV})/SiO_2$ samples at different temperatures. For all the $(M-E^{IV})/SiO_2$ systems the quantity of O_2 consumed in oxidation was higher than that corresponding to the stoichiometry of O/M = 1 that is characteristic of M/SiO_2 (Table 2). These data indicate that in the model catalysts the promoter ions occur in a low oxidation state.[173–184]

Table 2. Quantity of O_2 consumed in the oxidation of $(M + E^{IV})/SiO_2$ samples at 673 K.[176,177,183,184]

Catalyst, wt.%	M_s/M_t^*	Atomic ratio		N^{**}
		O/M	O/E^{IV}	
2.5% Pt	0.66	0.97	–	–
0.9% Ni+1.1% Ti	1.00	2.44	1.00	2.7
2.0%Pd+5.2%Zr	0.84	1.35	0.12	3.8
3.2%Pt+1.1%Ti	0.71	1.52	0.37	3.2
2.7%Pt+5.3%Zr	0.79	1.31	0.11	3.8
2.0%Pt+4.0%Hf	0.78	1.26	0.13	3.7

*Fraction of surface atoms of metal.
**Average degree of oxidation of E^{IV}.

2. Properties of the metal particles of $(M + E^{IV})/SiO_2$ catalysts

a) Dispersity of metal particles

In all cases the introduction of small quantities of E^{IV} into catalysts containing Ni, Pd, or Pt on SiO_2 results in a decrease in the metal particle size and a narrower distribution of particle size, while the stability of the metal particles towards sintering increases. This is suggested by the data of electron microscopy (Fig. 5), chemisorption (Table 2), and X-ray photoelectron spectroscopy.[176]

b) Chemisorptive properties

Palladium and platinum catalysts on TiO_2 and ZrO_2 obtained from organometallic compounds contain dispersed metal particles (15 Å after reduction at 823 K). These catalysts adsorb virtually no H_2 (H/M = 0.01) or CO (CO/M = 0.05).[176,183,184]

Modified Pd catalysts are also characterised by a reduced chemisorption of CO and H_2. It follows from a comparison of the dispersity of Pd in (Pd + Zr)/SiO_2 and (Pd + Ti)/SiO_2 catalysts with a quantity of adsorbed H_2 and CO that the degree of coverage of the surface of Pd with these molecules is less than 50%. In the presence of Ti ions on the surface of SiO_2 platinum also exhibits

decreased chemisorption of H_2 and CO (H/Pt = 0.2, CO/Pt = 0.2).[176,183,184] Thus, the introduction of E^{IV} ions on to the surface of SiO_2 leads qualitatively to the same effects relative to chemisorption on Group VIII metals as the deposition of these metals on TiO_2 or ZrO_2.

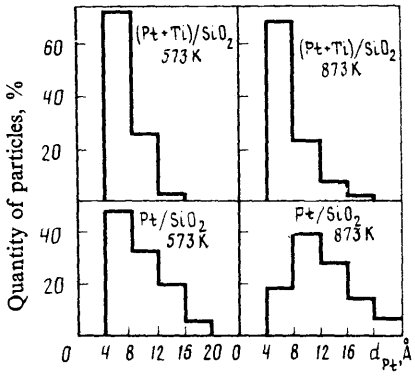

Figure 5. Dependence of the distribution of particle size on the temperature of reduction of the catalysts.[176]

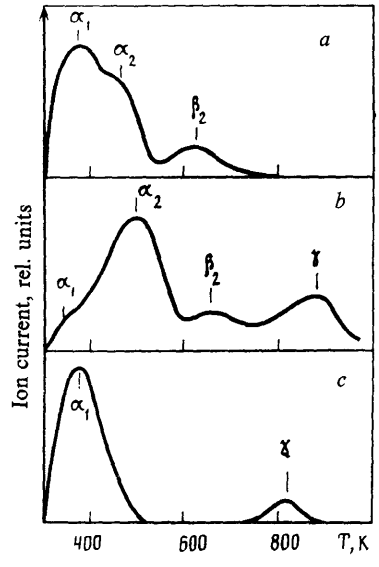

Figure 6. Thermal desorption spectra of ^{13}CO from nickel catalysts reduced at 823 K.[178] *a*, 0.72% Ni/SiO_2; *b*, (0.94% Ni + 1.1% Ti)/SiO_2; *c*, 0.47% Ni/TiO_2.

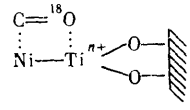
The nature of the adsorption of CO on Ni catalysts was studied by Alekseev et al.[178] by means of TPD. Three forms of adsorbed CO characterise the spectrum of the thermal desorption of CO from the surface of Ni/SiO_2 (Fig. 6). Two low-temperature molecular forms α_1 and α_2 occur with temperatures of the desorption maximum (T_{max}) at 370 and 450 K together with a medium-temperature form β_2 with T_{max} = 620 K, which results from the recombination of C and O on the surface of nickel.

The TPD spectrum of the desorption of CO from the surface of a (Ni + Ti)/SiO_2 can be represented qualitatively as the sum of the TPD spectra of desorption from the surface of Ni/SiO_2 and Ni/TiO_2 catalysts. This phenomenon suggests that Ni particles of two types are present in the modified catalyst: 1) particles with chemisorptive properties that are similar to Ni/SiO_2; 2) those with properties that are similar to Ni/TiO_2.

The spectrum of the thermal desorption of CO from the surface of Ni/TiO_2 differs from that for the thermal desorption from the surface of Ni/SiO_2 by virtue of the presence of a high-temperature dissociative γ form, which represents the dissociatively adsorbed CO at the metal–support interface. This assertion follows from the fact that for the Ni/TiO_2 catalyst the γ form plays an active part in the heteroexchange of the oxygen in $C^{18}O$ with lattice oxygen. In the case of Ni/SiO_2 this reaction does not occur. The heteroexchange of $C^{18}O$ with oxygen of the support on a (Ni + Ti)/SiO_2 catalyst suggests that Ti ions in an oxygen environment form part of the active sites on which dissociative adsorption of $C^{18}O$ occurs:[178]



For Pd catalysts the nature of the activation of CO was studied by means of IR spectroscopy. In addition to the absorption bands corresponding to the linear and bridged forms of CO adsorption on metallic palladium, in the adsorption of CO on (Pd + Zr)/SiO_2 an additional absorption band appears at 1610 cm^{-1}, whose intensity increases, and which is shifted 10 cm^{-1} to higher frequency with an increase in the CO pressure (Fig. 7).[184] From the results obtained and also the literature data the absorption band at 1600 cm^{-1} can be attributed to the adsorption of CO on mixed active sites involving Pd atoms and Zr ions.

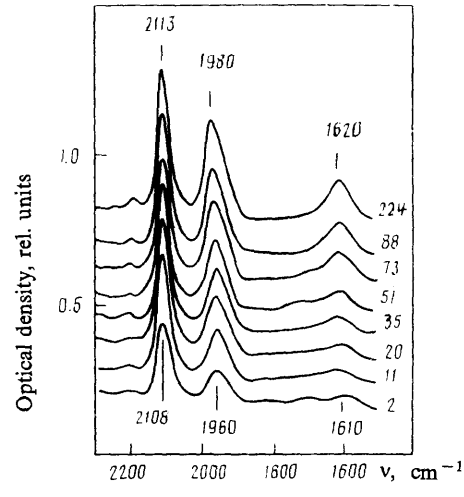


Figure 7. IR spectra of CO adsorbed on a (1.7% Pd + 5.2% Zr)/SiO_2 catalyst reduced at 573 K.[184] The figures by the curves correspond to the CO pressures (in Torr).

c) Study of the electronic state of supported elements

Information about the electronic state of Pd and (Pd + Zr)/SiO_2 systems was obtained by means of X-ray photoelectron spectroscopy. When Pd was supported on silica gel modified with Zr ions, there was an increase in E_{bind} for the $3d_{5/2}$ level of Pd by 0.6–1.0 eV compared to E_{bind} for this level in Pd/SiO_2, corresponding to a reduction in electron density on the Pd atoms in the presence of Zr ions. The electron-deficient nature of Pd in (Pd + Zr)/SiO_2 was also suggested by the IR spectroscopic data.[183,184] Since samples of similar dispersity were being compared, this positive shift could not be due to a dimensional effect but was caused by an interaction between supported components in the (Pd + Zr)/SiO_2. In the case of (Pt + Ti)/SiO_2 there was also a tendency for E_{bind} of the $4f_{7/2}$ level of Pt to increase, but these changes were of the same order as the experimental error.[176]

After deposition of Pd and Pt on samples of Zr/SiO_2 and Ti/SiO_2 it was not possible to detect changes in the binding energies of levels in Ti and Zr. However, deposition of Pd and Pt results in a decrease in the relative intensity of the spectrum of the promoting element by 20% on average. These findings suggest that a proportion of the ions of the promoting elements is shielded by the metal particles.

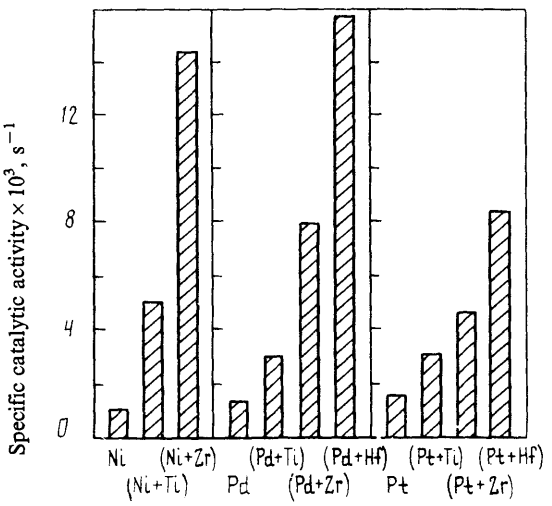

Figure 8. Effect of a Group IV element on the activity of a Group VIII metal in the hydrogenation of CO at 523 K.[176,177,183,184]

d) Catalytic properties

In all cases the presence of E^{IV} ions in Ni, Pd, and Pt catalysts causes an increase in activity of the supported metal in the hydrogenation of CO. At the same time the selectivity of the process also varies—for Ni the yield of C_2–C_3 hydrocarbons increases to 30%, while for Pd and Pt the output of hydrocarbons decreases and the yield of methanol increases, reaching 95–99% at 523 K and a pressure of 10 atm. For all the Group VIII metals the promoting effect of the E^{IV} ions increased in the series: Ti < Zr < Hf (Fig. 8).

In the hydrogenation of benzene a decrease in the activity of (M + E^{IV})/SiO_2 catalysts compared to M/SiO_2 occurred by a factor of up to 10. At the same time the activity of the model systems was similar to that of M/TiO_2 and M/ZrO_2 catalysts.[173–184]

In the hydrogenolysis of ethane the activity of (M + E^{IV})/SiO_2 systems, like that of M/E_xO_y catalysts, decreases by a factor of 100–1000 compared to MSiO_2. It should be noted that after high-temperature oxidation the inhibitory effect of E^{IV} ions on the activity of the model systems in the conversion of hydrocarbons disappears in a similar manner to that observed for M/E_xO_y systems.

We should point out that the decrease in activity of (M + E^{IV})/SiO_2 catalysts occurs even at low reduction temperatures (573 K). In this respect the model systems studied by Ryndin et al.[173–184] differ from metals on bulk oxides, where SMSI occurs after their reduction at high temperatures (above 773 K). This difference occurs because in the M/E_xO_y catalysts the active sites that are needed for SMSI to develop are only formed during high-temperature reduction. At the same time formation of the active sites for the model systems actually occurs during synthesis of the catalaysts when the second component is deposited on the silica gel modified with E^{IV} ions.[181,184] Therefore, high reduction temperatures are not needed for the effects of SMSI to be exhibited when model (M + E^{IV})/SiO_2 catalysts are used.

3. Possible causes of the effect of Group IV elements on the properties of supported metal particles

Let us examine the possible models of surface formations in supported model (M + E^{IV})/SiO_2 catalysts (Fig. 9).[179]

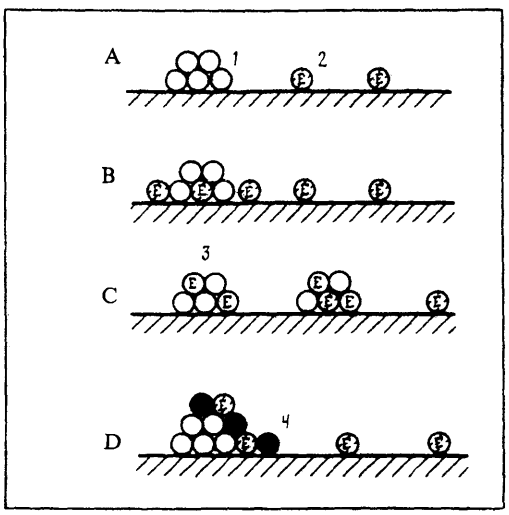

Figure 9. Possible models of surface formations in catalysts supported on SiO_2:[179] *1*, atom of Group VIII metal; *2*, surface ion of promoting element E^{IV}; *3*, atom of E^{IV} element in a zero valence state; *4*, oxygen ion.

Model A. Metal particles that are not bound to E^{IV} occur on the surface. This separate distribution of M and E^{IV} does not explain the increase in dispersity nor the decrease in catalytic activity in the

conversion of hydrocarbons. However, it cannot be excluded that a proportion of the metal particles is located on the surface of SiO_2 without interacting with E^{IV}.

Model B. In this case it is assumed that the metal particles interact directly with the surface ions of the transition element in a similar manner to that previously proposed.[8]

Model C. This model assumes the formation of particles of an alloy of modified element and metal. Theories of this type have also been advanced to explain the properties of M/E_xO_y systems.[3] However, for the model systems studied by Ryndin et al.[173-184] such a model is not consistent with the presence of E^{IV} ions in an intermediate oxidation state in the catalysts.

Model D. Adsorption of E^{IV} oxide occurs on the surface of a cluster of metal M. However, this model is at variance with the decrease in surface concentration of E^{IV}, as indicated by the data of X-ray photoelectron spectroscopy.

Thus, a model of the type B can explain the following results:

a) the increase in dispersity of metal particles in the presence of E^{IV} through the stabilisation of metal clusters on fixed E^{IV} ions;

b) the change in catalytic properties as a result of the change in electronic state of the metal cluster;

c) the effect of initial oxidation. Treatment of $(M + E^{IV})/SiO_2$ samples with oxygen at a high temperature leads to oxidation and segregation of the components (M and E^{IV}) followed by sintering of the metal;

d) the change in chemisorptive properties of the metal through a change in its electronic state.

At the same time the existence of $M-E^{IV}$ bonds was not revealed by the direct EXAFS method in these studies,[173-184] which would constitute the most important evidence in favour of model B occurring for the model systems. The absence of information about the existence of $M-E^{IV}$ bonds in the EXAFS spectra is evidently related to the reasons discussed in Section III. However, a set of evidence for the existence of an interaction between the metal and promoter in $(M + E^{IV})/SiO_2$ catalysts has been obtained.[173-184] Thus, it has been demonstrated that the following occur:

1) a change in the spectroscopic properties of Ti^{3+} ions when an active metal is deposited (EPR data);

2) a change in the electronic state of the components in model systems and also shielding of a proportion of the ions of promoter by metal clusters (IR and X-ray photoelectron spectroscopic data);

3) the presence in the model catalysts of an additional absorption band due to CO in the region of 1600 cm^{-1} (IR spectroscopic data);

4) the presence of a high-temperature γ form of adsorbed CO in the TPD spectra of model systems as well as data on the heteroexchange of $C^{18}O$ with oxygen of the support (TPD data);

5) retention of a chemical bond with the surface of silica gel for E^{IV} ions during reduction of the catalysts (IR and EXAFS spectroscopic data).

Thus, the data of TPD, EPR, EXAFS, and IR spectroscopy obtained from studies of model systems[173-184] in combination with chemisorption and catalytic electron microscopy data support the validity of model B for $(M + E^{IV})/SiO_2$ catalysts. This model does not exclude additional reasons (in addition to the change in electronic properties of a cluster of metal M) for the change in catalytic activity. For example, the increase in activity in the hydrogenation of CO may occur as a result of activation of CO on mixed active sites according to Scheme (I), as put forward in a number of studies.[18,49,130,131,135] At the same time the increase in activity of $(M + E^{IV})/SiO_2$ catalysts in the hydrogenation of CO in the promoter series Ti < Zr < Hf appears reasonable since the strength of the $E^{IV}-O$ bond increases in the same series.[185] Thus, by varying the nature of the Group IV ion in the chemisorption complex (Scheme I), the strength of the bond between the oxygen atom of the CO molecule and the E^{IV} ion will increase in the above series. This may assist the addition of hydrogen adsorbed on the metal to the carbon atom to form a formyl complex, which acts as an intermediate in the synthesis of methanol from CO and H_2.[185]

4. Mechanism of the metal–support interaction in M/E_xO_y systems

As has already been mentioned in Section III, in an examination of the effects of SMSI a considerable number of reasons have been suggested in the literature to explain the unusual properties of metals supported on TiO_2 and other oxides of transition elements. However, not one of these theories has received conclusive experimental confirmation. It is possible that for catalysts containing metal particles on transition element oxides there is no single cause of the effects of the so-called SMSI but the different characteristics of the metal properties have different causes. Let us examine the above mechanisms in terms of the results obtained by Ryndin et al.[173-184]

In one of the studies of Baker[89] it was found in a Pt/TiO_2 catalyst that Pt particles with a cross-section of several tens of Ångstroms had a flat, frequently hexagonal shape and were located on reduced sections of the surface of TiO_2 (Ti_4O_7 suboxide), which, according to Baker, gives rise to SMSI. The difference in shape and size of the metal particles in M/TiO_2 catalysts in this study[89] was due to the difference in the methods of preparing these catalysts. A study of M/TiO_2 catalysts prepared via fixed metal complexes showed that over a wide temperature range of reduction (573–823 K) the particles of supported metal retained a spherical form.[173-184] Furthermore, these catalysts exhibit all the catalytic and chemisorptive properties that are characteristic of SMSI. Consequently, the presence of flat metal particles located on the surface of suboxides such as Ti_4O_7 is not a necessary condition for the effects of SMSI to occur.

The results obtained in these studies[173-184] on $(M + E^{IV})/SiO_2$ catalysts suggest that intermetallic compounds and dispersed phases of E^{IV} oxides are not present in these catalysts. Hence the common nature of the catalytic and chemisorptive properties of M/E_xO_y and $(M + E^{IV})/SiO_2$ catalysts cannot be explained in terms of mechanisms that assume the formation of intermetallic compounds and the transfer of electron density to the metal particles from the bulk of the support.

In recent years in the literature there has been an increasing amount of publishd data to suggest that direct interaction between atoms of the active metal and low-valent surface ions of the transition element causes the SMSI effects.[67,161,186,187] Theoretical calculations of $PtTiO_5$ [67] and $Ni_3Ti_2O_5$ [187] clusters showed that in these cases a strong covalent bond exists between the metal atoms and the Ti^{n+} ion. At the same time it appears that the metal atoms are positively charged as a result of the transfer of electron density from the Ni atom to the Ti^{n+} ion. In an analysis of the properties of the model $(M + E^{IV})/SiO_2$ catalysts,[173-184] a model of the active sites involving interaction between the metal atoms and the promoter ions was put forward. Taking into account the similarity in the properties of $(M + E^{IV})/SiO_2$ and M/E_xO_y systems, this model can be extended to M/E_xO_y catalysts. In fact, $RhTi^+$ clusters were

detected in studies of a Rh/TiO_2 catalyst using secondary ion mass spectrometry[28,79] while the presence of $Rh-Ti^{n+}$ bonds in a Rh/TiO_2 catalyst was demonstrated by EXAFS in two studies.[86,87]

The idea that the reactants are activated at the boundary between the metal and support is a logical addition to the mechanism of Horsley,[67] since in its original exposition this theory[49,50] assumes that the catalytic and chemisorptive properties of M/E_xO_y catalysts change both as a result of a change in the electronic properties of the metal and through the activation of the reactants at the metal–support boundary. In the opinion of Burch et al.,[20,45] participation of cations of the support in the activation of a CO molecule will assist the hydogenation of CO and thus permit an increase in activity of M/E_xO_y catalysts. The existence of mixed active sites in M/E_xO_y catalysts has been demonstrated experimentally by Bredikhin et al.[136–139] The existence of such sites in $(M + E^{IV})/SiO_2$ catalysts has been demonstrated in the studies by Ryndin et al.[173–184]

The mechanism which assumes the diffusion of reduction products of the support to the surface of the metal particles has gained the widest recognition in the literature.[16,37,140] According to this mechanism, the reduction in chemisorptive properties of the metal and also the decrease in activity of M/E_xO_y catalysts in the conversion of hydrocarbons is due to blocking of the surface of the active metal with particles of the type TiO_x while the increase in activity of these systems in the hydrogenation of CO is due to the expansion of the metal–support interface, which results in an increase in concentration of mixed active sites incorporating metal atoms and ions of the support.[16,140] Results that would exclude this mechanism were not obtained in studies of M/E_xO_y catalysts.[173,184]

Furthermore, for the model $(M + E^{IV})/SiO_2$ catalysts the shielding of a proportion of the E^{IV} ions occurs as a result of their interaction with the metal atoms. Thus, a situation occurs for the model $(M + E^{IV})/SiO_2$ systems which is the opposite of what is proposed in the mechanism put forward by Meriaudeau[37] and Haller.[140] Consequently, when there are no E_xO_y residues on the surface of the metal (i.e., with no blocking of the surface of the metal), in the $(M + E^{IV})/SiO_2$ catalysts a reduction in chemisorption of CO and H_2 occurs as well as a decrease in activity of these catalysts in the conversion of hydrocarbons and an increase in their activity in the hydrogenation of CO. It may be assumed from these results and also the results of Burch and Flambard[50] which suggest that M/TiO_2 catalysts have high activity in the hydrogenation of CO even at low reduction temperatures, when the effect is absent that shielding of the surface of the metal with TiO_x particles is not a necessary condition for SMSI to occur.

It should be noted that the origins of SMSI in M/E_xO_y catalysts may be more complex than those in the model $(M + E^{IV})/SiO_2$ systems. Therefore, more rigorous arguments are required to prove the decoration mechanism for M/E_xO_y catalysts.

Thus, the results of a number of studies[4–8,28,79,86,136–139,173–184] suggest that SMSI in M/E_xO_y catalysts can be explained in terms of a mechanism which assumes a direct interaction between the metal atoms and low-valent ions of the support and the formation of mixed active sites involving metal atoms and support ions at the metal–support interface.

The above data show that supported metal catalysts obtained from organometallic compounds are convenient model systems for a study of the mechanism of SMSI. With the use of organometallic compounds it is possible not only to obtain highly dispersed metal catalysts but also to carry out the directed synthesis of active sites on the surface of supports and thus prepare catalytic systems with given chemical properties. From the synthesis and study of model $(M + E^{IV})/SiO_2$ catalysts obtained from organometallic compounds it is possible to make a critical investigation of the mechanisms that have been put forward in the literature to explain the effects of SMSI.

Inhibition–initiation in the pyrolysis of hydrocarbon mixtures

L V Shevel'kova, L E Gusel'nikov, G Bach, G Zimmermann
A V Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow
Central Institute of Organic Chemistry, Leipzig, Germany

ABSTRACT. **The results of investigations on the mutual influence of hydrocarbons of various classes on the rate and route of decomposition under copyrolysis conditions are correlated and discussed. A general concept has been formulated as to the mechanism of the inhibition–initiation phenomenon based on competing chain propagation reactions according to which a hydrocarbon may act both as an inhibitor and as an initiator of decomposition. The course of this action is determined by the character of partner behaviour and by the concentration of reactive radicals.**

I. Introduction

The pyrolysis of hydrocarbons lies at the basis of the manufacture of fundamental products such as monomers and starting materials for fine organic synthesis in the chemical and petrochemical industries. The traditional raw material for pyrolysis is gas condensate and directly distilled solvent naphtha consisting mainly of alkanes, naphthenic hydrocarbons and a small quantity of aromatics. The involvement of gas oil and residual fractions after oil refining, of coal liquefaction products, carrying out the process under conditions of recirculation of short chain fractions separated from the products and also the preliminary treatment of a raw material by hydrogenation or hydrocatalytic treatment, complicates the composition of the raw material even more and demands consideration of the mutual influence of the components of the reaction mixture on the pattern of their thermal decomposition. This is also important because in addition to the initial hydrocarbons the products of their pyrolysis (hydrogen, methane, alkenes, aromatic hydrocarbons) are always present in the reaction zone.

The first investigations of the effect of added unsaturated hydrocarbons on the thermal decomposition of alkanes appeared in the thirties. With the development of industrial processes interest in the mutual effect grew further. This was particularly so in connection with the development of kinetic models of pyrolysis for which information is needed on the detailed mechanism of the decomposition of individual hydrocarbons and mixtures of them. Up to the present many experimental data have been accumulated on the behaviour of mixtures of hydrocarbons of different classes during pyrolysis. However the results and their interpretation by various authors are frequently in conflict.

The aim of the proposed review is to discuss the results of investigations of the thermal decomposition of mixtures of hydrocarbons and to formulate a general concept for the overall mechanism of their mutual effect as a system of competing reactions of radicals (intermediates) of various types propagating the chain. The pyrolysis considered is mainly of model binary mixtures of hydrocarbons present in the raw material or formed under the conditions of an industrial process.

II. Pyrolysis of mixtures of alkanes and alkenes

The pyrolysis of mixtures of alkanes with propene and 2-methylpropene, which are classic inhibitors of the process, has been investigated most. In the earlier work the overall kinetics of the process were generally studied by the change in pressure in the system. In this way no attention was paid to the conversion of the actual inhibitor,[1–4] assuming for example that it polymerised.[4] Attempts to assess the influence of ethane on the rate of decomposition of propene[5] and the development of these investigations[6–9,11] enabled exhaustive results to be obtained on the effect of an alkane on the decomposition of propene and 2-methylbutene at 700–900 °C. The investigations were carried out using propene labelled with radioactive carbon ^{14}C which enabled the course and rate of disappearance of even very small additions of propene to be followed. It was established as a result that ethane and propane show an initiating action on the decomposition of propene in its inhibition of alkane pyrolysis.

The rate constant for the decomposition of propene ($k_{C_3H_6}$) initiated by ethane is sharply reduced when the content of ethane in the initial mixture is reduced. Thus in a mixture with 99.9 vol.% ethane the rate constant for the decomposition of propene was approximately two orders of magnitude greater than the rate constant for the decomposition of pure propene. At the same time the rate constants for the decomposition of pure propene and for its equimolar mixture with ethane were practically equal.[7]

A smoother dependence of the rate constant for the decomposition of propene on propane concentration in the initial mixture was observed in the case of mixtures of propane with propene. Even in a mixture containing about 32 vol.% propane at a

temperature of 850 °C the rate constant for the decomposition of propene was approximately 5 times greater.[9] A further increase in the propane concentration in the mixture is accompanied by a proportionate increase in the rate constant for propene decomposition. The mutual effect of propane and propene on pyrolysis of their mixtures was first noticed in a study[12] in which it was shown that at 900 °C and atmospheric pressure the rate constant for propane decomposition ($k_{C_3H_8}$) fell sharply when the propene content in the initial mixture was increased and $k_{C_3H_6}$ increased with increase in propane concentration.

The yield of the main products from the pyrolysis of ethane and propane mixed with C_3H_6 differed from that calculated using the additivity hypothesis for their formation.[6–10,13] Thus a six-fold increase in the yield of 1-butene was recorded in the pyrolysis of a mixture of propane with propene.[13]

From the character of the change in overall rate constants for the decomposition of hydrocarbons[10,11] it was established that 2-methylpropene also shows an inhibitory action on the decomposition of C_2-C_4 alkanes. The rate of decomposition of 2-methylpropene in the mixtures increases with an increase in alkane content. However the inhibitory action of propene on the decomposition of ethane and propane is stronger than that of 2-methylpropene. The rate constants for the decomposition of propane in the presence of 20 vol.% propene and 2-methylpropene at 850 °C are 25 and 33 s^{-1} respectively.[10]

In the case of n-butane both C_3H_6 and iso-C_4H_8 show a less strong and approximately identical inhibitory action. At 850 °C the rate constants for the decomposition of n-butane in the presence of 20 vol.% propene and 2-methylpropene are about 90 and 95 s^{-1} respectively.[11]

In its turn n-butane shows the strongest initiating action on the decomposition of an inhibitor among the alkanes considered above. Thus at 800 °C the rate constants for the decomposition of iso-C_4H_8 in equimolar binary mixtures with ethane, propane and n-butane are about 2, 8 and 17 s^{-1} respectively.[10]

The yield of pyrolysis products of mixtures of alkanes with 2-methylpropene also differed from additivity and the greatest deviation from that calculated was observed on pyrolysis of mixtures of ethane with 2-methylpropane and of propane with propene.

An inhibitory action of propene and 2-methylpropene on the overall decomposition process of the higher n-alkanes ($>C_5$) has been recorded. At relatively low temperatures (450–540 °C) propene and 2-methylpropene inhibit the decomposition of pentanes,[14–16] and 2-methylpropene is a stronger inhibitor than propene. The accelerating action of the pentanes and of n-hexane on the decomposition of the inhibitors has also been established.[17]

According to other data[18,19] propene and 2-methylpropene act both as inhibitors and as initiators of the thermal decomposition of n-hexane. At 545 °C small additions (up to 4 vol.%) of propene inhibit the decomposition of n-hexane. Limitation of the decomposition rate for n-hexane was observed with an increase in the propene concentration. At higher temperatures (570 and 595 °C) on the other hand addition of propene shows an initiating action on n-hexane decomposition. The inhibitory action of 2-methylpropene on the decomposition of n-hexane weakens even at a concentration of about 2 vol.% and is transformed into an initiating action on increasing it further.[19] The dual action of additions of propene on the decomposition of propane was established in more recent work by the same authors.[20] A transition from an inhibitory to an initiating action was detected above 580 °C. An increase in the yield of methane and ethylene was recorded during this.

The conclusions are far more ambiguous concerning the action of additions of other alkenes (ethylene, 1-butene, 2-butene and larger) to the decomposition of alkanes. The inhibitory action of these alkenes on the decomposition of various alkanes is recorded in several studies. For example ethylene and 2-butene inhibit the decomposition of propane at 445–575 °C.[21] Ethylene, propene, *trans*-2-butene and 2-methyl-2-butene are inhibitors of the decomposition of isobutane at 470–510 °C.[22] Propene, 2-methylpropene and 2-methyl-2-butene show an inhibitory action on the decomposition of 2,2-dimethylbutane at 450 °C.[22]

Inhibition of the decomposition of n-nonane by 2-pentene at 725 °C has been reported.[23] The rate constant for the decomposition of n-nonane on pyrolysis was reduced by approximately 34% on admixture with 2-pentene. The rate constant for the decomposition of 2-pentene was practically unchanged by this but the activation energy of the process was increased.

According to other data[1] ethylene, n-butene and 2,2,4-trimethylpentene do not show a marked inhibitory action on the decomposition of iso-octane (2,2,4-trimethylpentane) at 550 °C. No mutual effect on the rate and course of the decomposition was detected in the copyrolysis of ethane with ethylene in the temperature range 800–900 °C.[24] The same result was obtained when investigating the pyrolysis of mixtures of ethane with ethylene at a lower temperature (770 °C).[25] The addition of butenes (1-butene and 2-butene) also did not change the rate of decomposition of propane and n-butane at 590–635 °C, however they inhibited the decomposition of ethane.[26] The inhibition in the case of ethane is explained by the formation of propene from the butenes. Propene is one of the main decomposition products of propane and butane and consequently some increase in its yield at the expense of the butenes does not have an appreciable effect on the overall rate of the process.

However when investigating the pyrolysis of ethane with small additions of 1-butene labelled with radioactive carbon ^{14}C, no effect of the alkene on the decomposition of ethane was detected at higher temperatures (750–930 °C).[27] In this case a weak initiating action of ethane on the decomposition of 1-butene appeared; this was traced particularly clearly in mixtures with a small addition of 1-butene (0.2 vol.%). The weak initiating action of the C_5-C_7 n-alkanes on the decomposition of 1-alkenes with 6–8 carbon atoms at 600–800 °C was also recorded.[28] In this study, the overall rate constants for the decomposition of the n-alkanes were practically unchanged. The yield of hydrogen and methane was different from the additive value, but the yields of ethylene and propene were close to the calculated values. The initiating action of the thermally more stable ethylene on the decomposition of n-hexane on copyrolysis at 800 °C has been demonstrated.[29] In truth these authors also recorded that the conversion of n-hexane was also increased in the presence of ethylene. The decomposition of n-hexane initiated by 1-hexene has also been observed at 650–690 °C.[30]

III. Pyrolysis of mixtures of alkanes and dienes

1,3-Butadiene, 2-methyl-1,3-butadiene and 1,3-pentadiene display an inhibitory effect on the decomposition of alkanes[1,31–33] which was demonstrated by experiments with radioactive (^{14}C) ethane and 1,3-butadiene.[31] The extent of conversion of ethane falls with an increase in the concentration of 1,3-butadiene in the initial mixture reaching a minimum at an approximately equimolar mixture of ethane and 1,3-butadiene, which at 800 °C was 2.8 times lower than

the degree of conversion of pure ethane. In this, ethane shows an initiating action on the decomposition of 1,3-butadiene. At 800 °C the conversion of 1,3-butadiene in mixtures containing about 99 vol.% ethane was 1.8 times higher than in pure 1,3-butadiene. The content of the main pyrolysis products of mixtures of ethane with 1,3-butadiene (H_2, CH_4, C_2H_4) did not change linearly with the change in composition of the mixture, which indicates the non-additive nature of their formation.

1,3-Pentadiene inhibits the decomposition of propane but propane shows an initiating action on the conversion of 1,3-pentadiene at 730–880 °C.[32] At 780 °C the overall rate constant for the decomposition of 1,3-pentadiene in mixtures with propane (90 vol.% C_3H_8) was increased approximately five-fold. An appreciable increase in the yield of 1,3-butadiene and a fall in the yield of cyclopentadiene was observed during this. The decomposition of propane slowed with an increase in the 1,3-pentadiene added to the initial mixture.

1,3-Butadiene and 2-methyl-1,3-butadiene show a strong inhibitory action on the decomposition of octanes at 550 °C.[1,33]

On the other hand allene initiates the thermal decomposition of n-alkanes.[34–36] Small additions of allene (0.23 wt.%) strongly accelerate the decomposition of n-hexane in the temperature range 630–690 °C.[34] At 630 °C the extent of decomposition of 0.23 wt.% allene was 2.5 and 23.0% respectively. The composition of the products was unchanged. Small additions of allene (0.42 mol%) also accelerate the decomposition of ethane in the temperature range 800–860 °C.[36] However the initiating action of allene in the decomposition of ethane was far weaker than in the decomposition of n-hexane[34] and n-hexadecane.[35] At temperatures of 800, 835 and 860 °C the ratio of the rate constants for the decomposition of ethane mixed with allene and of pure ethane were 1.43, 1.40 and 1.25 respectively.

IV. Pyrolysis of mixtures of alkanes

The investigations of the pyrolysis of mixtures of alkanes refer mainly to mixtures of the gaseous C_2–C_4 hydrocarbons. The majority of the studies report weak, sometimes contradictory, mutual effects of alkanes on the rate and course of decomposition on pyrolysis of mixtures of them. The absence of a mutual effect is characteristic for mixtures of alkanes with similar thermal stabilities. No change in rate constant was detected for the decomposition by combined pyrolysis for ethane and propane.[37,38] On the other hand an increase in the rate constant for the decomposition of propane in the presence of ethane and a reduction in the rate constant for the decomposition of ethane was recorded,[39] although the conversion of ethane was increased and the conversion of propane was reduced at 760–925 °C and on dilution with nitrogen.[40–42] According to other data[43] the rate of decomposition of propane was higher at 750 °C but at 800 °C it was comparable with the rate of decomposition of pure propane. However at 750 °C no change was observed in the rate of decomposition of ethane in mixtures but at 800 °C it was less than in the case of pure ethane. In this case and in another study[39] the yield of ethylene may be calculated from the hypothesis of the additivity of its formation. In addition there are reports on higher[41,42,44,45] (than additive) and lower[46] yields of ethylene on pyrolysis of these mixtures.

The difference in the data on the selectivity of C_2H_4 formation must also be noted. In some cases a lower[44] and in others a higher[6,47] selectivity of C_2H_4 formation was indicated,

The results of investigations on the mutual effect of ethane and n- and isobutane are also ambiguous.[37–40,48–52] Both an initiating action of n- and isobutane on the decomposition of ethane[48,50,51] and a strong inhibition of C_2H_6 decomposition by n-butane[49] have been recorded. Small additions of the butanes initiate the decomposition of C_2H_6 without an appreciable change in the distribution of products but larger additions (> 25%) inhibit.[50]

The results of investigations on the pyrolysis of mixtures of C_2H_6 with larger alkanes are also inconsistent. At 800 °C, atmospheric pressure and carrying out the process in a fluidised bed of quartz sand, additions of n-heptane and n-octane initiate the pyrolysis of ethane.[51] The initiating action is strengthened with an increase in the n-alkane content in the mixture and n-octane is a stronger initiator. The initiating action of the n-alkanes on the decomposition of ethane increased in the series n-C_4H_{10} > n-C_7H_{16} > n-C_8H_{18}. A deviation in the yield of the main products from that calculated using the additivity hypothesis (particularly in the case of additions of n-octane) was noted which was expressed particularly in the increase in the yields of C_2H_4 and C_3H_6 and a reduction in the yield of hydrogen.

At the same time an inhibitory action of small additions of mixtures of C_{11}–C_{14} n-alkanes on the decomposition of ethane has been reported.[52] This seems even more unlikely since the same additions show an initiating action on the decomposition of propane. In both cases a change in the distribution of products was recorded which was manifestly greater in mixtures with propane.

On pyrolysis of binary mixtures of propane with isobutane and neopentane at 650–690 °C and a molar ratio of components of 0.5 and 1 an initiating action was established for isobutane on the decomposition of propane which was strengthened by an increase in the isobutane content of the mixture.[37] Propane inhibits the decomposition of isobutane to an insignificant extent. However this effect does not depend on the quantity of propane added. In the pyrolysis of binary mixtures of neopentane with propane and isobutane an initiating action was recorded for neopentane (which was stronger for mixtures with propane).

In the case of the thermal decomposition of mixtures of propane with isobutane of varied composition and also of equimolar mixtures of isobutane with neopentane at higher temperatures (700–850 °C) isobutane also initiates the decomposition of propane which like ethane (but to a lesser extent), shows an inhibitory action on the pyrolysis of isobutane.[48] The distribution of the products differed from that expected from additivity. In equimolar mixtures of isobutane with neopentane the mutual effect of the hydrocarbons on the rate and course of decomposition was almost not apparent.

The pyrolysis of mixtures of n- and isobutane was characterised by the insignificant initiating action of isobutane over a wide temperature range, viz. 650–690 °C,[37] 640–790 °C,[53] 575–850 °C.[40] n-Butane shows a weak inhibitory effect. The observed distribution of products differed from that calculated from the additivity hypothesis for their formation. Thus on pyrolysis of an equimolar mixture of n- and isobutane at 660 °C the rate of decomposition of isobutane was reduced and of n-butane increased 1.1 and 1.4 times respectively.[37] On increasing the temperature in the range 575–850 °C the mutual effect is strengthened.[40] At the same time it was recorded that in equimolar mixtures of n- and isobutane the mutual effect of the butanes on the rate and course of the decomposition was almost invisible at 700–850 °C.[48]

An insignificant mutual effect on the rate of decomposition was recorded in the pyrolysis (600–790 °C) of a mixture of n-heptane and iso-octane of composition close to equimolar. n-Heptane retards the decomposition of iso-octane to an insignificant extent and, in its turn, iso-octane accelerates insignificantly the pyrolysis of n-heptane. The distribution of the products follows the additivity principle in cases of low conversion but deviates somewhat from it on extended conversion.[54,55] In general, no changes were detected in the distribution of products and conversion on pyrolysis of mixtures of n-nonane and n-octane at 650–725 °C.[23]

On pyrolysis of mixtures of alkanes the mutual effect of the hydrocarbons on the rate and course of the decomposition is weak and the character of this effect is determined by the experimental conditions (temperature, pressure, mixture composition). The data considered above are summarised for clarity with the experimental conditions in Table 1.

Table 1. Mutual effects on the decomposition rate on pyrolysis of binary mixtures of C_2–C_9 alkanes.

Mixture	Content of second component in mixture, %	Temperature, °C	Total pressure, atm	Type of action of components	Ref.
$\frac{C_2H_6}{C_3H_8}$	25–75	850–875	1.4–2.0	Initiator Inhibitor	[40]

V. Pyrolysis of alkanes and cycloalkanes

The few investigations on the pyrolysis of alkanes in mixtures with cycloalkanes indicate unambiguously the initiating action of alkanes on the decomposition of cycloalkanes.

Ethane and n-pentane initiate the decomposition of cyclopentane at 800–870 °C, n-pentane showing the stronger initiating action.[56]

On pyrolysis of cyclohexane in the presence of ethane, propane[57,58] and n-hexane[59] (725–900 °C) the initiating action of the alkanes was manifest most strongly in mixtures with a small cyclohexane content (10–15%). The conversion of alkanes falls sharply on increasing the cyclohexane content of the mixture. The extent of conversion of ethane was reduced to a minimum value in mixtures containing 10–15 vol.% cyclohexane.

Propane and n-hexane show approximately the same initiating action on the decomposition of cyclohexane. Ethane is a less strong initiator. An appreciable deviation is observed in all cases in the yield of the main products from that calculated from the additivity hypothesis. This was particularly strongly shown for hydrogen, methane, ethylene, and propene.

n-Heptane and iso-octane also show an initiating action on the decomposition of cyclohexane over a wide temperature range (600–850 °C).[54,55] n-Heptane is a strong initiator of the pyrolysis of cyclohexane compared with iso-octane, the accelerating action of which on cyclohexane decomposition is insignificant at 600–790 °C.[54] An appreciable deviation from additivity of the yields of main products from the pyrolysis of the mixtures was recorded in cases of extended conversion.[55] For low conversion the yields of pyrolysis products from mixtures of n-heptane with cyclohexane and of iso-octane with cyclohexane may be calculated by the additivity hypothesis.

Similarly, n-heptane inhibits the decomposition of methylcyclohexane (680 °C) but the latter shows an insignificant inhibitory action on the breakdown of n-heptane.[60]

An inhibition–initiation effect was also recorded in an investigation of the pyrolysis of mixtures of decalin with n-decane at 685–760 °C [61] and with n-dodecane at 480–525 °C.[62] The initiation effect appeared more clearly in mixures of decalin with n-decane while the inhibitory action of decalin is more marked on copyrolysis of decalin with n-dodecane. A deviation of the product distribution from that calculated from additivity of the thermal decomposition of the hydrocarbons in the mixtures was noted.[62]

VI. Effect of aromatic hydrocarbons

There are practically no literature data on the effect of aromatic hydrocarbons on the decomposition of hydrocarbons of other classes.† Only the inhibitory action of the polycyclic hydrocarbons naphthalene and phenanthrene on the decomposition of n-hexadecane and decalin on combined pyrolysis of binary mixtures of cycloalkanes and aromatic hydrocarbons in the temperature range 800–900 °C have been recorded.[63] It was shown that the inhibitory action of the aromatic hydrocarbons was more strongly developed in the pyrolysis of decalin than of n-hexadecane.

† The toluene and xylene procedures for investigating thermal decomposition under conditions of inhibiting the radical process are not considered in the present review.

The lighter alkanes (methane, ethane, propane, butane) initiate the decomposition of toluene at 800–1200 °C.[64] In the presence of CH_4, C_3H_8 and butanes, which generate methyl radicals, the yield of ethylbenzene and styrene are increased. Ethane affects the yield of ethylbenzene to a lesser extent but it enables an increase in the yield of n-propylbenzene to be achieved.

The initiating action of 1-hexene on the decomposition of toluene takes place at 630–720 °C.[30] Initiation of the decomposition of benzene by toluene was also noted.

VII. Mechanism of inhibition–initiation in the pyrolysis of hydrocarbon mixtures

The theory of the radical–chain decomposition of n-alkanes, developed initially in the thirties by Rice[65,66] and refined by him with Kossiakoff,[67] has been applied successfully to the description of thermal conversions of hydrocarbons of other classes, particularly alkenes,[68] cycloalkanes[57,69] and aromatic hydrocarbons.[70]

The radical–chain mechanism comprises three stages. The first is chain formation by fission of the weakest bond in the hydrocarbon molecule, then chain propagation and a termination stage by recombination and disproportionation of the radicals propagating the chain. The chain propagation (or development) stage comprises the reaction of the radicals propagating the chain (β-radicals) with a molecule of the initial hydrocarbon (abstraction of a H atom or addition at a double bond), and also β-decomposition and isomerisation of the resulting heavy radicals (μ-radicals).

This concept is the basis of the formal kinetics of the pyrolysis process.[71] A particularly important role is played here by reactions leading to the formation and disappearance of β-radicals which are responsible for the yield of the main products. On carrying out the process in the presence of other compounds the latter are also involved in reaction with the β-radicals. In addition the β-radicals react with the pyrolysis products and this becomes important at greater convesions. The rate of carrying out these processes and the probability of regenerating β-radicals is reflected both in the distribution of products and in the rate of the overall process.

1. Early ideas on the mechanism of inhibition

a) Addition of β-radicals to a double bond

The retardation of the thermal decomposition of n-alkanes by the products formed and also by addition of alkenes was first established by Dintses and Frost.[72] During the pyrolysis of a n-alkane the β-radicals add to the double bond of an alkene with the formation of unreactive radicals,[73] such as

$$R + C_3H_6 \longrightarrow CH_3-\underset{\displaystyle R}{\underset{|}{CH}}-\dot{C}H_2,$$

$$R + C_3H_6 \longrightarrow CH_3-\dot{C}H-CH_2-R,$$

which leads to chain termination and a reduction in the decomposition rate of the alkane. These ideas were used to explain the effect of some unsaturated hydrocarbons (propene, 2-methyl-1,3-butadiene, 2-methylpropene, 1,3-butadiene, butene, 2,2,4-trimethylpentene) on the decomposition of iso-octane.[1] The unsaturated hydrocarbons investigated may be arranged in the following series according to their efficiency of inhibitory action.

$$C_4H_6 > C_3H_6 > \text{2-methyl-1,3-butadiene} > \text{2-methylpropene}$$

Butene and 2,2,4-trimethylpentene do not inhibit the decomposition of iso-octane since they do not form inactive radicals on reaction with β-radicals. The addition of methyl radicals to 2-methyl-1,3-butadiene does not lead to the formation of stable unreactive radicals, consequently its inhibitory action is weaker than the action of propene and 1,3-butadiene. 2-Methylpropene, having only one double bond in the molecule, is a weaker inhibitor than 2-methyl-1,3-butadiene. As a rule, addition of the ethyl radical at the double bond of an inhibitor does not lead to the formation of a stable unreactive radical consequently reactions involving the ethyl radical are not considered in the mechanism of inhibition (addition reactions of H atoms are not taken into account).

b) The formation of low reactivity allyl radicals in reactions of H atom extraction

A mechanism for the inhibition of alkane decomposition by certain alkenes (C_3H_6, iso-C_4H_8) was considered in studies by Stepukhovich and collaborators,[3,74] Leidler and collaborators,[4] in the early work, of Niclause and collaborators[16] and by several other authors.[4,75–77] This is based on the occurrence of a reaction involving abstraction of hydrogen atoms from the inhibitor by the reactive radicals propagating the chain with the formation of radicals of an allylic type which do not participate in chain propagation reactions, such as

$$R(\dot{H},\ \dot{C}H_3) + C_3H_6 \longrightarrow C_3H_5 + RH. \qquad (1)$$

In fact, in recent studies by Stepukhovich a kinetic scheme is proposed for alkane decomposition retarded by additions of inhibitors (C_3H_6) which includes a chain propagation reaction involving an allyl radical.[19]

$$M \longrightarrow 2R + 2M^1,$$

$$R + M \longrightarrow RH + mM^1 + R,$$

$$R + I \longrightarrow RH + R^1,$$

$$R^1 + M \longrightarrow R^1H + mM^1 + R,$$

$$R + \text{walls} \rightarrow \text{products},$$

$$R^1 + \text{walls} \rightarrow \text{products},$$

where M and M_1 are molecules of alkane and alkene, R and R^1 are alkyl and allyl radicals respectively, and I is the inhibitor molecule.

Inhibition is effected by the reduction in the rate of the chain propagation reaction by the participation of the less reactive allyl radicals.

2. Mechanism of inhibition–initiation on pyrolysis of mixtures of hydrocarbons

a) Inhibition–initiation on joint pyrolysis of alkanes with low molecular alkenes

A drawback of the schemes give above is the lack of data characterising the kinetics of decomposition of the inhibitor itself under conditions of joint pyrolysis.

This is linked with the fact that, as a rule, the inhibitor or its decomposition products are no different from the decomposition products of the alkanes themselves. Consequently only the use of special methods of investigation enables the decomposition of the inhibitor on pyrolysis of mixtures to be followed. The method of introducing a labelled inhibitor is the most suitable for this.

Detailed investigations on the pyrolysis of ethane and propane with added propene labelled with radioactive carbon (^{14}C) have enabled the course of the conversion of propene on pyrolysis in mixtures to be traced and the effect of the alkane on the rate and course of its decomposition to be assessed.[6,9,78] It was established that the alkane shows an initiating action on the conversion of propene which is stronger for increased alkane concentration in the mixture (Fig. 1). It is therefore possible to speak of the phenomenon of a simultaneous inhibition–initiation in the pyrolysis of alkanes with propene. A mechanism is proposed to describe this phenomenon, which includes the replacement (with the participation of propene) of the hydrogen atoms most reactive in the chain propagation reaction by less reactive methyl radicals. This is effected through successive stages in the addition of H atoms to propene with the formation of an excited propyl radical and its subsequent breakdown:

$$\dot{H} + C_3H_6 \rightleftharpoons [(CH_2CH_2CH_3)^{\cdot}]^* \longrightarrow \dot{C}H_3 + C_2H_4. \qquad (2)$$

This leads, on the one hand, to inhibition by propene of the decomposition of the alkanes and, on the other, to initiation of the conversion of propene by hydrogen atoms generated on decomposition of the alkane.

It was established from the data on the distribution of radioactivity in the pyrolysis products, when investigating the pyrolysis of ethane with added propene labelled with ^{14}C at the centre carbon atom ($H_2C=^{14}CH-CH_3$), that up to 95% propene was consumed in the formation of ethylene[6] and only 5% went to the formation of other products.

$$R + C_3H_6 \longrightarrow RH + \dot{C}_3H_5,$$

$$\dot{C}_3H_5 \longrightarrow C_3H_4 + \dot{H}, \qquad (3a)$$

$$\dot{C}_3H_5 \longrightarrow C_2H_2 + \dot{C}H_3, \qquad (3b)$$

$$R = \dot{H}, \dot{C}H_3.$$

In the pyrolysis of propane mixed with radioactive propene the selectivity of forming C_2H_4 is lower and is reduced on increasing the propene concentration in the initial mixture but the selectivity of forming the remaining products was increased. At 850 °C and an extent of conversion of radioactive propene of about 40%, the selectivity of forming radioactive ethylene was 70, 65, 52 and 22.5% at propene contents in the initial mixture of 1.77, 6.41, 30.78 and 68.18 vol.% respectively.[9] It follows from this that reaction (2) is not the sole route for the conversion of propene in this case. In fact on pyrolysis of mixtures of ethane with propene the overall decomposition rate of radioactive propene coincides with the rate of accumulation of radioactive ethylene and on pyrolysis of mixtures of propane with propene the overall decomposition rate of radioactive propene is appreciably higher than the rate of formation of radioactive ethylene (see Fig. 1).

Consequently when describing the decomposition of ethane in the presence of small additions of propene (up to 10 vol.%) it is possible to consider just one route for the conversion of propene by reaction (2).

$$C_2H_6 \rightleftharpoons 2CH_3^{\cdot}, \quad (4)$$

$$CH_3^{\cdot} + C_2H_6 \longrightarrow CH_4 + C_2H_5^{\cdot},$$

$$C_2H_5^{\cdot} \longrightarrow C_2H_4 + H^{\cdot},$$

$$H^{\cdot} + C_2H_6 \longrightarrow H_2 + C_2H_5^{\cdot}, \quad (5)$$

$$H^{\cdot} + C_3H_6 \longrightarrow CH_3^{\cdot} + C_2H_4, \quad (2)$$

$$CH_3^{\cdot} + C_2H_5^{\cdot} \longrightarrow C_3H_8,$$

$$2C_2H_5^{\cdot} \longrightarrow C_4H_{10}.$$

In the pyrolysis of propane with even small additions of propene it is necessary to consider routes in addition to reaction (2) for the decomposition of C_3H_6. The main route at high temperatures (> 800 °C) is that leading to the formation of acetylene and C_3H_4 hydrocarbons [reactions (1) and (3)]:

$$C_3H_8 \rightleftharpoons CH_3^{\cdot} + C_2H_5^{\cdot},$$

$$C_2H_5^{\cdot} \longrightarrow C_2H_4 + H^{\cdot},$$

$$R(\dot{H}, \dot{C}H_3) + C_3H_8 \rightarrow RH + pr\text{-}C_3H_7^{\cdot},$$

$$R(\dot{H}, \dot{C}H_3) + C_3H_8 \rightarrow RH + sec\text{-}C_3H_7^{\cdot},$$

$$pr\text{-}C_3H_7^{\cdot} \rightarrow C_2H_4 + CH_3^{\cdot},$$

$$sec\text{-}C_3H_7^{\cdot} \rightarrow C_3H_6 + H^{\cdot},$$

$$H + C_3H_6 \longrightarrow C_2H_4 + CH_3^{\cdot}, \quad (2)$$

$$H + C_3H_6 \longrightarrow C_3H_5^{\cdot} + H_2, \quad (1a)$$

$$CH_3^{\cdot} + C_3H_6 \longrightarrow C_3H_5^{\cdot} + CH_4, \quad (1b)$$

$$C_3H_5^{\cdot} \longrightarrow C_3H_4 + H, \quad (3a)$$

$$C_3H_5^{\cdot} \longrightarrow C_2H_2 + CH_3^{\cdot}, \quad (3b)$$

$$CH_3^{\cdot} + C_3H_5^{\cdot} \longrightarrow C_4H_8,$$

$$2C_2H_5^{\cdot} \longrightarrow C_4H_{10}.$$

The fairly marked contribution of reaction (1) on pyrolysis of mixtures of propane with propene causes a higher running concentration of CH_3 radicals, the addition of which to propene at high temperatures does not occur in practice.[79] On pyrolysis of ethane the concentration of methyl radicals which are formed only at the initiation stage is low and correspondingly the contribution of reaction (1*b*) is not appreciable.

According to this scheme the rate constant for the overall decomposition of propene is described by the equation

$$k_{C_3H_6} = k_2[H] + k_{1a}[H] + k_{1b}[CH_3]. \quad (I)$$

Since $k_2 \gg k_{1a}$ it may be taken that

$$k_{C_3H_6} = k_2[H] + k_{1b}[CH_3]. \quad (II)$$

The first term of equation (II) is the specific rate of formation of ethylene from propene which is calculated from the data on the distribution of radioactivity in ethylene and propene. For the pyrolysis of propane with added 1.77 vol.% C_3H_6 the ratio $k_2[H]/k_{1b}[CH_3]$ is 1.5 at 850 °C.[9] Thus in mixtures with a small propene content its rate of reaction with H atoms is at least 1.5 times greater than with methyl radicals. This ratio is reduced with an increase in the propene concentration (Table 2). The ratio of the concentrations of H atoms and methyl radicals therefore changes with the change in the composition of the initial mixture. The concentration of methyl radicals increases with an increase in propene concentration and the contribution of reaction (1*b*) becomes more noticeable.

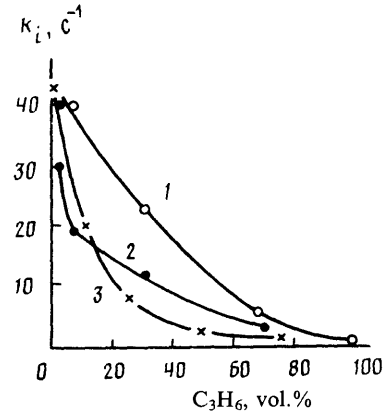

Figure 1. Change in rate constant for (*1*, *3*) the decomposition of propene and (*2*, *3*) the formation of ethylene with the change in composition of the initial mixture at 850 °C; *1*, *2*, mixture of propane and propene;[9] *3*, mixture of ethane and propene.[6]

Table 2. Ratio of hydrogen and methane and also rates of disappearance of propene with the partcipation of H atoms (k_2) and methyl radicals (k_{1b}) on pyrolysis of mixtures of propane and propene (850 °C).

C_3H_6 content in initial mixture, %	$[H_2]/[CH_4]$	$k_2[H]/k_{1b}[CH_3]$
1.77	1.0	1.5
6.41	1.0	1.0
30.78	0.8	1.0
68.18	0.5	0.8

The relative increase in the concentration of CH_3 radicals also shows in the ratio of hydrogen and methane in the pyrolysis products (Table 2).

The efficiency of the inhibitory action of propene is also dependent on reaction (2), since $k_2 \gg k_1$. In addition, in contrast to reaction (1) the conversion of C_3H_6 by reaction (2) leads to replacement of H by the less reactive methyl radical.

The concentration of H atoms is reduced as the concentration of propene in the initial mixture with propane is increased (Fig. 2).[9] In this way the rate of the overall decomposition of propane is also reduced practically in proportion (Fig. 3).

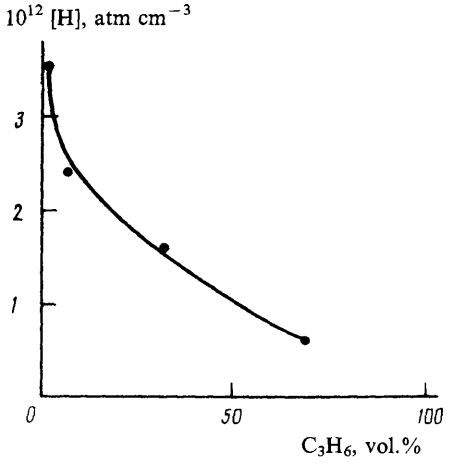

Figure 2. Change in concentration of hydrogen atoms in the pyrolysis zone of mixtures of propane and propene with the change in composition of the initial mixture at 850 °C.

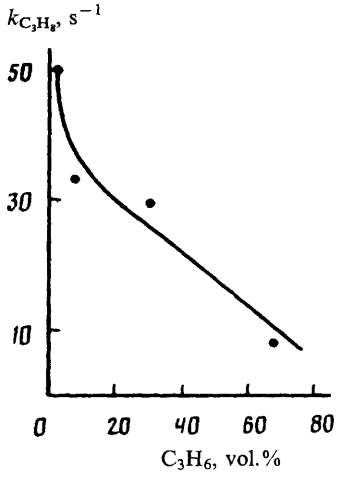

Figure 3. Reduction in the rate constant for propane decomposition with increasing content of propene in the initial mixture at 850 °C.

Propene is also converted according to reactions (1) and (2) on pyrolysis when mixed with n-butane. In this case too the inhibitory action of propene was dependent mainly on reaction (2). As a result the concentration of radicals propagating the chain was reduced and consequently chain propagation involving n-butane itself proceeds at a lower rate.

The inhibitory action of propene on the decomposition of alkanes was reduced on going from ethane to propane and n-butane (Fig. 4). This is linked with the increase in the contribution of the reactions of methyl radicals which are formed on pyrolysis of propane and n-butane both at the initiation and at the chain propagation stage.

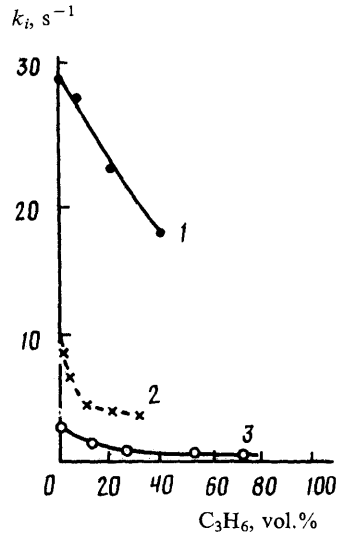

Figure 4. Dependence of the rate constant (k_i) for the decomposition of alkanes on C_3H_6 concentration in the mixture: *1*, $k_{n\text{-}C_4H_{10}}$; *2*, $k_{C_3H_8}$; *3*, $k_{C_2H_6}$, temperature 800 °C.

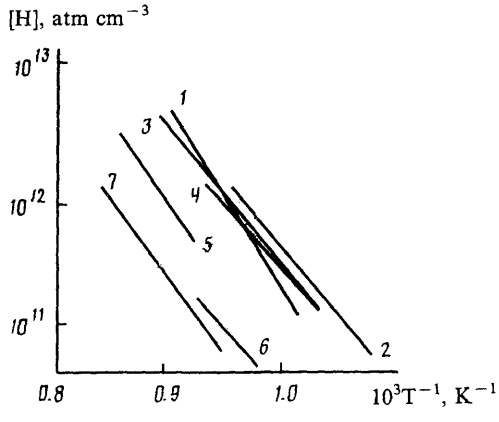

Figure 5. Temperature dependence of the hydrogen atom concentration in the pyrolysis zone of *1*, ethane; *2*, n-hexane; *3*, propane; *4*, n-butane; *5*, 1,3-butadiene, *6*, 1,3-pentadiene and *7*, propene at an overall pressure of 100 mmHg.

On pyrolysis of ethane, propene and butane the concentration of hydrogen atoms is approximately the same (Fig. 5).[80] It is possible to estimate the concentration of methyl radicals from the rate of accumulation of methane. Thus on pyrolysis of ethane the rate of hydrogen formation is more than an order of magnitude greater than the rate of methane formation.[31] On pyrolysis of propane these rates are approximately the same,[9] and on pyrolysis of n-butane methane is formed approximately 1.5 times more rapidly than

hydrogen.[11] Consequently in the pyrolysis of propane and n-butane the contribution of chain propagation reactions involving methyl radicals becomes more marked.

In addition it must be noted that according to the proposed mechanism the extent of the inhibitory action of an additive is determined by the ratio of the reaction rates of H atoms with the alkane and with the inhibitor. The rate constant for the reaction of H atoms with alkanes investigated increases on going from ethane to n-butane.[81] This leads to an increase in the contribution of reactions involving alkane in the series C_2H_6 < C_3H_8 < n-C_4H_{10} and consequently to a reduction in the inhibitory action of propene on this series of alkanes.

The stronger inhibitory action of propane compared with ethane in the decomposition of propene is explained by the higher overall concentration of the radicals propagating the chains (see Fig. 1). Regrettably due to the lack of data on the pyrolysis of mixtures of n-butane with radioactive propene it is as yet impossible to judge the extent of the inhibitory action of the former on the breakdown of the latter.

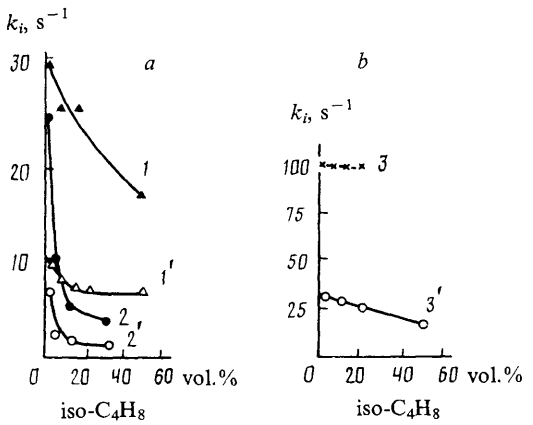

Figure 6. Dependence of the overall rate constant (k_i) for alkane decomposition on the 2-methylpropene concentration in the initial mixture with *a*: *1*, *1'*, propane; *2*, *2'*, ethane and *b*: *3*, 3', n-butane at 850 and 800 °C respectively.

On pyrolysis of mixtures of ethane, propane and n-butane with 2-methylpropene the mutual effect of hydrocarbons on their decomposition is also linked with the competing reactions:

$$R(\dot{H}, \dot{C}H_3) + \text{alkane} \rightarrow RH + R^1,$$

$$H + \text{iso-}C_4H_8 \rightarrow \text{iso-}\dot{C}_4H_9 \rightarrow \dot{C}H_3 + C_3H_6,$$

$$R(\dot{H}, \dot{C}H_3) + \text{iso-}C_4H_8 \rightarrow \text{iso-}\dot{C}_4H_7 + RH.$$

Like propene, 2-methylpropene shows a stronger inhibitory action on the decomposition of ethane (Fig. 6) but n-butane is the strongest initiator of the decomposition of 2-methylpropene (Fig. 7). However propene is a stronger inhibitor of the decomposition of the C_2-C_4 alkanes than 2-methylpropene (Figs. 4 and 6). This is seemingly caused by the higher value of the rate constant for the addition of H atoms to propene.

In principle Niclause and collaborators[22] arrived at the same mechanism of initiation–inhibition, based on literature data and on the results of their own kinetic investigations on the pyrolysis of ethane, isobutane and 2,2-dimethylbutane in the presence of alkenes (ethylene, propene, 2-methylpropene, *trans*-2-butene and two isopentenes, including 2-methyl-3-butene). However these authors considered that the addition of H atoms to the double bond of the inhibitor is responsible for the distribution of the products and the inhibitory action is caused by the removal of H atoms from the alkene.

$$\text{iso-}C_4H_{10} \rightarrow \text{radical formation},$$

$$R(\dot{H}, \dot{C}H_3) + \text{iso-}C_4H_{10} \rightarrow RH + \text{iso-}\dot{C}_4H_9, \qquad (6a)$$

$$R(\dot{H}, \dot{C}H_3) + \text{iso-}C_4H_{10} \rightarrow RH + \text{t-}\dot{C}_4H_9, \qquad (6b)$$

$$\text{iso-}\dot{C}_4H_9 \rightarrow \dot{C}H_3 + C_3H_6,$$

$$\text{t-}\dot{C}_4H_9 \rightarrow \dot{H} + \text{iso-}C_4H_8,$$

$$\dot{H} + C_3H_6 \leftrightarrows \text{sec-}\dot{C}_3H_7,$$

$$\text{sec-}\dot{C}_3H_7 + \text{iso-}C_4H_{10} \rightarrow C_3H_8 + \text{iso-}\dot{C}_4H_9,$$

$$\text{sec-}\dot{C}_3H_7 + \text{iso-}C_4H_{10} \rightarrow C_3H_8 + \text{t-}\dot{C}_4H_9,$$

$$\dot{H} + C_3H_6 \rightarrow \text{pr-}C_3H_7,$$

$$\text{pr-}\dot{C}_3H_7 \rightarrow \dot{C}H_3 + C_2H_4,$$

$$\text{t-}\dot{C}_4H_9 + \text{iso-}C_4H_{10} \rightleftarrows \text{iso-}\dot{C}_4H_9 + \text{iso-}C_4H_{10},$$

$$\dot{H} + C_3H_6 \rightarrow H_2 + \dot{C}_3H_5. \qquad (1a)$$

Chain termination occurs by recombination of CH_3, C_3H_5 and sec-C_3H_7 radicals.

The contributions of the following empirical reactions in the formation of the main products at 470 °C have been estimated for mixtures of propene and isobutane (at $[C_3H_6]/[\text{iso-}C_4H_{10}] = 0.10$).

$$\text{iso-}C_4H_{10} = CH_4 + C_3H_6, \quad 25.4\%$$

$$\text{iso-}C_4H_{10} = H_2 + \text{iso-}C_4H_8, \quad 51.2\%$$

$$\text{iso-}C_4H_{10} + C_3H_6 = C_3H_8 + \text{iso-}C_4H_8, \quad 13.7\% \qquad (7)$$

$$\text{iso-}C_4H_{10} + C_3H_6 = CH_4 + C_2H_4 + \text{iso-}C_4H_8, \quad 9.2\%$$

This mechanism differs from that given above in that the main route for the conversion of alkyl radicals formed by the addition of H atoms to the double bond of the inhibitor is the removal of a H atom from a molecule of the initial alkane. As a result the inhibitor is converted into the corresponding alkane [empirical reaction (7)]. However using radioactive additives it was shown convincingly that in mixtures with alkanes propene did not give rise to propane in practice. Such a difference is seemingly caused by the different pyrolysis temperatures 450–550 and 750–900 °C respectively.

The mechanism of the high temperature pyrolysis differs from that at lower temperatures by the fact that in practice only methyl radicals and H atoms participate in the chain propagation reactions. Other alkyl radicals are mainly decomposed. At temperatures below 600 °C for C_2-C_4 alkyl radicals not only is decomposition characteristic but also removal of H atoms from the initial alkene occurs.

b. Specific features of the inhibitory action of higher alkenes in the thermal decomposition of alkanes

In the thermal decomposition of mixtures of the higher n-alkanes with alkenes in contrast to mixtures of C_2-C_4 alkanes with propene the alkene is thermally less stable, due to the presence in the molecule of a weak C–C bond in the β-position to the double bond. It was established by low temperature IR spectroscopy in a nitrogen matrix[82,83] that the initiation stage of the decomposition of C_5-C_7 1-alkenes occurs by a radical mechanism under pyrolysis conditions with the formation of an allyl and the corresponding alkyl radical which initiates a radical chain process. It is assumed that in the pyrolysis of mixtures the alkene must initiate the decomposition of the alkane.[84] At the same time it was shown[23,27,28] that the alkene has an inhibitory action on alkane decomposition and the alkane initiates breakdown of the alkene. However the mutual effect is weakly expressed. This is linked with the fact that the alkene on the one hand acts as an initiator of the radical chain decomposition of the n-alkane and on the other as an inhibitor of the chain propagation stage since on pyrolysis the concentration of radicals propagating the chain is lower. Thus at 700–800 °C the concentration of hydrogen atoms in the decomposition of n-hexane is double that in the case of 1-hexene at a comparable concentration of methyl radicals.[85] On pyrolysis of mixtures of n-hexane and 1-hexene the ratio $[H_2]/[CH_4]$ is reduced on increasing the 1-hexene concentration (Fig. 8),[28] which indicates the fall in the relative concentration of H atoms in the reaction mixture. It follows from this that the initiating action of the alkanes is caused mainly by the increased rate of addition of H atoms, generated on decomposition of the n-alkane, to the alkene double bond and also by an increase in the rate of removal of H atoms, shown for the case of 1-hexene:

$$\dot{H} + C{=}C{-}C{-}C{-}C{-}C \longrightarrow \begin{cases} \dot{C}{-}C{-}C{-}C{-}C{-}C, \\ C{-}\dot{C}{-}C{-}C{-}C{-}C, \\ H_2 + C{=}C{-}\dot{C}{-}C{-}C{-}C, \\ H_2 + C{=}C{-}C{-}\dot{C}{-}C{-}C, \\ H_2 + C{=}C{-}C{-}C{-}\dot{C}{-}C, \\ H_2 + C{=}C{-}C{-}C{-}C{-}\dot{C}. \end{cases}$$

As a result the rate of chain propagation for the corresponding alkane is reduced [reaction (8)]

$$H + C{-}C{-}C{-}C{-}C{-}C \longrightarrow \begin{cases} H_2 + \dot{C}{-}C{-}C{-}C{-}C{-}C, & (8a) \\ H_2 + C{-}\dot{C}{-}C{-}C{-}C{-}C, & (8b) \\ H_2 + C{-}C{-}\dot{C}{-}C{-}C{-}C. & (8c) \end{cases}$$

As is known, the rate constant for the chain initiation reaction involving the alkene ($k_{C_nH_{2n}}$) is greater than that for the alkane ($k_{C_nH_{2n+2}}$). However the difference between them is not significant. Consequently the initiation rate of radicals on pyrolysis is determined mainly by the concentration of hydrocarbons in the initial mixture. For mixtures with a high alkene content, knowing that $k_{C_nH_{2n}}[C_nH_{2n}] \gg k_{C_nH_{2n+2}}[C_nH_{2n+2}]$, the alkene is responsible for the initiation of radicals and the decomposition of the n-alkane may be expected to be hastened. But this does not occur due to the low n-alkane concentration and the higher values of the rate constant for chain propagation involving 1-alkene. At the same time the overall concentration of radicals propagating the chain, for which the n-alkane is responsible, is not increased on pyrolysis of such mixtures. Consequently the initiating action of the n-alkane is not apparent in the decomposition of the 1-alkene.

On pyrolysis of mixtures with a low 1-alkene content when the rate of radical formation involving the alkane is at least comparable with the rate of their formation from the 1-alkene, initiation of 1-alkene decomposition by the n-alkane takes place and this effect is more apparent at lower 1-alkene concentrations. For these mixtures a higher concentration of H atoms propagating the chain is more characteristic than for 1-alkene.

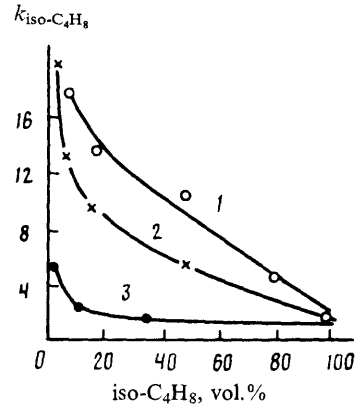

Figure 7. Rate constant for the decomposition of iso-C_4H_8 in mixtures with *1*, n-butane; *2*, propane; *3*, ethane at 800 °C.

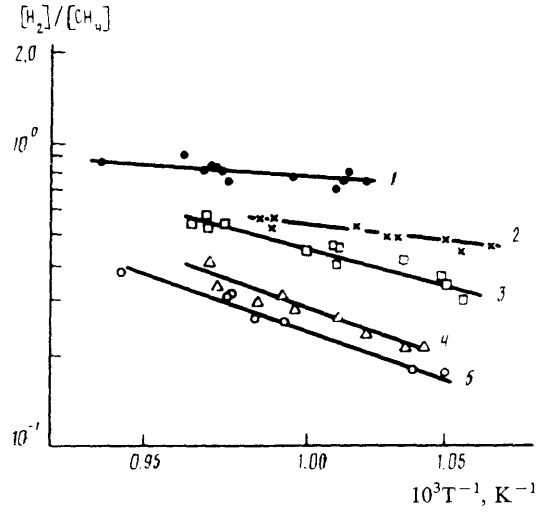

Figure 8. Temperature dependence of the ratio H_2/CH_4 in the pyrolysis products of *1*, hexane; *5*, 1-hexene and mixtures of hexane with *2*, 10% 1-hexene; *3*, 25% 1-hexene and *4*, 75% 1-hexene.

Consequently for the pyrolysis of mixtures of higher alkanes with 1-alkenes the mechanism of the mutual effect is also determined mainly by the competing chain propagation reaction involving

hydrogen atoms. But in contrast to mixtures with propene it is necessary to consider in the decomposition scheme the step of forming radicals involving the 1-alkene. Consequently the rate constants for radical formation in the decomposition of a n-alkane and 1-alkene, and also the concentration of H atoms are not appreciably different, the mutual effect of these hydrocarbons on the rate and route of the decomposition in mixtures is less clearly apparent and depends to a large extent on the composition of the mixture and the pyrolysis temperature.

c) Inhibition–initiation on pyrolysis of binary mixtures of hydrocarbons of other classes

The mutual effect on the rate and route of the decomposition of hydrocarbons on joint pyrolysis is readily explained by the difference in the concentration of the radicals propagating the chain as is the apparent inconsistency of the experimental data observed in the case of a weakly expressed inhibition–initiation effect.[86]

It was shown[80] that there is no significant difference in the concentration of hydrogen atoms formed in the pyrolysis of C_5-C_{15} n-alkanes. In fact at relatively low temperatures a small increase is recorded in the concentration of H atoms with chain length for C_3-C_6 alkanes (see Fig. 5). At the same time a very high concentration of hydrogen atoms exists in the pyrolysis at temperatures above 800 °C. Consequently at relatively low temperatures the n-alkanes show an initiating action on ethane decomposition which disappears at high temperatures.[49] The initiating action of ethane on the decomposition of n-alkanes at high temperatures may be apparent only in mixtures with a high ethane concentration, since only in this case can a higher concentration of H atoms be brought about in a mixture than on pyrolysis of an individual n-alkane. Thus a change in the composition of the initial alkane mixture and of the pyrolysis temperature leads to an inversion of the mutual effect.

Table 3. Concentration of radicals (mol litre^{-1}) on pyrolysis of hydrocarbons and their equimolar mixtures (660 °C).[37]

Starting material	$10^{11}[H]$	$10^{9}[CH_3]$	$10^{10}[C_2H_5]$
Propane	2.4	3.2	1.1
Isobutane	3.4	5.1	–
Neopentane	1.4	6.3	1.9
Propane + Neopentane	7.3	8.4	1.1
Isobutane + Neopentane	4.6	9.1	–

The thermal stability of the components of a mixture does not play a significant role. This is indicated by data on the pyrolysis of five binary equimolar mixtures based on ethane, propane, n- and isobutane and pentane at 650–690 °C.[37] It transpires that neopentane accelerates the decomposition of both the thermally less stable isobutane and of the thermally more stable propane. The decomposition rate of neopentane itself in the mixtures was practically unchanged. The authors of this study also arrived at the conclusion that the initiating action of a hydrocarbon on pyrolysis in a mixture is linked with the change in the concentration of the radicals propagating the chain at the expense of the partner (see Table 3).

As is seen from Table 3 $[R]_{C_3H_8} < [R]_{neo\text{-}C_5C_{12}}$ and $[R]_{iso\text{-}C_4H_{10}} < [R]_{neo\text{-}C_5H_{12}}$. However the concentration of the radicals driving the chain is greater in the case of the pyrolysis of mixtures of these hydrocarbons with neopentane. Consequently in the pyrolysis of mixtures chain propagation reactions proceed at a high rate due to the radicals generated on decomposition of neopentane. Since $[R]_{iso\text{-}C_4H_{10}} > [R]_{C_3H_8}$ and $[R]_{mix}/[R]_{iso\text{-}C_4H_{10}} < [R]_{mix}/[R]_{C_3H_8}$, the initiating actionof neopentane in the decomposition of propane is stronger than in the decomposition of isobutane.

Ethane, like propene, inhibits isobutane pyrolysis, but to a lesser exent.[48] In both cases the mechanism of the inhibition is described by competing reactions of chain propagation with the participation, mainly, of hydrogen atoms. In the case of mixtures of isobutane with C_2H_6 the reactions are:

$$\dot{H} + \text{iso-}C_4H_{10} \rightarrow H_2 + \text{iso-}\dot{C}_4H_9, \quad (6a)$$

$$\dot{H} + \text{iso-}C_4H_{10} \rightarrow H_2 + \text{t-}\dot{C}_4H_9, \quad (6b)$$

$$\dot{H} + C_2H_6 \rightarrow H_2 + \dot{C}_2H_5, \quad (5)$$

and in the case of isobutane with propene they are reactions (2) and (6*a*, *b*). The extent of the inhibitory action is determined by the ratio of the concentration of hydrogen atoms formed in the decomposition of ethane and propene. Since $[H]_{C_3H_6} \ll [H]_{iso\text{-}C_4H_{10}} > [H]_{C_2H_6}$, the rate of reaction (6) in the pyrolysis of mixtures is less than in the decomposition of pure isobutane.

The weaker inhibitory action of ethane compared with propene is linked with the fact that $[H]_{C_2H_6} \gg [H]_{C_3H_6}$ and consequently $[H]_{mix}/[H]_{C_2H_6} \ll [H]_{mix}/[H]_{C_3H_6}$.

In mixtures with other partners such as cyclohexane‡ ethane, like 1-hexene, displays an initiating action[57,87] which is caused by different ratios of the concentrations of H atoms, i.e. $[H]_{C_2H_6} \gg [H]_{cyclo\text{-}C_6H_{12}} < [H]_{C_6H_{12}}$.[80,85]

1,3-Butadiene acts both as an inhibitor and as an initiator of decomposition depending on the partner. On pyrolysis 1,3-butadiene shows an initiating action when mixed with propene.[88] At the same time 1,3-butadiene inhibits the decomposition of ethane.[31] The mechanism of inhibition–initiation on pyrolysis of these mixtures is determined in the first case by the competing reactions (2) and (9):

$$H + C_4H_6 \longrightarrow \dot{C}_4H_7 \longrightarrow \dot{C}_2H_3 + C_2H_4, \quad (9)$$

and in the second by reactions (5) and (9). But in the first case $[H]_{C_3H_6} < [H]_{C_4H_6}$, and in the second $[H]_{C_2H_6} > [H]_{C_4H_6}$. Consequently in mixtures with propene, reaction (9) proceeds more slowly and in mixtures with ethane more rapidly than in pyrolysis of 1,3-butadiene alone.

The mechanism of the initiating action of allene on the thermal decomposition of hydrocarbons of various classes is described[34–36] by the bimolecular reaction (10)

$$C_3H_4 + RH \longrightarrow \dot{C}_3H_5 + R, \quad (10)$$

‡ The radical chain character of cyclohexane pyrolysis with the formation of allyl and methyl radicals at the initiation stage was confirmed[83,88] by low temperature IR spectroscopy in a nitrogen matrix and also with radioactive additives.

providing the initiation stage is not unambiguous. The use of only small additions of allene (0.2–1.5%) and the lack of data on the effect of the partner on the rate and course of the decomposition of allene itself does not give a complete picture of the mutual effect of these hydrocarbons on pyrolysis in mixtures.

The allyl radical formed by reaction (10) being itself fairly reactive at relatively low temperatures in chain propagation reactions, [90] is mainly decomposed at relatively high temperatures under pyrolysis conditions generating H atom and the initial allene. It may therefore be suggested that allene does not simply initiate the radical formation stage but also acts as an additive which participates in the radical chain decomposition of the partner accompanied by an increase in the concentration of the radicals propagating the chains.

VIII. Conclusion

The vast majority of data considered above on the pyrolysis of mixtures of various classes of hydrocarbons is most adequately interpreted on the basis of ideas on the role of the components of the mixture in generating hydrogen atoms (and methyl radicals) the concentration of which controls the rate of chain propagation. This mechanism not only describes well the principles of the pyrolysis of mixtures of hydrocarbons of various classes but also enables the efficiency and course of action of one hydrocarbon on the decomposition of another to be explained as a function of its chemical structure and the reaction conditions. It also explains the non-additivity of product formation on pyrolysis of mixtures. The particularly significant deviation from additivity observed in the pyrolysis of alkanes with added propene and 2-methylpropene is caused by the rapid addition of hydrogen atoms to the alkene. The concentration of hydrogen atoms is greater than in the pyrolysis of the alkene alone. Under these conditions propene is decomposed mainly to methane and ethylene but the reaction associated with the formation of the hydrocarbons C_3H_4 and C_2H_2 is almost completely suppressed.

A deviation of the yield of products from additivity was observed even in the case of the pyrolysis of mixtures of the higher n-alkanes and 1-alkenes when the mutual effect of the hydrocarbons on the rate of decomposition is insignificant. This is linked with the high rate of reaction of 1-alkenes involving radicals generated in the decomposition of the alkane and mainly the addition of H atoms at the double bond. Since the selectivity of forming products is reduced on increasing the hydrocarbon chain length, it is difficult to separate the key course of decomposition of the 1-alkene and consequently to change significantly the selectivity of forming products in the mixture.

On pyrolysis of mixtures the mutual effect of one hydrocarbon on the thermal decomposition of another is therefore effected by a single mechanism based on competing chain propagation reactions involving the partner hydrocarbons, the rates of which are limited by the concentration of radicals progressing the chain. A single hydrogen may on copyrolysis act in some cases as an initiator and in others as an inhibitor of a process. The main characteristic of a hydrocarbon as an inhibitor is that the concentration of radicals propagating the chain and generated in the pyrolysis process is lower than that of its partner. The inhibition–initiation phenomenon of the radical chain process in the pyrolysis of mixtures is determined by a change in the concentration of radicals progressing the chain compared with that observed on pyrolysis of the individual hydrocarbons. In this way the thermal stability and the ability of a hydrocarbon to generate radicals unreactive in chain propagation reactions (for example radicals of the allyl type) are not determining and are important only as factors influencing the establishment of a definite level of radical concentration.

New bis(naphthalic anhydrides) and polyheteroarylenes based on them with improved processability

A L Rusanov
A N Nesmeyanov Institute of Heteroorganic Compounds, Russian Academy of Sciences, Moscow

ABSTRACT. New bis(naphthalic anhydrides) containing 'hinge' groups and/or bulky substituents are considered. It has been shown that the majority of these monomers may be synthesised from derivatives of naphthalic anhydride or acenaphthene with subsequent oxidation of the bisacenaphthyls obtained. Reaction of these compounds with aromatic diamines and bis(*o*-phenylenediamines) gives polynaphthalimides and polynaphthoylenebenzimidazoles combining solubility in organic solvents with high thermal and chemical stability.

The bibliography contains 154 references.

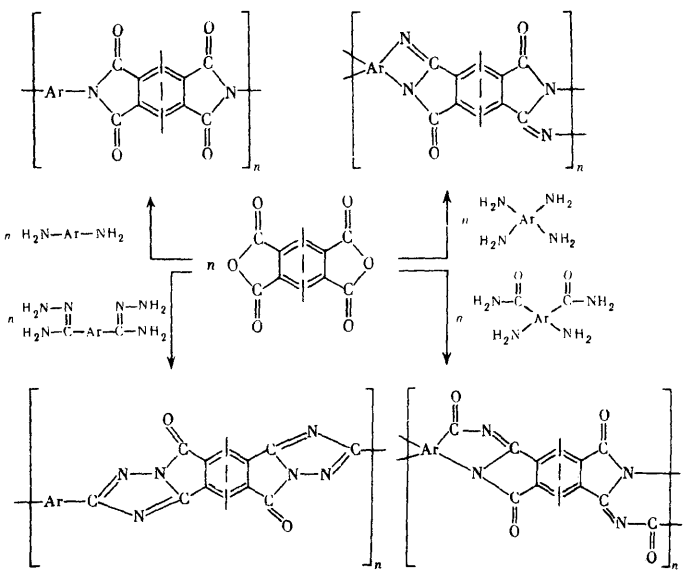
I. Introduction

The rapidly developing variety of modern techniques present ever-increasing requirements for the polymers used in them. Investigations on thermally and chemically stable polymers are fairly widespread[1–9] and in some of these the polyheteroarylenes, aromatic polymers containing heterocycles in the main chains of the macromolecule, have attracted particular interest. This interest is explained by the spectrum of valuable, occasionally unique, physicochemical and mechanical properties possessed by these polymers and the materials based on them.[1–21]

A significant portion of the studies on the synthesis of polyheteroarylenes is devoted to polymers based on bis(phthalic anhydrides). These monomers are widely used in the synthesis of polyimides[22–25] and of the completely and partially 'ladder' polyheteroarylenes,[26] the polybenzoylenebenzimidazoles, polybenzoylene-S-triazoles, polyisoindoloquinazolinediones,[27] etc., which are illustrated by the following scheme:

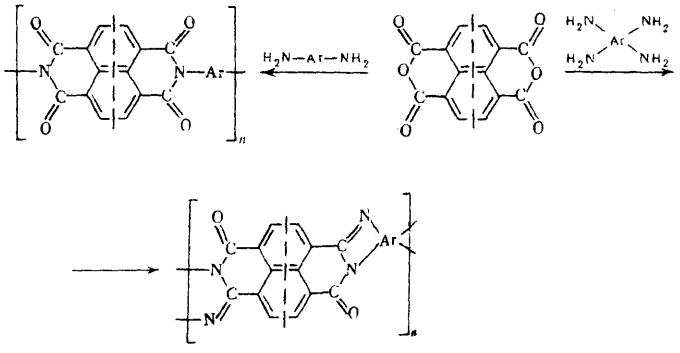


Practically all these polyheteroarylenes are obtained using stepwise processes with the possibility of stopping the reaction at the stages of formation, of prepolymers soluble in organic solvents, processing of the prepolymers into a product and subsequent cyclisation of them in the form of the finished products with the formation of the desired infusible and insoluble polyheteroarylenes as the already finished goods.

It must however be noted that both the polyimides and the ladder polyheteroarylenes based on bis(phthalic anhydrides) possess comparatively low thermal and chemical stability.[27] This is caused to a significant extent by the strain of the five-membered imide fragments of the resulting heterocycles and the high positive charges on the carbon atoms of the carbonyl groups of these systems.

The logical route leading to a potential increase in the thermal and chemical stability of the polyheteroarylenes is the replacement of the bis(phthalic anhydrides) in the above-mentioned reactions by bis(naphthalic anhydrides) the structure of which should be determined by the formation of systems containing six-membered imide rings, either on their own or condensed with other heterocyclic fragments.

Previous investigations[28–37] have shown that on using bis(naphthalic anhydrides) as monomers polynaphthalimides and polynapht'ioylenebenzimidazoles are obtained which possess high chemical and thermal stability and fire resistance compared with analogous systems based on the bis(phthalic anhydrides).[28–40]

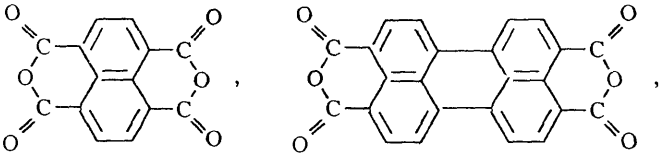


The polymers based on bis(naphthalic anhydrides) are therefore more promising than those based on bis(phthalic anhydrides) from the point of view of creating materials with improved properties.

It must however be noted that the polyheteroarylenes based on bis(naphthalic anhydrides) are generally systems with a low ability to be processed into articles. On the one hand the final polyheteroarylenes are infusible and are soluble in strong acids, such as sulphuric, methanesulphonic or polyphosphoric, and on the other the reactions using bis(naphthalic anhydrides) as stepwise processes are difficult due to the reduced electrophilic reactivity of bis(naphthalic anhydrides) and the ease of forming six-membered naphthalimide systems.

Hence it follows that the development of polyheteroarylenes based on bis(naphthalic anhydrides) characterised by a satisfactory processability into articles is an important and urgent problem in the chemistry of thermostable polymers. One of the most common routes of improving the processability of polyheteroarylenes is the conferring on them of solubility in organic solvents. The main ways to solve this problem are:

1. The synthesis of polyheteroarylenes based on the most common bis(naphthalic anhydrides), i.e. the anhydrides of naphthalene-1,4,5,8-tetracarboxylic and perylene-3,4,9,10-tetracarboxylic acids



and nucleophilic co-monomers differing in the structure which causes an improved processability of the desired polyheteroarylenes.

2. The development of bis(naphthalic anhydrides) containing structural elements causing improved processability of the polyheteroarylenes based on them and the use of the indicated bis(naphthalic anhydrides) in reactions with di- and tetra-functional nucleophilic comonomers.

Since the first of the above-mentioned approaches has been considered previously,[24,41,42] attempts will be undertaken in the present review to analyse the results obtained in the second direction.

The main approaches[43,44] to the conferment of solubility in organic solvents to the polyheteroarylenes by modifying the initial dianhydrides are:

a) the introduction of 'hinge' bonds into the molecules which facilitate to a maximal extent the rotation of the individual fragments of the macromolecule relative to one another and b) the introduction into the molecule of anhydrides with bulky substituents.

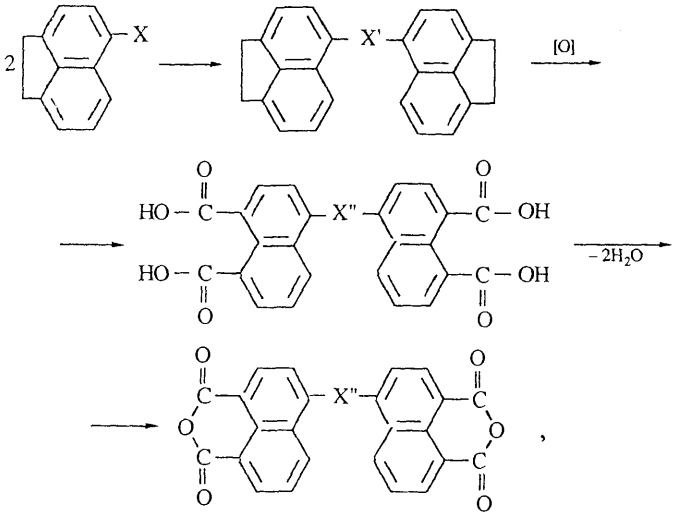
A combined approach is frequently used, i.e. both hinges and bulky substituents are introduced into the anhydride molecule.

These approaches and combinations of them were used in the development of new bis(naphthalic dianhydrides) intended for the preparation of polyheteroarylenes soluble in organic solvents.

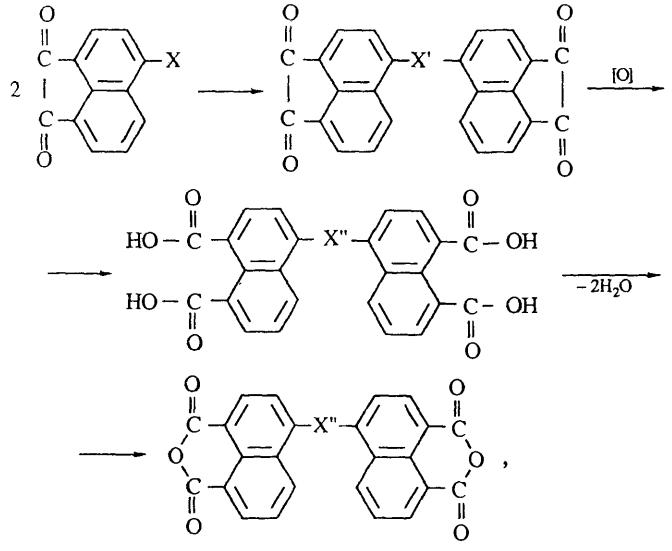
II. Bis(naphthalic anhydrides) containing structural elements causing improved solubility of the polyheteroarylenes based on them

The simplest modification of the most common bis(naphthalic anhydrides) directed towards improving the processability of the polyheteroarylenes derived from them is the introduction of a single bond or a hinge group between two naphthalic anhydride residues. Analogous bis(naphthalic anhydrides)[42] are most frequently obtained from acenaphthene[45] or its simplest derivatives using such approaches as:

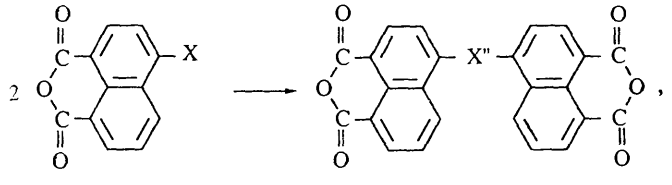
– the reaction of two molecules of acenaphthene or a derivative with the appropriate compounds leading to the formation of bis-acenaphthenes, subsequent oxidation[46] of them and dehydration of the resulting bis(naphthalic acids):



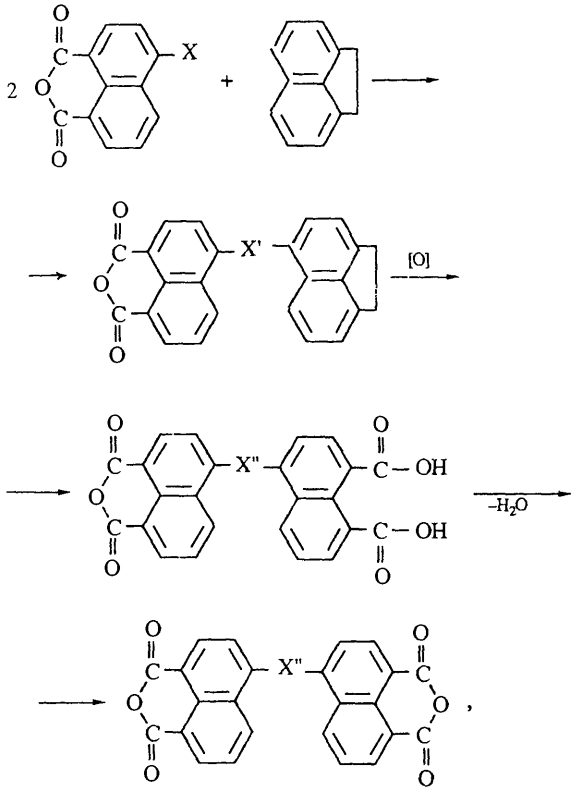
– the reaction of two molecules of acenaphthoquinone derivatives (product of partial oxidation of acenaphthene) with appropriate compounds and subsequent oxidation of the resulting bis-acenaphthoquinones to bis(naphthalic anhydrides):



– the reaction of two molecules of the naphthalic anhydride derivative (derived from acenaphthene[45]) with appropriate compounds leading to the formation of bis(naphthalic anhydrides):

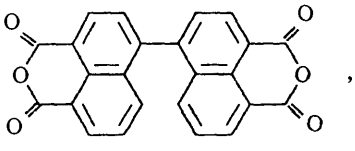


– the reaction of naphthalic anhydride derivatives with acenaphthene or a derivative of it leading to the formation of compounds containing both an acenaphthyl and an anhydride function with subsequent oxidation of the acenaphthyl group and dehydration of the resulting acid function:

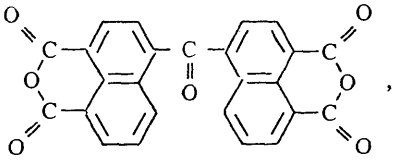


Certain monomers of this type containing separate naphthalic anhydride residues were obtained a fairly long time ago. Their simplest representatives are as follows:

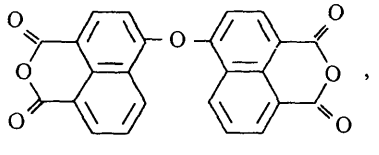
4,4′-Bis(naphthalic anhydride)[47,48]



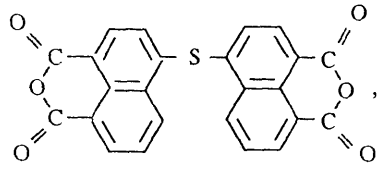
4,4′-Ketobis(naphthalic anhydride)[49,50]



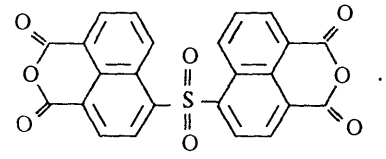
4,4′-Epoxybis(naphthalic anhydride)[51–54]



4,4′-Thiobis(naphthalic anhydride)[55,56]



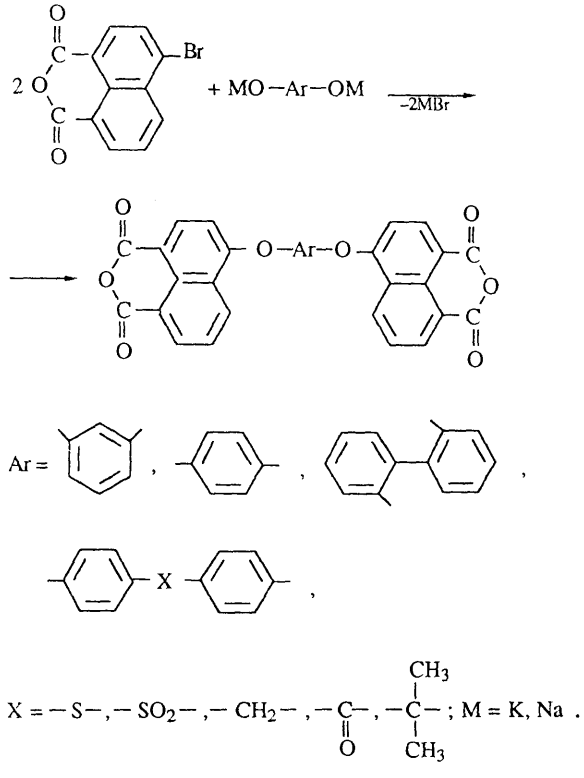
4,4′-Sulphonylbis(naphthalic anhydride)[56,57]



It must however be noted that polyheteroarylenes, primarily polynaphthoylenebenzimidazoles, obtained from bis(naphthalic dianhydrides) containing no more than one hinge group and the simplest bis(*o*-phenylenediamines), proved to be soluble only in strong acids and were practically insoluble in a single organic solvent.[55,57–61]

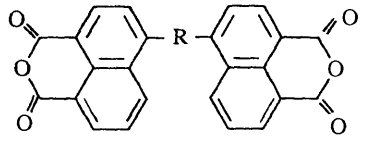
The simplest change in the structure of the bis(naphthalic dianhydrides) directed towards obtaining the desired polyheteroarylenes soluble in organic solvents is the introduction of additional hinge groups.

Significant attention has been paid to systems containing at least two ether bonds in several bis(naphthalic anhydrides) containing more than one hinge group. These monomers are obtained by the reaction of two moles of 4-bromonaphthalic anhydride with an alkali metal bisphenoxide in dipolar aprotic solvents[55,62–68] according to the following scheme:



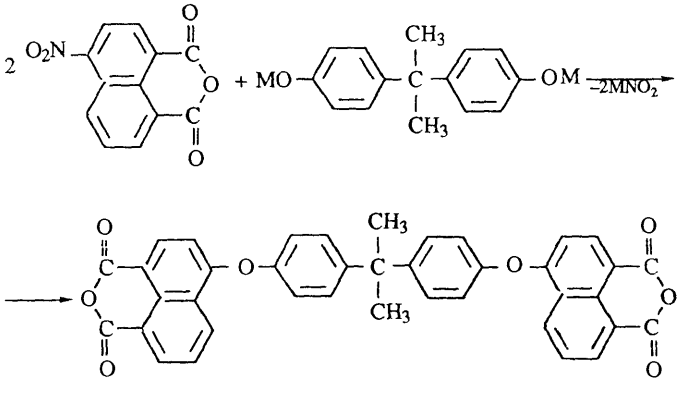
Some characteristics of individual bis(naphthalic anhydrides) containing ether groups are shown in Table 1.

Table 1. Bis(naphthalic anhydrides) of general formula

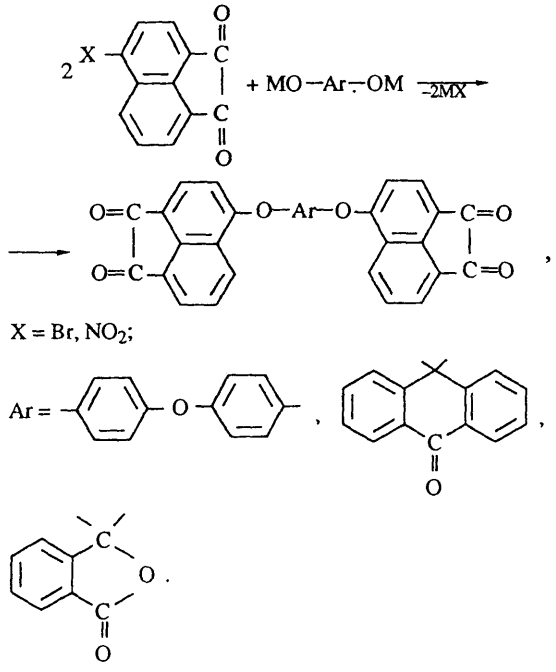


R	Mp, °C	Yield, %	Ref.
	271–272	81.6	[63]
	300	93.0	[63]
	287.5–287.6	95.0	[63]
	274.4–275.5	96.7	[63]
	294–295	70.0	[65]

An alternative method of synthesising similar bis(naphthalic anhydrides) is the use of 4-nitronaphthalic anhydride in place of 4-bromonaphthalic anhydride,[69] however this process has only been considered in an extremely fragmentary manner.



The 4-bromo and 4-nitro derivatives of acenaphthoquinone[66,70,72] also react with alkali metal bisphenoxides in the reactions considered above. In these cases bisacenaphthoquinones are formed in the first stage.



X = Br, NO_2;

Individual bisacenaphthoquinones were then oxidised further to bis(naphthalic acids) and then converted into bis(naphthalic anhydrides).[71,72]

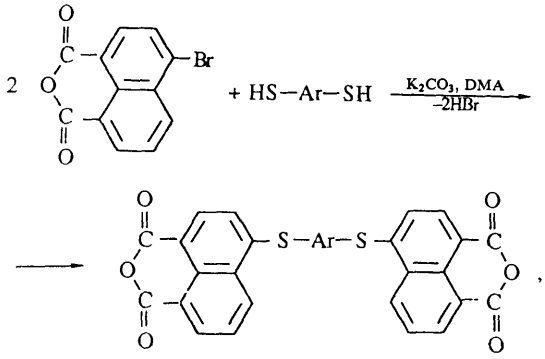
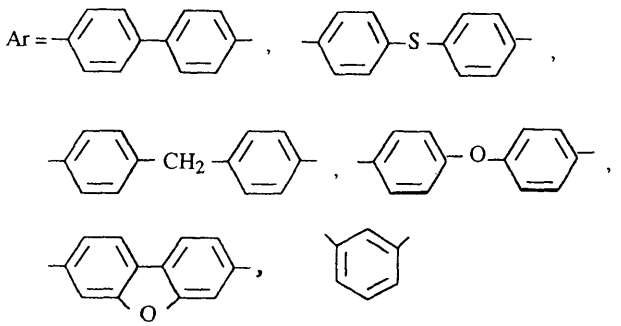
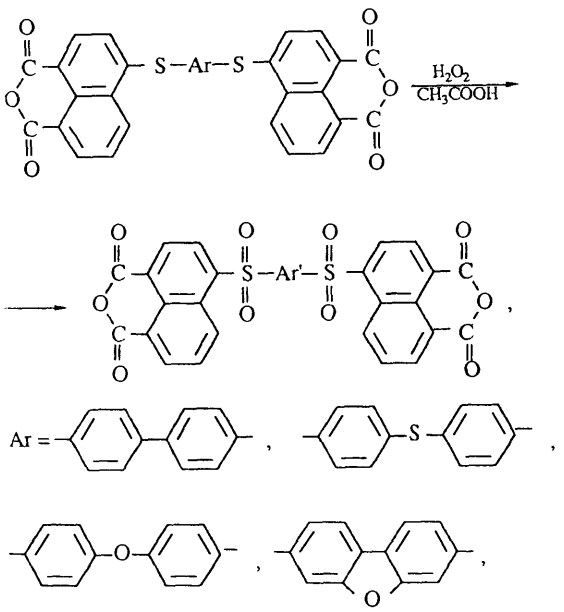
Practically all the reactions considered above for the synthesis of bis(naphthalic anhydrides) containing ether groups may be used for the preparation of bis(naphthalic anhydrides) containing thioether linkages.[55,63,73,74] In these reactions bis(thiophenoxides) are used as starting materials instead of alkali metal bisphenoxides.

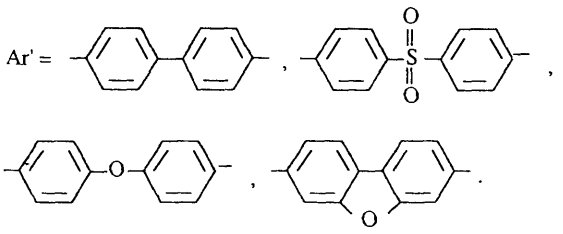




Some characteristics of bis(naphthalic anhydrides) containing thioether groups are given in Table 2.

The bis(naphthalic anhydrides) are characterised by a lower electrophilic reactivity than the bis(phthalic anhydrides). The introduction into them of ether and thioether groups, which are electron-donating substituents, causes a further reduction in their electrophilic reactivity. This led to a switch from electon-donating to electron-accepting hinge groups and in particular to the transition from dianhydrides containing thioether groups to dianhydrides with sulphone fragments. Synthesis was effected by the following scheme:[73,74]





Some characteristics of the bis(naphthalic anhydrides) containing sulphone groups are given in Table 2.

Another large group of bis(naphthalic anhydrides), the so-called bis(ketonaphthalic anhydrides), were obtained by the Friedel–Craft reaction of the diacid chlorides of aromatic dicarboxylic acids with two moles of acenaphthene with subsequent oxidation of the bis(acenaphthyls) to bis(ketonaphthalic acids) which undergo further dehydration to bis(ketonaphthalic anhydrides)[77–81] according to the following scheme:

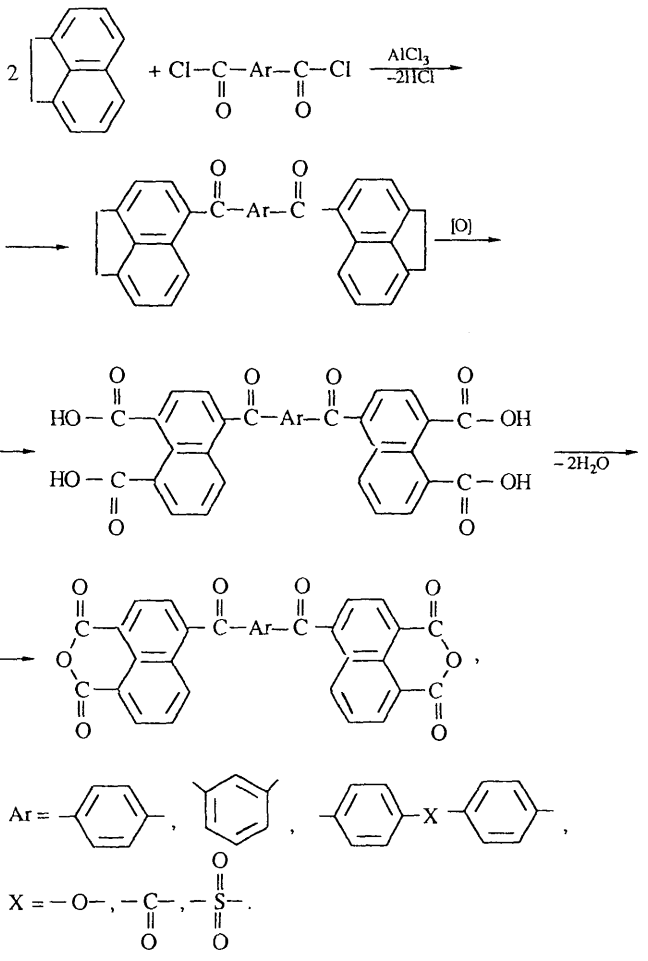


Table 3. Properties of aroylenebis(naphthalic anhydrides)

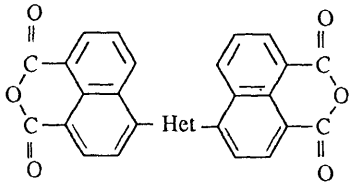
	308–309	57	[82, 84]
$-CB_{10}H_{10}C-$	278–280	35	[83, 84]

Some characteristics of the bis(ketonaphthalic anhydrides) synthesised are given in Table 3.

The same synthetic approach was used for obtaining bis(ketonaphthalic anhydrides) containing a heteroorganic central grouping, such as hexafluoroisopropylidene, diphenylsilyl and *m*-carboranylene (Table 3).[82–84]

An alternative method of synthesising the bis(ketonaphthalic anhydrides) considered above and systems isomeric with them is the Friedel–Craft reaction of a 4-chloroformylnaphthalic anhydride with aromatic hydrocarbons.[85]

Table 4. Some characteristics of heteryl-containing bis(naphthalic anhydrides) of general formula



Het	Mp, °C	Yield, %	Ref.

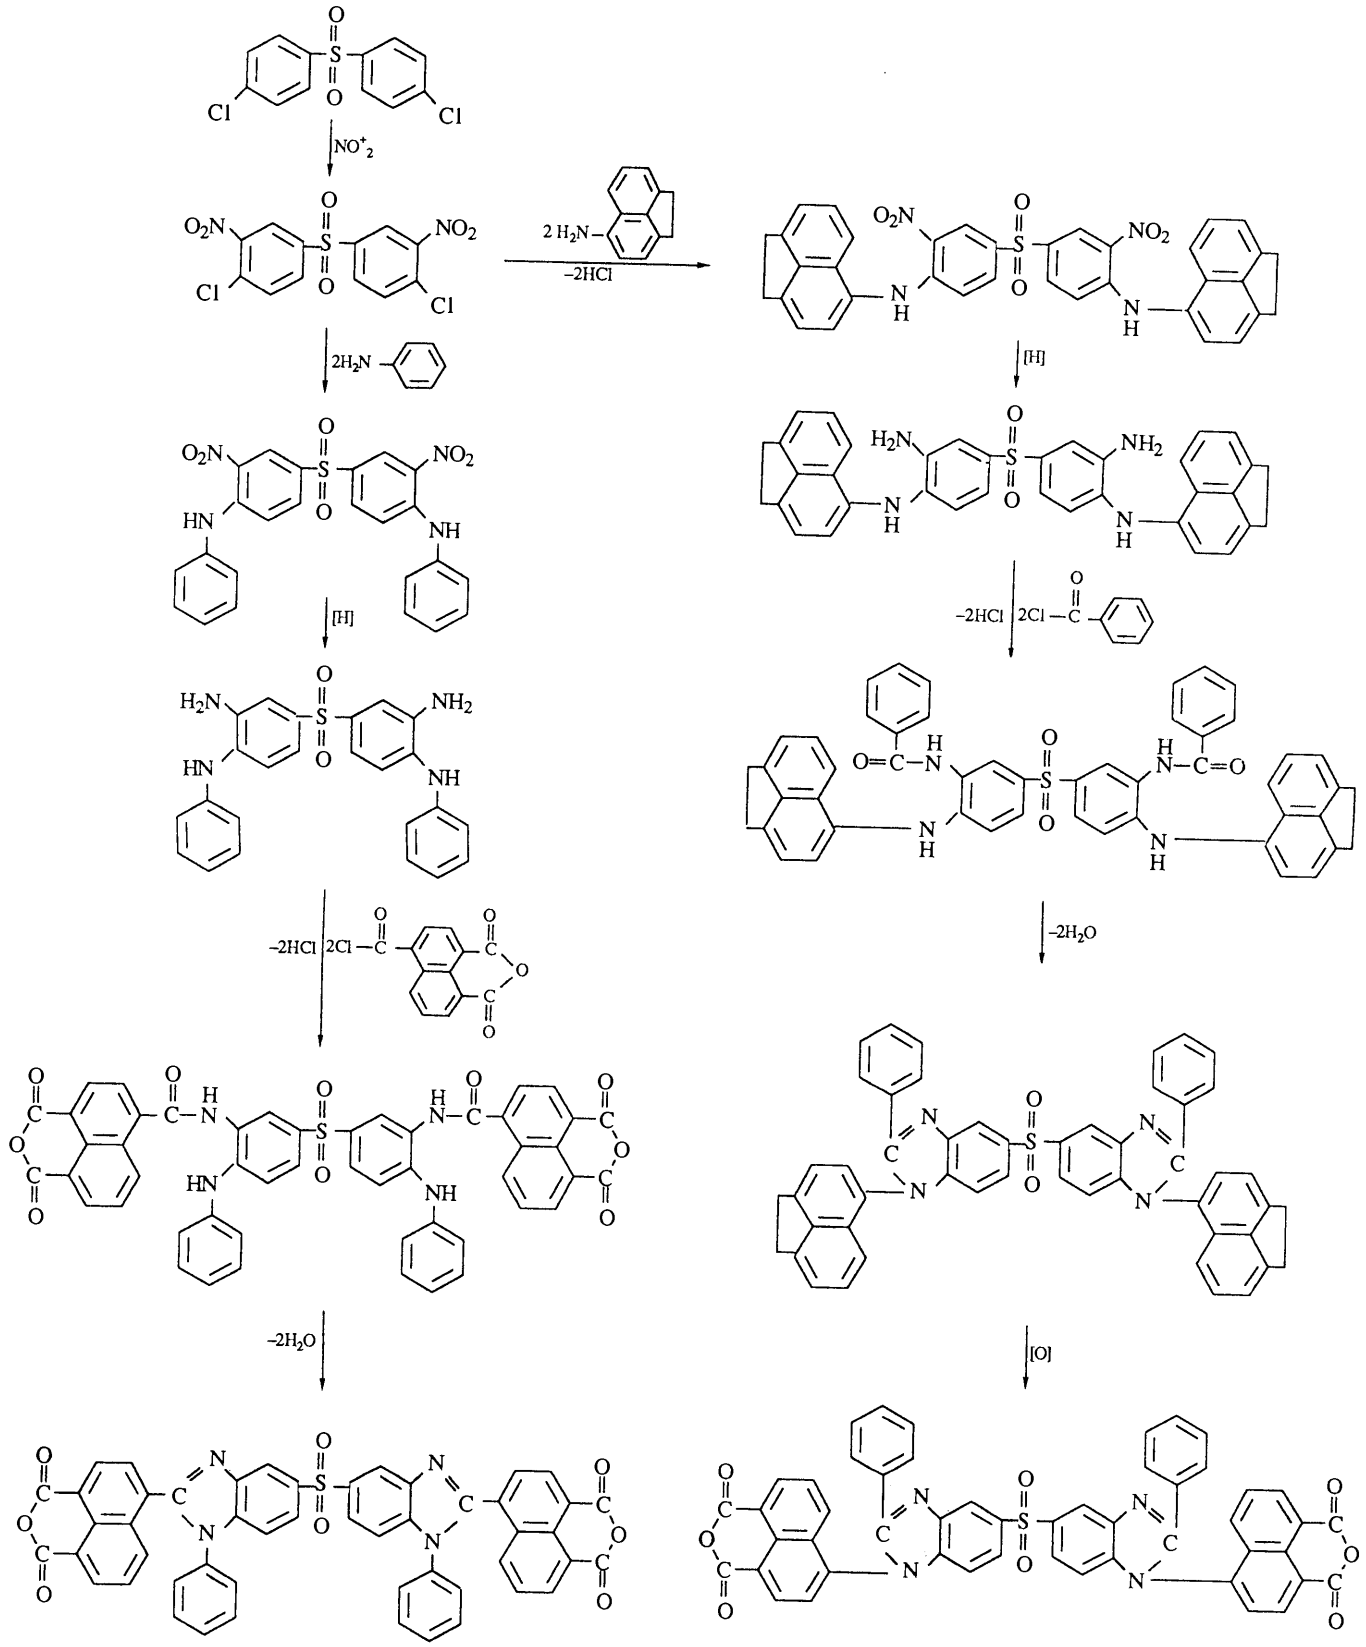
	352–364	73	[89]
	315–335	68	[89]

4-Chloroformylnaphthalic anhydride was also used for obtaining bis(naphthalic anhydrides) containing phenyl substituted heterocycles. The dianhydride of bis[1-phenyl-2-(4,5-dicarboxynaphthyl)-benzimidazol-5-yl] sulphone was obtained by treating bis[(3-amino-4-phenylamino)phenyl] sulphone, a product from 4,4′-dichlorodiphenyl sulphone produced on an industrial scale, with two moles

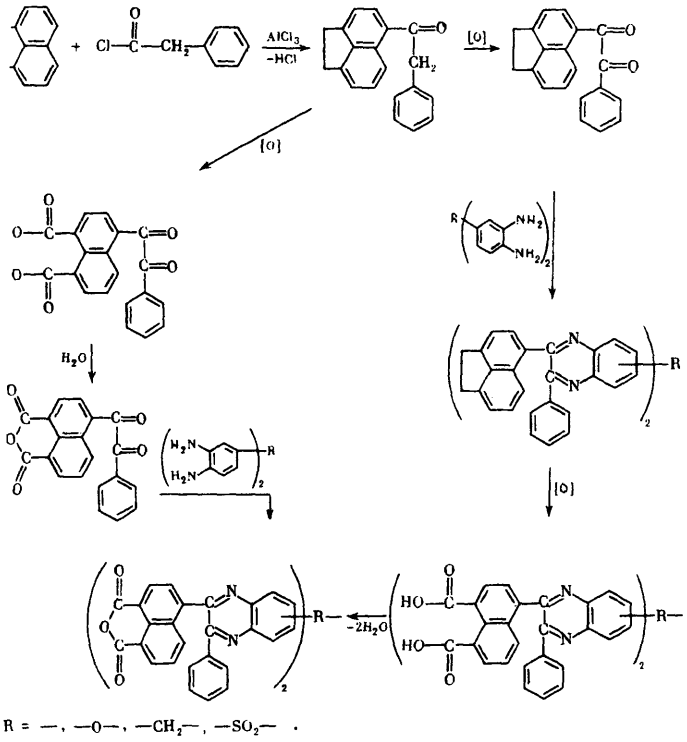
of 4-chloroformylnaphthalic anhydride and subsequent cyclodehydration of the compound obtained.[86,87]



The dianhydride of bis[2-phenyl-1-(4,5-dicarboxynaphthyl)benzimidazol-5-yl] sulphone, isomeric with this compound, was obtained by treating 4,4'-dichloro-3,3'-dinitrodiphenyl sulphone with 4-aminoacenaphthene, reduction of the nitro groups of the obtained 4,4'-di(aminoacenaphthyl)-3,3'-dinitrodiphenyl sulphone to primary amino groups, benzoylation of these amino groups, cyclodehydration of the 2-benzamido-imine fragments into 2-phenyl-1-acenaphthylbenzimidazole rings, oxidation of the acenaphthyl groups to peri carboxyl groups and anhydride formation of the latter.[87]

Individual characteristics of the synthesised bis(naphthalic anhydrides) containing various heterocycles are given in Table 4.

The derivatives of acenaphthene and naphthalic anhydride containing α-diketone groups in the 4 position have been used for obtaining bis(naphthalic anhydrides) containing phenylquinoxaline fragments.[88–91] The synthesis of these monomers was effected by the following scheme:

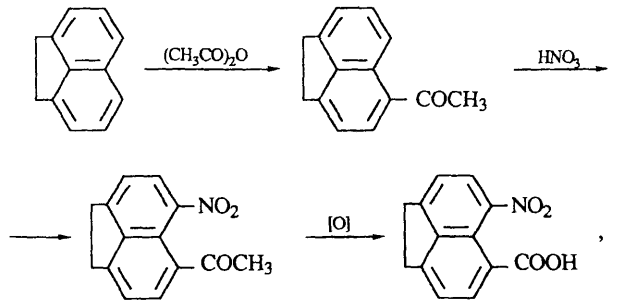


R = —, —O—, —CH_2—, —SO_2— .

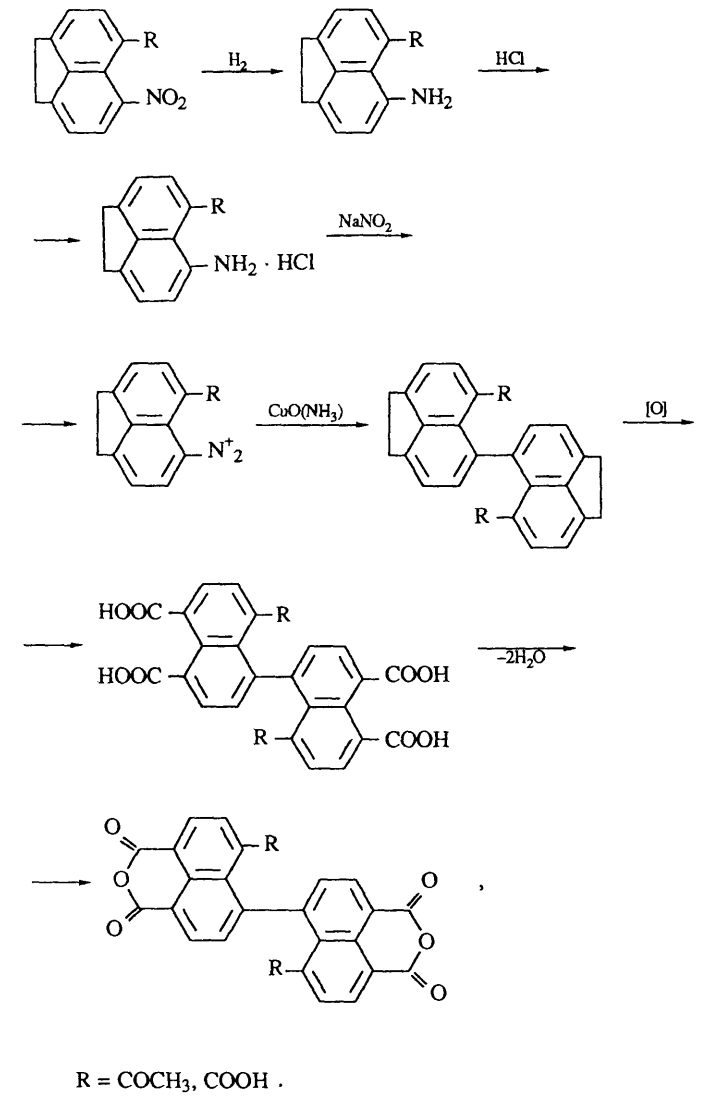
Some characteristics of the bis(phenylquinoxalinylnaphthalic anhydrides) are given in Table 4.

The diffuse melting points of the bis(phenylquinoxalinylnaphthalic anhydrides) are probably due to these products being mixtures of isomers, which is usual when forming bis and polyphenylquinoxaline systems.[92–94] In addition to phenyl, acetyl and carboxyl substituents, capable of increasing the solubility of the target polyheteroarylenes,[95] were also introduced into the bis(naphthalic anhydrides).

The diacetyl and dicarboxyl derivatives of bis(naphthalic anhydride) were obtained by the acetylation of acenaphthene, nitration of the 4-acetylacenaphthene obtained[96] and oxidation of the resulting acetylnitroacenaphthene[97]



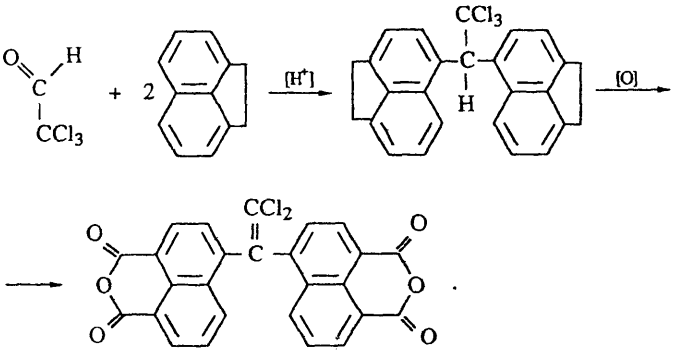
and subsequent formation and dimerisation of the diazo compounds.[98–100]



R = $COCH_3$, COOH .

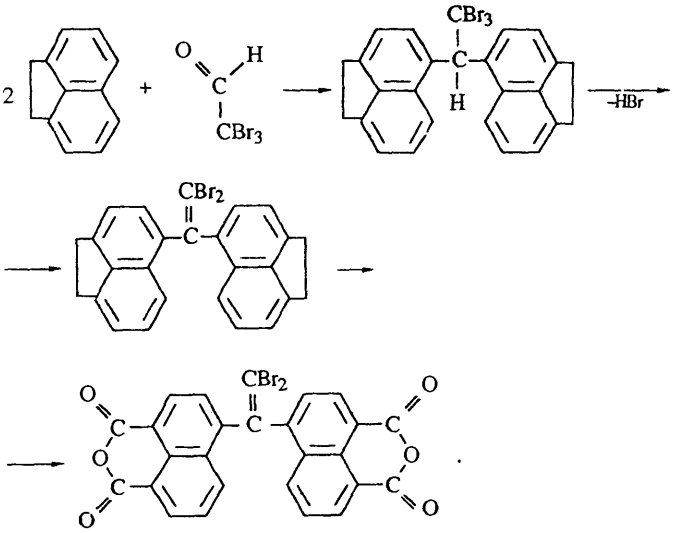
The dianhydride of 1,1′-bis(naphthyl)-4,4′,5,5′,8,8′-hexacarboxylic acid is manufactured in the USSR on a semi-industrial scale at the present time for the production of cubogens.[101,102]

Bis(naphthalic anhydrides) containing 1,1-dihaloethylene groups have been synthesised since it is known that the introduction of these fragments into macromolecules of various polyheteroarylenes are capable of improving the solubility of the latter.[102,108] Proceeding from the general chemistry of chloral derivatives,[103,114] it might be expected that the condensation of chloral with two molecules of acenaphthene must lead to di(acenaphth-4-yl)trichloroethane and this was found to be so. The oxidation of diacenaphthyltrichloroethane with potassium and sodium dichromate in glacial acetic acid at 90–110 °C was accompanied by dehydrochlorination of the central grouping and simultaneous anhydride formation of the peri dicarboxyl groups.[77,110,111]



Neither dehydrochlorination of the 1,1,1-trichloroethane groups to 1,1-dichloroethylene nor oxidation of the 1,1-dichloroethylene group to carbonyl occurred when the usual conditions of carrying out these processes were applied to this system.

It is interesting to note that on replacing chloral by bromal the reactions considered occurred totally as expected[103,107,109,113] and led to the formation of the dianhydride of 1,1-bis(1,8-dicarboxynaphth-4-yl)-2,2-dibromoethylene.[80,112]



Since there are no literature data on the relative reactivities of bis(naphthalic anhydrides) a quantum chemical calculation of certain parameters was carried out by the PPP method,[113] particularly of the value of the electron affinity (A) which is a measure of the electrophilic reactivity of the dianhydrides in reactions with amines.[114] The results of the calculations of the values of A for various bis(naphthalic anhydrides) are given in Table 5.

Table 5. Electronic characteristics of bis(naphthalic anhydrides).

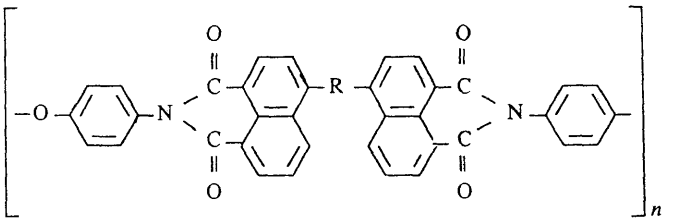
Compound	A, eV		q_1	q_2
	from Koopmans' theorem	from energy difference		
	3.1493	1.7426	0.2478	0.2478
	4.0102	2.6044	0.2477	0.2477
	3.7990	2.4770	0.2474	0.2469
	3.4488	2.0819	0.2097	0.2184
	3.8704	2.4896	0.2486	0.2475
	3.6475	2.1878	0.2490	0.2475

Note: q_1 is the positive charge on the 5 and 5′ carbon atoms, q_2 is the positive charge on the 4 and 4′ carbon atoms.

As in the case of the bis(phthalic anhydrides) the greatest value of A was found for the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid and the values of A for bis(naphthalic anhydrides)

containing electron-accepting hinge groups were greater than those for the bis(naphthalic anhydrides) with electron-donating groups. Comparison of the absolute values of A shows that the values of A for the bis(naphthalic anhydrides) were significantly greater than for the bis(phthalic anhydrides), which agrees with the literature[114] and is explained by the high aromaticity of the bis(naphthalic anhydrides). However the high values of A are not linked with the higher reactivity of the bis(naphthalic anhydrides) compared with the bis(phthalic anhydrides) since the reactivity depends on the strain in the anhydride ring.

Table 6. Some characteristics of polynaphthoylenebenzimidazoles of general formula[62,63]



R	η_{inh}(H_2SO_4, 30 °C)	T_g, °C
	0.15	260
	0.20	260
	0.26	253
	0.30	269
	0.29	317

Values have been calculated for the positive charges on the carbonyl carbon atoms to determine the reaction centre primarily subject to nucleophilic attack.[113] In the bis(naphthalic anhydrides) containing electron-donating hinge groups a high positive charge q is characteristic of the carbonyl carbon atoms at positions 5 and 5′. In bis(naphthalic anhydrides) with electron-accepting hinge groups the high positive charge is a characteristic of the carbonyl carbon atoms in the 4 and 4′ positions.

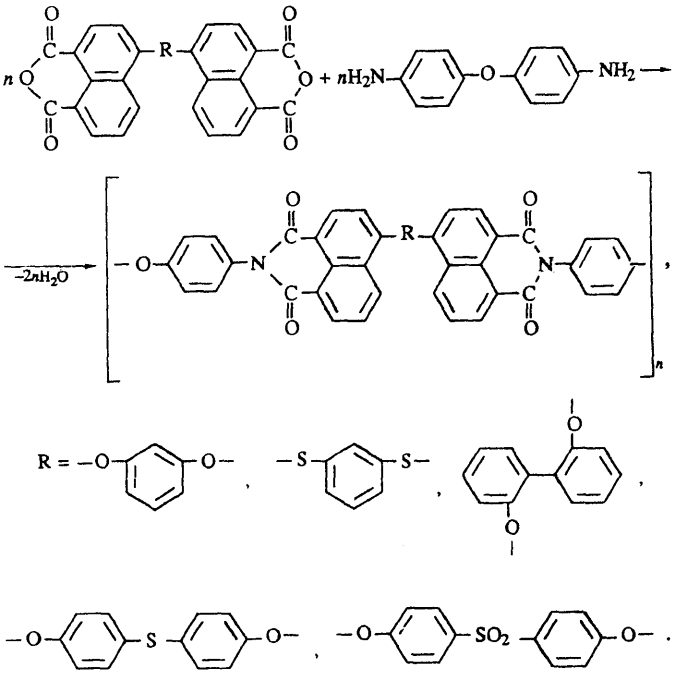
The fact that all the bis(naphthalic anhydrides) possess a lower reactivity than the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid points to the expediency of synthesising polyheteroarylenes from them using catalytic processes which are being used more in polycondensation and polycyclocondensation reactions.[115]

III. Polyheteroarylenes from bis(naphthalic anhydrides)

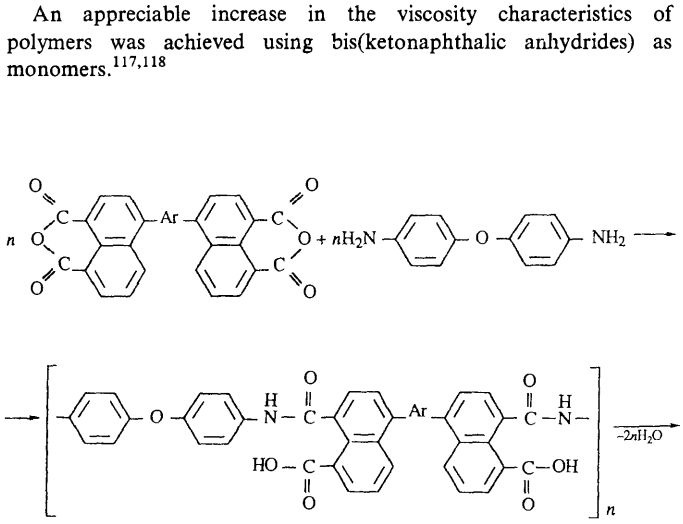
1. Polynaphthalimides

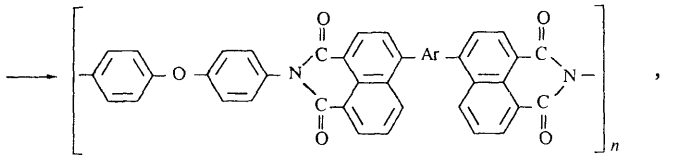
The majority of polynaphthalimides described in the literature are products of the reaction of naphthalene-1,4,5,8-tetracarboxylic acid with various diamines.[116] Several bis(naphthalic anhydrides) containing hinge groupings have been used for the synthesis of polynaphthalimides.

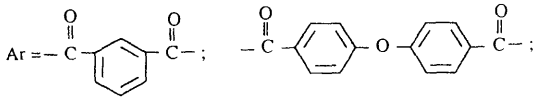
Polynaphthalimides containing ether and thioether groups, which are soluble in phenolic solvents, have been obtained by the reaction of ether- and thioether-containing bis(naphthalic anhydrides) with 4,4′-diaminodiphenyl oxide.[62,63] Reactions were carried out in *m*-cresol at 10% concentration (calculated on the final polymer) using quinoline or isoquinoline as catalyst. In contrast to the tougher polymer from the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid, which is precipitated from *m*-cresol at this concentration, the polyimides obtained were soluble in *m*-cresol up to 15% concentration though their molecular weights were fairly low (η_{inh} = 0.15–0.30 dlitre g^{-1}). The logarithmic viscosities and glass points of the polynaphthalimides synthesised are given in Table 6. Thermogravimetric analysis of the polymers showed the start of a mass loss at 450 °C in air and at 500 °C in a nitrogen atmosphere.

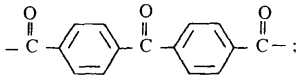


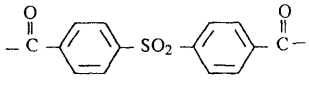
An appreciable increase in the viscosity characteristics of polymers was achieved using bis(ketonaphthalic anhydrides) as monomers.[117,118]





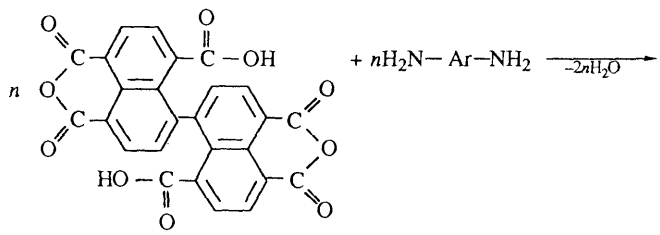


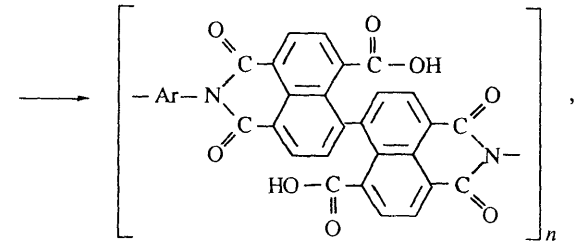


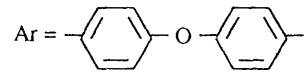


Synthesis of the polynaphthalimides was effected in *m*-cresol using benzoic acid as catalyst. The polynaphthalimides dissolved in H_2SO_4, phenolic solvents and mixtures of tetrachloroethane with phenol but polymers from dianhydrides containing ether bonds in the central group dissolved in tetrachloroethane as well. Some characteristics of the polynaphthalimides are given in Table 7.

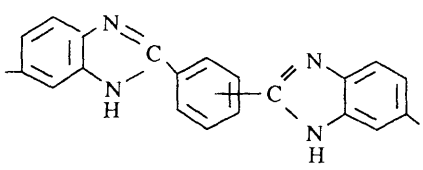
Polynaphthalimides containing free carboxyl groups were obtained by the reaction of the dianhydride of 1,1-dinaphthyl-4,4',5,5',8,8'-hexacarboxylic acid with 4,4'-diaminodiphenyl oxide and benzimidazole-containing aromatic diamines.[119–121]







$[\eta] = 1,4$

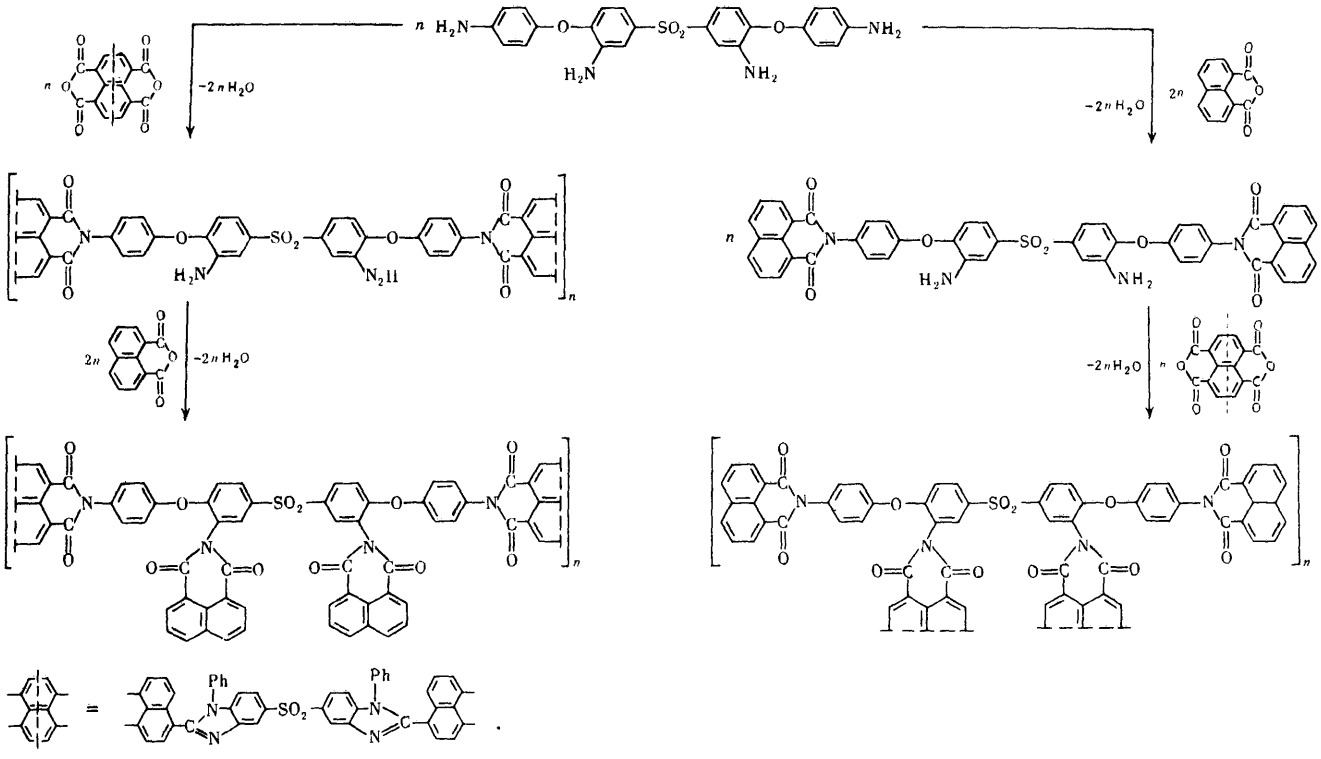


$[\eta] = 2,0$

High temperature (125–130 °C) polycyclocondensation was carried out in dipolar organic solvents with the addition of base. The polycondensation proceeds best of all in DMSO on adding sodium acetate in equimolar quantities. This is linked with the better solubility and stability of the monosodium salts formed at the strongly acidic carboxyl group of the dianhydride and the polynaphthalamide.[122] The remaining free carboxyl groups are probably catalysts of the polycyclocondensation process. The high molecular polynaphthalamides obtained dissolve readily in the presence of base in organic solvents (DMSO, DMAA) and in water. The polynaphthalimides do not soften until decomposition begins at 520–525 °C according to TGA (ΔT = 10 °C min^{-1}). When preparing polynaphthalimides in a chloride precipitating bath they form films and filaments with a strength up to 35 cN tex^{-1} and an elongation at break of up to 20%.

High solubility in organic solvents is also inherent of polynaphthalimides containing *N*-naphthylimide or *N*-(4-phenoxy)-naphthylimide substituents and which are synthesised as described[123]

by the following scheme:



Polynaphthalimides with *N*-naphthalimide *o*-substituents are obtained by the reaction of 3,3′-diamino-4,4′-di-(4-aminophenoxy)-diphenyl sulphone with an equimolar quantity of the bis(naphthalic anhydride) with subsequent treatment with two moles of the naphthalic anhydride under high temperature catalytic polycyclo-condensation conditions in *m*-cresol with benzoic acid. This polymer dissolves in phenolic solvents, in *N*-methyl-2-pyrrolidone (N-MP) and also in tetrachloroethane, it has a molecular weight of the order of 60000, softens at 340 °C and has a 10% weight loss temperature of 480 °C.

When the alternative sequence of adding mono- and dianhydride to the reaction is used a polynaphthalimide with even more bulky *N*-(4-phenoxy)naphthalimide *ortho* substituents is obtained which is soluble in a wide range of solvents, including those mentioned above and chloroform. The thermal characteristics of the polynaphthalimide synthesised were assessed from a thermomechanical curve and from dynamic TGA data and were comparable with the thermal characteristics of the polynaphthalimides with *N*-naphthalimide substituents (Table 8). The molecular weight of the synthesised polymer was of the order of 25000 but it was not possible to obtain films from it with satisfactory characteristics.

The high solubility of the systems obtained by both the first and second routes is seemingly determined by the lack of symmetry of the polymer molecules, by the presence of bulky side substituents, which aid its solubility by breaking up the polymer structure, and by the positive effect of the SO_2 group and the mild cyclisation conditions.

2. Polynaphthoylenebenzimidazoles

Significantly more attention has been paid to the polynaphthoylenebenzimidazoles based on the bis(naphthalic anhydrides) described above than to the polynaphthalimides. This is readily explainable even allowing for the fact that the bis(*o*-phenylenediamines), which are used to obtain the polynaphthoylenebenzimidazoles, are less accessible and more expensive than the aromatic diamines used in the synthesis of polynaphthalimides. The naphthoylenebenzimidazole ring is one of the most stable heterocycles (both thermally and hydrolytically),[124] and polynaphthoylenebenzimidazoles from naphthalene-1,4,5,8-tetracarboxylic acid dianhydride have been used successfully to obtain fibres with a unique set of properties.[125–135]

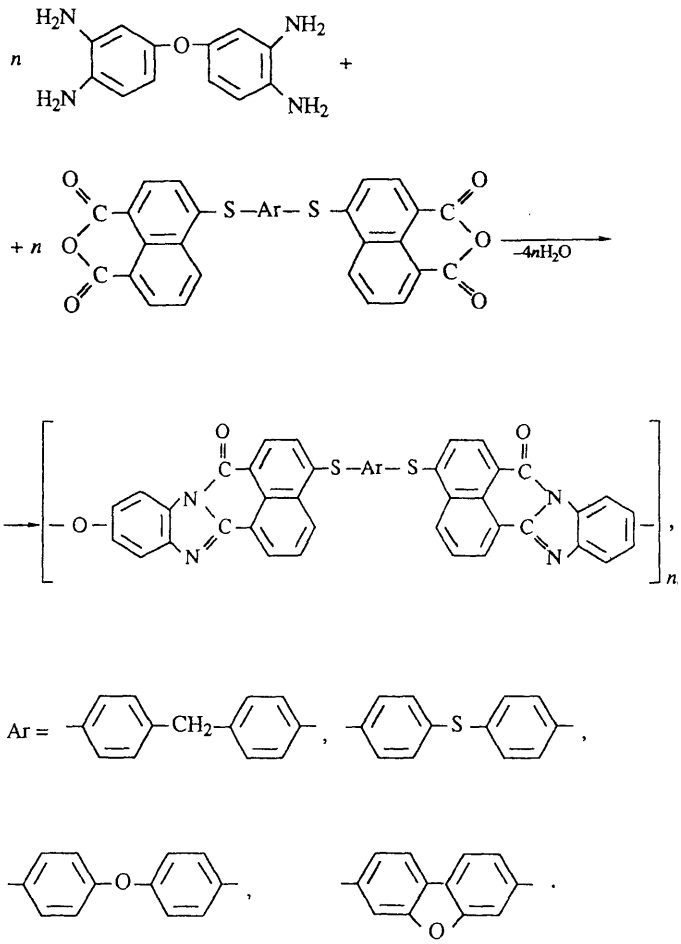
****+ signifies soluble, − insoluble, +/− partially soluble.

Sulphide-containing polymers were among the first to be synthesised among the polynaphthoylenebenzimidazoles from bis(naphthalic anhydrides) containing more than one hinge group.[55,73–76] These polymers were obtained by high temperature catalytic polycyclocondensation in *m*-cresol using benzoic acid as catalyst. The reaction proceeds as follows:



All the polycyclocondensations proceeded in solution (homogeneously) and led to the preparation of well cyclised polymers, the individual characteristics of which are given in Table 9.

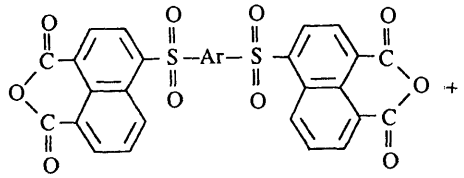
The sulphide-containing polynaphthoylenebenzimidazoles synthesised were soluble in H_2SO_4 and in phenolic solvents (*m*-cresol, phenol : tetrachloroethane mixture) which in conjunction with high temperatures for softening (T_{soft} = 310−380 °C) and decomposition (T_{dec} = 450−470 °C) determine the well-known practical value of these systems. At the same time all the sulphide-containing polynaphthoylenebenzimidazoles have low viscosity characteristics (η_{red} = 0.4−0.9 dlitre g^{-1}) which do not permit materials with usable deformational strength characteristics to be obtained from them.

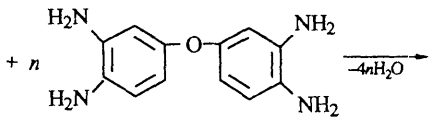
Table 8. Some characteristics of polynaphthalimides of general formula

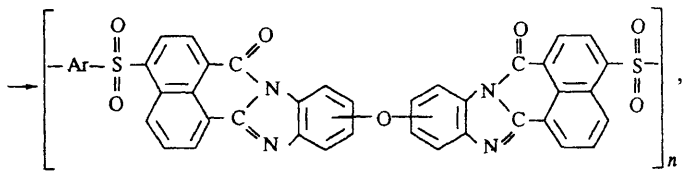
	$\bar{M}^*_w$	T_{soft}, °C	$T_{10\%}$, °C	Solvent			
				N-MP	*m*-cresol	TCE	$CHCl_3$
	25.000	340	480	+	+	+	+
	60.000	340	480	+	+	+	–

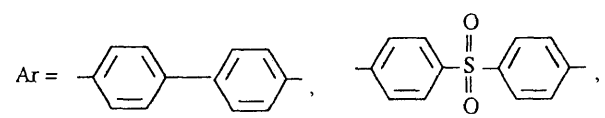
*Determined by sedimentation equilibrium.

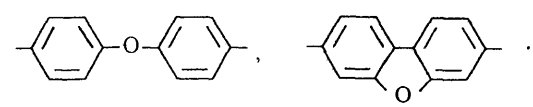
The low viscosity and corresponding molecular weight characteristics of the sulphide-containing polynaphthoylenebenzimidazoles may be due to the presence of the electron-donating sulphide groups in the initial bis(naphthalic anhydrides) which determines the reduced electrophilic reactivity of these monomers. With the aim of increasing the latter, attempts were undertaken to obtain polynaphthoylenebenzimidazoles using bis(naphthalic anhydrides) containing at least two sulphonyl groups in the molecule.[55,73–76]











These systems were synthesised by high temperature catalytic polycyclocondensation in *m*-cresol using benzoic acid as catalyst as in the preparation of the polynaphthoylenebenzimidazoles from sulphide-containing bis(naphthalic anhydrides).[55,73–76]

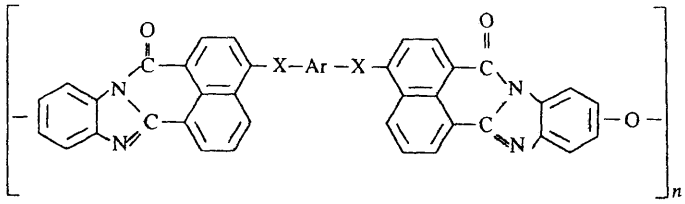
All the reactions for polyheteroarylene synthesis with the exception of processes using the dianhydride of 4,4′-bis(1,8-dicarboxynaphthalene-4-sulphonylphenyl) sulphone took place under homogeneous conditions and led to the preparation of the desired polyheteroarylenes in close to quantitative yield.

Some characteristics of the synthesised polynaphthoylenebenzimidazoles are given in Table 9.

The synthesised polynaphthoylenebenzimidazoles are more soluble than the polymers of this class obtained previously from 4,4′-sulphonylbis(naphthalic anhydride),[55] which indicates the positive effect of the introduction of a second sulphonyl group into the dianhydride and correspondingly into the main chain of the macromolecule. An exception is the polymer with three sulphonyl groups in the chain. The lack of solubility of this polynaphthoylenebenzimidazole in the solvents listed is explained by its crystallinity which was 20–30% according to X-ray data.

On the other hand the polynaphthoylenebenzimidazoles containing two or more sulphonyl groups were less soluble than the analogous systems containing sulphide groups.

Table 9. Some characteristics of polynaphthoylenebenzimidazoles of general formula[73–76]



Ar	X	η_{red}, dlitre g^{-1} (25 °C)		T_{soft}, °C	$T_{10\%}$, °C
		H_2SO_4	TCE, phenol		
	—S—	0.4	0.5	330	450
	—S—	0.5	0.5	310	470
	—S—	0.8	0.7	330	460
	—S—	-	0.4	380	460
		0.4	-	380	430
		0.4	-	-	400
		-	0.3	350	420
		0.4	-	370	410

The low viscosity characteristics of the polymers, which are somewhat unexpected for systems based on dianhydrides activated by sulphonyl groups, are probably explained by the occurrence of side reactions breaking the naphthoylenebenzimidazole rings by *o*-phenylenediamine fragments of the monomers or by the end groups of the growing chains of the macromolecule.

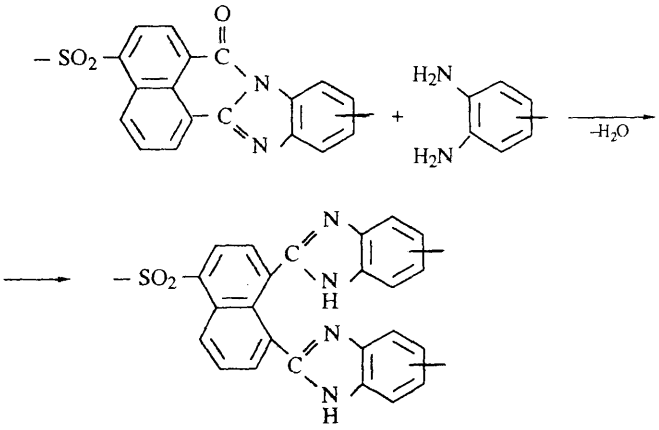


Table 10. Reduced viscosities of polynaphthoylenebenzimidazoles of formula

*η_{red} was measured in tetrachloroethane : phenol mixture at 25 °C.

This hypothesis is in complete agreement with the concept of a correlation between the electrophilic reactivity of the initial anhydrides and the sensitivity of the desired carbonyl-containing heterocycles towards hydrolysis and the action of nucleophilic reagents.[136] The same circumstance determines the low thermal stability of the synthesised polynaphthoylenebenzimidazoles during TGA in air. As is seen from Table 9 the 10% weight loss temperature was 400–430 °C under these conditions. The

unsatisfactory properties of the synthesised polyheteroarylenes indicates the inexpediency of using bis(naphthalic anhydride) systems containing sulphonyl groupings bound directly to the anhydride rings.

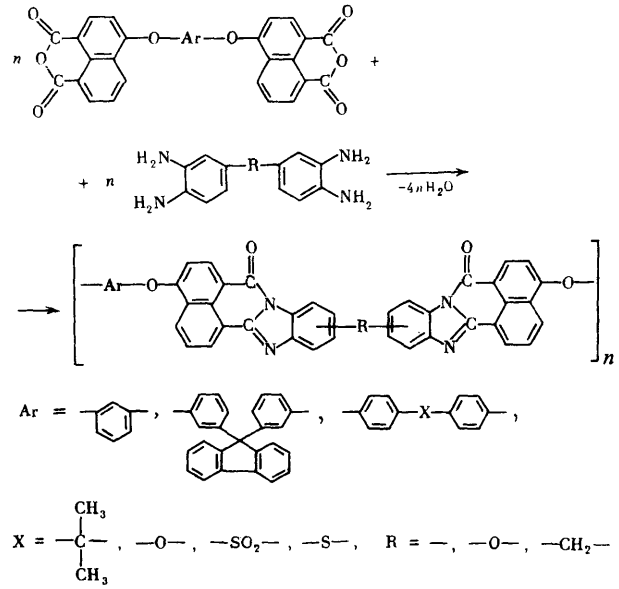
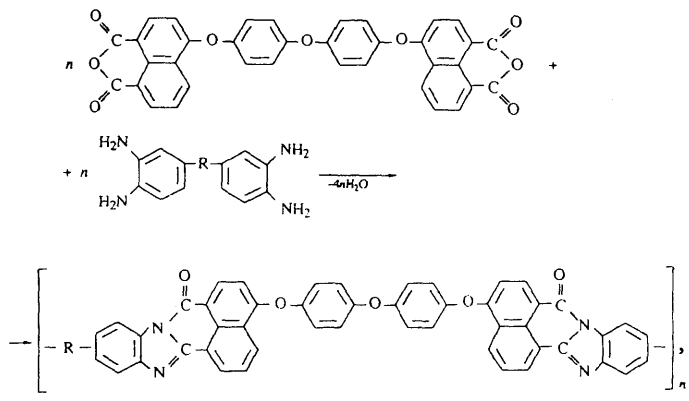
Significantly better results were obtained in the synthesis of polynaphthoylenebenzimidazoles from bis(naphthalic anhydrides) containing ether bonds.[65–68] These reactions were effected under conditions traditional for the synthesis of similar systems, viz. high temperature polycondensation in *m*-cresol using benzoic acid as catalyst,[65] and in other solvents[137] (mixtures of *m*-cresol with polyphosphoric acid, *m*-cresol with di-*m*-cresyl phosphate, *m*-cresol with P_2O_5, phenol with P_2O_5 and *p*-chlorophenol with P_2O_5).



The best of the systems studied proved to be *m*-cresol with P_2O_5 which is particularly obvious from the comparative data given in Table 10 on the viscosity characteristics of the polynaphthoylenebenzimidazoles obtained in mixtures of *m*-cresol with P_2O_5 and *m*-cresol with benzoic acid.[137] Nevertheless the polynaphthoylenebenzimidazoles synthesised in other solvents and particularly in a mixture of *m*-cresol and benzoic acid possessed viscosity characteristics (Table 11) and molecular weights which are sufficiently high for obtaining strong and elastic films (Table 12) possessing interesting electrical and physical properties.

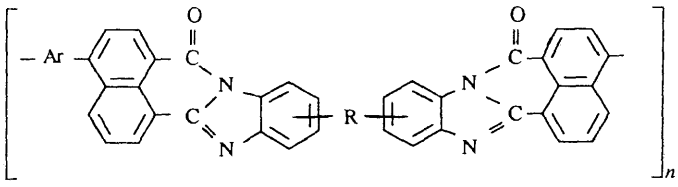
The thorough investigations on the thermal,[138] dynamic, mechanical[138] and relaxation[139,140] characteristics of the polynaphthoylenebenzimidazoles of this series showed that these systems are of significant practical interest.

A logical evolution and continuation of the studies in this field is the development of polynaphthoylenebenzimidazoles from the dianhydride of 4,4′-epoxybis[(*p*-phenyloxy)dinaphthalene-1,1′,8,8′-tetracarboxylic acid].[71] Reaction of this with bis(*o*-phenylenediamine), 3,3′,4,4′-tetra-aminodiphenyl oxide, 3,3′,4,4′-tetra-aminodiphenylmethane and 3,3′-diaminobenzidine occurred according to the following scheme:



under conditions of high temperature catalytic polycyclisation in phenolic solvents. All the reactions in the synthesis of the polynaphthoylenebenzimidazoles proceeded from beginning to end under homogeneous conditions and led to the formation of polymers with moderate viscosity characteristics (Table 12).

Table 12. Properties of films based on polynaphthoylenebenzimidazoles of general formula



Ar	R	Mechanical properties, 25 °C		Electrical properties

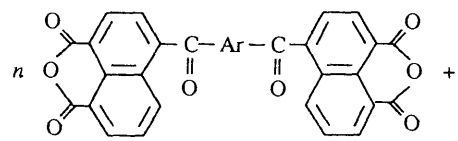
	–O–	1110	80	3	1.4
	–	950	70	6	0.94
	–O–	980	113	1	1.6

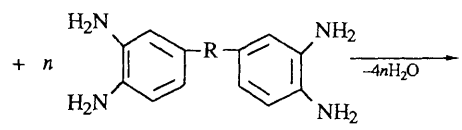
*ρ is the bulk resistance, **tan δ is the loss factor.

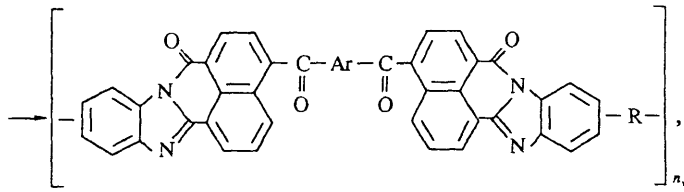
The introduction of an additional oxygen atom did not lead to an improvement in polymer solubility. The polymers were soluble in acidic and phenolic solvents but were insoluble in DMSO and N-MP.

Comparison of the softening temperatures and the region of marked thermal destruction indicated that these polymers may be successfully processed into objects by pressing.

Polynaphthoylenebenzimidazoles based on aroylene-bis(naphthalic anhydrides) are of significant interest and are obtained according to the following scheme:[77,80,81]





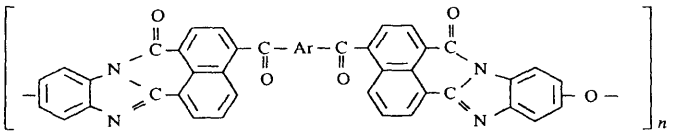


R = –, –O–, $-SO_2-$, $-C(CF_3)_2-$, $-CH_2-$;

Ar = 
X = 
The synthesis of these polynaphthoylenebenzimidazoles was effected by high temperature polycondensation in *m*-cresol using benzoic acid as catalyst. All the reactions to synthesise polynaphthoylenebenzimidazoles occurred in a homogeneous manner and led to the preparation of fully cyclised high molecular polymers. Some characteristics of the polynaphthoylenebenzimidazoles based on aroylene-bis(naphthalic anhydrides) and 3,3',4,4'-tetra-aminodiphenyl oxide are given in Table 13.

As is evident from the data of Table 13 the polynaphthoylenebenzimidazoles synthesised are soluble in H_2SO_4 and in phenolic solvents. The molecular weights of the polymers were sufficiently high to make stable films from them and the decomposition temperature (490–550 °C) was sufficiently large for these polymers to be processed into objects by pressing.

Table 13. Some characteristics of polynaphthoylenebenzimidazoles of general formula[77,80,82–84]



Ar	η_{red}, dl litre g^{-1} (H_2SO_4)	T_{soft}, °C	$T_{10\%}$, °C	Solvent				Film properties, 25 °C

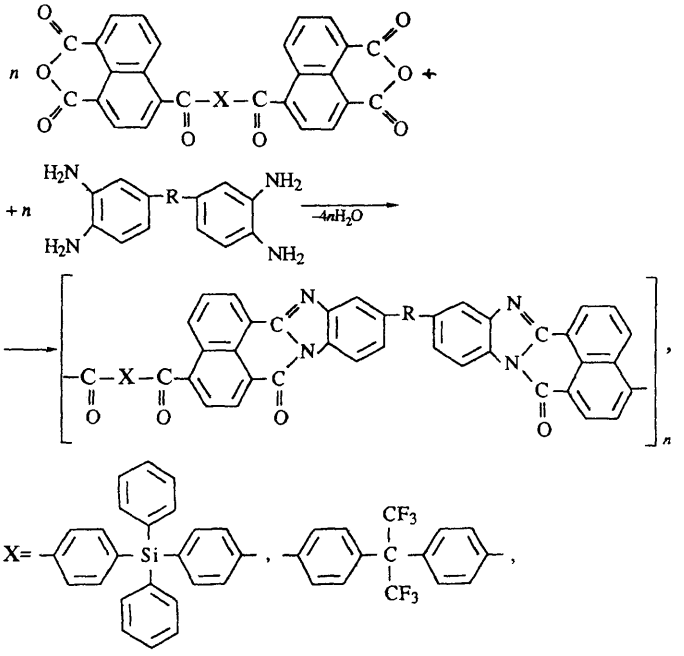
	0.53	–	490	+/–	+	+	–	–	–
	1.80	360	545	+	+	+	–	1080	13
	1.57	375	550	+	+	+	–	920	10
$-CB_{10}H_{10}C-$	0.40	–	550	+	+	+	+	–	–

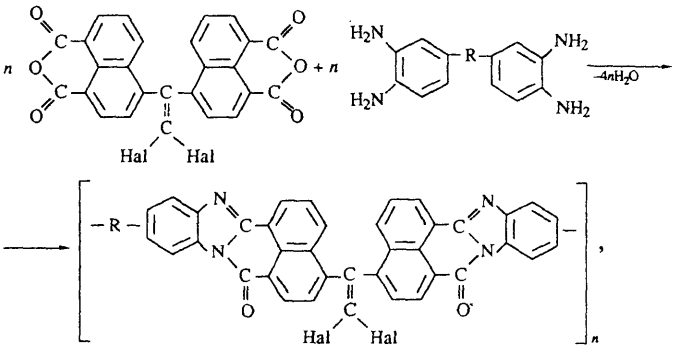
Even better solubility was a characteristic of the polynaphthoylenebenzimidazoles based on bis(naphthalic anhydrides) with a heteroorganic central group, such as hexafluoroisopropylidene,[82,84] diphenylsilyl[83,84] and *m*-carboranylene.[82,84] These polymers were synthesised by the following scheme:



$-CB_{10}H_{10}C-$, R = –, –O–.

The synthesis of these polymers was effected by high temperature catalytic polycyclocondensation in *m*-cresol using benzoic acid as catalyst. Some characteristics of the polynaphthoylenebenzimidazoles containing heteroorganic central groupings are given in Table 13. The introduction of diphenylsilyl and hexafluoroisopropylidene groups led only to a quantitative increase in the solubility of the polynaphthoylenebenzimidazoles in phenolic solvents[82–84] while the introduction of the *m*-carboranylene group into the macromolecule was accompanied by conferment of solubility in N-MP to the polymer.[83,84]

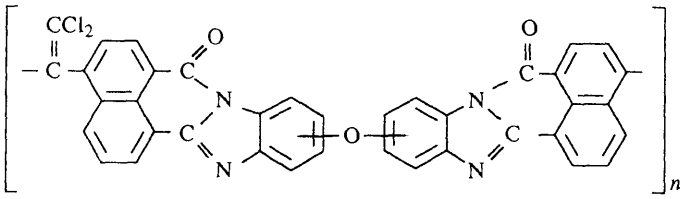
The introduction of the 1,1-dichloroethylene and 1,1-dibromoethylene groups into the macromolecule by the use of the appropriate bis(naphthalic anhydrides) has an extremely important effect on the properties of the polynaphthoylenebenzimidazoles.[111,112,141]



R = –, –O–, ; Hal = Cl, Br.

The synthesis of polynaphthoylenebenzimidazoles with 1,1-dichloroethylene and 1,1-dibromoethylene bridge groups[77,80,111,112,141] was effected in *m*-cresol with benzoic acid fulfilling the function of catalyst. In every case the synthesis of the polynaphthoylenebenzimidazoles took place homogeneously and led to the formation of fully cyclised and in some cases high molecular systems.

Table 14. Viscosity and molecular weight characteristics of polynaphthoylenebenzimidazoles of formula[141]

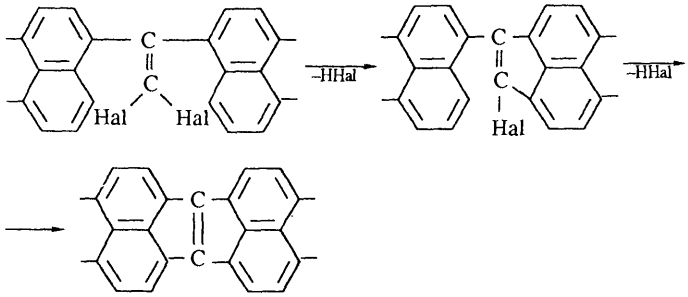


η_{sp}, H_2SO_4, 25 °C	10^{-3}M
0.39	33
0.73	80
0.98	108
1.14	117

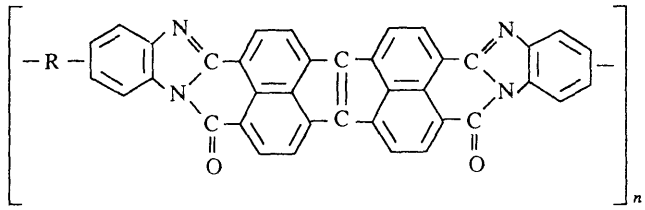
Comparison of the viscosity and molecular weight characteristics[142] of one of the similar polynaphthoylenebenzimidazoles is shown in Table 14.

Some characteristics of the synthesised polynaphthoylenebenzimidazoles containing 1,1-dihaloethylene groups are given in Table 15. It follows from an analysis of these data that all the polynaphthoylenebenzimidazoles synthesised are soluble in sulphuric acid and in phenolic solvents. High softening temperatures and high decomposition points under conditions of dynamic TGA are characteristic of the majority of these systems.

Under conditions of isothermal storage at temperatures exceeding 300 °C all the polymers considered underwent significant weight loss mainly with evolution of hydrogen halide. Among the alternative dehydrohalogenation reactions, monomolecular and intramolecular, the latter is more probable since in the heat treatment process the polymers do not lose their solubility in H_2SO_4. In view of the high lability of the peri protons[143] it might be suggested that the most probable course for the dehydrohalogenation is that expressed by the following scheme:



Similar 'naphtho-(9,10)-acenaphthyl' structures have been described in the literature.[144] When applied to the polymers their formation may lead to a new highly condensed system of general formula



which enables the results obtained to be considered as a new approach to the synthesis of ladder or double-chain polymers.[26,27]

Table 15. Some characteristics of polynaphthoylenebenzimidazoles of general formula

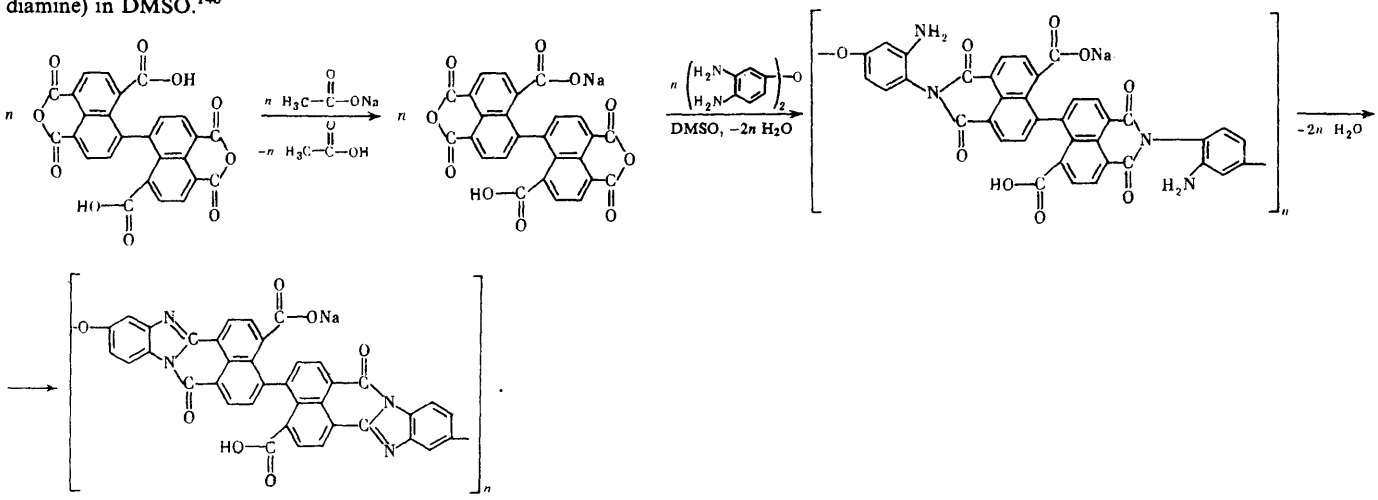
-O-	$-C(=CBr_2)-$	0.30	380	490	+	+	+

In appearance the polymers based on 1,1'-bisnaphthyl-4,4',5,5',8,8'-hexacarboxylic acid[145–148] are systems extremely close to the polynaphthoylenebenzimidazoles containing 1,1-dihaloethylene groups.

The polynaphthoylenebenzimidazole based on 3,3',4,4'-tetraaminodiphenyl oxide and the dianhydride of 1,1'-binaphthyl-4,4',5,5',8,8'-hexacarboxylic acid has been studied in most detail. The optimum method of synthesising this polymer is the reaction of the

monosodium salt of the acid component with the bis(*o*-phenylenediamine) in DMSO.[146]



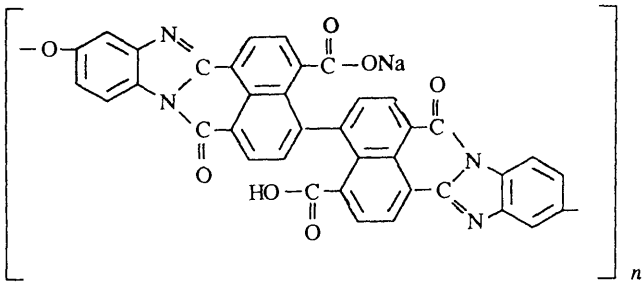
As a result of the increased basicity of the tetramine compared with the diamines[149] the reaction to prepare the polynaphthoylenebenzimidazole took 3–5 h at 115–120 °C, i.e. was more rapid than the synthesis of the polynaphthalimides, leading to the preparation of a polymer with $[\eta] \geqslant 1.3$ dlitre g^{-1}. Carrying out the synthesis of the polynaphthoylenebenzimidazole at higher temperatures led to gel formation and an increase in polymer viscosity.

This polynaphthoylenebenzimidazole dissolved in organic solvents only on addition of concentrated alkali solutions (10% KOH). After precipitation in an acid bath the polymer underwent 10–15% destruction.

Stable films were obtained by drying solutions of the monosodium salts of the polynaphthoylenebenzimidazole. The formation of fibres took place in a stable manner in baths of composition DMSO–water–conc. HCl.

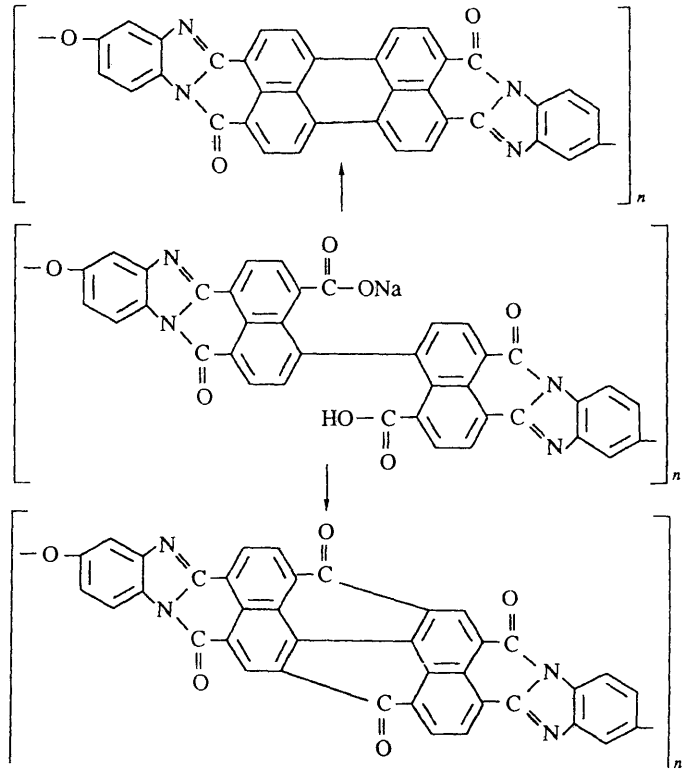
Significant attention has been paid to the product of converting polynaphthoylenebenzimidazole into perylene-[147] and anthanthrone-containing[148] systems.

Table 16. Characteristics of the threads and elementary fibres from the initial polynaphthoylenebenzimidazole



and of the products of its chemical and thermal cyclisation.

Characteristic	Initial polymer	Chemical cyclisation products		Thermal treatment product
		perylene-containing	anthanthrone-containing	
σ_{thr}, sR tex^{-1}	20–25	7	12	20–25
Elongation to break thread, %	20–25	13	15–27	15–30
Tensile strength *E*, GPa	5.7	–	–	6.9
T_{dec}, °C				
in air	530	540	550	550
in inert medium	600	610	620	610
Zero tensile strength temperature T_0, °C	580	–	–	630
OI, %	–	–	–	65



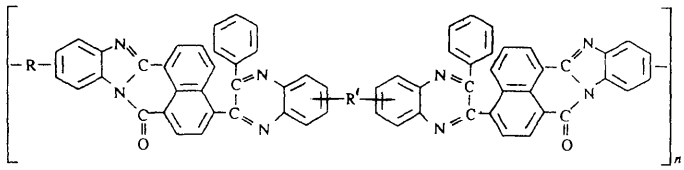
In order to convert the initial polynaphthoylenebenzimidazole into a perylene-containing structure it was decarboxylated in 10% KOH solution (attempts to prepare a 1% solution of the polymer in a less alkaline medium were unsuccessful). The conversion of the dicarboxydinaphthyl into perylene fragments produced 70% but [η] for the polymer solutions reached 0.8 dlitre g^{-1} which is significantly greater than the viscosity of the polynaphthoylenebenzimidazoles from the dianhydride of perylene-3,4,9,10-tetracarboxylic acid.[150,151]

A cyclisation reaction with H_2SO_4 was used to convert the initial polynaphthoylenebenzimidazole into an anthranthrone-containing structure. The process proceeded efficiently in 2% oleum at 40 °C giving 80% cyclisation after 2 h and the reduction of [η] of the polymer did not exceed 0.1 dlitre g^{-1}.

In addition to cyclisation by alkaline and acidic reagents the highly condensed systems may be obtained by thermal treatment of the initial polynaphthoylenebenzimidazoles in an inert medium. Not only was cyclodehydration observed but in addition cyclodecarboxylation processes occurred as a result of which the thermally treated systems contain both perylene and anthanthrone rings. Thermal treatment is the optimum method of cyclisation of polynaphthoylenebenzimidazole fibres which is confirmed by the data of Table 16.

The products of thermal treatment of the initial polynaphthoylenebenzimidazole exceed the threads 'Arimid-PM' and 'LOLA' in the magnitude of the oxygen index (OI). In decomposition point they are superior to 'LOLA' however they are inferior to it in thermal stability assessed by heat treatment and are inferior to 'Arimid-PM' threads in strength. Polynaphthoylenebenzimidazoles soluble in organic solvents were obtained by the reaction of various bis(*o*-phenylenediamines) with bis(naphthalic anhydrides) containing phenylquinoxaline rings[88,90] according to the following scheme:

Table 17. Some characteristics of polynaphthoylenebenzimidazoles of general formula



R	R'	η_{red}, dlitre g^{-1} (H_2SO_4, 25 °C)	T_{soft}, °C	$T_{10\%}$, °C	Solvent			Film properties, 25 °C	
					m-cresol	TCE: phenol	phenol	σ, kg cm^{-2}	ε, %
–	–O–	1.4	340	455	+	+	+/–	1020	18
–O–	–O–	2.1	320	470	+	+/–	+/–	950	24
$–CH_2–$	–O–	1.0	320	455	+	+	+/–	1080	20
$–SO_2–$	–O–	0.8	340	460	+	+	+/–	990	20
–	$–SO_2–$	1.6	360	480	+	+	+/–	1100	20
–O–	$–SO_2–$	2.3	340	470	+	+	+	1300	25

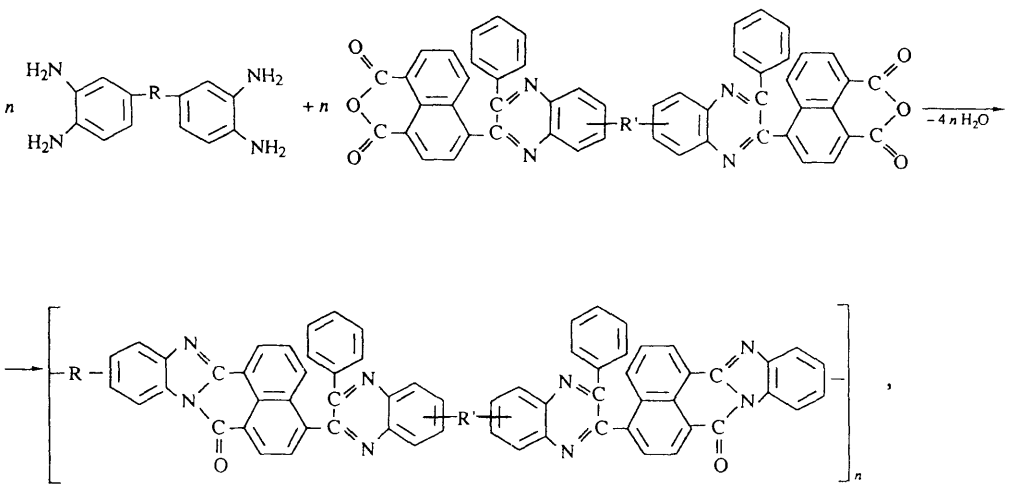
$–SO_2–$	$–SO_2–$	0.4	350	490	+	+	+/–	980	23

The synthesis of these polynaphthoylenebenzimidazoles was effected in *m*-cresol using benzoic acid as catalyst. The polycondensation reaction occurred in a homogeneous manner and led to the formation of high molecular (Table 17) polymers with a high degree of cyclisation.



R = –, –O–, $–CH_2–$, $–SO_2–$; R' = –, –O–, $–CH_2–$, $–SO_2–$

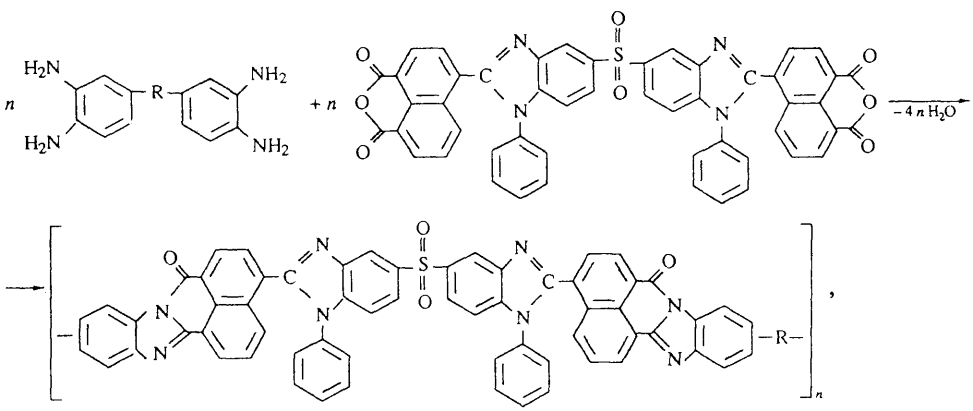
Polynaphthoylenebenzimidazoles based on other bis(naphthalic anhydrides) containing phenylquinoxaline rings also possess characteristics closely similar to those given in Table 17.

These systems combine high (350 ± 20 °C) softening temperatures with high viscosity characteristics (sufficient for reliable film formation) and solubility in organic solvents. It must however be noted that these polymers are only soluble in phenolic solvents or mixtures of the latter with halogenated hydrocarbons. From this point of view there is considerable interest in polynaphthoylenebenzimidazoles obtained from bis(*o*-phenylenediamines) and bis[1-phenyl-2-(1,8-dicarboxynaphth-4-yl)benzimidazol-5-yl] sulphone[152] by the following scheme:



R = R = –, –O–, $-CH_2-$, –CO–, $-C(CF_3)_2-$.

The polynaphthoylenebenzimidazoles were synthesised in *m*-cresol using benzoic acid as catalyst at 160–190 °C. The polycondensation reactions were carried out under homogeneous conditions and led to the formation of the desired polymers possessing high viscosity characteristics (Table 18) and a high degree of cyclisation.

A distinctive feature of the polynaphthoylenebenzimidazoles considered is their solubility in N-MP which is a most acceptable solvent.

It is interesting to note that the polynaphthoylenebenzimidazoles are more soluble than the corresponding polynaphthalimides which is explained by the presence in their molecules of a 'pyridine' nitrogen atom[153,154] which is readily protonated (being the first stage of the solution of these polymers in protogenic solvents) and also by the amorphous nature of these systems caused by the presence in them of a broad set of isomeric structures.[153,154]

- - - o0o - - -

Analysis of the data given in this review indicates the emergence during the last two decades of many new accessible bis(naphthalic anhydrides) characterised by the presence in their structures of elements determining improved solubility (and general processability) of the polyheteroarylenes based on them. The bis(naphthalic anhydrides) containing ether groups may be used for preparing systems related to the polyesterimides but differing from them in a higher glass point. At the same time the majority of the new bis(naphthalic anhydrides) may be used for preparing new polynaphthoylenebenzimidazoles combining satisfactory processability with very high thermal, fire and chemical resistance.

Stereoelectronic effects in silicon, phosphorus, and sulphur molecules. Quantum-chemical calculations and qualitative orbital models

A A Korkin
Institute of Physiologically Active Substances, Russian Academy of Sciences, Chernogolovka

ABSTRACT. The results of non-empirical quantum-chemical calculations for silicon, phosphorus, and sulphur compounds of different structure are discussed. Qualitative orbital models, which establish a relation between the distribution of electrons and molecular structure and properties, are analysed. A general definition of stereoelectronic effects is presented.

The bibliography includes 176 references.

I. Introduction

The comparative study of the structure and the electronic and energetic characteristics of silicon, phosphorus, and sulphur molecules has been traditional in quantum chemistry in view of the existence of many similar relations, problems, and trends in the chemistry of these elements.[1–23]

The concept of the "stereoelectronic effect" is widely used in both experimental and theoretical studies in organic and organoelement chemistry.[24–31] Until recently, stereoelectronic effects were indissolubly linked to ideas concerning hyperconjugation in its broad interpretation, involving the interaction of lone pairs (LP) with unoccupied σ^* and π^* orbitals. The need to introduce a general concept is associated with the fact that it has been quite firmly established that conformational effects are common to different classes of compounds.[24,32–34] The stability of certain conformations, the changes in the structural parameters and relative reactivities in a series of related compounds, as well as other characteristics can be explained in many instances and treated systematically on the basis of models which include as the initial postulates the "classical" ideas concerning localised electron pairs with allowance for the interaction between these pairs and the antibonding orbitals of neighbouring, mainly vicinal bonds. Deslongchamps[24] defined stereoelectronic effects as "the stereochemistry of particular electron pairs—bonding and anti-bonding".

It is quite evident, however, that, if one considers particular electron pairs as localised pairs, then, within the framework of the above definition, one can discuss only the molecular characteristics which have come to be referred to as cooperative: energies, dipole moments, polarisabilities, vibration frequencies in spectra, structural parameters, etc. We emphasise the term "have come to be referred to as cooperative" because one-electron characteristics such as ionisation potentials, electron affinities, and electronic transition energies are also in essence functions of the entire multielectron system of the molecule. However, the one-electron characteristics and different "effects" coupled with them are not embraced by the definition of "stereoelectronic effects" if the latter are considered within the framework of the model of localised electron pairs, because one-electron characteristics are determined by the properties of delocalised molecular orbitals or, more rigorously, by the behaviour of an individual electron in the field of other electrons and nuclei of the molecule (see also Dewar[35]).

If one abandons the idea that the isolated electron pairs should be regarded from the start as localised, then the definition of stereoelectronic effects includes also the energetic and spatial changes in the frontier molecular orbitals, which occur when the molecular conformations change, this being manifested in the electronic,[36] photoelectron,[37] and X-ray electronic[38] spectra.

In the present review, we shall discuss the literature data in the context of a broader definition (compared with that given by Deslongchamps[24]), in which the stereoelectronic effect is understood as the "deviations of the characteristics of molecules from the values predicted by the base model which can be explained as a result of disregarded interactions and represented in the form of fine details of the spatial distribution of electrons".[39] This definition includes explicitly the concept of the "base model", whose equivalent in the Deslongchamps definition is "isolated electron pairs". Base models can be different in the work of different workers depending on the selected method of study and the ideas concerning the structure and properties of molecules, so that in certain cases it is important to consider beforehand the initial postulates (null approximation) on the basis of which the orbital models of stereoelectronic effects are constructed.

Orbital models of molecules with participation of Third Period atoms are constructed as a rule on the basis of analogous models of the structural analogues, including atoms of the Second Period referring to the same Group in the Periodic Table. Here account is taken of the difference between the electronegativities, the sizes of the valence orbitals, and the presence of the *d* shell in the Third Period atoms.

On passing from the Second to the Third Period, the difference between the energies of the valence *s* and *p* orbitals diminishes, which should promote the hybridisation of the atomic orbitals. However, the opposite trend, caused by the increase in the size of the atoms and in the difference between the radii of the 3*s* and 3*p* orbitals, exerts a greater influence.[17] The presence of 2*p* electrons in

the inner layer results in a greater size of the valence 3*p* orbitals than that of the 3*s* orbitals, which lowers in its turn the effectiveness of hybridisation.[40] The relative increase in the size of the 3*p* orbitals makes the 3*s* orbital "quasi-inner" and, in the presence of non-bonding electron pairs in the atom, the latter are predominantly of the *s* type (see, for example, Magnusson[41] and Korkin[42,43]). Accordingly, the contribution of *p* electrons predominates in the bonding electron pairs. The stabilisation of the "non-hybridised" state of the Third Period atoms is associated also with increase in the size of the atom and decrease of the repulsion of the ligand and the geminal electron pairs, which leads to a smaller steric strain of the bond angles formed by the "pure" *p* orbitals (~90°).

The above differences in the nature of the orbitals of the Second and Third Period atoms make it possible to explain the characteristic features of the structure and chemical properties of silicon, phosphorus, and sulphur compounds. The aim of the present review is to discuss the general trends and the comparative aspects in the development and use of orbital ideas in the chemistry of these elements. We did not attempt to embrace all the available publications on calculations for the silicon, phosphorus, and sulphur molecules. Their number is very great, which undoubtedly reflects the interest of theoreticians in this field. The review deals to a greater extent with studies in which comparative calculations are presented for silicon, phosphorus, and sulphur molecules in relation to one another and in relation to their structural analogues (carbon, nitrogen, and oxygen) and the results obtained are discussed in the language of qualitative orbital models.

II. *d* Orbitals in the chemistry of silicon, phosphorus, and sulphur

The question of the role of *d* orbitals occupies a special place in the theoretical chemistry of non-transition elements. In order to account for the structure and stability of highly coordinated molecules, Pauling[12,44] put forward the hypothesis of the involvement of *d* orbitals in the formation of hybrid atomic orbitals (sp^3d, sp^3d^2). However, whereas in the case of transition metal atoms one is concerned with the hybridisation of *ns*, *np*, and $(n-1)d$ orbitals which have similar energies, the excitation of an electron to the 3*d* shell in the silicon, phosphorus, and sulphur atoms requires an energy of the order of 10 eV, which is close to the ionisation potential of 3*p* electrons.[17,45] In neutral atoms the 4*s* orbitals have lower energies under these conditions than the 3*d* orbitals by an amount of the order of 2eV.[46] When electrons are abstracted, the energy of the 3*d* orbitals decreases to a greater extent than that of the 4*s* orbitals and in the dication M^{2+} the positions of the 4*s* and 3*d* orbitals are reversed.[46] The abstraction of electrons is accompanied by a decrease in the diffuseness of the 3*d* orbitals and their sizes approach those of the valence 3*s* and 3*p* orbitals.

The increase in the coordination number and the increase in the electronegativity of the substitutuent entail an increase in the effectiveness of the charge on the central atom. In this case, as in ionisation, the effective charge of the 3*d* orbitals diminishes and their population increases.[1,17,47]

The fraction of electrons occupying *d* orbitals depends not only on the molecular structure but also on the initial basis set and the exponents of the Gaussian or Slater functions. Since the *d* orbitals of silicon, phosphorus, and sulphur atoms in the ground state are unoccupied, the choice of the exponents of the *d* functions is usually made by optimising the energies of a series of molecules.[47,48] Depending on the nature of the problem and the computational facilities available to the investigator, the *d* orbitals are added to all the atoms of the Second and Third Period or only to those of the Third Period (for further details, see Clark[49]).

The question arises whether one should consider the *d* orbitals of silicon, phosphorus, and sulphur atoms as "normal" valence orbitals, as in the case of transition elements, or as polarisation functions. This problem has been discussed to some extent in numerous publications devoted to non-empirical calculations for silicon, phosphorus, and sulphur molecules. In the general case, an unambiguous answer is apparently not available to this question, because, firstly, the role of the *d* orbitals depends significantly on the molecular structure and the nature of the characteristic investigated and, secondly, the very concept of "valence orbital" permits different interpretations.

Comparative non-empirical calculations in terms of *sp* and *spd* basis sets have shown (see, for example, Refs. 1, 2, 6, and 48–50) that the influence of the *d* orbitals on different molecular characteristics increases with increase in the coordination number of the atom, but the populations of the *d* orbitals are then much smaller than the values which are attributed to the sp^3d^n hybridisation and do not exceed 0.3 of an electron even for SF_6.[51]

The influence of *d* orbitals on molecular geometry has been studied most thoroughly. Calculations using the 3-21G* and 6-31G* basis sets make it possible to determine the bond lengths and bond angles, on average, to within 0.01 Å and 1° respectively,[48] while the 3-21G and 6-31G basis sets lead to much too high bond lengths. This applies to both single bonds in molecules of the type PF_5 or SF_6 and to semipolar or multiple bonds of the type of the phosphoryl or sulphoxide bonds, for example, in the F_3PO and F_2SO_2 molecules. The multiplicity of the P=O abnd S=O bonds in these molecules is due to the reverse transfer of electron density from the O atom to the P or S atom, the contribution of *d* orbitals in this bond not exceeding 25%.[1,52]

The majority of conformational effects in silicon, phosphorus, and sulphur molecules can be described satisfactorily at a qualitative level also without taking into account *d* orbitals, within the framework of hyperconjugation ideas (see the next Section), but the quantitative results as a rule agree best with experimental data when account is taken of *d* orbitals.[48] Exceptions may arise as a consequence of the cancelling of errors due to the incompleteness of the basis set and failure to take into account correlation effects. The presence or absence of *d* orbitals in the basis set can alter the relative stabilities of conformations, but their role is then related to non-specific electrostatic and van der Waals interactions, which depend on bond lengths, bond angles, and electron populations of the atoms.[53–62] For example, allowance for 3*d* orbitals lead indirectly to an increase in the relative stability of the *cis*-conformation of the H_2NSH molecule, because the nitrogen atom becomes less pyramidal,[59] and to a decrease of the relative stabilities of the eclipsed conformation of methyl alcohol and of its S, Se, and Te analogues as a result of the increase in the steric repulsion caused by the decrease in the C–X bond length.[61] The overall populations of *d* orbitals depend only slightly on the molecular conformations.[62]

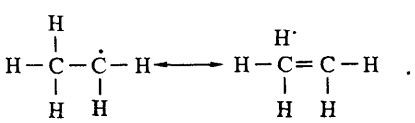
The inclusion of *d* orbitals in the basis set improves the quantitative description of electronic characteristics such as the dipole moments and ionisation potentials. Since, as already mentioned, the bond lengths calculated in terms of *sp* basis sets exceed the experimental values, dipole moments are also found to be too high.[48,62] The electronic characteristics associated with direct electron transfer to unoccupied orbitals, such as UV spectra[63,64] and

electron affinity,[65,66] are more sensitive to the quality of the basis sets and a satisfactory quantitative description of these characteristics requires the inclusion of diffuse functions and functions with a high multiplicity in the basis set. The requirements imposed on the basis set in such cases are also due to the fact that quantitative calculation of the energies of excited states and anions requires allowance for electron correlation effects whose calculation using small basis sets does not lead in many instances to an increase in the accuracy of the results.[48,49] However, it is of interest to note that, as shown by the results of calculations by the X_α method, the lowest-energy states of the SiH_4^-, PH_3^-, HCl^-,[67] R_3SiPh^-,[68] and $RSPh^-$ [69] anions correspond to the presence of an additional electron in the σ^* orbital in the initial molecules, while the σ^* orbitals of the structural analogues of these anions, containing the atoms of Third Period elements, have higher energies than the Rydberg orbitals and do not correspond to stationary states of the anions.

The idea that *d* orbitals are involved in chemical bonding has undergone a significant evolution as computational quantum-chemical methods developed. At the present time, it is possible to test directly many postulates and corollaries of qualitative orbital theories, including also "*d*-orbital effects", by calculating molecular characteristics in terms of *sp* and *spd* basis sets. At the same time, the usual practice in the organic chemistry of silicon, phosphorus, and sulphur is to formulate orbital ideas on the basis of the analysis of molecular characteristics (obtained from experimental studies) using correlation analysis. If any molecular characteristics do not vary in conformity with linear relations of the Hammett–Taft type under these conditions, then this is explained by the effects of $p_\pi-d_\pi$ conjugation, a decrease in the diffuseness of the *d* orbitals under the influence of electronegative substituents, the involvement of *d* orbitals in chemical bonding on the grounds of symmetry considerations, etc. (see, for example, Refs. 23 and 70–75 and the literature quoted therein). Attempts are then made at a quantitative determination of the contribution of *d* orbitals to the measured characteristics and at a comparative estimation of the reliability of alternative orbital models (for example $d_\pi-p_\pi$ or n,σ^* conjugation) from the results of experimental studies.[76–79] Such empirical models can undoubtedly be useful for the classification of particular sets of experimental data, but their importance for the theoretical justification of ideas concerning the nature of chemical bonding should not be overestimated. The majority of "*d*-orbital effects" can be explained in a different way within the framework of models taking into account only valence *s* and *p* orbitals.[27,45]

III. Structural and energetic manifestations of hyperconjugation

The idea of the involvement of C–H σ-bonds in resonance interactions was put forward in the middle of the 1930s[80–82] to explain the structural features and reactivity of hydrocarbons. Wheland[80] attributed the increased stability of the ethyl radical relative to the methyl radical to the resonance stabilisation of the $CH_3CH_2^\cdot$ radical with participation of the so called "non-bonded structures":



Similar structures but with resonance of the ionic type were put forward by Baker and Nathan[81] to explain the reactivity in the series of *p*-alkyl-substituted bromotoluenes. The orbital model for the description of the resonance interaction of this type was developed by Mulliken,[83] who suggested that the term hyperconjugation be used for the description of the resonance interaction of C–H σ-bonds with unsaturated fragments. From the standpoint of the molecular orbital method, hyperconjugation arises as a consequence of the non-orthogonality of the σ and π orbitals, which leads to their mutual delocalisations. For the coplanar disposition of the sp^3 and p_π orbitals of two carbon atoms forming a chemical bond, their overlap amounts to 80% of the $p_\pi-p_\pi$ overlap.[84] However, the energetic and structural manifestations of hyperconjugation in the molecules of unsaturated hydrocarbons are not quite so pronounced as those of the formation of π-bonds in the ethylene molecule or of the conjugation in the benzene or even butadiene molecule, which is associated with the large energy gap between the occupied (σ) and unoccupied (π^*) orbitals.

Immediately after its appearance, the idea of hyperconjugation gained wide currency for the interpretation of various features observed experimentally, which, as shown in Dewar's critical review,[84] were either incorrectly interpreted or were susceptible to an equally acceptable qualitive description within the framework of other models. Dewar's review[84] resulted in appreciable cooling of the chemists' enthusiasm as regards hyperconjugation ideas, the development of which underwent a fresh start only after the appearance of modern computer programmes for non-empirical LCAO-MO calculations with automatic optimisation of the geometry. In particular, many structural features and spectroscopic and chemical properties of silicon, phosphorus, and sulphur compounds, which had been previously explained within the framework of the *d*-orbital model, could be interpreted as hyperconjugation effects.[1,18,85–90]

Three types of resonance stabilisation are considered within the framework of the hyperconjugation ideas: radical (I), cationic (II), and anionic (III):

$$\underset{\text{(I)}}{Y-E-\dot{X}\longleftrightarrow\dot{Y}\ E=X}\ , \qquad \underset{\text{(II)}}{Y-E-\overset{+}{X}\longleftrightarrow Y\ E=X}\ ,$$

$$\underset{\text{(III)}}{Y-E-\bar{X}\longleftrightarrow Y\ E=\bar{X}}\ .$$

For molecules with a closed shell, the direction of the shift of electron density [resonance of type (II) or (III)] is determined to a first approximation by the deficiency or excess of electron density on the group X and the polarised bond E–Y.

The general structural and chemical consequences of hyperconjugation have not been discussed in detail in the studies quoted above and we shall consider here the characteristic features of its manifestation in non-empirical calculations for silicon, phosphorus, and sulphur molecules and their structural analogues containing Second Period atoms.

One of the ways of investigating hyperconjugation effects involves the calculation of the energies of isodesmic reactions. This method was used by Schleyer, et al.[91] to calculate the energies of isodesmic reactions involving disubstituted methanes CH_2XY (X, Y = NH_2, OH, F, PH_2, SH, Cl):

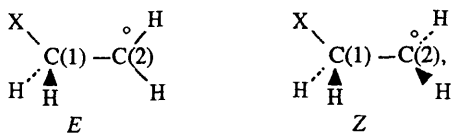
$$CH_4 + XCH_2Y = CH_3X + CH_3Y + \Delta E.$$

According to their data,[91] the stabilisation energy diminishes following the replacement of the group X and/or Y containing Second Period atoms by its structural analogue containing Third Period atoms. When X, Y = PH_2 or SH, the stabilisation energy is small ($0 < \Delta E < 0.5$ kcal mol^{-1}), whereas in the case where X = Cl and Y = PH_2, SH, or Cl, ΔE assumes negative values. A more detailed analysis shows that hyperconjugation involving the lone pairs of the Second Period atoms X predominates (NH_2 > OH > F), decreasing with decrease in the electronegativity of Y (F > OH > NH_2 > Cl > SH > PH_2).

Another way of estimating the effectiveness of hyperconjugation involves the study of the behaviour of structural parameters and molecular energies in the study of conformations. Such study has been described by Magnusson[92] for the series of molecules $X-CF_3$ (X = SiH_3, SiH_2^-, PH_3^+, PH_2, PH^-, SH_2^+, SH) and their structural analogues (X = CH_3, CH_2^-, NH_3^+, NH_2, NH^-, OH_2^+, OH). As in the study of Schleyer, et al. mentioned above, it was concluded here that hyperconjugation weakens on passing from Second Period atoms to Third Period atoms.

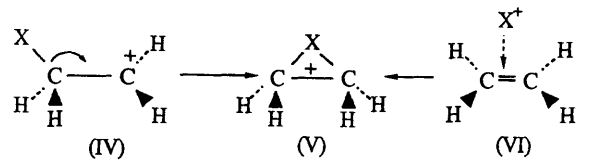
This conclusion is not, however, universal. For example, in the cations $X-CH_2^+$ the π-donor capacity of X = SH and Cl is higher than that of X = F and OH, whereas in the neutral molecules Ph−X, HC≡C−X, and $H_2C=CH-X$ the opposite picture is observed.[93] The authors[93] explained this by the fact that in neutral molecules the resonance integral of the interaction of the lone pair of X and the *p* orbital of the carbon atom of the unsaturated fragment is decisive, its values being higher for Second Period atoms, whereas in the cations the energy gap between the occupied orbital (*n* orbital of X) and the unoccupied orbital (*p* orbital of the carbon atom) is decisive, diminishing on passing from Second Period atoms to Third Period atoms.

The structural and energetic manifestations of hyperconjugation are well illustrated by the relative stabilities of (*E*)- and (*Z*)-conformations of β-substituted ethyl cations, radicals, and anions:[60,93,94]



where the circle denotes "plus" and "minus" signs or the "radical". The cation is stabilised as a result of the interaction of the σ_{CH} and σ_{CX} orbitals with the unoccupied *p* orbital of the C(2) atom. An increase in the electronegativity of the substituent *X* diminishes the contribution of the atomic orbital of the C(1) atom to the σ_{CX} orbital and hence weakens the conjugation with participation of the C−X bond. As a result, the (*E*)-conformation, where σ_{CH} orbitals are involved in conjugation, is more stable for electronegative substituents.[94] The opposite picture is observed in the anions, because in this case stabilisation is achieved as a result of $n-\sigma^*$ interaction. An increase in the electronegativity of the substituent X increases the contribution of the atomic orbital of the C(1) atom to the σ_{CX} orbital and increases the effectiveness of its interaction with the occupied *n* orbital of the C(2) atom.[94,95] In radicals, the interaction of the singly occupied *p* orbital of the C(1) atom with both σ and σ* orbitals is stabilising.[32,96] As a result of this, the electronegativity of X has only a weak influence on the relative stabilities of the (*E*) and (*Z*)-conformations. If X includes Second period atoms, then virtually free rotation about the C(1)−C(2) bond is observed in radicals,[60,97–99] but if X contains Third Period atoms[60] the (*Z*)-conformation is more stable owing to the greater polarisability of the C−X bonds. Analysis showed that under these conditions an increase in the electronegativity of the group X entails a decrease in the contribution of the $\sigma_{CX}-p_C^*$ interaction to the stabilisation of the (*Z*)-conformation, while the contribution of the $\sigma_{CX}^*-p_C^*$ interaction increases.[60]

However, in reality, the situation is more complex. For example, high level *ab initio* calculations with complete optimisation of the geometry (see, for example, Ford and Raghuver[100] and the references therein) have shown that in cations a competition is observed between the "classical" structure (IV) and the "non-classical" structure (V):



Structure (V) can apparently be regarded as a result of very effective $\sigma_{CX}-p_C$ interaction, although at a qualitative level the model of the complex of X^+ with the molecule of ethylene (VI) is no less justified. In β-substituted ethyl anions with electropositive substituents X, the (*Z*) conformation is additionally stabilised as a result of the overlap of the unoccupied atomic orbitals of the atom X (Li, Be, Na, Mg) and the doubly occupied orbital of the carbon atom.[95]

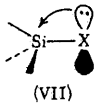
In the Introduction, we already noted that one of the important elements of the construction of orbital models of the structure of molecules containing atoms of non-transition elements of the Third and subsequent Periods is the idea of the decrease of the effectiveness of hybridisation for heavy atoms.[17] This is perhaps most clearly manifested when the structures of molecules comprising tricoordinate nitrogen and phosphorus atoms are compared. In the molecules of tetracoordinate silicon, the "enforced" sp^3-hybridisation of the atomic orbitals is observed by virtue of symmetry, which brings it closer to carbon. In the molecules of dicoordinate sulphur, as in those of oxygen, there is, apart from the predominantly *s*-type hybridised lone pair, a second lone pair formed by the pure *p* orbital capable of participating effectively in conjugation.[56,89,101–103]

The lone pairs of the nitrogen and phosphorus atoms differ significantly in their capacities for $n-\sigma^*$ and $n-\pi^*$ interactions.[41–43,103–107] In the ammonia molecule, the lone pair of the nitrogen atom is localised predominantly in the *p* orbital of the nitrogen atom, whereas in the phosphine molecule the lone pair is localised mainly in the *s* orbital of the phosphorus atom.[43] The energy expenditure on the transition from the pyramidal tricoordinate nitrogen atom to the planar atom, in which the hybrid orbital of the lone pair becomes a pure *p* orbital, is readily "made good" by the energy gain as a result of conjugation with the low-lying unoccupied σ* or π* orbitals of the substituents at the nitrogen atom. On the other hand, the phosphorus atom in the structurally analogous molecules always retains a pyramidal structure. In terms of localised orbitals and hybridisation, this can be explained at a qualitative level by the fact that energy factors are unfavourable for the planar structure involving tricoordinate phosphorus in which the lone pair occupies a *p* orbital. Within the framework of the qualitative molecular orbital theory, the same result is attributed to the smaller (compared with nitrogen) energy gap between the HOMO and the LUMO in the planar PH_3 molecule

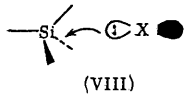
and to its instability as regards pyramidal distortion.[108] The stability of the pyramidal structure of phosphorus-containing molecules is associated, in addition, with the decrease in the steric repulsion of the ligands on passing from Second Period atoms to Third Period atoms due to the increase in size of the central atom.

The difference in the nature of the hybrid orbitals of the lone pairs of the nitrogen and phosphorus atoms is manifested in the protonation of the aminophosphine (H_2NPH_2) molecule.[42,109] The addition of H^+ to the nitrogen atom lengthens the P–N bond, whilst its addition to the phosphorus atom shortens it. This result can be explained by the different capacities of the lone pairs of the nitrogen and phosphorus atoms for $n-\sigma^*$ interaction and is used in the consideration of the mechanism of the acid catalysis of the dissociation of the P–N bond in aminophosphines.[110] The lengthening of the P–N bond on protonation of the nitrogen atom is caused by the inhibition of the $n_N-\sigma^*_{PH}$ interaction and by the increase in the steric repulsion in the coordination sphere of the nitrogen atom. When the phosphorus atom is protonated, the shortening of the P–N bond is explained by the rehybridisation of the valence atomic orbitals of phosphorus (by the increase in the contribution of the *s* orbital to the hybrid atomic orbitals participating in the formation of bonds) and by the strengthening of the $n_N-\sigma^*_{PH}$ interaction in the cation $H_2NP^+H_3$. Such qualitative analysis makes it possible to explain the influence of various substituents on the basicity of amines and phosphines.[43,105,111,112]

The π-acceptor effect of the silyl group is well known (see, for example, Egorochkin[86] and Pitt [87] and the references therein). Previously, this effect was explained by the $p_\pi-d_\pi$ conjugation, but this interpretation was not confirmed by modern non-empirical calculations, which indicate the decisive role of the σ^*_{SiX} orbitals in the π-acceptor capacity of SiX_3 groups[55,56] [$n-\sigma^*$ interaction, structure (VII)]. Another form of the manifestation of the increased acceptor capacity of the SiX_3 groups is $n_\sigma-\sigma^*$ interaction [structure (VIII)], which leads to the formation of *trans*-annular bonds in linear, cylic, and bicyclic silicon-containing molecules.[113–116]



(VII)

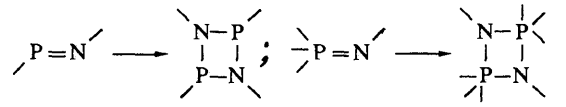


(VIII)

The influence of substituents on the length and strength of the *trans*-annular bond has been studied thoroughly in relation to silatranes.[117,118] A model calculation by the MNDO method[119] showed that the main factor determining the strength of this bond is the energy gap between the n_N and σ^*_{SiX} orbitals. Steric interactions, determining the energy of the transition from the tetrahedral structure of the silicon atom to the bipyramidal structure, also play an important role. The formation of dative bonds as a result of the $n_\sigma-\sigma^*$ interaction has been observed also in molecules of tricoordinate phosphine[120,121] and dicoordinate sulphur,[90,122,123] although not on such a broad scale as for silicon.

IV. Multiple bonds and conjugation

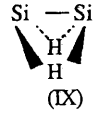
Multiple bonds can be divided into two types depending on whether the octet rule is fulfilled or infringed in the structural formula of the molecule. The first type of multiple bonds are observed in compounds of "normal" valence, in the structural formula of which the octet rule is fulfilled for each atom. For example, the P=N double bond in the iminophosphine (HP=NH) molecule is consistent with this definition, whereas the P=N bond in the iminophosphorane ($H_3P=NH$) molecule, which is usually represented as a double bond, has a different nature.[124] The difference in the nature of the P–N bonds in HP=NH and $H_3P=NH$ is manifested in the analysis of localised molecular orbitals calculated by the Boys method.[125] In the former case, the calculation leads to two equivalent localised "banana" molecular orbitals in the region of the P=N bond, whereas in the second, the presence of two lone pairs at the nitrogen atom, somewhat displaced in the direction of the phosphorus atom, is demonstrated.[124] At the same time, it is essential to note that, despite the difference in the nature of the electron distribution in the region of the PN bonds in iminophosphines and iminophosphoranes, there are also considerable structural (similarity of bond lengths) and chemical similarities between these compounds.[126,127] In particular, the dimerisation reaction



is characteristic of both.

In fact the boundary between the double bonds in "normal" and hypervalent molecules is to some extent arbitrary. For example, the SiO bond in the H_2SiO molecule is so polar that it corresponds to a large extent to the formula $H_2Si^+-O^-$; this brings it close to the PO bond in the H_3PO molecule.[52] On the other hand, hypervalent molecules of the type HPX_2 (X = CH_2, NH, O)[128–131] have a planar structure in which the double bonds are formed as a result of the overlap of the coplanar p_π orbitals, as in the ethylene molecule. At the same time, the polarity of the bonds in the HPX_2 molecules is high, so that their electron distribution is to a large extent consistent with ionic structures.

Compounds containing double bonds involving silicon and trivalent phosphorus remained for a long time chemically "exotic" in view of their instability, which was in its turn determined by the instability of the $p_\pi-p_\pi$ bonds in these compounds. The weakening of the π-bonds in the molecules involving Third Period atoms is caused by the appearance of inner *p* shells in the electronic structure of these atoms.[17,132] The instability of the π-bonds involving Third Period elements has a multiplicity of structural manifestations. For silicon-containing molecules, a series of interesting examples have been quoted in the review of Gordon and co-workers.[133] The replacement of a C atom by a Si atom increases the relative stability of the isomers containing a smaller number of multiple bonds involving silicon. For example, the main isomer of disilaacetylene has the bridged structure (IX) and disilaethylene (X) is more stable than silylsilylene (XI) only to the extent of 3.5 kcal mol^{-1}, while the structural analogue of silapropene has no minimum on the potential energy surface corresponding to the structural formula (XII).



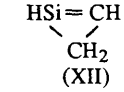
(IX)

$H_2Si=SiH_2$

(X)

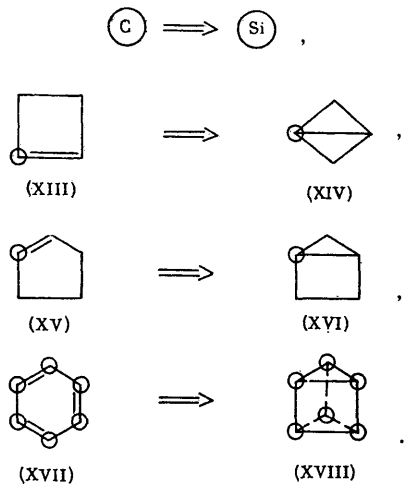
$H_3Si-\dot{S}iH$

(XI)



(XII)

In cyclic molecules the replacement of a C atom by a Si atom diminishes the stability of the unsaturated cyclic compounds (XIII), (XV) and (XVII) compared with the condensed compounds (XIV), (XVI), and (XVIII).

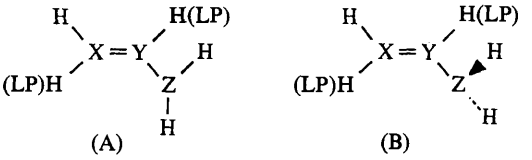


As already mentioned, on passing from Second Period to Third Period atoms, the relative contribution of *p* electrons to the hybrid atomic orbitals participating in the formation of bonds increases and there is a corresponding increase in the *s* electron fraction in the non-bonding orbitals. This factor makes the sp^2-hybridised state of the silicon atom, in which the contribution of *s* orbitals to bonding is large, unfavourable on energy grounds.[134]

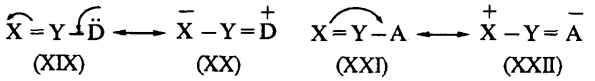
As a result of the endeavour of the unpaired electrons in this instance to occupy the *s* orbital, SiH_2 has a singlet ground state, while CH_2 has a triplet ground state. The stability of the singlet state relative to the triplet state in the X_2E (E = C, Si, Ge, Sn) molecules increases with increase in the relative electronegativity of the substituents X.[135] The strength of the double bonds involving the X_2E fragment and the stability of the planar molecular structure are inversely related to the energy of the singlet–triplet transition in X_2E:.[136,137] The stability of the planar structures of unsaturated molecules involving Group IV atoms has been attributed[137] to the competition between the "triplet" and "singlet" mechanisms of the formation of the double bond:

In the former case the optimum overlap of the interacting orbitals is achieved in the planar molecular structure, while in the latter it is achieved in the non-planar structure. The triplet mechanism describes best the formation of the double bond in the ethylene molecule, whereas in the disilene molecule there is a considerable contribution of the structure with dative bonding, which leads to the instability of the planar structure.[138–141]

In our view, the question of the characteristic features of conjugation with participation of double bonds involving Third Period atoms compared with the analogous bonds involving Second Period atoms is of undoubted interest. Calculations have been carried out[142] in terms of the 3-21G* basis set for the molecules $H_nX{=}YH_m{-}ZH_2$ (X, Y = C, N, Si, P; Z = B, N; n = 1, 2; m = 0, 1) in two conformations: (A) and (B).

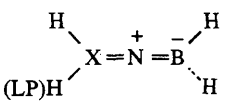


The structural, energetic, and electronic effects, associated with the conformational transitions (A)⟷(B) were analysed. The "classical" ideas concerning the conjugation of the donor (acceptor) group with the double bond are reflected in the form of the resonance of the structures (XIX)⟷(XX) and (XXI)⟷(XXII):



They can be formulated as three main corollaries: (1) conjugation lengthens the double bond and shortens the single bond participating in the conjugation (structural effect); (2) the electron density on the donor (acceptor) group diminishes (increases) in the conformation favouring conjugation (electronic effect); (3) in the absence of steric hindrance, the conformation where the p_π orbitals of the double bond in the substituent overlap to the maximum extent is energetically preferred (energetic effect).

When Y = C, conjugation takes place in conformity with the above rules when account is taken of the polarity of the X=C bond. When Y = N and Z = B, the stronger dative interaction of the lone pair of the nitrogen atom and the unoccupied *p* orbital of the boron atom is superimposed on the conjugation effect, which leads in conformation (B) to the linearisation of the molecule with formation of the allene-like structure (XXIII).



(XXIII)

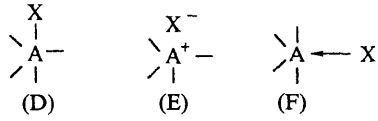
When Y = Si or P, the effects of the conjugation and polarisation of the σ- and π-bonds under the influence of conformational transitions are similar in magnitude and, depending on their direction, can strengthen one another or cancel out. For example, in the conformational transition (B)→(A) in the $HN{=}P{-}NH_2$ molecule a shortening and not a lengthening of the P=N bond is observed. Similar results were detected also in X-ray diffraction studies on substituted aminoiminophosphines.[143] Analysis of the Mulliken populations has shown that the transition to the conformation (A) is accompanied by an increase in the polarity of the PN bond, as a result of which the latter is shortened. Similar effects had been observed earlier in the study of the influence of the substitution of H by F in the $HN{=}CH_2$ and $HP{=}CH_2$ molecules.[144]

V. Hypervalent molecules and radicals

The concept of hypervalence in the chemistry of non-transition elements is associated with the description of molecular structure in which the octet rule breaks down. This means that in the structural formulae of such molecules the number of ligands and lone pairs surrounding the central atom is greater than four. Compounds containing multiple bonds of the phosphoryl or sulphoxide type (R_3PO, R_2SO, R_2SO_2, etc.) are also classified as hypervalent. Although the number of ligands in these molecules does not exceed four, the multiplicity of the bonds presupposes the involvement of more than four electron pairs in their formation [structure (A)]. The octet rule can be formally fulfilled if the structural formulae of such molecules are written using mesoionic (B) or dative (C) bonds.

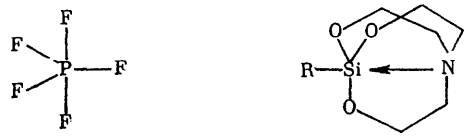
(A) (B) (C)

In many respects, the multiple bonds in the usual and hypervalent compounds exhibit similar properties (see also the previous Section). At the same time, the structural formulae (B) and (C) also reflect definite specific features of these bonds. The formulae (D)–(F), analogous to (A)–(C), are used to represent the structures of molecules in which the hypervalence is due to the increase in the number of ligands linked to the central atom.



(D) (E) (F)

As in the usual molecules, the nature of the chemical bonds in hypervalent molecules is extremely varied: ranging from weak to strong and from covalent to ionic bonds. The use of a particular formula for the representation of hypervalent molecules is determined to a large extent by the specific situation and the wish of the author to emphasise particular properties of the compound. The molecule of phosphorus pentafluoride is usually represented by the formula (XXIV), despite the high polarity of the P–F bonds, whereas in silatranes the *trans*-annular bond between silicon and nitrogen is represented by the dative formula (XXV).

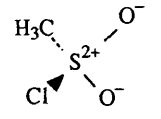


(XXIV) (XXV)

The structural formula (XXV) does not reflect the increase in the positive charge on the silicon atom on formation of a bond with nitrogen, which is observed in calculations for model molecules of pentacoordinate silicon.[145,146]

The wide variety of different types of chemical bonds in hypervalent molecules hinders the selection of the structural, energetic, or electronic parameters which could reflect quantitatively the degree of "hypervalence" of the atom in the molecule. The population of the 3*d* orbitals has been usually employed as such a parameter, although recently this criterion has been subjected to serious criticism (see Reed and Schleyer[1] and the references therein). At the same time, the important role of *d* orbitals in the description of the properties of hypervalent molecules has been emphasised in a number of studies (see, for example, Refs. 147–150). It appears evident nowadays that the quantitative description of the structural, energetic, and spectroscopic characteristics of hypervalent molecules can be achieved only using wide basis sets including 3*d* orbitals. At the same time, qualitative concepts such as that of the model of the reverse transfer of π-electron density from the ligands to the *d* orbital of the central atom (for the description of the multiplicity of bonds of the phosphoryl type) or the model of hybridisation with participation of *d* orbitals in highly coordinated molecules have not been confirmed by the results of modern non-empirical calculations.

According to the data of Reed and Schleyer,[1] based on the results of NBO (Natural Bond Orbitals) analysis,[151,152] the molecule of chlorosulphone and structurally similar hypervalent molecules have a predominantly ionic character corresponding to the Lewis structure (XXVI). The increased multiplicity of the S–O bond is due mainly to the effect of negative hyperconjugation with participation of the lone pair of oxygen and the antibonding bond orbitals σ^*_{SCl} and σ^*_{SC}:



(XXVI)

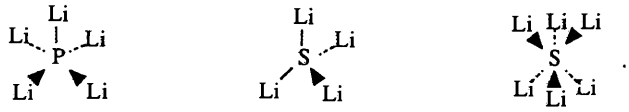
In pentacoordinate and hexacoordinate molecules, the three-centre four-electron bond model is more consistent with the qualitative concept of the hypervalent bond than the model of hybridisation with participation of 3*d* orbitals.

The method of correlation diagrams, proposed previously by Shaik[153] for the analysis of nucleophilic substitution reactions, was used to explain the stability of SiH_5^-,[154,155] sulphuranes, and sulphuranyl radicals.[156] In contrast to Walsh diagrams, in which the dependence of the molecular orbital energies on structural parameters is analysed, the Shaik diagram method is based on the analysis of the energies of the Lewis structures obtained by the valence bond method. The qualitative difference between CH_5^- (transition state in the S_N2 reaction between CH_4 and H^-) and SiH_5^- (a relatively stable intermediate[157]) can be explained by the stabilisation of the latter as a result of the involvement of the σ^* orbital of the equatorial SiH_3 fragment in bonding.

The σ^* orbital of the SiH_3 fragment has less antibonding character, in contrast to the analogous orbital in the carbon analogue, and is localised predominantly on the silicon atom. Although the *d* orbitals do in fact increase the relative stability of the bipyramid in this case, nevertheless they do not determine the qualitative nature of the effect.[158]

The stability of hypervalent molecules as a rule increases with decrease in the electronegativity of the ligands, which is consistent with the ideas based both on the molecular orbital theory and on the valence bond diagram method. At the same time, calculations for the hypervalent phosphorus- and sulphur-containing molecules with the most electropositive ligands (lithium atoms), namely PLi_5, SLi_4, and SLi_6,[159] are in our view of considerable interest.[159] When the geometry is optimised in terms of the HF/3-21G* approximation (with *d* orbitals only in the S and P atoms), all the above molecules have energy minima corresponding to the "non-classical" (from the standpoint of the Gillespie–Nyholm model[160]) structures

(XXVII)–(XXIX), which are stable as regards decomposition into atoms and the segregation of the Li_2 molecule. Such behaviour is caused mainly by two factors: the increase in electron density on the central atom and the effective bonding of neighbouring lithium atoms via diffuse *p* orbitals:

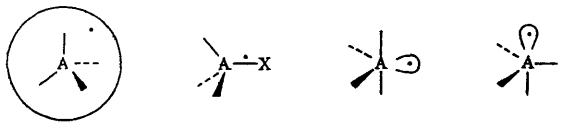


C_{4v} (XXVII) C_{3v} (XXVIII) D_{3d} (XXIX)

All three molecules are structurally non-rigid. The $SiLi_4$ molecule, whose energy minimum corresponds to the C_{2v} structure, exhibits a similar behaviour.[161]

Until recently quantum-chemical calculations for molecules containing unpaired electrons were predominantly qualitative (estimates). Modern non-empirical programs for high-speed computers make it possible in many instances to calculate quantitatively the structures and energies of radical species. This increases in its turn the predictive and conceptual value of orbital models based on modern non-empirical calculations for such systems.

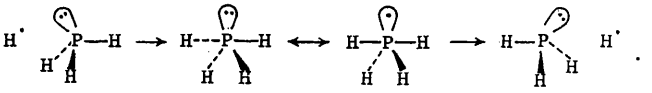
From the standpoint of orbital ideas, the excess electron in hypervalent radicals can be located in the diffuse Rydberg orbital (A) or the antibonding bond orbitals (B) or can occupy one of the coordination sites in the manner of a lone pair [(C) and (D)].



(A) (B) (C) (D)

According to non-empirical calculations, the unpaired electron in the metastable radicals $\dot{N}H_4$[162–165] and $\dot{O}H_3$[166,167] is located in the Rydberg orbital, while the radical $\dot{C}H_5$ is a transition state in the reaction of methane with a hydrogen atom.[168,169] On passing from Second to Third Period elements, the energies of the antibonding orbitals diminish and the "capacity" of the coordination sphere of the central atom increases.

The structure of phosphoranyl radicals (PX_4) is intermediate between (B), (C), and (D) and depends on the nature of the substituents. In radicals of the $Ar_3\dot{P}Cl$ type, the excess electron is located, according to EPR data, in the σ^* orbital of the P–Cl bond.[170–172] On the other hand, according to the results of *ab initio* calculations,[173] such radicals should have a trigonal-bipyramidal structure with the excess electron on the phosphorus atom in the apical position. In the $H_3P-\dot{X}$ (X = PH_3, SH_2, ClH) series, the first member is a σ^* radical with the excess electron localised on the P–P bond, whilst the third has a trigonal-bipyramidal structure, the difference between the apical and equatorial positions of the unpaired electrons amounting to only 0.15 kcal mol^{-1} in terms of the MP2/4-31G* approximation.[174] The radical $H_3P-\dot{S}H_2$ has an intermediate configuration both from the standpoint of its structure and of the distribution of the unpaired electron density. The stabilities of the radicals $\dot{S}iH_5$, PH_4, and $\dot{S}H_3$ have been analysed[175] by the method of correlation diagrams for valence bonds.[153] The phosphoranyl radical is most stable as regards decomposition with evolution of atomic hydrogen. Analysis[175] showed that the stability of hypervalent radicals increases with decrease in the A–H bond energies. The phosphoranyl radical is traditionally stabilised as a result of the involvement of the lone pair of the phosphorus atom in the redistribution of electron density on formation of the trigonal bipyramid:



In $\dot{S}H_3$ such stabilisation is less effective, owing to the greater energy of the abstraction of the lone pair electron from the H_2S molecule.

The radicals $H_2\dot{P}=X$ (X = O, S), investigated by the *ab initio* method,[176] are also hypervalent like the initial $H_3P=X$ molecule. The abstraction of a hydrogen atom from $H_3P=X$ is accompanied by lengthening of the P–X bond and an appreciable decrease in the HPX bond angles. The P–X bond lengths are intermediate under these conditions between the lengths of double ($H_3P=X$) and single (H_2P-XH) bonds. The distribution of spin density also shows that the unpaired electron in the radicals H_2PX is delocalised between the P and X atoms. Thus the structure of radicals of this kind is intermediate between $H_2\dot{P}=X$ and $H_2P-\dot{X}$.

- - - o0o - - -

Modern non-empirical calculations are a source of a wide variety of qualitative and quantitative information, which makes it possible to rethink the existing ideas and formulate new ones concerning the structure of chemical bonds (especially in silicon, phosphorus, and sulphur compounds). This stimulates in its turn the development of experimental research and the synthesis of chemical compounds of new classes.

Radiation chemistry of crown-compounds

V V Makhlyarchuk, S V Zatonskii
Faculty of Chemistry, Lomonosov Moscow State University

ABSTRACT. **The results of studies on the radiation-chemical reactions in various systems containing crown-ethers and their analogues are surveyed and analysed in the review. The use of crown-compounds as extractants for the selective isolation of radionuclides is considered from the standpoint of radiation chemistry. Data concerning the radiolysis of individual crown-ethers as well as their aqueous and non-aqueous solutions are described. Good prospects for the application of macrocyclic compounds and their complexes in the study of the mechanisms of radiation-chemical processes are demonstrated.**

I. Introduction

Crown-compounds are macrocyclic compounds containing in their structures electron-donating heteroatoms such as those of oxygen (crown-ethers), nitrogen, or sulphur and possessing the ability to form with a high degree of selectivity stable "guest-host complexes" with cations and neutral molecules. Polycyclic compounds consisting of two (cryptands) and more rings can also be included among crown-compounds.[1–3] The chemistry of crown-compounds has been developing vigorously and the synthesis of numerous new macroheterocycles with unusual properties has stimulated studies not only in the field of organic chemistry but also in adjacent fields where these substances have found important practical applications.[4–6] The first studies concerning the radiation chemistry of crown-ethers were published in 1984.[7–12]

The capacity for the selective binding, separation, and transport of metal cations stimulated the use of crown-compounds as extractants for the selective isolation of radionuclides in radiochemical technology,[13] which in fact induced the initial practical interest in the radiation chemistry of macrocyclic polyethers and their solutions. The complex of a crown-ether and an inorganic salt is formed as a result of the ion–dipole interaction between the cation and the negatively charged oxygen atom of the polyether ring. The stability of the complex formed then depends on the relative diameter of the cavity within the crown-compound and the diameter of the cation. The complex-forming capacity is also influenced by the charge and hardness of the cation and the nature of the electron-donating heteroatoms of the crown-compounds and the substituents in the macrocycle.[1,3,14–16] As a result of the formation of a complex with a crown-compound, the relatively small alkali metal or alkaline earth metal ion is converted into a bulky organic cation capable of dissolving in the organic phase. Thus inorganic salts are solubilised in weakly polar organic solvents, which is favoured by the highly lipophilic properties of the ligand skeleton.[3,17] The weakly solvated, almost "bare" anions formed on complex formation in weakly polar solvents differ appreciably from their solvated analogues. The electron-donating properties of the weakly solvated anion are enhanced and it becomes a potentially strong base and nucleophile. Such an anion is activated by the crown-compound and its reactivity increases.[18] The degree of activation depends on the nature of the anion, the solvent, and the macrocyclic ligand.

The ability of crown-compounds to transport ionic reactants from the solid or aqueous phase to the organic phase and to act on the state of ion pairs in the solution influences the kinetics and stereochemistry of many reactions. Under these conditions, certain reactions can be carried out only in the presence of macrocyclic compounds.[19] This permits the application of these substances in the study of reaction mechanisms in organic chemistry. By virtue of the ability of crown-ethers and cryptands to dissolve alkali metals even in weakly polar organic solvents such as benzene and toluene,[20–23] it becomes possible to extent significantly the range of solvents in which the solvated electron and related species, which are the objects of study in radiation chemistry, may be obtained.[24] The weakly solvated alkali metal anions, present in such solutions, have very powerful reducing properties.[17] Strong oxidants, insoluble in the majority of organic solvents, such as potassium dichromate and permanganate, dissolve even in benzene in the presence of crown-ethers.[25–28] Thus a powerful instrument becomes available for the study of the oxidation-reduction processes occurring in the radiolysis of non-aqueous solutions.[29,30] Crown-compounds, which make it possible to alter the state and reactivity of not only ionic reactants but also of ionic reaction intermediates, can serve as an effective means for the study of the mechanisms of radiation-chemical reactions.[31,32] Macrocyclic polyethers and their analogues give rise to the possibility of increasing appreciably the number of compounds soluble in weakly polar media, which helps to create new antiradiation agents or reagents and phase-transfer catalysts for radiation-chemical synthesis.

II. Crown-compounds as extractants for radionuclides. Radiation-chemical aspects

Extraction is one of the most important fields in which macrocycles are used.[33] In particular, the employment of crown-compounds for the selective isolation of radionuclides is extremely

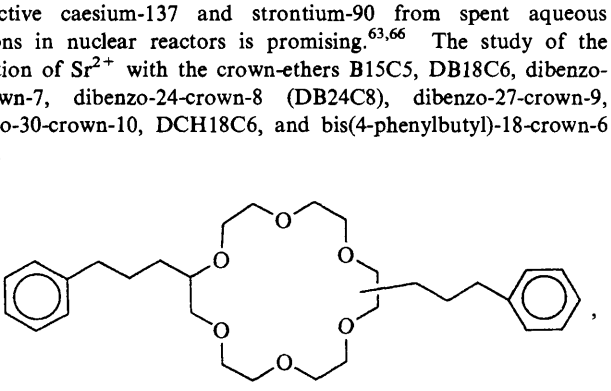
promising.[34,35] In the processing of spent nuclear fuel,[36] the extractant can receive a dose of the order of 0.4–40 kGy in one cycle depending on the organisation of the extraction process, while under conditions of multiple employment of the extractant the integral radiation dose received by the latter can reach tens of megagrays.[37] The radiolysis of extraction systems can also have negative consequences important for technology such as the degradation of the extractant and the decrease in the efficiency of the extraction, the formation of radiolytic products influencing unfavourably the selectivity of the extraction and the phase separation, and the formation of corrosive acids and oligomers which hinder the regeneration of the extractants. For this reason, the radiolytic reactions of organic compounds and of two-phase aqueous organic systems, the search for new more effective and radiation-resistant extractants which are satisfactorily compatible with the organic liquids used as diluents, as well as the behaviour of salts of the actinide elements, which are the main components of nuclear fuel, have been the subject of vigorous studies.[13,37–39]

Numerous studies have been devoted in this connection to crown-ethers. For example, a review[40] quotes data on the extraction of tervalent actinides by crown-compounds and their linear analogues. Another review[41] reports the complexes of divalent actinides with crown-ethers and their physicochemical properties and demonstrates the similarity to and differences from alkaline earth elements. The uranium(III) complexes of a series of crown-ethers have been investigated.[42] The processes involving the extraction of uranium, thorium, neptunium, and plutonium from nitric acid solutions by crown-ethers have also been studied.[43–46] A wide variety of compounds can be used as extractants and diluents, for example: 15-crown-5 (15C5) and dicyclohexano-18-crown-6 (DCH18C6) in nitrobenzene and 1,2-dichloroethane for uranium(VI), neptunium(IV), and americium(III); DCH18C6 in nitrobenzene for neptunium(IV);[47] 12-crown-4 (12C4), 15C5, 18-crown-6 (18C6), dibenzo-18-crown-6 (DB18C6), and DCH18C6 with 4-benzyl-3-methyl-1-phenylpyrazolone in toluene for uranium(VI), americium(III), and thorium(IV);[48] five different crown-ethers in 1,2-dichloroethane for uranium(VI),[49] DCH18C6, DB18C6, and 18C6 with thenoyltrifluoroacetone in benzene[50] and 12C4, 15C5, 18C6, DB18C6, and DBH18C6 in chloroform[51,52] for americium(III); DCH18C6 or benzo-15-crown-5 (B15C5) with 3-methyl-1-phenyl-4-trifluoroacetyl-5-pyrazolone in chloroform for trivalent americium, curium, californium, and europium.[53] The application of 18C6 makes it possible to carry out the selective extraction of thorium in the form of the picrate complex from a mixture containing cerium, uranium, zirconium hafnium, yttrium, and lead.[54]

The use of crown-ethers (for example, DCH18C6 or DB18C6) as extractants in the processing of irradiated nuclear fuel permits the isolation of uranium and plutonium from aqueous solutions containing nitric acid.[55,56] It has been shown that DCH18C6 (especially the *cis*, *syn*, *cis*-isomer of this macrocycle) is an effective extractant for plutonium present in highly radioactive solutions resulting from the processing of nuclear fuel. This crown-ether is more radiation-resistant and selective in the isolation of plutonium(IV) than tri-n-butyl phosphate (TBP) usually employed. Thus, in a study of a 10% solution of DCH18C6 in chloroform irradiated from a ^{137}Cs source (absorbed dose 168 kGy) by UV, IR, and ^{1}H and ^{13}C NMR spectroscopic methods as well as high performance liquid chromatography (HPLC), no products of the radiation-chemical reactions of the crown-ether were detected. In addition, a comparative study has been made of the extraction of plutonium from moderately active solutions by commercial DCH18C6 (mixture of isomers) and with the crown-ether subjected to preliminary washing with nitric acid. The extractant was irradiated during its contact with the solution containing plutonium(IV), uranium(VI), and fission products in the course of eight months. In this case, the overall absorbed energy was 611 kJ mol^{-1}, including 80.5 kJ mol^{-1} as the α-emission energy, which corresponds to 5000 cycles involving extraction from highly active solutions. It has been shown that, even if the selectivity in the isolation of plutonium does actually decrease as a result of the strong irradiation of the polyether, the decrease is extremely insignificant. The amount of extracted plutonium is 92 and 90% respectively for the commercial products and the irradiated DCH18C6. Thus, according to the authors,[56,57] the use of crown-ethers as extractants makes it possible to create a new industrial technology for the processing of nuclear fuel.

Apart from actinides, other radioactive elements and isotopes can be extracted with crown-ethers. The extraction of technetium(IV) with DB18C6 and 18C6 has been investigated in a study,[58,59] where the organic phase was nitrobenzene, benzene, and acetylacetone; the extraction of astatine-211 with crown-ethers from various media and its mechanism have been discussed.[60] The selective isolation of iodine-131 from irradiated uranium and tellurium oxides can be achieved with a high efficiency using DB18C6 in 1,2-dichloroethane as the extractant.[61] The equilibria in the extraction system involving the extraction of radium from an aqueous medium containing sodium nitrate and hydroxide into a solution of dicyclohexano-21-crown-7 in toluene in the presence of 2-heptyl-2-methylnonanoic acid has been investigated.[62] The possibility of the selective separation of radium from other alkali and alkaline earth elements was demonstrated.

The use of crown-ethers in the technology of the extraction of radioactive caesium-137 and strontium-90 from spent aqueous solutions in nuclear reactors is promising.[63,66] The study of the extraction of Sr^{2+} with the crown-ethers B15C5, DB18C6, dibenzo-21-crown-7, dibenzo-24-crown-8 (DB24C8), dibenzo-27-crown-9, dibenzo-30-crown-10, DCH18C6, and bis(4-phenylbutyl)-18-crown-6 (I), i.e.



(I)

for nitric acid solutions containing $NaNO_3$ showed that the crown-ethers (I) and DCH18C6 (mixture of two *cis*-isomers) can be used for this purpose. The latter extractant is more effective and the best diluent is 1,1,2,2-tetrachloroethane.[67] Similar results were obtained by Filippov, et al.,[68] who investigated the extraction of magnesium, calcium, strontium, and barium nitrates from nitric acid solutions with the crown-ether DCH18C6 in dichloroethane. The possibility of the selective extraction of Sr^{2+} was demonstrated, the crystalline complex $Sr(NO_3)_2$.DCH18C6 was isolated, and its IR spectroscopic characteristics were obtained. It has been noted[69] that DCH18C6 is an effective extractant not only for Sr^{2+} but also for Tl^{+} (diluent – 1,1,2,2-tetrachloroethane and trichlorobenzene).

A method is available for the isolation of strontium from spent solutions in the nuclear reactors in atomic power stations,[70] where ^{90}Sr is extracted with a solution of crown-ether in chloroform, benzene, toluene, or alkanes at pH 2–6 after adding picric acid, trialkylphenol, or phenyltetrazoline-5-thione. This method makes it possible to separate strontium from potassium, lead, silver, and mercury usually present in the solutions.

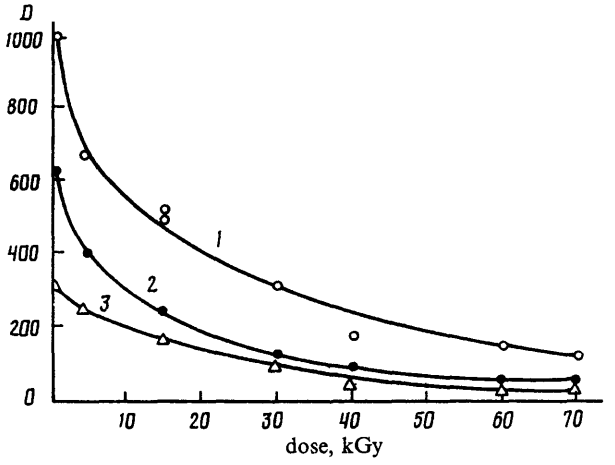


Figure 1. The effect of the absorbed radiation dose on the partition coefficient in the extraction of strontium by irradiated solutions of DCH18C6 in chloroform. Molar crown-ether concentration: *1*, 0.05; *2*, 0.01; *3*, 0.005. ^{60}Co γ-radiation dose rate 24 Gy s^{-1}.[71]

The results of a study[71] of the extraction of strontium from aqueous solutions of picric acid with solutions of crown-ethers in chloroform subjected to ^{60}Co γ-irradiation are of interest in this connection. It was established that the partition coefficient *D* decreases significantly in the dose range up to 70 kGy for DCH18C6 (Fig. 1). Similar relations were observed also for solutions of 18C6 (Fig. 2), DB18C6, DB24C8, and D15C5 in chloroform, the effectiveness of the extractant decreasing in the sequence DCH18C6 > 18C6 > DB24C8 > DB18C6 > B15C5. This effect is due to the radiolytic reactions of chloroform, since the radioactive degradation or dehydrogenation of the crown-ether was not observed.

Comparison of the ^1H NMR spectra of pure DCH18C6 and of the crown-ether irradiated in chloroform (70 kGy) shows that either chlorination (1 or 2 halogen atoms) takes place or the complex H^+DCH18C6)Cl^- is formed under the influence of irradiation. However, later results of the study of γ-radiolysis of solutions of B15C5 in chloroform[72] failed to confirm the occurrence of radical reactions of the crown-ether and Cl atoms with formation of products mono- or di-chloro-substituted in either the aromatic or the polyether ring. On the basis of NMR and mass-spectrometric data, it was postulated that the radiolysis of chloroform containing B15C5 results in the formation of complexes of the type (H^5B15C5)Cl^- and (H^+B15C5)Cl^-_2 (the appearance of the red-violet colour on irradiation of the solution is attributed to this). The macrocycle decomposition products were not identified, although the appearance of carbonyl groups resulting from the opening of the polyether ring was detected by IR spectroscopy.

After the chloroform has been removed by evaporation from the irradiated DCH18C6 solution, the residue, dissolved in a fresh portion of choroform, was used to extract strontium.[71] In this case, the partition coefficient (D = 442) proved to be much higher than that obtained in the extraction of strontium with a solution of DCH18C6 in irradiated chloroform (D = 54). Evidently the decrease in the partition coefficient *D* is not a result of the reactions of the extractant. The data obtained[71,72] show that the main factor inducing the sharp decrease in the partition coefficient is the formation of HCl in the radiolytic decomposition of chloroform. Other products of the radiolysis of the latter influence the partition coefficient to a lesser degree. The formation of C_2Cl_6 diminishes the dielectric constant of the solvent, leading to a lower value of *D* at high concentrations. Comparison of the dose dependence of the partition coefficient *D* for 18C6 dissolved in irradiated chloroform and for the irradiated solution of this crown ether (Fig. 2) emphasises yet again that the decisive factor in the decrease of the effectiveness of the extraction is radiation-chemical processes occurring in the diluent.

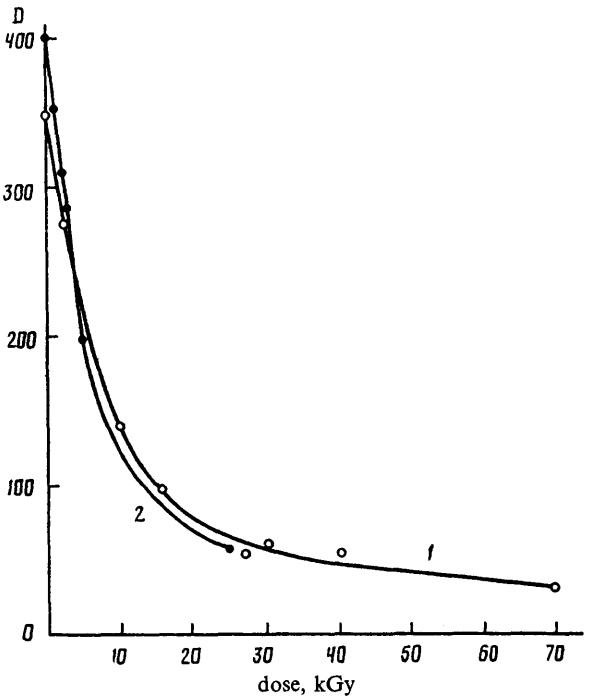

Figure 2. The effect of the absorbed γ-radiation dose on the partition coefficient in the extraction of strontium by an irradiated 0.1 M 18C6 solution in chloroform (curve *1*) and 0.13 M solution of 18C6 in chloroform subjected to preliminary irradiation (curve *2*).[71]

Interesting results were obtained in the study of the influence of γ-radiation on the ionophoric capacity of the ligand in the transfer of alkali and alkaline earth metal ions through a liquid membrane consisting of a 1×10^{-3} M solution of 18C6 in chloroform.[73] The

irradiated membrane has the greatest effect on the transport of cations in the case of caesium and barium (Table 1). The selectivity in the transport of ions shifts from K^+ to Cs^+ and from Sr^{2+} to Ba^{2+} under the influence of radiation. A similar effect has also been noted for another ligand—1,10-phenanthroline. The authors[73] have not reached unambiguous conclusions concerning the causes of the observed phenomenon and note that it can be due both to radiolytic reactions of the ligand and to a change in the properties of the organic phase, in particular the formation of HCl. The rate of the membrane transport is related directly to the extraction properties of the metal ion in the systems considered.

Table 1. The effect of γ-irradiation on the membrane transport of cations from 1×10^{-3} M aqueous solutions of picrates.[73]

Cation	Concentration of cation transferred to the aqueous phase 10^6C, M		$10^6\Delta C$, M
	non-irradiated 18C6–$CHCl_3$ system	irradiated* 18C6–$CHCl_3$ system	
Li^+	0.044	0.196	0.152
Na^+	0.399	0.458	0.115
K^+	8.900	11.970	3.070
Cs^+	7.640	21.840	14.200
Mg^{2+}	0.135	1.00	0.865
Ca^{2+}	0.360	3.990	3.650
Sr^{2+}	5.120	10.330	5.210
Ba^{2+}	6.790	18.680	9.100

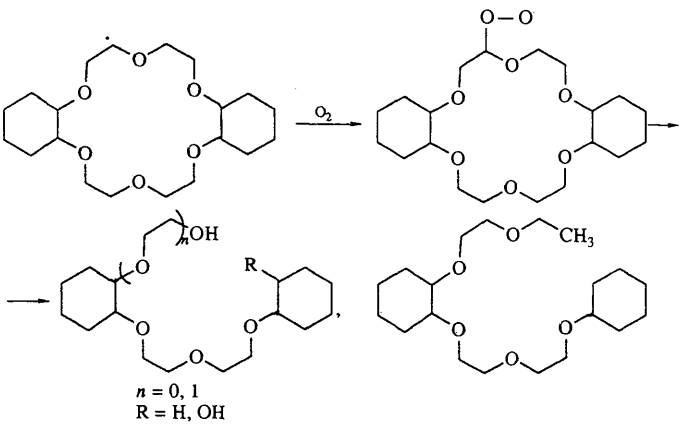
*The 1×10^{-3} M 18C6 solution in chloroform was irradiated from a ^{60}Co γ-source. Dose rate 1.5 Gy s^{-1}, absorbed dose 450 Gy.

An appreciable increase in the radiation-chemical yield $G(HCl)$ on passing from the individual compounds to two-phase aqueous organic systems has been noted for trichlorobenzene and tetrachloroethane.[74] The presence of the crown-ether DCH18C6 or DB18C6 leads under these conditions to an appreciable decrease in $G(Cl^-)$. This can be explained by the proton-solvating properties of the crown-ethers and their ability to form complexes of the type DCH18C6.HCl.

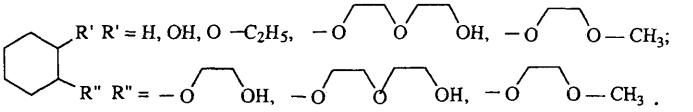
The presence of lanthanum(III) nitrate does not affect the accumulation of Cl^- ions in the 0.1 M crown-ether in tetrachloroethane–3 M HNO_3 extraction system.[75] The radiation-chemical reactions of DCH18C6 and DB18C6 in such aqueous organic systems have been examined.[76] The products of the radiolysis of the crown-ethers after irradiation from a ^{60}Co γ-source (absorbed dose ~100 kGy) were identified with the aid of UV, IR, and ^1H NMR spectroscopy. On the basis of the data obtained, in combination with the results of elemental analysis, the authors[76] proposed a probable mechanism of the formation of nitro- and chloro-derivatives of the products of the radiolysis of macrocyclic polyethers in the extraction system containing tetrachloroethane.

Further studies of the qualitative composition and of the pathways leading to the formation of the products of the radiolysis of DCH18C6 forming part of the 0.1 M DCH18C6 in 1,1,2,2-tetrachloroethane–3 M HNO_3 model extraction system by chromatograph-linked mass spectrometry[77,78] made it possible to refine the process mechanism. More than 40 products of the reactions of the crown-ether were identified and it was established that their structure is determined to a large extent by the nature of the diluent and the composition of the aqueous phase of the extraction system. The proposed mechanism of the radiation-chemical reactions of DCH18C6 includes five main product formation pathways.

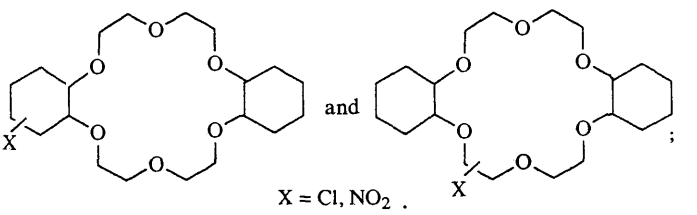
The radical with the unpaired electron localised on a carbon atom of the macrocycle, produced in the first stage, can interact with oxygen, further reactions of the peroxide radical formed leading to the appearance of degradation products (pathway *1*) with partial retention of the polyether bridge between the cyclohexane rings.



Further degradation to products containing only one cyclohexane fragment is postulated (by analogy with the behaviour of the peroxide radicals of ethers).

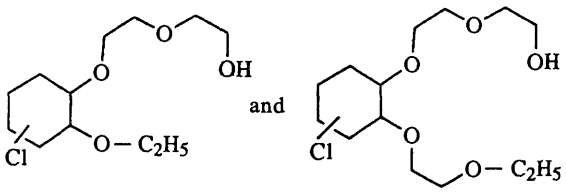


The formation of different chloro- and nitro-substituted crown-ethers



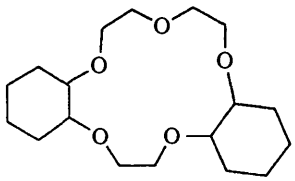
is a result of the reactions of the products of the radiolysis of tetrachloroethane and HNO_3 with DCH18C6 (pathways *2* and *3*).

For the chloro-derivatives, degradation with formation of structures of the type

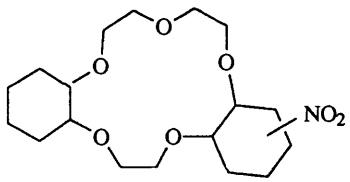


is also postulated.

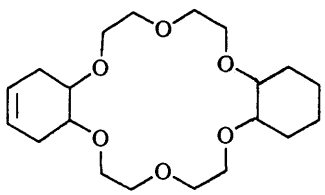
The decomposition of the crown-ether with loss of the epoxyethane fragment and retention of the ring



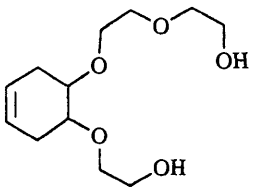
in the case of the liquid-phase radiolysis of DCH18C6 (pathway *4*) is probably analogous to the previously observed process occurring under electron impact in the mass spectrometer[79] and also leads, according to the authors,[78] to the appearance of nitro-substituted cyclic structures.



The partial dehydrogenation of the cyclohexane ring in the DCH18C6 molecule (pathway *5*) leads to the corresponding unsaturated compounds

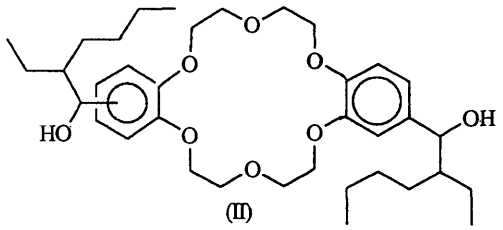


and subsequent fragment of the type



In addition, monocyclohexyl-substituted crown-ethers and the products of the methylation of DCH18C6 were identified in the irradiated extraction system.

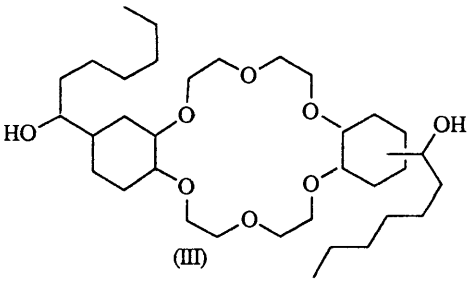
Another approach to the extraction of caesium and strontium from solution in nitric acid with the aid of crown-ethers has been used by Schulz and Bray[80] and Bowers and co-workers.[81,82] They used for the extraction four-component organic systems containing tributyl phosphate (28 vol.%), dinonylnaphthalenesulphonic acid (NNS) or didodecylnaphthalenesulphonic acid (5 vol.%), a macrocyclic polyether (0.05 M), and a hydrocarbon diluent (kerosene, 68 vol%). In these systems, dinonylnaphthalenesulphonic acid is used to substitute the relatively hydrophilic nitrate by a much more lipophilic anion, which increases the partition coefficient of strontium. Tributyl phosphate acts as a modifying agent, inhibiting the formation of a third phase and increasing the solubility of the crown-ether and dinonylnaphthalenesulphonic acid. It is recommended that 4,4′(5′)-bis(2-ethyl-1-hydroxyhexyl)benzo-18-crown-6 (II) be used for the effective extraction of caesium.



(II)

In this case, about 60% of the caesium is transferred from the spent model solution to the organic phase, whereas for solutions of a number of other crown-ethers the above quantity is only approximately 30%.[82]

Similarly, the selective extraction of strontium is promoted by the presence of 0.02 M 4,4′(5′)-bis(1-hydroxyheptyl)cyclohexano-18-crown-6 (III) in the four-component system.



(III)

It was established in comparative experiments that, when the TBP–NNS–crown-ether (II) or (III)–kerosene system is irradiated from a ^{60}Co γ-source up to an absorbed dose of 100 kGy, the partition coefficient of caesium falls from 1.6 to 1.0 and that of strontium diminishes from 2.0 to 1.6.[81]

The selective isolation of Sr^{2+} and Cs^{+} from nitric acid solutions with the aid of liquid membranes containing dinonylnaphthalenesulphonic acid and DCH18C6 dissolved in n-dodecane has been described.[83] The likely usefulness of immobilised liquid membranes for the regeneration and separation of strontium and caesium ions in industry and in analytical chemistry has been demonstrated. The crown-ether DCH18C6 and its derivatives have found applications in the extraction[84–87] and extraction-chromatographic[88–90] isolation and concentration of strontium radioisotopes in the analysis of waste waters, biological samples, and objects in the environment. With the

aid of DB24C8 and dichloromethane as the diluent, it is possible to separate caesium not only from alkali and alkaline earth metals but also from zirconium, hafnium, thorium, lead, bismuth, and other elements usually present in fission products.[91] Sorbents and membranes based on crown-ethers immobilised on different carriers and designed for the extraction and concentration of the ^{137}Cs and ^{90}Sr radionuclides from the alkaline waste produced by atomic power stations have been investigated[92,93] and optimum conditions for the selective transport of the $^{137}Cs^+$ ions through the crown-ether-containing membrane have been developed.

The latest studies by Horwitz and co-workers[94,95] showed that strontium can be effectively extracted from nitric acid by the crown-ether DCH18C6 or its derivatives in various oxygen-containing aliphatic diluents (for example, in alcohols and ketones), which are less toxic than chlorine-containing solvents and do not form corrosive HCl on radiolysis.

Table 2. The effect of radiolysis on the extraction system of the SREX process.[95]

Absorbed dose*, kGy	Partition coefficient of strontium D	
	0.01 M HNO_3	3 M HNO_3
0	0.020	39.6
116	0.056	41.5
244	0.080	36.3
317	0.038**	27.0**
321	0.12	18.5
386	0.11	14.1

* γ-radiation dose rate from a ^{60}Co source 0.7 Gy s^{-1}.
** The values obtained for a 0.2 M solution of DBC18C6 in 1-octanol subjected to preliminary irradition are presented.

In a new process,[95] called SREX, which has many advantages over the methods proposed earlier, the selective extraction of strontium from acid spent solutions is achieved using a 0.2 M solution of di-t-butylcyclohexano-18-crown-6 (DBC18C6) in 1-octanol. It has been shown experimentally that 99.7% of the strontium present initially in the solution can be extracted after only three extraction cycles. Table 2 summarises the results of the study of the influence of γ-radiolysis on the effectiveness of the SREX process. For absorbed doses not exceeding 240 kGy, the partition coefficient of strontium between the organic phase and 3 M HNO_3 does not change appreciably, but for higher doses D falls significantly and at ~390 kGy it diminishes by a factor of almost three compared with the initial value. On the other hand, the data obtained for 0.01 M HNO_3 show that, even for the lowest absorbed radiation dose investigated, the system undergoes radiolytic reactions leading to an almost threefold increase in the partition coefficient. It has been noted that radiolysis does not impair the selectivity of the strontium extraction process.

In connection with the high radiation stability of crown-ethers noted in a number of studies,[7,12,71,72] Horwitz, et al.[95] decided to check whether the observed change in the partition coefficient is merely a consequence of the radiation-induced degradation of the diluent. For this purpose, a 0.2 M solution of DBC18C6 was prepared in 1-octanol subjected to preliminary irradiation (317 kGy) and the strontium partition coefficients were determined. The measured values of D for 0.01 and 3 M HNO_3 occupy an intermediate position between the values obtained for the initial solution and the irradiated solution used in the extraction process. Thus the radiolysis of the system entails the degradation of both the diluent and the extractant. In the absence of other data apart from the measured partition coefficients, it is impossible to establish definitely the nature of the influence of the irradiation on the extraction system, although the rupture of the crown-ether ring and the formation of hydrocarbons with a smaller chain length and low-molecular-weight alcohols and aldehydes from 1-octanol is likely. It is important to note that the absorbed radiation doses used in the experiments appreciably exceed the values which may be expected in the processing of real radioactive liquid waste. Consequently, the radiation-chemical reactions do not create serious obstacles to the extraction process over a long period.

The complexity of the radiation-chemical behaviour of crown-compounds in multicomponent two-phase aqueous organic extraction systems used under the conditions of the industrial processing of radioactive materials necessitates a profound study of the mechanisms of the formation of the main products of the radiolysis of the extractants on the basis of simpler systems,[96] which may permit the determination of the details of the reaction mechanisms presented above as well as similar mechanisms.

It is therefore useful to examine in the Sections below the radiolysis of individual crown-compounds as well as their aqueous and non-aqueous solutions.

III. Radiolysis of macrocyclic polyethers

As a rule, the description of the radiation-chemical reactions in various systems is usually begun with the consideration of the primary radiolysis products and the reactive intermediates participating in such reactions. It has been shown that the products of this kind in liquid polar media are solvated electrons, various ions, free radicals, and excited molecules.[24] However, the available information about the primary products of the radiolysis of crown-ethers and their analogues is so far scanty and does not permit the formulation of a detailed picture of the primary processes occurring.

The formation of solvated electrons in the radiolysis of liquid crown-ethers has been observed by a pulse method in relation to 12C4 and 12C5.[97,98] The optical spectrum of e^-_{solv} in 12C4, obtained in the pulse radiolysis of the pure crown-ether, is illustrated in Fig. 3. The assignment of the peak in the wavelength range between 1100 and 1500 nm to e^-_{solv} is based on the complete disappearance of this peak when the solution is saturated by the N_2O electron acceptor. The wavelength at the absorption maximum of the solvated electron in 12C4 is close to the corresponding wavelength in ammonia (1504 nm).[97]

When 15C5 is subjected to pulse radiolysis and also when metallic potassium and caesium are dissolved in it, a very broad absorption band (from 0.8 to 1.8 μm) predominates in its near IR optical spectrum. By analogy with pulse radiolysis data for pure 15C5, the band was assigned to the solvated electron e^-_{solv}. The spectra of the

potassium solutions show a shoulder at 0.85 μm, which is characteristic of the K^- anion. On the other hand, solutions of alkali metals in 12C4 do not exhibit an appreciable absorption due to the solvated electron (Fig. 4). Instead, the presence of appreciable concentrations of the alkali metal anion is manifested in the spectrum. It is of interest to note that solutions of metals in 15C5 are less stable than their analogues in 12C4. Studies by pulse radiolysis showed that the rate constant for the first-order reaction involving the disappearance of the electron in 15C5 ($\sim 5 \times 10^6$ s^{-1}) is appreciably lower than in 12C4 ($\sim 2.5 \times 10^7$ s^{-1}).,[98] i.e. the solvated electron is longer-lived (or is more solvated) in liquid 15C5 than in the smaller ionophore 12C4.[99]

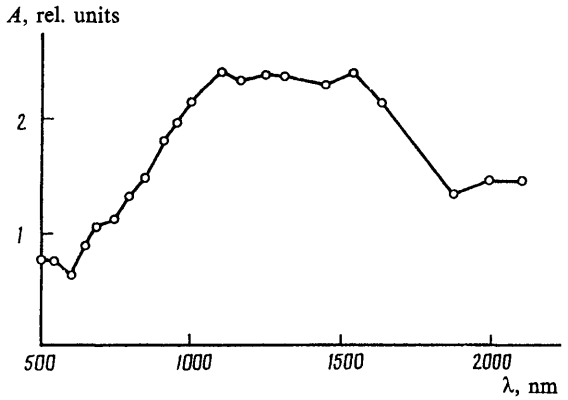


Figure 3. The optical spectrum of the solvated electron obtained on pulse radiolysis (0.2 μs) of 12C4 at room temperature.[97]

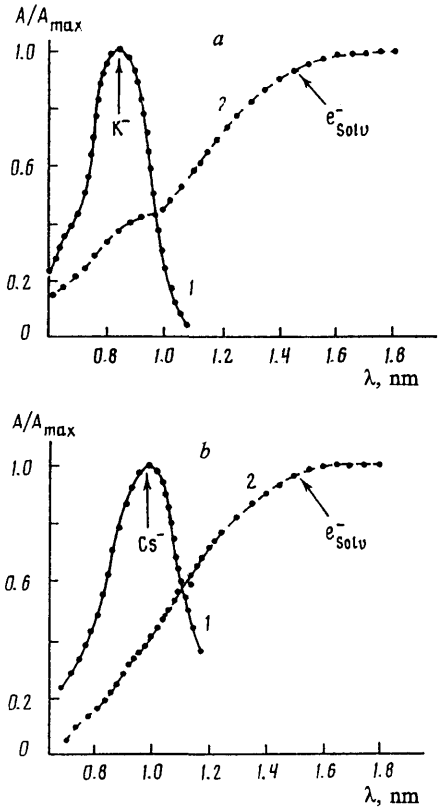

Figure 4. The optical absorption spectra at room temperature of metallic potassium (*a*) and caesium (*b*) dissolved in 12C4 (curves *1*) and 15C5 (curves *2*).[98]

Table 3. The radiation-chemical yields of molecular hydrogen and stabilised paramagnetic species in crown-ethers (absorbed doses 10–180 kGy).[101]

Crown-ether	$G(H_2)$	G(R)		
	T_{irr} = 77 K	T_{irr} = 77 K	after UV irradiation	T_{irr} = 300 K
18C6	0.3	5.7	5.7	0.8
DCH18C6	0.2	3.3	3.0	0.2
DB18C6	0	1.9	1.6	–

The radical intermediates formed in the low-temperature γ-radiolysis of a number of crown-ethers and their analogues with different ring sizes[100] as well as crown-ethers having an 18-membered macroheterocycle with different substituents[101–103] have been investigated by EPR spectroscopy. The results of the study of the primary products of the radiolysis of the polyethers 18C6, DCH18C6, and DB18C6 as well as mass-spectrometric data are presented in Table 3.

The introduction of substituents into the macrocycle leads to an appreciable change in the EPR spectra of the irradiated compounds and the specimens become coloured brown. The effect of UV radiation leads to the decolorisation of the specimen and to the disappearance of one of the spectral lines, which permits its assignment to stabilised electrons. After the "annealing" of the stabilised electrons, the concentration of the paramagnetic species does not increase. On raising the temperature to the melting point of the crown-ethers, the EPR spectra vanish. The appearance of a yellow colour and the presence of stabilised electrons in the irradiated 12C4, 15C5, DCH18C6, and their analogues tetrahydrofuran (THF) and 1,4-dioxane (the smallest member of the family of cyclic epoxyethane oligomers), has also been observed in the study of Kuruc and Sersen,[100] who also noted the instability of the radical intermediate at temperatures above 297 K.

The inconsistency between the radiation-chemical yields of molecular hydrogen and of the paramagnetic species formed (Table 3) and also the complexity of the EPR spectra of the irradiated crown-ethers are a consequence of the simultaneous occurrence during radiolysis of several primary processes, the main one being, according to the authors,[101–103] the rupture of the macrocycle at the C–O bonds. However, Kuruc and Sersen[100] believe that the formation of radicals containing the $-O-\dot{C}H-CH_2-$ fragment is more likely in the given instance, by analogy with the reactions in dioxane and THF.

The EPR study of γ-irradiated solutions of 1,4-dioxane in Freon matrices permitted the conclusion that the primary radical-cation undergoes an ion-molecule reaction with a neutral molecule and leads to the formation of a radical, resulting from the α-abstraction of hydrogen, and of a protonated dioxane molecule.[104] Other data[105] show that the THF radical-cations in the ground state, generated in freon matrices, are resistant to ring rupture reactions, but in the parent compound matrix the radical-cations, having an excess energy, are capable of forming radicals as a result of ring rupture.

In the case of mono- and di-alkyl derivatives of DB18C6, the abstraction of a H atom from the CH_2 groups of the macrocycle and the alkyl substituents in the crown-ether has been postulated.[102,103] The C-centred nature of the radicals is confirmed by the results of a study by the spin trapping method,[106] since it was established that the EPR spectra of the radical adducts formed on capture by the spin-trapping agent of the crown-ether radicals (generated at 77 K) on heating the specimen and measuring the spectrum at room temperature as well as the spectra of the radical adducts observed on irradiation at room temperature are identical. The EPR spectra of the radicals generated at 77 K, measured at the same temperature in the presence of a spin-trapping agent are consistent with the spectra of the pure crown-ethers.

The analysis of the EPR spectra obtained after irradiating the crown-ethers 12C4, 15C5, DCH18C6, as well as THF and 1,4-dioxane in the presence of a spin-trapping agent established the formation of spin adducts with H atoms and C-centred radicals. Under these conditions, it cannot be that the radical centre is located on the polyether or cyclohexane ring of the substituted macrocycle. We may note that in the case of THF two spin adducts are detected, which indicates the formation of both α- and β-radicals.[105]

Table 4. The radiation-chemical yields of free radicals in organic compounds at 77 K.[109]

Compound	*G*(R), radical/100 eV
Ethanol	4.0
Ethylene glycol	5-6
Diethyl ether	3.7
THF	1.7
Furan	1.1
Trioxane	1.1
Tetrahydropyran	4
Cyclohexane	3.8
Benzene	0.15

The introduction of substituents, especially aromatic rings, into the polyether ring increases the radiation stability of the crown-ethers as a result of the intramolecular energy transfer from the macrocycle to the substituent.[100-103]

The effect of γ-radiation on solid complexes of crown-ethers with metal salts has been investigated by EPR spectroscopy.[107,108] The radiation-chemical yields of the radicals were measured for $MgCl_2$.18C6, $CaCl_2$.18C6, and $CaCl_2$.15C5. They are 3.3, 8.1, and 3.1 radical/100 eV respectively. The presence of atomic hydrogen was detected in the irradiated specimens of $FeCl_3$.18C6 and $FeCl_3$.15C5.[108] It was noted that the radiation-chemical processes in the molecular complexes of the crown-ethers are determined not only by the nature of the macrocyclic ligand but to a large extent by the properties of the metal cation.

Comparison of the yields of radicals (Table 3) in crown-ethers irradiated at 77 K with the analogous values obtained at the same temperature for a number of other organic substances[109] (Table 4) does not indicate any kind of unusually high radiation stability of the crown-ethers. Their properties are similar to those of ethers and alcohols. The yields of the final radiolytic products are extremely important for the characterisation of the radiation stability of the compounds (as the factor influencing their practical employment).

The γ-radiolysis of DB18C6, DCH18C6, and 18C6 in the condensed phase in the presence and absence of air has been investigated in a series of studies[7,9,79,101] by gas–liquid chromatography and UV and NMR spectroscopy. No radiolysis products were found under these conditions in the condensed phase in the range of absorbed doses up to 640 kGy. Mass spectrometry of the gas phase of the irradiated crown-ethers made it possible to detect the formation during radiolysis of molecular hydrogen and of traces of epoxyethane (Table 5), but the yields of these products were not quoted.[7,9] Since the irradiation of DB18C6 and DCH18C6 results in the formation of $\sim 7 \times 10^{-5}$ and $\sim 8 \times 10^{-3}$ mol of H_2 per mole of the crown-ether,[7] it was possible to estimate the radiation-chemical yield of hydrogen taking into account the molecular weights of the crown-ethers and the absorbed dose of ionising radiation (~640 kGy). It amounts to ~0.003 molecule/100 eV for DB18C6 and ~0.3 molecule/100 eV for DCH18C6. In a later study by the same workers,[79] yields of hydrogen, amounting to 0.12, ~0.01, and ~0.01 molecule/100 eV were obtained respectively for DCH18C6, DB24C8. The upper limits of the decomposition are ~0.004 and ~0.2 molecule/100 eV for DB18C6 and DCH18C6 respectively.[7]

Table 5. Mass spectra of the gas-phase products of the radiolysis of DCH18C6 and DB18C6 (absorbed dose rate 0.51 Gy s^{-1}, dose ~640 kGy).[7]

m/e	Peak intensity, rel. units		Proposed structure of fragments
	DB18C6	DCH18C6	
2	70	1000	H_2^+
15	10	20	CH_3^+
26	10	10	$C_2H_2^+$
28	10	20	$C_2H_4^+$, CO^+
44	60	50	$C_2H_4O^+$, CO_2^+

In the proposed radiolysis mechanism,[7,79] it is assumed that epoxyethane is formed in a small amount from the cyclic polyether as a result of ion-molecule reactions and that, after the elimination of the C_2H_4O fragment from the molecular ion of the crown-ether,

the opening of the macrocycle does not occur, a cyclic structure with a smaller ring size being formed instead. It is assumed that the source of hydrogen in the irradiation of DCH18C6 is the cyclohexyl fragments.

The study by Langrock, et al.[12] was also devoted to the radiation stability of crown-ethers. They investigated the γ-radiolysis of B15C5, DB18C6, DB24C8, and dithio-18C6 in the presence of air in the temperature range 293–313 K (absorbed dose range 0.1–1 MGy). The yields of the gaseous radiolysis products were determined by gas chromatography and those of the decomposition of the polyethers were found by ^{1}H NMR spectroscopy (Table 6). The authors[12] state that the resistance of the crown-ethers to γ-radiation can be regarded as satisfactory in the dose range up to 0.2 MGy and is acceptable up to 1 MGy. The radiation stability diminishes in the sequence DB24C8, B15C5 > DB18C6 > dithio-18C6. Crown-ethers containing only oxygen heteroatoms in the macrocycle are recommended for practical use in radiochemical separation processes.

Table 6. The yields G of the products of the γ-radiolysis of crown-ethers for an absorbed dose of 0.1 MGy.[12]

Crown-ether	Yields of gaseous products			Yield in the decomposition of the solid substance

Table 7. The radiation-chemical yields of the products of the γ-radiolysis of polyethers at different temperatures (dose rate 4 Gy s^{-1}, absorbed doses 2–15 kGy).[110]

Compound	State of aggregation	$G(H_2)$		$G(C_2H_4)$	
		290K	300K	290K	300K
1,4-Dioxane	Liquid	–	1.41	–	0.364
PEG-300	"	1.46	–	0.048	–
PEG-600	Oil	2.06	–	0.043	–
	Liquid	–	1.51	–	0.026
15C5	"	1.60	1.94	0.081	0.158
18C6	Crystalline	2.14	–	0.020	–
	Liquid	1.62	1.85	0.108	0.163
DB18C6	Crystalline	0.175	–	0.014	–
DCH18C6	Oil	1.03	–	0.078	–
	Liquid	0.86	1.18	0.089	0.118

The results of studies on gaseous products of the γ-radiolysis of deaerated specimens of the cyclic polyethers 15C5, 18C6, DB18C6, and DCH18C6, their acyclic analogues—the poly(ethylene glycols) PEG-300 and PEG-600, and also 1,4-dioxane have been described.[110] It was established on the basis of the results of chromatographic analysis that the principal gaseous products are hydrogen and ethylene (Table 7), together with which a small amount of methane (G = 0.012 molecule/100 eV for 15C5) and traces of acetylene and carbon monoxide [G(CO) < 0.002] were detected. The low yield of ethylene formed in the γ-radiolysis of crown-ethers as well as polyglycols, compared with $G(C_2H_4)$, for dioxane is associated with the fact that the probability of the simultaneous dissociation of two C–O bonds in a single $-O-CH_2-CH_2-O-$ unit is greater for the dioxane molecule.

Thus the radiation-chemical behaviour of crown-ethers is similar to that of dioxane and poly(ethylene glycols) and, from the standpoint of radiation stability, macrocyclic polyethers do not differ fundamentally from the acyclic analogues and also from 1,4-dioxane which is in its turn more stable in this respect by a factor of 1.5–2 than, for example, diethyl ether.[109]

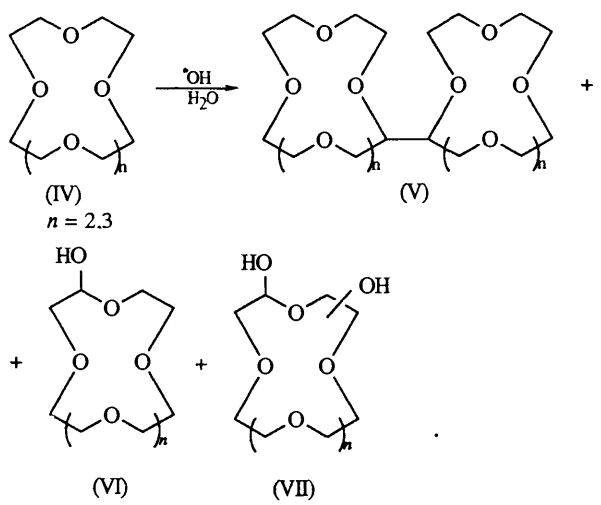
IV. Radiation-chemical reactions in solutions of crown-compounds

1. Radiolysis of crown-ethers in aqueous solutions

Aqueous solutions of crown-ethers have been the objects of study by pulse radiolysis.[111–114] The study of the interaction of 18C6 (as well as its complexes with alkali metal perchlorates) and DCH18C6 with the primary water radiolysis products showed that crown-ethers exhibit a high reactivity in relation to hydrogen atoms and OH and O^- radicals and are significantly less reactive in relation to hydrated electrons (Table 8). It has been found[111,113] that at pH 6.5–6.7 the radiation-chemical yield of hydrogen is 0.9 molecule/100 eV both for 18C6 and DCH18C6, i.e. is close to the sum $G(H) + G(H_2) = 1.0$ in the radiolysis of pure water. In acid solutions (pH 1.0), the yield of hydrogen is $G(H_2) = 3.8$ molecule/100 eV for 18C6 and 3.0 molecule/100 eV for DCH18C6, i.e. is close to the sum of the yields $G(H) + G(H_2) + G(e_{aq}) = 4.1$. On this basis, it was concluded that hydrogen atoms interact with crown-ethers in the dehydrogenation reaction.

It follows from the identity of the optical absorption spectra of the short-lived products (λ_{max} = 260 nm) in acid as well as neutral and alkaline solutions of crown-ethers that H atoms, OH radicals, and O^- radical-ions dehydrogenate the polyether molecule with formation of the same radical. On the basis of EPR spectroscopic data, it is claimed[111,113] that both in the radiolysis of aqueous solutions of 18C6 and in the case of DCH18C6 the radical centre is located on the carbon atom of the polyether ring $-O-CH_2-CH-O-$, while the cyclohexyl groups in DCH18C6 are not involved to an appreciable extent. This mechanism has been confirmed also in the study of the dehydrodimerisation of crown-ethers in aqueous solution in the presence of hydrogen peroxide and iron(II) sulphate:[117]



Apart from the dimerisation products (V), the hydroxy-substituted crown-ethers (VI) and (VII) were isolated from the reaction mixture. The formation of the latter is possible as a result of the recombination of the corresponding radicals. Compounds (V)–(VII) are colourless oily substances whose composition and structure have been confirmed by elemental analysis, ^1H NMR, and mass spectrometry.[117]

It has been established[111,114] that absorption with $\lambda_{max} \simeq 260$ nm arises also in the pulse radiolysis of solutions of complexes of alkali metal perchlorates with 18C6. The presence of the potassium ion increases the rate constant for the reaction of the OH radical with the crown-ether but reduces the rate constant for the reaction of the H atom (Table 8). The disappearance of crown-radicals obeys the kinetic equation for second-order reaction (the values of $2k$ are listed in Table 8). Thus the presence of the alkali metal ion does not affect the mechanism of the interaction of OH and H radicals with the macrocyclic ligand and the reaction results in the appearance of analogous crown-radicals. On the other hand, the nature of the cation bound in the complex influences the reactivity of the crown-ether. It follows from the data in Table 8 that the rate constants for the interaction with the OH radical diminish from sodium to rubidium. Such variation is probably associated with the decrease in the energy of the C–H bond in the metal complex of the crown-ether as a consequence of the polarisation of the C–O bonds, which is greater the smaller the ionic radius of the metal.

Table 9. The rate constants for the reactions of complexes incorporating macrocyclic tetraaza-ligands with the primary water radiolysis products in aqueous solutions.

*The rate constants (k, s^{-1}) for the decomposition of the manganese(IV) complexes formed are indicated in brackets. Their final decomposition reaction product is manganese(IV) oxide.[118]

**Certain spectroscopic characteristics of the complex $[Ni(L^6)]^+$, obtained on γ-irradiation of a solution of $Ni(L^6)(ClO_4)_2$ (saturated with helium at pH 7.6) with a dose of ~0.5 kGy have been published.[124]

Reduction of the cadmium(II) complexes of the cryptands [2.2.1] and [2.2.2] {C[2.2.1] and C[2.2.2]} by hydrated electrons has been investigated by pulse radiolysis.[115] The study of the interaction of

the primary water radiolysis products with cryptands showed that there are reactions of the OH radical (with abstraction of a hydrogen atom from a C—H bond in the cryptand) which are virtually controlled by diffusion (Table 8), while the reactions of the hydrated electron with C[2.2.1] and C[2.2.2] have not been observed. The hydrated electron reacts with the cadmium ion as follows:

$$e^-_{aq} + Cd^{2+} \rightarrow Cd^+.$$

The rate constant for this reaction involving the aqueous $Cd(ClO_4)_2$ solution is $k_{\Psi=0} = 4.8 \times 10^{10}$ litre mol^{-1} s^{-1} after extrapolation to zero ionic strength. In solutions of cadmium(II) perchlorate in the presence of an excess of the cryptand, the disappearance of hydrated electrons via the reactions

$$e^-_{aq} + [Cd\{C[2.2.2]\}]^{2+} \rightarrow [Cd\{C[2.2.2]\}]^+,$$

$$e^-_{aq} + [Cd\{C[2.2.1]\}]^{2+} \rightarrow [Cd\{C[2.2.1]\}]^+$$

is described by a pseudo-first order kinetic equation; the reaction rate constants are listed in Table 8. The appreciable differences between the reactivities of cadmium cryptates in relation to e^-_{aq} have been related[115] to the crystallographic ionic radii, the size of the cryptand cavity, and the stability constant of the corresponding cryptates.

Table 9 lists the kinetic characteristics of certain oxidation-reduction reactions with participation of the primary water hydrolysis products obtained in the pulse radiolysis of solutions of manganese(III) and nickel(II) complexes of cyclam (L^2) and other nitrogen-containing analogues of crown-ethers.

Irradiation of aqueous solutions of 18C6 up to large absorbed doses (0.25 MGy) does not lead to the formation of insoluble products.[113] The formation of compounds containing an aldehyde group with a radiation-chemical yield $G = 0.4$ was established from the results of the chemical analysis of the residue after the removal of water and from IR spectroscopic measurements. The overall yield in the decomposition of 18C6 is 0.6 molecule/100 eV. In aqueous solutions of DCH18C6, starting from a dose of 5 kGy, a pale-yellow deposit is formed. It contains compounds with an aldehyde group which are insoluble in the usual organic solvents. The overall decomposition yield is 0.9 molecule/100 eV for DCH18C6. Since the cyclic structure does not decompose in the stage involving the interaction of the primary water radiolysis products with crown-ethers, it has been suggested[113,114] that the aldehydes are formed in secondary reactions. The aldehydes are probably formed mainly as a result of the interaction of the crown-ether with hydrogen peroxide:

$$-CH_2-\dot{C}H-O-CH_2-CH_2- + H_2O_2 \longrightarrow$$
$$\longrightarrow -O-CH_2-CH_2-O-CHO + \dot{C}H_2-O-CH_2- .$$

Another possible pathway is the disproportionation reaction of the radicals:

$$2\,-CH_2-\dot{C}H-O-CH_2-CH_2- \longrightarrow$$
$$\longrightarrow -CH_2-CHO + CH_2{=}CH-O- +$$
$$+ -CH_2-CH_2-O-CH_2-CH_2- .$$

On irradiation of solutions of DCH18C6, a deposit may appear as a result of the formation of aldehydes and also as a result of the dimerisation of radicals.[113]

We may note that, when poly(ethylene glycols)—high-molecular-weight linear analogues of crown-ethers—are acted upon by radiation in aqueous solutions in the absence of dissolved oxygen, gel formation takes place and the radiation-chemical yield of the cross-linking reaction is 0.27 in 0.5% solution, but the ratio of the cross-linking yield to the polyether chain degradation yield in a neutral medium is 4:1.[125] Degradation predominates in acid solutions. The hydrogen formed in the radiolysis of a 2% solution of poly(ethylene glycol) in D_2O consists mainly of HD (G = 0.59 molecule/100 eV) whereas $G(H_2) = 0.05$ molecule/100 eV. When recalculated in terms of the dose absorbed by the solute, this gives $G(H_2) \simeq 2.5$ molecule/100 eV, which agrees with data[110] for poly(ethylene glycols) (Table 7).

Chain degradation of poly(ethylene glycol) takes place in the presence of oxygen. The reactive products of the radiolysis of the solvent (H, OH) abstract hydrogen from the α-position in the ether linkage and oxygen adds to the macroradical arising in this way and gives rise to a peroxide radical. The chain propagation reaction is that between the peroxide radical and the initial molecule with formation of a hydroperoxide:

$$-CH_2-\underset{\displaystyle O-O^{\cdot}}{\overset{|}{CH}}-O- + -CH_2-CH_2-O- \longrightarrow$$
$$\longrightarrow -CH_2-\underset{\displaystyle O-OH}{\overset{|}{CH}}-O- + -CH_2-\dot{C}H-O- .$$

The decomposition of the hydroperoxide and the recombination of the peroxide radicals afford the alkoxyl radicals $-CH_2-\underset{\displaystyle O}{\overset{|}{CH}}-O-$, which rapidly decompose with rupture of the molecular skeleton.[125,126]

The radiation-chemical reactions of the macrocyclic polyethers examined above may be compared with the behaviour in 0.1 M aqueous solutions of heterocyclic compounds such as 1,3-dioxolans,

1,3- 1,4-dioxanes, etc.[127] The main products of the radiolysis of these compounds are ethylene, carbon monoxide (or dioxide), and aldehydes. The radicals, formed predominantly as a result of the dissociation of the C–H bond in the α-position relative to the heteroatom by the H and OH radical species into five- and six-membered oxygen-containing heterocycles, can rearrange to linear radicals on ring cleavage. However, among the products of the radiolysis of dioxanes, there are substances whose formation cannot be explained by the occurrence of the above processes. The initial radical species derived from dioxanes can decompose, as in the case of 1,3-dioxolans, in accordance with a concerted mechanism (with the simultaneous dissociation of two bonds), which results in the formation of the degradation products. The occurrence of this process in the radiolysis of 1,4-dioxane leads to the formation of acetaldehyde (G = 0.03 molecule/100 eV). Other products of the radiolysis of this compound are ethylene and CO. Under these conditions, $G(C_2H_4)$ = 0.07 and $G(CO)$ = 0.0014 molecule/100 eV in 0.1 M aqueous solution.[127] The radiation-chemical yields of ethylene and carbon monoxide exceed respectively by one and two orders of magnitude the values which would be expected in the case of the formation of the given compounds as a result of the direct action of γ-radiation on the dissolved 1,4-dioxane (the calculation was performed using the values of G for pure dioxane quoted by Zatonsky and Povolotskaya[110]). Thus the radiation-chemical degradation of the cyclic and macrocyclic ethers in aqueous solutions is associated with the indirect action of ionising radiation.

2. Radiolysis of solutions of crown-compounds in aromatic hydrocarbons

Together with the systems, examined in Section II, based on organochlorine solvents, numerous studies, concerned with the radiation-chemical reactions in non-aqueous solutions of crown-compounds, have been devoted to the radiolysis of their solutions in arenes. Aromatic hydrocarbons are much more reactive than aliphatic compounds and solutions of DCH18C6 and other crown-ethers in toluene and benzene are used for the effective extraction isolation from nitric acid solutions of radioactive elements such as uranium(VI) and plutonium(IV).[128]

Table 10. The radiation-chemical yields of the gaseous products of the γ-radiolysis of benzene solutions of crown-ethers.

* Solution of crown-ether in C_6D_6; irradiation in the presence of air.

** The sum of $G(C_2H_4)$ and $G(C_2H_6)$ is quoted.

*** Calculated taking into account the direct effect of radiation on the solute using the corresponding values of G for 18C6 in the liquid state taken from the literature.[110]

Table 10 presents data characterising the radiolytic formation of gaseous products in benzene solutions of crown-ethers. The presence of crown-ethers has only a slight effect on the gas evolution caused by the radiolysis of solvents; the increase in the radiation-chemical yield of hydrogen and the appearance of ethylene and methane are associated in this instance with the direct action of ionising radiation and the solute. This is confirmed by the results of the study of the γ-radiolysis of a solution of 18C6 in fully deuteriated benzene[130] and also by the calculated values of G presented in Table 10. The presence of t-butyl substituents in the molecule of 4,4′(5′)-di-t-butyldibenzo-18-crown-6 (DBB18C6) is responsible for the high yields of ethylene and methane—the polyether degradation products—in a benzene solution of DBB18C6 compared with 18C6.[129] The yield in the radiation-chemical decomposition of 18C6 on γ-irradiation of its solution in C_6D_6 (initial concentration 0.435 M) is ~1.25 molecule/100 eV,[130] which corresponds to the decomposition of about 15% of the compound on absorption of a dose of 1 MGy.

Table 11. The influence of crown-compounds and their complexes on the formation of dimeric benzene γ-radiolysis products.

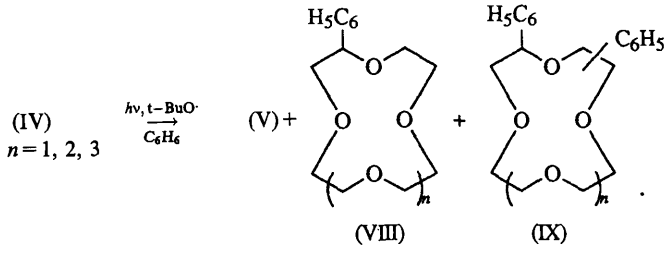
Thus from the standpoint of gas evolution processes and also the degradation of crown-ethers dissolved in benzene, macrocyclic polyethers are extremely radiation-resistant compounds for absorbed

doses not exceeding 200 kGy and can be used for many radiochemical separation processes as selective extractants.

Another process determined by radiolysis and inducing an impairment of the extraction-technological characteristics of the system is the formation of high-boiling products. Studies of the formation of dimeric products of the radiolysis of aromatic hydrocarbons in the presence of various crown-ethers have shown[8,131] that crown-compounds do not induce an additional reaction of the matrix via this pathway. On the contrary, in most cases, they, as it were, protect the solvent against the action of radiation. Examples of a decrease in the yield of biphenyl and phenylcyclohexadienes — the main benzene radiolysis products — in the presence of crown-compounds are presented in Table 11. This effect of crown-ethers agrees with the model of the formation of high-boiling products via the cationic polymerisation mechanism (including the addition of primary arene radical-cations to neutral molecules).[30,31]

Bearing in mind the powerful proton-accepting properties of crown-ethers,[133,134] one may expect the occurrence of reactions involving proton transfer from the molecular arene ion to the polyether molecule. The introduction of benzene rings into the polyether molecule lowers its proton affinity[133] and the effect of dibenzocrown-ethers on the yield of dimeric products is therefore much weaker than that of, for example, 18C6. On the other hand, a cryptand acts more effectively than crown-ethers because it is a stronger proton-solvating agent.

We may note that, although phenyl radicals are in fact formed as a result of the deprotonation of the benzene radical-cation, they may react further with the crown-ether without giving rise to biphenyl and phenyl cyclohexadienes. Thus the decrease in the yield of dimers in the radiolysis of benzene solutions of 1,4-dioxane has been explained[135] by the interaction of phenyl radicals with solute molecules leading to α-abstraction of a hydrogen atom. In the study of the dehydrodimerisation of 12C4, 15C5, and 18C6 in benzene in the presence of t-butyl peroxide, whose decomposition was initiated photochemically, phenyl-substituted crown-ethers (VIII) and (IX), formed on recombination of the corresponding radicals, were isolated and characterised in addition to the expected dimerisation products (V):[117]



Similar processes occur in the radiolysis of toluene in the presence of crown-ethers. Since the deprotonation reaction

$$C_6H_5CH_3^+ \longrightarrow C_6H_5CH_2^{\cdot} + H^+$$

is extremely important for the toluene radical-cations in the liquid phase while the benzyl radicals formed are less reactive than phenyl radicals and are destroyed predominantly as a result of recombination, in the presence of 18C6 there is some increase in the yield of the dimeric radiolysis products. In the case of a solution of DB24C8, the yield of bibenzyl falls somewhat, although the overall yield of the dimers remains unchanged.[131]

Another aspect of the use of crown-compounds in radiation-chemical studies is associated with attempts to act on the processes involving the radiolysis of liquid matrices of aromatic hydrocarbon,[29–32,132,136–138] based on the hypothesis that electron-donating agents present in solution should diminish the probability of the formation of radiolysis products, whereas electron-accepting agents (i.e. substances with oxidising properties) should promote radiolysis. The unique properties of crown-ethers, which make it possible to solubilise inorganic substances of different nature in organic (including hydrocarbon) solvents, provide very extensive possibilities for this purpose.

For example, dissolution of metallic potassium in arenes containing a crown-ether or a cryptand results in the formation of systems with a homogeneous distribution of electron-donating species, namely K^- anions or electrons, which are present in the form of crown-separated pairs $[K^+, L]K^-$ or $[K^+, L]e^-_{solv}$, where L is the macrocyclic ligand. On irradiation of such benzene solutions, the yield of biphenyl is extremely low, while phenylcyclohexadienes are not formed at all (Table 11). The yield of bibenzyl is also significantly reduced in the toluene–18C6–potassium system, while benzylmethylcyclohexadienes are detected only in trace amounts. The inhibition of the formation of dimeric products in the radiolysis of aromatic hydrocarbons, induced by the charge-transfer process (the transfer of an electron to the parent radical-cation)

$$ArH^+ + K^- \longrightarrow ArH + K$$

probably proceeds extremely effectively, because the reactant with a low ionisation potential (the reductant) is not simply the neutral solute molecule but an active weakly solvated electron-donating species bearing a negative charge.[31]

Potassium hydroxide and halides solubilised by crown-ethers do not manifest pronounced reducing or oxidising properties and do not lead to such appreciable inhibition of the formation of dimers,[136,137] while additives with oxidising properties induce the opposite effect. Thus the presence of $KMnO_4$ suppresses the formation of phenylcyclohexadienes, but increases appreciably (by 80%) the yield of biphenyl.[29,138] The electrons arising in the primary radiolytic steps interact with additives of this type, being converted into chemically more inert species and increasing thereby the lifetime of the benzene radical-cations and hence the probability of the occurrence of ion–molecule reactions. The absence of phenylcyclohexadienes is caused by the complete oxidation of their precursors to biphenyl by permanganate ions.

Combination of additives of different types, for example, crown-ethers and spin-trapping agents[139] or crown-ethers and transition metal acetylacetonates,[140,141] in the radiolysis of aromatic hydrocarbons can serve as an extremely effective instrument for the study of the mechanism of the formation of the products. Investigation of the latter systems is of independent importance because the combination of the crown-ether–β-diketone–diluent components is encountered in real extraction systems used for the isolation of radionuclides.[59,142]

The mechanism of photolysis of aromatic azides

N P Gritsan, E A Pritchina
Institute of Chemical Kinetics and Combustion, Siberian Section of the Russian Academy of Sciences
Novosibirsk State University, Novosibirsk

ABSTRACT. A survey has been made of data published in recent years on the nature, spectra and reactivity of intermediates obtained on photolysis of aromatic azides. Aspects requiring further investigations have been highlighted.

The bibliography includes 147 references.

I. Introduction

The photochemical reactions of organic azides have been a focus of study for more than 60 years, and interest in this field is in no way declining. This is principally because these compounds have many practical applications, e.g. in polymer chemistry, in photolithography, and as light-sensitive agents for use in photographic processes which are not based on silver salts.[1–3] Aryl and heteroaryl azides are also used as reactive reagents in the photoaffinity modification of biopolymers.[4,5] Interest in the photochemistry of organic azides has also developed from mechanistic considerations, many of which are complex and unresolved.

It was towards the end of the 1950s, with the advent of new analytical methods, that exhaustive studies were first made on the structure and reactivity of the intermediates obtained on photolysis of organic azides. The results obtained up to 1983 have been reviewed[6,7] and presented as monographs.[8–10] In the Soviet literature of 1975, there is also a review on the photochemistry of organic azides,[11] together with a number of short surveys published as monographs.[1,2] However, in spite of the enormous interest in the photochemistry of organic azides, many mechanistic details remain unclear, and certain data from a number of authors are contradictory.[10] Significant progress has been made during the last 5–6 years as a result of using new methods[12–14] and applying traditional methods in a more sophisticated way.[15–17]

II. The structure, electronic spectra and properties of azides

1. Structure and electronic spectra of azides

Azides are a class of compound with the general formula, RN_3. The three atoms of nitrogen are linear.[18–21] The atom of nitrogen bonded to substituent R is sp^2-hybridised (the R–N–N angle being close to 120°).[18–22] In aryl azides all three nitrogen atoms are involved in conjugation with the aromatic system, although such interaction is weak.[22] As a consequence there is a similarity between the absorption spectra of azides and those of the corresponding aromatic hydrocarbon.

Table 1. Electronic spectral absorption of phenyl azide derivatives.

* $n\pi^*$-region.

The principal bands in the absorption spectra of aromatic azides have been assigned to $\pi\pi^*$ transitions in the aromatic system. There is also absorption, thought to correspond with $n\pi^*$-type transitions,[22–24] which is not evident in the spectra of the corresponding hydrocarbon. The values of these absorption maxima are approximate because they appear as shoulders on the

absorptions due to the more intense ππ*-transitions. These weak absorptions are not a consequence of complex formation or associations,[26] nor due to impurities.[27] Recently, it was proposed that the extended asymmetric tail in the absorption spectra of aromatic azides is due to their transition into dissociated singlet states.[27] Spectral data for a number of substituted phenyl azides are given in Table 1.

2. Quantum yields for the photo-decomposition of aromatic azides

Azides are unstable compounds, decomposing with elimination of N_2 to form nitrenes on photolysis and thermolysis[6–11]

$$ArN_3 \xrightarrow{h\nu} ArN + N_2.$$

Table 2. Quantum yields (φ) for the photolysis for phenyl azide derivatives on irradiation at 254 nm.

Substituent	Concentration ArN_3, mol/l	Solvent	φ at 298 K	φ at 77 K	Refs.

* Mixture of methylcyclohexane and isopentane (1 : 1).
** Irradiation at 280 nm.
*** Irradiation at 313 nm.

The quantum yields for the photolysis of aromatic azides, presented in Tables 2 and 3, are a consequence of excitation in the ππ*-transition. The values of the quantum yield are not dependent on the temperature. It can be seen that the quantum yields for the photolysis of polynuclear aromatic azides are higher than those for PhN_3 and its derivatives. Quantum yields are also available for the photolysis of di-, tri- and tetra-azides.[24,28] Photo-decomposition of PhN_3 and its derivatives on irradiation with visible light ($\lambda < 430$ nm) has also been observed.[23]

Table 3. Quantum yields for the photolysis of poly-condensed aromatic azides.[28]

Compound	λ_{irr}, nm	φ at 298 K	φ at 77 K
1-Azidonaphthalene	303	1.00±0.02	0.95±0.05
3-Azidoquinoline	303	0.84±0.05	0.87±0.05
1-Azidoanthracene	365	1.00±0.03	1.02±0.05

For quenching of triplet nitrenes by reaction with an azide molecule [Eqn. (1)],

$$^3ArN + ArN_3 \rightarrow ArN{=}NAr + N_2, \quad (1)$$

the quantum yield may exceed 1 (but not 2).[35,36] However, Waddell and Lee Go have found that the quantum yield for the photolysis of PhN_3 in acetonitrile can reach $\simeq 300$.[31] In subsequent work devoted to more detailed studies of the photolysis of PhN_3 and certain of its derivatives, even higher quantum yields (up to 15 300) were recorded, consistent with the following chain mechanism:[29,30,37–39]

$$^3ArN + ArN_3 \rightarrow 2\,^3ArN + N_2. \quad (2)$$

Apart from information reported by Waddell et al.,[29,30,37–39] there are no other data in the literature on the effect of concentration on the quantum yield for the photolysis of aromatic azides, and no other references to quantum yields greater than unity have been reported. The quantum yield for the photolysis of 1-azidonaphthalene does not depend on the concentration of the azide in the range 10^{-5} to 10^{-2} M and is equal to 1.[28] Schuster and Liang[32] were unable to reproduce the results of Waddell et al. for the photolysis of *p*-nitrophenyl azide.[30] According to the latter authors, the quantum yield increased from 0.54, at an azide concentration of 10^{-4} M, to 434 at 10^{-1} M.[32] However, according to Schuster et al., the value is independent of concentration in the interval 10^{-3} to 10^{-1} M, the quantum yield being 0.7 under these conditions. Thus, there are contradictory data on the photolysis of PhN_3 and its derivatives.

3. Initial processes in direct and sensitised photolysis

It is generally accepted that singlet nitrenes are the species obtained initially on dissociation of azides in the excited singlet state, while triplet nitrenes are predominantly formed from azides in the excited triplet state.[10–14,40–42] For all aryl azides which have been studied thus far, the main excited state is the triplet one.[40] This has been verified from the ESR characteristics of the triplet species formed on azide photolysis in glass matrices[43–48] or as single crystals[49–50] at 77 or 4 K.

Mechanistic information on the role of triplet azides and nitrenes has been gained by studying the sensitised photolysis of aromatic azides.[15–17,26–28,41,51–54] Leyshon and Reiser[26] found that PhN_3 and 1-$C_{10}H_7N_3$ quench both the singlet and triplet states of the sensitiser. In kinetic experiments, the rate constants for quenching the triplet state of the sensitiser [$k_q(T)$] have been calculated. Based on the relationship between $k_q(T)$ and the position of the triplet level of the sensitiser, it has been proposed that quenching involves

transfer of energy to a thermally populated non-linear azide [ground] state. It is thus considered that in the excited triplet state the non-linear configuration of the azide has the minimum energy.[26] Quantum chemical calculations have in fact shown that distortion of the terminal nitrogen from the plane of the azido group leads to a decrease in the energy of the lower excited triplet state.[51,55]

It has been established that aromatic ketones (benzophenone, acetophenone) function as triplet sensitisers in the photolysis of PhN_3 and 1-$C_{10}H_7N_3$.[15,53] However, the $k_q(T)$ value for quenching the triplet excited state of benzophenone by phenyl azide was found to be 2×10^9 l/mol/s,[15] which is significantly different from the value reports by Leyshon et al.[26] [$k_q(T) = 1.8 \times 10^6$ l/mol/s]. With such a discrepancy, it would be difficult to draw meaningful conclusions.[26]

The quantum yield (φ) for the sensitised decomposition of *o*-azidobiphenyl in the presence of acetophenone is 0.3 [52] (for PhN_3 $\varphi < 0.1$ [15]). In the triplet-sensitised photolysis of *p*-dimethylaminophenyl azide, the quantum yield is very small (in direct photolysis $\varphi \approx 1$).[14] In the sensitised decomposition of 1-$C_{10}H_7N_3$ with benzophenone[53] and of 1-azidopyrene with biacetyl,[42] quenching of the triplet state of the sensitiser is accompanied by the appearance of the corresponding triplet nitrene. The spectrum of ^{3}PhN was not recorded during the sensitised photolysis of PhN_3.[16] There was no sensitised decomposition of *p*-dimethylaminophenyl azide in the presence of 2-acetonaphthone.[27]

Table 4. Excitation energies for the singlet state E_s and rate constants [k_q(S)] for fluorescence quenching of sensitisers by phenyl and 1-naphthyl azide.[26]

Sensitiser	E_S, kcal/mol	k_q(S), l.mol^{-1} s^{-1}	
		PhN_3	$C_{10}H_7N_3$
Phenanthrene	81.7	$1.3 \cdot 10^{10}$	$1.4 \cdot 10^{10}$
Anthracene	75.1	$6.6 \cdot 10^9$	$1.0 \cdot 10^{10}$
9,10-Dimethylanthracene	70.2	$2.5 \cdot 10^9$	$5.4 \cdot 10^9$
Perylene	64.9	$3.4 \cdot 10^8$	$2.7 \cdot 10^9$
Tetracene	60.0	$2.3 \cdot 10^7$	$3.5 \cdot 10^8$
Rubrene	51.1	$1.0 \cdot 10^5$	$5.5 \cdot 10^6$

The efficiency of singlet sensitisation has been studied by determining the fluorescence quenching of the sensitiser (Table 4). The authors[26] came to the following conclusions:

1) singlet sensitisation is more effective in promoting azide decomposition than triplet sensitisation if the energy of the sensitiser is the same;

2) sensitisation is observed well below the estimated acceptor level of the azide;

3) singlet sensitisation of aryl azides is effected by two competing processes: a) S–S-transfer of energy; and b) transfer of an electron [from the azide to the excited hydrocarbon (sensitiser) molecule]. The latter conclusion was based on indirect information [namely the dependence of the rate constant for quenching $k_q(S)$ on the free energy of the electron transfer (ΔG_{ET}) in accordance with the Rehm–Weller equation[56]].

In studying the sensitised photolysis of *p*-dimethylaminophenyl azide in the presence of a series of aromatic hydrocarbons (pyrene, 1-acetamidopyrene, 9-acetamidoacridine),[27] the authors came to the same conclusion as Leyshon et al.,[26] i.e. that two mechanisms of singlet sensitisation, a) and b) were operative. However, in contradiction to Reiser et al.,[26] Schuster et al. consider that the electron transfer takes place from the excited hydrocarbon to the azide.[27] This is supported by the appearance of absorption corresponding to the pyrene cation. It is thought that the electron transfer may take place on the azide molecule in a dissociated state.[27] Such energy transfer to singlet and triplet repulsive states of organic peroxides has already been reported.[57]

4. The mechanism of photo-dissociation of aromatic azides

Aromatic azides have proved interesting as model compounds for studying photo-dissociative processes. In order to gain information on the initial processes, it is necessary to apply highly sensitive methods to measure the very short relaxation times. Basic information on the mechanism of dissociation can be derived by determining the spatial and energy distribution of the resulting molecular fragments.[58–61] In a picosecond time-resolved study of the flash photolysis of aromatic azides, it was shown that photo-dissociation of *p*-dimethylaminophenyl azide in toluene at room temperature proceeds in the singlet excited state within <6 ps.[14]

In order to ascertain mechanistic details, it is important to measure quantum yields as a function of the excitation wavelength.[58] Reiser and Marley[28] considered three possible mechanisms operative in the preliminary stage:

1) uncoupling of the spin of the electrons forming in the N–N σ-bonds (repulsive state T_{σ^*});

2) transfer into dissociated and pre-dissociated states;

3) supply of kinetic energy in excess of the bond energy to a critical vibrational mode (collapse from a principal "hot" electron state).

The first pathway can be discounted because, on this basis, either an aromatic nitrene or a molecule of nitrogen would be found in the triplet state;[28] as has been demonstrated, dissociation of singlet-excited azides results in the formation of *singlet* nitrenes.[9–14,40–42] The formation of a triplet-excited molecule of nitrogen is also unlikely because the energy of the $^3\Sigma_u^+$ state for nitrogen is 6.224 eV.[19,62] Furthermore, triplet-excited nitrogen has not been detected experimentally.[63]

According to Reiser and Marley, the mechanism of azide photo-dissociation involves a collapse of a vibrationally-excited electron state.[28] In our opinion and those of other authors,[24,55,64,65] this is also unlikely. From an analysis of the relationship between the quantum yield for the photolysis of *p*-azidomalachite green and both wavelength and temperature, it has been concluded that dissociation proceeds from an electronically-excited state.[24,64] Two mechanisms are possible:[24] a non-adiabatic dissociation and a pre-dissociation.[66] It is considered that the latter is more likely.[24,64]

Having analysed absorption spectra and performed quantum chemical calculations, Kondratenko and Shrubovich[65] came to the same conclusion as Shields et al.,[27] namely that the long wavelength absorption in the spectra of aromatic azides was a result of a transfer into a dissociated state ($\pi\sigma^*$-type). In their view, the initial mechanism of photolysis is a dissociative one, although they do not exclude a contribution due to pre-dissociation on excitation to higher electronic states.

From semi-empirical quantum chemical calculations, Tsuda et al. came to the conclusion that the motive forces behind the dissociative process of phenyl azides are involved with the displacement of the terminal nitrogen atom from the plane of the other atoms, which leads to a lowering of the activation barrier.[55] A distortion of the terminal nitrogen atom also leads to a shifting of the lower excited states $^1n\pi^*$ and $^1\pi\pi^*$, excitation of which precedes the dissociation. For aromatic azides it is considered that all the excitation energy is concentrated on the azido group, while the aromatic ring functions as an antenna for the photoabsorption.[55]

III. The nature and properties of key intermediates

The formation of nitrenes on photolysis and thermolysis of azides was first postulated on the evidence of product analyses.[6–11] It was not until 1962 that Wasserman et al. provided, through ESR studies, the first spectroscopic indication of the existence of triplet nitrenes.[46] This was based on the observation of a $\Delta m = 2$ transition in a moderate field and a $\Delta m = 1$ transition in a weak field (at 1620 and 6701 G, respectively, for ^{3}PhN).

1. ESR spectroscopy of aromatic nitrenes

The ESR spectroscopic characteristics of triplet molecules are determined by the spin-spin dipole interaction of unpaired electrons. In the absence of a magnetic field, this leads to a splitting of the triplet levels, as described by the spin Hamiltonian:[67]

$$H_{SS} = D(S_z^2 - {}^1/_3S^2) + E(S_x^2 - S_y^2). \quad (3)$$

The splitting parameters in a zero field, D and E, are given by:

$$D = \left\langle \Phi_k \left| \frac{3g^2\beta^2}{4} \frac{r_{12}^2 - 3z_{12}^2}{r_{12}^5} \right| \Phi_k \right\rangle, \quad (4)$$

$$E = \left\langle \Phi_k \left| \frac{3g^2\beta^2}{4} \frac{y_{12}^2 - x_{12}^2}{r_{12}^5} \right| \Phi_k \right\rangle, \quad (5)$$

where Φ_k is the coordinated part of the wave function of unpaired electrons in the triplet state; g is the g-factor, equal to ~ 2; β is the Bohr magneton; and r_{12} is the inter-electronic distance. The spin Hamiltonian takes the form (3) for a specific system of coordinates relative to the axes of the molecule, which, for high symmetry, coincides with the axes of symmetry.[67]

In an external magnetic field, the spin Hamiltonian becomes:

$$H = g\beta HS + H_{SS}. \quad (6)$$

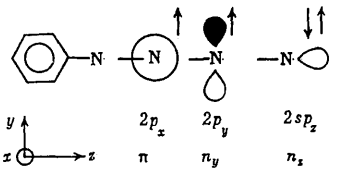
When the applied field is oriented to align with one of the molecular axes, the spin Hamiltonian, as defined by Eqn. (6), can be readily determined.

In the general case, the value of the applied magnetic field strength at absorption depends on the orientation of the field relative to the axes of the molecule. The intensity of the signals in a glass matrix and in the semicrystalline state is noticeably lower than that registered for single-crystals possessing the same number of oriented triplets.[45] The experimentally observed resonances in glass matrices and in the semi-crystalline state are due to the relatively few molecules in which one of the three magnetic axes is approximately aligned with the direction of the applied magnetic field.[45]

For arylnitrenes the main axis z coincides with the C–N bond; the axes x and y are equivalent so that $E \approx 0$.[45,47] The ESR spectra of triplet nitrenes are characterised by a D value which is significantly greater than the microwave quantum of energy.[43,46] From a calculation of the values of the resonance fields for allowed transition with $\Delta m = 1$ when the applied field is oriented to align with one of the axes (using ESR spectrometers where $H < 10\,000$ G), it can be concluded that the recorded signals correspond to an orientation of the applied magnetic field parallel to the plane xy.[45,46] The value of the resonance field can be determined from the equation:

$$H^2 = H_0(H_0 + D), \quad (7)$$

where H_0 is the resonance field for the isolated doublet state, and H is the resonance field for the triplet nitrene (assuming that E = 0).



Mapping of the orbitals of phenylnitrene.[16]

Table 5. Splitting parameters in a zero field (D) for triplet aromatic nitrenes (^{3}RN).

R	D, cm^{-1}
Phenyl	0.998 [47]; 1.003 [68]; 0.999 [48, 49]
Substituted phenyl	0.871—1.065 [47, 48,50,69]
1-Naphthyl	0.789 [47]; 0.798 [68]; 0.79 [71]
2-Naphthyl	1.008 [47]
1-Anthryl	0.663 [47]; 0.65 [72]
2-Anthryl	0.778 [47]; 0.75 [72]
1-Pyrenyl	0.73 [70]

For the simple nitrene, :NH, $D = 1.863$ cm^{-1} (the contribution of spin-spin interaction being 1.595 cm^{-1}, and the contribution of spin-orbital interaction being 0.268 cm^{-1}).[67] The parameter D for various alkylnitrenes lies in the region 1.57–1.66 cm^{-1}.[46] For aromatic nitrenes one of the unpaired electrons is localised in a p_y-orbital of the nitrogen atom (see above), while a second occupies a delocalised π-orbital. Delocalisation leads to a decrease in the spin density at the atom of nitrogen and, correspondingly, to a decrease in the value of D for aromatic nitrenes relative to alkyl nitrenes (Table 5). The following equation may be used for determining the approximate value of the spin density of a π-type unpaired electron on the nitrogen atom:

$$\rho_\pi^N \approx D/D_0 \ , \quad (8)$$

where D is the parameter for an aromatic nitrene, and D_0 for alkyl nitrenes (D_0 = 1.6 cm^{-1}). For arylnitrenes the value ρ_π^N lies in the region of 0.42–0.64.[46]

From ESR spectroscopic data for a series of fourteen para-substituted phenyl azides, recorded under identical conditions hyperfine splitting at the nitrogen nuclei was detected in five instances (a_N = 17 ± 1 G), as well as at the fluorine nucleus (a_F = 17.5 G) and at iodine (a_I = 85 G) in the para-position.[48] The value of D for para-substituted phenylnitrenes lies in the region 0.874–1.008 cm^{-1}, the spin density at the nitrogen nucleus being sensibly independent of the nature of the substituent.[48] Consequently, the simplified Eqn. (8) gives only a rough assessment of the ρ_π^N value. To obtain a quantitative correlation with experimental findings, it is necessary to consider more accurately the effects of delocalisation. The effect of substituents on the value of the parameter D has been studied for 8-substituted 1-naphthylnitrenes[71] and for variously substituted 9-anthracenylnitrenes.[72]

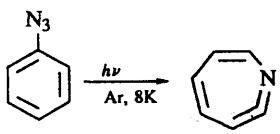
Constrasting with alkyl- and aryl-nitrenes, for which the triplet state predominates, aroylnitrenes fail to provide recordable ESR spectra.[47,73,74] Furthermore, the products obtained by both direct and triplet-sensitised photolysis of aroyl azides ($ArCON_3$) are typical of those obtainable from singlet nitrenes.[73–76] On the basis of these data, one can assume that aroylnitrenes (ArCON) exist principally in the singlet state.[73,74] These are potentially electrophilic, being readily and effectively inserted even into non-activated CH-bonds. Thus, aroyl azides may be used for photo-affinity modification of the lipophilic residues of biopolymers.[77,78]

2. The nature and optical spectra of intermediates

Shortly after the ESR spectra of triplet nitrenes were recorded, Reiser et al. studied the electronic absorption spectra of the species obtained by photolysis of a number of aromatic azides under the same conditions (in oranic glass matrices at 77 K).[22,79,80] They came to the conclusion that the recorded spectra were due to nitrenes in the triplet state. This was based on the following: firstly, the conditions under which the spectra were recorded were the same as those under which the ESR spectra were taken; and, secondly, there was a close similarity between the electronic absorption spectra of [presumed] triplet nitrenes and those of radicals having an unpaired π-electron. For example, the spectrum of ^{3}PhN (λ = 314 and 402 nm) is similar to that of $^2PhCH_2$ (λ = 318 and 463 nm) and, more strikingly, to those of ^{2}PhO (λ = 300 and 403 nm) and ^{2}PhNH (λ = 309 and 403 nm).[22] These results were later reproduced, and low-temperature absorption spectra were recorded for the species obtained from other aromatic azides. Here, too, absorption was assigned to triplet aromatic nitrenes[23,24,40,70,72,81,82] (see Table 6).

a) Photolysis of phenyl azides and its derivatives

In 1978, Chapman et al. showed that 1-aza-1,2,4,6-cycloheptatetraene (1,2-didehydroazepine) was the major intermediate formed on irradiation on PhN_3 in an argon matrix at 8 K.[83] This assumption was based on the appearance of an absorption band at 1895 cm^{-1}, in the IR spectrum, which was characteristic of an intermediate having a cumulene structure.[83]



Similar results were obtained for the photolysis of 3- and 4-substituted phenyl azides.[84] The participation of didehydroazepines and/or azirines in the photochemical conversions of aryl azides had already been suggested on the evidence of product analyses for photolytic reactions in the presence of amines (primary and secondary)[10,85–87] or other nucleophiles.[10,88–91]

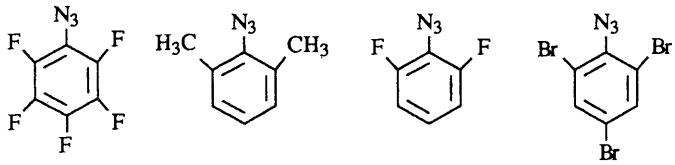
According to IR spectroscopic data, neither didehydroazepine nor benzazirine intermediates are formed on irradiation of pentafluorophenyl azide[92] or 2,6-dimethylphenyl azide[93] in an argon or nitrogen matrix at 12 K. Here, triplet nitrenes are the key intermediates; however, prolonged irradiation of 2,6-dimethylphenyl azide affords only small amounts of didehydroazepine (ν = 1898 cm^{-1}), presumably as a result of secondary photolysis.[94] An ESR spectroscopy study indicated that irradiation of PhN_3 in an argon matrix at 12 K yields both 1,2-didehydroazepine and ^{3}PhN, while prolonged irradiation affords 2-pyridylmethylene.[94]

After the publications of Chapman et al.[83,94] and Dunkin et al.,[84] some doubts were raised about the authors interpretation of the electronic absorption spectra of azides recorded at 77 K in a glass matrix.[15,16] As a consequence, Platz et al. reproduced the earlier results of low-temperature photolysis (77 K) of PhN_3 and some of its derivatives.[16,95] In this context, low-temperature UV spectra were recorded, and an analysis was made of the product obtained on warming the photolysate to room temperature. The temperature of the photolyses was in the range from room temperature to 77 K. Platz found that, on irradiation of PhN_3 in diethylaniline, the yield of 3*H*-azepine fell from 80% at 273 K to 3% at 153 K and to 0% at 77 K.[95] Irradiation of PhN_3 at 77 K afforded azobenzene and aniline,[95] both of which would be anticipated if photolysis proceeds through triplet nitrenes.[10] There is also reference to the absorption spectra of the products obtained by photolysis of PhN_3 and azides (I–IV) at 77 K, as well as fluorescence spectra and excitation

fluoresecence spectra of the products obtained by photolysis of PhN_3 and azides (I) and (II).[16]



(I) (II) (III) (IV)

The similarity between the absorption spectra and the excitation spectra confirms that the same species is formed.[16] An analysis of results obtained by flash photolysis of PhN_3 in the presence of DEA in a wide temperature interval, [16] as well as the data obtained by Leyva et al.,[95] indicate that the efficiency of didehydroazepine formation decreases as the temperature is reduced, and that ^{3}PhN is the principal species formed on photolysis of PhN_3 at 77 K in a glass matrix.[16] Thus, the electronic spectroscopic interpretations made by Reiser and others are correct.[22–24,40,70–72] (see Table 6).

It should be pointed out that triplet aromatic nitrenes are unstable on prolonged irradiation at 77 K,[16,22,23,79,96,97] which may be associated with the formation of an aniline-solvent radical pair. Recombination of the latter in the gaseous state leads to a substituted amine.[23,96,97] Prolonged photolysis of ^{3}PhN leads to the formation of didehydroazepine.[16] The photochemical reactions of triplet nitrenes also complicate the interpretation of their absorption spectra and make it difficult to determine extinction coefficients (Table 6).

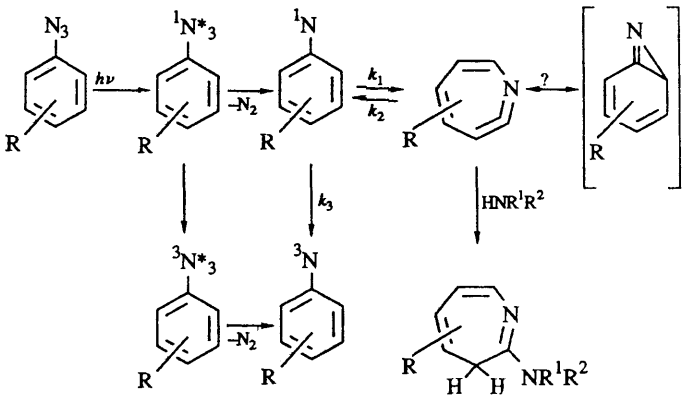
In order to explain why the products obtained by photolysis of aromatic azides at 10 K in an inert gas matrix are different from those obtained in a glass matrix at 77 K, Platz et al.,[16] advanced the hypothesis that at 10 K, in an inert gas matrix, secondary photolysis of the triplet nitrenes takes place to give a didehydroazepine; it is also considered that high-temperature chemistry is manifested in locally heated areas. In recent work, it has been shown that ^{3}PhN is the principal product obtained by photolysis of PhN_3 in a hydrocarbon glass matrix (3-methylbutane at 45 K) and in an inert gas matrix (N_2 or Ar at 12 K).[98] Didehydroazepine has even been detected as the primary species formed on photolysis of ^{3}PhN.[83,84] Hayes et al. argued that didehydroazepine, which had always been formed in small amounts (~20%) on photolysis of ^{3}PhN in a number of matrices, is the result of isomerisation of a vibrationally- or electronically-excited singlet nitrene state, ^{1}PhN.[98]

At present, there are around 20 publications devoted to systematic kinetic studies of the photo-reactions of aryl azides.[12–17,27,32,34,36,42,53,70,82,99–107] In the majority of these, electronic absorption spectra of intermediates were recorded, and, in two instances,[12,13] IR absorption data for the intermediates are available. Essentially, the electronic spectra of the intermediates were interpreted in terms of triplet aromatic nitrene absorption because of the similarity with the absorption spectra of the products obtained by low-temperature photolysis.[36,42,70,99–101]

Flash photolysis of PhN_3 [13,15,16,102,106] and certain of its derivatives[12–14,16,32,102,104–107] has been widely reported. In an early study of azide photolysis in the presence of amines, only the absorption of 1*H*-azepine was detected.[102] Later, the absorption of an intermediate, presumed to be ^{3}PhN, was detected in the absence of an amine.[82,105] However, this was subsequently disputed.[15] A detailed comparison of the absorption spectrum of ^{3}PhN at 77 K with that of the intermediate formed at room temperature showed that the similarity was far from exact. For example, the well-defined splitting in the spectrum of ^{3}PhN with maxima at 490, 382 and 303 nm was absent in the absorption spectrum of the intermediate, which exhibited a broad, poorly-defined band with a maximum at ~350 nm.[16] Only with compound (IV) was there a complete superposition of the spectrum obtained by flash photolysis with that obtained at low temperature. The spectra of compounds (I) and (III) were consistent with absorption of triplet nitrenes, exhibiting a poorly-defined maximum in the region ~340–350 nm.[16] A similar low-intensity absorption in the region 320–380 nm was registered for PhN_3 (λ_{max} ~ 340 nm) [15] and for *p*-dimethylaminophenyl azide (λ_{max} ~ 360 nm).[12] On pulsed excitation of 4,4′-diazidobiphenyl in cyclohexane, an intermediate absorption with λ_{max} = 380 nm ($\Delta\lambda$ = 50 nm) and a life-time of 19 ± 2 ns was detected.[107] This was assigned to a singlet intermediate (a singlet mononitrene or a didehydroazepine).[107]

The IR spectroscopic absorption at 1887 cm^{-1} (and that at 1877 cm^{-1} for the ^{15}N isotope), registered during the photolysis of PhN_3 and its derivatives, provided further evidence that reaction proceeds via didehydroazepines (azacycloheptatetraenes), formed by dehydrogenation of the corresponding 1*H*-azepine;[12,13] this was also consistent with product analyses from photolyses in the presence of amines. The IR spectra of intermediates obtained by pulsed excitation of PhN_3 and its derivatives did not exhibit absorption corresponding to benzazirines. Thus, the following scheme may be proposed for the photolysis of PhN_3 and its derivatives:[10,12–16,40]

Scheme 1



b) Spectral characteristics of intermediates

The electronic spectra absorptions of ^{3}PhN and its derivatives are given in Table 6.[22,23] The data relate only to $\pi\pi^*$-transitions. There is a long-wavelength absorption for ^{3}PhN, but it does not correspond with a specific transition.[23] The absorptions for ^{3}PhN and its derivatives were recorded with the following characteristics: $\lambda_{max} \approx 500$ ($\lg\varepsilon$ ~ 2.5); ~400 (~3); ~320 (~3.5), and ~240 nm ($\lg\varepsilon \approx 4$).[16] It is considered that the long-wavelength absorption of ^{3}PhN (λ_{oo} = 489 nm) corresponds with transitions of the type $n_y \rightarrow \pi^*$ and $\pi \rightarrow n_y$, while $\pi\pi^*$ transitions are primarily responsible for the other absorptions. It is possible that the first absorption peak is due, in part, to a transition of the type $n_z \rightarrow n_y$.

Luminescence is characteristic of triplet aromatic nitrenes which possess neutral or donor substituents. This has been classified as $T_1 \rightarrow T_0$ fluorescence.[16,23,42,108] The fluorescence quantum yield for *p*-tolylnitrene is 0.01 ± 0.02 [24] and for *p*-aminophenylnitrene it is 0.10 ± 0.02.[34]

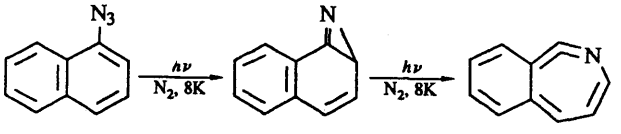
The absorption spectrum of ^{1}PhN is unknown at present. It cannot be ruled out that the broad absorption in the region 400–480 nm, obtained on flash photolysis of *p*-dimethylaminophenyl azide, is due to the presence of singlet *p*-dimethylaminophenylnitrene.[14] It is not clear which singlet species (a didehydroazepine or a singlet mononitrene) is responsible for the absorption at λ_{nm} = 380 nm, recorded on impulse excitation of 4,4′-diazidobiphenyl.[107]

The IR spectra of didehydroazepines (azacycloheptatetraenes) are characterised by absorption with $\nu_{max} \sim 1990$ cm^{-1}; there is also weak, poorly-defined, absorption in the near UV region with a maximum at 340–360 nm. 1*H*-Azepines — the products obtained by addition of primary and secondary amines to didehydroazepines — show significantly higher absorption in this region ($\lambda_{max} \approx 360$ nm). 3*H*-Azepines, formed by subsequent photo-conversion of 1*H*-azepines, absorb in a shorter wavlength region.[15,102]

c. Photolysis of polynuclear aromatic azides

Annelation of azidobenzenes to other aromatic ring systems has a profound effect on the chemical behaviour of the intermediate nitrenes and other species obtained on photolysis.[10] Thus, contrasting with the photolytic behaviour of PhN_3 and its derivatives, the photolysis of polynuclear aromatic azides in the presence of primary and secondary amines leads to aromatic dialkylamines rather than 3*H*-azepines.[10,53,109–111] These products would be anticipated for photolysis via azirines.

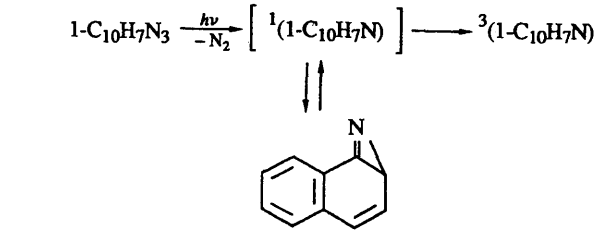
The IR spectra of the products obtained by irradiation of 1- and 2-naphthyl azide in an argon or N_2 matrix at 8 K are characterised by a cluster of absorption bands (typical of tricyclic azirines (1708–1736 cm^{-1}).[112] On prolonged irradiation they disappear and are replaced by a new cluster of bands (1910–1930 cm^{-1}) which possibly correspond to the intermediate didehydroazepines:



However, triplet ^{3}(1-$C_{10}H_7N$) is formed on irradiation of 1-$C_{10}H_7N_3$ in a glass matrix at 77 K.[113]

There are only a few references to flash photolysis of polycondensed azides.[36,42,53,70] Reiser et al. were first to record the absorption of intermediates obtained on flash photolysis of 1-azidonaphthalene and 1-azidoanthracene, and concluded that triplet nitrenes were responsible.[36] Sumitani et al. showed that excitation of 1-azidopyrene using a laser pulse of less than 15 ns produces a species with an absorption maximum in the region 455 n.[42] This was supported later by Schrock et al.[53] After a period of 22 ns at room temperature and 34 ns at 77 K, this species is converted into another with a maximum at 420 nm.[42,53] The latter species was also formed on triplet sensitisation and had an absorption spectrum identical to that of ^{3}(1-PyN) at 77 K. Under the conditions of laser excitation it disappeared in a second-order process to give 1,1′-azopyrene. The Japanese authors assigned the absorption maximm at 420 nm to ^{3}(1-PyN), and that in the region of 455 nm to ^{1}(1-PyN).[42] However, Schrock et al. did not exclude the possibility that the latter absorption was due to the corresponding azirine.[53]

The photolysis of 1-azidonaphthalenes in benzene leads to the formation of 1,1′-azonaphthalene, but in diethylamine a significant amount of 1-aminonaphthalene is formed.[53,109] No absorption was detected in the region 350–650 nm directly after 13 ns laser impulse excitation at this azide in benzene. However, the intensity of the absorption in the near UV region, with a maximum at 370 nm, increased exponentially with time over a period of 2.8 ± 0.2 μs. The species absorbing at 370 nm would appear to be ^{3}(1-$C_{10}H_7N$). It disappeared in a second-order process to give 1,1′-azonaphthalene. The precursor of ^{3}(1-$C_{10}H_7N$), having a lifetime of 2.8 μs, is presumed to be an azirine.[53]

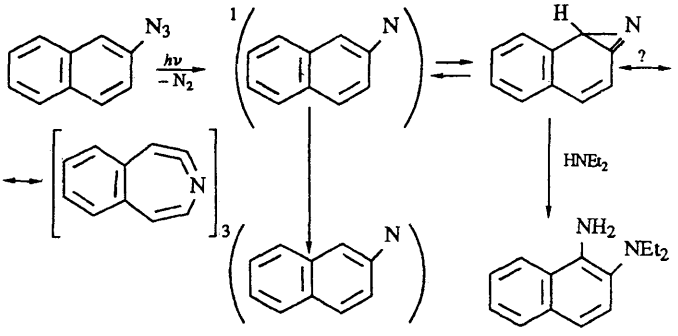


Azo compounds were isolated on irradiation of 2-azidonaphthalene and 2-azidopyrene in benzene, whereas, in the presence of diethylamine, the products were 2-diethylamino-1-naphthylamine and 2-diethylamino-1-pyrenylamine, respectively.[53,113] The triplet-sensitised photolysis of 2-$C_{10}H_7N_3$ in the presence of diethylamine does not lead to the formation of diamines.[53] There was absorption in the region 350–650 nm immediately after laser excitation of 2-$C_{10}H_7N_3$. Then, with a time frame of ~1 ms, azonaphthalene was formed in a second-order process. In the presence of benzophenone as triplet sensitiser, ^{3}(2-$C_{10}H_7N$) was formed with an absorption maximum in the near UV region at 365 nm. This disappeared in a second-order process, more rapidly by direct photolysis, to give azonaphthalene.[53] No novel intermediate species were detected in the presence of diethylamine. However, the yield of azonaphthalene was much lower. The differences in the photochemical behaviour of 1- and 2-azidonaphthalene are evidently associated with the fact that the life-time of the azirine intermediate is significantly longer in the latter case.[53]

After laser pulse irradiation of 2-azidopyrene, an absorption was detected with a maximum at 420 nm, this being assigned to ^{3}(2-PyN_3). The same absorption was evident in diethylamine as solvent. This disappeared after 2.5 μs with the formation of 2-diethylamino-1-pyrenylamine, absorbing in the region 445 nm. Schuster et al. proposed that the conversion of singlet 2-PyN to the triplet form was reversible.[53]

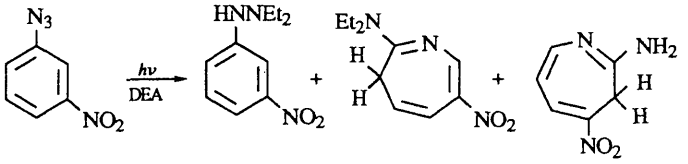
The primary processes involved in the photolysis of polycondensed azides are exemplified by the photo-conversion of 2-azidonaphthalene, as shown below:

Scheme 2

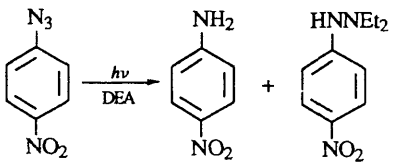


IV. The reactivity of intermediate singlet species

Singlet aromatic nitrenes are not dispersed to insert into C–H bonds or add across double bonds.[10] Compounds which, formally, are products of C–H bond insertion are often obtained as a result of cleavage of hydrogen by triplet nitrenes.[114,115] There are several references to N–H insertion by singlet arylnitrenes having acceptor substituents.[32,116–118] Thus, hydrazine compounds are formed together with 3*H*-azepines by irradiation of 4-cyanophenyl azide in dimethylamine[116,117] and of 3-nitrophenyl azide in diethylamine:[118]



Furthermore, irradiation of 4-nitrophenyl azide in diethylamine affords a mixture of 4-nitroaniline and *N*-(4-nitrophenyl)-*N'*,*N'*-diethylhydrazine (9%):[32]



The yield of the hyrazine falls significantly on triplet sensitisation,[117] and the variation in the yield of hydrazine and azepines,[116,117] or aniline and hydrazine,[32] as a function of the concentration of amine confirms the fact that a singlet nitrene is the precursor of the hydrazine.

1. Isomerisation of singlet aromatic nitrenes

Isomerisation into didehydroazepines (Scheme 1) or into tricyclic azirines (Scheme 2) are the most characteristic reaction of singlet aromatic nitrenes. It is known that these isomerisations take place within 10 ns (the period of the laser pulse).[12–16] The isomerisation is activated thermally, the rate constant for the isomerisation of ^{1}PhN at room temperature being approximately $10^{11\pm1}$ s^{-1}.[16] 3*H*-Azepines were not formed on irradiation of the following aromatic azides in the presence of amines: *p*-nitro=, *o*- and *p*-cyano-, *o*-chloro-, *p*-amino- and *p*-dimethylaminophenyl azide.[10,13,32,119,120]

In contrast to the above-mentioned azides, PhN_3 and the majority of its derivatives are converted into 3*H*-azepines in high yield in the presence of amines.[10,13] The efficiency of formation of the intermediate didehydroazepines was assessed from IR absorption in the region 1887 cm^{-1} relative to that obtained for *p*-chlorophenyl azide[13] (Table 7).

The effect of a heavy halogen atom (Cl, Br, I) on the yield of didehydroazepine is thought to be associated with enhancement of inter-system crossing (ISC) into the initial azide.[13] In our opinion, introduction of a nitro group into the 3- and 4-position of the azidoarene ring has a significant effect on ISC into the azide and is responsible for the low yield of didehydroazepine. With 2-dimethylaminophenyl azide, the efficiency of isomerisation is assumed to be low, as is confirmed by MDNO calculations for the potential barrier to reaction.[13]

Table 7. Relative values for the optical density of the IR absorption of intermediates at 1887 cm^{-1} (ΔD_{rel}) on impulse excitation of para-substituted phenyl azides (p-$XC_6H_4N_3$), and the values of rate constant (k_4) for the reaction of 5-substituted 1,2-didehydroazepines with diethylamine in cyclohexane.[13]

2. Reactions of 1,2-didehydroazepines

It has been shown that the rate of 1,2-didehydroazepine conversion increases with the concentration of PhN_3, the pseudo-first-order rate constant being linearly proportional to the concentration.[13] The bimolecular rate constant for the reaction of didehydroazepine with PhN_3 in heptane at room temperature is 7.5×10^4 l/mol/s.[13] Evidently, this reaction leads to the formation of unidentified polymeric products on both photolysis and thermolysis of PhN_3 as well as its derivatives.[10] The reaction of didehydroazepines with azides may lead to an increase in the quantum yield of azide photolysis as the concentration is increased.[29–31]

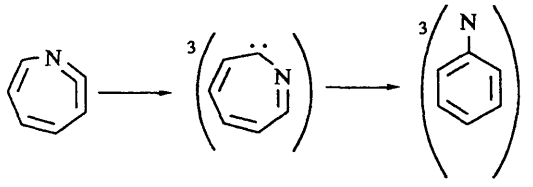
On extrapolation to zero concentration of the azide, the life-time of 1,2-didehydroazepine in heptane at room temperature was found to be 4.8 ms.[13] The life-time (τ) of the 1,2-didehydroazepine formed on impulse photolysis of *p*-tolyl azide was measured in different solvents in the temperature range to 13–60 °C.[17,25] This study of *p*-tolyl azide was undertaken at very low concentration ($< 5 \times 10^{-5}$ M) so that its reaction with the intermediate didehydroazepine does not make a contribution to the measured life-time. The

activation parameters ($\tilde{k}_0$ and E) relating to the effective rate constant for the irreversible conversion of the didehydroazepine into triplet nitene ($\tilde{k} = 1/\tau$) are given in Table 8. The effective constant $\tilde{k}$ is expressed in terms of the rate constants for the individual steps (see Scheme 1) as follows:

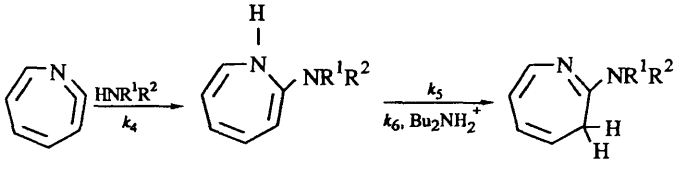
$$\tilde{k} = k_3k_2/(k_1 + k_3) \approx k_3k_2/k_1. \quad (9)$$

Since the rate constant for ISC (k_3) does not normally depend on the temperature, the value of E will equate to the enthalpy of isomerisation of *p*-tolylnitrene into the corresponding didehydroazepine. On conducting the reaction in ethanol, since it was not established whether the didehydroazepine reacts with ethanol under these conditions, it cannot be excluded that the decrease in the value of E is associated with the occurrence of this side-reaction.

Constrasting with the outlined scheme for the irreversible conversion of 1,2-didehydroazepines into triplet nitrenes via singlet nitrenes (Scheme 1),[9,16] an alternative pathway has been proposed on the basis of MNDO calculations:[13]



The reaction of didehydroazepines with amines leads to 1*H*-azepine derivatives which then isomerise into stable 3*H*-azepine derivates.[12,13,15,88,102]



The 1*H*-azepines obtained from a number of ortho-substituted phenyl azides are relatively stable, and their formation has been detected by NMR spectroscopy.[88]

The nature of the solvent and substitution of the phenyl ring affects the rate of formation of 1*H*-azepines (Table 9).[102] When the concentration of the amine is above 3 M the rate of formation of 1*H*-azepine becomes independent of the concentration and nature of the amine.[15] The negative activation energy (Table 9) and the non-linear dependence of the rate on the concentration of amine would suggest that the reaction with amines involves two intermediates.[102]

The rate constant k_4 has been determined by measuring the rate of disappearance of the IR absorption for the intermediate didehydroazepines.[13] It was found that the value of k_4 changes by more than two orders of magnitude on varying the substituent in the 5-position of the 1,2-didehydroazepine (see Table 7) and increases with the electron-accepting properties of the substituent. A reasonable linear dependence (Hammett plot) was found for $\lg k_4$ against the σ-substituent constant.[13]

The rate of isomerisation of 1*H*-azepines to the corresponding stable 3*H*-azepine does not depend on the concentration of the amine and increases significantly in the presence of dibutylammonium ion.[102] The activation parameters relating to the rate constants for the monomolecular and $Bu_2NH_2^+$-catalysed isomerisation of 1*H*-azepines to 3*H*-azepines are given in Table 10.

Table 9. Activation parameters and values of the rate constant for the reaction of didehydroazepines (formed on impulse excitation of derivatives of PhN_3) with dibutylamine (k_4); and the values of the rate constants for the unimolecular (k_5) and $Bu_2NH_2^+$-catalysed (k_6) isomerisation of 1*H*-azepines into 3*H*-azepines in acetonitrile at 21.7 ± 0.3 °C.[102]

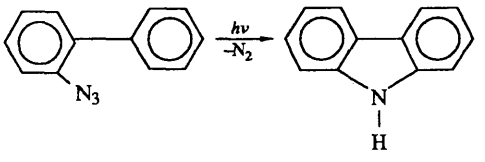
3. Cyclisation of ortho-substituted aromatic azides

A large number of photochemical and thermal cyclisation of ortho-substituted aryl azides are known.[10] Only the photochemical cyclisation of *o*-azidobiphenyl (*o*-AB) to carbazole will be examined in this review.



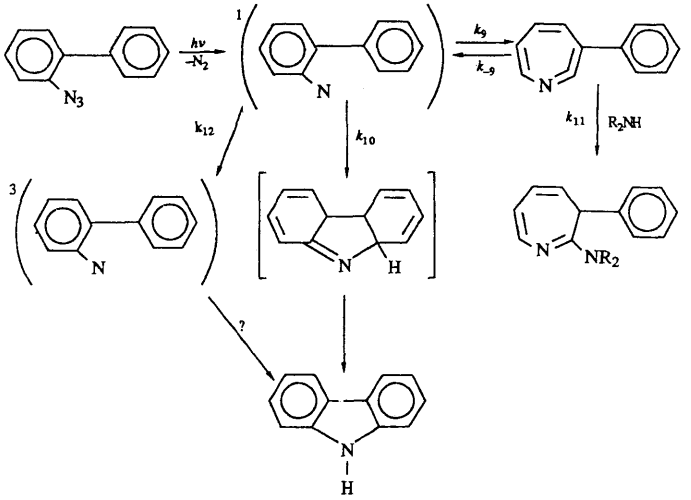
Swenton et al. isolated carbazole (68−74%) and 2,2′-azobiphenyl (8−12%) as a result of photolysis of *o*-AB at a concentration of 10^{-2} M.[52] Triplet quenchers (dienes, pyrene, oxygen) decreased, and triplet sensitisers (benzophenone, acetophenone) increased, the yield

of the azo compound (to 39–49%).[52] A 3*H*-azepine was obtained in addition to carbazole on irradiating *o*-AB in the presence of diethylamine.[101,103,121] The yield of carbazole derivatives was significant on photolysis of *o*-AB and its 2′,3′-disubstituted analogues, even in pure diethylamine (49% for *o*-AB). As the concentration of diethylamine increases the relative proportion of carbazole and 3*H*-azepine begins to fall and then remains sensibly constant.[103]

A kinetic study has been made of carbazole formation (λ_{max} = 289 nm) and of the decay of the intermediate (absorbing at λ_{max} = 342 nm), assumed by the authors to be a triplet nitrene.[100] The rate constant for carbazole formation (k_7) and decay of the intermediate (k_8) in cyclohexane agreed with a factor of 2. On this basis, the authors concluded that a triplet nitrene was a precursor of the carbazole.[100] Later, Sundberg reproduced the results and found that the rate constants k_7 and k_8 in hexane differed by a factor of 2, whereas in other solvents the difference was two orders of magnitude.[101] The intermediate formed during the course of the reaction was not converted into carbazole in significant amount. A kinetic study of the photolysis of 2′,4′,6′-trideuterio-3′,5′-dimethyl- and 3′,5′-bis(trifluoromethyl)-derivatives of *o*-AB (Table 11) has also been undertaken, as a result of which three hypothetical mechanisms were proposed for the formation of carbazole.[101]

The following mechanism for carbazole formation (Scheme 3) may be proposed on the basis of the results obtained for the photolysis of *o*-AB,[52,101,103,121,122] with reference to the conversions of other aryl azides (Scheme 3):

Scheme 3



The reactions of triplet nitrene may lead to the formation of azo compounds.[52] However, it cannot be excluded that a small amount of carbazole is also formed via these species.

The effective rate constant k_7, assuming that k_{12} is negligible, is given by Eqn. (10):

$$k_7 = k_{10}k_{-9}/(k_9 + k_{10}). \quad (10)$$

In the presence of an amine the proportion of carbazole can be expressed by the ratio:

$$\Phi_{min} = k_{10}/(k_{10} + k_9).$$

For *o*-AB, $\Phi_{min} \approx 0.5$, so that $k_{10} \approx k_9$. The activation energy for carbazole formation is evidently close in value to the enthalpy of isomerisation of the intermediate singlet nitrene to didehydroazepine. In cyclohexane, the calculated value of the activation energy (11.5 kcal/mol [100]) is close to the value of that relating to the rate constant ($\tilde{k}$) for the conversion of 5-methyl-1,2-didehydroazepine to triplet tolylnitrene (10.3 kcal/mol [17,25]). The increase in k_7 on passing from hexane to acetonitrile and methanol (see Table 11) coincides with a similar variation in the value of $\tilde{k}$ (see Table 8). The proposed mechanism outlined in Scheme 3 is in reasonable accord with experimental findings, but the nature of the intermediate absorbing in the region $\lambda_{max} \approx 340$ nm has not been established.

Table 11. The values of the effective rate constant for the formation of carbazole (k_7) and the decay of the intermediate (k_8) for the reaction of *o*-azidobiphenyl and its derivatives at 20 ± 1 °C.[101]

V. Reactions of triplet aromatic nitrenes

1. Formation of azo compounds

There are two mechanisms by which azo compounds are formed.[32,36,53,70,106]

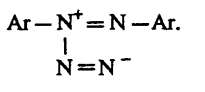
$$^3ArN + Ar'N_3 \xrightarrow{k_{13}} [ArN_4Ar'] \rightarrow ArN{=}NAr' + N_2, \quad (11)$$

$$^3ArN + {}^3ArN \xrightarrow{k_{14}} ArN{=}NAr. \quad (12)$$

The existence of pathway (11) is substantiated by the formation of unsymmetrical azo compounds on irradiation of 1- or 2-azidonaphthalene in the presence of PhN_3.[53] However, no (4-nitrophenyl)azobenzene was detected on photolysis of *p*-nitrophenyl azide

in the presence of PhN_3.[32] Reaction (11) was observed on flash photolysis of 1-azidoanthracene (k_{13} = 0.5 × 10^9 l mol^{-1} s^{-1}) in ethanol.[36]

The yield of azonaphthalene, formed on irradiation of 1-azidonaphthalene with a non-laser source, increases after a few hours in the dark from 22 to 46% (for 2-azidonaphthalene, the increase is from 22 to 45%).[53] This confirms the existence of a relatively stable intermediate adduct. A tetrazene structure, Ar–N=N–N=N–Ar, has been proposed for this compound.[53] It is also possible that it has a 1,2-tetrazene structure:[9,10]



The yield of azobenzene from PhN_3 does not increase when irradiation has been ceased.[15]

The rate of reaction (12) is controlled by diffusion,[36] the approximate value of the rate constant k_{14} being just under the theoretical limit for a diffusion-controlled process (Table 12).

Table 12. Values for the rate constant for recombination (k_{14}) of triplet aromatic nitrenes (^{3}ArN).

Ar	Solvent	$k_{14}.10^{-9}$, l.mol^{-1} s^{-1}	Refs.
1-Naphthyl	hexane	0.55±0.05	[36]
	benzene	0.45	—
	ethanol	0.40	—
	liq. paraffin	0.09	—
1-Pyrenyl	benzene	2.1±0.2	[70]
4-Nitrophenyl	"	1.0	[32]

A third pathway for the formation of azo compounds was examined in Smith's review:[9] dimerisation of aminyl radicals formed by abstraction of an atom of hydrogen from the solvent, substrate or product by a triplet nitrene, followed by dehydrogenation of the resulting hydrazo compound.

2. Abstraction of a hydrogen atom

Amines are often formed together with azo compounds via triplet aromatic nitrenes.[10,36]

$$^3ArN + RH \xrightarrow{k_{15}} Ar\dot{N}H + \dot{R}, \quad (13)$$

$$Ar\dot{N}H + \dot{R} \rightarrow ArNHR, \quad (14)$$

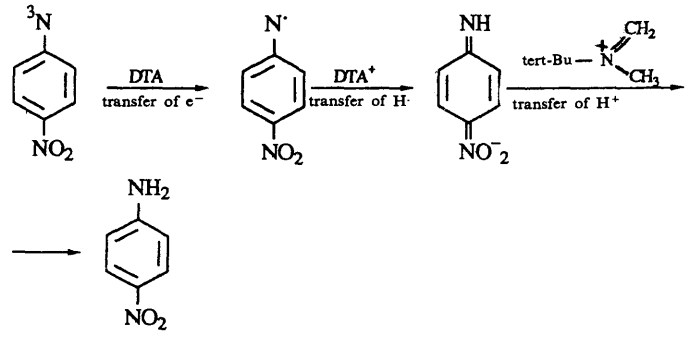
$$Ar\dot{N}H + RH \rightarrow ArNH_2 + \dot{R}. \quad (15)$$

Reaction (13) does not compete with reaction (12) on pulsed irradiation, so that the amount of information on this step is limited. The value of the rate constants for the abstraction of hydrogen from hexane by triplet ^{3}(1-$C_{10}H_7N$) and from ethanol by 4,4′-dinitrobiphenyl† have been evaluated at 2.6 × 10^2 l/mol/s.[36] It is thought that abstraction of hydrogen from the aromatic ring of the azide or the nitrene leads to a polymeric product.[36]

The contribution of pathway (13) predominates in a polymeric matrix, under which conditions amines (principally primary amines) are the main product.

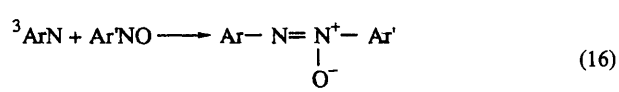
The kinetics of the decay of ^{3}ArN in polymeric matrices cannot be described by a simple kinetic equation.[36] The kinetic curves are characterised by three points in time: τ_0, the estimated time after which the curve starts to slope $\tau_{1/2}$, when the concentration of ^{3}ArN falls by half; and τ_1, the period of the entire process. Time $\tau_{1/2}$ varies between 10^{-3} s in weak polymeric matrices (polystyrene, plasticised toluene) to 0.1–2 s in hard polymeric matrices. The limiting factor in the reaction would appear to be the nature of the surroundings (configurational diffusion). Electron-accepting substituents increase the rate of hydrogen abstraction, the logarithm of the half-life time ($\lg\tau$) being −0.2 (for *p*-morpholinophenylnitrene), −0.8 (for 2,4,6-trimethylphenylnitrene), and −1.5 (for *p*-acetylphenylnitrene).[99]

An alternative pathway for the formation of amine has been proposed for the conversion of *p*-nitrophenyl azide in the presence of *N,N*-dimethyl-tert-butylamine (DTA):[32,106]



3. Photochemical oxidation of aromatic azides

Reiser et al. were first to study the reactions of triplet aromatic nitrenes with oxygen.[22] At 77 K, the reaction is limited by the mobility of oxygen and is associated with the formation of compounds absorbing in the region 400–650 nm. This disappears on thawing the matrix. For a long time, it was thought that nitro compounds were the principal oxygen-containing products formed on photolysis of aromatic azides.[69,70,104,123,124] However, azoxy compounds, arising by interaction of triplet nitrenes with nitroso compounds, have also been detected.[32,124,125]



$$^3ArN + Ar'NO \longrightarrow Ar-N=N^+(O^-)-Ar' \quad (16)$$

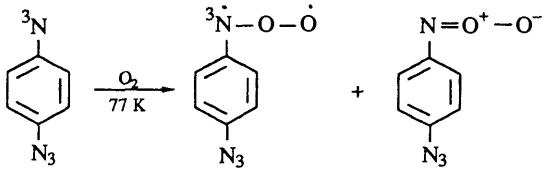
It has been shown that nitrobenzene ($PhNO_2$) is the main product from the oxidative photolysis of PhN_3 in acetonitrile at a high concentration of the azide (1.2 × 10^{-2} M). However, on decreasing the concentration to 10^{-4} M, nitrosobenzene (PhNO) becomes the sole product.[29] The authors propose that PhNO is the initial product, and that $PhNO_2$ is formed therefrom in a secondary photolytic process (a mechanism for formation of PhNO was not proposed).

Shortly after, it was demonstrated that irradiation of *p*-azidoaniline in oxygen-saturated aprotic solvents affords *p*-nitroso- and *p*-nitro-aniline.[126] However, the latter was not considered to arise

† According to Miura et al., pulsed excitation of 4,4′-diazidobiphenyl produces a triplet mononitrene.[107]

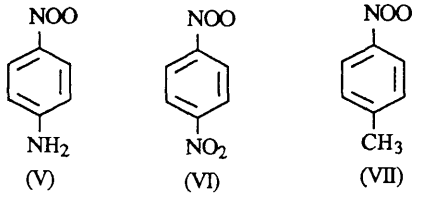
by secondary photolysis. A number of authors reported the simultaneous formation of nitro- and nitroso-compounds on photolysis of PhN_3 and its derivatives.[25,32–34,125] Sawaki et al. also argued that $PhNO_2$ was not formed by secondary photolysis of PhNO.[127]

It has been shown that triplet *p*-azidophenylnitrene reacts in a glass matrix at 77 K with dissolved oxygen to give two types of product: a paramagnetic compound, characterised by ESR spectroscopy (D = 0.11 cm^{-1}) as a triplet species; and a diamagnetic compound, absorbing intensely in the visible region (400–500 nm).[69] By analogy with carbene chemistry, it was proposed that these species are, respectively, a *p*-azidophenylaminodioxide biradical and a bipolar nitroso oxide.



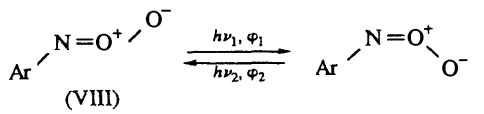
The formation of a paramagnetic adduct has also been recorded in the reaction of O_2 with 4,4′-dinitrenoazobenzene.[69] The reaction of ^{3}PhN and its *p*-nitro-, *p*-methoxy-, *p*-amino- and *p*-dimethylamino-derivatives with oxygen leads to coloured diamagnetic adducts, paramagnetic adducts not being recorded.[25,34,69] Evidently, the simultaneous formation of diamagnetic and paramagnetic adducts is more an exception than a rule.

Quantum chemical calculations by the AM1 method have shown that adducts (V–VII) can exist as two geometric isomers (*cis* and *trans*).[25]

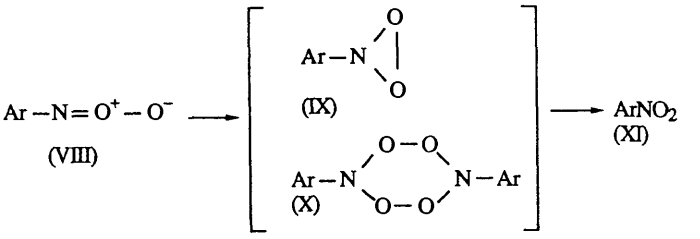


The *cis*-isomers exist principally in the singlet state (the triplet state being higher by 8–10 kcal/mol). Calculations for the *trans*-isomers point to effectively degenerate singlet and triplet states. Thus, diamagnetic and paramagnetic adducts not only have different electronic states, but also exist in isomeric forms. As a result, relaxation into the more stable adduct is not observed.[69]

Two diamagnetic adducts (λ_{max} = 495 and 588 nm), presumed to be *cis*- and *trans*-forms of (V), are produced by reaction of triplet *p*-aminophenylnitrene with O_2 at 95 K. The more stable form, absorbing at λ_{max} = 495 nm, is the sole product at 100 K. It is possible that a reversible equilibrium between the two forms is established on exposure to light ($\varphi_1 + \varphi_2 \sim 1$).[17,25]



In the thermal conversion of nitroso oxides, Brinen et al. proposed the intermediate formation of compounds (IX) or (X),[69] by analogy with carbene chemistry.[127,128]



In practice, warming compound (V) to 115 K produces a species exhibiting an absorption maximum in the region 336 nm (in methylcyclohexane) and at 318 nm (in toluene/THF). On freezing the matrix, *p*-nitro- (XII) and *p*-nitroso-aniline (XIII) are formed in comparable amounts.[17,25] The simultaneous formation of nitro and nitroso compounds would be consistent with the intermediate formation of compound (X).

Compound (V) has been detected at room temperature:

$$^3ArN + O_2 \xrightarrow{k_{16}} \underset{(V)}{ArNOO} \quad . \qquad (17)$$

$Ar = NH_2C_6H_4$.

By measuring the absorption against time, the kinetics of the decay of (V) was found to be of the second order [as would be anticipated if (X) is the initial reaction product]

$$(V) + (V) \xrightarrow{k_{17}} (X). \qquad (18)$$

In toluene, the rate constant k_{17} is (1.4 ± 0.4) × 10^9 l mol^{-1} s^{-1} and (0.72 ± 0.2) × 10^{10} l mol^{-1} s^{-1} in hexane.[34,130]

The dimeric peroxide (X) decomposes in two ways (Table 13):

$$(X) \xrightarrow{k_{18}} 2(XII), \qquad (19)$$

$$(X) \xrightarrow{k_{19}} 2(XIII) + O_2 \quad . \qquad (20)$$

Table 13. Activation parameters for the rate constants for the formation of *p*-nitro- (k_{18}) and *p*-nitroso-aniline (k_{19}).[33,34]

Solvent	k_{18} (298 K), s^{-1}	$\lg k^{\circ}_{18}$	k_{19} (298 K), s^{-1}	$\lg k^{\circ}_{19}$	$E_{18} = E_{19}$, kJ/mol
Hexane	1.9	15.8±0.8	0.8	15.4±0.8	88.5±4.6
Toluene	0.8	12.9±0.6	1.0	13.1±0.6	74.5±3.8

Thus, the mechanism of the photo-conversion of *p*-azidoaniline (XIV) in the presence of O_2 can be described as follows:[17,33,34]

Scheme 4

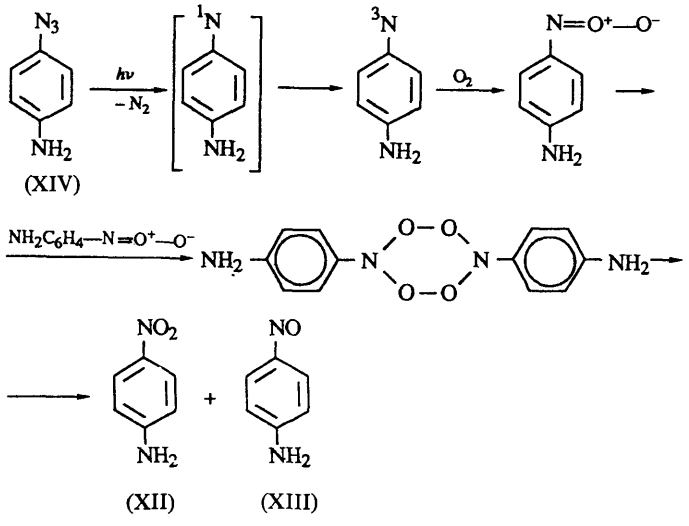


Table 14. Experimental and theoretical values for the long-wavelength maxima in the spectra of phenylnitroso oxide derivatives.[17,25]

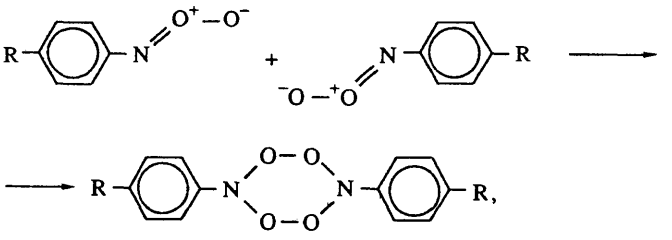
Substituent	λ_{max}^{exp} (77 K), nm	λ_{max}^{exp} (300 K), nm	λ_{max}^{theor}, nm	
			cis	*trans*
p-NH_2	495 and 588	440±5	406	430
p-NO_2	388	380±5	381	393
p-Me	400	395±5	393	415

Table 15. Values of the rate constants (k_{16}) for the reaction of triplet aromatic nitrenes (^{3}ArN) with oxygen.[17,25]

Ar	Solvent	*T*, K	$k_{16}.10^{-6}$, l.mol^{-1} s^{-1}
p-Aminophenyl	hexane	285	4.5±1.2
	toluene	—	8.0±2.0
p-Nitrophenyl	hexane	293	0.8±0.1
	ethanol	290	1.1±0.1
p-Tolyl*	acetonitrile	290	1.9±0.2
1-Pyrenyl**	benzene	—	0.9±0.1**

* The photolysis of *p*-tolyl azide was sensitised by benzophenone.
** The value of k_{16} was determined by Yamaoka et al.[70]

The formation of nitroso oxides has also been detected on low-temperature and flash photolysis of *p*-nitro- and *p*-methyl-phenyl azide (Table 14). However, intermediate species with structure (IX) and (X) were not evident. Kinetic data for the decomposition of (VII), based on absorption measurements, are in accord with a first order process, the rate constant being 0.2 s^{-1} in hexane at 20 °C. The kinetic curve for the decay of (VI) was not exponential, nor corresponded to a second order process ($\tau_{1/2} \approx 0.2$ s).[25] One may assume that the photo-conversion of *p*-nitro- and *p*-methyl-phenyl azide proceeds by a mechanism other than that described by Scheme 4, although the experimental observations are in accord with the process in outline. It is possible that the dimeric peroxide is formed by the cycloaddition of two *trans*-arylnitroso oxide molecules:



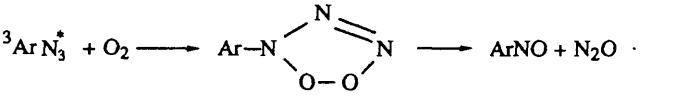
R = NO_2, Me.

The cyclodimerisation of *cis*-arylnitroso oxides would be sterically inhibited. Thus, it would appear that the adduct (V) is either formed in the *trans*-configuration or is readily converted into this form prior to dimerisation into (X) at a rate approximating to that of diffusion. If *cis*-(VI) and *cis*-(VII) are primary intermediates formed on reaction of *p*-nitro- and *p*-methyl-phenylnitrene, respectively, in the presence of oxygen, and if *cis*–*trans* isomerisation is a limiting step, then the decay of (VI) and (VII) would not follow second order kinetics.[25]

In order for reaction (17) to become dominant, a low concentration of azide and intermediate species is required. The desired conditions would also exist in polymeric matrices.[25,36,131–133] It has not been possible to detect reaction (17) on laser excitation in solution. Only the upper limit of the rate constant has been determined: $k_{16} \leqslant 10^6$ l mol^{-1} s^{-1} for 2,4,6-tribromophenylnitrene[16] and $k_{16} \leqslant 2 \times 10^5$ l mol^{-1} s^{-1} for *p*-nitrophenylnitrene.[32] The rate constants k_{16} obtained by flash photolysis are given in Table 15.[17,25,70] As can be seen, the values of k_{16} are significantly lower than that for a diffusion-controlled process and there is effectively no dependence on the nature of the aromatic nitrene. It should be noted that the rate constant for the reaction of oxygen with triplet carbenes[134–136] is significantly higher, being $(1-5) \times 10^9$ l mol^{-1} s^{-1} (1.9×10^8 l mol^{-1} s^{-1} for dimesitylcarbene[137]):

$$^3(R^1R^2C) + O_2 \rightarrow R^1R^2COO$$

A small propotion (~20%) of *p*-nitrosobenzene is formed without the involvement of triplet nitrenes, possibly by the route:[32,124]



Ar = $NO_2C_6H_4$. (21)

Recently, attempts were made to study the reactivity of PhNOO,[127] which, in the opinion of the authors, is a biradical. Irradiation of PhN_3 in the presence of diphenyl sulphide, diphenyl sulphoxide or *p*-chloronitrosobenzene results in oxidation of the additive. It is thought that oxidation takes place by interaction of the additive with PhNOO, as shown below with a nitrosoarene.

$$PhNOO + ArNO \longrightarrow Ph-\dot{N}-O-O-\underset{\underset{O\cdot}{|}}{N}-Ar \longrightarrow$$

$$\longrightarrow PhNO + ArNO_2 \qquad (22)$$

The following order of reactivity has been established

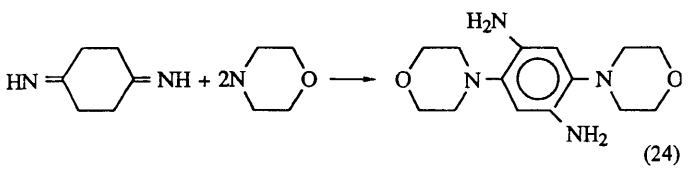
$$PhNO >> Ph_2S > Ph_2SO > PhH \quad \text{(Ref.127)}.$$

The observed increase in the yield of $PhNO_2$ on increasing the concentration of azide could be explained by the intervention of reaction (22).[29]

The photoconversion depicted in Scheme 4 proceeds only on irradiation of *p*-azidoaniline (XIV) in aprotic media. *p*-Benzoquinone diimine (XV) is formed on photolysis of (XIV) in water or in hexane containing an alcohol, amine, or a mercaptan at a concentration of 10^{-2} to 10^{-1} M. Presumably this takes place by the reaction:[25,120]

(XV) (23)

Compound (XV) readily reacts with nucleophiles, as exemplified below.[120]



(24)

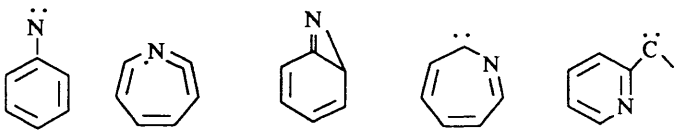
Derivatives of (XIV), e.g. nucleoside-5′-triphosphate γ-*p*-azidoanilides,[138,139] are used in the photo-affinity modification of proteins. It cannot be excluded that in such protein modification an intermediate *p*-benzoquinone diimine is implicated in a nucleophilic addition process.[140]

VI. Quantum chemical calculations on the properties of intermediates

The first quantum chemical calculations on the properties of triplet aromatic nitrenes were carried out by π-electron approximation.[44,81,141] Later, INDO calculations were made in order to interpret the ESR spectra of aromatic nitrenes.[48,50]

Information on the properties of singlet aromatic nitrenes is limited. From the photo-electron spectrum of the NH^- anion in the gas phase, a measurement was made of the splitting between the primary ($^3\Sigma^-$) state and the first excited ($^1\Delta$) state of nitrene itself (NH). This was found to be 34.6 ± 0.4 kcal/mol.[142] For a long time, it was only possible to deduce information on singlet-triplet splitting in PhN by quantum chemical calculations.[143] It was not until 1984 that experimental states of PhN in the gas phase (4.3 ± 0.4 and 8.8 ± 0.5 kcal/mol).[144,145]

Shillady et al.[143] applied the MINDO/2 method to calculate the geometry of all the possible intermediates in the photolysis and thermolysis of PhN_3:



(PhN) (A) (B) (C) (D)

The relative energies of these species were calculated by the MINDO/2 and INDO/P method (of Pople), and an assessment of the multi-configurational character of the electronic states of the intermediates was made by the INDO/P/INO method. The long-wavelength maxima in the spectrum of ^{3}PhN, as calculated by the INDO/S method, were assigned to $n_z \rightarrow \pi$ (380 nm) and $n_z \rightarrow n_y$ (330 nm) transitions,[143] although earlier it has been reported that the ^{3}PhN spectrum corresponds essentially to ππ*-type transitions. The long-wavelength transition with λ_{00} = 489 nm was not reproduced by calculation.

Table 16. Calculated values for the relative energy (E_{rel}) and absorption spectra of hypothetical intermediates from the photolysis of phenyl azide.[143]

Species	E_{rel}, kcal/mol			λ, nm (strength of the oscillator)
	MINDO/2	INDO/P	INDO/P/INO	
^{1}PhN	0	0	0	354(0.17), 307(0.03), 250(0.13)
^{3}PhN	—	-18.4	-15	380, 330, 297, 274, 222
^{1}A	6.9	—	—	—
^{1}B	-19	-68.2	-64.6	398(0.03), 313(0.02), 252(0.10)
^{3}B	—	11.3	—	382, 358, 315, 301, 284, 275
^{3}C	1.2	58.3	60.6	422(0.08), 354(0.10), 262(1.03)
^{1}D	6.3	—	—	—

It has been suggested that ^{1}PhN is formed in a configuration with seven π-electrons ($n_z^2 n_y^1 \pi^1$).[143] However, it is not known whether the singlet-triplet splitting (15–18 kcal/mol) corresponds essentially to this state or to a state with six π-electrons ($n_z^2 n_y^2$) (according to the INDO calculations of Pople et al.,[146] the latter is a lower singlet state). It has been calculated (Table 16)[143] that the bicyclic azirine (B) is a stable intermediate species, a fact which is not borne out experimentally.[12,13]

Schuster et al. calculated the heat of formation of all the considered intermediates by the MINDO method,[147] although the electronic configuration of ^{1}PhN was not specified. By comparison with other data,[17,25] it would appear that this configuration involves six π-electrons ($n_z^2 n_y^2$) (Table 17). According to these data[17,25] and the results obtained by *ab initio* 3−21G calculations,[145] the lower singlet state of ^{1}PhN is in the $n_z^2 n_y^1 \pi^1$ configuration. More detailed *ab initio* calculations on a broader basis are required in order to ascertain the exact electronic structure of singlet aromatic nitrenes.

Table 17. Results from calculations of the enthalpy of formation of intermediates (MNDO method).

Species	ΔH, kcal/mol		
	(Ref.13)	(Refs.17, 25)	MNDO+KB (2×2)
^{1}PhN	120	121 ($n_z^2 n_y^2$)	118
	—	105 ($n_z^2 n_y^1 \pi^1$)	
^{3}PhN	99	98($n_z^2 n_y^1 \pi^1$)	
^{1}A	100	—	
^{1}B	110	—	
^{3}C	103	—	

The MNDO calculations (Table 17) are roughly in accord with experimental data: the calculated singlet-triplet splitting (7 kcal/mol) is close to that measured experimentally,[144,145] and the calculated energy difference between ^{1}(PhN) and ^{1}(A) (5 kcal/mol) accords with the experimental value (5−10 kcal/mol) obtained in different solvents[17,25] (see Table 8). It follows that a didehydroazepine (^{1}A) is the most likely intermediate species formed on impulse photolysis of PhN_3, AM1, MNDO and MNDOC calculations are essentially in agreement in that acceptor (*p*-NO_2) and donor (*p*-NH_2) substituents lead to a small (1−2 kcal/mol) decrease in the singlet−triplet splitting in ArN.[17,25]

VII. Conclusions

From the material examined, it is evident that the mechanism of photolysis of azides is understood in broad outline. However, the possibility of parallel reaction pathways, involving key intermediate species (nitrenes didehydroazepines and/or azirines, etc.), adds to the overall complexity, and specific variations may simply be substrate-dependent. The precise course of the reaction may also depend on the concentration of the reactants, the temperature and presence of impurities. Thus the results obtained under different experimental conditions may differ significantly. The precise structure of the intermediate species, and their involvement in a particular pathway of azide photo-decomposition, has not been established in each instance, and more extensive kinetic data are required to obtain further information in this respect. This is particularly true for the initial processes involving singlet intermediate species. As there are no data on the rate of isomerisation of singlet aromatic nitrenes into didehydroazpines (and/or azirines), it is not possible to ascertain the effect of substitution on the formation of isomers.

Significantly more studies have been made on the reactions of triplet aromatic nitrenes, although quantitative data is still lacking. For example, the rate constant for reaction (11) has only been established under one set of conditions. Our understanding of the mechanism of azide photolysis in the presence of oxygen is limited, and contradictory results have been reported on the photo-decomposition of azides by chain propagation. In practice, when studying the reactions of aromatic azides, it is important to consider a large number of competing processes and the effect of experimental conditions on them.

Polyfluoroalkanesulphenyl chlorides

A Yu Sizov, A K Kolomiets, A V Fokin
A N Nesmeyanov Institute of Heteroorganic Compounds, Russian Academy of Sciences, Moscow

ABSTRACT. **Data appearing since 1975 are correlated for the methods of synthesis of polyfluoroalkanesulphenyl chlorides, their reactions with O-, S-, N-, P- and C-nucleophiles, with unsaturated aromatic and heteroaromatic compounds, for their behaviour in oxidation and heterocyclisation reactions and in free radical conversions.**

I Introduction 517
II. Methods of Preparation 517
III. Reactivity 520

I. Introduction

The first information on polyfluoroalkanesulphenyl chlorides (PFASC) appeared in the fifties.[1,2] Certain unusual properties of these compounds served as a spur towards a wider study of the chemistry of the fluorine-containing sulphenyl chlorides. By 1975 more than 190 publications had appeared on the synthesis and reactivity of PFASC and have been correlated in a detailed review.[3]

Theoretical interest in the chemistry of these compounds has grown markedly in recent years. As functionally substituted aliphatic compounds of two-coordinate sulphur the PFASC and their numerous conversion products are an interesting subject for studying the dependence of reactivity on intramolecular *pd* interactions. In several unfluorinated analogues these are particularly strongly displayed in C–C–S triads and determine the high reactivity of these compounds towards heterocyclisation and numerous rearrangements through the episulphonium state.[4,5] The appearance of the abundant 2*p* electrons of fluorine atoms at positions 3, 4 and 5 to the sulphur atom does not affect these properties appreciably.

However in the last two decades most attention has been paid to the investigation of the applied chemistry of PFASC. The high electron-accepting properties of polyfluoroalkylthio groups and particularly of their oxidation products,[6] imparting to the molecule a reduced light sensitivity and combustibility, have stimulated syntheses of numerous compounds desirable in practice and materials derived from these compounds. Opportunities for using PFASC as effective precursors of biologically active compounds have been more widely investigated.

The main types of compound studied from this point of view are given below in Tables 1 and 2. They reflect the main trend in the development of the chemistry of biologically active fluorine-containing compounds, viz. a continuation of the study of the highly reactive fluoroalkanesulphenamides, on the basis of which the fungitoxic preparations Euparen and Euparen-M were designed previously and are in use. A second direction has also developed based on the modification, using polyfluoroalkylthio groups, of known natural and synthetic biologically active compounds, their analogues and precursors. The opportunities in this direction are caused by the relatively low stability of the S–R_F bond, which is inclined to ready biodegradation with the elimination of fluoride ion, the appearance of which in the cytosol of cells aids normalisation of cellular hormone metabolism disturbed in numerous pathological states.[7] Information already available in this area enables consideration of various PFASC as efficient synthons for the synthesis of target preparations for medicine and agriculture.

The most important data on the chemistry and application of PFASC appearing during 1975–1991 are correlated in this review. Mainly, attention is paid to a consideration of the features of their methods of formation and reactivity and also to the opportunities for use in syntheses of biologically active compounds.

II. Methods of preparation

In the search for methods of obtaining PFASC the usual reactions for the unfluorinated analogues have been studied, such as the chlorination of disulphides, sulphides with labile leaving groups, thiols, thiocarbonyl compounds and thiiranes, the hydrochlorination of sulphenamides, reactions of sulphur chlorides with unsaturated compounds, the functionalisation of compounds with an S–Cl bond and also certain methods specific to fluorine chemistry. The features of the general methods of synthesising PFASC are most frequently displayed under the more forcing conditions of highly selective conversions and in side reactions which do not occur in the chemistry of the unfluorinated analogues.

1. Chlorination of disulphides

Symmetrical bispolyfluoroalkyl disulphides are usually converted unequivocally into PFASC on chlorination.[8–14]

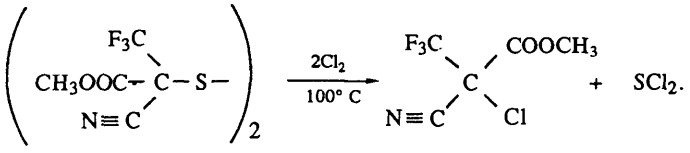
$$R_FSSR_F \xrightarrow{Cl_2} 2R_FSCl,$$

R_F = $ClCH_2-CH(CF_3)$, $CF_3CHClCH_2$, $CF_3OCFClCF_2$, $ClCF_2CF_2$, Cl_2CFCF_2, $CF_3(CF_2)_2$, $CF_3(CF_2)_6$, $(CF_3)_2CFO(CF_2)_2$, $(CF_3)_2CF$, $(CF_3)_3C$, $ClCF_2-C(CF_3)_2$, $CH_3OOC-C(CF_3)_2$,  .

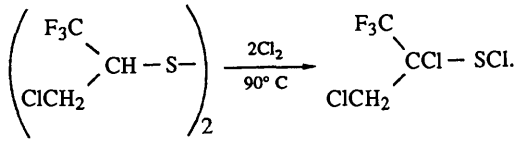
The reaction conditions depend appreciably on the nature of the polyfluoroalkyl group. The introduction of a CF_3 group into the α and β positions of the alkyl group does not show a marked effect on the conditions of chlorolysis of the S–S bond. Thus 2-chloro-1-trifluoromethylethanesulphenyl chloride was obtained in high yield from the corresponding disulphide at 20 °C or on mild cooling.

Disulphides with a CF_2 group on the sulphur atom are chlorinated at 90–110 °C. Replacement of one or two fluorine atoms of the CF_2 group by trifluoromethyl or a methoxycarbonyl group leads to a further reduction of the nucleophilicity of the sulphur atom and an increase in the chlorolysis temperature to 100–130 °C. The chlorolysis of bis(2-chloroperfluoro-1-hexenyl) disulphide occurs at 150 °C. In these reactions the nucleophilicity of the polyfluoroalkyl disulphides is controlled mainly by the efficient three-centre 2*p*3*d* interactions of the fluorine and sulphur atoms and also by the electron-withdrawing effects of the substituents at the α-carbon atom. Chlorolysis of the S–S bond of low reactivity disulphides is facilitated on UV irradiation.[12] The bispolyfluoroalkyl polysulphides undergo chlorolysis into PFASC under the same conditions as the corresponding disulphides.

In sulphides with strongly electron-accepting groups the R_F–S bond as well as the S–S bond may undergo chlorolysis:[13]



When a CH bond is present in the α position to sulphur it is readily chlorinated at increased temperature.[15]



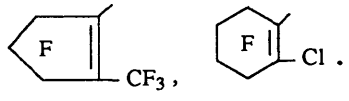
2. Chlorination of sulphides and other polyfluoroalkylthio derivatives

The conditions of forming PFASC from polyfluoroalkyl sulphides are determined mainly by the nature of the readily leaving alkyl group. However the structure of the polyfluoroalkyl group also has some effect.

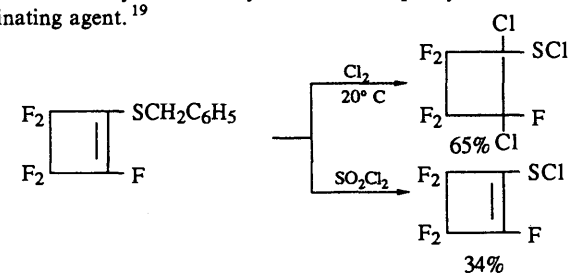
Various polyfluoroalkyl and polyfluoroalkenyl benzyl sulphides are chlorinated to PFASC at 20 °C in polyfluoroalkanes or without a solvent[16–22]

$$R_FSCH_2C_6H_5 \xrightarrow[20^\circ C]{Cl_2} R_FSCl + C_6H_5CH_2Cl,$$

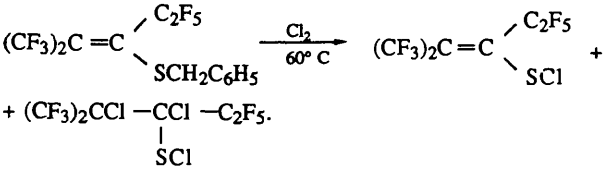
$R_F = CHF_2$, $(CF_3)_2CHCF_2$, CF_3CFCl, $(CF_3)_2CF$, $CHFClCF_2$, $(CF_3)_2C{=}CF$, $(CF_3)_2C{=}C{-}C_2F_5$, $((CF_3)_2CF)_2C{=}C{-}CF_3$,



In some cases chlorination of a multiple bond occurs simultaneously. This is successfully excluded by the use of sulphuryl chloride as the chlorinating agent.[19]

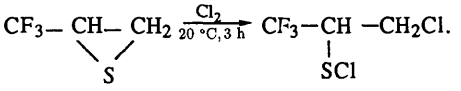


In the case of polyfluoroalkenyl benzyl sulphides the reaction may by accompanied by a chlorotropic conversion of the resulting PFASC. This leads to a mixture of compounds.[22]



Chlorination of benzyl 2,2,2-trifluoroethyl sulphide occurs initially at the C–H bond of the trifluoroethyl group and fission of the benzyl group occurs after this.[23]

Chlorolysis of cyclic sulphides, for example trifluoromethylthiirane, is a reaction of this type[24]



The ethyl group may act as the leaving group on chlorination in trifluoroacetic acid, which enables β-methoxycarbonyltetrafluoroethanesulphenyl chloride to be obtained.[25]

As with the unfluorinated analogues the t-butyl group is eliminated more readily than benzyl. In this case the PFASC are formed in the cold even on chlorination with sulphuryl chloride.[26]

$$R_FSC(CH_3)_3 \xrightarrow[10^\circ C]{SO_2Cl_2} R_FSCl + (CH_3)_3CCl,$$

$R_F = CH_3OOC{-}\underset{\displaystyle CF_3}{\underset{|}{CH}}{-}CF_2$, $CH_3OOC{-}\underset{\displaystyle CF_3}{\underset{|}{C}}{=}CF$

Chlorinating agents split S–P [26] and S–N [27] bonds even more readily.

$$R_FSP(OC_2H_5)_2 \xrightarrow{SO_2Cl_2} R_FSCl,$$

$R_F = (CF_3)_2CHCF_2$, $(CF_3)_2CHC(O)$;

$$CF_3SN{=}S{=}S \xrightarrow[-30^\circ C,\ CCl_4]{Cl_2} CF_3SCl.$$

Polyfluoroalkanesulphenamides are converted into PFASC on treatment with dry HCl.[28]

$$R_FSN(C_2H_5)_2 \xrightarrow{HCl} \underset{60\text{—}70\%}{R_FSCl},$$

$R_F = (CF_3)_3C$, $CH_3OOC{-}C(CF_3)_2$.

3. Chlorination of thiols and thiocarbonyl compounds

Stable polyfluoroalkenethiols are readily chlorinated to give PFASC at 20 °C.[21,29] However 2-chlorooctafluoro-1-cyclohexenesulphenyl chloride was obtained by this method only at 150 °C,[14]

which indicates the extremely strong *pd* atomic interactions in the four-centre Cl–C=C–S system.

$$R_FSH + Cl_2 \longrightarrow R_FSCl,$$
$$R_F = (CF_3)_2C{=}\ C{-}\ C_2F_5,\ ((CF_3)_2CF)_2C{=}\ C{-}\ CF_3,$$

Chlorolysis of 1,1-diphenyltrifluoroethanethiol occurs under mild conditions with sulphuryl chloride.[30]

$$CF_3{-}\ C(C_6H_5)_2SH \xrightarrow{SO_2Cl_2} CF_3\ {-}C(C_6H_5)_2SCl.$$
96%

Many PFASC which are impossible to synthesise by other methods have been obtained by the reaction of highly reactive thiocarbonyl compounds with chlorine and chlorine fluoride under mild conditions.[11,22,31–34]

$$\begin{matrix} X \\ \diagdown \\ C=S \\ \diagup \\ Y \end{matrix} \xrightarrow[-80\text{ to }90\ ^\circ C]{Cl_2} XYCCl-SCl,$$

$X = CF_3$, $Y = F$, Cl, CF_3; $X = CF_3$, $Y = Br$; $X = Y = F$;
$X = C_2F_5$, $Y = (CF_3)_2CH$, $(CF_3)_2CCl$;

$$\begin{matrix} X \\ \diagdown \\ C=S \\ \diagup \\ Y \end{matrix} \xrightarrow[-100^\circ C]{ClF} XYCF-SCl,$$

$X = Y = CF_3$; $X = Y = Br$; $X = CF_3$, $Y = F$, Br; $X = S = C = N$, $Y = F$.

4. Addition of sulphur chlorides to unsaturated compounds

The thermal reactions of sulphur chlorides with polyfluoroalkenes has been studied widely in the search for methods of synthesising precursors of PFASC such as the bis(2-chloropolyfluoroalkyl) disulphides.[35] Trifluoroethylene, tetrafluoroethylene, chlorotrifluoroethylene, perfluoromethyl vinyl ether and 2H-pentafluoropropene participate in these reactions. Symmetrical and unsymmetrical dichlorodifluoroethylenes, hexafluoropropene and octafluoromethylpropene do not react. The electrophilic addition of SCl_2 on thermolysis always gives a complex mixture of compounds including PFASC, polyfluoroalkylpolythiosulphenyl chlorides, sulphides, polysulphides and products of alkene chlorination. The addition of S_2Cl_2 with the predominant formation of disulphides occurs only under forcing conditions (140–155 °C) with a large excess of polyfluoroalkene, which has made several PFASC available for investigation.

$$\begin{matrix} R \\ \diagdown \\ C= \\ \diagup \\ X \end{matrix} CF_2 \xrightarrow{S_2Cl_2} \left(\begin{matrix} R \\ \diagdown \\ CCl \\ \diagup \\ X \end{matrix} -CF_2 \right)_2 S_2 \xrightarrow{Cl_2} \begin{matrix} R \\ \diagdown \\ CCl-CF_2SCl, \\ \diagup \\ X \end{matrix}$$

R = H, F, Cl, CF_3, CF_3O; X = H, F.

The preparative value of these reactions is markedly extended by carrying out the process in the presence of catalysts. 1,2-Dichlorodifluoroethylene is converted into 1,2-dichlorotrifluoroethanesulphenyl chloride in the system $SF_4-HF-S_2Cl_2$ under relatively mild conditions.[36] It is considered that ionisation of S_2Cl_2 in the presence of SF_4 and HF facilitates the electrophilic addition of sulphur monochloride cation at the multiple bond and the presence of fluoride ion and the chlorine formed in the reaction mixture enables the unequivocal formation of the sulphenyl chloride.

$$S_2Cl_2 \xrightarrow{HF,\ SF_4} Cl^- + {}^+SSCl,$$
$$SF_4 + 4Cl^- \xrightarrow[-4F]{} SCl_4 \longrightarrow SCl_2 + Cl_2,$$
$$CFCl{=}CFCl \xrightarrow{{}^+SSCl} \left[{}^+CFClCFClSSCl \xrightarrow{F^-} \right.$$
$$\left. \longrightarrow CF_2ClCFClSSCl \right] \xrightarrow{Cl_2} CF_2ClCFClSCl.$$

Chlorotrifluoroethylene reacts similarly with S_2Cl_2 under these conditions, however the reaction products proved to be the two possible regioisomers.

$$CF_2{=}\ CFCl \xrightarrow{SF_4-HF-S_2Cl_2} CF_3CFClSCl + CF_2ClCF_2SCl.$$

Hexafluoropropene forms a combined addition product with sulphur dichloride and fluorosulphonic acid (1:3) with elimination of HCl at 40–60 °C.[37,38]

$$CF_3CF{=}\ CF_2 \xrightarrow[-HCl]{SCl_2,\ HSO_3F} CF_3-\underset{\displaystyle SCl}{\underset{|}{CF}}-CF_2OSO_2F.$$
75%

A mixture of chlorosulphonic acid and SCl_2 gives a similar product in 34% yield. In combined reactions of this type S_2Cl_2 gives a mixture of compounds containing thiosulphenyl chlorides and trisulphides in addition to sulphenyl chlorides.

Under conditions of the specific solvation of the S–Cl bond (acetonitrile, benzonitrile, $POCl_3$ and SO_2) sulphur mono- and dichlorides add to hexafluorodimethyl ketene with the formation of sulphenyl and thiosulphenyl chlorides.[39]

$$(CF_3)_2C{=}C{=}O + S_nCl_2 \longrightarrow (CF_3)_2C \begin{matrix} \diagup\ C(O)Cl \\ \diagdown\ S_nCl \end{matrix}.$$
$n = 1, 2.$ 90%

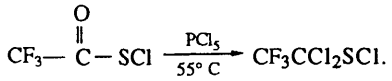
These reactions are effected particularly readily (at negative temperatures) in acetonitrile.

5. Functionalisation of compounds with an S–Cl bond

The C–H bond in the α position to a sulphur atom is readily chlorinated. This enables 1,2-dichloro-1-trifluoromethylethanesulphenyl chloride, which is inaccessible by other methods, to be obtained.[15]

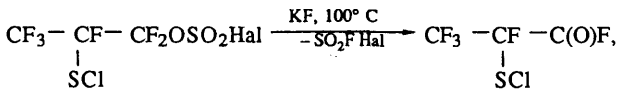
$$\begin{matrix} F_3C \\ \diagdown \\ CH-SCl \\ \diagup \\ ClCH_2 \end{matrix} \xrightarrow[90^\circ C]{Cl_2} \begin{matrix} F_3C \\ \diagdown \\ CCl-SCl. \\ \diagup \\ ClCH_2 \end{matrix}$$
86%

Trifluoroacetylsulphenyl chloride is converted into 1,1-dichlorotrifluoroethanesulphenyl chloride on reaction with PCl_5.[40]



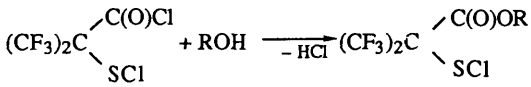
75%

The sulphenyl chloride formed on combined addition of SCl_2 and HSO_3F or HSO_3Cl to hexafluoropropene is converted on heating with KF into the acid fluoride of α-chlorosulphenyltetrafluoropropionic acid.[38]



Hal = F, Cl. 74%

The acid chloride of α-chlorosulphenylhexafluoroisobutyric acid reacts under mild conditions with saturated and unsaturated alcohols forming esters in the absence of HCl acceptors.[41] The S–Cl bond is not affected by this.



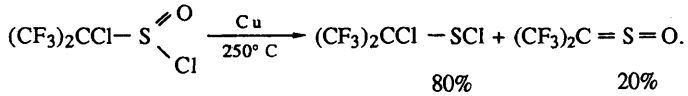
R = CH_3, CH_2=$CHCH_2$.

Chloro- and chlorofluoroalkanesulphenyl chlorides react by replacement of chlorine by fluorine exclusively at the C–Cl bond in the position α to the sulphur atom. In these reactions, which were widely studied for trichloromethanesulphenyl chloride previously,[3] HF, FeF_3, HF/CrF_3 and NH_4F have also been studied as fluorinating agents.[42–45] Hexafluorotrichloro-sym-triazine proved to be a new fluorinating agent in principle. Its application enables selective replacement by fluorine of one or two chlorine atoms in 1,1-dichlorotrifluoroethanesulphenyl chloride.[40]

X = Cl, F.

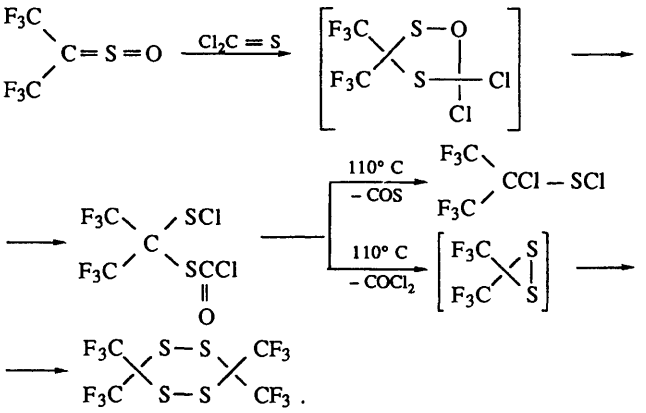
6. Other preparative routes

On heating α-chlorohexafluoroisopropanesulphinyl chloride with activated copper under forcing conditions it undergoes deoxygenation with the formation of a sulphenyl chloride.[46] Only a small portion of the starting material is converted into the dechlorination product bis(trifluoromethyl)methylene sulphoxide.



80% 20%

The (2 + 3) cycloaddition of thiophosgene to bis(trifluoromethyl)methylene sulphoxide leads to α-chloroformylthiohexafluoroisopropanesulphenyl chloride, seemingly through the intermediate dithioxolane.[46] On heating to 110 °C the sulphenyl chloride is decomposed with the elimination of carbonyl sulphide or phosgene with the formation of the corresponding α-chlorohexafluoroisopropanesulphenyl chloride and 3,3,6,6-tetrakis(trifluoromethyl)-1,2,4,5-tetrathiane.



III. Reactivity

The reactivity of PFASC has been studied in the majority of conversions typical of aliphatic sulphenyl chlorides. The polyfluoroalkylthiolation of various nucleophilic reagents, aromatic and heteroaromatic compounds has been widely clarified as has the reaction of PFASC with unsaturated compounds. The information obtained enables PFASC to be considered to be compounds with high reactivity, though appreciably more moderate than their unfluorinated analogues.

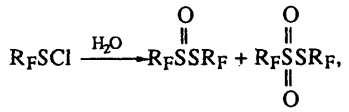
1. Reactions with nucleophilic reagents

The reaction of PFASC with nucleophilic reagents takes place according to the following equation

$$Nu(H) + R_FSCl \rightarrow NuSR_F + Cl^- + (H^+).$$

It is assumed that these reactions occur by an S_N2 mechanism in which the entering and leaving groups are at the vertices of a trigonal bipyramid.[47]

Reaction with O-nucleophiles. The hydrolysis of PFASC was considered in detail in the review[3] using CF_3SCl as example. In addition it was shown that these compounds are stable to water, unlike their unfluorinated analogues. Only on prolonged shaking with water were the final hydrolysis products, sulphides and sulphonic acids, obtained in some cases. The hydrolysis of the chlorofluoromethanesulphenyl chlorides was successfully stopped at the stage of forming thiosulphinates and/or thiosulphonates.[48]



R_F = $CFCl_2$, CF_2Cl.

1,1-Dichlorotrifluoroethanesulphenyl chloride is partially converted after 48 h at 45 °C into chloro(trifluoromethyl)methylene sulphoxide.[23,49]

$$CF_3CCl_2SCl \xrightarrow[45^\circ C]{H_2O} \begin{matrix} CF_3 \\ \diagdown \\ C=S=O \\ \diagup \\ Cl \end{matrix} \quad 28\%$$

α-Chlorohexafluoroisopropanesulphenyl chloride is unchanged under these conditions.[46]

The PFASC are as stable to alcohols as to water. The stable esters of polyfluoroalkanesulphenic acids are obtained under relatively mild conditions in the presence of acceptors of HCl [$N(C_2H_5)_3$, Py] [50,51] and without acceptors only in certain cases on heating.[26]

$$R_FSCl + ROH \rightarrow R_FSOR,$$

$R_F = CF_3$, $R = C_2H_5$, $CH_3OC_6H_4CH_2$, $CF_3SNHCH_2CH(C_6H_5)$;

$R_F = (CF_3)_2CHCF_2$,

$R = C_2H_5$.

The PFASC react more readily with alkoxides and phenoxides of the alkali metals and particularly of mercury.[30,52] Under these conditions the acylsulphenyl chlorides give desulphurisation products.

$$CF_3 - C(C_6H_5)_2SCl + ROH \xrightarrow[20\ ^\circ C, 3\ h]{NaH/THF} CF_3 - C(C_6H_5)_2SOR,$$

$R = (CH_3)_3CCH_2$, $C_6H_5CH_2O(CH_2)_2$, $4\text{-}O_2NC_6H_4$,

$CH_3(CH_2OCH_2)_3CH_2$.

$$(CF_3)_3COHgCl \xrightarrow[0\ ^\circ C,\ 24\ h]{CF_3SCl} (CF_3)_3COSCF_3$$

$$(CF_3)_3COHgCl \xrightarrow[0\ ^\circ C,\ 24\ h]{CF_3CSCl} (CF_3)_3COSC(=O)CF_3 \xrightarrow{-S} (CF_3)_3COC(=O)CF_3$$

On reacting PFASC with allyl alcohol in the presence of pyridine, equilibrium mixtures are formed of sulphuric acid esters and products of their [2,3]-sigmatropic rearrangement with a significant preponderance of the latter.[53] On heating or on increasing the electron-donating properties of the polyfluoroalkyl group the content of sulphenate in the mixture is increased.

$$R_FSCl + HOCH_2CH=CH_2 \xrightarrow[CH_2Cl_2]{Py} R_FSOCH_2CH=$$

$$= CH_2 \rightleftharpoons R_FSC(=O)CH_2CH=CH_2,$$

$R_F = CCl_2F$, $CClF_2$, CF_3, $(CF_3)_2CH$, $(CF_3)_2CCl$.

The PFASC form mixed anhydrides with salts of carboxylic acids which differ from the unfluorinated analogues in increased stability.[54,55] Their yield was increased with an increase in the number of fluorine atoms at the α-carbon atom.

$$R_FSCl + MOC(O)R \rightarrow R_FSOC(O)R,$$

$R_F = CCl_2F$, $CClF_2$, CF_3; $R = CH_3$, C_2H_5, CF_3, C_2F_5; $M = Na$, Ag.

The mixed anhydrides obtained were more reactive than PFASC in their activity in reactions of electrophilic addition and substitution.[55]

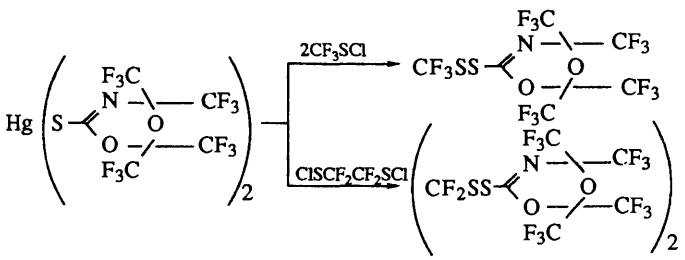
Reactions with S-nucleophiles. Thiolates and thiols react with PFASC in the presence of acceptors of HCl giving unsymmetrical disulphides.[22,24,26,32,56–63] Strong bases aid the symmetrisation of these compounds which may be the reason for the sharp reduction in the yield of the desired products.

$$R_FSCl + RSH \xrightarrow[-HCl]{\ddot{B}} R_FSSR \xrightarrow[RSH]{\ddot{B}} R_FSSR_F + R_2S_2,$$

$R_F = CCl_2F$, CF_3, $FC(O)$, $ClCH_2 - CH(CF_3)$, $(CF_3)_2CHCF_2$, $CF_3 - CCl(CH_2Cl)$, $(CF_3)_2C=C-C_2F_5$, $CF_3C(O)$;

$R = H$, CH_3, $C_6H_5CH_2$, $HOOCCH_2$, CF_3, $C_6H_5NH-C(S)$.

$$2CF_3SCl + \begin{matrix} NaS \\ \diagdown \\ C=S \\ \diagup \\ NaS \end{matrix} \longrightarrow \begin{matrix} CF_3SS \\ \diagdown \\ C=S, \\ \diagup \\ CF_3SS \end{matrix}$$



Dialkyl disulphides also react analogously. Thus CF_3SCl reacts under mild conditions with dimethylsulphide with the formation of an unsymmetrical disulphide.[64]

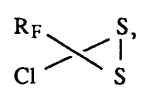
$$CF_3SCl + CH_3SSCH_3 \xrightarrow[-50\ to\ 25\ ^\circ C]{} CF_3SSCH_3 + CH_3SCl.$$

The disulphides formed in reactions of α,α-dichloropolyfluoroalkanesulphenyl chlorides with thioacetic acid are readily split by morpholine with the formation of morpholides of chlorofluorothioacetic acids.[65]

$$R_FCCl_2SCl + \underset{+HSCCH_3}{\overset{O}{\parallel}} \xrightarrow[60^\circ C,\ CCl_4]{} R_FCCl_2SSCCH_3 \xrightarrow{HN\langle O\rangle} R_FC(=S)-N\langle O\rangle,$$

$R_F = CFCl_2$, CF_2Cl.

Initially, decomposition of the disulphide to a dithiirane is proposed



the desulphurisation of which leads to the thioacid chloride $R_FC(S)Cl$ giving the corresponding morpholide with morpholine.

Reaction with N-nucleophiles. The reaction of PFASC with N-nucleophiles with the formation of polyfluoroalkanesulphenamides has been widely studied. Ammonia,[15,30,66] primary[30,51,67–69] and secondary[10,15,19,30,70–74] amines, primary and secondary amides of

carboxylic acids[75–78] and sulphonic acid amides[79] participate in these reactions.

$$R_FSCl + HN\!\!\begin{array}{l}\diagup\\\diagdown\end{array} \xrightarrow[-HCl]{} R_FSN\!\!\begin{array}{l}\diagup\\\diagdown\end{array}\ .$$

The reaction is usually effected in the presence of HCl acceptors such as trimethyl-, triethylamine, pyridine or an excess of the reacting amine. In certain cases better results are obtained when reacting PFASC with metal amides.

When reacting ammonia and primary amines with an excess of PFASC a second or third polyfluoroalkylthio group is introduced at the nitrogen atom.[3] Tetrafluoroethane-1,2-disulphenyl chloride reacts with primary amines giving 1,3,2-dithiazolidines.[69]

$$ClSCF_2CF_2SCl + H_2NR \longrightarrow \begin{array}{l} CF_2 - S \\ | \quad\quad \diagdown \\ CF_2 - S \end{array} \!\!> N - R$$

The polyfluoroalkanesulphenamides are markedly more stable than their unfluorinated analogues. Their thermal and hydrolytic stability is increased with an increase in the electron-accepting properties of the polyfluoroalkyl group and is reduced with an increase in the basicity of the amine. Many of the sulphenamides obtained possess high biological activity. Highly active compounds are found among them which are of interest in agriculture and medicine. Data on the structure and biological activity of the sulphenamides obtained from N-nucleophiles and PFASC are given in Tables 1 and 3.

N-Silylated compounds are sulphenylated by PFASC with elimination of chlorotrimethylsilane. Stable fluorocarbonylated azides and thionylimines are obtained in this way.[59]

$$FC(=O)-SCl + (CH_3)_3SiX \xrightarrow[-(CH_3)_3SiCl]{} FC(=O)-SX,$$

$X = N_3, \quad -N{=}S{=}O.$

Trifluoromethylthioazide obtained in a similar way is converted even at 20 °C into tetrakis(trifluoromethylthiazyl).[127]

$$CF_3SCl + (CH_3)_3SiN_3 \xrightarrow[-(CH_3)_3SiCl]{-50 \text{ to } -30\ ^\circ C} CF_3SN_3 \xrightarrow[-N_2]{20\ ^\circ C} (CF_3SN)_4\,.$$

Sulphodiimides silylated at nitrogen form crystalline 1,3,5-trithia-2,4-diazepines in high yield with 1,2-bis(chlorosulphenyl)-tetrafluoroethane.[128]

$$ClSCF_2CF_2SCl + \begin{array}{l}(CH_3)_3SiN \\ (CH_3)_3SiN\end{array}\!\!>S\!<\!\begin{array}{l}R\\R\end{array} \xrightarrow[-78 \text{ to } 20\ ^\circ C]{CH_2Cl_2} \begin{array}{l} CF_2-S-N \\ | \quad\quad \diagdown \\ CF_2-S-N \end{array}\!\!>S\!<\!\begin{array}{l}R\\R\end{array}$$

$R = CH_3, C_2H_5.$

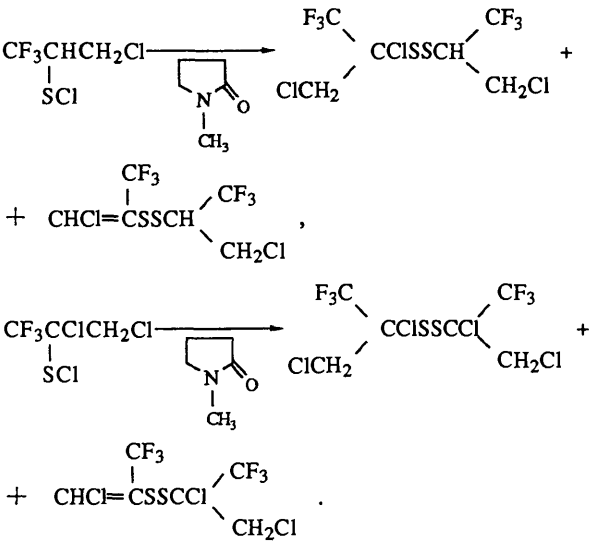
On the other hand hexamethyldisilazane is thiolated by CF_3SCl at the N–H bond. A second molecule of hexamethyldisilazane acts as HCl acceptor in this reaction.[28,51]

Tertiary amines convert PFASC into disulphides.[129] Disulphides are frequently byproducts in reactions where tertiary amines are used as HCl acceptors for this reason.

$$R_FSCl + R_3N \rightarrow R_FSSR_F + [R_3N \cdot Cl_2],$$

$R_F = CF_3, CF_2Cl, CFCl_2.$

2-Chloro-(1-trifluoromethyl)ethanesulphenyl chloride and 1,2-dichloro-(1-trifluoromethyl)ethanesulphenyl chloride are converted in *N*-methylpyrrolidone into the thiocarbonyl compound $CF_3C(S)CH_2Cl$ and the thiirene $CF_3-C=CH$ respectively, which give a mixture of unsymmetrical disulphides with the initial sulphenyl chlorides.[15]



Reactions with P-nucleophiles. The reaction of PFASC with P-nucleophiles has been widely studied in the search for new insecticides. The reaction of trialkyl and diaryl alkyl phosphites with trichloro-, chlorodifluoro-, and dichlorofluoro-, and trifluoromethanesulphenyl chlorides[130,133] occurs under milder conditions than for the unfluorinated alkanesulphenyl chlorides. The main reaction products are the corresponding trihalomethyl thiophosphates. In addition products of the 'anomalous' breakdown of the intermediate phosphorane, viz. trihalomethyl alkyl sulphides, were formed with some contamination by other compounds.

$$(RO)_3P + CCl_{3-n}F_nSCl \rightarrow (RO)_2P(O)SCCl_{3-n}F_n + CCl_{3-n}F_nSR +$$
$$+ (RO)_2P(O)Cl + RCl,$$

$n = 0$ to 3; R = Alk, Ar.

The trihalomethanesulphenyl chlorides react analogously with dialkyl or sodium dialkyl phosphites. Conditions have successfully been found[133] under which diisopropyl and di(trimethylsilyl) phosphites are converted quantitatively into the corresponding trihalomethyl thiophosphates.

$$CCl_{3-n}F_nSCl + (RO)_2P(O)H \rightarrow (RO)_2P(O)SCCl_{3-n}F_n,$$

$n = 1$ to 3; $R = iso\text{-}C_3H_7, (CH_3)_3Si$.

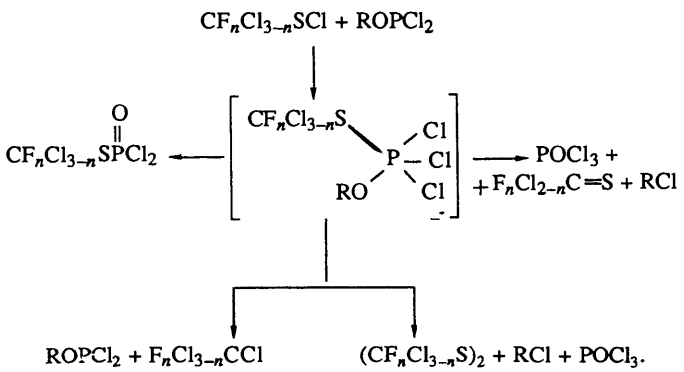
Sulphenyl chlorides with highly electrophilic perfluoroalkenyl groups react with trialkyl phosphites with the exclusive formation of perfluoroalkenyl alkyl sulphides.[19]

$$R_FSCl + P(OC_2H_5)_3 \xrightarrow{-78^\circ C} [(C_2H_5O)_3PCl]^+(SR_F)^- \longrightarrow R_FSC_2H_5,$$

$R_F = (CF_3)_2C{=}CF$,  .

The reaction of trihalomethanesulphenyl chlorides with alkyl dichlorophosphites at −30 to 20 °C leads to trihalomethylthio dichlorophosphates in about 50% yield.[134,135] In addition the products were contaminated by many byproducts the relative quantities of which depend appreciably on the number of fluorine atoms in the trihalomethyl group.



Mono-, di- and trithiophosphites with trihalomethyl groups are cleaved by trihalomethanesulphenyl chlorides to a mixture of symmetrical and unsymmetrical disulphides.[135]

$$(R_FS)_xPCl_{3-x} + R'_FSCl \longrightarrow R_FSSR_F + R_FSSR'_F + R'_FSSR'_F + PCl_3$$

$x = 1$ to 3; R_F, $R'_F = CF_nCl_{3-n}$, $n = 1$ to 3.

In contrast, methylthio dichlorophosphite behaves in these reactions as a CH acid.[13]

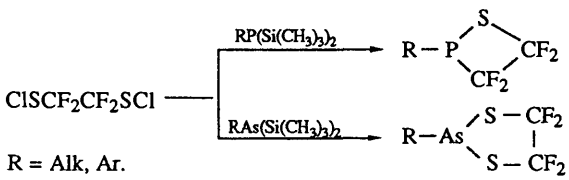
$$CF_3SCl + CH_3SPCl_2 \rightarrow CF_3SCH_2SPCl_2.$$
34%

The trihalomethanesulphenyl chlorides react with white phosphorus under mild conditions (−80 °C) forming mainly dialkyldithiochlorophosphites with contamination by other substances.[135]

$$R_FSCl + P_4 \rightarrow (R_FS)_xPCl_{3-x} + R_FSSR_F + F_mCl_{2-m}C{=}S,$$

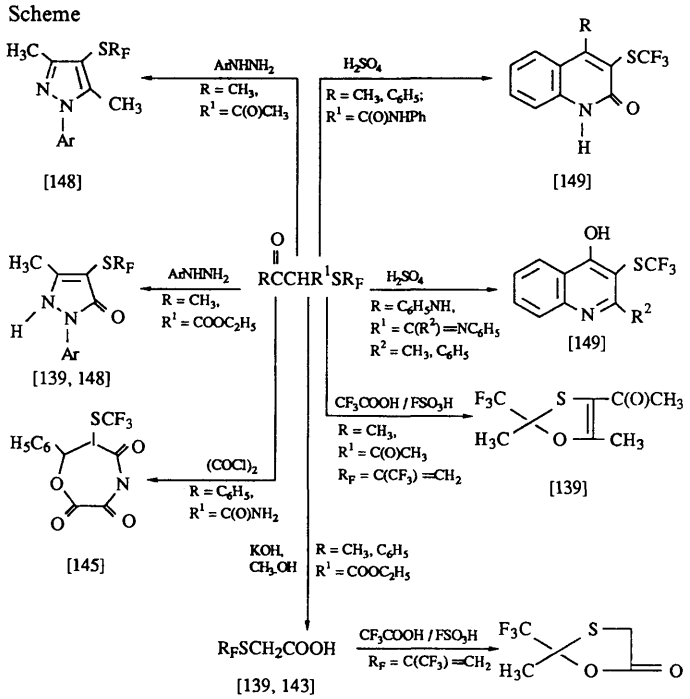
$R_F = CF_nCl_{3-n}$, $n = 1$ to 3, $x = 1$ to 3; $m = 1.2$.

The reaction of 1,2-bis(chlorosulphenyl)tetrafluoroethane with bis(trimethylsilyl) phosphonites and with bis(trimethylsilyl) arsenites leads to thiophosphetanes and dithiarsolanes respectively.[136]



Reactions with C-nucleophiles. Reactions of this type arouse increased interest from the point of view of synthesising numerous polyfluoroalkylthiolated biologically active substances and their precursors. PFASC display a more moderate activity than their unfluorinated analogues when reacting with various C-nucleophiles.

Scheme



Enolising carbonyl compounds, including aldehydes, ketones, α- and β-diketones and various β-ketocarboxylic acid derivatives, are *C*-polyfluoroalkylthiolated most readily and unequivocally in the majority of cases.[16,26,137,147] Actual examples of reactions of this type are given in Table 3. Carbonyl compounds modified by PFASC are widely involved in syntheses of biologically active compounds (see Scheme) and include pyrazoles and pyrazolones,[139,148] oxazepines,[145] quinolinones[149] and 1,3-oxathioles.[139] These are used in the synthesis of cephalosporin antibiotics, polyfluoroalkylthiocarboxylic acids[139,143,150] and 1,3-oxathiolanones.[139]

Only products of monosubstitution are formed in the majority of reactions of PFASC with carbonyl compounds,[143,147] however the formation of products of bispolyfluoroalkylthiolation was recorded in the case of acetone and benzoylacetamide.[137,139,145]

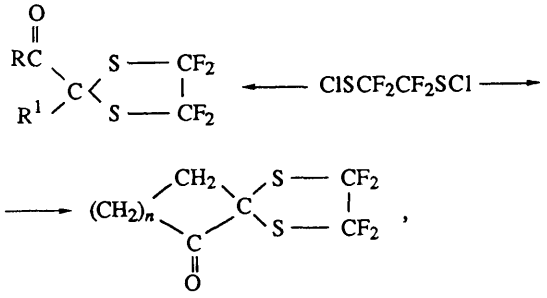
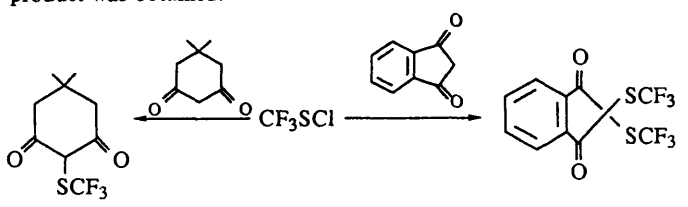
CF_3	H	(R–C=N–CH_2–)$_2$ R = CH_3, C_6H_5	CH_3, C_6H_5	[146]

1,2-Bis(chlorosulphenyl)tetrafluoroethane forms only heterocyclic disubstitution products with acyclic and cyclic carbonyl compounds.[142,151]

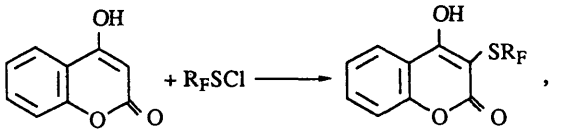


R = CH_3, $(CH_3)_3C$; R^1 = H, $C(O)CH_3$; n = 1. 2.

Monosubstitution products of 1,3-cyclohexadiones are formed with CF_3SCl even with an excess of sulphenyl chloride but in the analogous reaction with indane-1,3-dione only the disubstituted product was obtained.[147]

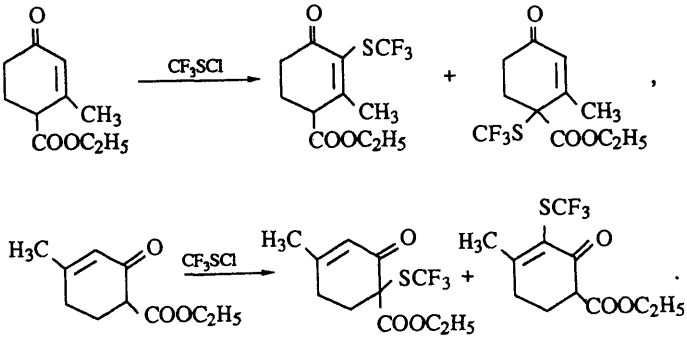


The effect of the PFASC structure on the conditions for thiolating carbonyl compounds has not yet been studied. Only in the example of 4-hydroxycoumarin was it established that the formation of 3-polyfluoroalkylthiolated derivatives was hampered by an increase in the electron-accepting properties of the polyfluoroalkyl group.[52]

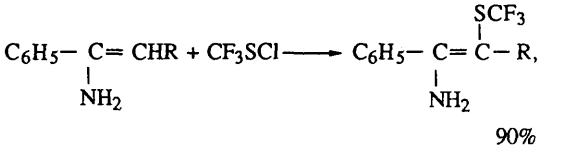


R_F = $ClCH_2-CH(CF_3)$, CCl_2FCF_2, $CH_3OOC-C(CF_3)_2$.

The polyfluoroalkylation reaction is usually effected regiospecifically at the α position to the C=O group. Moreover cyclohexenenonecarboxylic acids, having two CH-acid centres, give a mixture of two products with a predominance of the thiolation product at the more reactive centre.[144]

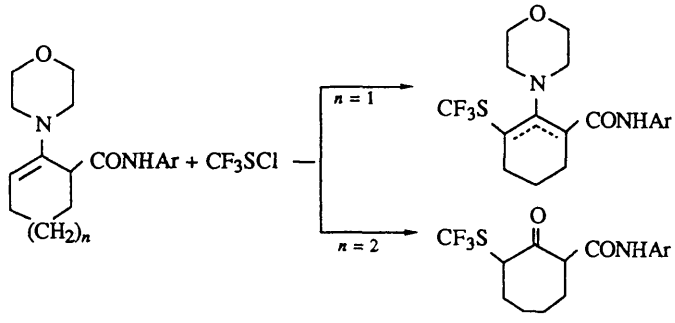


Enamines react with PFASC like the enolised ketones giving monosubstitution products.[145]



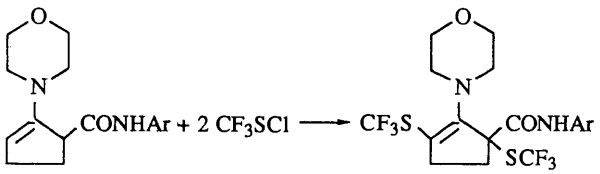
R = $C(O)NH_2$, CN.

Enamines based on derivatives of cyclohexanone- and cycloheptanone-2-carboxylic acids are thiolated in the presence of pyridine only at the unsubstituted 2 position of the ring.[153]



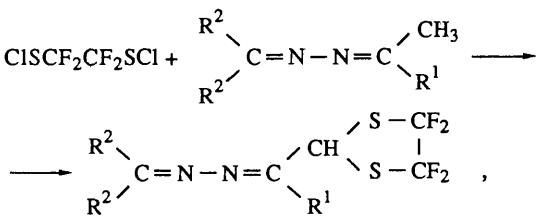
Ar = C_6H_5, 4-ClC_6H_4.

In contrast, the more strained derivatives of cyclopentanone-2-carboxylic acid are converted by an excess of CF_3SCl into 2,5-dithiolation products.[153]

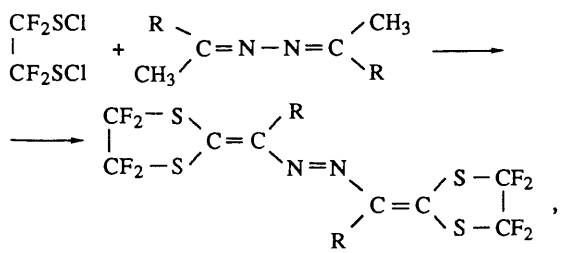


$Ar = C_6H_5$, 4-ClC_6H_4.

1,2-Bis(chlorosulphenyl)tetrafluoroethane readily thiolates azines containing methyl groups. The reaction is accompanied by the evolution of HCl and leads either to dithiolanylazines or to a *trans*-diazene.[154]

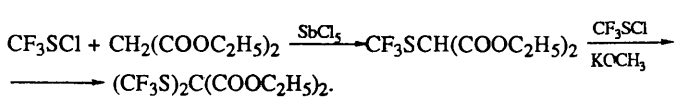


$R^1 = CH_3$, C_6H_5; $R^2 = CF_3$, C_6H_5;

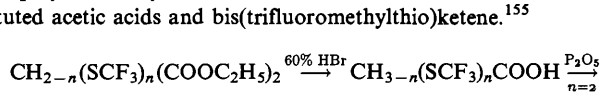


$R = CH_3$, C_2H_5, C_6H_5.

In contrast to ketones, malonic ester reacts with trifluoro- and chlorodifluoromethanesulphenyl chlorides only on heating above 100 °C giving mono- and disubstituted products.[148] Mild trifluoromethylthiolation of malonic ester occurs only on electrophilic catalysis. The monothiolation product reacts further with CF_3SCl in the presence of base.[155]

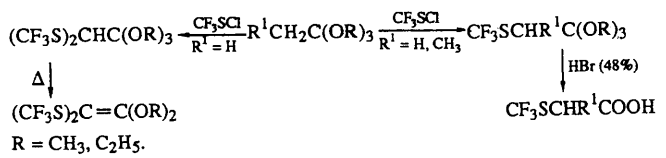


The polyfluoroalkylthiomalonates obtained are converted into substituted acetic acids and bis(trifluoromethylthio)ketene.[155]



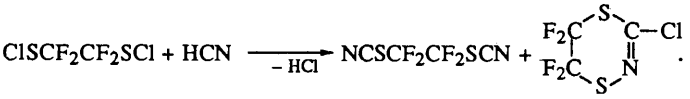
n = 1, 2.

Under mild conditions (−5 °C) orthoesters of carboxylic acids form products of mono- and in certain cases ditrifluoromethylthiolation which proved to be good precursors for a series of valuable products.[156]

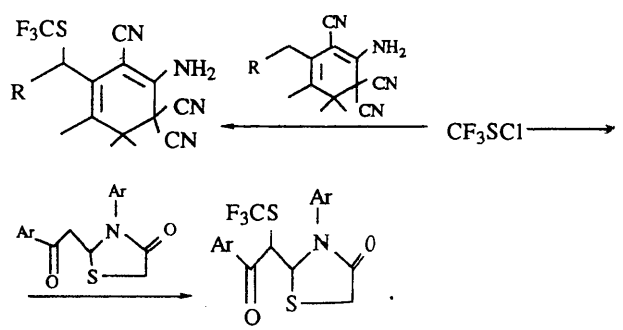


$R = CH_3$, C_2H_5.

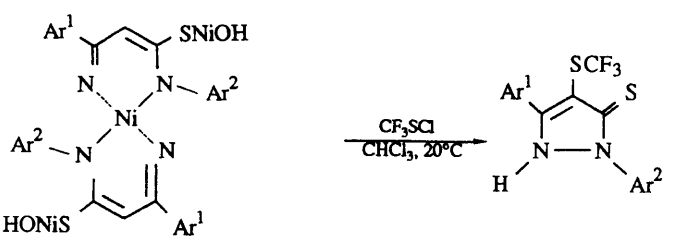
1,2-Dithiocyanotetrafluoroethane, with a 1,4,2-dithiazene as contaminant (4%), is readily formed in the reaction of 1,2-bis-(chlorosulphenyl)tetrafluoroethane with HCN.[157]



Trifluoromethylthiolation occurs fairly readily at the CH-acid centre activated by the cyclohexadiene[158] or thiazolidine[159] rings.



In some cases the trifluoromethylthiolation of compounds is accompanied by heterocyclisation. For example the nickel complex of β-aminothiocinnamic acid anilide is converted into a substituted 3-pyrazoline-5-thione.[160]



Ar^1, $Ar^2 = C_6H_5$, ClC_6H_4, $CH_3C_6H_4$.

The anilines of the *N*-benzoylamide of benzoylthioacetic acid are converted on trifluoromethylthiolation into 1,3-oxazoline-4-thione and the CF_3S group is lost on heterocyclisation.[145]

Organometallic compounds react readily with PFASC. This enables sulphenylation of lithium alkyl compounds to be carried out with fluorocarbonylsulphenyl chloride,[59] and of various lithium-acetylenes with 1,2-bis(chlorosulphenyl)tetrafluoroethane.[161] The

reaction of perfluoroalkenesulphenyl chlorides with KCN is effected unambiguously under mild conditions.[162] Stable alkenyl thiocyanates are formed by this which indicates the stabilising effects of the *pd* interactions in the F–C–S triad and in the F–C–C–S four-centre systems.

$$R_FSCl + KCN \longrightarrow R_FSCN,$$

$R_F = (CF_3)_2C{=}CF,\ (CF_3)_2C{=}C{-}C_2F_5,$ 
The trifluoromethylthiolation of sodium derivatives of nitromalonic ester is effected less unequivocally,[163] and also the reaction of trihalomethylsulphenyl chlorides with salts of such strong CH-acids as a tetraalkyl methylenediphosphonate.[164]

2. Reactions with aromatic and heteroaromatic compounds

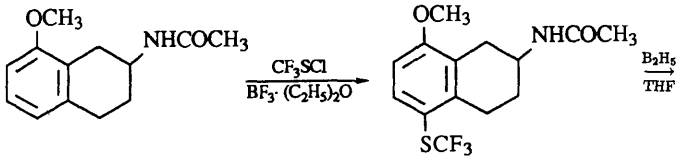
In the last decade interest in polyfluoroalkylthiolated aromatic and heteroaromatic compounds has grown in connection with the prospect of biologically active compounds with valuable properties. The number of studies on the direct thiolation of various types of aromatic and heteroaromatic compounds with PFASC has increased for this reason. Presently this method competes in many cases with the previously widely studied indirect routes of forming polyfluoroalkylthio groups in an aromatic matrix.[6]

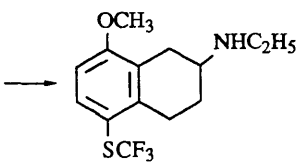
Benzene is thiolated by CF_3SCl on heating (100 °C) in the presence of BF_3 or at 20 °C in the presence of catalytic quantities of CF_3SO_3H.[165]

$$C_6H_6 + CF_3SCl \xrightarrow[[CF_3SO_3H]]{20\ ^\circ C,\ 5\ h} C_6H_5SCF_3 + HCl.$$

Toluene reacts similarly giving a mixture of *ortho* and *para* substitution products but chloro- and bromobenzene in the presence of HF form mixtures of all the possible isomers only at 200 °C.

Trifluoromethanesulphenyl chloride reacts mainly as a chlorinating agent with trifluoromethyl phenyl sulphide in the presence of CF_3SO_3H.[165] A methoxy group in the ring facilitates thiolation and was used in the synthesis of trifluoromethylthiolated compounds with antidepressant activity.[166]



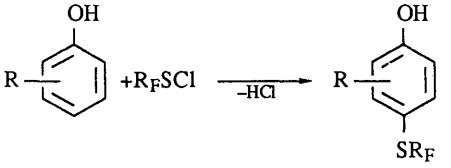


Di- and trimethoxybenzenes are distinguished by an increased ability to polyfluoroalkylthiolate. Both 1,3-di- and 1,3,5-trimethoxybenzenes react without a catalyst.[167,168] It is convenient to use magnesium and mercury derivatives for the thiolation of aromatic compounds with electron-accepting groups, PFASC do not display a marked chlorinating action with these compounds.[168]

$$4\text{-}XC_6H_4HgCl + CF_3SCl \rightarrow 4\text{-}XC_6H_4SCF_3 + 4\text{-}XC_6H_4Cl + C_6H_5X,$$

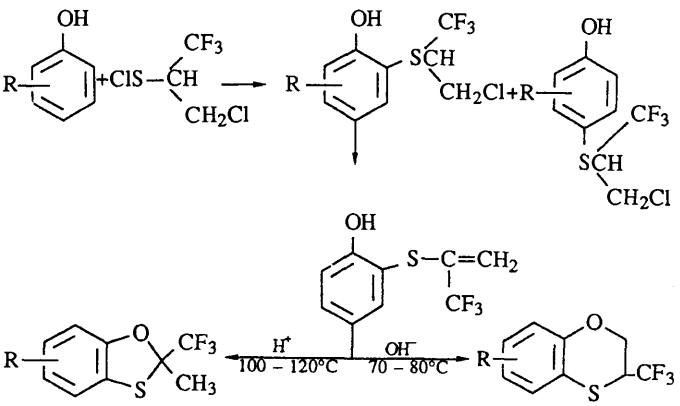
$X = CH_3O,\ CH_3,\ H,\ Cl,\ NO_2.$

Phenol and its derivatives containing electron-donating substituents in the aromatic ring react with PFASC in the absence of catalyst. Reactions are carried out in the presence of pyridine to bind the evolved HCl in the case of the volatile CF_3SCl. Otherwise Lewis acids are used as catalysts to increase the thiolation rate.[3,41,72,167,168,170] Under these conditions *ortho* and *meta* substituted phenols are usually thiolated at the *para* position.



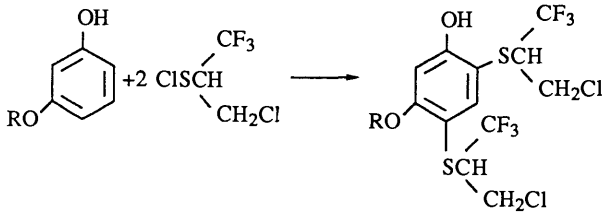
R = H, Alk, Cl, F, OH, OCH_3; $R_F = CF_3,\ C_7F_{15},\ ClCF_2CF_2,$
$Cl_2CFCF_2,\ CH_3OOC{-}C(CF_3)_2,\ AllOOC{-}C(CF_3)_2$

Only particularly reactive PFASC such as $ClCH_2{-}CH(CF_3)SCl$ form *ortho* and *para* substitution products with phenols. The selectivity of the reaction increases in the presence of solvent, the nature of which determines the direction of thiolation to a significant degree.[167] To separate the *ortho*-thiolated phenols it is possible to use their tendency to cyclise.



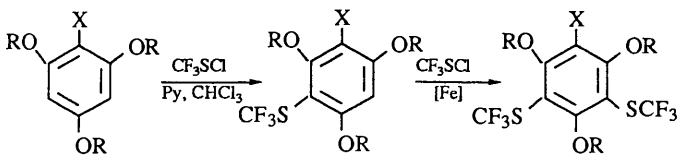
In the absence of a catalyst *para* substituted phenols usually form *ortho* substitution products on heating.[41] Monosubstituted phenols in general are characterised by a marked reduction in the ability to be thiolated by PFASC in the series *meta* > *ortho* ≫ *para* and electron-donating substituents are arranged in the usual series CH_3O > CH_3 > F ≫ Cl in inactivating ability. *m*-Methoxyphenol proved to be the most reactive of the studied phenols of this series and gave a mixture of *ortho* and *para* substitution products. Even disubstitution products are formed with an excess of sulphenyl chloride.[167] Dihydroxybenzenes are arranged in the same series as monosubstituted phenols in their reactivity towards PFASC.

Resorcinol is the most reactive and also forms a dithiolation product at 20 °C.



R = H, CH_3 .

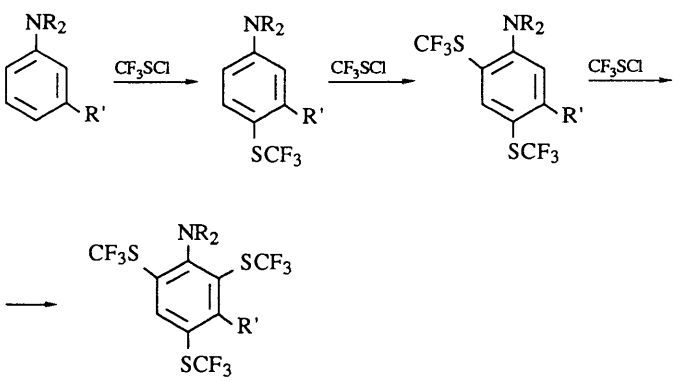
Phenols with electron-withdrawing substituents do not react with PFASC. The only exceptions are derivatives of resorcinol and phloroglucinol which, depending on the conditions, form substitution products with one or two molecules of CF_3SCl.[168]



R = H, CH_3; X = $CH_3(O)C$, CH_3OOC, C(O)H.

The conditions of the reactions under consideration are also determined in many cases by the nature of the PFASC. The polyfluoroalkylthiolation of phenols is appreciably suppressed by an increase in the electron-accepting properties of the polyfluoroalkyl group and the steric effects at the S—Cl group.[41,167]

The *N,N*-dialkylanilines are appreciably more reactive towards CF_3SCl and form *para* substitution products and 2,4-di- and 2,4,6-trisubstitution products when activating OH and CH_3O groups are present.[72]

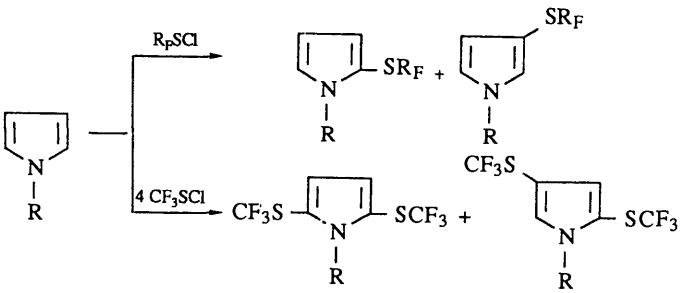


R = CH_3, C_2H_5; R' = H, OH, OCH_2CF_3.

Only *meta*-hydroxy and *meta*-alkoxy derivatives of primary and secondary arylamines give *C*-trifluoromethylthiolation products.[72]

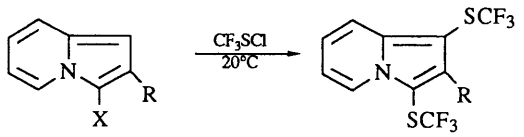
Of the heteroaromatic compounds only compounds with high π-donor properties react with PFASC in the absence of a catalyst.

Pyrrole and *N*-methylpyrrole readily form 2- and 2,5-substitution products in the presence of HCl acceptors. Contamination of 3(4)-substitution compounds as side products has been recorded.[171,172]



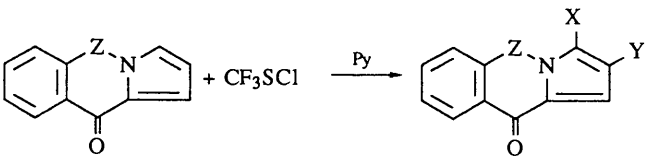
R = H, CH_3; R_F = CF_3, CF_2Cl, $CFCl_2$, CF_3SCFCl, F(O)C, C_7F_{15}.

Indole gives a C(3) thiolation product with CF_3SCl under these conditions.[172] Donating substituents in the pyrrole ring facilitate and accepting substituents hinder thiolation directing it to the 3(4) position.[172] Indolizines react particularly readily with CF_3SCl forming 1,3-disubstituted derivatives even in the case of indolizines acetylated at the 1 position.[173]



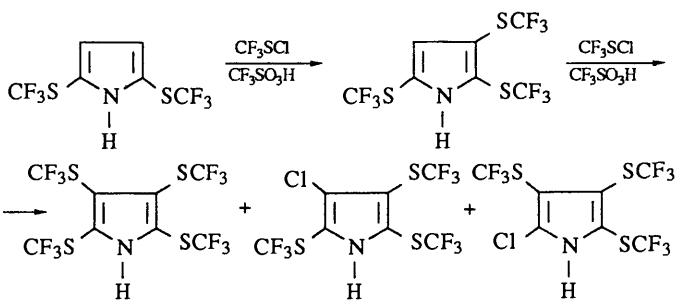
X = H, $C(O)CH_3$; R = H, CH_3, C_6H_5.

The polyfluoroalkylthiolated derivatives of pyrroles possess high biological activity.[174,175] The pyrrolo[2,1-*b*][3]benzazepines with CF_3S substituents in the pyrrole ring are of particular interest, possessing myorelaxant and tranquilising action.[176,177]

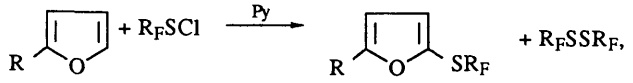


Z = —CH=CH—, X = SCF_3, Y = H; Z = $—CH_2—CH_2$;
X = SCF_3, Y = H; X = H, Y = SCF_3.

The exhaustive trifluoromethylthiolation of the pyrrole ring is of theoretical interest. In the presence of CF_3SO_3H this is accompanied by chlorinating effects of CF_3SCl and 1,2-migration of a trifluoromethylthio group.[178]

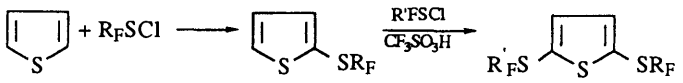


Furan and sylvane (α-methylfuran) react with significantly more difficulty with trihalomethanesulphenyl chlorides in the presence of pyridine. The products are 2- and 5-trihalomethylthio derivatives of furan (sylvane) together with disulphides and polymeric compounds.[171,179] The use of Lewis acids as catalysts or $(C_2H_5)_3N$ as an HCl acceptor proved to be ineffective.



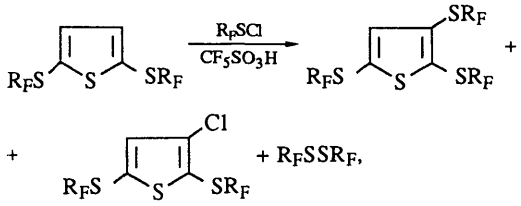
R = H, CH_3; R_F = CF_3, CF_2Cl, $CFCl_2$.

Thiophene reacts with even more difficulty. Monothiolation occurs only on catalysis by $SnCl_4$,[180] in the presence of pyridine under pressure[171] or in CF_3COOH.[181] Disubstitution products were successfully obtained on catalysis by perfluoroalkanesulphonic acids.[180,182]



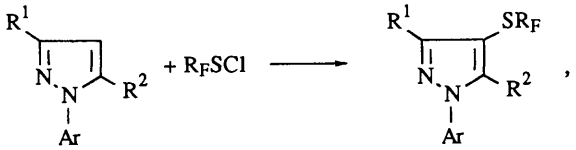
R_F, R_F = CF_3, CF_2Cl, $CFCl_2$.

On further thiolation of thiophene the chlorinating action of R_FSCl is shown.[165]



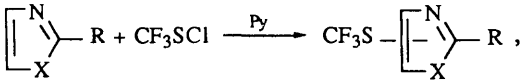
R_F = CF_3, CF_2Cl.

Selophene reacts with CF_3SCl like thiophene.[179] Five-membered heteroaromatic compounds with two heteroatoms react with PFASC only in the presence of electron-supplying substituents. Thus *N*-arylpyrazoles with an OH or NH_2 group in the 5 position are thiolated by trihalomethanesulphenyl chlorides at the C(4) atom. The compounds obtained and also their sulphoxides and sulphones display high insecticidal, acaricidal and nematocidal activity.[183–189]



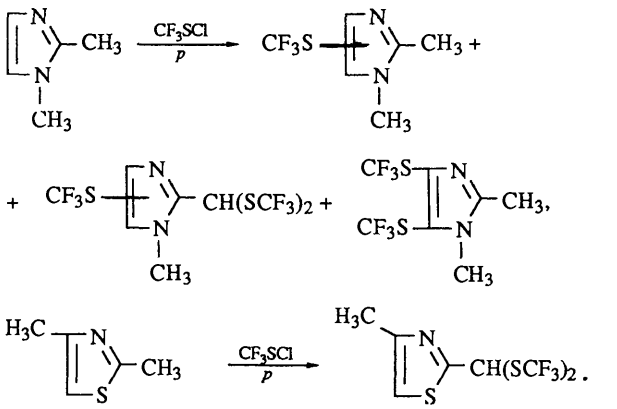
R_F = CF_3, CF_2Cl, $CFCl_2$; R^1 = H, Alk; R^2 = OH, NH_2.

Imidazoles and thiazoles activated by substituents display similar properties. The course of thiolation in this case has not been established precisely.[171,190]

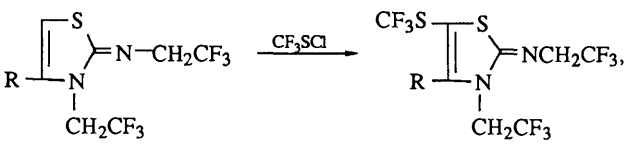


X = S, R = $NHSO_2CH_3$, $NHSO_2CF_3$, $NHCOCH_3$,
X = NCH_3, R = SCH_3, SCH_2CF_3.

The trifluoromethylthiolation of the 1,2-dimethylimidazole ring under pressure is accompanied by the side thiolation of the CH_3 group in the 2 position but in the analogous reaction of 2,4-dimethylimidazole the thiolation of the 2-CH_3 group is the sole course of the reaction.

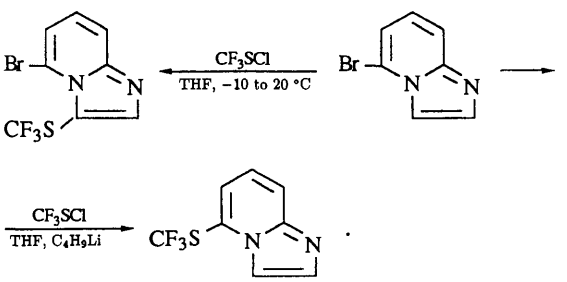


On the other hand derivatives of 2-aminothiazole are readily trifluoromethylthiolated at the C(5) atom.[171]



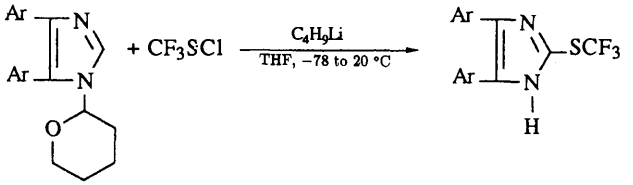
R = H, CH_3.

The reaction of CF_3SCl with 5-bromoimidazo[1,2-a]pyridine under mild conditions is effected in the imidazole ring after generation of a carbanionic centre with butyllithium in the pyridine ring.[191,192]

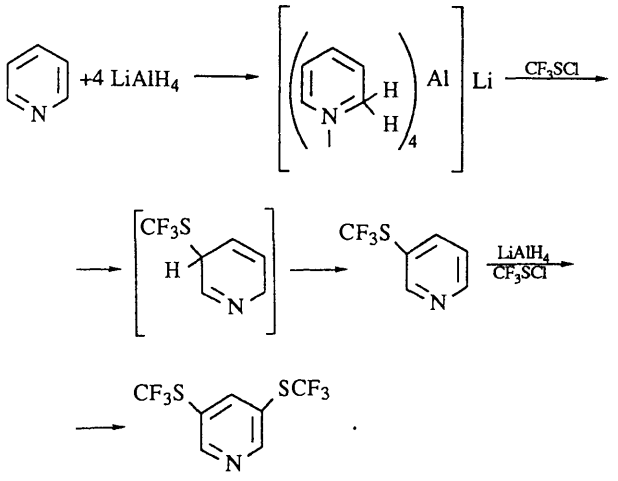


The compounds obtained possess a hypotensive action.

Butyllithium is widely used to generate anions of aromatic[193] and heterocyclic[186,194] compounds which are reactive towards PFASC. A series of active blood pressure regulators was obtained by this route among the 2-trifluoromethylthio-4,5-diarylimidazoles.[194]

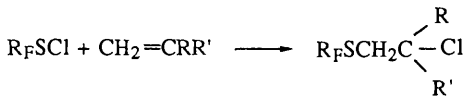


The trifluoromethylthiolation of pyridine was successfully effected only after reducing it to a dihydropyridine derivative.[179,195] The main reaction product is that of 3 substitution together with contamination by the 3,5-bisthiolated compound.



3. Reactions with unsaturated compounds

Features of the electrophilic properties of PFASC are most clearly displayed in their reactions with alkenes.[10,13,36,39,142,196–203] Only 2-chloro-1-trifluoromethylethanesulphenyl chloride reacts with ethylene and its homologues at 20 °C. With the appearance of fluorine atoms or CF_3 and other electron-withdrawing groups in the α position to the S–Cl bond the reaction temperature is abruptly increased (to 100–150 °C). Under relatively mild conditions such compounds add to ethylene only in polar solvents such as CH_3CN. Sterically hindered PFASC generally do not react in the absence of CH_3CN.[10,13,196,198] The addition of PFASC to a terminal ethylene occurs exclusively according to the Markownikov rule with the formation of products under thermodynamic reaction control.



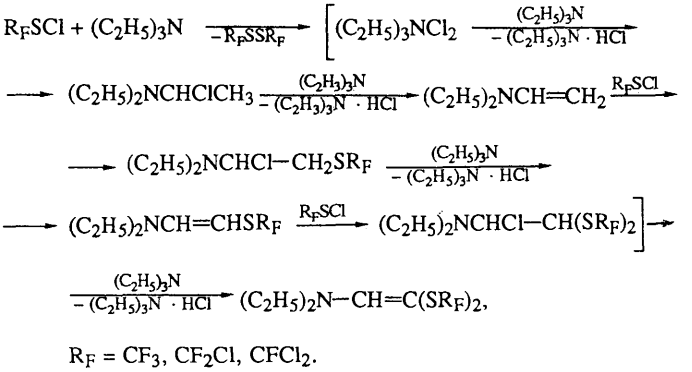
R, R' = H, Alk, Cl, OC_4H_9, $OC(O)CH_3$; R_F = $ClCH_2CH(CF_3)$, $ClCF_2CF_2$, Cl_2CFCF_2, $CH_3OOC-C(CF_3)_2$.

The formation of both regioisomers was observed only on carrying out the reaction in the presence of CF_3COOH which increases the reaction rate markedly.[197]

R = C_4H_9, $BrCH_2$, Br; R_F = CF_3, CF_2Cl, $CFCl_2$.

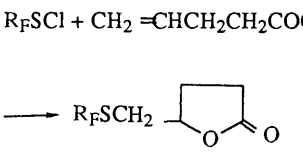
An important feature of the products formed under kinetic control is their stability on storage and fractionation which indicates the significant difficulties in this case of forming an episulphonium ion.

Of the functionally substituted ethylenes only vinyl alkyl ethers and vinyl acetate react readily with PFASC.[198] Seemingly enamines react even more readily as is indicated by the results of the mild reaction or perhalomethanesulphenyl chlorides with triethylamine.[129]



R_F = CF_3, CF_2Cl, $CFCl_2$.

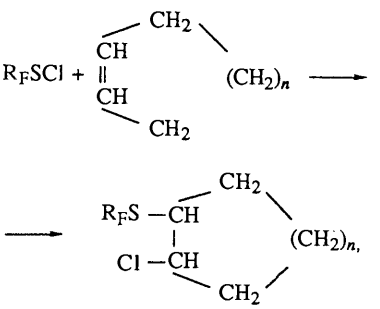
γ,δ-Unsaturated acids and their esters react under unusually mild conditions (−30 to 0 °C) with PFASC forming lactones.[200]



R_F = $ClCH_2-CH(CF_3)$, $ClCF_2CF_2$.

On the other hand β,γ-unsaturated acids and their esters react with PFASC as with other ethylenic compounds giving a mixture of regioisomers.[200] Evidently nucleophilic cooperation in the transition state by the carboxyl or carbalkoxyl groups favours a mild reaction of these compounds with the β,γ-unsaturated acids and their esters.

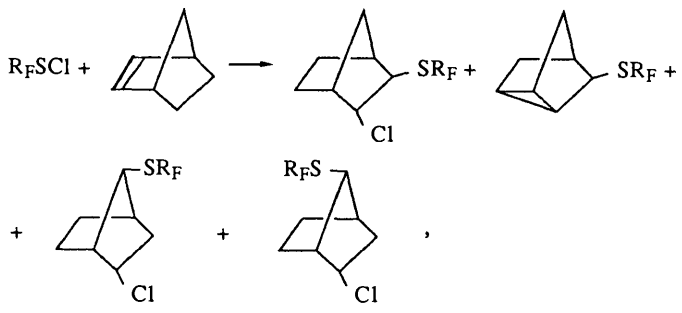
The PFASC, like their unhalogenated analogues, react more readily with strained cycloalkenes than with ethylene homologues. Thus cyclopentene and cycloheptene, differing in the higher strain and lower steric hindrance at the multiple bond, are more reactive in these reactions.[10,13,36,39,196,197]



R_F = CF_3, CF_2Cl, $CFCl_2$, Cl_2CFCF_2, $CF_3OCFClCF_2$, $ClSCF_2CF_2$, $CF_2ClCFCl$, $(CF_3)_3C$, $CH_3OOC-C(CF_3)_2$, $Cl(O)C-C(CF_3)_2$; n = 1, 2, 3.

The addition is effected *trans*-stereospecifically, including when CF_3COOH is present.[197]

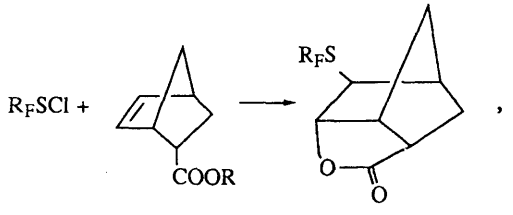
The more strained norbornene molecule reacts vigorously with chlorofluoro-containing methanesulphenyl chlorides in the absence of solvent giving products of *trans*-addition and Wagner–Meerwein rearrangement.[201]



$R_F = CF_3$, CF_2Cl, $CFCl_2$.

Trifluoromethanesulphenyl chloride is particularly reactive in this reaction and forms all four products even at −40 °C. This indicates an episulphonium mechanism for the reaction. The CF_3 group is capable of transforming the primary episulphonium ion into a norbornyl carbonium ion to a greater extent than a $ClCF_2$ or a Cl_2CF group.

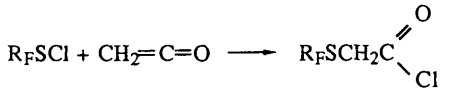
In contrast to norbornene, norbornene-5-carboxylic acid and its esters are lactonised unequivocally like acyclic γ,δ-unsaturated acids.[199]



R = H, CH_3; $R_F = ClCH_2-CH(CF_3)$, $ClCF_2CF_2$, Cl_2CFCF_2, $ClCH_2CCl(CF_3)$, $CH_3OOC-C(CF_3)_2$.

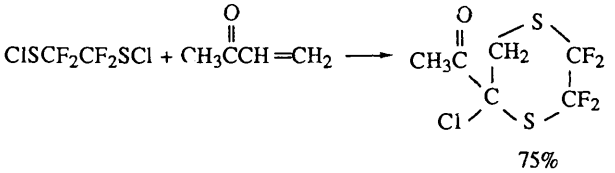
Under more forcing conditions the regioisomeric *trans*-addition products are formed in addition to the lactones. The acid chloride and nitrile of this acid react under more forcing conditions and give only a mixture of the products of *endo* and *exo* addition.

Under mild conditions at −20 to 20 °C PFASC add to ketene giving acid chloride of *S*-polyfluoralkylthioglycolic acid although this is more difficult than with the unfluorinated sulphenyl chlorides.[202,203]



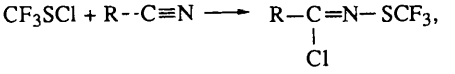
$R_F = CF_3$, $ClCH_2-CH(CF_3)$, $ClCF_2CF_2$, Cl_2CFCF_2.

1,2-Bis(chlorosulphenyl)tetrafluoroethane reacts with methyl vinyl ketone at 20 °C.[142] The primary addition product cyclises into a 1,4-dithiane with elimination of HCl.



75%

Highly electrophilic unsaturated compounds usually do not react with PFASC. However hexafluorodimethylketene forms an adduct with the highly reactive 2-chloro-1-trifluoromethylethanesulphenyl chloride in acetonitrile.[39] Under forcing conditions (150 °C) fluoro-olefins are predominantly chlorinated by PFASC. Addition products are also isolated in 20% yield.[39,196] On heating, in the presence of catalysts or on UV irradiation trifluoromethanesulphenyl chloride adds at the C≡N bond activated by electron-withdrawing substituents.[204–206]



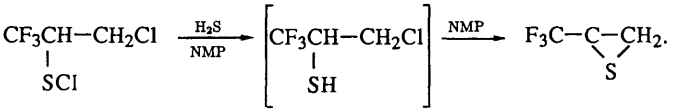
R = CF_3, Cl, $F_2S{=}N$, $F_2S(O){=}N$.

Products of combined trifluoromethylthiolation and fluorination of the C≡N bond were obtained on carrying out this reaction with ClCN, CF_3CN and CCl_3CN in the presence of HgF_2, i.e. $CF_3N(SCF_3)_2$, $CF_3CF{=}NSCF_3$ and $CCl_3CF{=}NSCF_3$ respectively.[207]

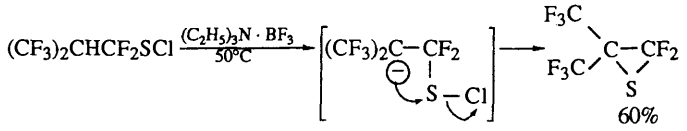
The above information enables it to be assumed that PFASC, like their unfluorinated analogues, react with unsaturated compounds by an Ad_E2 mechanism through an episulphonium transition state. The features of these reactions are determined by the reduction in the energy of formation and stability of the transition states connected with the efficient intramolecular $2p3d$-interactions of the F and S atoms, particularly in the F–C–S triad, and also the high electron-withdrawing ability of the polyfluoroalkyl groups.

4. Cyclisation reactions

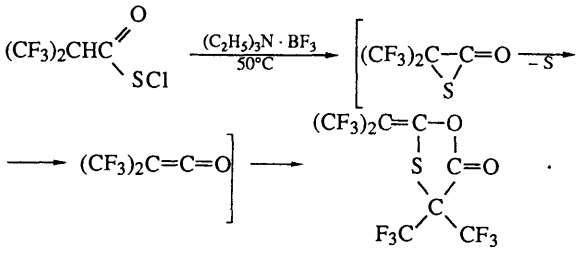
The ability of PFASC to form rings is linked primarily with anionotropic conversions in three-centre C–C–S systems. Thus 2-chloro-1-trifluoromethylethanesulphenyl chloride reacts with H_2S in *N*-methylpyrrolidone (NMP) with the formation of trifluoromethylthiirane. 2-Chloro-1-trifluoromethylethanethiol is an intermediate reaction products.[24]



2-Hydrooctafluoroisobutanesulphenyl chloride is smoothly dehydrochlorinated on heating with the $(C_2H_5)_3N.BF_3$ complex with the formation of perfluoroisobutene episulphide.[26]

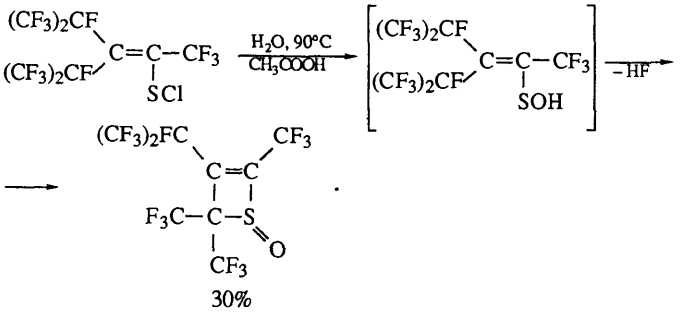


2-Hydrohexafluoroisobutyrylsulphenyl chloride also reacts in this way. However the intermediate thiiranone is desulphurised under the reaction conditions and the resulting bis(trifluoromethyl)ketene undergoes a (3 + 2) cycloaddition with the thiiranone.[26]



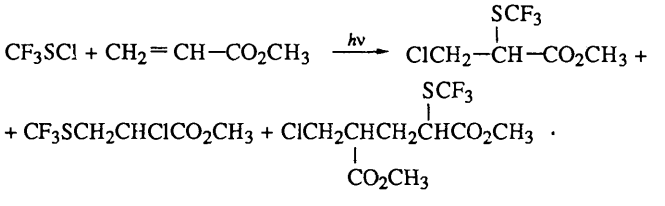
This reaction scheme was confirmed by the positive effect of bis(trifluoromethyl)ketene on the yield of final product.

Mild formation of a thietene ring, which is unusual for sulphur compounds, was observed on acid hydrolysis of the α,β-unsaturated sulphenyl chloride perfluoro-3-isopropyl-4-methyl-2-pentene-2-sulphenyl chloride. In the authors' opinion[137] an unstable sulphenic acid is the intermediate product.



5. Free radical reactions

PFASC undergo free radical conversions on UV or X irradiation and on catalysis by azo compounds. The addition of PFASC to olefins, including fluorine-containing olefins, initiated by UV light leads to both possible isomers and several byproducts.[3] For example CF_3SCl adds to methyl acrylate with the formation of a mixture of three main products,[203] from which CF_3S-containing acrylates are obtained by dehydrochlorination.



Irradiation with UV light initiates a reaction between PFASC and hydrocarbons. Depending on the structure of the sulphenyl chloride and the hydrocarbon the reaction leads to the predominant formation of four types of organic compound.[11,208–210]

$$R_FSCl + RH \rightarrow R_FSH + R_FSR + R_FSSR_F + RCl + HCl.$$

The mechanism of their formation is as follows:

$$R_FSCl \longrightarrow R_FS^{\cdot} + Cl^{\cdot}, \quad (1)$$

$$Cl^{\cdot} + RH \longrightarrow R^{\cdot} + HCl, \quad (2)$$

$$R_FS^{\cdot} + RH \longrightarrow R^{\cdot} + R_FSH, \quad (3)$$

$$R_FSCl + R_FSH \longrightarrow R_FSSR_F + HCl, \quad (4)$$

$$R^{\cdot} + R_FSCl \longrightarrow RCl + R_FS^{\cdot}, \quad (5)$$

$$R^{\cdot} + R_FSCl \longrightarrow R_FSR + Cl^{\cdot}, \quad (6)$$

$$R^{\cdot} + R_FSSR_F \longrightarrow R_FSR + R_FS^{\cdot}. \quad (7)$$

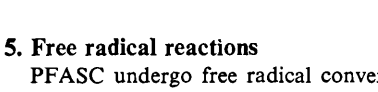
The chief factors determining the composition of the product mixture in these reactions are steric effects at the reaction centres of the sulphenyl chloride and the hydrocarbon. In a series of R_FSCl where R_F was $CF_3 < HCF_2CF_2 < n\text{-}C_3H_7 < (CF_3)_2CF < (CF_3)_3C$ and also in the series $CF_3 < ClCF_2 < Cl_2CF$ the yield of sulphide is significantly reduced. Sulphide was not detected in the reaction mixture in the case of perfluoro-t-butanesulphenyl chloride and stage (4) of the process did not occur for steric reasons. Consequently perfluoro-t-butanethiol and a chlorohydrocarbon are formed exclusively in the free radical reaction of $(CF_3)_3CSCl$ with hydrocarbons. Similarly the ratio of sulphide to chlorohydrocarbon is reduced in the series benzyl < butyl < sec-butyl < cyclohexyl with increasing bulk of the alkyl groups.

6. Oxidation reactions

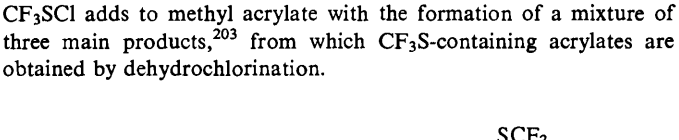
The possibility of obtaining polyfluoroalkanesulphonyl chlorides by the oxidation of PFASC with chlorine in water or hydrochloric acid has been shown in several cases.[12,14,25,196]

$$R_FSCl \xrightarrow[H_2O]{Cl_2} R_FSO_2Cl,$$

$R_F = (CF_3)_2CFOCF_2CF_2$, $CH_3OOCCF_2CF_2$,



Perfluoroalkyl hypochlorites react with CF_3SCl giving either sulphuranes of S(IV) fluorides.[211]



The PFASC are oxidised by peracids under controlled conditions to polyfluoroalkanesulphinyl chlorides.[23,30,46]

$R_F = CF_3CCl_2$, $CF_3{-}C(C_6H_5)_2$, $(CF_3)_2CCl$.

On oxidising $ClSCF_2CF_2SCl$ with 30% hydrogen peroxide di-(2-chlorosulphonyltetrafluoroethyl) disulphide is formed in addition to oxidation to the sulphonyl chloride.[212]

Various fluorinating agents (ClF_3, AgF_2, BrF_3/HgF_2) convert PFASC to a mixture of different products including organic fluorides of tetra- and hexavalent sulphur,[213,214] such as

$$ClCF_2SCl \xrightarrow[60-70°C]{AgF_2} ClCF_2SF_3 + CF_3SF_3 + CF_3SF_5.$$

The information discussed above show that the chemistry of PFASC and of their unfluorinated analogues are mainly similar. In addition, important features of the fluorine-containing sulphenyl chlorides may also be noted. They are more difficult to form, they possess higher stability and markedly less reactivity and their reactions usually occur by thermodynamically controlled routes. The R_FS group of perfluoroalkanesulphenyl chlorides has a clearly expressed 'pseudo-halogen' character as the PFASC display chlorinating properties and the perfluoroalkanethiol group frequently acts as a leaving group in rearrangements and heterocyclisations.

All these features are undoubtedly linked with the effective intramolecular $2p3d$-interactions of the F and S atoms which leave an imprint on the properties of the products of the numerous conversions of PFASC. The stabilising effects of these interactions determine the unusually high static and kinetic stability of the new type of compound, viz. the α-polyfluoroalkenesulphenyl chlorides.

From a practical point of view the PFASC are more convenient reagents for organic synthesis than the functionally unsubstituted alkanesulphenyl chlorides. They store well and are not afraid of moisture. Their reactions are sensitive to solvent effects which enables processes to be controlled reliably. In spite of the somewhat reduced reactivity the PFASC possess a wide spectrum of properties and are efficient precursors of fluorine-containing compounds of numerous types.

Up to the present completely halogenated fluorine-containing methane- and ethanesulphenyl chlorides have been predominantly studied to obtain fluorine-containing analogues of first and second generation pesticides in the synthesis of biologically active compounds for agriculture. The corresponding derivatives of hormonal preparations are practically uninvestigated. In medicine only trifluoromethylthiolated derivatives of neuroregulators of hormone metabolism have been investigated. However the result of even these few investigations indicate that the time has now arrived for an intensive development of the chemistry of PFASC as potential precursors of biologically active compounds for various purposes.

Organic derivatives of manganese(II) in organic synthesis

A N Kasatkin, O Yu Tsypyshev, T Yu Romanova, G A Tolstikov
Institute of Organic Chemistry, Urals Division, Russian Academy of Sciences, Ufa

ABSTRACT. Literature data on the use of organic compounds of Mn(II) as reagents for organic synthesis have been correlated. Methods of obtaining and using them in acyl-, alkenyl- and allyldemetallation reactions and in 1,2- and 1,4-additions to carbonyl substrates are considered. The reactions of manganese derivatives containing Mn–Si and Mn–Sn bonds are discussed.

The bibliography contains 99 references.

I Introduction

The synthesis of organic derivatives of Mn(II) with a metal–carbon bond was achieved for the first time in 1937 by Gilman and collaborators.[1] It was found that on reacting MnI_2 with 1 or 2 equiv. PhMgI red-brown solutions of the complexes PhMnI and Ph_2Mn were formed. In spite of the intensive development in recent years of the chemistry of organomanganese compounds containing carbonyl ligands,[2,3] during the period from 1937 to 1976 only a few studies were published which were devoted to the preparation and properties of derivatives of the type of RMnI, R_2Mn and R_3MnLi (R = Alk, Ar).[4–10] The main reason for this is the extremely low stability of such complexes which exist (with rare exceptions) only as solutions in ether or THF, frequently at low temperatures and for a limited time. After 1976 progress became focussed, thanks to the work of Normant and collaborators,[11–13] on the use of organic Mn(II) derivatives as efficient reagents for forming new carbon–carbon bonds. Methods have been developed for obtaining the various alkyl-, alkenyl-, aryl- and alkynylmanganese halides, the corresponding di-organo derivatives and the lithium and magnesium triorganomanganates, without isolating them in the free state. In spite of the absence of detailed information on the structure of the reagents (the formulae RMnX, R_2Mn, R_3MnLi and R_3MnMgX reflect only the ratio of the starting materials) their application has in many cases proved to be extremely successful.[14]

The main applications of Mn(II) derivatives with a Mn–C bond and also with Mn–Si and Mn–Sn bonds in synthetic organic chemistry are considered below.

II. Preparation, stability and structure of organic compounds of Mn(II)

The most general method of obtaining organic compounds of Mn(II) in ether is the reaction of RLi or RMgX with MnI_2 at 0–20 °C (R = n-alkyl, alkenyl, aryl, alkynyl) or at −30 to −50 °C (R = sec-, t-alkyl).[14,15] Complexes of the type of RMnI or R_3MnLi are obtained depending on the ratio of RLi (or RMgX) and MnI_2. It must be noted that in ether the treatment of MnI_2 with 3 equiv. RMgX does not lead to the formation of the corresponding triorganomanganate R_3MnMgX. The synthesis of the di-organo derivatives R_2Mn was in all cases carried out at temperatures below −30 °C.

$$RM + MnI_2 \xrightarrow{Et_2O} RMnI + MI,$$
$$2\,RM + MnI_2 \xrightarrow{Et_2O} R_2Mn + 2\,MI,$$
$$3\,RLi + MnI_2 \xrightarrow{Et_2O} R_3MnLi + 2\,LiI,$$
M = Li, MgCl, MgBr, MgI.

The reagents are suspensions or homogeneous red-brown solutions but occasionally, when R = CH_2=CH or Ar, they are green. They are extremely sensitive to oxygen and moisture of the air.

The use of the more readily available $MnCl_2$ and $MnBr_2$ in place of MnI_2 is less efficient due to their low solubility in Et_2O.[14] The synthesis of organic compounds of Mn(II) from $MnBr_2$ in ether is successful if the practically insoluble dibromide is replaced by the soluble complex Li_2MnBr_4, prepared by treating $MnBr_2$ with an ether solution of LiBr (the latter was obtained from metallic lithium and Br_2 in Et_2O).[16] It is also possible to use previously prepared complexes of Grignard reagents with LiBr or ether solutions of organolithium compounds containing lithium halides.

$$MnBr_2 \xrightarrow[Et_2O]{LiBr} Li_2MnBr_4 \xrightarrow[Et_2O]{RMgX} RMnBr,$$
$$RMgX \xrightarrow[Et_2O]{LiBr} \text{«RMgX}\cdot\text{LiBr»} \xrightarrow[Et_2O]{MnBr_2} RMnBr,$$
$$RX \xrightarrow[Et_2O]{Li} RLi;\ RLi \xrightarrow[Et_2O]{MnBr_2} RMnBr,$$
X= Cl, Br.

It is best to use the readily available $MnCl_2$ or its soluble complex Li_2MnCl_4 in combination with 1–3 equiv. RLi or RMgX (R is alkyl, alkenyl, aryl, alkynyl) to synthesise organic derivatives of Mn(II) in THF.[14] The reaction is effected at 20 °C and in the majority of cases leads to the formation of homogeneous yellow or

brown solutions of derivatives of RMnCl, R_2Mn or R_3MnM (M = Li, MgX). All three types of complex may be synthesised using Grignard reagents in THF (in contrast to Et_2O).

$$MnCl_2 + 2LiCl \xrightarrow{THF} Li_2MnCl_4,$$

$$RM + MnCl_2(Li_2MnCl_4) \xrightarrow{THF} RMnCl + MCl(+2LiCl),$$

$$2RM + MnCl_2(Li_2MnCl_4) \xrightarrow{THF} R_2Mn + 2MCl(+2LiCl),$$

$$3RM + MnCl_2(Li_2MnCl_4) \xrightarrow{THF} R_3MnM + 2MCl(+2LiCl),$$

M = Li, MgCl, MgBr, MgI.

The stability of organomanganese compounds is determined by the type of complex, the nature of the organic fragment and the solvent. The tri-organomanganates R_3MnM (M = Li, MgX) possess the greatest stability. The thermal stabilities of the RMnX complex and particularly of R_2Mn are markedly less.[14] The decomposition point of Bu_3MnLi in ether is above 35 °C and of BuMnI and Bu_2Mn it is 20 and −30 °C.

The stability of Mn(II) derivatives with a Mn−C bond depends chiefly on the ease of β-elimination determined by the presence of alkyl β-hydrogen atoms.[9,10,14,17] It was found that the stabilities of the complexes RMnX and R_2Mn increase in the folowing series of R: t-alkyl < sec-alkyl < n-alkyl < methyl, alkenyl, aryl.[14] The decomposition points of the compounds RMnI in Et_2O are

R	t-Bu	iso-Pr	n-Bu	Me, Ph, $Me_2C=CH$
T, °C	−35	−30	20	>35

The formation of hydride intermediates during decomposition of the manganese reagents was confirmed by the isolation of hydrogenation products of unsaturated hydrocarbons introduced into the reaction mixture.[10,18]

On changing from ether to THF a marked increase was observed in the stability of organic Mn(II) compounds which is seemingly associated with stronger coordination.[14,15] The complexes t-BuMnCl, iso-PrMnCl, n-BuMnCl and PhMnCl do not undergo marked decomposition in THF even at 66 °C. A similar effect may also be caused by certain other donor ligands. Thus the addition of 5 equiv. DMF to a solution of iso-PrMnI in Et_2O raises the decomposition temperature of the complex from −30 to 35 °C.

Allyl derivatives of manganese of the type RMnCl may be obtained by the reaction of allyl Grignard reagents with Li_2MnCl_4 in THF at −78 °C.[19] The allylmanganese halides are significantly less stable than the alkyl, alkenyl, aryl and alkynyl σ-complexes considered above. Their decomposition with the formation of a mixture of regioisomeric 1,5-dienes occurs even at −78 °C.

$$R^1CH=C(R^2)CH_2MgX + Li_2MnCl_4 \xrightarrow{THF}$$

$$\longrightarrow R^1CH=C(R^2)CH_2MnCl + Mg(X)Cl + 2LiCl$$

R^1, R^2 = H, Alk; X = Cl, Br.

The direct synthesis of allyl compounds of Mn(II) from metallic manganese and allyl halides is described in section III.3.

Only a few examples are known of the isolation of organic Mn(II) derivatives in the free state. The existence of molecular associates (dimer, trimer and polymers) has been proved for $(Me_2PhCCH_2)_2Mn$, $(Me_3SiCH_2)_2Mn$ and $(Me_3CCH_2)_2Mn$ by X-ray structural analysis.[20] Intermolecular interaction is effected by bridging bonds between the Mn atoms and CH_2 groups and is confirmed by a shift of the appropriate absorption bands in the IR spectrum. The elemental analysis of the isolated Me_2Mn and Ph_2Mn shows that they exist as associates with Mg salts.[20] On attempting to isolate Me_3MnLi a compound was obtained the composition of which corresponded to the formula $Li_2MnMe_4.0.5Et_2O$.[20]

III. Reactions of organic compounds of Mn(II)

1. Alkenyl- and allyldemetallation

The first attempts to use organic compounds of Mn(II) in cross-coupling reactions generally did not give positive results. In contrast to the lithium dialkylcuprates[21,22] the alkyl derivatives of manganese of type R_3MnLi and R_2Mn gave cross-coupling products in less than 10% yield on reaction with alkyl halides.[23] Reaction with alkenyl and allyl halides (bromides and iodides) occurred relatively smoothly only in the case of the most stable Me_3MnLi.

$$Me_3MnLi + RX \xrightarrow[0°C]{Et_2O} R{-}Me$$

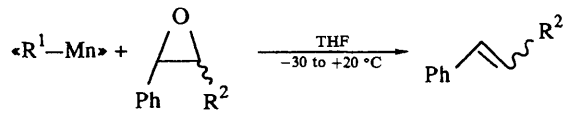
65—82%

R =  , (E)-PhCH=CH,

(E)-(n-C_7H_{15})CH=CH; X = Br, I.

The main side reactions were reduction of the substrates RX to 'dimeric' products R_2 and the formation of dehalogenation products RH (when β-hydrogen atoms are present in the reagent).

The complexes MeMnCl and Bu_3MnLi may be used for deoxygenating epoxides.[24] The reaction occurs selectively under mild conditions and leads to the *trans*-olefin using either *cis*- or *trans*-oxiranes.



R^1	R^2	Yield of olefin, %
Me	H	63
Bu	*E*-Ph	66 (*E*:*Z* = 100:0)
Bu	*Z*-Ph	59 (*E*:*Z* = 90:10)

Further study of the cross-coupling reaction involving organomanganese compounds led to the development of efficient methods of synthesis of alkenyl- and allyl-demetallation products.

The alkyl derivatives of manganese RMnCl react with β-chlorovinyl ketones forming the corresponding β-alkyl substituted α,β-unsaturated ketones in good yield as a mixture of *trans* and *cis* isomers. The *cis* isomeric enones are readily isomerised in the presence of trace amounts of I_2.[25,26] Under the same conditions the dimanganese derivatives give unsaturated diketones as the main

product. It must be noted that replacement of halogen by alkyl using organocuprate complexes proceeds smoothly only in the case of the cyclic β-chloro-α,β-enones.[27,28]

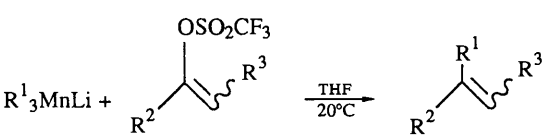
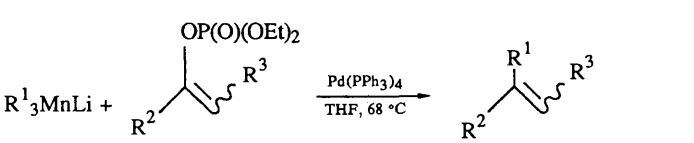
49% (n = 4).

The formation of alkenyldemetallation products is observed in reactions of Ph_3MnLi and trialkylmanganates with enol phosphates and enol triflates.[29] the enol phosphates, unlike the enol triflates, react only in the presence of a palladium catalyst [10 mol% $Pd(PPh_3)_4$]. On changing from Me_3MnLi and Ph_3MnLi to Bu_3MnLi the yield of cross-coupling products was reduced due to the reduction side reactions.

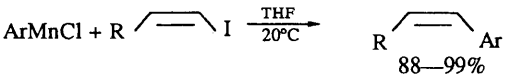


R^1 = Me, Bu, Ph;
R^2 = n-$C_{10}H_{21}$, R^3 = H; R^2, R^3 = n-C_5H_{11};

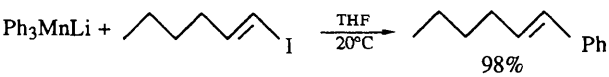


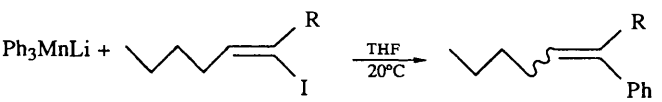
R^1 = Me, Bu, Ph; R^2 = n-C_5H_{11}, R^3 = Bu; R^2–R^3 = –$(CH_2)_{10}$– .

The cross-coupling of aryl manganese compounds with alkenyl iodides is a convenient and efficient method of synthesis of various substituted styrenes.[30] It was found that the reaction of reagents of the type of ArMnCl and Ar_3MnLi with substrates containing a 1,2-disubstituted double bond is accompanied by the complete retention of its geometry. In the case of the less reactive trisubstituted iodides a high yield of alkenyldemetallation products was achieved only when using the "ate" complexes Ar_3MnLi. The reactions lead to the formation of a mixture of stereoisomers.



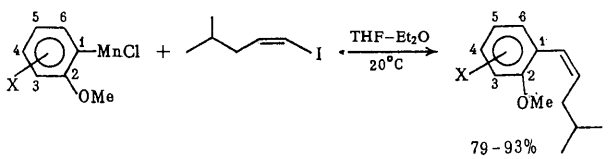
Ar = Ph, p-MeC_6H_4, p-$MeOC_6H_4$, p-ClC_6H_4,
p-BrC_6H_4, α-napthyl; R = Bu, iso-Bu.



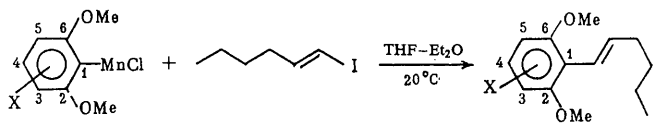


68% (R = Bu, E:Z = 38:62)
58% (R = $SiMe_3$, E:Z = 88:12)

Aryl *ortho*-*o*-substituted σ-complexes of manganese as well as p-$MeOC_6H_4MnCl$ undergo cross-coupling with alkenyl iodides.[31] Since the corresponding lithium reagents may readily be obtained by the *ortho* lithiation of ethers of di- and trihydroxybenzenes,[32] the combination of the stages of lithiation, transmetallation and cross-coupling is a convenient method for introducing an alkenyl fragment into aromatic polyhydroxy compounds.



X = 3-OMe, 5-OMe, 6-OMe



88% (X = 3-OMe),
60% (X = 4-OMe)

It must be noted that the cross-coupling of aryl manganese compounds with alkenyl iodides, unlike the analogues reactions with derivatives of Li,[33] Mg,[34] Zn,[35] Al [36]and several other metals, proceeds without a catalyst (Pd or Ni complex). The corresponding organocopper reagents react with alkenyl iodides without a catalyst but under far more forcing conditions.[37]

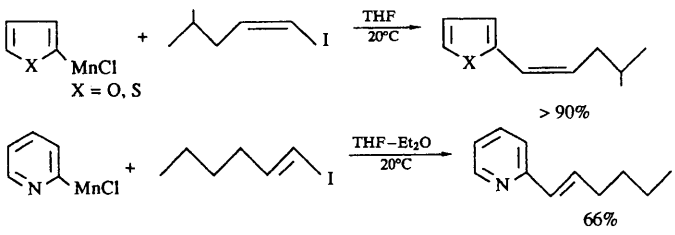
The mechanism of alkenyldemetallation seemingly includes an oxidative addition step (*a*) [the intermediate (I) containing tetravalent manganese is formed] and a reductive elimination step (*b*).[30,38]

$$Ph_3MnLi + RI \xrightarrow{(a)} \underset{(I)}{Ph_3MnR} + LiI,$$

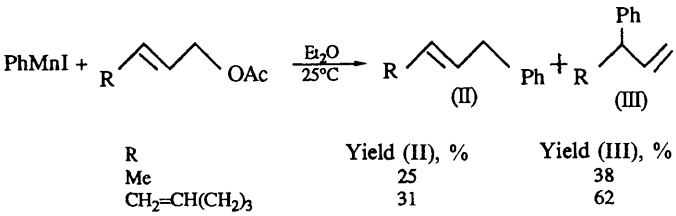
$$Ph_3MnR \xrightarrow{(b)} PhR + Ph_2Mn.$$

The fact that in several cases the yield of cross-coupling product continues to grow after complete disappearance of the initial alkenyl substrate supports this scheme. A possible explanation is that step (a) proceeds at a higher rate than step (b). Furthermore the formation of dehalogenation products RH [by hydrolysis of complex (I)], the yield of which falls depending on the accumulation of compounds RPh, becomes understandable.[30]

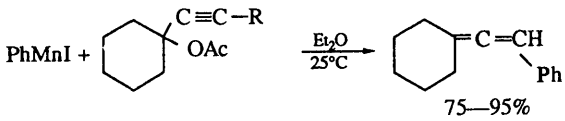
The organomanganese derivatives of furan, thiophene, pyridine and *N*-methylindole react with alkenyl iodides to give the corresponding α-alkenyl substituted O-, S- and N-containing heterocycles in high yield with complete retention of the configuration at the double bond.[39]



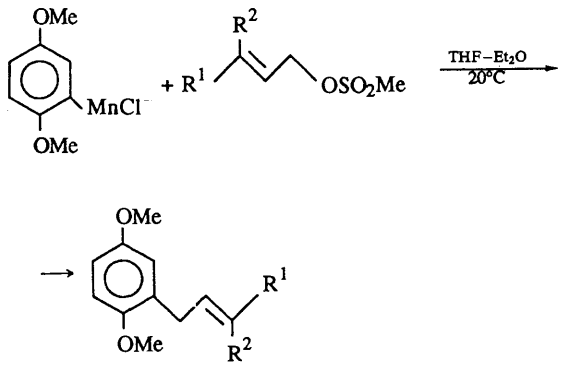
The reaction of PhMnI with allyl and propargyl acetates leads to substituted allylbenzenes and phenylallenes.[40] Unlike phenylmanganese iodide, the 2,5-dimethoxyphenyl derivative does not react with allyl acetates.[31] The synthesis of the practically important *O,O*-dimethylhydroquinones containing an allyl fragment may be effected by replacing the acetates by the corresponding mesylates.[31] The reactions take place with high regiospecificity (products of cross-coupling contain a dimethoxyphenyl group at the least substituted carbon atom of the allylic system) and are accompanied by the retention of the geometry of both *trans* and *cis* double bonds.



R	Yield (II), %	Yield (III), %
Me	25	38
CH_2=$CH(CH_2)_3$	31	62

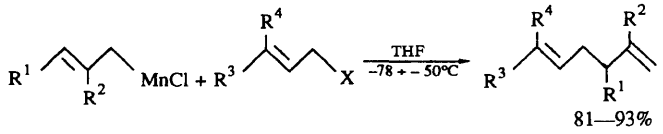


R = H, Ph, n-C_5H_{11}.



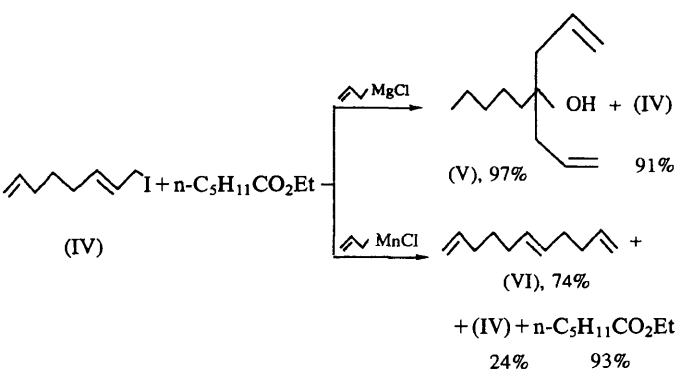
R^1 = CH_2=$CH(CH_2)_3$, R^2 = H; R^1 = H, R^2 = Bu;
R^1 = Me_2C=$CH(CH_2)_2$, R^2 = Me.

Allyl compounds of manganese of the type RMnCl may also be used in cross-coupling reactions. Their reaction with allyl bromides and iodides is effected under mild conditions and is an efficient method for synthesising 1,5-dienes.[19] The formation of allyldemetallation products occurs with the participation of the α-carbon atom of the substrate and the γ-carbon atom of the reagent with high stereoselectivity.

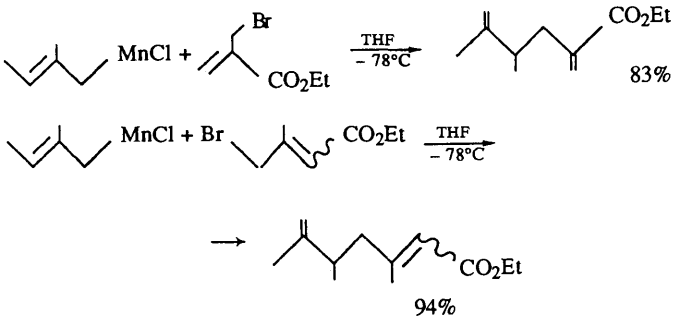


R^1, R^2 = H; R^1 = Me, R^2 = Me, Bu; R^3 = Ph, *E*-MeCH=CH, CH_2=$CH(CH_2)_3$, R^4 = H; R^3 = Me_2C=$CH(CH_2)_2$, R^4 = Me; X = Br, I.

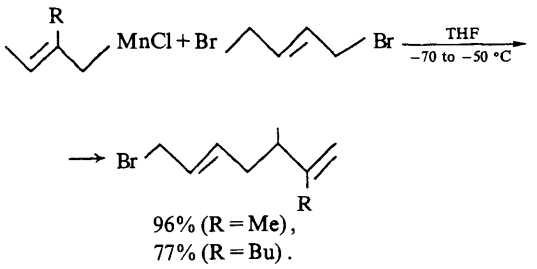
Allyl derivatives of magnesium, like the manganese derivatives, react with allyl halides giving 1,5-dienes,[41] however in contrast to the latter several functional groups are affected.[19] Treatment of an equimolar mixture of the iodide (IV) and ethyl caproate with 2 equiv. CH_2=$CHCH_2MgCl$ leads to the tertiary alcohol (V). The initial iodide is practically unreacted. Reaction of the same mixture with 2 equiv. CH_2=$CHCH_2MnCl$, on the other hand, leads to the formation of the hydrocarbon (VI) and the ester is completely unaffected. A similar result was observed in the reaction of CH_2=$CHCH_2M$ (M = MgCl, MnCl) with an equimolar mixture of the iodide (IV) and BuCN.



The inert nature of the organomanganese compounds in relation to ester groups enables cross-coupling reactions to be effected with esters of α,β-unsaturated carboxylic acids (2-methylacrylic, 3,3-dimethylacylic, tiglic, angelic) containing an allylic halogen atom which cannot be achieved using Grignard reagents.[42] In the case of alkyl 3-bromocrotonates the main course of the reaction is the formation of cyclopropanes (see section III.3).



The use of allyl complexes of manganese enables a selective monoallylation of allylic 1,4-dibromides to be effected while magnesium derivatives give chiefly diallylation products.[43]



96% (R = Me),
77% (R = Bu).

Comparatively little has been published on work devoted to the use of Mn(II) compounds as catalysts in cross-coupling reactions. It was shown that reaction of Grignard reagents RMgX (R = Ph, $PhCH_2$, $CH_2=CHCH_2$, $MeCH=CHCH_2$; X = Cl, Br) with enol triflates in the presence of 10 mol% Li_2MnCl_4 leads to the alkenyldemetallation product in 74–92% yield. On changing to MeMgI, EtMgBr and $CH_2=CHMgBr$ the yield was reduced to 6–35%.[29] Under approximately the same conditions iso-PrMgBr reacts with alkenyl and aryl halides to give mainly products of reduction.[44]

$$RX + \text{iso-PrMgBr} \xrightarrow[\text{THF, 25 to 45 °C}]{\text{1 mol.\% } MnX_2} RH \quad 65-93\%$$

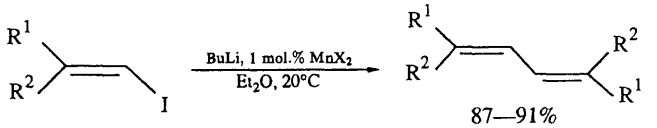
α-napthyl; X = Br, I.

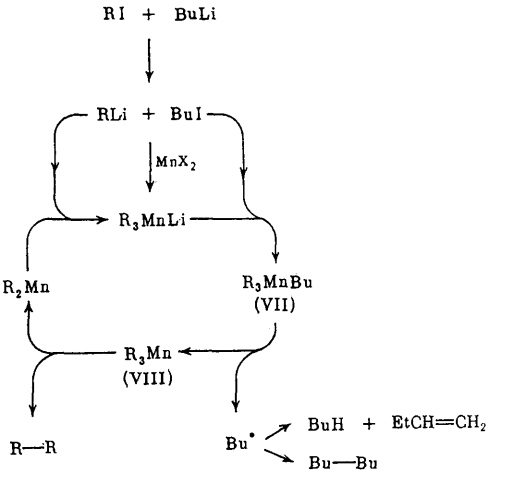
Manganese halides (1 mol% $MnCl_2$ or $MnBr_2$) efficiently catalyse the reductive 'dimerisation' of alkenyl iodides to symmetrical 1,3-dienes on treatment of the iodides with 1 equiv. n-butyllithium.[45] Both double bonds in the reaction product have the same geometry as in the substrate.



87—91%

R^1 = H, R^2 = n-C_7H_{15}; R^1 = Me, Bu, R^2 = Et; R^1 = Et, R^2 = Bu.

The mechanism proposed for the 'dimerisation' is the formation *in situ* (by metal–halogen exchange) of a lithium alkenyl derivative and butyl iodide. The successive reaction of the catalyst with the lithium reagent and BuI leads to the mixed tetraorgano-derivative (VII) containing quadrivalent manganese which is converted into the trialkenyl complex (VIII) by expulsion of a butyl radical. Decomposition of the intermediate (VIII) gives a conjugated diene and a dialkenylmanganese which continues the catalytic cycle.



2. Acyldemetallation

The acyldemetallation of organic Mn(II) derivatives is one of the most efficient and well characterised routes for using these reagents in synthesis. In comparison with organic compounds of cadmium, zinc and aluminium, which are traditionally used to obtain unsymmetrical ketones from acid chlorides or anhydrides of carboxylic acids,[46–49] the manganese reagents generally give a higher yield of ketone particularly in the case of substrates containing other reactive functional groups in place of the acid chloride (or anhydride).[14] The preferential use of the latter must be attributed to the accessibility, cheapness and lack of toxicity of the initial manganese halides, the ease of preparing reagents of various types from them, and also the possibility of carrying out the reactions at temperatures close to ambient in a relatively short time. Frequently the use of organocopper complexes gives better results,[21,50,51] however the smooth acyldemetallation of many of them occurs only at low temperatures (−78 °C) and with a large excess of reagent (unlike the manganese reagents).

The reaction of alkyl-, aryl-, alkenyl- and alkynylmanganese halides, obtained by treating MnI_2 (in ether) or Li_2MnCl_4 (in THF) with organolithium or organomagnesium compounds, with carboxylic acid chlorides leads to the formation of alkyl, aryl, alkenyl and alkynyl ketones respectively in high yield.[11,12,14,52]

$$R^1MnX + R^2COCl \xrightarrow[-10 \text{ to } +20\ ^\circ C]{Et_2O \text{ or THF}} R^1COR^2$$

R^1 = Me, Bu, n-C_7H_{15}, Ph, (*Z*)-BuCH=CH, (*Z*)-Et(Me)C=CH,

$Me_2C=CH$, $BuC\equiv C$;

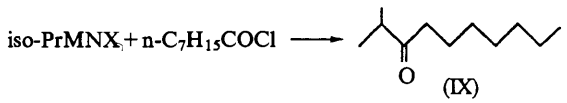
R^2 = Et, Bu, n-C_7H_{15}, iso-Pr, t-Bu, Ph, $Me_2C=CH$; X = Cl, I.

Reactions involving alkenyl derivatives of manganese are accompanied by complete retention of the double bond geometry. On changing from complexes RMnI (R = Alk) to the di-organo

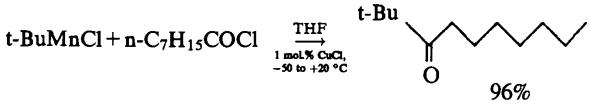
derivatives R_2Mn and the trialkylmanganates R_3MnLi the yield of ketone is reduced by 5–10%. In the case of R_2Mn two and in the case of R_3MnLi three alkyl fragments are transferred. The introduction of α,β-unsaturated acid chlorides into the reaction is only possible when two β-alkyl substituents are present in the latter. β-Monosubstituted α,β-unsaturated acid chlorides polymerise in the presence of the manganese reagents.

The initial use of Et_2O almost exclusively as solvent (in combination with MnI_2) and not THF [11,12,14] was associated with the possible opening of the tetrahydrofuran ring by an acid chloride in the presence of a Lewis acid, viz. the manganese dihalide, formed in addition to the ketone.[53] It was found subsequently that this process does not take place under the usual acyldemetallation conditions.[52]

Replacement of ether by THF enables the cheaper and more available $MnCl_2$ or its soluble complex Li_2MnCl_4 (see section II) to be used instead of MnI_2 to prepare organomanganese compounds. There are other advantages. The higher stability of the thermally unstable secondary and tertiary alkyl derivatives of manganese in an ether–THF mixture, in comparison with pure Et_2O, leads to an increase in the yield of acyldemetallation products.[14] The yield becomes practically quantitative on carrying out the reaction in THF in the presence of 1 mol% CuCl.[52]

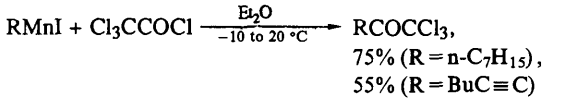


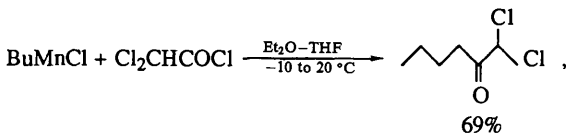
X	Solvent	T, °C	Yield of ketone (IX), %
I	Et_2O	−35	65
I	Et_2O–THF	−35	78
Cl	THF (1 mol.% CuCl)	−30 to +20	93

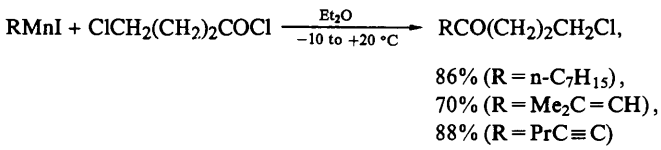


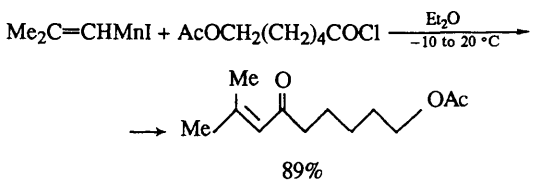
It turned out that on using THF (but no Et_2O) the addition of catalytic amounts of CuCl markedly increased the yield of ketone in reactions involving MeMnCl and also σ-complexes of manganese RMnCl (R is aryl, alkenyl).[52]

Smooth acyldemetallation is also observed in the case of more complex substrates containing other functional groups in addition to the acid chloride.[12,14,52,54,55] The acid chlorides of trichloroacetic, α,α-dichloro- and α-chlorocarboxylic acids react with organomanganese compounds to give the corresponding trichloromethyl-, α,α-dichloroalkyl- and α-chloroalkyl ketones in high yield. β-Chloro-containing acyl chlorides are subject to elimination of HCl in the presence of manganese complexes. On the other hand γ-chloro derivatives (and also substrates with a halogen atom removed even further from the COCl fragment) react in the usual way. A high yield of acyldemetallation product was also achieved on using acid chlorides of α-alkoxy- and α-alkylthiocarboxylic acids.

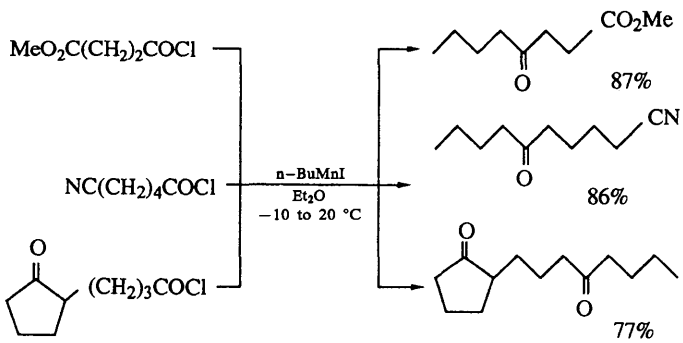




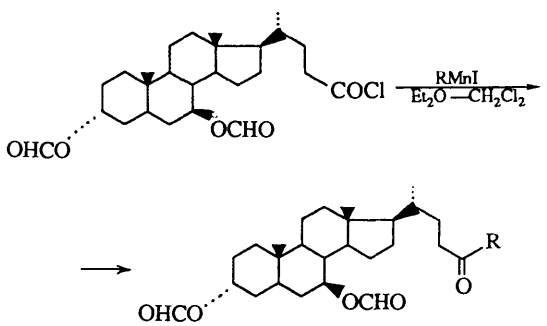




Reactions involving substrates containing ester, nitrile and keto groups are characterised by complete retention of these groupings and lead to keto-esters, ketonitriles and diketones.



The possibility of retaining two formate ester groups is shown using a steroid acid chloride as an example.[56]



88% (R = iso-Bu),
78.5% (R = Me_2C=CH),
73.5% (R = PrC≡C)

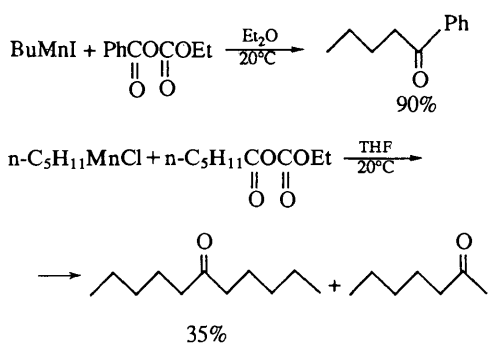
The less reactive carboxylic acid anhydrides[14,15,54,57] have been used in this reaction in addition to acid chlorides. Symmetrical anhydrides react with the complexes RMnI (in Et_2O) or RMnCl (in THF) to give the corresponding ketones in high yield. The yield of acyldemetallation product was reduced somewhat on replacing RMnX derivatives (R = Alk; X = Cl, I) by trialkyl manganates R_3MnM (M = Li, MgBr). It is reported that the latter react with transfer of all three organic fragments.

$$R^1MnX + (R^2CO)_2O \xrightarrow[20°C]{Et_2O \text{ or } THF} R^1COR^2 \quad 81—96\%$$

$R^1 = n\text{-}C_7H_{15}$, Ph;
R_2 = Et, iso-Pr, iso-Bu, t-Bu;
X = Cl, I.

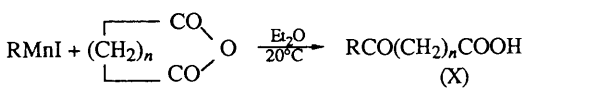
The reaction of $n\text{-}C_7H_{15}MnI$ with the mixed anhydride of a carboxylic acid and pivalic acid proceeds exclusively by replacing the t-butyl carboxylate group and leads to heptyl pentyl ketone (72% yield).[15]

Acyl ethyl carbonates, which may readily be obtained by treating carboxylic acids with phosgene in the presence of Et_3N, are efficient substrates for carrying out the acyldemetallation of organomanganese compounds.[14,15] These derivatives react with RMnI complexes in ether giving the corresponding ketones in high yield. On using THF or a THF—Et_2O mixture as solvent the yield of ketone was reduced due to a side reaction forming an ethyl ester.



The use of other mixed anhydrides of the form $R^1C(O)OC(O)ZR^2$ (ZR^2 = OMe, OPh, SEt) and $RC(O)OP(O)(OMe)_2$ in place of acyl ethyl carbonates gives poorer results.[15]

The reactions of alkyl σ-complexes of manganese with cyclic anhydrides of dicarboxylic acids is a convenient method of synthesising aliphatic keto-acids.[54]



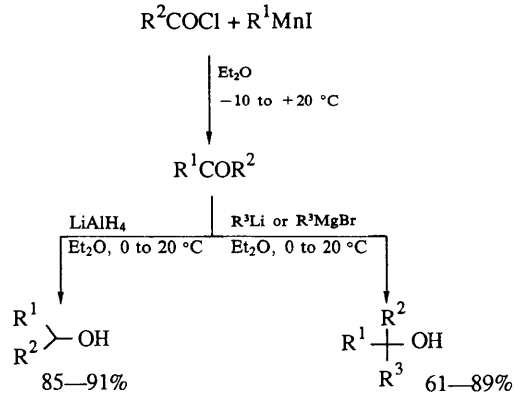
R	n	Yield (X), %
$n\text{-}C_7H_{15}$	2	77
n-Bu	3	55

The reaction of alkyl-, aryl- and alkenylmanganese iodides with ethyl chloroformate leads to the ethyl esters of alkyl-, aryl- and alkenylcarboxylic acids.[13]

$$RMnI + ClCOOEt \xrightarrow[20\ °C]{Et_2O} RCOOEt$$

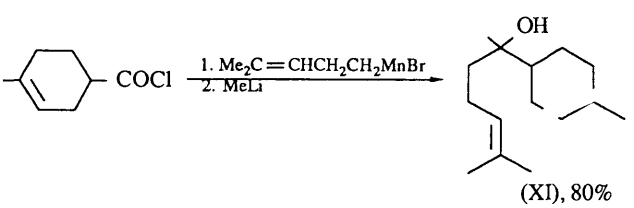
83% (R = $n\text{-}C_7H_{15}$),
77% (R = Ph),
70% ($R = Me_2C{=}CH$)

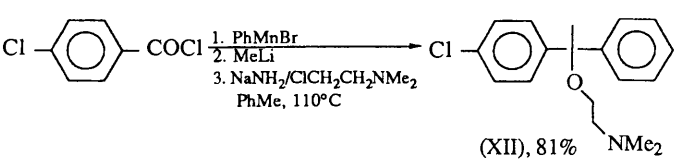
A more detailed study of the acyldemetallation of organomanganese compounds revealed several interesting features.[58] It turned out that the difference in reaction rates of RMnI derivatives with the initial acid chloride and with the ketone isolated from the reaction mixture was too small to guarantee conduct of the acylation without subsequent condenstion with the formation of a tertiary alcohol (which is observed in practically every case). In the reaction of BuMnI with BuCOCl (ether, 20 °C) the yield of BuCOBu is 80 and 92% after 5 and 10 min but in the reaction of BuMnI with BuCOBu the yield of Bu_3COH is 78 and 81% after the same times. It was shown that the acyldemetallation product formed *in situ* is a complex of the ketone with the metal halides present in solution (MnX_2 + LiX or MnX_2 + MgX_2, whre X = Cl, Br, I) which are practically unreactive towards RMnI unlike the free ketone. Treatment of such a complex with the more reactive organic compounds of lithium and magnesium and with $LiAlH_4$ and $NaBH_4$ leads to the formation of tertiary and secondary alcohols respectively in high yield. Various tertiary alcohols may therefore be synthesised directly from acid chorides by the sequential action on them of first organomanganese compounds and then organolithium or organomagnesium reagents.[58]



R^1 = Et, Bu, iso-Bu, $n\text{-}C_7H_{15}$;
R^2 = Et, iso-Bu, t-Bu, $n\text{-}C_5H_{11}$, Ph, $Me_2C{=}CH$;
R^3 = Me, Et, Bu, sec-Bu, Ph, $Me_2C{=}CH$, $MeCH{=}CH$, $CH_2{=}CHCH_2$.

The procedure developed has been used successfully to obtain biologically active compounds, viz. the diastereomeric (±-α-bisabolols (XI) and (±)-chlorphenoxamine (XII).[59]





3. 1,2- And 1,4-addition

The reaction of organomanganese compounds with aldehydes and ketones occurs similarly to the corresponding reaction of organolithium and organomagnesium compounds and leads to secondary or tertiary alcohols in high yield.[14,60,61] However, the σ-complexes of manganese react significantly more selectively than the lithium or magnesium derivatives. They are inert towards esters, nitriles and apparently several other functional groups, the preservation of which during a condensation at an aldehyde or ketone group has been shown in only a few examples.[14,62]

Reaction of alkyl-, alkenyl-, aryl- and alkynylmanganese halides with an equimolar mixture of an aldehyde and a ketone occurs only with the aldehyde. The initial ketone does not react.[60,61]

$$R^1MnX + R^2CHO + R^3COR^4 \longrightarrow R^1R^2CHOH + R^3COR^4$$

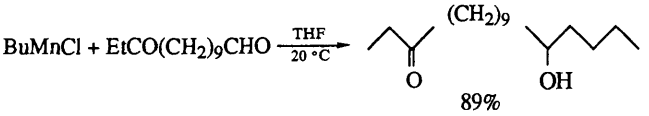
X	Solvent	T, °C	Additive
Cl	THF	20	LiCl or MgClBr
Br	Et_2O	20	LiBr
I	Et_2O	−50	MgBrI

Under the same conditions aliphatic ketoaledhydes give secondary ketoalcohols.



The temperature for carrying out a chemoselective condensation is determined by the reactivity of the manganese derivative which in its turn depends on the nature of the solvent and the metal salts in solution. It was found that complexes RMnX (X = Br, I) in ether in the presence of MgX_2 are more reactive than in the presence of LiX.[61] The reason for this is apparently that MgX_2, being a stronger Lewis acid, is coordinated at the oxygen atom of the carbonyl group, increasing its electrophilicity.

It is known that organic derivatives of trialkoxytitanium are used most frequently to achieve a high chemoselectivity in reactions of this type.[63—65] Organic compounds of Mn(II) at the same selectivity (>99%) give secondary alcohols in higher yield (5—10% more on average). In addition the reaction of σ-complexes containing alkenyl and secondary alkyl fragments becomes possible (the corresponding titanium reagents are unstable even at −78 °C.

Allylmanganese halides, unlike alkyl-, alkenyl-, aryl- and alkynylmanganese halides, may be obtained by direct synthesis from metallic manganese and allyl halides.[66—68] The synthesis of allylmanganese halides in the presence of a carbonyl substrate, such as an aldehyde or ketone, is the most expedient and preparatively convenient.[67,68] This modification enables both the decomposition of the unstable allyl manganese complexes and the formation of 1,5-dienes by the Wurtz reaction, which reduce the yield of condensation products, to be reduced to a minimum.

Heating the carbonyl compound, allyl halide and metallic manganese in ethyl acetate or THF in the presence of 10 mol% $ZnCl_2$ leads to the preparation of the corresponding homoallyl alcohols in high yield.[68]

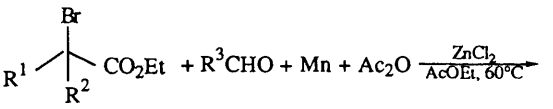
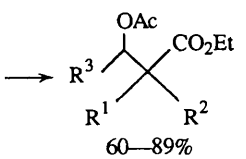
The reaction is characterised by complete retention of ester and dimethylacetal groups, and of alkyl and aryl halogen atoms in the initial aldehyde or ketone. On using α,β-unsaturated ketones only 1,2-addition is observed. Crotyl and isoprenyl bromides react giving condensation products formed from the most substituted carbon atom of the allyl fragment.

Carrying out the reaction in THF in the absence of $ZnCl_2$ requires the use of a large excess (6—7 equiv.) of both manganese and allyl halide.[67] Furthermore, it is necessary to add 1 equiv. I_2 to the reaction mixture to achieve a high yield of the homoallyl alcohol.

In the presence of metallic manganese and 10 mol% $ZnCl_2$ it is possible to effect the condensation of α-bromocarboxylic acid esters with aldehydes and ketones by a type of Reformatsky reaction.[68] The use of acetic anhydride to acylate the alkoxide formed *in situ* inhibits the retroaldol reaction.





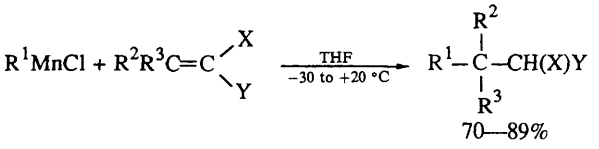
60—89%

R^1 = H, R^2 = H, n-C_6H_{13}; $R^1 = R^2$ = Me;
R^3 = n-C_6H_{13}, t-Bu, Ph.

The conjugate addition of σ-complexes of Mn(II) to an α,β-unsaturated carbonyl substrate was described for the first time by Gilman and collaborators[4] for the reaction of PhMnI and PhCH=CHCOPh. A detailed study of the reaction of alkyl-, aryl- and alkenylmanganese compounds with 2-cyclohexenone showed their unsuitability for the smooth synthesis of 3-substituted cyclohexanones. The latter were obtained in relatively low yield as a result of the competing processes of 1,2-addition and reductive dimerisation with the formation of 3,3′-bis(cyclohexanone).[69] The product ratio depended markedly on the type of complex (RMnX, R_2Mn, R_3MnLi or R_3MnMgX) and the nature of the solvent (Et_2O or THF).

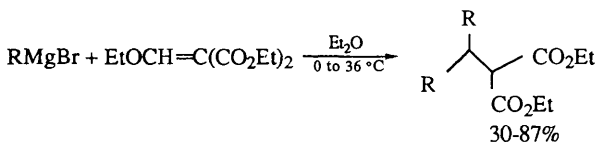
The reaction of cyclic α,β-unsaturated ketones with RMgX (R = Alk, Ar; X = Br, I) catalysed by manganese salts also proceeds nonselectively.[69–71]

In contrast to the α,β-enones, substrates containing a double bond activated by two electron-accepting groups (alkylidenemalonic, -cyanoacetic and -acetoacetic esters) react with RMnCl derivatives (R is alkyl, alkenyl, aryl, alkynyl) obtained from $MnCl_2$ and RMgCl in THF, forming conjugate addition products in high yield.[72] The yield is reduced when using the corresponding lithium reagents instead of RMgCl to obtain the organomanganese compounds.

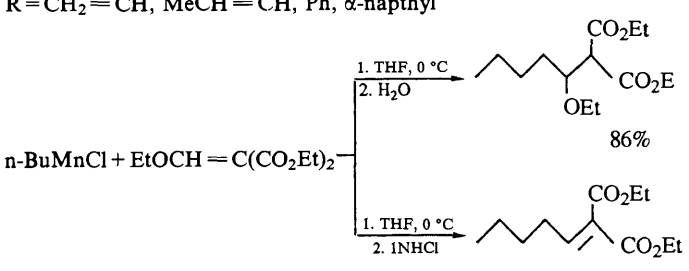


R^1 = Me, Bu, iso-Pr, $Me_2C=CH$, Ph, $BuC\equiv C$;
R^2 = H, R^3 = Me, Pr, Ph; R^2, R^3 = Me;
X, Y = CO_2Et, CN, COMe.

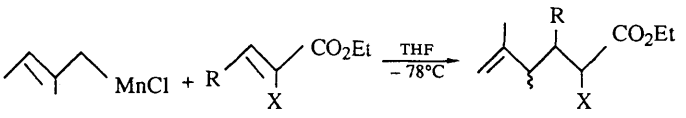
The initial Grinard reagents also give β-substituted alkylmalonic or alkylcyanoacetic esters on reaction with alkylidenemalonates or alkylidenecyanoacetates[73,74] though often in significantly lower yield (particularly with β,β-disubstituted substrates).[72] An even more clear difference in behaviour of the manganese and magnesium derivatives is displayed in reactions involving diethyl (ethoxymethylene)-malonate.[72,73,75]



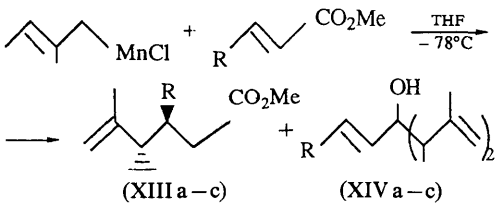
R = $CH_2=CH$, MeCH=CH, Ph, α-napthyl



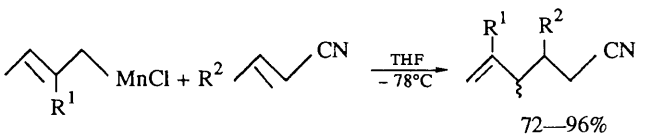
The introduction of γ-substituted allylic organomanganese compounds into the reaction leads to the formation of 1,4-addition products involving exclusively the γ-carbon atom of the reagent.[76] The esters of alkylidenemalonic, alkylidenecyanoacetic, maleic and fumaric acids containing a doubly activated double bond give 1,4-addition products. In contrast methyl crotonate, methyl 2-hexenoate and methyl cinnamate give the 1,2-addition products, the tertiary alcohols (XIVa–c), in addition to the 1,4-addition products (XIIIa–c). On changing from the ester to the nitrile the analogous 1,2-addition process does not take place.



R = n-C_6H_{13}, *E*-MeCH=CH; X = CO_2Et, CN.



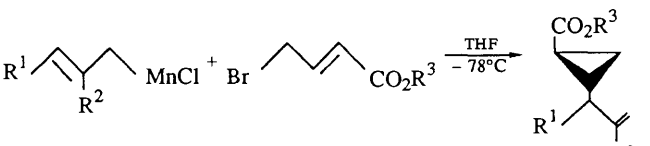
Compound	R	Yield (XIII), %	Yield (XIV), %
(a)	Me	69	18
(b)	Pr	45	39
(c)	Ph	27	36



R^1 = H, Me, Bu; R^2 = Me, Pr, Ph.

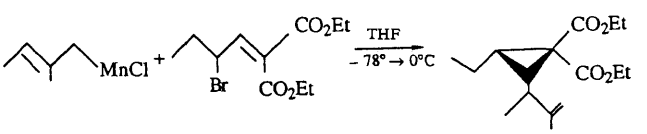
The reaction of allylic organomanganese compounds with esters of α,β-unsaturated monocarboxylic acids is characterised by a high stereoselectivity. Each of the products (XIIIa) and (XIIIb) is a single diastereomer with an *anti* disposition of alkyl groups at the β- and γ-carbon atoms.[77] The configuration of compounds (XIIIa) and (XIIIb) was confirmed by converting them into the 3,4-*cis* isomers of 3-alkyl-5-iodo-4,5-dimethylpentanolide by saponification and iodolactone formation.

The reaction of allylic complexes of manganese with alkyl 4-bromocrotonates is accompanied by cyclisation of the manganese enolates formed initially and leads to esters of allyl substituted cyclopropanecarboxylic acids.[42,78]



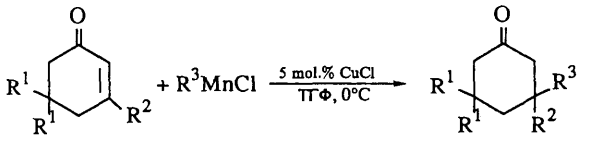
$R^1=R^2$=H; R^1 = Me, R^2 = H, Me, Bu; R^3 = Me, iso-Pr.

γ-Bromo-containing alkylidenemalonates and alkylidenecyano-acetates react similarly.[42]

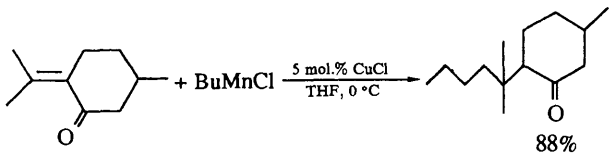


It should be noted that the corresponding α-, β- and γ-substituted crotonic acids give products of cross-coupling or condensation at the ester group (see section III.1).

The problem of the selective 1,4-addition of organomanganese reagents to α,β-unsaturated ketones may be resolved by conducting the reaction in the presence of catalytic quantities of copper salts.[79] The reaction of BuMnCl with 2-cyclohexenone (THF, 0 °C) leads to the preparation of 3-butylcyclohexanone in no more than 10% yield,[69] but in the presence of 0.1–5 mol% CuCl its yield becomes practically quantitative. The reactions of alkyl-, aryl- and alkenylmanganese chlorides with various conjugated enones (including those containing a tri- and even a tetrasubstituted double bond) catalysed by CuCl are efficient methods of synthesis of the corresponding β-branched alkyl ketones.

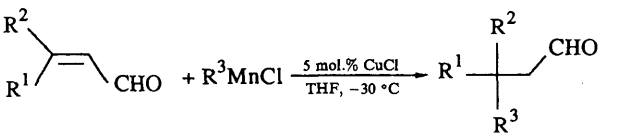


R^1 = H, R^2 = H, Me; R^1 = R^2 = Me;
R^3 = Me, n-Bu, iso-Pr, t-Bu, Ph, $Me_2C{=}CH$, $PrCH{=}CH$.



It must be recorded that the yield of 1,4-addition products when using RMnX is significantly greater in many cases than when using organocopper reagents of the type RCu, R_2CuLi and $R_2Cu(CN)Li_2$ and Grignard reagents under conditions of copper salt catalysis.[80]

In the presence of catalytic quantities of CuCl the conjugated addition of manganese σ-complexes to β-mono- and β,β-disubstituted α,β-unsaturated aldehydes (the α,β-disubstituted substrates react giving a mixture of products of 1,4-addition and condensation at the aldehyde group).[81] The reaction course indicated is effected for organocopper compounds only on promotion with Me_3SiCl and leads to the formation of enol silyl ethers.[82,83]



R^1 = H: R^2 = Me, Bu, n-C_7H_{15}, Ph;

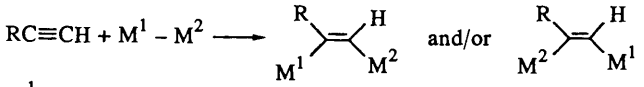
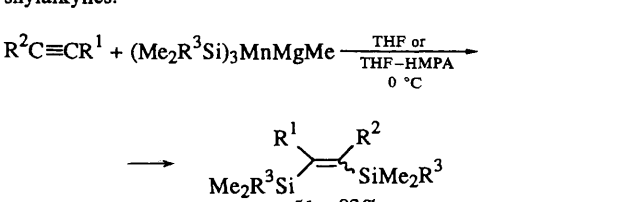
IV. Reactions of manganese derivatives containing Mn–Si and Mn–Sn bonds

The regio- and stereoselective addition of reagents with Si–Mg, Si–Al, Si–Zn,[84–86] Si–Cu,[87] Sn–Mg, Sn–Al, Sn–Zn,[88] or Sn–Cu [89,90] bonds to acetylene with the formation of 1,2-dimetallated alkenes has a high synthetic potential due to the possibility of further selective conversions at each of the two metal–carbon bonds.



M^1 = Me_2PhSi, Me_3Sn, Bu_3Sn, Ph_3Sn;
M^2 = MeMg, Et_2Al, $^1/_2Zn$, Cu, $^1/_2Cu$.

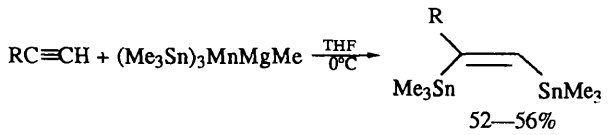
It was found that, in contrast to the "ate" complexes of manganese mentioned above, both $(Me_3Si)_3MnMgMe$ and $(Me_2PhSi)_3MnMgMe$, prepared by sequential treatment of Me_3SiLi or $Me_2PhSiLi$ with 1 equiv. MeMgI and 0.33 equiv. $MnCl_2$, give 1,2-disilylation products on reaction with terminal and 1-trimethylsilylalkynes.[91,92]



[(*E*)/(*Z*) from 33 : 67 to 65 : 35]

R^1 = H: R^2 = Me_3Si, n-C_6H_{13}, Ph, $PhCH_2O(CH_2)_2$, $(THP)O(CH_2)_2$;
R^1 = Me_3Si: R^2 = n-C_6H_{13}, $PhCH_2O(CH_2)_2$.
$(THP)O(CH_2)_2$(where THP is tetrahydropyranyl); R^3 = Me, Ph.

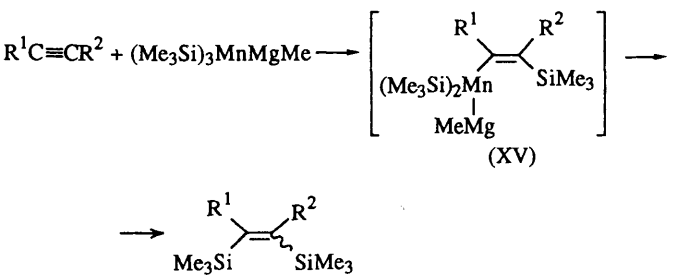
The stannylmanganese complex $(Me_3Sn)_3MnMgMe$ reacts analogously.



R = n-$C_{10}H_{21}$, $PhCH_2O(CH_2)_2$, $(THP)O(CH_2)_2$.

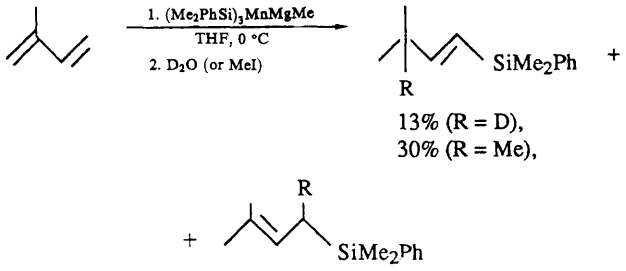
Replacement of $(Me_3Si)_3MnMgMe$ by the lithium derivative $(Me_3Si)_3MnLi$ leads, after hydrolysis, to a mixture of mono- and disilyated alkenes.

The reaction mechanism obviously includes a step for the *syn* addition of the Mn–Si fragment to the triple bond and the reductive elimination of zero-valent manganese from the alkenylmanganate intermediate (XV).



The proposed scheme is confirmed by the formation on reaction of $PhCH_2O(CH_2)_2C{\equiv}CMe$ and $(Me_3Si)_3MnMgMe$, after treatment with H_2O, D_2O and MeI, of the (*E*)-isomeric products of hydrolysis, deuterolysis and methylation of the complex (XV) (R^1 = $PhCH_2O(CH_2)_2$, R^2 = Me) at the C–Mn bond.[92]

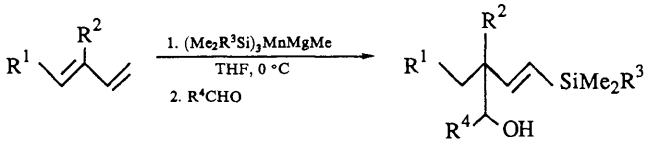
The reaction of $(Me_2PhSi)_3MnMgMe$ with 1,3-dienes (butadiene, isoprene, *trans*-piperylene) and subsequent deuterolysis gives in each case a mixture of γ-deuteroalkyenyl- and α-deuteroallylsilanes.[92,93] An analogous picture is also observed on replacing D_2O by MeI.



13% (R = D),
30% (R = Me),

65% (R = D),
60% (R = Me)

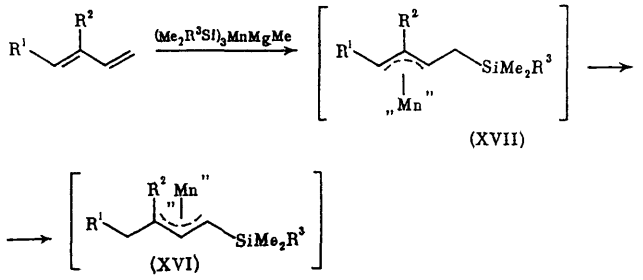
The use of aldehydes and ketones as electrophiles leads exclusively to the preparation of γ-substituted alkenylsilanes in high yield.



$R^1 = H$, $R^2 = H$, Me; $R^1 = Me$, $R^2 = H$; $R^3 = Me$, Ph;
$R^4 = Bu$, n-C_8H_{17}, Ph, *E*-MeCH=CH, *E*-PhCH=CH, Ph.

We note that, in contrast to the complexes $(Me_3Si)_3MnMgMe$ and $(Me_2PhSi)_3MnMgMe$, the lithium manganate reagents $(Me_3Si)_3MnLi$ and $(Me_2PhSi)_3MnLi$ do not react with conjugated dienes under the same conditions.

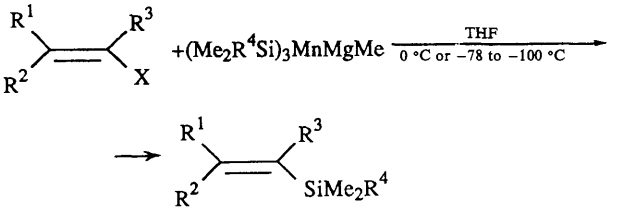
The synthesis of the indicated products of deuterolysis, alkylation and condensation indicates the participation of the allyl manganese intermediate (XVI) in the reaction. It is most probably formed by silylmanganation of the monosubstituted double bond in the diene and further isomeriation of complex (XVII) to complex (XVI) as a result of reversible β-elimination–addition of an Mn–H fragment.[92,93]



„Mn" = $(Me_2R^3Si)_2MnMgMe$

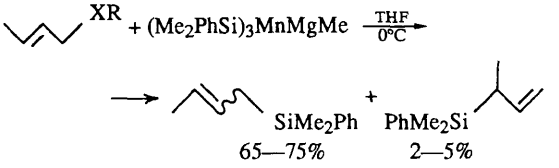
It is known that the diethylaluminosilane $Me_2PhSiAlEt_2$ is an efficient reagent for obtaining alkenyl- and allylsilanes from enol and allyl phosphates.[94,95] The silylmanganates $(Me_3Si)_3MnMgMe$ and $(Me_2PhSi)_3MnMgMe$ may also be used successfully for this purpose.

The reaction of these derivatives with alkenyl halides (bromides and iodides) is effected under mild conditions and leads to the corresponding alkenylsilanes in high yield.[92,96] In the cross-coupling process complete retention of both *trans* and *cis* geometry of the double bond is observed (to retain the *cis* geometry it is necessary to reduce the temperature from 0 to −78 or −100 °C). Alkenyl sulphides, enol phosphates and enol triflates also react in addition to the alkenyl halides.



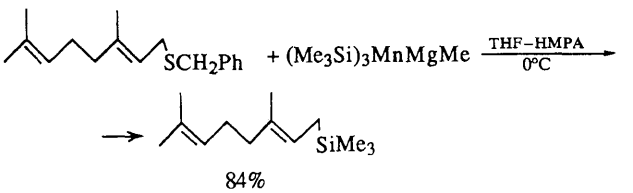
$R^1 = Me$, n-C_6H_{13}, n-$C_{10}H_{21}$, Ph, $R^2 = R^3 = H$;
$R^1 = R^3 = H$, $R^2 =$ n-$C_{10}H_{21}$, Ph;
$R^1 = Me$, n-$C_{10}H_{21}$, $R^2 = Me$, $R^3 = H$;
$R^1 = R^2 = H$, $R^3 = Pr$, n-C_6H_{13}, n-$C_{10}H_{21}$;
$R^1 - R^3 = -(CH_2)_4-$, $-(CH_2)_6-$, $R^2 = H$;
$R^4 = Me$, Ph;
X = Br, I, SMe, SPh, $OP(O)(OEt)_2$, $OP(O)(OPh)_2$, OSO_2CF_3.

Allyl sulphides and allylethers react forming allylsilanes.[92,96] Monosubstituted (α or γ) substrates give a mixture of regioisomeric silylation products with a predominance of the compound in which the Si atom is bound to the least substituted carbon atom of the allyl fragment. It should be noted that the regioselectivity of cross-coupling is significantly greater when using silylmanganate reagents than when using the complex $Me_2PhSiAlEt_2$.[92]



(*E*/*Z* from 5 : 1 to 20 : 1)

XR = SPh, OCH_2Ph, $OSiMe_2Bu$-t.



V. Conclusion

The organic compounds of Mn(II) are therefore efficient reagents for the selective formation of a carbon–carbon bond in acyl-, alkenyl- and allyldemetallation, and in 1,4- and 1,2-addition to aldehydes, ketones and esters. The availability and cheapness of the initial manganese halides, the possibility of obtaining *in situ* complexes of various types and their inertness towards several functional groups favourably distinguish the manganese derivatives from the corresponding derivatives of many other metals.

In addition, as follows from the data presented above, only a few examples are known of the use of manganese reagents in the synthesis of biologically active natural compounds. The stereochemistry of the condensation reactions involving γ-substituted σ-allylic complexes of Mn(II) (simple diastereoselectivity[97]) and α-chiral aldehydes and ketones (1,2-asymmetric induction[98]) are practically uninvestigated. The synthesis of organomanganese compounds from organic reagents containing aluminium or zinc has not as yet been described. The latter may contain functional groups.[99] The chemistry of enolates of Mn(II) is almost completely unstudied.

It may be expected that the development of these and other routes will enable organic derivatives of Mn(II) to be applied even more successfully to the solution of the problems of fine organic synthesis.

The synthesis, properties, and applications of hydrophilic polymers and copolymers of hydroxyalkyl esters of acrylic and methacrylic acids

Z G Asadov, V S Aliev
Institute of Petrochemical Processes, Academy of Sciences of Azerbaijan

ABSTRACT. The scientific-technical and patent literature on the synthesis of hydroxyalkyl esters of acrylic and methacrylic acids by their catalytic reactions with epoxyalkanes, by the radical copolymerisation and polymerisation of presynthesised monomeric esters, and also by the chemical modification of polymerisation and copolymerisation products is surveyed. A wide variety of physicochemical properties of the polymers and copolymers based on the hydroxyalkyl esters of acrylic and methacrylic acids are described. The principal trends and prospects in the application of the high-molecular-weight products obtained in various branches of the national economy are indicated.

The bibliography includes 158 references.

I. Introduction

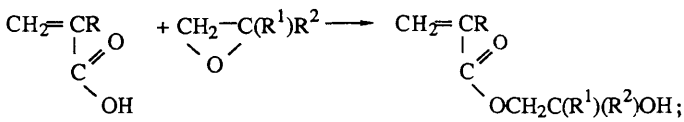
Water-soluble and hydrophilic polymers and copolymers are valuable products with unusual physicochemical characteristics. A specific feature of these compounds is the presence in their macromolecules of definite functional groups—hydroxy-, carboxy-, carbonylate, hydroxyalkyl, sulpho-, and other groups. The ratio of the hydrophilic and hydrophobic fragments in the macrochain determines the solubility in water and hydrophilicity of the polymers and copolymers. Here it is essential to bear in mind also the possibility of interchain and intrachain chemical bonds (the so called cross-links), which are formed in the synthesis of the macromolecular compounds or are introduced deliberately into the final product. They give rise to significant amendments to the physicochemical properties of the product, including a change in its solubility. These features must be taken into account in selecting approaches to the synthesis of the polymers and copolymers used to produce various materials with a specified range of physicochemical properties.

Water-soluble and hydrophilic polymers and copolymers are widely used in industry, agriculture, medicine, and science.

II. Synthesis of hydroxyalkyl esters of acrylic and methacrylic acids by the reaction of the monomeric acids with epoxyalkanes

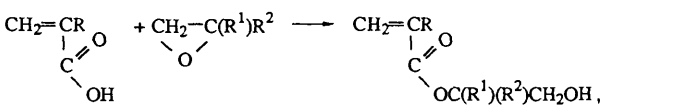
The hydroxyalkylation of acrylic (AA) and methacrylic (MAA) acids is of great applied importance because the final products of this reaction (unsaturated glycol esters) are valuable monomers from which it is possible to obtain polymeric materials with a wide variety of properties.

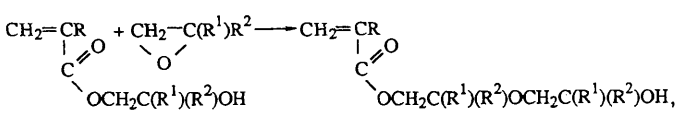
The addition of an epoxyalkane (EA) to AA and MAA, leading to the initiation of the formation of the hydroxyalkyl group, proceeds in accordance with the following scheme:

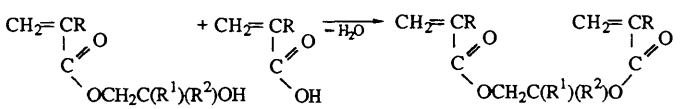


where R = H, CH_3, R^1 = H, CH_3, C_2H_5, R^2 = H, CH_3.

Apart from the formation of glycol monoesters, the following reactions are also possible theoretically:







The probability of each of these reactions is determined by the experimental conditions (molar ratio and concentrations of the reactants, temperature, nature of the reaction medium, etc.).

The addition of the epoxyalkane to AA and MAA in the presence of a catalyst is observed at temperatures below 100 °C. Inorganic and organic compounds of different classes have been proposed as catalysts. The weight of the catalyst is between 0.1 and 10% of that of the monomeric acid.

Among inorganic compounds, one may point to derivatives of tervalent iron: alkoxides (triethoxide, tri-δ-chlorobutoxide) and carboxylic acid salts (iron triacetate),[1] acetylacetonate and ethyl acetoacetate,[2] acrylate and methacrylate,[3] halides, $Fe(NO_3)_3$, $Fe(SCN)_3$, $Fe_2(CO_3)_3$, and $Fe_2(SO_4)_3$.[4,5] Mercury, chromium, copper, and iodine compounds are used as promoting agents in these reactions. Hydroquinone serves as a polymerisation inhibitor. In order to prevent the formation of quinone, compounds of alkali or alkaline earth metals, quaternary ammonium bases, amines, pyridine, and their salts are added. The yield of the monomeric esters exceeds 90% and their purity is 94–99%. The content of the unreacted monomeric acid is 0.2 wt.%. Hydroxyalkyl esters of AA and MAA are obtained also in the presence of other tervalent iron compounds,[6–10] for example, the hydroxide[9] and salts with aromatic carboxylic acids.[10] In the latter case, a small amount of diesters and dialkylene glycol monoacrylates and monomethacrylates is also formed.

$AlCl_3$ may be used as the catalyst of the hydroxyalkylation of AA and MAA;[11–16] $SnCl_4$ and BF_3 are unsuitable for this purpose, since they induce the polymerisation of the unsaturated acid even in the presence of an inhibitor.[11] A number of compounds of tervalent chromium (simple salts of aliphatic C_1-C_{36} acids and carbocyclic acids, coordination compounds with aliphatic or aromatic acids or *o*-hydroxyacids) have also been proposed.[17,18] When chromium is replaced by manganese and vanadium, the catalyst becomes ineffective. Chromium(III) halides[19,20] and chromium(III) salts of unsaturated aliphatic acid,[19] as well as Cr_2O_3 [19] and oxochlorochromium(III) acrylate and methacrylate[21] (the content of diesters in the products is 0.09%) have also been recommended.

Hydroxyalkyl acrylates and methacrylates (HOAA and HOAMA) can be obtained by the reaction of AA and MAA with an epoxyalkane in the presence of LiOH or $LiOH.H_2O$,[22] LiCl,[23] and lithium acrylate or methacrylate.[24] It is of interest that hydroxyalkyl methacrylates are formed with the involvement of potassium methacrylate, but potassium acrylate does not exhibit catalytic activity in the synthesis of hydroxyalkyl acrylates.[25] The use of titanium and zinc chlorides and alkoxides, their chelate compounds, and the products of their partial hydrolysis,[26] as well as vanadium compounds such as VCL_3, VCl_4, VOCl, $VOCl_3$, $V_2(SO_4)_3$, vanadyl sulphate, vanadyl acetylacetonate[27] (diesters are hardly formed as side products), and free iodine[28] has also been reported.

The esterification of AA and MAA by C_2-C_4 epoxyalkanes can be achieved under the influence for both an anion-exchange resin containing quaternary ammonium groups $[CH_2N^+(CH_3)_2C_2H_4OH]X^-$, where X^- is a univalent anion, for example the Dowex resin which is a copolymer of styrene with 8% of divinylbenzene[29–31] (the product contains 0.62% of the diglycol ester, 1.49% of the glycol diester, and 0.87% of the initial acid), as well as a cation-exchange resin of the sulphonic acid type with an aniline derivative.[32]

The hydroxyalkylation of AA and MAA is also possible in the presence of organic bases: triphenylphosphine, tributylphosphine, triethyl phosphite[33] (diacrylates and dimethacrylates are absent from the final product), cyclic and acylic compounds containing the paramagnetic nitroxy-group serving simultaneously as a polymerisation inhibitor,[34] carboxylic acid amides,[35] trialkylamines and dialkylanilines,[36–43] secondary aliphatic amines[37] (the content of diesters reaches 0.7% in the products), substituted ammonium and ammonium acrylate salts,[38] pyridine and alkylpyridines[42,44,45] and their salts with organic or inorganic acids,[43,44] quaternary pyridinium salts of the type of *N*-ethylpyridinium bromide[46] (the product does not contain appreciable amounts of diesters), and *N*-(carbamoyl-oxyalkyl)pyridinium halide or similar salts of other heterocyclic nitrogen-containing compounds[47] (high purity of the products and the absence of side products have been noted).

The hydroxyalkyl esters of AA and MAA are purified by fractional distillation,[48] where the polyalkylene glycols $HO[CH_2CH(R)O]_nH$ ($R = H, CH_3$; $n = 3-20$) may be added to prevent the formation of diesters,[49,50] or by distillation in the presence of polymerisation inhibitors (for example, hydroquinone) and various bases—alkali and alkaline earth metals, ammonia and its derivatives, amines or pyridines,[51] and hydrazine hydrate or β-hydroxyethylhydrazine.[52] In order to prevent the polymerisation of hydroxyalkyl acrylates and methacrylates during distillation, the liquid acrylate may be introduced into the mixture.[53] A procedure is available for the distillation of hydroxyalkyl esters of AA involving the addition of nitrosodiphenylamine in order to prevent their polymerisation during manufacture, transport, and storage.[54]

III. Polymerisation of hydroxyalkyl esters of acrylic and methacrylic acids

The existing publications on the polymerisation of hydroxyalkyl esters of AA and MAA are mainly devoted to processes involving the preparation of polymers of 2-hydroxyethyl methacrylate (2-HOEMA) (see, for example, the communications of Lavrov and co-workers[55–58]).

The radical polymerisation of 2-hydroxyethyl methacrylate can be achieved in bulk, in solution, and in emulsion (in organic solvents and in water). A number of procedures are used to obtain soluble polymers. For example, mixtures of dimethacrylates are removed from the aqueous solution of the monomer by their extraction with an organic solvent—preferentially hexane, heptane, and toluene. It is desirable that the polymerisation of 2-hydroxyethyl methacrylate be carried out in the presence of chain-transfer agents. The solubility of the 2-hydroxyethyl methacrylate polymer can be achieved also when the polymerisation is carried out in dilute solutions in organic solvents (benzene, chloroform) in which the monomer and the initiator dissolve, while the polymer itself does not dissolve and does not swell. The polymer is water-soluble also when the polymerisation is carried out in solvents such as dimethylformamide (DMF) and dimethyl sulphoxide (DMSO) as well as in water (for polymerisation in water, it is recommended that an oxidation-reduction initiating system of the type of persulphate salts–ascorbic acid be used). Peroxides, hydroperoxides, and azo-compounds can serve as radical initiators for the polymerisation of 2-hydroxyethyl methacrylate.[59] Application of the method described leads to the formation of a 2-hydroxyethyl methacrylate polymer with a molecular weight between 500 and 700 000.

High-molecular-weight polymers of 2-hydroxyethyl acrylate and methacrylate can be obtained without an initiator by freezing a mixture of an aqueous solution of the monomer with a hydrophobic

solvent of the type of alkyl acetates or dialkyl ethers and by irradiation from the ionised gas of a plasma discharge.[60]

In the study of the kinetics of the polymerisation of 2-hydroxyethyl methacrylate, features close to the classical ones are mainly observed. The order of the reaction in organic solvents with respect to the radical initiator, azobisisobutyronitrile (ABIBN), was found to be half. In ethanol, the reaction order with respect to the monomer was 1.2 and in dethylene glycol 0.9. In polymerisation in water initiated by the ammonium persulphate–ascorbic acid system, the reaction order was found to be unity with respect to 2-hydroxyethyl methacrylate. The order with respect to ammonium persulphate was found to be 0.8 and that with respect to ascorbic acid was zero.

The presence in the system of chain-transfer agents affects both the rate of polymerisation of 2-hydroxyethyl methacrylate and the possibility of the manifestation of the gel effect observed in polymerisation in bulk in the absence of chain-transfer agents.[59] The yield of the polymer obtained with the aid of ABIBN and methyl azobisisobutyrate then reaches 80% (at 70 °C).[61]

In the presence of ethylene glycol dimethacrylate (EGDMA) as the cross-linking agent, 2-hydroxyethylmethacrylate forms films[62] and gel-like products[63] as a result of polymerisation in water. These swell in water and in water–dioxane mixtures. The study of the kinetics of the radical polymerisation of 2-hydroxyethyl methacrylate in bulk in the presence of 0.07–1.00% of EGDMA (using ABIBN and dicyclohexyl prooxydicarbonate as the initiator) by heat flux microcalorimetry[64] showed that, for a conversion less than 10%, the polymerisation process obeys the classical rules, while for a higher conversion of the monomer a significant self-acceleration of the process is observed, its strength depending on the content of EGDMA and 2-hydroxyethyl methacrylate. For the 0.2% content of EGDMA, the polymers formed (yield 90–96%) are completely insoluble owing to their cross-linked structure. A decrease in the EGDMA content to 0.07% makes it possible to obtain soluble polymers with a molecular weight of 315 000–792 000.

The radical polymerisation of 2-hydroxyethyl methacrylate in the polyvinylpyrrolidinone (PVP) matrix in different solvents is of interest.[65] The study of the process kinetics showed that an increase in the rate of polymerisation in the absence of highly polar electron-donating solvents is induced by the complex formation reaction between polyvinylpyrrolidinone and monomer.

The conformational characteristics of the 2-hydroxyethyl-methacrylate polymer (isotactic) were investigated by Kim and co-workers using viscometric[66,67] and fluorescence[67] methods. It was established that the chain of the 2-hydroxyethyl methacrylate polymer is more expanded in the salt solution containing ions incorporated in the water structure. In terms of their disruptive effect on the conformation of the given polymer, anions can be arranged in the sequence $SO_4^{2-} < F^- < I^- < NO_3^- < SCN^-$. The polymer conformation is more sensitive to changes in the anion than in the cation. The conformational characteristics of the isotactic 2-hydroxyethyl methacrylate polymer in water–alcohol (methanol, ethanol, propanol, isopropyl alcohol, ethylene glycol) mixtures were detected from the change in the intensity of the fluorescence of auramine introduced into the polymer solution and in the specific viscosity of the solutions. It was shown that in water the 2-hydroxyethyl methacrylate polymer has a compact structure stabilised by the hydrophobic interactions of the CH_3 groups. The structure is disrupted by alcohols. The disruption of the complex compact structure is accompanied by a decrease in the fluorescence intensity and by an increase in the specific viscosity of the solution over a narrow range of variation of the solvent composition for all alcohols other than ethylene glycol. With increase in the length of the aliphatic group of the alcohol, the compact structure is disrupted for a lower content of the latter in water. The disruptive effect of ethylene glycol can be explained by the formation of hydrogen bonds between the polar groups of the 2-hydroxyethyl methacrylate polymer and the alcohol.

The viscous properties of aqueous solutions of isotactic 2-hydroxyethyl methacrylate polymer are influenced by urea and its derivatives (thiourea, methylurea, ethylurea, 1,3-dimethylurea, and tetramethylurea, and tetramethylurea).[68] Comparison of the excess molar heat capacities of the urea or its derivatives and of the ratio of the intrinsic viscosities $[\eta_{urea}]/[\eta_{water}]$ of solutions of the 2-hydroxyethyl methacrylate polymer in water containing urea or its derivatives and in pure water respectively shows, firstly, that in aqueous solutions the isotactic polymer has the structure of a compact statistical coil and, secondly, that the addition of urea or its derivatives leads to a disruption of the compact structure of the 2-hydroxyethyl methacrylate polymer. This can be explained by the breakdown of the water structure under the influence of urea or its derivatives and by the interaction between the polymer and the additive. The temperature variation of $[\eta_{water}]$ shows that at 20 °C the isotactic 2-hydroxyethyl methacrylate polymer has the most compact conformation.

The state of water in the hydrated 2-hydroxyethyl methacrylate polymer was studied by NMR spectroscopy and differential scanning calorimetry.[69] It was shown that the onset of the mobility of water corresponds to a temperature of approximately 180 K (below which the system is a glass). In specimens with a higher water content, an appreciable proportion of mobile water freezes at 230–260 K. Near 273 K, the behaviour of water is complex and above room temperature chemical exchange processes are manifested. The equilibrium water content in the 2-hydroxyethyl methacrylate and 2-hydroxypropyl methacrylate polymers has been measured in distilled water and in phosphate buffer.[70] It was noted that in distilled water the equilibrium water content increases with increase in the hydrophilicity of the polymer and is almost independent of its molecular weight. In the buffer solution the degree of swelling and the amount of "frozen" water in the polymer are anomalously high, which can be explained by the ionisation of small amounts of methacrylic acid present in the polymers.

A macromonomer with two terminal COOH groups and OH side groups, having the formula $HOOCCH_2CH(COOH)S[CH_2C.(CH_3)COOCH_2CH_2OH]_nH$, was synthesised by the radical polymerisation of 2-hydroxyethyl methacrylate in tetrahydrofuran (THF) at 60 °C in the presence of thiomalic acid $HOOCCH(SH)CH_2COOH$.[71] It is used for the preparation of grafted polyamide copolymers.

The kinetics of the polymerisaiton of 2-hydroxypropyl methacrylate[39–41,72] and 2-hydroxypropyl acrylate (2-HOPA) [41,72,73] were investigated by the dilatometric method in ethanol with the process influenced by persulphate salts. In the case of 2-hydroxypropyl acrylate, the orders of the polymerisation reaction with respect to the monomer and initiator are close to the classical values (1 and 0.5), but in the case of 2-hydroxypropyl methacrylate the order with respect to the monomer is higher (1.77) and that with respect to the initiator is zero (because of its insolubility in ethanol, the persulphate is introduced in aqueous solution, which leads to the separation of the monomer and initiator phases). It was shown that the polymerisation of 2-hydroxypropyl methacrylate is described by the equation

$$1/0.77\ [M]^{0.77} = k\tau + 1/0.77\ [M]_0^{0.77}$$

where $[M]$ and $[M]_0$ are the current and initial concentations of the monomeric ester, k is the overall polymerisation rate constant, and τ is the time. The activation energy for this process was found to be 8.75 kcal mol^{-1} and the pre-exponential factor was 7.76×10^5.

In the study[73] of the effects of the nature of the reaction medium on the polymerisation of 2-hydroxypropyl acrylate at 50 °C with ammonium persulphate as the initator, it was established that the highest rate of reaction is observed in ethanol, THF, and DMSO and the lowest in acetone and DMF. The rate decreases further in the sequence water–isopropyl alcohol–methanol–1,4-dioxane, but under these conditions the final degree of conversion in methanol is much higher than in isoropyl alcohol. A lower rate of polymerisation of 2-hydroxypropyl acrylate was noted in acetonitrile.

The results of studies[73] of the kinetics of the polymerisation of 2-hydroxypropyl acrylate in ethanol–water and acetone–water binary mixtures indicate an inverse correlation between the rate of polymerisation and the volume fraction of water in the system, but in the case of the complete replacement of ethanol or acetone by water the rate of polymerisation increases. The 2-hydroxypropyl acrylate polymer is soluble in water only when its molecular weight is low.

The study[73] of the temperature variation of the polymerisation of 2-hydroxypropyl acrylate in ethanol with ammonium persulphate as the initiator at 40–70 °C showed that the rate of polymerisation increases as the temperature is reduced in the range from 40 to 65 °C. At 70 °C, the rate of polymerisation and the final degree of conversion of 2-hydroxypropyl acrylate have the minimum values in the experimental temperature range, which is probably associated with the predominance of the chain termination reaction.

The most effective initator, leading to the attainment of the optimum rates of the process and the optimum final conversion of 2-hydroxypropyl acrylate, is ammonium persulphate. Potassium persulphate exhibits a much lower initiating activity. Hydrogen peroxide occupies an intermediate position. ABIBN and benzoyl peroxide are fairly powerful initiators of the radical polymerisation of 2-hydroxypropyl acrylate. It has also been shown experimentally[73] that sodium sulphite and thiosulphate, which form redox systems with the persulphate salt, exhibit an activating affect on the polymerisation of 2-hydroxypropyl arylate.

Table 1. Rate constants for the polymerisation of 2-hydroxypropyl acrylate in ethanol (with ammonium persulphate as the initiator) at different temperatures.[73]

Constant	50 °C	55 °C	60 °C
k_i, s^{-1}	$7.24 \cdot 10^{-5}$	$11.06 \cdot 10^{-5}$	$13.85 \cdot 10^{-5}$
k_p	0.646	65.242	102.259
k_t	$5.388 \cdot 10^3$	$5.433 \cdot 10^5$	$8.531 \cdot 10^5$
k	$1.059 \cdot 10^{-3}$	$1.315 \cdot 10^{-3}$	$1.843 \cdot 10^{-3}$

2-Hydroxypropyl arylate is capable of photochemically initiated polymerisation (on irradiation with blue light). This makes it possible to employ the rotating sector method for the determination of the rate constants for the propagation (k_p) and termination (k_t) stages in the polymerisation process. These constants as well as the initation constant k_i, calculated by the inhibition method, are listed in Table 1 (k is the overall rate constant for the polymerisation of 2-hydroxypropyl acrylate).

The activation energy for the polymerisation process proved to be 10.37 kcal mol^{-1}. The Arrhenius equation assumes the following form:

$$k = 11.04 \cdot 10^7 \exp(-5220/T).$$

The activation energy for the initiation of the polymerisation of 2-hydroxypropyl acrylate with ammonium pesulphate as the initiator is 13.81 kcal mol^{-1}. The temperature variation of the initiation rate constant is described by the following equation:[73]

$$k_i = 17.69 \cdot 10^8 \exp(-6953/T).$$

IV. Copolymerisation of hydroxyalkyl esters of acrylic and methacrylic acids

Most of the published studies on the copolymerisation of the hydroxyalkyl esters of AA and MAA are devoted to the 2-hydroxyethyl methacrylate copolymers. The results of studies of its copolymerisation with a number of other methacrylate esters have been described:[74–79] methyl methacrylate (MMA),[74,79] ethyl methacrylate (EMA),[75,78] butyl methacrylate (BMA),[74,75,79] tributyltin methacrylate,[76] lauryl methacrylate,[77] and decyl methacrylate.[79] The copolymerisation is carried out in solution[74,77,79] or in bulk.[75] The solvents employed are methanol,[74,79] benzene, THF, t-butyl alcohol, and DMF.[77] The initiators used are benzoyl peroxide,[75] ABIBN,[77] and ammonium persulphate[79] (temperature 50–70 °C). With increase in the mole fraction of 2-hydroxyethyl methacrylate in the copolymer, its intrinsic viscosity also increases (the molecular weights reach one million and above[75]). There is a parallel increase in the swelling coefficient of the copolymer, its values being in the range 21.27–27.14 in the case of the copolymers with ethyl and butyl methacrylates. It was established that the introduction of up to 10% of alkyl methacrylate into the chain greatly alters the solubility and the physicomechanical properties of the polymer. The copolymers form transparent films with good adhesion to glass and metal. The copolymerisation constants (r_1 and r_2), calculated by the Kelen–Tudes, Feynman–Ross, and Ezrielev methods and from data based on the $Q-e$ scheme, are presented in Table 2.

The copolymerisation of 2-hydroxyethyl methacrylate with both 2-hydroxyethyl arylate (2-HOEA) and acrylic and methacrylic acids and their sodium or potassium salts has also been investigated.[80] Dispersion (derivatives of cellulose or anhydrosorbitol ethers served as dispersing agents) of 2-hydroxyethyl methacrylate together with an aqueous solution of the comonomer in an organic solvent immiscible with water (benzene, heptane, hexane, $CHCl_3$, CCl_4, xylene) makes it possible to obtain powdered water-soluble copolymers.

The copolymerisation of 2-hydroxyethyl methacrylate with acrylic acid has been investigated[81] in water at 20 °C in the presence of the ammonium persulphate–ascorbic acid initiating system. It was shown that, with increase in the overall concentration of the monomers from 0.4 to 1.0 M, the rate of reaction rises from 3.6×10^{-5} to 3.5×10^{-4} mol $litre^{-1}$ s^{-1}. The copolymerisation constants are 1.55 and 0.36 respectively. The best unit alternation effect in the

macrochain is observed for a 2-hydroxyethyl methacrylate mole fraction in the mixture of comonomers of 0.2–0.4.

It has been shown[82] that the rate of copolymerisation of 2-hydroxyethyl methacrylate with *N*-vinylsuccinimide increases with increase in the ester content in the initial mixture. The rate of copolymerisation in benzene is significantly higher than in DMSO and the copolymerisation constants, calculated taking into account the influence of the preterminal unit differ, which leads to different microstructures of the copolymers. According to ^{1}H NMR data the probability of the formation of the $M_1M_2M_1$ triads is greater in benzene.

Table 2. Constants for the copolymerisation of 2-hydroxyethyl methacrylate (r_1) with other monomers (r_2).

Comonomer (solvent)	r_1	r_2	Refs.
Methyl methacrylate (methanol)	0.96	0.5	[74]
	0.81±0.10	0.45±0.03	[79]
Butyl methacrylate (methanol)	0.52	0.62	[74]
	0.76±0.14	0.61±0.06	[79]
Decyl methacrylate (methanol)	0.66±0.05	2.65±0.01	[79]
Lauryl methacrylate			
(benzene)	11.2	0.7	[77]
(THF)	2	1	[77]
(t-butyl alcohol)	1.6	0.5	[77]
(DMF)	0.8	0.8	[77]
Tributyl methacrylate	2.45	0.39	[76]
Acrylic acid (water)	1.55	0.36	[81]
N-Vinylsuccinimide			
(benzene)	7.36±1.66	0.09±0.02	[82]
(DMSO)	8.5	0.05	[82]
Styrene			
(butanol, propanol, DMF)	0.59	0.53	[85]
(toluene)	1.65	0.50	[85]
Acrylamide (water)	0.98	0.14	[87]
p-Nitrophenyl acrylate (alcohol)	1.4	0.7	[96]
N-acryloyloxyethylsuccinimide (alcohols)	1.0	0.8	[96]

Lavrov et al.[83] synthesised the copolymer of 2-hydroxyethyl methacrylate with *N*-vinylamidosuccinic acid. The study of the properties of aqueous solutions of the copolymer by the viscometric titration method showed that an increase in the viscosity of the solution is observed up to a degree of ionisation $\alpha = 0.85$, which indicates the uncoiling of the macrocoil. The maximum size of the macromolecules exhibiting polyelectrolyte properties is observed at pH 7.5–8.5 ($\alpha = 0.85-0.95$). On further increase in the pH of the medium, the molecules assume a more twisted conformation.

The 2-hydroxyethyl methacrylate–N-vinyl-2-pyrrolidinone copolymer was obtained in the form of a hydrogel with the aid of ABIBN at 70 °C.[84] It was shown by optical and refractometric methods that the degree of hydration of the copolymers and their linear expansion on hydration increase in the ranges 10–80 and 5–40% respectively with increase in the content of the second comonomer units in the copolymer from 0 to 75%. The permeability of the swollen hydrogels to oxygen increases with increasing degree of hydration.

The copolymerisation constants have been determined[85] for the 2-hydroxyethyl methacrylate–styrene system in solutions in butanol, propanol, DMF, and toluene (Table 2).

The possibility of obtaining cross-linked (in the form of hydrogels) and non-cross-linked 2-hydroxyethyl methacrylate–acrylamide (AAM) copolymers by radical copolymerisation in water initiated by the ammonium persulphate–ascorbic acid system has been demonstrated.[86] Methylenebisacrylamide and triethylene glycol dimethacrylate were used as cross-linking agents. It was established that the introduction of acrylamide units into the polymer chain increases the water-absorbing properties of the product. Calculation of the probability of the distribution of the units of the comonomers from the copolymerisation constants determined by the Kelen–Tudes method[87] (Table 2) indicates a tendency towards the alternation of the units to give the ratio acrylamide:2-hydroxyethyl methacrylate = 2:1.

The copolymers of 2-hydroxyethyl methacrylate with sodium 2-acrylamidomethylpropanesulphonate (2-AA-2-MPSNa) having different compositions (78:22, 60:40, 40:60, and 20:80) have been synthesised.[88] The heterogeneity of the copolymers was investigated by the isotachophoresis method — the separation of aqueous buffer solutions into series of consecutive zones in conformity with their electrophoretic mobility. Aqueous solutions of the 60:40 and 40:60 copolymers at copolymer concentrations in excess of 10% separate into two phases. The upper layer contains the copolymer enriched in 2-AAM-2-MPSNa and the lower is enriched in 2-hydroxyethyl methacrylate. The effective electrophoretic mobilities increase with increase in the mole fraction of 2-AAM-2-MPSNa to 0.5–0.6 and are almost independent of the composition of the copolymer for high contents of 2-AAM-2-MPSNa.

Polymers with a degree of polymerisation of approximately 300 and free from betaine groups have been obtained[89] by the polymerisation of 2-hydroxyethyl acrylate, 2-hydroxyethyl methacrylate, 2-hydroxypropyl acrylate, or 2-hydroxypropyl methacrylate with methyl acrylate and *N,N*-dimethyl-*N,N*-diethylaminoethyl methacrylate in 10–20% KOH solution at 65–90 °C or in an emulsion at 50–70 °C with subsequent hydrolysis of the final product in an alkaline medium.

High-molecular-weight acrylic copolymers with $[\eta] = 12-17$, which are suitable as flocculating agents, have been synthesised[90] by the copolymerisation of hydroxyethyl acrylate or methacrylate and the vinyl monomer $CH_2=CR^1COY(CH_2)_n.N^+R^2R^3R^4X^-$ (where R^1 = H, CH_3; R^2-R^4 = alkyl; X^- = acid residue), for example, methacryloyloxyethyltrimethylammonium chloride, in a thin layer on a moving strip under the influence of UV light in the presence of non-ionic surfactants and a photoinitiator. The polymer layer is continually removed from the strip.

Copolymers of 2-hydroxyethyl methacrylate and 2-hydroxypropyl methacrylate with vinyl acetate (VA) have been obtained by the radiation method[91] in the presence of cross-linking agents, for example ethylene glycol.

The radical copolymerisation of 2-hydroxyethyl methacrylate monomers containing active functional groups (*p*-nitrophenyl acrylate and *N*-acryloyloxyethylsuccinimide) initiated by ABIBN has been investigated[92] in alcohol in order to produce reactive carriers for the immobilisation of proteins, enzymes, and aminoacids. The copolymerisation constants were determined by the Feynman–Ross and Ezrielev methods (Table 2).

Polymeric products with a high mechanical strength have been obtained[93] by the suspension copolymerisation of 2-hydroxyethyl

methacyrlate with the monomers $\{CH_2=CRCOO(CH_2CH_2O)_n.[CH_2CH(CH_3)O]_m\}_3P=O$ (where R = H, CH_3; m = 0–30; n = 0–3; $m + n \geqslant 1$) in 50:50 to 10:90 ratios.

The radical copolymerisation of 2-hydroxyethyl methacrylate with both *N,N'*-diethyl-*N*-(4-vinylphenylethyl)ethylenediamine and with its self-condensation product (initiated by lithium diisopropylamide in THF at 20 °C) in benzene, ethanol, and *o*-dichlorobenzene has been described.[94]

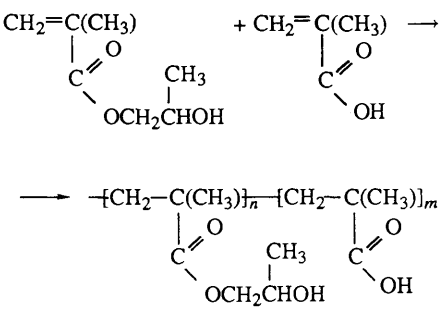
Terpolymers based on hydroxyalkyl acrylates and methacrylates (with C_6-C_{12} alkyl groups) and styrene (α- or *p*-methylstyrene) have been obtained in solution in ketones with the reaction initiated by peroxides.[95,96] Mono-, di-, or tri-alkyl acrylates and methacrylates (with C_2-C_{18} alkyl groups) [95] or acrylic (methacrylic) acid were used as the third comonomer. The copolymers are suitable for coatings and have a narrow molecular weight distribution and a molecular weight less than 4000.[96] The OH groups in the copolymer are partly esterified by treatment with natural or synthetic aliphatic acids in the presence of a catalyst.[95]

Copolymers used as current conducting salts, flocculants, and additives to cosmetic compositions have been obtained[98] by the radical copolymerisation of hydroxyalkyl arylates and methacrylates in an aqueous medium at 40–100 °C with the monomers $[R^1R^2R^3N^+CH(R^4)CH(R^5)OH]A^-$, where R^1 = C_2-C_4 alkenyl, n = 1–18, X = O or NH, R^6 = H or CH_3, R^2 = C_1-C_{18} hydroxyalkyl, R^3 = C_2-C_4 alkenyl or C_1-C_{18} alkyl, R^4, R^5 = H or C_1-C_{28} alkyl, and A = anion.

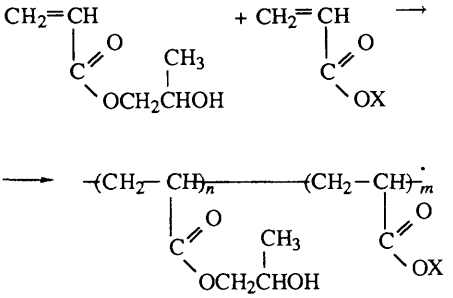
Copolymers of 2-hydroxyethyl acrylate, vinyl acetate, and ethylene, whose microstructure was investigated by ^1H and ^{13}C NMR, have also been synthesised.[98] It was shown that, for a 2-hydroxyethyl acrylate content of 5%, its units are not distributed statistically. For a vinyl acetate content of 25%, ethylene–vinyl acetate–vinyl acetate and ethylene–vinyl acetate–ethylene triads are formed in the chain, but there are no ethylene–vinyl acetate–hydroxyethyl acrylate and hydroxyethyl acrylate–ethylene–vinyl acetate triads. With increase in the molecular weight of the fractions of the copolymer with 25% of vinyl acetate, isolated by gel-permeation chromatography, the content of 2-hydroxyethylacetate also increases.

As can be seen from the data presented above, 2-hydroxyethyl methacrylate and its analogues are very active monomers in copolymerisation reactions. This is confirmed also by the Alfrey–Price parameters quoted in the literature:[81–83] Q = 1.16, e = 0.30 and Q = 0.80, e = 0.20.

The radical polymerisation of 2-hydroxypropyl methacrylate with methacrylic acid[39–41]



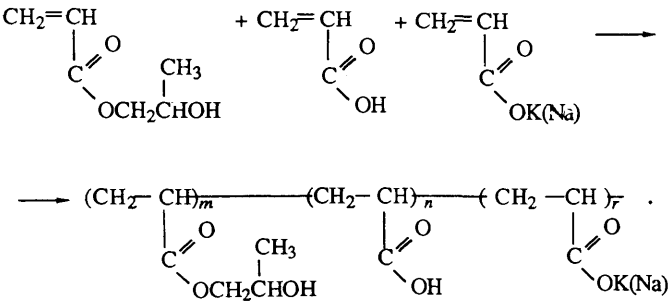
and of 2-hydroxypropyl acrylate with both acrylic acid and acrylate salts[73]



where X = H, K, or Na, has been achieved. The initiator was ammonium persulphate.

It has been shown that the highest solubility of the 2-hydroxypropyl methacrylate–methacrylic acid copolymer in water is achieved when the product is obtained in organic media, which is due to its lower molecular weight. With increase in the mole fraction of both 2-hydroxypropyl methacrylate and 2-hydroxypropyl acrylate in the copolymer, its solubility in water is impaired. The constants for the copolymerisation of 2-hydroxypropyl methacrylate and methacrylic acid proved to be 0.99 and 0.31, which indicates the higher reactivity of the ester. In the copolymerisation of 2-hydroxypropyl acrylate with acrylic acid, the difference between the reactivities of the comonomers is much greater (r_1 = 17 and r_2 = 0.02), the overall order of the reaction with respect to the comonomers being 2 and that with respect to the initiator (ammonium persulphate) being 0.7. Alkali metal acrylates (potassium and sodium acrylates) exhibit a much higher reactivity in copolymerisation with 2-hydroxypropyl acrylate than does acrylic acid. Thus the constants for the copolymerisation of 2-hydroxypropyl acrylate and potassium acrylate are 1, 10, and 0.96.

The ternary copolymers of 2-hydroxypropyl acrylate, acrylic acid, and the alkali metalacrylates indicated above have been synthesised:[73]



It is of interest that, in order to attain the best solubility of both binary and ternary copolymers involving 2-hydroxypropyl acrylate in water, it is desirable to obtain the acrylate salts *in situ* (by the reaction of acrylic acid and alkali), without isolating them from aqueous solution, to make them undergo the polymerisation reaction initiated by ammonium persulphate.

There have been a number of studies on the graft polymerisation of hydroxyalkyl esters of acrylic and methacrylic acids. Graft copolymers based on 2-hydroxyethyl methacrylate and poly(vinyl

alcohol) (PVA) have been obtained[99] in DMSO using hydroperoxides and azo-initiators. The process characteristics indicate a matrix reaction mechanism. The activating effect of the hydrogen-bonded complex between 2-hydroxyethyl methacrylate, the initiator, and the OH groups of PVA on the course of the reaction has been demonstrated.[100]

The graft copolymerisation of 2-hydroxyethyl methacrylate (in DM using ABIBN) on unsaturated polyurethane, obtained from poly(ethylene glycol) (M = 1500), methylenebis-4-phenylene isocyanate, *cis*-but-2-ene-1,4-diol, and butane-1,4-diol (in a mixture of DMSO with 4-methyl-2-pentanone as the solvent) has been carried out.[101] 2-Hydroxyethyl methacrylate can be grafted also on a polyurethane in the form of an emulsion (with t-butyl-hydroperoxide as the initiator)[102] or a film (under the influence of γ-irradiation).[103] In the latter case, the degree of grafting increases with increase in the swelling time of the film. 2-Hydroxyethyl methacrylate is grafted with an induction period of 0.5–1 h.

Studies on the photografting of 2-hydroxyethyl methacrylate on polyvinylpyrrolidinone (PVP) have been carried out.[104–107] The component ratio was 70–95:30–5. The photosensitiser was benzoyl peroxide. With increase in the PVP content, the degree of conversion of 2-hydroxyethyl methacrylate and the maximum rate of its polymerisation diminish. At the same time, the gel formation time is reduced. On irradiation with UV light, the compositions harden in a thin layer, which makes it possible to obtain hydrophilic coatings and films with valuable properties. The formation of highly permeable copolymers with a network structure has been established. 2-Hydroxyethyl methacrylate can be grafted to PVP also electrochemically.[108] An initiator-free polymerisation of 2-hydroxyethyl acrylate and methacrylate in the presence of 10–40% of PVP (molecular weight 12000) at 50–80 °C has also been described.[109] The formation of the graft copolymer is observed at a temperature as low as 50–60 °C, while homopolymerisation of the ester does not occur under analogous conditions. The yield of the copolymer and the content of the gel-fraction in the system increase with increase in temperature and with decrease in the content of PVP in the initial mixture. The rate of polymerisation increases with increasing PVP content. Dilution of the mixture of the ester and PVP with hydroxylated solvents (water, cyclohexanol, ethanol, ethylene glycol, and diethylene glycol) increases the rate of polymerisation compared with polymerisation in bulk.

Chinese investigators have achieved[110] the graft copolymerisation of 2-hydroxyethyl methacrylate on polyethylene membranes initiated by ^{60}Co γ-rays in ethanol solution at 25 °C. The initial rate of grafting was proportional to the ester concentration and the irradiation intensity raised to powers of 1.0 and 0.5 respectively. The apparent activation energy in the range 25–66 °C and the frequency factory for the graft copolymerisation are 8.0 kcal mol^{-1} and 1.505 × 10^7 respectively. The dependence of the apparent grafting rate constant k on the absolute temperature is described by the equation

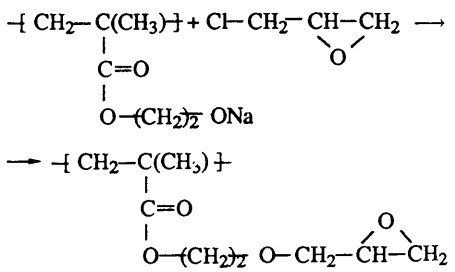
$$\ln k = 16.5269 - 4026(1/T).$$

It is suggested[111] that macroporous sorbents can be obtained by the polymerisation of 2-hydroxyethyl methacrylate initiated by ABIBN at 60–110 °C (or thermally at 100–150 °C or by exposure to radiation) in the presence of a copolymer of 2-hydroxyalkyl methacrylate (C_2–C_4 alkyl group) and a polyvinyl monomer, for example, C_2–C_4 alkylene dimethacrylate, as the carrier.

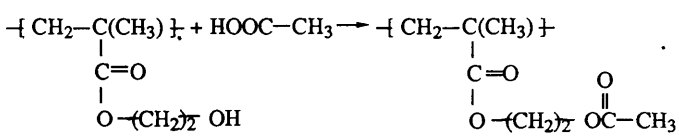
Gel-free hydroxylated graft copolymers, ensuring an effective distribution of metallic pigments without additives, are obtained[112] by the copolymerisation of monomers containing hydroxy-groups (2-hydroxyethyl methacrylate, 2-hydroxypropyl acrylate, and 2-hydroxypropyl methacrylate) and carboxy-groups (monoesters of maleic fumaric acids, acrylic acid, and methacrylic acid) in the presence of an acrylic polymer contaning ethoxy-groups, the ratio of the numbers of COOH groups in the monomer and of the epoxy-groups in the acrylic polymer ranging from 1:0.5 to 0.5:1. Grafting occurs as a result of the condensation fo the epoxy- and carboxy-groups.

V. Chemical modification of the polymers and copolymers of hydroxyalkyl esters of acrylic and methacrylic acids

One of the methods for the chemical modification of 2-hydroxyethyl methacrylate polymers involves the carrying out of polymer-analogue transformations via the hydroxy- or ester groups. The course of the reaction is inferred from the results of elemental and functional as well as IR spectroscopic analyses. The hydroxy-group in the 2-hydroxyethyl methacrylate units can react with alkali metals to form alkoxides and with acids and acid anhydrides to form esters.[113,114] When the 2-hydroxyethyl methacrylate units interact with maleic anhydride, ethylene glycol methacrylate maleates are formed.[115] The reaction with thionyl chloride leads to 2-chloroethyl methacrylate units. The reaction with phosgene can yield 2-chlorocarbonyloxyethyl methacrylate fragments. 2-Hydroxyethyl methacrylate oligomers react with diisocyanates to form polyurethanes.[115] Glycidyl ethers have been obtained by the reaction of the sodium alkoxide derived from the 2-hydroxyethyl methacrylate units with epichlorohydrin:[116]



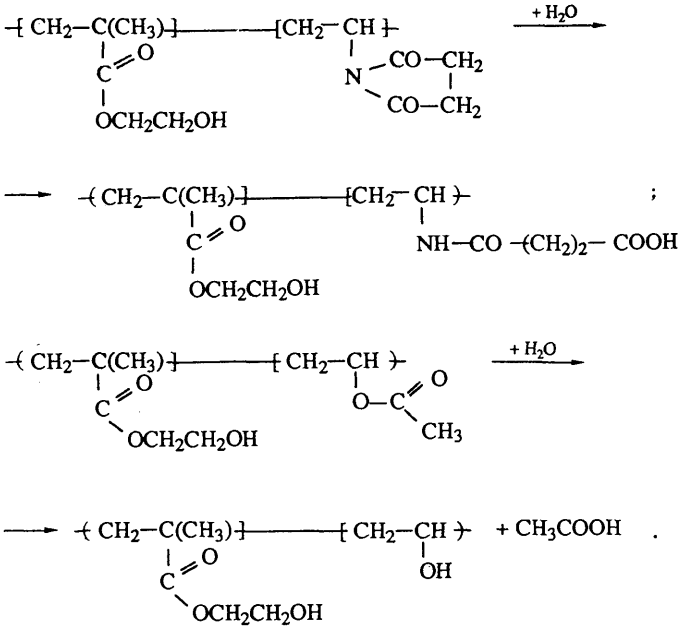
2-Hydroxyethyl methacrylate polymers enter into the acetal formation reaction involving the hydroxy-group. It has been suggested that this reaction be carried out with acetic acid in pyridine:[114]



The ester group in the 2-hydroxyethyl methacrylate units is very resistant to the action of hydrolysing agents. Alkaline hydrolysis of polymeric 2-hydroxyethyl methacrylate gels proceeds at a low rate only above 100 °C and acid hydrolysis with sulphuric acid under the

same conditions is slower still.[114] The possibility of hydrolysis at temperatures below 100 °C appears only when a non-cross-linked polymeric 2-hydroxyethyl methacrylate is used. In this case, the reaction is carried out in water (heterogeneous hydrolysis) or in a DMSO–water mixture (homogeneous hydrolysis) at 60–80 °C.[117,118] The kinetics of the alkaline hydrolysis of the polymer obey rules governing second-order reactions. In a heterogeneous medium, the hydrolysis is appreciably slower. At 20 °C, the 2-hydroxyethyl methacrylate units in the chain are not hydrolysed in either homogeneous or heterogeneous media.[117]

The *N*-vinylsuccinimide (VSI) and vinyl acetate units differ appreciably in their hydrolytic stability from the 2-hydroxyethyl methacrylate units,[117,119] which creates conditions for specific hydrolysis involving the vinylsuccinimide and vinyl acetate units in copolymers of 2-hydroxyethyl methacrylate with vinylsuccinimide and vinyl acetate, in which 2-hydroxyethyl methacrylate units are retained. The reaction results in the formation of copolymers of 2-hydroxyethyl methacrylate with *N*-vinylamidosuccinimic acid[117,118] and vinyl alcohol:[119]

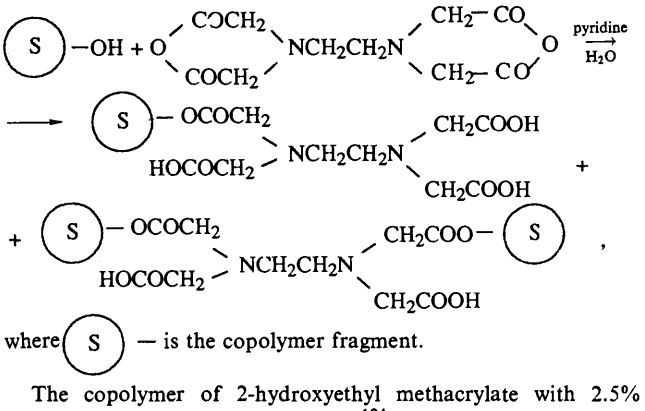


The degree of reaction involving the vinyl succinimide or vinyl acetate units is affected by the structure of the macrochain. The high reactivity of 2-hydroxyethyl methacrylate in copolymerisation with vinyl succinimide[120] and vinyl acetate[121] leads to single vinyl succinimide or vinyl acetate units separated by several 2-hydroxyethyl methacrylate units, which facilitates the interaction of the vinylsuccinimide or vinyl acetate units with the OH^- ion and permits their complete hydrolysis.

2-Hydroxyethyl methacrylate polymers can react with amines (ethanolamine, aniline, hydroxylamine), but the reaction is very slow even at 100 °C. The reaction with hydrazine proceeds most effectively.[114]

The reaction of the copolymer of 2-hydroxyethyl methacrylate and ethylene glycol dimethacrylate with the organosilicon compounds $(XR_m)_nSiR_{4-n}$, where X = NH_2, CO, COOH, HCO, etc., R and R′ = alkyl, n = 0–20, n = 1–3, has been described.[122]

By treating the copolymer of 2-hydroxyethyl methacrylate and ethylene glycol dimethyacrylate with dianhydride-complexones, it is possible to obtain chelating macromolecular products:[123]

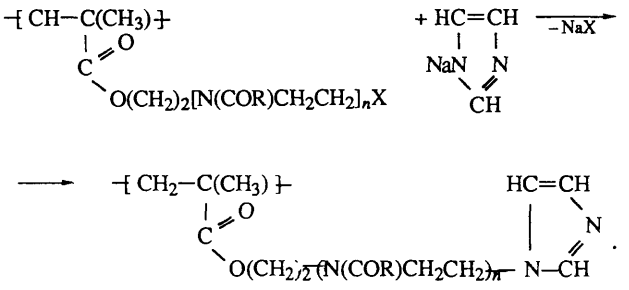


where (S) — is the copolymer fragment.

The copolymer of 2-hydroxyethyl methacrylate with 2.5% of methyl acrylate has been synthesised[124] and the interaction of gels of this copolymer with calcium ions has been shown that 2590 μg of calcium ions is absorbed per gramme of the gel at pH 8.5, while at 5.5 the gel collapses, which promotes the removal of calcium ions.

When the OH groups in the 2-hydroxyethyl methacrylate polymer are replaced by halogens (Br, Cl) and the product interacts with 2-R-oxazoline at 80–120 °C, polar graft copolymers are formed[123,125] with the units $-CH_2C(CH_3)COOCH_2CH_2.[N(COR)CH_2CH_2]_nX$, where R = H, C_1–C_3 alkyl, or phenyl, X = Br or Cl, and n = 1–20.

On treatment with sodioimidazole in methanol, THF, or DMF, the above haloderivatives of the polymeric 2-hydroxyethyl methacrylate give rise[123,126] to a product containing 0.9 mmol g^{-1} of imidazole groups:



Reactions in an aqueous medium on thin films of the cross-linked gel of the copolymer of 2-hydroxyethyl methacrylate with 2-isopropenylanthraquinone have been investigated[127] by UV and fluorescence spectroscopy. It was shown that fragments of anthrahydroquinone and of its tautomer (oxanthrone) are formed simultaneously on irradiation with near UV light.

VI. Properties and applications of the polymers and copolymers of hydroxyalkyl esters of acrylic and methacrylic acids

Polymers based on 2-hydroxyethyl methacrylate have many valuable properties: they are non-toxic, biologically compatible, and transparent and they adhere effectively to various substrates.

They are therefore recommended for use in the preparation of contact lenses, hydrogels for different purposes, membranes, films, adhesives, coatings, etc.[115,128–131]

The copolymers of 2-hydroxyethyl methacrylate with acrylic and methacrylic acids, methyl, butyl, and 2-hydroxypropyl methacrylates, as well as *N*-vinylpyrrolidinone,[132] N-1-(2-pyrrolidinonyl)ethylacrylamide,[133] styrene, and ethyl vinyl malonate are used for the manufacture of contact lenses.[115,129] Multicomponent copolymerisation is usually carried out in special moulds using a cross-linking agent (ethylene glycol dimethacrylate, etc.).[130,134]

Hydrophilic gels based on the 2-hydroxyethyl methacrylate polymers are used as carriers for physiologically active compounds,[135] the immobilisation of enzymes,[136,139] medicinal drugs,[140–143] and antigens and immunogenic substances,[130] for the preservation of enzymes and aromatic essential oils,[130] and in the manufacture of ion-exchange resins for the separation of biologically active substances.[130]

It has been established that the activity of immobilised enzymes depends on the gel structure. The introduction of a hydrophilic monomer into the polymeric 2-hydroxyethyl methacrylate gel increases appreciably the activity of the cells by virtue of the formation of a more porous gel structure, while the addition of a hydrophobic monomer lowers the activity of the cells immobilised in the gel as a result of the formation of a more rigid and finely porous gel structure.[138]

Ternary copolymers of 2-hydroxyethyl methacrylate, methyl methacrylamidoglycolate, and methyl methacrylate, deposited on a support, can be used[144] to eliminate specific pathological effectors from biological liquids of patients. These copolymers may contain covalently bound biologically active compounds capable of adsorbing the effectors.

The copolymers of 2-hydroxyethyl methacrylate with methyl methacrylate,[145,146] acrylamide,[147] and methyl acrylate[148,149] swell effectively in water. Thus the swellability of the 2-hydroxyethyl methacrylate–methyl acrylate copolymer in alkaline solutions reaches 3600% relative to the volume in an acid solution.[148]

2-Hydroxyethyl methacrylate-based gels are used to prepare implant for example, urinary bladder prostheses,[150] and catheters.[151] Membranes permeable to salts,[152–155] sugars,[152,154] urea,[154,155] dextran,[154] etc. have been developed on the basis of 2-hydroxyethyl methacrylate homopolymers and copolymers partly cross-linked with the aid of ethylene glycol dimethacrylate. Antithrombogens can be obtained by grafting 2-hydroxyethyl methacrylate on polystyrene, polyethylene, polytetrafluoroethylene, polyurethanes, PVA, and collagen.[130]

The copolymer of 2-hydroxyethyl methacrylate, methyl methacrylate, as well as sodium alginate can be used for the microencapsulation of immobilised cells,[156] while the copolymer of 2-hydroxyalkyl, acrylate and alkyl acrylate or methacrylate can be used for the microencapsulation of medicinal preparations.[157] The high capacity of 2-hydroxyethyl methacrylate polymers and copolymers for adhesion to various supports has led to its use for the preparation of coatings and adhesives.[130] The copolymers with methyl and butyl methacrylates, acrylic and methacrylic acid, etc. are used as aqueous compositions, solutions, and powdered compositions. 2-Hydroxyethyl methacrylate polymers and copolymers are employed in the preparation of transparent materials with a satisfactory wear resistance, hardness, and resistance to the appearance of turbidity,[130] and also for the preparation of compositions susceptible to thermal hardening[130] and photohardening.[158]

The copolymers of 2-hydroxypropyl methacrylate with methyl acrylate,[39,40] 2-hydroxypropyl acrylate, and potassium and sodium arylates as well as ternary copolymers of 2-hydroxypropyl acrylate with the above acrylate salts and acrylic acid[73] exhibit effective petroleum displacing properties. The copolymers of 2-hydroxypropyl acrylate with both potassium acrylate and acrylic acid exhibit bactericidal properties in relation to sulphate reducing bacteria evolving hydrogen sulphide, which stimulates the corrosion of metallic equipment in petroleum deposits.[73] In addition, the 2-hydroxypropyl acrylate–acrylic acid copolymer is an effective insulating agent, which to a large extent prevents the losses of drilling solutions and this increases the rate of drilling of petroleum and gas bore-holes.[73]

The hydroxyalkyl esters of acrylic and methacrylic acids are extremely promising and interesting monomers. A convenient method for the synthesis of these substances is believed to be the catalytic interaction of acrylic and methacrylic acids with the corresponding epoxyalkane. Homopolymers and copolymers with a wide range of exceptionally valuable properties can be synthesised from these esters. The homopolymers are obtained by the radical polymerisation of the hydroxyalkyl esters of acrylic and methacrylic acids, while the copolymers are obtained by the radical copolymerisation of the esters with monomers of different nature or by the chemical modification of homopolymers and copolymers. As a result of the above chemical reactions, it is possible to synthesise specifically high-molecular-weight compounds containing in their chains functional groups of the same or several different types. Depending on the chosen method of synthesis, there are then extensive possibilities for the regulation of the microstructure of the copolymers, i.e. of the nature of the alternation of the comonomer units in the chain.

Most of the studies published in this field have been devoted to the synthesis and applications of the polymers and copolymers of the esters synthesised by the reaction of methacrylic acid with epoxyethane. However, bearing in mind the comparative scarcity of epoxyethane and the much greater amounts of epoxypropane available as the starting material as well as certain difficulties involved in work with epoxyethane (its virtually gaseous state, explosive nature, high toxicity, and lower reactivity as a consequence of its symmetrical structure compared with hydroxypropane, which is an asymmetric epoxy-derivative), one may expect a growth of interest in the immediate future in the synthesis and application of the polymers and copolymers of the hydroxypropyl esters of acrylic and methacrylic acids. The results of studies included in this review and carried out at the Institute of Petrochemical processes of the Azerbaijan Academy of Sciences by the present authors and their co-workers are consistent with such forecasts.

Induced optical activity in cyclodextrin complexes

ABSTRACT. The phenomenon of induced optical activity (IOA) is briefly described. The IOA that occurs in complexes of cyclodextrins (CYDs) with achiral and chiral organic molecules is examined. The types of information obtained using chiroptical spectroscopic methods are described. It is shown how these methods in conjunction with the theoretical representation of this phenomenon can be used to obtain information about the fine structure of the complexes, including the orientation of the "guest" molecule in the cavity of the "host" molecule, the formation of two-guest complexes, and the selection of chiromers by complexation.

The bibliography includes 188 references.

I. Introduction

Rapid progress in the chemistry of cyclodextrins has occurred because of the unique ability of these compounds to react with a large number of organic and inorganic compounds to form complexes of the type "host–guest" (H–G),[7] which are classed as virtual topological isomers,[8] and it is very closely related to the development of a new topic–supramolecular organic chemistry.[9] As a result of this property CDXs can be used as models of enzymes,[3,10] catalysts of chemical reactions,[11] modifiers of pharmaceutical compounds,[12–14] and in a number of other areas of science and industry.[14]

One of the most important properties of CDXs that distinguishes them from the majority of synthetic hosts, such as podands, coronands, cryptands, etc.,[7] is their chirality, namely the property that distinguishes a compound from its mirror image.[15] It is true that the overall chirality of CDX molecules is regarded as insignificant because of their symmetrical structure,[16] but sufficient information has been collected for the chiral field of the CDX cavity to be considered capable of inducing optical activity in the electronic transitions of the guest molecule. In this review an attempt is made for the first time to correlate these data in order to demonstrate the potentialities of chiroptical methods, induced optical rotatory dispersion (IORD), and principally induced circular dichroism (ICD) for studying the fine structure of CDX complexes.

II. Induced optical activity

Induced optical activity (IOA) denotes[17] the induction of optical activity in the molecules of an achiral compound (the chromophore) when they are in contact with the molecules of a chiral compound (the inducer). The main consequence of this interaction is asymmetric perturbation of the electronic transitions of the chromophore by the chiral field of the inducer, with the result that the transitions become optically active and are exhibited in the optical rotatory dispersion (ORD) or induced optical rotatory dispersion (IORD) spectra and circular dichroism (CD) or induced circular dichroism (ICD) spectra. The asymmetric perturbation can be so intense that it stabilises certain chiral conformers of the chromophore, thus intensifying the parameters of the ICD spectra by many times. This occurs in many CDX complexes (see below). The phenomenon of ICD occurs for low-molecular-weight chromophores, such as saturated and aromatic ketones,[18–21] aliphatic nitrites,[20–21] azulenes,[22] and free-radical hydrazines[23] in the presence of the following inducers: 2,3-butanediol,[18] menthol,[19,27] diethyl tartrate,[20] nopinone,[22] 2-octanol,[23] and *N*-cetyl-α-phenylethylamine.[24] Metal complexes can also be subject to induced optical activity[18,25–29] from butanediols,[18,26] ethyl tartrates,[25] amino alcohols,[27,29] and amino acids.[28]

High-molecular-weight inducers, in particular biopolymers, have proved more effective than low-molecular-weight inducers. Thus, polypeptides give rise to strong IOA in dyes[30,31] and bile pigments,[32] while nucleic acids produce IOA in dyes.[33–35] Carbohydrates also give rise to IOA, with both monosaccharides (in ketones[36] and metal complexes[37]) and particularly polysaccharides being active. The IOA of pyrene and tetracyanonaphthodimethane in triacetylcellulose films,[38] azo dyes and bacterial polysaccharides.[39] and chitosan[40] can be given as an example. The IOA in the complexation of amylose with iodine[41] and in the complexation of anionic polysaccharides with cationic dyes[42,43] have been studied in particular detail. The IOA produced by the cyclic oligosaccharides—cyclodextrins—is discussed in the present review. Synthetic chiral polymers also give rise to IOA,[44–47] and the inducer and chromophore can be present in the same polymer molecule.[45] The induction of optical activity by supermolecular chiral structures such as liquid crystals[48,49] and micelles[50–52] is worthy of note.

The degree of IOA depends primarily on the structure of the inducer and chromophore. If the chirality of the inducer were the only condition for IOA to occur, there would be an infinite number of inducer–chromophore systems with IOA, which does not correspond to reality. It is evident that the chirality of the inducer is a necessary but incomplete condition for IOA to occur. However, for the present it is not possible to give comprehensive details of the precise conditions (they will be briefly reviewed in the concluding section). It may simply be stated that one of the sufficient

conditions for IOA to occur is an ordered supermolecular organisation in the system polymeric inducer–chromophore which restricts the number of rotational and translational degrees of freedom of the chromophore. In fact, the most intense IOA has occurred in systems with internally organised polymeric inducers that have sections of regular spiral conformation of the polymer chain, which evidently gives rise to a chiral configuration of the chromophore molecules (the formation of an internally asymmetric chromophore). This situation occurs, for example,[43] in the system sodium carboxymethylcellulose (anionic polysaccharide, inducer)–safranine T (cationic dye, chromophore), in which the value of the apparent molar ellipticity [θ] in the ICD spectrum is 10^5.

The nonspecific inducer–chromophore interactions that occur when chromophores are dissolved in chiral solvents[18,19,21–23,26,36] or in achiral solvents with chiral additives[19,20,24,25,27–29,36,37] constitute the opposite extreme for IOA. It is thought that the inducer–chromophore interaction is a dispersion interaction, which is expressed as dispersion-induced optical activity and hence dispersion-induced circular dichroism (DICD).[37]

Since information about the relative configuration of guest–host molecules in CDX complexes may be derived from the chiroptical properties of the complexes based on a correlation between the structure and the rotational properties (see below), a brief consideration of the general theory of IOA is worthwhile.

The central model of the quantum mechanical theory of optical activity (OA) is the Rosenfeld equation[53,54]

$$R_{0k} = I_m\left\{\left\langle\psi_0\left|\overline{\mu}\right|\psi_k\right\rangle\left\langle\psi_k\left|\overline{m}\right|\psi_0\right\rangle\right\},$$

where R_{0k}, the rotatory strength of the kth electronic transition of a molecule, is generated when electric ($\overline{\mu}$) and magnetic ($\overline{m}$) dipole transition moments occur in it. The rotatory strength of the transition corresponds to the strength of the oscillator in the theory of electronic spectra and is therefore determined as the area under the band of the corresponding Cotton effect in the CD spectrum. The Rosenfeld equation, like the Schrödinger equation, requires a knowledge of the exact form of the wave functions of the ground (ψ_0) and excited (ψ_k) states of the molecule, which is known to be impracticable. That is why the quantum mechanical theory of OA is essentially a combination of different approximated approaches to the solution of the Rosenfeld equation.

The arbitrary division of a chiral molecule into achiral residues—oscillators or chromophores—forms the basis of all these approximations. At the same time it is thought that the optical activity of the electronic transitions of a given chromophore is induced by the nearest chiral centre, namely, it is induced optical activity.

One of the most widely used approximations for calculation is the Kirkwood–Tinoco theory of polarisabilities,[54–57] which is based on the rather broad assumption that it is possible to generate the rotatory strength R solely the interactions of the electric dipole transition moments of the chiral residue (inducer) and that of the chromophore. Since the electric dipole transition moment is proportional to the polarisability of the respective residue, it may be replaced experimentally by the more accessible polarisability of this residue. This theory is discussed in greater detail in Section III.

All the approaches to an approximate solution to the Rosenfeld equation essentially calculate the intramolecular IOA, so they can in principle also be used[58] to estimate intermolecularly induced optical activity, namely, IOA.

III. Information obtained from interpretation of the chiroptical properties of cyclodextrin complexes

The chiroptical properties of CDX complexes with various chromophores or guest molecules have been studied as follows:

Chromophore (guest)	Refs.
Carboaromatic compounds	59–119
benzene derivatives (including dyes)	59–88
napthalene derivatives (including dyes)	83, 85–87, 89–108
other carboaromatic derivatives	100, 109–119
Heteroaromatic compounds (including nucleic acids and their heteroaromatic components)	72, 73, 120–141
Organometallic compounds (ferrocence and its derivatives)	8, 101, 142–145
Metal complexes	81, 146–150
Carbonyl derivatives of alicyclic compounds (including prostaglandins)	151–155
Drugs	64, 65, 68, 72, 73, 128–131, 155–157

The vast majority of the above compounds fall into the category of carbo- and hetero-aromatic compounds, which is typical of COX complexes.[1,2]

Because of the symmetrical structure of CDX molecules as mentioned above,[17] their chiral cavities should not have a very marked ability to cause IOA. Another reason for this may be the generally low stability constants of these complexes,[1,2] which indicate that the chromophore is held insufficiently firmly in the CDX cavity. The experimentally determined values of [θ] lie in the region of 0.4–43 000 deg cm^2 dmol^{-1}, and in the majority of cases they gravitate to the upper end of this range, i.e., they are unexpectedly high. It is true that on the whole they are values of apparent molar ellipticity that are calculated assuming complete complexation of the guest. With the most frequently occurring guest–host molar ratio of 1 : 100 and stability constants of CDX complexes in the region of 30–3000 M^{-1} there is no doubt that complete complexation occurs.

In the vast majority of cases, studies have been made of the spectra of aqueous solutions of complexes, which are buffered in the case of proteolytic guest molecules. It has been shown, however,[142] that complexation is also possible in solutions of alcohols (ethylene glycol, diethylene glycol, triethylene glycol, etc.).

The information obtained from studies of the chiroptical properties of CDX complexes is analysed below in an order corresponding to the increase in its quantitative content.

1. Information similar to that obtained from electronic absorption spectra

The chiroptical spectra—ORD spectrum (Fig. 1*a*) (dependence of the molar rotation [M] on the wavelength λ) and CD spectrum (Fig. 1*b*) (dependence of the dichromic absorption ΔE or molar ellipticity [θ] on wavelength)—of a given chiral compound correspond to the electronic absorption spectrum of the same compound (Fig. 1*c*) in the form of a Cotton effect (positive Cotton effects are shown). If the compound is transparent in a given spectroscopic region, only a section of the electronic transition occurs in the ORD spectrum in the form of the so-called plain ORD curve (curve *AB* in Fig. 1*a*) and there is no Cotton effect in the CD spectrum or peak in the electronic absorption spectrum.

CDX complexes are particularly convenient for a study of their chiroptical properties, since CDXs as inducers (hosts) are transparent in the accessible spectroscopic region, while the chromophores (guests) listed above have at least one electronic transition in this region.

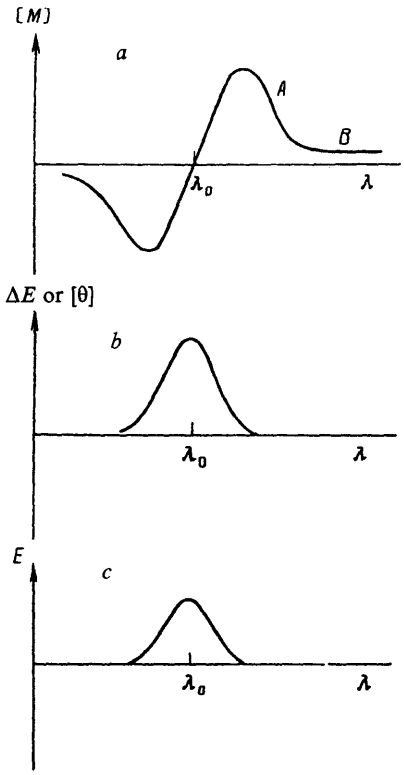

Figure 1. Cotton effects of a chiral compound with an electronic transition at λ_0 (*c*) in the ORD (*a*) and CD (*b*) spectra.

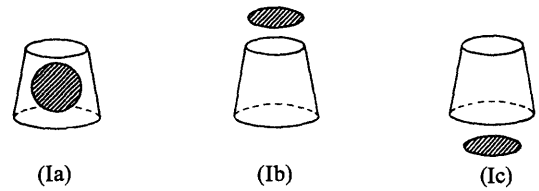
The ORD spectra of all CDXs comprise intense positive plain curves which mask possible induced Cotton effects (ICEs) of the chromophores in the ORD spectra of CDX complexes. Therefore, such spectra have little informative value. Thus, in the first study[108] on complexation with CDXs using chiroptical methods, ORD spectroscopy was used, with dyes serving as chromophores. In this case the Cotton effects appeared as weak deviations from a plain positive ORD curve on the sections of the spectrum corresponding to absorption of the dye in the UV spectrum. These deviations were largest for the dye Congo red and α-CDX. The assumption made from these observations that a complex is formed was, however, disrupted by Takeo and Kuge,[71] who used CD spectroscopy. It appeared that the deviations from the plain ORD curve discussed by Sensse and Kramer[108] were of the same order as the background noise of the instrument.

The ORD spectrum of a CDX complex contains additional rotatory contributions of the CDX molecule both through the slight change in conformation of the CDX on complexation and through induction of optical activity in the CDX molecule on the part of the guest molecule. The question concerning the methods of obtaining this information from the ORD spectra of CDX complexes still remains open.

In studies of the chiroptical properties of CDX complexes with azo dyes, much more accurate results in the form of several induced bands of the Cotton effect corresponding in wavelength to the electronic transitions of the dye were obtained.[106,107] It is true that the occurrence of an induced Cotton effect in the ICD spectra of a mixture of the guest and CDX in aqueous solution is merely an indication of complexation, which does not have to result in the formation of a G–H complex (1a) but may be restricted to conventional molecular complexes † of type (1b) or (1c).



In the studies of Suzuki and Sasaki[106,107] structures of type (1a) were unequivocally chosen because of additional information obtained from ^{1}H NMR spectra. This choice can be made with sufficient assurance when the following arguments are applied:

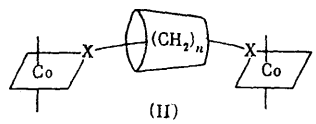
1. the cavity of the CDX molecule is hydrophobic[1–3] since it is formed by C–O–C and C–H bonds. Hence, the formation of complexes of type (1a) is assisted by guest molecules or their residues of a hydrophobic nature.

2. The size of the guest molecule must not exceed the diameter of the CDX molecule.[1–3]

3. The degree of IOA rises to a maximum in complexes of type (Ia), since contact between the inducer and chromophore is greatest in this case.

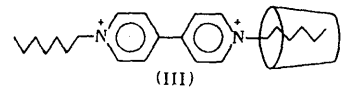
Thus, in a study of the ICD spectra of β-CDX complexes with hydrophobic uracil derivatives,[131] the choice was made in favour of structures of type (Ib) and (Ic) on the basis of the small values of [θ]. A similar choice was made by Blais et al.[134] in a study of the IORD spectra of β-CDX complexes with hydrophobic derivatives of isonicotinic acid.

Complexation of CDXs with a chromophore has only a slight effect on its chiroptical properties if a part of the chromophore contained in the cavity of the CDX is transparent in the spectroscopic region used. Thus, in the spectra of rotaxanes (II)[146–148]



(II)

X = N, S,



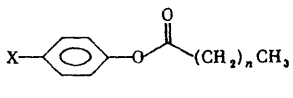
(III)

obtained as a mixture of diastereomers a very weak induced Cotton effect has been detected[146] in the visible region, which is probably

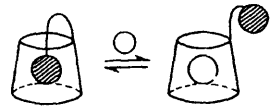
† Here and subsequently we shall use the standard notation[1–3] of a CDX molecule as a truncated cone on whose base are located the secondary hydroxyl groups and on the opposite side are located the primary hydroxyl groups of the CDX's α-*D*-glucopyranose residues.

caused because there is only a weak interaction between the chelate centres and hydroxyl groups in the CDX [contribution from complexation of type (Ib) and (Ic)]. At the same time pure diastereomers of (II) exhibit very strong Cotton effects[147,148] in this region of the spectrum, due to the chirality of these chelate centres. The even more intense induced Cotton effect in the case of the related heptylviologen complexes (III) is evidently caused by the large contribution from complexation of type (Ib) and (Ic).[122] It is interesting to note that in this case complexation cannot be detected in the Raman spectrum or ^{1}H NMR spectrum.

Competition between the aromatic and acyclic residues of *p*-substituted phenyl alkanoates (IV) for inclusion in the cavity of CDXs has been observed[76] in the ICD spectra as a progressive decrease in intensity of the aromatic induced Cotton effects with increase of n, while inclusion of the aromatic residue still occurs when $n = 6$ for α-CDX and at $n = 5$ for β-CDX. In all of these examples inclusion of the hydrophobic aliphatic residues is preferred, which clearly demonstrates the hydrophobic nature of the CDX cavities.



(IV)

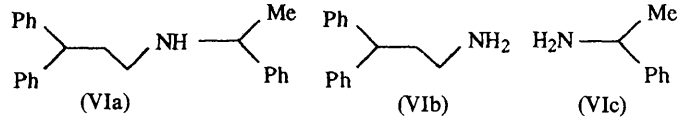


(Va) (Vb)

Complexation of CDX with a spectroscopically transparent guest can be detected in ICD spectra if at the same time a spectroscopically opaque guest is displaced from the CDX cavity. This situation occurs[81,92,136,138] in CDX complexes of type (Va) which are functionalised with an opaque chromophore (naphthyl,[92] a nucleic base,[136,138] nitrophenylacyl[81]). When a transparent chromophore (sodium 1-adamantanecarboxylate,[81,92,136,138] cyclododecanol,[92] 1-adamantylammonium chloride[81]) is added in increasing concentration to aqueous solutions of these complexes, the induced Cotton effect in the ICD spectrum gradually disappears as a result of the formation of complex (Vb). A more complex example of this type is provided by complex (Va) with an *N*-methylacetyl residue as a chromophore located in the cavity.[153] The induced Cotton effect of this complex in the region of amide absorption decreases with the addition of conjugated cyclohexanone derivatives, but an induced Cotton effect appears and then increases at the longer-wavelength region of conjugated carbonyl. Furthermore, this competing complexation can be used to determine the stability constants of CDX complexes with transparent chromophores (see below).

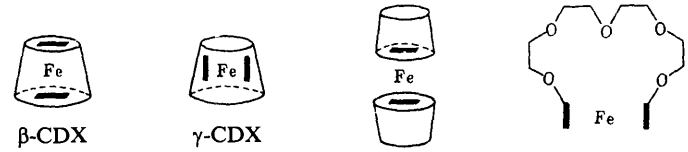
Qualitative information on complexation obtained from ICD spectra is by no means limited to these examples. This information is particularly useful for studying the complexation of CDXs with pharmacological compounds. Thus, the IOA which occurred in ORD[134] and CD[78,131,155] spectra constituted decisive evidence for the complexation of CDXs with derivatives of isonicotinic acid,[134] uracil,[131] indomethacin,[78] and prostaglandins.[155]

The fruitful approach of modelling in the interpretation of ICD spectra has been demonstrated[82] by a comparison of the ICD spectra of complexes of β-CDX with the drug fendiline (VIa) and models of its residues, 3,3-diphenylpropylamine (VIb) and 1-phenylethylamine (VIc). From the similarity between the ICD spectra of complexes of β-CDX with fendiline (VIa) and with 3,3-diphenylpropylamine (VIb) it was possible to conclude that the diphenyl residue of fendiline was included in the β-CDX cavity.



(VIa) (VIb) (VIc)

A semi-quantitative interpretation of ICD spectra using absolute values of the dichroic absorption ΔE or molar ellipticity [θ] may in certain cases provide a fairly reliable assessment of the stability of the respective complexes. In principle a direct correlation between the stability constants K and the corresponding values of ΔE or [θ] is not to be expected, since the latter incorporate the rotatory strength[53] (see the Rosenfeld equation), which is known not to depend on K but which is governed by the geometry of the G–H complex. Thus, in studies of the complexation of ferrocene with CDXs using ICD[8,142–144] it has been established that a strong induced Cotton effect occurs in the β-CDX complex, a weak effect occurs in the γ-CDX complex, while the α-CDX complex does not exhibit IOA, although according to other information complexes are formed in all cases. The proposed structures (VIIa–c) have geometries that are too diverse for comparison to be made from the magnitudes of the induced Cotton effects. Of these the structure (VIIa) has been demonstrated[145] by means of modelling. The ferrocene-containing crown ether (VIId),



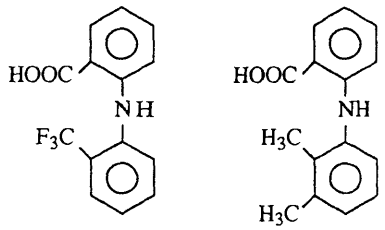
β-CDX (VIIa) γ-CDX (VIIb) α-CDX (VIIc) (VIId)

which can only be included equatorially, exhibited an induced Cotton effect when complexed with β-CDX that was opposite in sign to that of complex (VIIa). This correlation between the geometry of the complex and the sign of the corresponding induced Cotton effect will be discussed in detail below.

However, in certain systems (same chromophore—different CDXs, same CDX—structurally related chromophores) with similar fixed geometries a qualitative correlation between [θ] and the stability of the complex may occur. For example, in the complexation of α- and β-CDX with cyclohexanone[151] and cyclopentanone[154] the magnitudes of the induced Cotton effects of the α-CDX complexes proved to be greater than those for the β-CDX complexes. This result is consistent with the cavity sizes of the two CDXs.

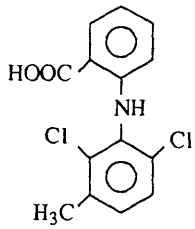
In a number of complexes of structurally related chromophores (VIIIa–c) with β-CDX a parallel decrease in intensity of the induced Cotton effect and stability of the complexes has been observed.[64] However, this pattern no longer occurs for the similar derivatives (VIIId), which are more extensively varied,[63] although [θ] increases with an increase in size of the CDX cavity, i.e., in the series α-CDX < β-CDX < γ-CDX. For *ortho* compounds [θ] is

considerably lower than for *meta* and *para* derivatives, which is apparently due to the nonplanar structure of the chromophore

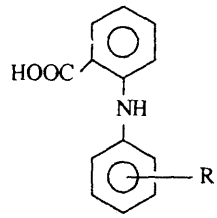


(VIIIa)

(VIIIb)

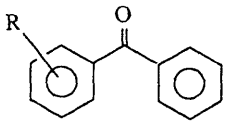


(VIIIc)

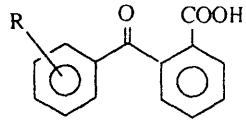


(VIIId)

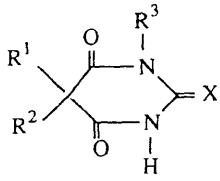
in the first case. There is also no correlation between [θ] and K in complexes of substituted benzophenone (IXa) and benzoic acids (IXb), barbiturates and thiobarbiturates (X),[128,129]



(IXa)



(IXb)



(X)

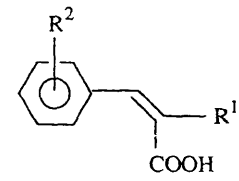
$R^1 = CH_3(CH_2)_n$ ($n = 0-6$), Ph;
R^2 = MeEt, R^3 = H, Me; X = O, S.

and probably in the majority of similar cases. Consequently, assumption of a correlation between [θ] and K should be treated with considerable caution, even if it is supported by matching the size of the chromophore and the radius of the CDX, the study of molecular molecules being particularly useful in this case.

According to the theory of optical activity, a more intense electronic transition corresponds to a lower rotatory strength and vice versa. Therefore, the anisotropy factor g—the ratio of the dichroic absorption ΔE to the extinction coefficient E or the equivalent ratio involving [θ]—may be regarded as a generalised characteristic of a chiral molecule:

$$g = \Delta E/E = \theta/3300E.$$

Cases where there is agreement between g and the stability of complexes are, however, fairly rare. They occurred in a number of phenylanthranylic acids (VIIIa–c)[64] and (VIIId)[65] and cinnamic acids (XI),[70]



(XI)

R^1 = H, Me;
R^2 = Me, Cl, OH, NO_2

but not in barbiturates (X).[129] A comparison of the values of g obtained at different CDX concentrations with the literature data was used[78] to estimate the stability of β-CDX complexes with the drug indomethacin. The use of g instead of [θ] evidently has no particular advantages.

The stability constant K—the most reliable criterion of the stability of a complex—may be determined by means of ICD using the same methods as for UV spectroscopy, since in essence the CD spectra represent a modification of the UV spectra (see Figs. 1*b* and 1*c*). The simplest method of Hildebrand and Benesei[158,159] used in several studies[60,67,69,85,143] has been applied quite extensively together with the modification of Scott[160] used by Otagiri et al.[124] and the modification of Rose and Drago[161] used by Harata.[75] The approximation of Mack[162] was used in three studies[87,98,101] while the approximation of Monk[163] was used by Formoso.[135,137]

The least squares method has become the most widely used of the calculation methods.[62,74,92,154] Individual cases are represented by the adjustment method[156] and nonlinear regression analysis.[130] Computational methods will probable find considerable application as a result of the computerisation of chemical calculations. In certain studies[63,136,138,153] no indication of the method of determination is given.

All these methods are applicable to complexes with an established or assumed 1 : 1 composition. In certain cases the composition was determined[60,67,70,120,142] using ICD with the method of continuous variations of the composition. Calculation of K from the ICD data at different temperatures made it possible[67,74,75,85] to determine the thermodynamic parameters of complexation. The phenomenon of displacement of an opaque chromophore by a transparent chromophore from the CDX cavity was used[81,92] to determine K for the complex of a transparent chromophore with CDX by means of ICD spectroscopy. The possibility of determining the composition of complexes polarimetrically was demonstrated by Giordano et al.[152]

2. Specific information

In this section an analysis is made of the specific information on CDX complexes which in principle cannot be obtained by methods other than chiroptical spectroscopy methods and which is based on the pseudoscalar property of the Cotton effect—its sign. The quality of such information is considerably improved by the applicaton of OA theory.

Interpretation of the CD spectra of CDX complexes with chiral chromophores[73,74,135–141,150–152,154–157] is frequently made difficult because the small induced Cotton effects are masked by the more intense inherent Cotton effects of the chromophore. In some cases[73] it is possible to limit this by recording the CD spectra of CDX complexes with both enantiomers of the chromophore, and the absence of mirror reflection properties suggests that complexation is occurring. A lack of change in the CD spectrum of one of the enantiomers of a chromophore when CDX is added to it may indicate[73] the absence of complexation. Otherwise[137] it may be a reliable indication of complexation, while the extent of change between the CD spectra of the initial enantiomer of the chromophore and its mixtures with different CDXs is proportional[155] to the degree of complexation. The changes in the CD spectra of a pure enantiomer on addition of CDX may be significant if the chromophore contains achiral residues that can undergo complexation and bulky chiral residues, such as in the case of *p*-nitrophenylglycoside.[74] Calculation of the stability constants in these cases[73,74,135–137,154] is complicated by the fact that the apparent values of [θ] include the inherent and induced ellipticity of the chromophore.

The superior sensitivity of CD spectroscopy over UV spectroscopy is particularly evident in the case of CDX complexes with chiral chromophores. Thus, according to the data from differential UV spectroscopy,[164] β-CDX selectively complexes the monophosphates of adenosine and inosine, while according to the data of CD spectroscopy[135,137] this type of complexation occurs for all nucleotides. Thus the idea of using CDXs as probes for the structural analysis of nucleic acids can be rejected. From the CD spectra of CDX complexes with chiral guests it is possible to distinguish drugs qualitatively,[73] especially between chiral and achiral ones, while it is possible to identify cocaine quantitatively.[156] The complex of a chelated pyridoxal aldimine with γ-CDX has been successfully used[150] for studying the kinetics of the stereodifferentiating transamination of phenylpyruvic acid with pyridoxamine.

Let us now consider the correlation between the magnitude and sign of rotation of the Cotton effect, on the one hand, and the geometry of the inclusion of the guest, on the other hand. Specific definition of the Rosenfeld equation in terms of the geometric parameters of specific chiral molecules, based on the classical theory of interacting oscillators[165,166] and the principle of pairwise interactions,[167] led Kirkwood[168] to develop the first "practical" quantum-mechanical theory of optical activity that could be used to calculate the rotational parameters of simple chiral molecules. Starting from the concept of a molecule as a combination of arbitrarily discrete groups (chromophores) that are not exchanging electrons with each other (this concept was subsequently developed as the "discrete chromophore model"),[169] Kirkwood represented[56,168] the rotatory strength of such a molecule as the sum of several terms, one of which represents the interaction between electric dipole transition moments of different chromophores (which is true under certain conditions) and replaced these values with the polarisabilities of the respective groups, which are proportional to them, the latter being values that are more easily obtained experimentally. Kirkwood derived a relatively simple formula for calculating rotatory strength. Tinoco[55] subsequently developed the theory of Kirkwood in relation to polymers and put forward a more general equation for rotatory strength. Harata[62,90] used the Kirkwood–Tinoco equation in a form that was suitable for calculating the rotatory strengths of cyclodextrin complexes in the jth transition from the ground state 0 to an excited state a:

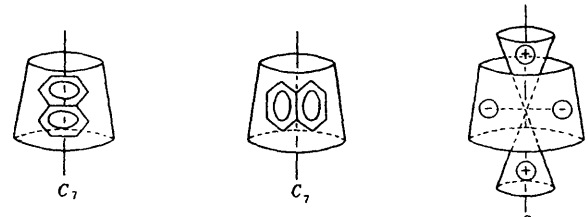
$$R_{0aj} = \frac{\pi \nu_a \nu_0^2 \mu_{0a}^2 \left(\alpha_{33} - \alpha_{11}\right)_j \left(GF\right)_j}{c\left(\nu_0^2 - \nu_a^2\right)},$$

$$\left(GF\right)_j = \left[\frac{1}{r_j^3}\vec{e}_{0a}\vec{e}_j - \frac{3\left(\vec{e}_{0a}\vec{r}_j\right)\left(\vec{e}_j\vec{r}_j\right)}{r_i^2}\right]\vec{e}_{0a}\vec{e}_j\vec{r}_j,$$

$\vec{e}_{0a}$ is the unit vector along the electric dipole transition $\vec{\mu}_{0a}$ of the guest chromophore; ν_a is the corresponding frequency; $\vec{e}_j$ is the unit vector along the axis of symmetry of the jth group; r_j is the distance from the chromophore to the jth group with frequency ν_0; α_{33} and α_{11} are the electric polarisabilities, corresponding to the parallel and perpendicular axes of symmetry of the jth group.

The origin of the system was located in the centre of the CDX molecule, while the z axis passed up along the C_7 axis (in the case of β-CDX). The C–O and C–C bonds in the α-*D*-glucopyranose residue of the β-CDX molecule were regarded as the jth groups with the corresponding tabular values of α_{11} and α_1. The frequency ν_0 of the host was taken from the absorption spectrum of cyclohexanol as a model compound while the values of μ_{0a} for the ^1L_a and ^1B_b transitions of the naphthalene ring for which r was calculated were taken from literature data. The details of the calculations are given in a study of Shimizu et al.[60] For the complexes of β-CDX with naphthalene derivatives that were studied, the calculated values of R differed from the experimental values by a factor of several times, which suggests that there was a small interaction in this case, but the predicted signs proved to be correct. As a result the following rule was developed (the rule of Harata):

If the electric dipole transition moment μ in the chromophore is aligned parallel to the C_7 axis of the symmetry of the β-CYD molecule, the corresponding induced Cotton effect is positive (+ICE). When μ is aligned perpendicular to this axis the induced Cotton effect is negative (−ICE). On the basis of this rule it was concluded that inclusion of the guest was axial (XIIa) rather than equatorial (XIIb), since the induced Cotton effect of the ^1L_a transition directed along the long axis of the naphthalene molecule proved to be positive. The rule of Harata is evidently valid for all CDXs.



(XIIa) (XIIb) (XIIc)

Shimizu et al. subsequently performed similar calculations of the rotatory strengths of β-CDX complexes with substituted benzenes[59,60] and azanaphthalenes.[120] Without starting the rule of Harata as such, the authors merely concluded that inclusion of these chromophores was axial. The rule of Harata was used to establish the form of inclusion of aromatic chromophores in CDX complexes,[77,79,93,119] and to postulate a "lid-type" complex (Ib) between 1,3,6,8-pyrenetetrasulphonate anion and β-CDX[111] with induced Cotton effects of the same sign as well as an axial complex between β-CDX and a nickel complex of a 14-membered macrocyclic

tetraamine.[149] In the latter case, because of the correspondence between the Cotton effect and the $d-d$ transitions, the method was considered to be useful in studying $d-d$ transitions.

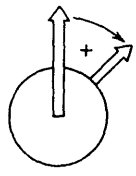
The reverse problem—to establish the direction (polarisation) of the electric of the electric dipole transition moment from the ICD spectra of CDX complexes of known structure—was resolved in four studies.[94,96,102,109] The method used for this was an improvement on those proposed previously which were technically more complex methods for determination of the direction of polarisation in oriented polymer films[170] or in cholesteric liquid crystals.[171] However, the new method is not suitable for chromophores of low symmetry or when there are strongly overlapping transitions of opposite sign.[120]

The rule of Harata has been stated more graphically[83] as a sector rule (XIIc) similar to the octant, quadrant, and sector rules in the quantitative theory of optical activity:[172–174] *if the electric dipole moment of a transition of an aromatic guest lies within a hypothetical double cone, the centre of which coincides with the centre of the CYD, and the generants form angles of 30° with the C_7 axis, the rotatory strength and the corresponding induced Cotton effect will be positive, while the same parameters that are induced by an electric dipole transition moment outside this cone will be negative. The maximum positive anisotropy factor g is approximately twice as high as the maximum negative g, corresponding to the maximum, negative induced Cotton effect of the electric dipole moment of the transition perpendicular to the C_7 axis.* This is in agreement both with the Kirkwood–Tinoco calculations[60] and with the experimental results.[83]

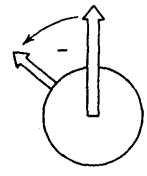
The eminent theoretician in the field of IOA, P E Schipper, having given the equation for the induced rotatory strength of a guest in a generalised form according to the model of interacting oscillators, demonstrated[175] that the correlation between the geometry of the complex and the sign of the induced Cotton effect, corresponding to the rule of Harata, is derived automatically from this equation on the basis of general selection rules for chromophores in perturbing fields.[176]

It was also possible to use the rule of Harata to assign the vibrational bands of aromatic chromophores in complexes of monosubstituted benzenes[61,66] and the 4,4-bipyridyl radical.[123]

The theory of interacting oscillators[17,177,178] represents the interaction of two chromophores that are identical or have a similar structure in terms of exciton theory[179] and it predicts the so-called Davydov splitting of the corresponding absorption band of the interacting chromophores. In the UV spectrum this splitting is insignificant and frequently does not occur, whereas in CD spectra the Davydov (exciton) splitting appears as a double Cotton effect of opposite sign, the so-called exciton couplet, which is positive (Fig. 2*a*) or negative (Fig. 2*b*) depending on whether the relative configuration of the electric dipole of the transition of these chromophores forms part of a right-handed (XIIIa) or left-handed (XIIIb) spiral respectively in the Newman projection.[17,177]



(XIIIa)



(XIIIb)

The electric dipoles of transitions approximate to the projections of planes of rings in the case of aromatic and heteroaromatic chromophores or to C=O bonds for carbonyl chromophores.

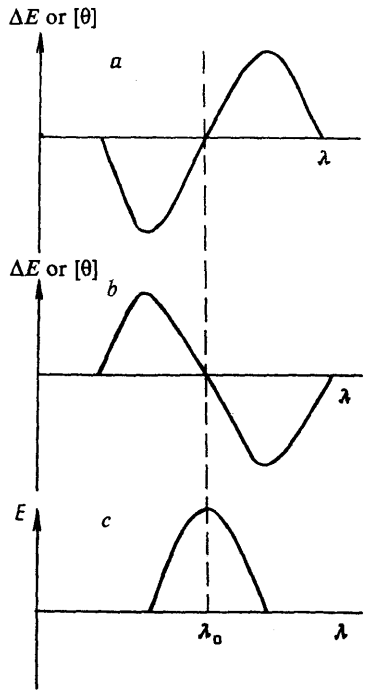


Figure 2. CD spectra with positive (*a*) and negative (*b*) exciton couplets by the absorption band at λ_0 in the UV spectrum (*c*).

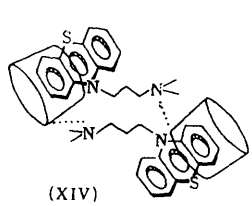
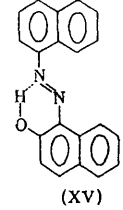
The simple and graphic rule of exciton chirality has been extended to a determination of the absolute and relative configuration of natural compounds.[180] It has also recently successfully "started to work" in the field of CDX complexes, primarily in cases of the dimerisation of one-guest complexes or the formation of two-guest complexes.

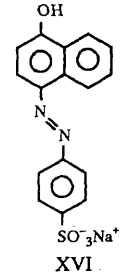
In a study of the complexation of β-CDX with phenothiazine tranquillisers it transpired[124] that 1:1 complexes with chlorpromazine and related derivatives with long alkyl substituents on the nitrogen atom have excited couplets in their ICD spectra, which may suggest that dimers (XIV) are formed through hydrogen bonding of the alkyl chains. An analogous dimeric structure was assigned[117] to a complex between β-CDX and benz[*b*]anthracene on the basis of similar arguments.



(XIV)

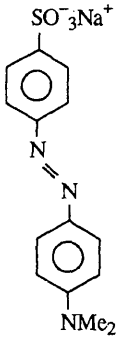


(XV)

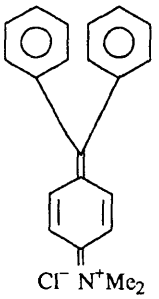


XVI

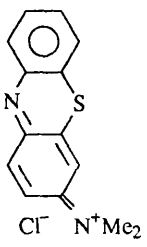
Reaction of chloropromazine with γ-CDX in aqueous solution gives a 2:1 complex (two-guest complex),[125] which was supported[115] by the observation of a negative exciton couplet in the ICD spectrum corresponding to a negative angle between the two chromophores as in structure (XIIIb), i.e., a laevospiral chirality of the guest dimer [(*S*)-chirality according to Cahn, Prelog, and Ingold]. Similar phenomena were observed in complexes of γ-CDX with a number of dyes such as roccellin (XV),[104] tropaeolin 000 (XVI),[103] methyl orange (XVII),[87,88] crystal violet (XVIII),[87] methylene blue (XIX),[87] and acridine orange (XX),[100] and the exciton couplets occurred in both the visible and ultraviolet regions of the spectrum.



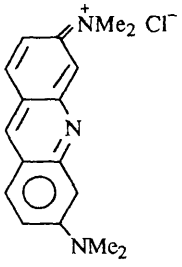
(XVII)



(XVIII)



(XIX)

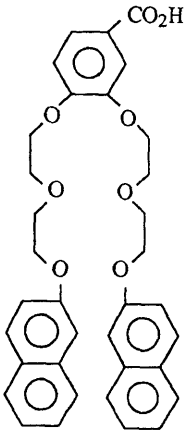


(XX)

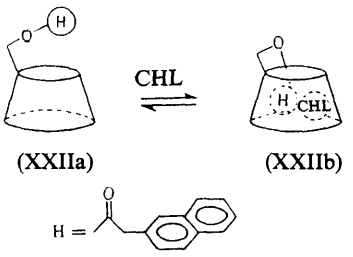
When β-CDX or γ-CDX is added to a mixture of a donor (naphthalene derivatives) and acceptor (nitrobenzene derivatives), a change in colour of the solution occurs and two Cotton effects of opposite sign (possibly an exciton couplet) appear in the charge-transfer region of the ICD spectrum, suggesting that a D^+A^- complex enters the CDX cavity.[85]

In the case of luminescent guests, the formation of two-guest complexes is also detected in the luminescence spectra. Thus, the formation of a (pyrene)$_2$-γ-CDX complex, detected by Kobayashi et al.[113] from its negative exciton couplet in the CD spectrum, was confirmed[114] by the presence of an excimer band in the luminescence spectra. The formation of an (anthracene-2-sulphonate)$_2$-γ-CDX complex with a positive exciton couplet was established in a similar manner,[16] but no excimer band was observed because of rapid photodimerisation of the dimer.

It was shown[100] that naphthalene and also the bis(naphthyl) derivative (XXI) form two-guest complexes with γ-CDX that can be readily detected from the excimer emission in their luminescence spectra. There are no exciton couplets, however, in the corresponding ICD spectra. Such a situation is possible when the naphthalene rings are situated parallel to each other in the CDX cavity, corresponding to the configuration of an achiral dimer.



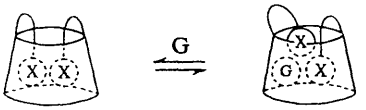
(XXI)



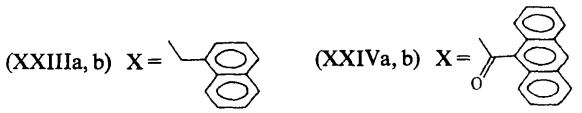
(XXIIa) (XXIIb)

Interesting results were obtained with functionalised γ-CDX. Contrary to expectation, the addition of the transparent chromophore cyclohexanol (CHL) to an aqueous solution of the derivative (XXIIa) increases[91,101] the intensity of the induced Cotton effect in the ICD spectrum, apparently because of the formation of a two-guest complex (XXIIb). A similar result was obtained[101] when the naphthalene residue in the host molecule (XXIIa) was replaced by an azobenzene or ferrocene residue.

In the ICD spectrum of a modified γ-CDX (XXIIIa) with two naphthalene residues there is a positive exciton couplet with its centre at 270 nm which corresponds to the ^1L_a absorption band of naphthalene and an excimer emission in the fluorescence spectrum, which is consistent with structure (XXIIIa). When transparent guests (adamantanecarboxylic acid, cyclohexanol, borneol) are added, the exciton couplet disappears but the excimer emission remains, suggesting that there is a conversion to structure (XXIIIb).[92,98,99] The similar conversion (XXIVa) → (XXIVb) was detected[115] by the same methods for a dianthracene derivative of γ-CDX (XXIVa).



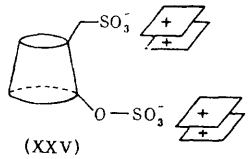
(XXIIIa) (XXIVa) (XXIIIb) (XXIVb)



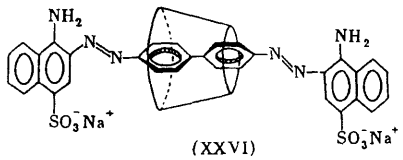
(XXIIIa, b) X = (XXIVa, b) X =

A special case occurs for the complex of acridine orange (XX) with the disulphate of β-CDX,[133] in whose spectrum a strong exciton couplet has been detected in the visible region of absorption of the dye. However, the intensity of this couplet is sensitive to pH and the ionic strength of solution, which is inconsistent with the occurrence of two dye molecules in the β-CDX cavity. It follows from the fact that such a couplet is absent from the ICD spectrum of a complex of acridine orange (XX) with glucose sulphate[181] while it is present in complexes of spiral conformations of sodium carboxymethylcellulose

with acridine orange[185] and safranine T[43,183] that the complex of β-CDX disulphate with acridine orange should be assigned structure (XXV) (the rectangles correspond to planar dye molecules).



(XXV)



(XXVI)

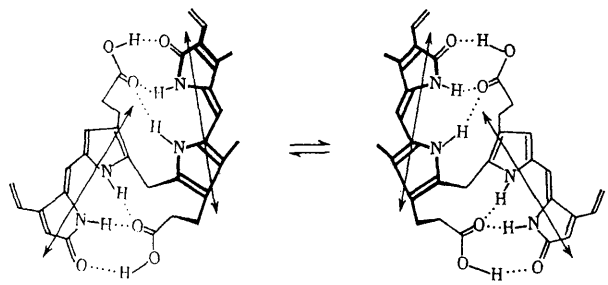
The presence of a chiral excimer can be recorded using circularly polarised luminescence spectroscopy (CPL spectroscopy),[184,185] which measures the emission anisotropy factor g_{em}.

$$g_{em} = 2(I_L - I_R)/(I_L + I_R),$$

where I_L and I_R are the intensities of emission of left- and right-handed circularly polarised light respectively. The method has so far not been widely developed mainly because of the elaborate recording equipment, and in the area of interest to use it has been used in two instances—for recording the chiral excimers of pyrene in the cavities of γ-CDX[110,112] and modified γ-CDX[110] and also for 1,3-dinaphthylpropanes in the cavity of modified γ-CDX.[110]

The dimeric guest in two-guest complexes is essentially a chromophore with its own internal[172,173] chirality (if, of course, the monomers are not parallel to each other) and therefore the components of exciton couplets are characterised by high [θ] values ($10^3 - 10^4$). With regard to the direction of chirality of the guest, it would appear that it should always be the same because of the uniform chirality of the CDX cavity. However, this is not so. While, for example, dimers of pyrene and acridine orange with γ-CDX have (*S*)-spiral chirality, the dimer of naphthalene is achiral, whereas in complex (XXIIIa) with covalently bonded naphthalene residues (*R*)-spiral chirality occurs, as in complex (XXIVa). The dimer of tropaeolin 000 (XVI) in the cavity of γ-CDX has (*S*)-chirality while in the cavity of β-CDX it has (*R*)-chirality. It is evident that the direction of this form of induced chirality is determined not only by the direction of spiral chirality of the cavity but also by the translational and rotational degrees of freedom of the guest in the host cavity.

However, ICD spectra of one-guest CDX complexes with exciton couplets have been recorded. Thus, the dye Congo red forms a one-guest complex with γ-CDX that exhibits a positive exciton couplet in its ICD spectrum.[87] This can be explained by the formation of the complex (XXVI) with one of several chiral conformers of the guest molecule located in the chiral cavity. The most studied[139–141] example of this type is complexation of CDX with the bile pigment bilirubin, which exists in aqueous solution as a mixture of interconvertible enantiomeric conformers—laevospiral (XXVIIa) and dextrospiral (XXVIIb).

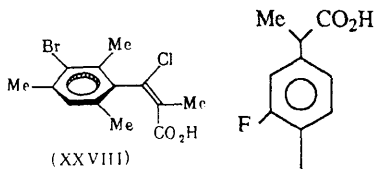


(XXVIIa) (XXVIIb)

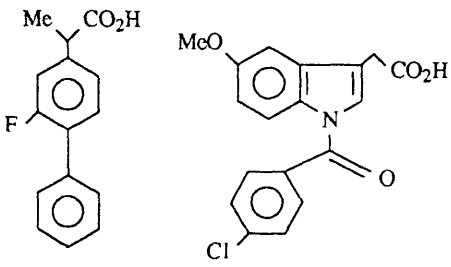
(The arrows denote the calculated directions of the electric dipole transition moments of the pyrromethene chromophores, the relative configuration of which corresponds to sections of a left- and right-handed spiral).

On complexation of bilirubin with α-, β-, and γ-CDX, negative exciton couplets were recorded with a centre at 460 nm corresponding to the absorption of bilirubin, which indicates that in the CDX cavity the specific chiral conformer (XXVIIa) has been selected from the racemate (XXVIIa, b) in aqueous solution. On similar complexation benzil and diacetyl have no exciton couplets in their ICD spectra but the high intensities of the recorded single Cotton effects ([θ] values up to 40 000 deg cm^2 dmol^{-1}) have led to the assumption[139–141] that in these cases also selection of one of the chiral conformers occurs during complexation.

Intense Cotton effects ([θ] of the order of 2600–11 900 deg cm^2 dmol^{-1}) also occurred in the complexation of cinnamic acids (XI) with α- and β-CDX. Since all the recorded intense Cotton effects were positive and the optically active (*R*)-β-(3-bromo-2,4,6-trimethyl-β-chloromethylacrylic acid (XXVIII) had a positive Cotton effect in its CD spectrum, the authors came to the fairly plausible conclusion that the guests (XI) were held in the CDX cavities as (*R*)-conformational enantiomers.



(XXVIII)



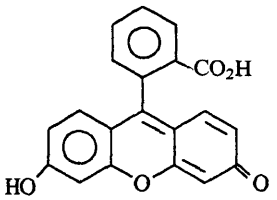
(XXIX) (XXX)

The same configuration is also selected[140] in the complexation of biphenyl derivatives with β-CDX.

An analysis of the literature data given in the present review in relation to the possible selection of chiral conformers of guest molecules when they are included in CDX cavities as indicated by high-intensity Cotton effects showed that this situation is highly probable for flurbiprofen (XXIX),[68] indomethacin (XXX),[78] and

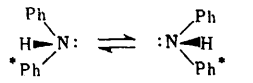
substituted barbiturates (X).[132] In the case of flurbiprofen (XXIX) this selection may occur with respect not only to the conformational enantiomer but also the configurational enantiomer (see below) because it has a chiral centre. The presence of a maximum in the region of 530 nm in the CPL spectrum of the complex of fluorescein (XXXI) with β-CDX has also been interpreted[126] as the selection of one of the chiral conformer of fluorescein during complexation.

Thus, the following conclusion is suggested: any sufficiently complex molecule having even one residue with restricted rotation can undergo complexation with CDXs as one of its rotational enantiomers. This phenomenon has been called[154] chiral conformational discrimination induced by complexation.



(XXXI)

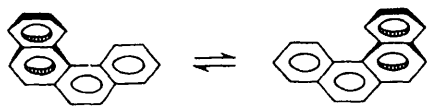
We should also note the ability of CDXs to select one of the two enantiomorphic pyramidal conformations (XXXIIa, b) of substituted diphenylamines.[65] Because of this property there is reason to expect the selection of configurational enantiomers of the type $R_1R_2R_3N$ when they are complexed with CDXs.



(XXXIIa) (XXXIIb)

The selection of configurational enantiomers has been demonstrated[151] using ICD in the complexation of racemates of 2- and 3-methylcyclohexanol with α- and β-CDX. The resolution of racemic esters[186] and sulphinyl compounds[187] using CDXs provides indirect evidence for the ability of CDXs to select configurational enantiomers of guest molecules, although the low optical yields (1–15%) indicate the limited enantiodifferentiating ability of CDX molecules with respect to small guest molecules. This conclusion has been supported[154] in the case of the complexation of α-CDX with cyclopentanol derivatives.

The enantiodifferentiating ability of CDXs probably increases for large guest molecules. At least one example of this kind is known, which relates, admittedly, to chiral conformational discrimination induced by complexation[140]—the appearance of a very intense Cotton effect ($[\theta] \simeq 40\,000$ deg cm^2 dmol^{-1}) in the ICD spectrum of the complex between γ-CDX and the racemate of 4-helicene, both enantiomers of which (XXXIIIa, b) are interconverted in solution.



(XXXIIIa) (XXXIIIb)

When the enantiodifferentiating ability of the CDX is weak, the observed ICD spectrum of the complex between CDX and racemate evidently represents the sum of the ICD spectra of the corresponding diastereomers provided that complete complexation occurs. With absolute enantiodifferentiation the opposite enantiomer is present in solution while the observed ICD spectrum essentially represents the optical activity induced by the CDX cavity in complexation of the guest enantiomer through additional hydrophobic interactions and/or hydrogen bonding of the guest with the hydroxyl groups of the host.[151] The high values of [θ] that occur for 4-helicene (XXXIIIa, b) may be due to the additional chiral distortion of the flexible conformational changes of a guest in the form of achiral and chiral molecules and a racemate in complexation with CDXs are discussed in detail by Boiswin et al.[154]

Thus, the data presented here provide a sufficiently convincing illustration of the ability of CDXs to distinguish between chiromers (conformational and configurational isomers).

IV. Conclusion

The material presented here shows that progress in the chemistry of CDXs is impossible without chiroptical spectroscopic methods[188] (ORD, CD, and CPL spectroscopy as well as infrared CD spectroscopy in the future). The most widely used method is ICD, with which it is possible to derive a variety of information about CDX complexes. Thus, an induced Cotton effect provides an indication of the complexation of a given chromophore with given CDXs, while small values of [θ] (less than 1000 deg cm^2 dmol^{-1}) most likely suggest the formation of conventional molecular complexes of type (Ib) and (Ic) and large values of [θ] (1000–10 000 deg cm^2 dmol^{-1}) indicate the presence of guest–host complexes (Ia). The shift in [θ] values to the upper end of this range may signify an increase in stability of the complex and/or a restriction of the rotational and translational degrees of freedom of the guest molecule in the CDX cavity. Even higher values of [θ] or the appearance of an exciton couplet may signify chiral conformational discrimination induced by complexation. This relates to complexes with a 1:1 composition which can be determined from the ICD spectra in the same way as the stability constants of the complexes.

If the directions of the electric dipole transition moments of an asymmetric chromophore are known, the nature of inclusion of the chromophore (axial or equatorial) in the CDX cavity can be established from the rule of Harata. If the nature of inclusion of the complex is known, the reverse problem—to establish the directions of the electric dipole transition moments of a chromophore—can be solved using the same rule.

Exciton couplets in the ICD spectra may also suggest that dimerisation of one-guest complexes is occurring or two-guest complexes are being formed.

Some of the information derived from ICD spectra (the complexation, composition, and stability constant of the complex) may also be obtained by other methods. However, the information (the geometry of the complex, dimerisation of complexes, chiral conformation discrimination induced by complexation) obtained from the pseudoscalar property of the Cotton effect—its sign—is unique, since it is impossible (or extremely difficult) to obtain it by other methods.

Crystal phosphors for storage luminescent screens

A M Gurvich, V V Mikhailin
Scientific-Research X-Ray Radiological Institute, Moscow
M V Lomonosov State University, Moscow

ABSTRACT. A review is given of the work on photostimulated crystal phosphors as materials of storage luminescent screens used in digital radiography. The properties of barium fluorohalides, particularly of BaFBr:Eu, important in these applications are considered. Much attention is given to the influence of conditions during preparation on these properties, to physicochemical relationships describing the processes of formation and interaction of crystal lattice defects, and to the current ideas on the mechanism of photostimulated luminescence.

The bibliography contains 94 references.

I. Introduction. Storage luminescent screens as alternatives to silver-halide photographic materials

Inorganic (crystal) phosphors, storing energy and liberating it in the form of light—photostimulated luminescence excited by infrared or visible radiation—have been known for a long time. They are used in dosimetry and in visualisation of infrared radiation.[1–4] The development of computers and lasers has opened up new opportunities for the applications of these materials and this has led to the development of luminescent digital (computer) radiography.[5,6] This method differs from conventional radiography because instead of a photographic (radiographic) film or its combination with amplifying screens, use is made of an image-storing crystal phosphor (we shall use just the word phosphor) screen capable of emitting luminescence.

The latent image is developed by scanning such a screen with a sharply focused beam of a helium–neon laser. The light flashes (scintillations) generated are converted in a photomultiplier into a series of electrical signals and then, after discretisation, they are made up into a digital code. The data digitalised in this way are stored in an optical disk or on a magnetic tape, and—after computer processing—are converted back into analog signals, modulating the intensity of an electron beam used in a display or modulating radiation from a second laser which scans a photographic film†.

Luminescent digital radiography has a number of advantages over conventional (film) radiography,[7] the main of these is a wide dynamic range.[8,9] This makes it possible, for example, to attain a high-contrast resolution of parts of an object which differ greatly in respect of the absorption of ionising radiation, and also to reduce the risk of obtaining a poor-quality image because of an incorrect selection of the exposure conditions.

The idea of luminescent digital radiography has long been in the "air" (see, for example, Ref. 10), but it has been realised only after the development of phosphors satisfying the full range of the necessary requirements.

II. Selection of crystal phosphors for storage screens

Phosphors used in luminescent screens should satisfy the following requirements:[7,11] 1) a high energy efficiency of the room-temperature photostimulated luminescence in order to reduce the noise associated with fluctuations of the photon flux; 2) luminescence and excitation bands sufficiently far apart for spectral separation of the laser radiation from the photostimulated luminescence; 3) a rapid decay of the laser-excited light flashes, so as to ensure the necessary speed of image readout (reconstruction) and prevent superposition of signals due to different parts of the image; 4) long-term retention of the stored energy (weak fading); 5) a linear dependence of the photostimulated luminescence intensity on the exciting-radiation dose, which is the precondition for the attainment of a wide dynamic range; 6) efficient absorption of ionizing radiation in order to minimize the quantum noise and reduce the dose necessary to obtain a high-quality image.

These requirements were taken as the basis of an investigation of the feasibility of using a large number of phosphors capable of the photostimulated luminescence. These phosphors included zinc and alkaline-earth sulphides, for example SrS:Ce:Sm and SrS:Eu:Sm;[1,17] alkali halides,[10,13] particularly RbBr:Tl;[9,11] oxides (ThO_2:Er) and oxysulphides (La_2O_2S:Eu:Sm);[12] alkaline-earth fluorohalides;[5,14] some sulphates, borates, and silicates;[11,13,15] haloborates, halosilicates, halophosphates, and halogermanates of alkaline-earth metals, particularly $Ba_5SiO_4Br_6$:Eu.[11,16] In the case of luminescent digital radiography the best of these phosphors have proved to be barium fluorohalides activated with europium (BaFHal:Eu), the ability of which to emit the photostimulated luminescence had been investigated early,[5,14] as well as later on a large number of occasions. A particularly favourable combination

† In the latest systems made by Fuji the same laser is used to scan a storage screen and a photographic film.

of properties is exhibited by the BaFBr:Eu phosphor,[12,17–19] used in storage screens manufactured on a commercial scale.[17] The energy efficiency of its photostimulated luminescence can reach 5%[19] and the luminescence (λ_{max} = 390 nm) and excitation (λ_{max} = 590–600 nm) bands are far apart, the photostimulated luminescence decay time is τ = 0.8 μs,[8] the fading does not exceed 25% in 8 h,[17] and the presence of barium in the phosphor base ensures a strong absorption of X-rays.[20] It should be pointed out that unsuccessful attempts had been made and are still being made to improve some properties of BaFBr:Eu by partial replacement of Br with Cl or I.[13]

III. Structure and principal properties of barium fluorohalides

The first barium fluorohalide to attract attention was BaFCl as an object of investigations of colour centres[21–24] and (when activated with europium) as an efficient phosphor for amplifying X-ray screens.[25,26] The high efficiency of the photoluminescence and cathodoluminescence of MFHal:Eu^{2+} phosphors (M = Sr, Ba; Hal = Cl, Br) was mentioned in Ref. 27.

Barium and strontium fluorohalides have a layer tetragonal structure of the PbFCl type,[28,29] which can be represented by a sequence of layers F_2MHalHalM..., oriented along the [001] direction (Fig. 1). The subscript 2 of fluorine indicates that the number of ions in an F^- layer is twice as high as in Hal or M layers. The distances between the F^- ions are $\sqrt{2}$ times less than the distances between the Br^- and Ba^{2+} in the relevant layers.

The presence of anions of two types in barium fluorohalide crystals facilitates the formation of two different types of the colour (F) centres, for example, fluorine‡ (V_F) and chlorine (V_{Cl}) vacancies in BaFCl, and of fluorine and bromine (V_{Br}) vacancies in BaFBr, when these vacancies have captured electrons. The appearance of the corresponding bands in the absorption spectra of crystals had been confirmed experimentally, and an investigation of the ESR spectrum[22] and a theoretical analysis[23] have resulted in an attribution of the short-wavelength band to the V_F centres, which are frequently denoted also by the symbol $F(F^-)$. It has also been shown that additive colouring produces only the F centres of the V_F type.[30] This can be explained by the fact that an excess of Ba penetrates deeper into crystals along dislocations, which are formed at the edge between two adjacent F_2 and Ba layers that terminate inside the crystal (at the edges of BrBrBa layers the formation of dislocations is less probable for steric reasons).

We investigated earlier[14] the characteristics of the luminescence emitted by the $BaCl_2-BaF_2$ system and showed that an excess of BaF_2 formed a solid solution in BaFCl. This implied that some of the Cl^- ions were replaced with F^- giving rise to antisite defects F_{Cl}.[19] The presence of similar defects was postulated also for BaFBr.[33] The association of these defects§ with $V_{Cl}^{\cdot}$ ($V_{Br}^{\cdot}$) gave rise to F centres with parameters differing somewhat from those of non-associated centres of this type.[19]

‡The subscript of the symbol for a defect identifies the lattice sites at which this defect is formed or an interstitial position (i), as is usual in the literature on the physical chemistry of solids.[31,32]

§Here and later a dot (bullet) is used to denote an effective positive charge of a defect relative to the surrounding lattice and a prime is used for an effective negative charge (the number of the primes indicates the magnitude of the charge).

Barium fluorohalides are capable of emitting luminescence unrelated to the presence of impurities. As in the case of other halide phosphors,[34] it can be explained by the recombination of electrons with V_k centres (molecular Hal_2 centres, formed by the capture of a hole shared by two adjacent halogen ions).[35,36] The presence of two different halogens in a crystal facilitates the formation of at least two types of V_k centres, for example F_2^- and Cl_2^- in BaFCl. The F_2^- ions are taken to be responsible for a short-wavelength luminescence band observed only at low temperatures for all the fluorohalides and for BaF_2.[35] The room-temperature luminescence of nonactivated BaFCl and BaFBr has been attributed to the recombination of electrons with the Cl_2^- and Br_2^- centres, respectively. They are formed by Hal^- ions located at the shortest distance from one another in adjacent layers. In view of the lower electronegativity of Br, compared with Cl, it is found that the V_k centres of the Br_2^- type predominate in mixed $BaFCl_xBr_{1-x}$ crystals.[35] The presence of V''_{Ba} barium vacancies may have a stabilising influence on the adjoining V_k centres.

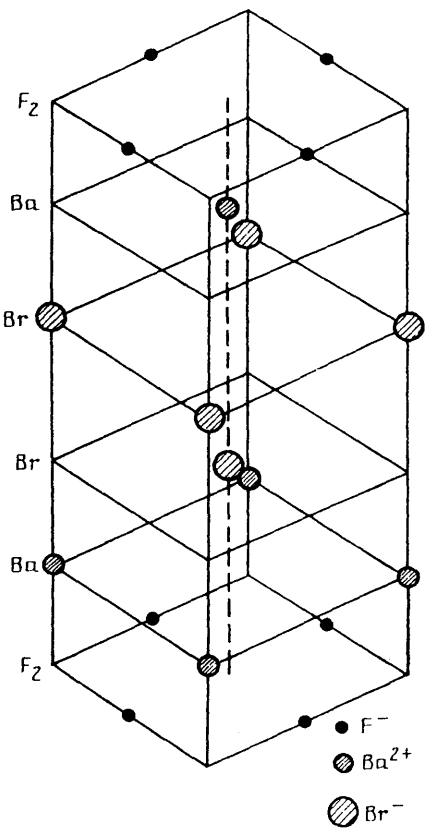

Figure 1. Positions of ions in the crystal lattice of BaFBr. The symbols F_2, Ba, and Br identify the layers formed by the F^-, Ba^{2+}, and Br^- ions, respectively.

Barium and strontium fluorohalides are readily activated by divalent rare-earth ions such as Eu^{2+} [5,25,37,38] and Sm^{2+},[39,40] because such activation does not require charge compensation. The

luminescence spectrum of Eu^{2+}, characterised by a strong room-temperature band with a maximum at 385 nm for BaFCl and at 390 nm for BaFBr, is very suitable for luminescent digital radiography, because this spectrum corresponds to the maximum sensitivity region of ordinary photocathodes and at the same time is shifted significantly relative to the excitation bands,[5] as demonstrated in Fig. 2 using the example¶ of BaFBr: 10^{-4} Eu.[41]

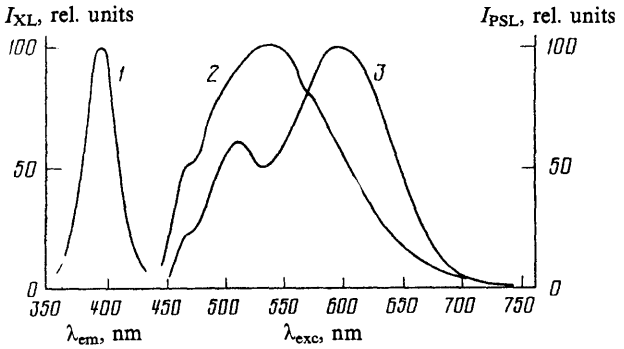

Figure 2. The luminescence (*1*) and excitation (*2*, *3*) spectra of BaFBr: 10^{-4} Eu phosphor prepared by heating a charge at 800 °C without further annealing (*2*) and after annealing at 550 °C (*3*). The spectra were recorded at 20 °C. The abscissa gives the wavelengths of the emitted luminescence (λ_{em}) and of the exciting (λ_{exc}) light and the ordinate gives the intensities of the X-ray luminescence (I_{XL}) and of the photostimulated luminescence (I_{PSL}). The spectra distribution of the photostimulated luminescence of BaFBr: Eu phosphor is identical with its X-ray luminescence spectrum. The curves are normalised to the maximum.[41]

In addition to the luminescence band due to the $4f^6 5d \rightarrow 4f^7$ transition in the Eu^{2+} ion, there may be a line 363 nm due to the $4f^7 \rightarrow 4f^7 ({}^6P_{7/2} \rightarrow {}^8S_{7/2})$ transition.[37] This transition becomes possible because, due to the relatively weak splitting of the 5*d* state into ^2e_g and $^2t_{2g}$, the lowest excited 4*f* level lies somewhat below the ^2e_g levels. The line at 363 nm becomes weaker, compared with the above-mentioend luminescence band, when Sr is replaced with Ba and when Cl is replaced with Br or I, and it also becomes weaker with increase in temperature,[37] so that in the case of BaFBr: Eu and BaFI: Eu this band is no longer observed at room temperature.

When the BaFCl: Eu phosphor is used in the preparation of amplifying screens, one of the most difficult tasks is to suppress a weak but very persistent afterglow,[26,38,42] indicating the presence of deep traps. It is an investigation of this effect, manifested more clearly in the case of BaFBr: Eu,[25] that has led to the discovery of the ability of fluorohalides to store a large amount of light energy and to liberate this as a result of optical stimulation. Charge separation, which is the condition for storing the energy, is due to a strong capture of holes by the Eu^{2+} centres and of electrons by the anion vacancies. The participation of the $V_F^{\cdot}$ and $V_{Hal}^{\cdot}$ in this process is confirmed by a comparison of the stimulation and absorption spectra of the *F* centres, which are formed by the capture of electrons.[43] The energy efficiency of the photostimulated luminescence of BaFBr: Eu excited by X-ray radiation can reach 5%.[19] Moreover, a rapid decay of the photostimulated luminescence flashes is important: it is due to the fact that the rate-limiting stage of the process is the allowed intracentre $4f^6 5d \rightarrow 4f^7$ transition. In the case of continuous optical stimulation, the rate of emptying of traps τ_{em}^{-1} is proportional to the maximum photostimulated luminescence intensity I_{PSL}, which in turn is governed by the intensity of the exciting (stimulating) light I_{st} and by the initial concentration of electrons n_F captured by the *F* centres:

$$I_{PSL} = \sigma I_{st} n_F. \quad (1)$$

Here, τ_{em} is the time during which the photostimulated luminescence intensity decreases by a factor *e* under the conditions of continuous excitation and σ is the cross section of the optical excitation process.[44]

IV. Dependences of properties of BaFBr: Eu phosphor on the conditions during its preparation

Among the many known methods for the preparation of barium fluorohalides,[20,25,29,45] three have been found suitable for the preparation of BaFBr: Eu phosphors. One of them, mentioned in the majority of the investigations (see, for example, Refs. 12, 18, and 44), is a solid-phase reaction involving heating of a charge composed of a mixture of BaF_2 and $BaBr_2$, containing europium bromide[12] or fluoride.[42] The second method differs from the first because the initial stage of the process occurs in an aqueous suspension of fine grained BaF_2 in a solution of $BaBr_2$.[25,46,47] After evaporation of the suspension and addition of $EuBr_3$, the resultant charge is heated usually in a reducing atmosphere. A special feature of the third method is that the source of fluorine is NH_4F,[19,41,48,49] interacting with $BaBr_2$ first in the solution and then (after evaporation) in the solid phase.

The properties of BaFBr: Eu depend very strongly on the conditions during its preparation.[10,41,50,51] The highest photostimulated luminescence efficiency is usually obtained when the concentration of europium is less than that needed to ensure the strongest steady-state luminescence.[41] If NH_4F is used as a fluorinating agent, this concentration is almost an order of magnitude less than for the interaction of $BaBr_2$ with BaF_2, and it amounts to 10^{-4} g-atom/mol.[52] The fluorinating effect of NH_4F favours also the incorporation of other rare-earth activators in the lattice and removal of oxygen† from it, which increases the phosphorescence intensity and reduces the photostimulated luminescence intensity, obviously due to the formation of defects of the $O'_{Br}V_{Br}^{\cdot}$ type.[19] Although the activation of BaFBr by divalent europium is quite efficient when a charge is heated together with NH_4F and with a flux (the flux may be, for example, KBr—see Ref. 41) in air, it is preferable to use a weakly reducing medium such as nitrogen containing an admixture of hydrogen[12,44] or of CO.[19,26,53] Even in this case we cannot prevent the formation of the

¶ The number in front of the activator symbol is its concentration in gramme-atoms per mole in the charge from which the phosphor was prepared.

† The source of oxygen can be water of crystallisation with which barium halides readily interact.[21]

O'_{Hal} centres.[54] The nature of the flux has a considerable influence on the excitation spectrum[52] and its concentration—and the temperature to which it is heated—affects the grain size.[45] In selecting the method for removal of the flux we must bear in mind that the hygroscopic nature of MFHal compounds and their tendency to hydrolyse increases on reduction in the size of the M^{2+} cation and on increase in the size of the Hal^- anion;[29] in the case of BaFBr it is considerably greater than in BaFCl.

An important aspect is the choice of the temperature at which a charge is heated[41] and of the ratio of the components forming the base of a phosphor. This ratio influences the completeness of the solid-phase reaction,[29,57] as well as the excitation spectrum and fading.[12] The changes in the properties of BaFBr:Eu with the rate of its cooling and the conditions during annealing are particularly striking.[41,55,56] It is found that if the excess of $BaBr_2$ is reduced before annealing,[52] the subsequent annealing of the phosphor at 450–650 °C shifts the maximum in the excitation spectrum (Fig. 2) from the yellow–green region (520–540 nm) and orange–red (595–600 nm). This reduces the intensity of the steady-state X-ray luminescence, weakens greatly the room-temperature phosphorescence, and lowers the total light (liberated due to thermal excitation) by at least an order of magnitude; the high-temperature peaks on the thermoluminescence curve are much stronger than the low-temperature peaks. On the other hand, the photostimulated luminescence efficiency sometimes even rises. The determination of the excitation spectra at liquid nitrogen temperature during the subsequent annealing of the thermally stimulated luminescence (thermoluminescence) peaks provides additional support for the conclusion that there is no direct relationship between the characteristics of thermally and optically stimulated luminescence.[41] This follows from the fact that optical de-excitation of the investigated phosphor does not suppress the thermoluminescence or phosphorescence.[50,52]

V. Crystal lattice defects in BaFBr:Eu phosphor and photostimulated luminescence mechanism

If we assume that thermal disordering of the BaFBr lattice can produce both the Frenkel and the Schottky defects, and that the antisite defects can also be present, we have to allow for the formation of the following point defects in BaFBr:Eu phosphors:[19,33,57,58] V''_{Ba}, $V_{\dot{F}}$, $V_{\dot{Br}}$, F'_i, Br'_i, F_{Br}, and Eu_{Ba}. Computer modelling of defects in crystals[59] has made it possible to calculate the enthalpy and entropy of the processes of disordering of the BaFBr lattice.[33] A thermodynamic analysis based on these data shows[58] that among the effectively charged point defects in a regular lattice at the temperatures of formation and annealing of these phosphors the $V_{\dot{Br}}$ and F'_i defects shoud predominate (at 550 °C their concentration should be an order of magnitude less than at 800 °C). The following approximate equation corresponds to equilibrium:

$$[F'_i] \approx [V^*_{\dot{Br}}]. \qquad (2)$$

A comparison of the excitation spectra with the action spectra for attenuation of the ESR signal under the influence of exciting light[8] leads to the conclusion that the vacancies $V_{\dot{Br}}$ are responsible only for the long-wavelength part of the excitation spectrum with its maximum at 595–600 nm, whereas the short-wavelength region, which predominates in the case of the nonannealed phosphor (Fig. 2), is associated with $V_{\dot{F}}$.

This apparent disagreement between the theoretical calculations and experiments is removed if we allow for the data on the influence of annealing BaFBr:Eu given in the preceding section on the thermally stimulated luminescence and the photostimulated luminescence.[41,58] Obviously, annealing (like slow cooling) in the preparation of ZnS:Cu electroluminescent phosphors[32,60] results in segregation of point defects, so that they concentrate near dislocations and block boundaries. As pointed out already (see Section III), dislocations are more likely to form at the edges between two adjacent F_2 and Ba layers. Such dislocations can generate $V_{\dot{F}}$ and V''_{Ba}) vacancies, but these remain in the region of a crystal adjoining an extended defect. Annealing a phosphor causes the $V_{\dot{Br}}$ vacancies, which predominate in the bulk of a crystal, as well as interstitial F'_i ions and the Eu_{Ba} impurity defects to migrate towards dislocations and block boundaries. This process is accompanied by the interaction of F_i with $V_{\dot{F}}$,

$$F'_i + V^*_{\dot{F}} = F_F, \qquad (3)$$

which increases the concentration ratio $[V_{\dot{Br}}]/[V_{\dot{F}}]$. If we now assume that the photostimulated luminescence is generated mainly near linear and surface defects, whereas the thermally stimulated luminescence is primarily due to the processes that occur in a regular lattice, we can account for all the reported data on the influence of annealing: the enhancement of the photostimulated luminescence in the long-wavelength part of the excitation spectrum, which corresponds to $V_{\dot{Br}}$, the absence of a direct relationship between the thermally stimulated luminescence, which is weakened by annealing, and the photoluminescence which is then even enhanced, as well as the reduction in the afterglow and in the energy efficiency of steady-stage luminescence caused by annealing. Moreover, we can also account for the results of a number of investigations supporting the tunnel mechanism of the photostimulated luminescence. These include a weak temperature dependence of the decay time of the photostimulated luminescence when excitation is in the form of short light pulses[18] (this is also true of KI:Tl-type phosphors[10]) and the absence of photoconductivity when excitation occurs under conditions such that the photostimulated luminescence is generated with the participation of effectively only the V_F centres.[61] From this point of view, the possibility of tunnel transitions of electrons is the result of the following: segregation of point defects near linear and surface defects brings close together the luminescence centres (Eu_{Ba}) and the anion vacancies.[41] The fact that the photostimulated luminescence involving the V_{Br} centres is accompanied by photoconductivity, whose excitation spectrum is similar to the luminescence excitation spectrum,[43,61] should be regarded as evidence of the coexistence of the tunnel mechanism of optical excitation with photostimulated luminescence occurring due to transitions of electrons via the conduction band,[41] although the former mechanism clearly predominates. On the other hand, the thermally stimulated luminescence and the room-temperature phosphorescence are emitted in all cases with involvement of the conduction band and are primarily due to defects located in the regular lattice.

In the course of determination of the excitation spectra of BaFBr:Eu phosphors at liquid nitrogen temperature, following successive annealing of the thermally stimulated luminescence peaks, it has been established that such annealing increases considerably the energy efficiency of the photostimulated luminescence and the contribution of the short-wavelength components in the excitation spectrum.[41] This can be explained by the transfer of electrons from traps, responsible mainly for the thermally stimulated luminescence, to traps which are the most active in the photostimulated

luminescence process. Exactly the same explanation has been applied to the partial recovery of the photostimulated luminescence after complete optical de-excitation of a phosphor.[52] The kinetics of this process, described by the equation

$$I_{PSL} = k\sqrt{t} \quad (4)$$

(where t is the storage time of a phosphor after the de-excitation and k is a coefficient), is evidence of the diffusive nature of the transfer of electrons. It should be pointed out that a model allowing for the tunnel mechanism of the photostimulated luminescence and based on the hypothesis of radiative formation of the F centres as a result of formation of $F-H$ pairs on decay of excitons located near activators[18,36] fails to account for all the observations, particularly for the strong influence of the conditions during cooling and annealing of a phosphor on the excitation spectrum and on the photostimulated luminescence energy efficiency.

A careful investigation of the excitation spectrum reveals its complex structure, which cannot be reduced to the presence of two bands.[19,41] This can be explained by the fact that the F-centres governing the form of the spectrum differ from one another not only by the nature of the anion vacancy (V_F, V_{Br}), but also in respect of its environment, particularly because of the already mentioned association with other defects, primarily with antisite defects of the F_{Br} type.[19,62] Some role may be played here also by the distribution of the excited p-state of the F-centres.[22,63]

In investigations of phosphors based on BaFCl and activated with Eu^{2+} and Sm^{2+} it has been found that their properties change greatly, and the changes include enhancement of the phosphorescence, in the presence of an excess of BaF_2.[38,39,45] There are indications that an excess of BaF_2 influences also the properties of BaFBr:Eu by increasing the proportion of the bands associated with V_{Br} in the excitation spectrum.[12] This can be attributed to intercrystalline reactions of the type

$$F_{Br} = V^{\bullet}_{Br} + F'_i, \quad (5)$$

$$F_{Br} + V^{\bullet}_{F} = F_F + V^{\bullet}_{Br}. \quad (6)$$

The first of these can be called the antisite Frenkel disordering.[52] It obviously plays a specially important role, because it involves participation of the $V^{\bullet}_{Br}$ and F'_i defects which dominate in the regular lattice. It therefore follows that it is necessary to control rigorously the conditions during preparation, which influence the excess of BaF_2, particularly during the stage of washing away the flux and annealing of BaFBr:Eu phosphors[52,64] (hydrolysis during washing of BaFBr can remove a certain amount of $BaBr_2$).

VI. Excitation spectra of steady-state luminescence, phosphorescence, and photostimulated luminescence of barium fluorohalides

The excitation spectra of steady-state luminescence, phosphorescence and photostimulated luminescence of barium and strontium fluorohalides, which are of interest from the purely scientific and utilitarian points of view, had been investigated in a wide range of energies on a number of occasions.[14,36,38–40,50,64–70] The long-wavelength edge of the main (strongest) band in the excitation spectrum of the phosphorescence, which is obviously associated with interband transitions, has been used to estimate the band gap E_g of BaFCl.[14] This band gap is 8.5–9 eV. The corresponding band gap of BaFBr is 8–8.5 eV.[40,43,71]

In the range $E < E_g$ the excitation spectra of the steady-state luminescence depend on the nature of the luminescence centres and, therefore, they are different for nonactivated phosphors and for phosphors containing Eu^{2+} and Sm^{2+}.[39,40] They depend at least in the case of activation with europium, also on the oxidation—reduction properties of the medium in which a phosphor is heated during preparation.[38] For example, the excitation spectrum of BaFCl:2×10^{-2} Eu, prepared in a CO medium, includes a strong activator band extending from 3.3 to 5.4 eV with a barely detectable splitting into two bands due to the $5d(^2e_g)$ and $5d(^2t_{2g})$ states of the Eu^{2+} ion. Howevever, heating of this phosphor in air at 650–700 °C weakens strongly the Eu^{2+} band (although the intensity of the steady-state X-ray luminescence even rises somewhat[26]). Then, a weak peak at 318 nm remains in the long-wavelength part of the excitation band whereas a structure appears in the short-wavelength part corresponding to the t_{2g} state and this structure is due to transitions of electrons from the $4f^7(^8S)$ level to the levels of the $4f^6(^7F_J)5d(^2t_{2g})$ state split by the spin–orbit interaction. Heating in CO smears out this structure because of reduction of europium on the phosphor surface, where the Eu^{2+} ions may be in a different environment.[38] The structure of the part of the spectrum located between the band corresponding to the intracentre transitions and the energy E_g is attributed to the ionisation of Eu^{2+} and the presence of the edge Γ excitons [at 8.4 eV in the case of BaFCl and at 7.4 and 7.9 eV in the case of BaFBr [39,66,71]] associated with the $4p$-states of the Cl^- and Br^- ions.

The nature of the excitation spectra of the steady-state luminescence recorded in the range $E > E_g$ is practically independent of the activator and there is a considerable qualitative similarity of the BaFCl and BaFBr spectra (Fig. 3). The most remarkable feature of the spectra in the range 9–30 eV is the presence of a two-hump maximum at 16–20 eV in the case of BaFCl and 15–19.5 eV in the case of BaFBr. It can be attributed to the simultaneous influence of the formation of a plasmon and a core exciton,[40] due to the excitation of electrons in the $5p$-shell of the Ba^{2+} ions. The formation of an exciton increases the absorption coefficient and thus enhances the surface losses and gives rise to a narrow dip in the spectrum at 18.1–18.3 eV. The photon multiplication is manifested largely by a tendency to establish a constant energy efficiency η of the luminescence rather than by an abrupt increase in the quantum efficiency η_q.[39,40] Already in the range 20–30 eV the value of η becomes approximately equal to the energy efficiency of X-ray luminescence: 11–12% for BaFCl:10^{-2} Eu and 16–18% for BaFBr:Eu.[40,41] In the case of BaFBr:Eu the constancy of η is supported by measurements in the range from 10 to 1000 eV.[70] The annealing of BaFBr:Eu at 550 ± 100 °C reduces the energy efficiency of the steady-state luminescence at $E > 11$ eV by a factor of about 2; on the other hand, at 10 eV a strong excitation band is observed (Fig. 4 *a*) and this band is difficult to detect in the case of nonannealed phosphors. It is possibly due to the formation of F_{Br} clusters (10 eV is the initial energy of the appearance of excitons, bound to the $2p$-states of the F^- ions[36]).

The excitation spectrum of the photostimulated luminescence of BaFBr:Eu had been determined under somewhat different conditions by two research teams independently.[36,50,64–66] We can see from Fig. 4 that in the range $E > 11$ eV this spectrum is basically similar to the excitation spectrum of the steady-state luminescence. On the other hand in the range $E < 11$ eV of the two spectra are very different. For example, at 10 eV instead of a maximum, observed in the excitation spectrum of the steady-state

luminescence of the annealed phosphors, the corresponding photostimulated luminescence spectrum has a dip. A narrow intense peak at 7 eV is very typical of the excitation spectrum of the photostimulated luminescence. Following the two concepts of the mechanism of the photostimulated luminescence mentioned above, this peak is attributed to a transition of an electron from Eu^{2+} to an adjacent vacancy or to an exciton, the dissociation of which forms a $F-H$ pair.[36,50] It is important to stress that the phosphorescence of BaFBr:Eu begins to be excited effectively at higher energies of about 8 eV.[50]

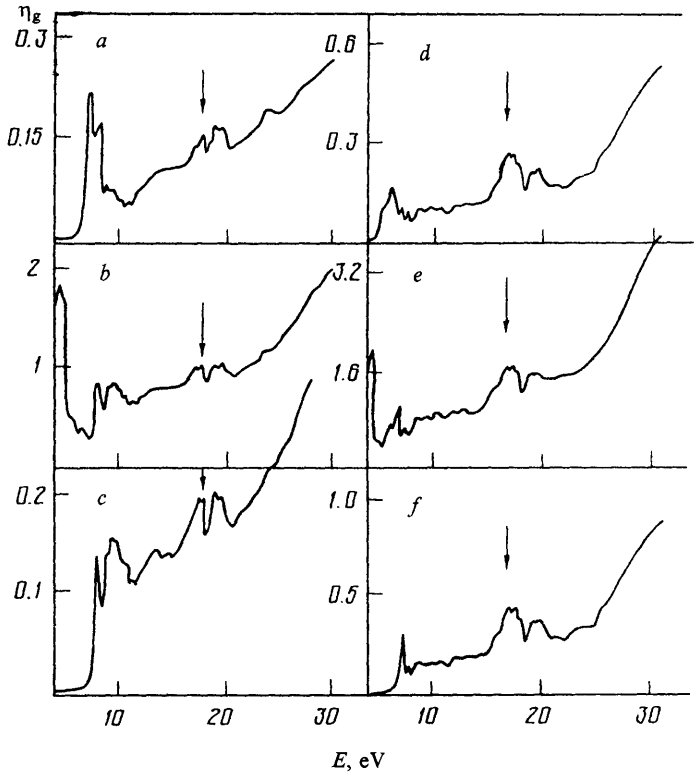

Figure 3. Excitation spectra of steady-state luminescence of nonactivated BaFCl (*a*), BaFCl:2×10^{-2}Eu (*b*), BaFCl:10^{-2}Sm (*c*), nonactivated BaFBr (*d*), BaFBr:10^{-3}Eu (*e*), and BaFBr:10^{-2}Sm (*f*). The ordinate represents the quantum efficiency relative to sodium salicylate. The arrows identify the calculated values of the plasmon energy.[40]

VII. Some applications of storage luminescent screens

The development of storage luminescence screens and of the luminescent digital radiography based on them has opened up new opportunities in X-ray diagnostics. This is based on the combination of computer techniques with the large area of the images required in medicine, a relatively high spatial resolution, and a wide dynamic range. There have been several reports on the application of luminescent digital radiography in examination of lungs, breasts, and other organs,[72–77] and in checking the position of a radiation beam as well as in obtaining information on the distribution of the dose in a body being irradiated by radiotherapy.[56,78,79] Technical difficulties and cost are hindering the extension of a wider use of the method in medicine.[7,80]

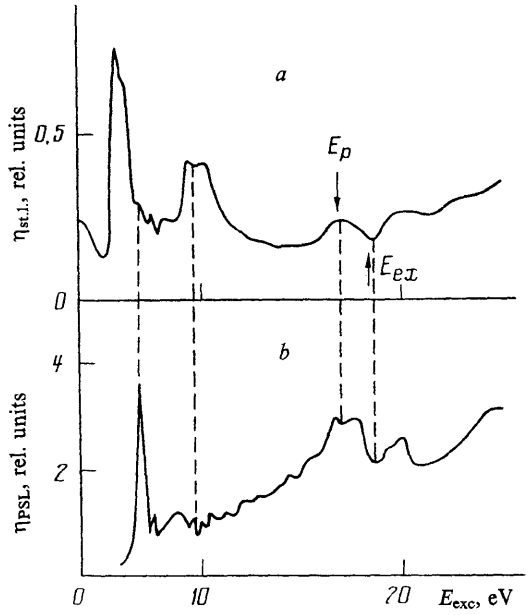

Figure 4. Excitation spectra of the steady-state luminescence (*a*) and of the photostimulated luminescence (*b*) of BaFBr:10^{-4}Eu phosphor annealed at 550 °C. The arrows identify the calculated values of the plasmon energy (E_p) and of the energy of the core exciton (E_{ex}), formed on excitation of electrons from the 5*p*-shell of the Ba^{2-} ion.[50]

There have been several descriptions of the application of luminescent digital radiography in obtaining diffractograms,[81,87] particularly in studies of biological objects with the aid of synchroton radiaiton. This method can be used to obtain high-quality records after exposures tens of times shorter than usual.[81,84,85] There have been suggestions of the use of luminescent digital raidography in transmission electron microscopy[88] and in recording various radiations both electromagnetic—from the VUV range[40,89] to the bremsstrahlung emitted by electron accelerators[56]—and the corpuscular,[89] including determination of the natural background. One should bear in mind that barium salts employed as phosphors usually contain a small amount of radium.[17,20] Obviously, luminescent digital radiography can be used also in astrophysics research, including X-ray astronomy, where a wide dynamic range of energy storing luminescent screens can be particularly valuable.

The different applications of these screens have led to studies of the parameters governing the quality of the images obtained by luminescent digital radiography and of threshold values of the flux

of the radiation being detected.[6,81,90–92] As usual, a dominant role is played by the efficiency of energy conversion of the radiation which excites the emitted luminescence, by the noise, by the frequency–contrast characteristic, by the dynamic range, and by the kinetic parameters.[93] On the other hand, these screen quality factors and systems as a whole are influenced by a number of factors specific to luminescent digital radiography.[7,90] These factors depend on the properties of the phosphors and screens employed and include the scattering of exciting light,[11] fading,[13,94] and fluctuations of photon fluxes (luminescence noise).[87] The last of these factors is particularly important as a component of the general noise in the case of a low energy efficiency of the photostimulated luminescence and high light losses between a screen and a photomultiplier.

We can thus see that the development of efficient crystal phosphors or image-storing screens and of the luminescent digital radiography method based on these screens has laid the foundation stone for a new branch of research, which is now developing rapidly in various directions.

Current approach to the problem of nitrenium ions

T P Simonova, V D Nefedov, M A Toropova, N F Kirillov
Perm State University
St. Petersburg State University

ABSTRACT. This review is devoted to the chemistry of nitrenium ions, which are highly reactive species whose bivalent nitrogen atom has an incomplete (sextet) electron shell and bears a formal positive charge. All known methods for generating these ions, including a nuclear chemical method developed by the authors, their reactions, structure, and also the role of nitrenium ions in the chemistry of nitrogen-containing compounds are examined.

The bibliography includes 159 references.

I. Introduction

The idea that it is possible to form charged species containing bivalent nitrogen (nitrenium cations) was first put forward at the beginning of this century in the studies of Stieglitz et al.[1–3]

Up to the 1970s the publications devoted to studies on these species were not only limited but also contradictory. Different schemes for the same reaction of nitrogen-containing compounds were put forward, assuming and excluding the formation of nitrenium ions as intermediates. It is sufficient to say that an unequivocal affirmation of the fact that nitrenium ions are actually formed only became possible as a result of studies during the last 20–25 years.

The first attempt to correlate the available information on nitrenium ions was made in 1970.[4] However, an extensive series of studies by Gassman marked the beginning in the development of the chemistry of these reactive nitrogen-containing intermediates. The results of Gassman's studies, which were published in a review article,[5] contained fundamental data that demonstrated the possibility of such cations existing as independent species. Gassman produced convincing data on the electronic structure of nitrenium ions and evidence for their possible existence both in a singlet and triplet state.

Subsequent experimental studies[6–8] and quantum-mechanical calculations[9–25] confirmed the basic conclusions of Gassman. It was shown that nitrenium ions containing alkyl groups occur mainly in a triplet ground state while those containing aryl groups occur mainly in a singlet ground state.

In the 1970s and 1980s physicochemical[26–27] and nuclear chemical[28–32] methods for generating nitrenium ions were developed. It should be noted that with nuclear chemical methods it is possible to obtain these species in a free state and to study their reactions.

During the last ten years research on nitrenium ions and their reactions has been conducted with particular intensity.[28–48] The increased interest in this problem is mainly due to the important role of these species in carcinogenetic processes. Nitrenium ions are known to constitute the active form of strong chemical carcinogens, such as arylamines, *N*-arylhydroxylamines, and arylnitroso and arylnitro compounds.[24,49–53] It has been established that the active forms of chemical carcinogens are strong electrophilic reagents that are covalently bonded with the nucleophilic forms of nucleic acids and proteins. One of the main problems is to obtain information about the macromolecularly bonded products for each carcinogen. This is important in determining the relative role of each adduct in the carcinogenetic process.[49]

Furthermore, reactions of nitrenium ions open up exceptional opportunities for direct amination and on this basis the development of novel synthetic methods for preparing nitrogen-containing compounds.[54]

II. General characteristics and electronic structure of nitrenium ions

Nitrenium ions are nitrogen-containing organic compounds in which the nitrogen atom has an incomplete (sextet) electron shell and bears a formal positive charge (+1).

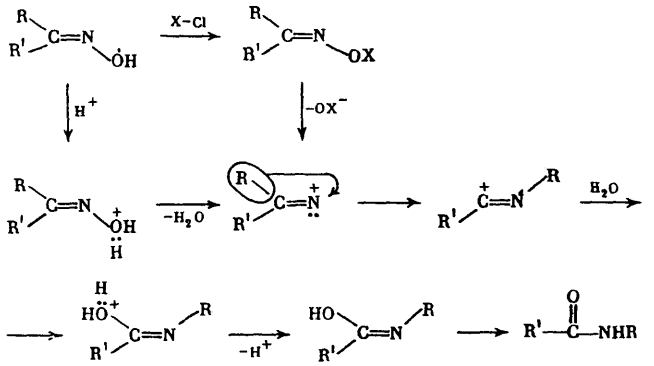
Nitrenium ions are formed as a result of the heterolytic elimination of a substituent from amines of two structural types:[55]

$$R_3N \xrightarrow[-R^-]{} R_2\overset{+}{N}: \qquad \text{(A)}$$

$$R^1R^2C{=}NX \xrightarrow[-X^-]{} R^1R^2C{=}\overset{+}{N}: \qquad \text{(B)}$$

Nitrenium ions of type (A) form the subject of our investigation.

An example of a reaction in which cations of type (B) are formed as an intermediate is provided by the Beckmann rearrangement (see the study of Donaruma and Heldt).[56] The mechanism by which this rearrangement occurs is described by Saik.[57]



X = $R''CO^-$; $R''SO_2^-$ etc.

In this case the synchronous cleavage of the N–O bond and migration of the group without formation of a nitrenium ion also cannot be excluded (possibly via a three-centred transition state), which is supported by the stereoselectivity of the reaction.

Nitrenium ions resemble carbocations in their behaviour. However, a number of significant differences in their behaviour caused by the nature of the heteroatom should be noted. Because of the presence of a positive charge on the more electronegative nitrogen atom compared to a carbon atom, the stability of nitrenium ions is expected to be lower than that of carbocations. By analogy with carbocations, nitrenium ions have a sextet of electrons and a vacant *p* orbital, but in contrast to carbocations there is a free electron pair on the nitrogen atom. The presence of the latter is responsible for several characteristics of the chemical behaviour of nitrenium ions that distinguish them from carbocations—the possibility of these species occurring in singlet (A) and triplet (B) states.[58]

(A) (B)

The singlet nitrene cation differs from triplet biradical species by virtue of its chemical behaviour and it displays a similarity to carbocations.

Quantum-chemical calculations carried out for the parent nitrenium ion $\overset{+}{N}H_2$,[9–13,16–19,23] its alkyl homologues $MeNH$,[11,14,21,23] Me_2N,[14,21,23] and others[15,23] and also for phenylnitrenium ions[24,25] demonstrated that the difference in energy between the singlet and triplet states is 20–40 kcal mol^{-1} in certain cases. For the unsubstituted $\overset{+}{N}H_2$ and the simplest alkyl homologues the ground state is the radical-like triplet state.†

Arylnitrenium ions occur preferentially in a singlet ground state.[24] Both forms (singlet and triplet) in the case of arylnitrenium ions are stabilised through transfer of electron density from the phenyl substituent to the nitrogen atom, but for the triplet form this transfer, and hence the magnitude of the stabilising effect, is less than for the singlet, since the *p* orbital in the triplet state is partly filled[24] (Fig. 1).

The calculated heats of formation of certain nitrenium ions (ΔH_f) and their relative stabilisation energies (ΔE) are given in Table 1.

S T

Figure 1. Mesomeric stabilisation of singlet and triplet nitrenium ions.

Table 1. Heats of formation (ΔH_f) and relative stabilisation energies (ΔE) of the singlet and triplet states of certain nitrenium ions (MNDO method).

Ion	ΔH_f, kcal mol^{-1} (Ref.24)		(S_0-T_1), kcal mol^{-1}	ΔE^*, kcal mol^{-1} (Ref.24)	
	S_0	T_1		S_0	T_1
$\overset{+}{N}H_2$	313.4	292.2	21.2	0	0
$MeNH$	277.9	271.7	6.2	-37**	-22
Me_2N	259.1	251.1	8.0	-57	-44
	240.4	250.9	-10.5	-70	-38
$PhNH$	241.5	267.6	-26.1	-106**	-59

*Values of the stabilisation energies given relative to $\overset{+}{N}H_2$.

**The corresponding stabilisation energies of $MeCH_2$ and $PhCH_2$ relative to CH_3 are −37 and −56 kcal mol^{-1}.

The data shown are in good agreement with the results of experimental studies by Japanese research workers.[45,48] In the case of the reactions between alkyl- and phenyl-nitrenium ions with different aromatic nucleophiles it is possible to establish a trend for the decrease in energy of singlet nitrenium ions:

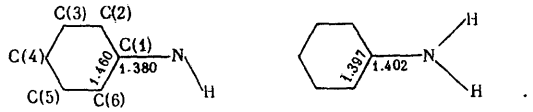
$$\overset{+}{N}H_2 > Alk\overset{+}{N}H > Ph\overset{+}{N}H.$$

It can be seen from Table 1 that aromatic nitrenium ions have a higher stabilisation energy than the aliphatic ions.[5]

Quantum-chemical calculations of the energy, geometry, and electronic structure of phenylnitrenium ions were made in two studies.[24,25] Calculation of electron density by the MNDO method

† At the same time it was established[58] that solvents containing heavy atoms can catalyse spin inversion. This effect has been observed in three studies.[41,43,59]

for phenylnitrenium ions[24] assumes an optimum geometry for planarity of the cation.‡ From the calculations of Krylov[25] the following optimum geometry of the phenylnitrenium ion was established (the geometry of aniline is shown for comparison):



It should be noted that the C–N bond in phenylnitrenium ions is considerably shorter than in alkylnitrenium ions. As expected, the results of calculation of the electronic structure of phenylnitrenium ions suggest that a partial positive charge occurs on the second (0.112), sixth (0.112), and fourth (0.169) carbon atoms of the benzene ring. At the same time the charge on the carbon atom at the *para* position exceeds the positive charge on the nitrogen atom (0.123) (Table 2).

Table 2. Charges on the electrophilic sites of phenylnitrenium ions.

Atom	MNDO method (Ref.24)		CNDO/2 method (Ref.25)
	LUMO	*q* (total)	*q* (total)
N	0.444	0.001	0.123
C(1)	-0.087	-0.065	—
C(2)	-0.459	0.346	0.112
C(3)	0.043	-0.010	—
C(4)	0.590	0.384	0.169
C(5)	-0.004	-0.041	—
C(6)	-0.496	0.233	0.112

Krylov[25] concluded from the charge distribution data that there is a considerable contribution from mesomeric carbocation structures in phenylnitrenium ions.

(I) (II) (III) (IV)

The values of the LUMO coefficients§ shown in Table 2 also show that four electrophilic sites occur in phenylnitrenium ions.

‡ Similar calculations[63,64] give a nonplanar structure for aniline.

§ According to general multielectron perturbation theory, a donor-acceptor interaction may be charge-controlled (type I) or (frontier) orbital-controlled (type II). Electrophilic aromatic substitution (benzene as a mild nucleophile) is a "frontier orbital-controlled" reaction. The reaction sites of the electrophile will be atoms having the highest charge density on their lowest unoccupied molecular orbital (LUMO).[65]

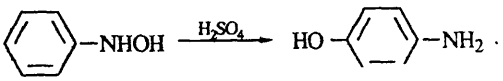
The experimental data (see Section IV) suggest that nitrenium ions with aromatic substituents do in fact behave both strictly as nitrenium ions (I) and as carbocations (II)–(IV).

III. Methods of generation

1. Bamberger and Stieglitz rearrangements

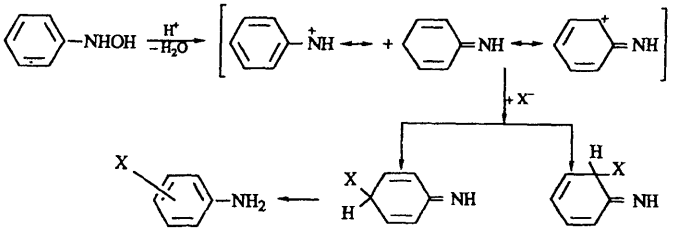
The original ideas about the existence of unstable bivalent nitrogen intermediates developed as a result of studies on the rearrangements of *N*-arylhydroxylamines — the so-called Bamberger and Stieglitz rearrangements.

The Bamberger rearrangements takes place on treatment of *N*-phenylhydroxylamine with aqueous mineral acid, resulting in the formation of *p*-aminophenol.[66–68]



Bamberger assumed that arylhydroxylamines are dehydrated to nitrenes, which react with nucleophilic reagents to give rearrangement products.

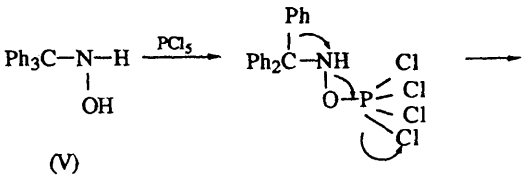
Subsequent studies of this reaction[69–72] demonstrated that a nitrenium ion is formed at an intermediate stage. In an investigation of the acid catalyst trifluoromethanesulphonic acid (TFMSA), *ortho*- and *para*-substituted anilines were obtained.[72]



X = HO, PhO, MeO, Cl, Ph etc.

It could be assumed from kinetic studies that the nitrenium ion is formed in a slow stage and then rapidly adds a nucleophile molecule.[73]

Stieglitz et al.[1,2] initially studied the rearrangement of *N*-monoalkylhydroxylamines in which the carbon atom adjacent to the nitrogen was fully substituted, such as in tritylhydroxylamine (V).



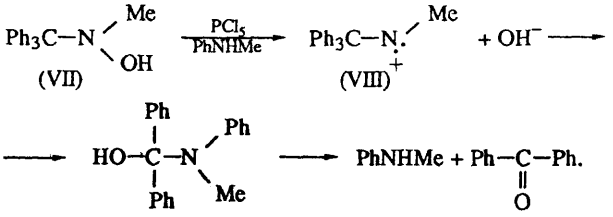
(V)

(VI)

Treatment of (V) with phosphorus pentachloride causes one of the phenyl groups to migrate to the nitrogen atom with the formation of the imine (VI), and after hydrolysis benzophenone and aniline are formed. At the same time migration was thought to be an

intramolecular process. Stieglitz et al. put forward the suggestion that species with a univalent nitrogen atom (nitrene as interpreted at the present time) were formed as an intermediate.

This interpretation of substituted hydroxylamines as originally proposed by Stieglitz encounters difficulties when attempts are made to distinguish between nitrenium ions and nitrenes in *N*-monosubstituted hydroxylamines. In order to exclude the formation of nitrene, Stieglitz et al.[3] studied the rearrangement of a dialkyl-substituted hydroxylamine, namely, triphenylmethyl-*N*-methylhydroxylamine (VII) under similar conditions (with PCl_5), as a result of which only triphenylchloromethane was formed. However, when the reaction was carried out in the presence of small quantities of *N*-methylaniline, the rearrangement products—benzophenone and *N*-methylaniline—were isolated in low yield together with triphenylchloromethane. In this case it is impossible to depict the formation of nitrene, and the authors put forward another reaction scheme, which actually features the nitrenium ion (VIII):



Later studies[5] supported the conclusion of Stieglitz, by demonstrating that under certain conditions the rearrangement of disubstituted hydroxylamines actually occurs via the formation of a nitrenium ion.

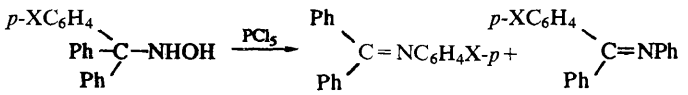
Research on the rearrangements of Stieglitz and Bamberger assisted in the development of different methods for the synthesis of nitrenium ions. For a long time the most widely studied of the reactions that occur via intermediate nitrenium ions were the reactions of hydroxylamine and *N*-haloamine derivatives.

Other methods of generating nitrenium ions are reactions involving organic azides and hydrazine derivatives and the photolysis and thermolysis of pyridinium and sulphonium salts and other salts. At the present time nitrenium ions may also be obtained by physicochemical and nuclear chemical methods. Let us examine these methods in greater detail.

2. Generation of nitrenium ions at intermediate stages of organic reactions

a) Reactions of hydroxylamines. It was possible to conclude from an examination of the rearrangements of Stieglitz and Bamberger that the formation of nitrenium ions is affected both by the nature of the actual nitrogen-containing organic compounds (sources of nitrenium ions) and by the medium in which these reactions occur.

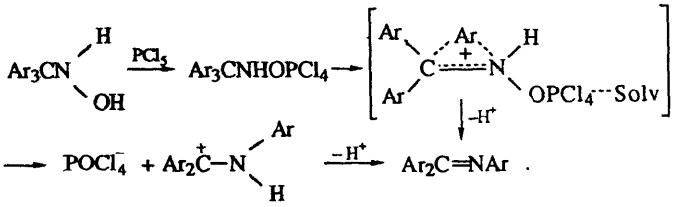
Studies by Newman and Hay[74] also provide evidence for the formation of nitrenium ions in the Stieglitz rearrangement. In a study of the effect of substituents in the aromatic ring on the migrating ability of the ring in the rearrangement of triarylhydroxylamines on treatment with PCl_5



X = OMe, Cl, NO_2 ,

it was established that a decrease in the electron-donating properties of the substituents leads to a reduction in the migrating ability of the corresponding group: 9.10 (C_6H_4OMe), 0.55 (C_6H_4Cl), and 0.38–0.18 ($C_6H_4NO_2$). The authors concluded that, by analogy with the pinacol rearrangement (a typically ionic process), the Stieglitz rearrangement is also accompanied by the formation of ionic species.

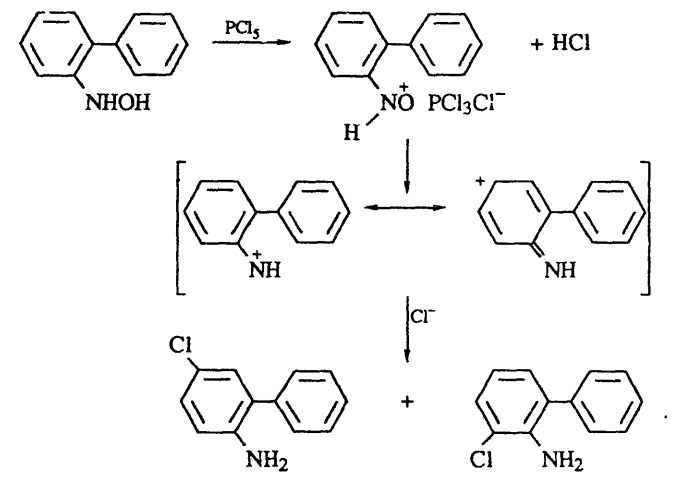
We should not that this rearrangement is interpreted by Krylov[25] as the synchronised cleavage of the N–O bond and migration of a group to the nitrogen atom



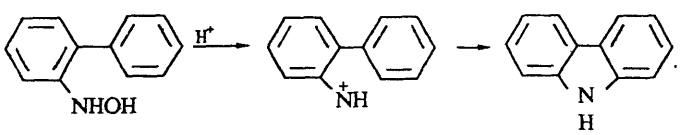
However, the possibility of nitrenium ions being formed in very polar media (in polyphosphoric acid, for example) cannot be excluded.

It should be noted that the mechanism of the Stieglitz rearrangement by treatment with various Lewis acids[75–77] depends on the electrophilicity of the reagent used. The probability of a nitrenium ion being formed increases with an increase in the electrophilicity of the reagent and is reduced to zero in the case of weak electrophiles (*o*-isopropyl methylphosphonochloridate, for example).[78]

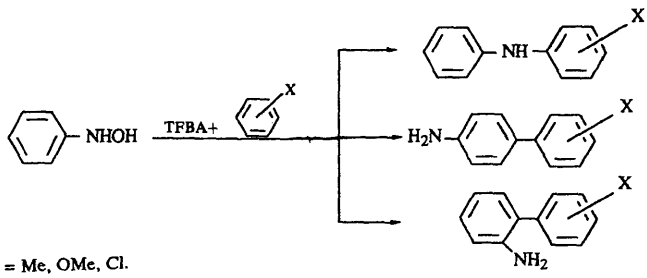
For the rearrangement of 2-hydroxylamino-1,1′-biphenyl, which takes place on treatment with PCl_5, a scheme involving the formation of an intermediate nitrenium ion was proposed by Potts et al.[79]



A similar process, but one that occurs on treatment with strong proton acids, gives carbazole which is formed from a nitrenium ion.[80]



Considerable attention has been given recently to intermolecular reactions involving the introduction of aminophenyl groups into an aromatic ring. On treatment of phenylhydroxylamine with tetrafluoroboroic acid (TFBA) in aromatic hydrocabons, the arylamination products were isolated in 20–50% yield:[81]

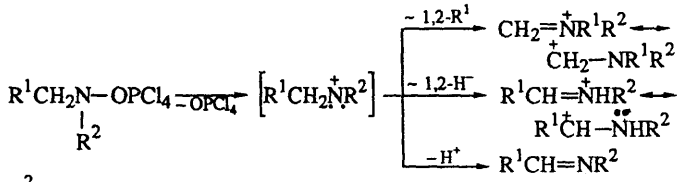


X = Me, OMe, Cl.

It was assumed in this case that initially a phenylnitrenium ion is formed, which subsequently reacts with an aromatic ring.

Further studies in this area showed that other acids, such as acetic acid (AA),[33,34,36] trifluoroacetic acid (TFAA),[35,37,40,41,43] and trifluoromethanesulphonic acid (TFMSA)[39,43,72,82] can act as catalysts of arylamination occurring via the formation of a nitrenium ion. It was found, moreover, that the nature of the acid has an effect on the ratio of the final products.

Four studies by Krylov et al.[6–8,25] investigated the rearrangements of *N*-alkyl- and *N,N*-dialkylhydroxylamines and also their salts with phosphorus pentachloride involving migration of hydrogen and alkyl groups:



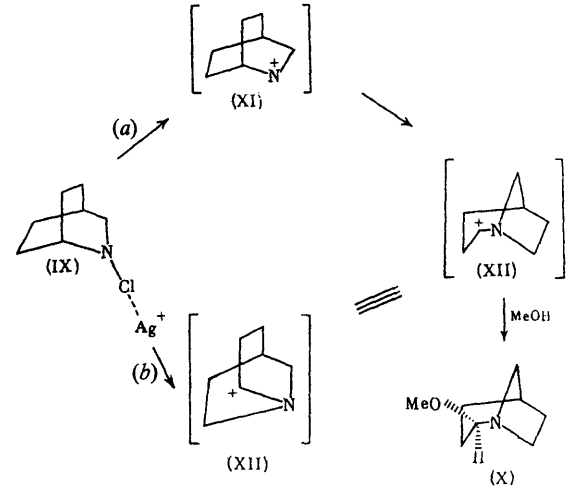
R^2 = H, CH_2R.

The authors assumed that the primary and secondary amines were formed as a result of the rearrangement of nitrenium ions, accompanying migration of a group to the electron-deficient nitrogen atom.

b) Reactions of *N*-haloamines. The first, rather contradictory, studies on the preparation of nitrenium ions as a result of the cleavage of the N–Hal bond in *N*-haloamines were published in the mid-1960s.[83–85] Because of the large number of studies in this area, it has been shown at the present time that many of the compounds that contain an N–Hal bond are very convenient substrates for the preparation of nitrenium ions.[5,59,86–108] Such compounds include azabicyclic compounds, haloamines with cyclic groups (cyclopropane and cyclobutane) and aromatic groups (anilines), etc.

Scheme 1 illustrates the formation of nitrenium ions by solvolysis of *N*-chloroisoquinuclidine (IX) in a methanol solution of silver nitrate.[5]

Scheme 1

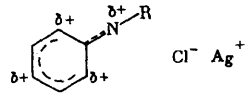


The conversion of (IX) to (X) can occur by two routes: route (*a*)—the heterolytic cleavage of a chloride anion resulting in the formation of nitrenium ion (XI): route (*b*)—simultaneous loss of a chloride anion and migration of an alkyl group with its pair of bonding electrons, giving product (XII). Regardless of which of the two routes is followed in this rearrangement, the species (XI) with a deficiency of electrons on the nitrogen atom participates in this process.

In studying the reaction depicted in Scheme 1, Gassman and Cryberg[59] conducted an experiment on the conversion of nitrenium ions from a singlet to a triplet state. By using solvents containing heavy atoms, it was possible to control the conversion of singlet to triplet states according to a previously established method.[109–110] The authors[59] believe that this constitutes evidence for the existence of nitrenium ions.

A series of studies[90,94,97,101,102,105] is concerned with the formation of nitrenium ions in nucleophilic aromatic substitution in anilines. Thus, on solvolysis of *N*-chloroanilines, products that were similar to those of the Bamberger rearrangement[72] were isolated, as illustrated by Scheme 2. It is clear from Scheme 2 that, at the initial stage of the reaction, ionisation of (XIII) occurs with the formation of arylnitrenium ions with various resonance structures [(XIVa) ⟷ (XIVb) ⟷ (XIVc)].

Even though an excess of silver ions is present in the reaction mixture, chloro derivatives are formed. Gassman et al.[101] attribute this phenomenon to the formation of an intimate ion pair at an intermediate stage of the reaction.



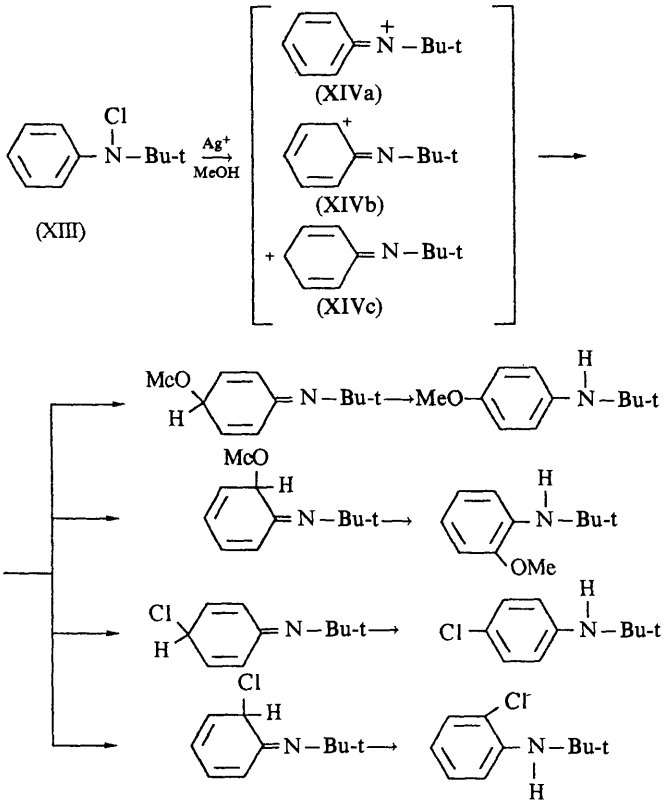
Similar results were obtained from the thermal rearrangement of *N*-chloroanilines.[102]

The formation of nitrenium ions as intermediate species was also detected in the solvolysis of *N*-chloroamines containing a multiple bond.[89,96,111–115] It should be noted that in the solvolysis of *N*-haloamines, cleavage of the N–Hal bond can take place both heterolytically and homolytically, depending on the structure of the

initial compound and the reaction conditions. The presence of rearrangement products in the reaction mixture may be regarded as an important argument in favour of heterolytic cleavage of the bond.

It has been shown in a number of studies[116–123] that the rearrangements of *N*-haloamines on treatment with Lewis acids also occur via the formation of nitrenium ions.

Scheme 2



c) Reactions of organic azides. It was shown in studies in the 1950s and then particularly in research carried out in the 1980s that organic azides represent convenient sources of nitrenium ions. The majority of organic azides are unstable compounds. They readily decompose with the elimination of molecular nitrogen on exposure to heat, light, and various chemical reagents. Reactions involving the acid-catalysed decomposition of azides and their possible conversions through reaction of the latter with carbocations (Schmidt reaction) are of interest in relation to the problem of nitrenium ions

$$RNN_2 + X^+ \longrightarrow \left[R-\underset{\displaystyle X}{\underset{|}{N}}-N_2\right]^+ \longrightarrow R-\overset{+}{\underset{\cdot\cdot}{N}}-X + N_2$$

X = H, R etc.

Despite the considerable quantity of experimental data, the question as to whether nitrenium ions are formed during acid-catalysed decomposition of azides and in the Schmidt rearrangement remains open. In a number of studies[124–129] the concept of the intermediate formation of nitrenium ions was introduced to explain the acid-catalysed rearrangement of azides. However, the alternative possibility of synchronous migration of a group to the nitrogen atom and the elimination of a nitrogen molecule generally cannot be excluded. In three review articles devoted to the rearrangement of azides[130–132] it is noted that despite the concept of nitrenium ions being introduced to explain a number of azide reactions, it has not been possible to date to provide significant evidence for their formation at an intermediate stage of the reaction.

It was shown in four studies[133–136] that rearrangements similar to the Schmidt reaction occur by interaction of azides with a nitrosonium cation. Doyle et al.[134] assumed that nitrosonitrenium ions are formed at an intermediate stage of the reaction. However, in two subsequent studies[135,136] another reaction scheme was put forward:

$$Ph_2CH-N_3 + NO_2^+ \longrightarrow Ph_2CH^+ + N_2 + N_2O,$$

$$Ph_2CH-N_3 + Ph_2CH^+ \longrightarrow Ph_2CHN(N_2^+)CHPh_2 \xrightarrow{-N_2} PhCH=\overset{+}{N}(Ph)CHPh_2 \xrightarrow{-Ph} Ph_2CH-\overset{+}{N}-CHPh_2$$

$$PhCH=\overset{+}{N}(Ph)CHPh_2 \xrightarrow{H_2O} PhCHO + PhNHCHPh_2 .$$

The constant ratio of unsubstituted to substituted benzaldehydes for reactions of phenylarylazidomethanes with nitrosonium tetrafluoroborate or $PhAr\overset{+}{C}H\ BF_4^-$ whatever the reagent used was regarded[135,136] as evidence for the participation of dialkylnitrenium ions in these reactions.

A group of Japanese scientists directed by H Takeuchi[33–48] studied the photolysis and thermolysis of azides, pyridinium and sulphonium salts, and other products in the presence of proton acids, which result in the formation of nitrenium ions. They generate nitrenium ions with various structures: $\overset{+}{N}H_2$ and its alkyl homologues,[45,46,48] ethoxycarbonylnitrenium ions,[33,35,40] unsubstituted phenylnitrenium ions,[34,37,39,41,46] and phenyl-substituted[42–44,46] and naphthyl-substituted[39] nitrenium ions with different substituents.

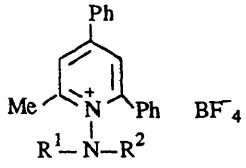
It was found that in proton acids such as acetic acid, trifluoroacetic acid (TFAA), and trifluoromethanesulphonic acid (TFMSA), phenyl azide completely decomposes after a few minutes at 25 °C,[43] whereas in aromatic solvents azides decompose at temperatures above 130 °C.[43] Furthermore, Takeuchi et al. studied the decomposition of azides in a mixture of an aromatic solvent and a proton acid. For example, in a mixture of benzene (70%) and trifluoroacetic acid (30%) at 25 °C, phenyl azides decompose over a period of 10 h. In the opinion of Takeuchi et al.[43] photolysis (thermolysis) of azides yields a nitrene, which is protonated by the acid to form its conjugate base and a nitrenium ion.

For example, in the thermolysis of ethyl azidoformate in acetic acid, nitrene (XV) is first formed, then the ion pair (XVI) is formed:[33,34]

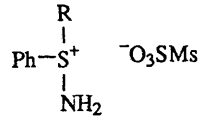
Scheme 3

$$N_3CO_2Et \xrightarrow{h\nu \text{ or } \Delta T} :\ddot{N}CO_2Et \xrightarrow{MeCOOH} [MeCOO^- \ ^+NH_2CO_2Et].$$
(XV) (XVI)

d) Photolysis (thermolysis) of pyridinium and sulphonium salts. In addition to azides, Takeuchi et al.[45,47,48] proposed the use of sulphonium and pyridinium salts as sources of nitrenium ions. The photolysis or thermolysis of pyridinium tetrafluoroborate (XVII) or *S*-aminosulphonium salts (XVIII) in the presence of TFAA



(XVII)



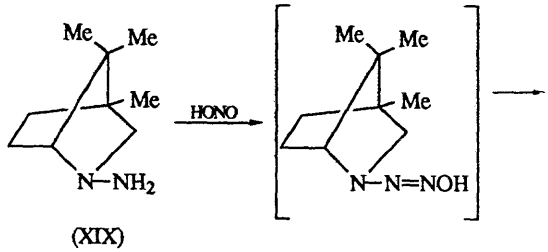
(XVIII)

$R^1 = R^2 = H$; $R^1 = H$, $R^2 = Ph$;
$R^1 = R^2 = Alk$.

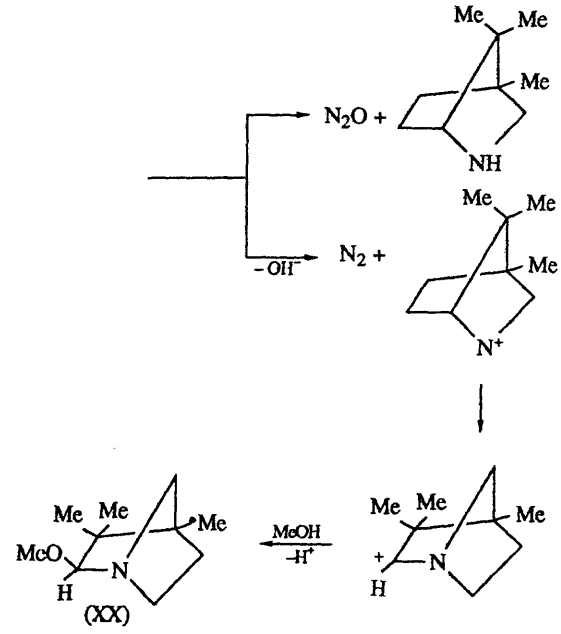
generates nitrenium ions in both singlet and triplet states. These studies are of particular interest because quantum-chemical calculations showed that for the simplest nitrenium ion and its alkyl homologues the ground state is triplet (see Section II).

e) Other reactions that occur via the formation of nitrenium ions. Together with the previously studied solvolysis reactions of *N*-haloamines, where the formation of intermediate nitrenium ions was established, reactions of hydrazines with a similar structure were also studied.[98] On nitrosation of the hydrazine (XIX) with isoamyl nitrite, the product (XX) was isolated (21% yield), derived from a hypothetical rearranged nitrenium ion (Scheme 4). Unfortunately, in this study there was no analysis of the gaseous products that was necessary to establish the actual pathway for formation of the secondary amine.

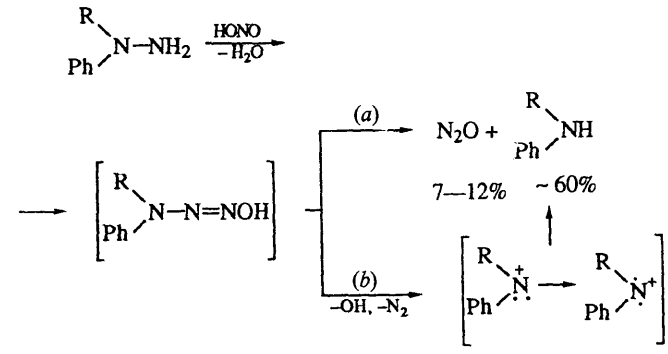
Scheme 4



(XIX)



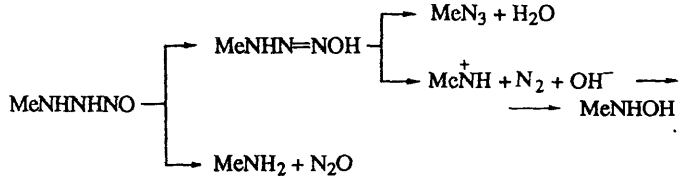
The reactions of 1,1-alkylarylhydrazines with nitrosating agents were studied in greater detail by De Rosa,[137] who put forward the following reaction scheme:



Analysis of the products showed that the yield of secondary amine was much higher than that of nitrous oxide. This phenomenon, in the opinion of De Rosa,[137] demonstrates the possibility that the secondary amine is formed via the conversion of a nitrenium ion from a singlet to a triplet state [route (*b*)].

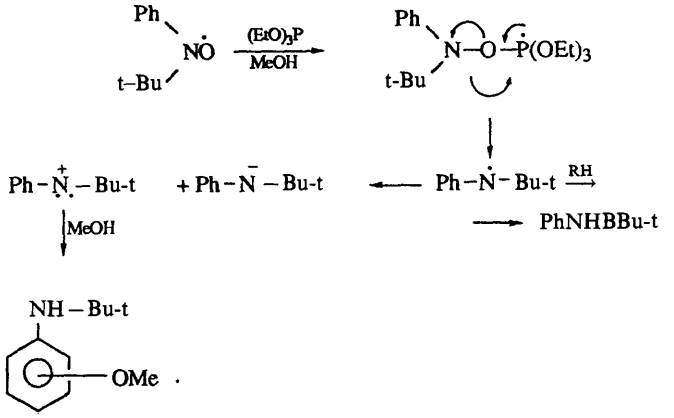
The possible formation of monosubstituted alkylnitrenium ions was also noted by Perrott et al.[138] A study of the kinetics of the nitrosation of hydrazines suggested the possibility of this reaction occurring by two routes (Scheme 5)

Scheme 5

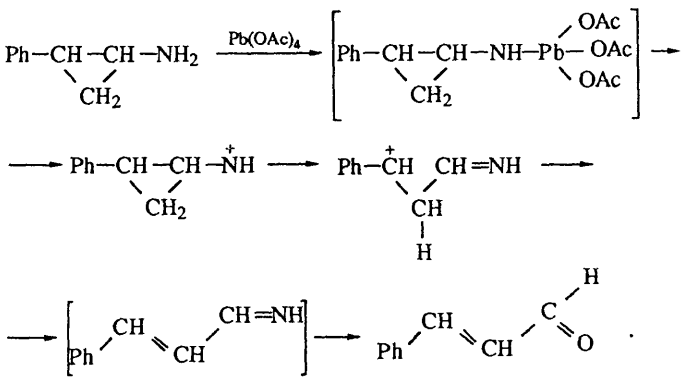


It is clear from Scheme 5 that nitrosation on the unsubstituted atom can result in the formation of a nitrenium ion.

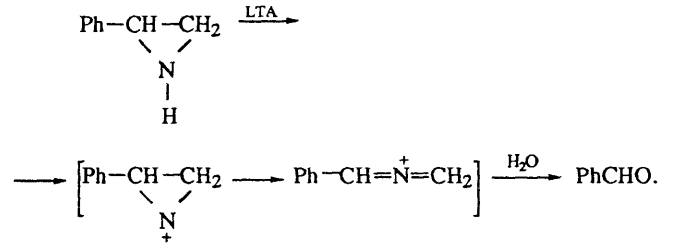
A further route for the generation of nitrenium ions was investigated by Cadogan and Rowley:[139]



It is assumed that the oxidation of the *trans*- and *cis*-isomers of 2-phenylcyclopropylamine with lead tetraacetate (LTA) to the *trans*-isomer of cinnamaldehyde also occurs via the formation of an intermediate nitrenium ion.[140]

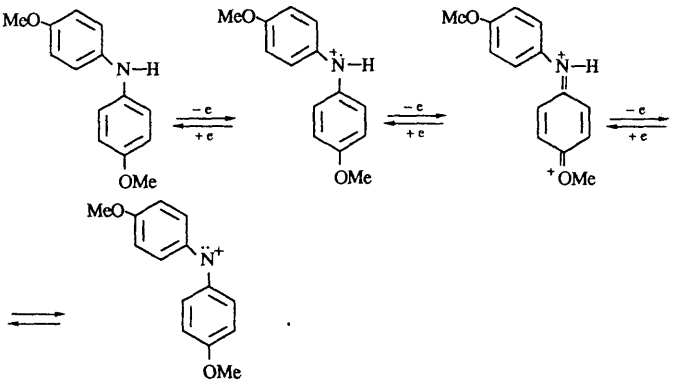


Isomerisation of an intermediate nitrenium ion to an azaallyl ion also occurs on oxidation of aziridines with ring opening:[140]



3. Physicochemical methods of generating nitrenium ions.

Electrochemical methods have been used to generate and study the behaviour of nitrenium ions.[26,27,141,142] It was through the use of electrochemical research methods such as polarography and different forms of voltammetry that the first direct evidence for the existence of nitrenium ions was obtained.[26] Cyclic voltammetry was used to study the oxidation of dianisylamine and to establish the lifetime of the dication formed by two-electron oxidation of dianisylamine (~1 s). In acetonitrile the equilibrium is probably shifted towards the unprotonated form—a nitrenium ion.



Similar studies were carried out for a number of other diarylamines:[141]

Scheme 6

* Values of $E_{1/2}$ given relative to Ag/10^{-2} M Ag^+.

Solutions of nitrenium ions (XXII) were obtained by controlled-potential electrolysis of amines (XXI). Values of λ_{max} for amines (XXI) and for cations (XXII) are given in Table 3. The spectra of the initial amine and radical cation differ considerably from the values given for the nitrenium ion.

Electrolysis was also employed subsequently in the oxidation of different substituted pyrroles[142] and the UV spectra of the corresponding nitrenium ions were obtained.

It has been reported[143] that nitrenium ions are also formed by electron bombardment of a mixtures of methane and ammonia, but the reactions investigated only apply to the gas phase.

$$CD_3^+ + NH_3 \longrightarrow [CD_3NH_3^+]^* \begin{cases} \longrightarrow (CD_2{=}NH_2^+)^* + HD \quad 70\% \\ \longrightarrow CD_3{-}NH^+ + H_2 \quad 30\% \end{cases}$$

4. Nuclear chemical method for generating nitrenium ions

The nuclear chemical method of obtaining reactive species is based on the chemical consequences of the β^--decay of atoms forming part of the different molecules.[28,144,145]

β^--Decay is known to be the spontaneous conversion of the nuclei that accompanies the emission of a nuclear electron and antineutrino. At the same time changes occur in the nucleus in accordance with the following scheme:

$$^0_1n \rightarrow {}^1_1p + e^- + \tilde{\nu},$$

where n and p are nuclear particles (neutron and proton); e^- and $\tilde{\nu}$ are an electron and antineutrino. Such a conversion signifies the formation of the nucleus of an atom of a new element that lies one square to the right relative to the mother (initial) element in the Periodic Table. This process occurs within about $10^{-22}-10^{-21}$ s. The electron formed in the nucleus leaves the atom after about 10^{-18} s.

Since the process of β^--decay is accompanied by an increase in the number of protons (nuclear charge) by one and the electron shell is inherited from the mother atom, there is a deficit of electrons in the latter in relation to the new (daughter) nucleus. Thus, the charge state of the daughter atom increases by one. If the decaying atom forms part of a molecule, the composition and charge state of the new chemical structure—the primary molecular ion (PMI)—is given by the general scheme

$$\left[{}^A_ZXY\right]^q \xrightarrow{\beta^-} \left[{}^A_{Z+1}XY\right]^{q+1},$$

where ${}^A_ZX$ is the atom undergoing β^--decay and Y is the normal state of the molecular system. For example,

$$^{14}CH_4 \xrightarrow{\beta^-} [^{14}NH_4]^+,$$

$$NH_2{}^3H \xrightarrow{\beta^-} [NH_2He]^+ \rightarrow NH_2^+ + He.$$

It is quite clear that there is continuity between the electronic structure of the initial molecule and the primary molecular ion formed as a result of β^--conversion of one of the atoms. The number and nature of the ligands also remains unchanged. Thus, the initial and final molecular forms are isoelectronic, isostructural, and have the same number of ligands.

Furthermore, there is a definite correlation between the free energy in the initial molecule and in the primary molecular ion. Will the PMI be stable? In the examples shown the resulting NH_4^+ ion is the familiar stable ammonium ion while NH_2He^+ is an unstable ion which fragments to form a nitrenium ion and helium.

Theoretical calculations and numerous experimental results suggest that in the vast majority of cases β^--decay of the atoms in molecules results in the formation of stable PMIs in high yield.[28]¶ Only in the β^--conversions of tritium (and the lightest halogens) does the formation of unstable ions occur.[145]

The instability of helium-containing organic primary molecular ions is primarily due to the migration of positive charge from the helium atom to the organic group:

$$[RHe^+] \rightarrow [R^+He].$$

This redistribution of charge occurs because the ionisation potential of the helium atom is higher than that of the organic groups. At the next stage the species $[R^+He]$ decomposes to form positively charged ions (carbenium, nitrenium, etc.) and helium atoms (the energy of the C–He bond is close to zero):[146,147]

$$[R^+He] \rightarrow R^+ + He.$$

The time required for such processes to occur is 10^{-13} s, which is considerably less than the time between collisions of two interacting particles. Therefore, the resulting reactive species will interact with molecules of the surrounding medium as free particles.

The nuclear chemical method of obtaining intermediate reactive species has a number of advantages over known methods, in particular classical methods. It follows from the above description that the nuclear chemical method provides the possibility of obtaining reactive charged species in a free state (without counterions or solvent cage),† with a strictly defined structure and a given initial charge localisation.

The rate of generation of reactive species using the nuclear chemical method is determined solely by the rate of radioactive decay of tritium [$T_{1/2}(^3H)$ = 12.2 years] and does not depend on external conditions (temperature, pressure, state of aggregation, composition of reaction mixture, etc.).

The number of molecular ions (N_{R^+}) formed after a given time t from N_{R-^3H} mother molecules can be calculated from the equation

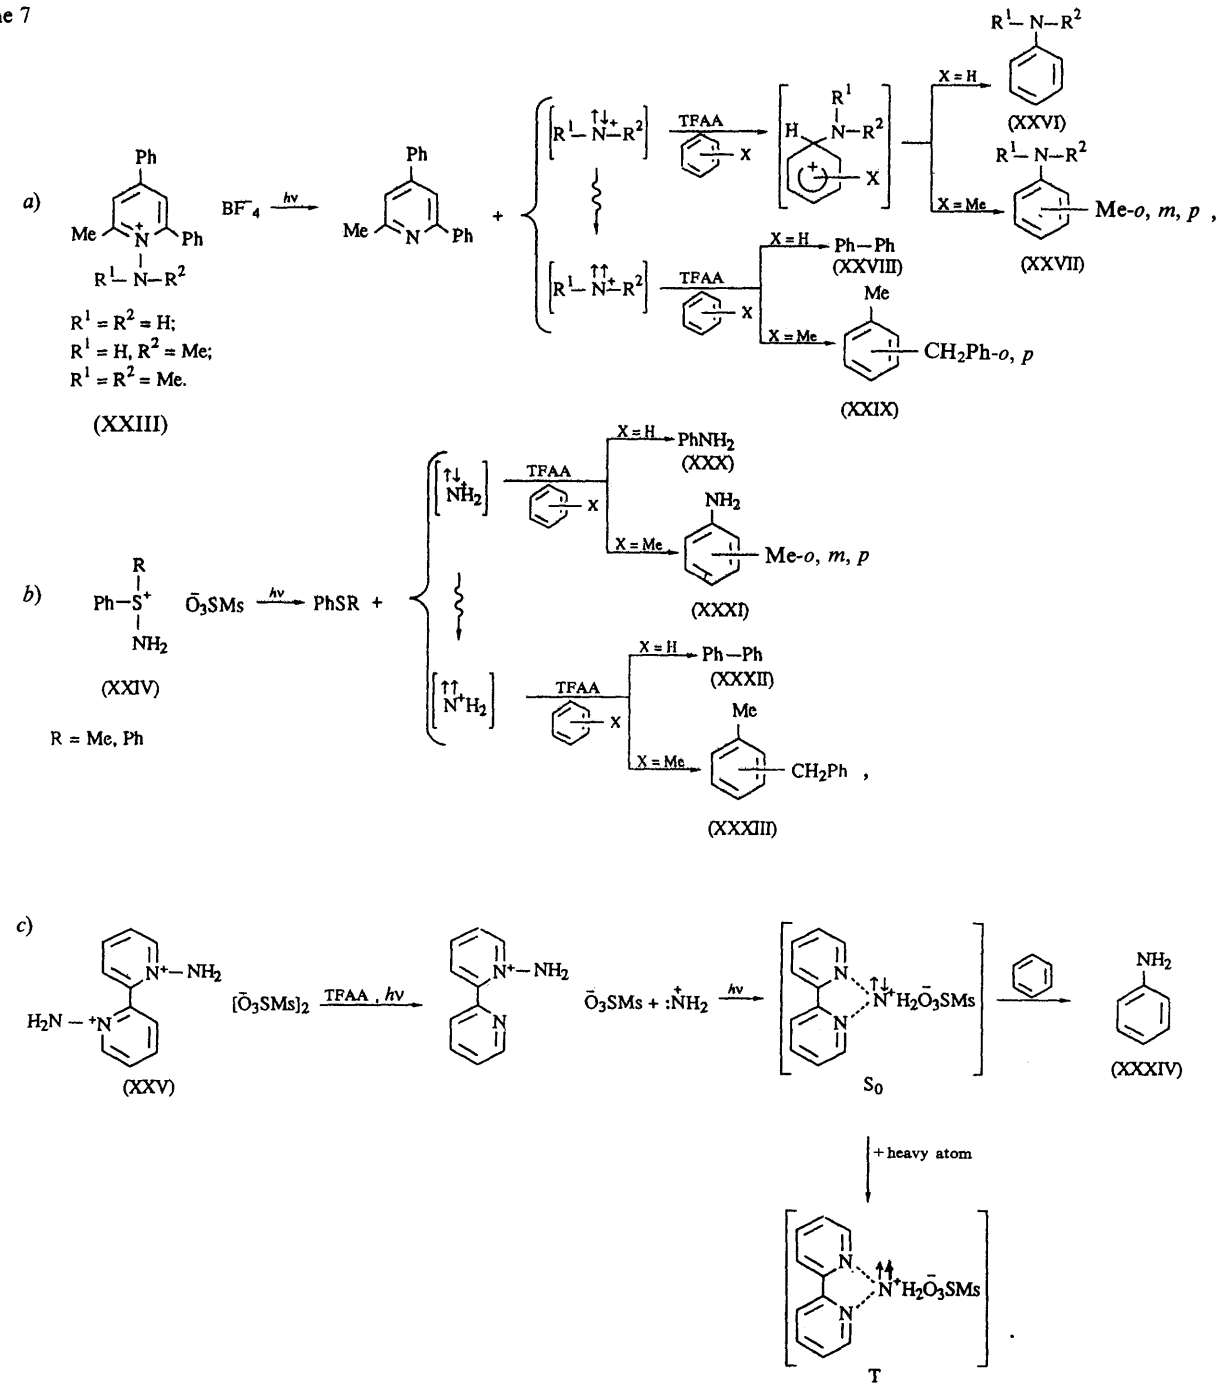
$$N_{R^+} = kN_{R-^3H}\cdot(1-e^{-\lambda t}) \approx k\lambda N_{R-^3H}t \quad \text{when} \quad t \ll T_{1/2},$$

where N_{R-^3H} is the number of molecules of hydrocarbon labelled with tritium; λ is the radioactive decay constant of tritium; k is the coefficient of probability of particle formation; $k = ng$ (n is the number of tritium atoms in the mother molecule; g is the proportion of β^--emissions resulting in the formation of unexcited primary molecular ions).

¶ We have deliberately not considered processes involving the excitation and ionisation of the electron shells of daughter atoms which result in decomposition of PMIs, since the proportion of such β^--conversions does not exceed 30%.

† The β^--particle (nuclear electron) emitted in the process of decay cannot serve as a counterion since it escapes to a distance at which the interaction energy between the ion and the nuclear electron is very low.

Scheme 7



Let us consider the decay of tritium in PhN^3H_2 as an example. If the activity of aniline in this series is 3.7×10^{10} Bq, the total number of nitrenium ions formed in 24 hours is 4.8×10^5.

An undoubted merit of the nuclear chemical method is its potential for studying the reactions of free reactive species with pure compounds and their mixtures in the gas, liquid, and solid states. Considerable experience in the generation of carbocations[28,144,145,148–151] and silicenium[152] ions using the nuclear chemical method has been gained to data. This method has also been used during the last ten years to generate nitrenium ions. The nuclear chemical method has been successfully used by Nefedov et al.[29–32] for the synthesis of free phenylnitrenium ions and to study their reactions with aromatic hydrocarbons.

The formation of phenylnitrenium ions occurs as a result of the β^--decay of tritium in aniline that has doubly tritiated amino group according to the following scheme

$$PhN^3H_2 \xrightarrow{\beta^-} [PhN^3HHe]^+ \rightarrow [PhN^3H^+Hc] \rightarrow PhN^3H^+ + He.$$

IV. Reactions of nitrenium ions

As indicated above, nitrenium ions are reactive species having a positive charge and free *p* orbital. With these characteristics they can be classified as species with well-defined electrophilic properties. The large heats of formation[23] (for example, for phenylnitrenium ions in singlet and triplet states these are 241.5 and 267.5 kcal mol^{-1} respectively)[24] and the presence of a charge and free orbital govern not only the reactivity but also the strictly controlled interaction pathway of these species. These species interact with residues with high electron density in substrate molecules. These reaction characteristics of nitrenium ions also govern the nature of the resulting intermediate complexes and reaction products.

1. Reaction of alkylnitrenium ions

The simplest nitrenium ion $:\overset{+}{N}H_2$ and its alkyl homologues have a triplet ground state[23] and are not capable of causing direct aromatic amination.[48]

Takeuchi et al.[48] carried out the direct amination of benzenes in arene–TFAA (30%) mixtures with singlet alkylnitrenium ions generated by photolysis of pyridinium (XXIII), sulphonium (XXIV), and bipyridinium (XXV) salts (Scheme 7) containing an amino substitutent on the nitrogen or sulphur atoms. The reactions depicted in Scheme 7 indicate that the products (XXVI), (XXVII), (XXX), (XXXI), and (XXXIV) are typical examples of the aromatic substitution of hydrogen in benzene or toluene by a singlet nitrenium ion. Products (XXVIII), (XXIX), (XXXII), and (XXXIII) are characteristic of the reaction of triplet nitrenium ions. It was noted that S → T conversion is more favourable in toluene. Takeuchi et al. established the following pattern of change in energy of the singlet state on going from an unsubstituted to an aliphatic and aryl nitrenium ion:

$$\overset{+}{N}H_2 > Alk\overset{+}{N}H > Ph\overset{+}{N}H,$$

which is supported by the fact that aromatic amination with singlet alkylnitrenium ions, in contrast to aryl ions, has both low substrate and positional selectivity.[40,42,46,48]

It was established[48] that the reactivity of the simplest nitrenium ion generated from *N*-aminopyridinium salt (XXIII) is governed by the nature of the substituent in the pyridine ring of salt (XXIII) and by the nature of the counterion. An electron-withdrawing group (for example, CN) in the pyridine ring and a counterion capable of forming an H-bond with the nitrenium ion increase the selectivity factor. It is assumed that the unsubstituted nitrenium ion which is generated at the first stage is not free but interacts with both the unshared electron pair of the pyridine and with the counterion (Fig. 2).

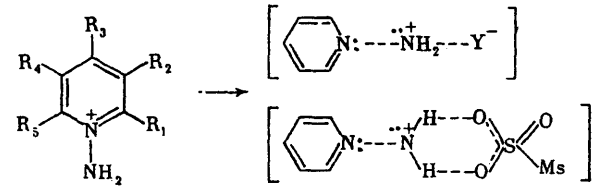


Figure 2. Interaction of an unsubstituted nitrenium ion with an electron pair and hydrogen bonding.[48]

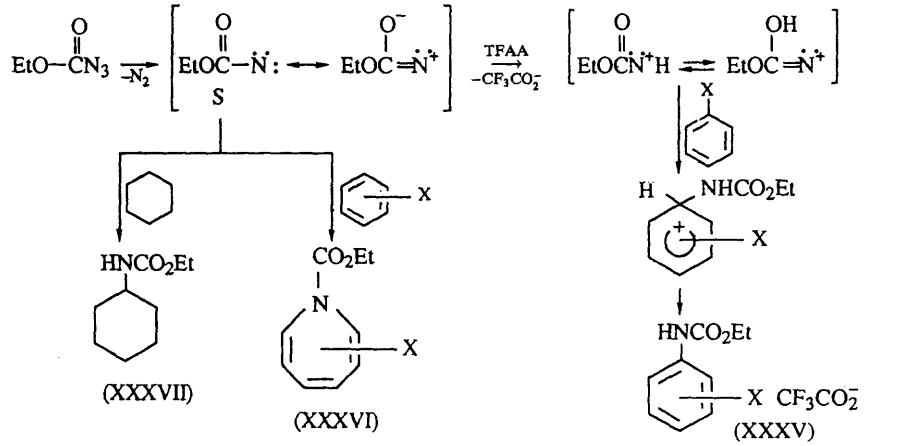
This type of interaction assumes a favourable singlet reaction. A similar interaction of the unshared electron pairs of heteroatoms was predicted in the chemistry of nitrenes.[153–155]

By comparing pyridinium (XXIII) and sulphonium (XXIV) salts (Scheme 7) as sources of nitrenium ions, Takeuchi et al.[48] established that for (XXIII) for nitrenim ions were predominantly in the singlet state while for (XXIV) they were mainly in the triplet state. The explanation for this is that the electron pair of sulphur interacts with the nitrenium more weakly than the electron pair of nitrogen in pyridine, since sulphides are less electrophilic then pyridine. Thus, it may be concluded that interaction of nitrenium ions with a free electron pair plays an important part in stabilisation of the singlet

Scheme 8



X = H (a), Me (b).

X = H (a), *o*-Me (b), *p*-Me (c) *o*-NO_2 (d), *m*-NO_2 (e).

state. A weakening of this interaction assists a more rapid S → T triplet conversion.

In the photolysis of pyridinium or sulphonium salts in solvents containing heavy atoms (for example, dichloromethane, dibromomethane, an oxygen molecule, etc.), the yields of singlet products are considerably reduced.

Stabilisation of the singlet state through hydrogen bonding between the nitrenium ion and counterion is currently being investigated.[48]

Takeuchi et al.[33,35,40] studied the electrophilic substitution reaction between the ethoxycarbonylnitrenium ion generated from the corresponding azide and certain aromatic compounds (benzene, toluene, nitrobenzene) in different media that affect the nature of the intermediate (Scheme 8).

Product (XXXV) in Scheme 8 results from the reaction of ethoxycarbonylnitrenium ion with substituted benzenes. In the absence of TFAA, products (XXXVI) and (XXXVII) are obtained, resulting from the reaction between the intermediate nitrene in a singlet state and benzene (toluene) or cyclohexane. The subsequent addition of TFAA to (XXXVI) and (XXXVII) gives products (XXXVa)–(XXXVc).

The reactions of ethoxycarbonylnitrenium ions with aromatic substrates having electron-donating and electron-withdrawing substituents, as shown in Scheme 8, suggest that this nitrenium ion has low substrate selectivity and high positional selectivity. The latter relates to the selective attack at the *ortho* and *para* positions in toluene and the *ortho* and *meta* positions in nitrobenzene. This phenomenon is in good agreement with the assumption that the transition state with the highest energy, which governs substrate selectivity, depends on the nature of the π-complex, and the resulting σ-complex governs the positional selectivity.[156,157] The activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for thermolysis of azide do not differ in TFAA and benzene. This demonstrates that thermolysis of the azide in TFASA does not occur via the azide–acid conjugate but via a nitrene. Thus, the keto and enol forms of the nitrenium ion occur on transfer of a proton from TFAA to nitrene.

This review of the above classical studies on the reactions of alkylnitrenium ions indicates that a considerable number of factors influence the chemical behaviour of these species. These are primarily the methods and conditions of their generation, the nature of the source of nitrenium ions, the nature and concentration of the components of the media in which these reactions occur, etc. This introduces certain difficulties in the interpretation of the chemical nature of these reactive species.

2. Reactions of phenylnitrenium ions

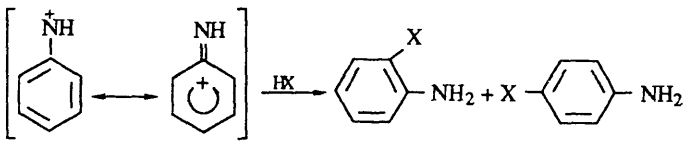
As indicated above, arylnitrenium ions are reactive metabolites of carcinogenic amines and act as intermediates in many organic syntheses. This accounts for the fact that the greatest number of studies have been devoted to the reactions of these species.

The qualitative composition of the products of the ion-molecule reactions between phenylnitrenium ions and different nucleophilic reagents can be predicted from the structural characteristics of these species. The occurrence of four mesomeric structures of the phenylnitrenium ion with an almost equal contribution from each to the actual hybrid structure (see Section II) suggests that these cation sites interact with nucleophilic reagents and that various aminophenylation products of the latter are formed.

Despite the results of quantum-chemical calculations[24,25] which indicate the preference for attack on the carbon atoms of the benzene ring in the phenylnitrenium ion, the experimental data, with a few exceptions,[81] suggest that reactions on the nitrogen cation site of arylnitrenium ions are preferred.

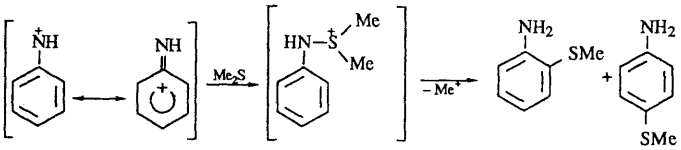
It is shown in a number of studies[37,39,41,43,46,72,81,124–126] that arylnitrenium ions are usually formed at the intermediate stages of reactions in strong proton acids. The chemical behaviour of phenylnitrenium ions usually does not depend on their source of generation (phenyl azides or phenylhydroxylamines) but is dependent on the specific nature of the media in which this ion is formed.

a) Interaction of phenylnitrenium ions with the unshared electron pair of a nucleophile. When nucleophiles containing atoms with an unshared electron pair (alcohols, phenols, acids, water) are treated with phenylnitrenium ions generated from phenylhydroxylamine in the presence of TFMSA, *ortho*- and *para*-substituted anilines are formed in significant yield.[72,124–126]



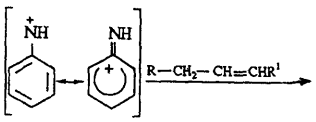
X = OH, PhO, MeO, Cl.

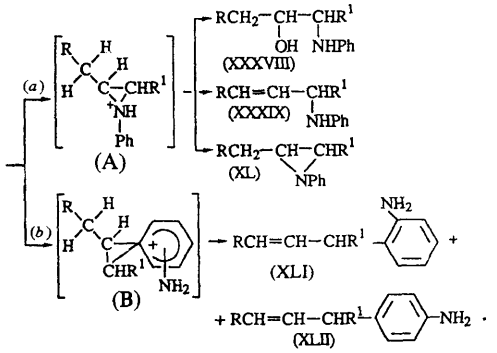
The reaction of phenylnitrenium ions with dimethyl sulphide results in the formation of similar products.[47]



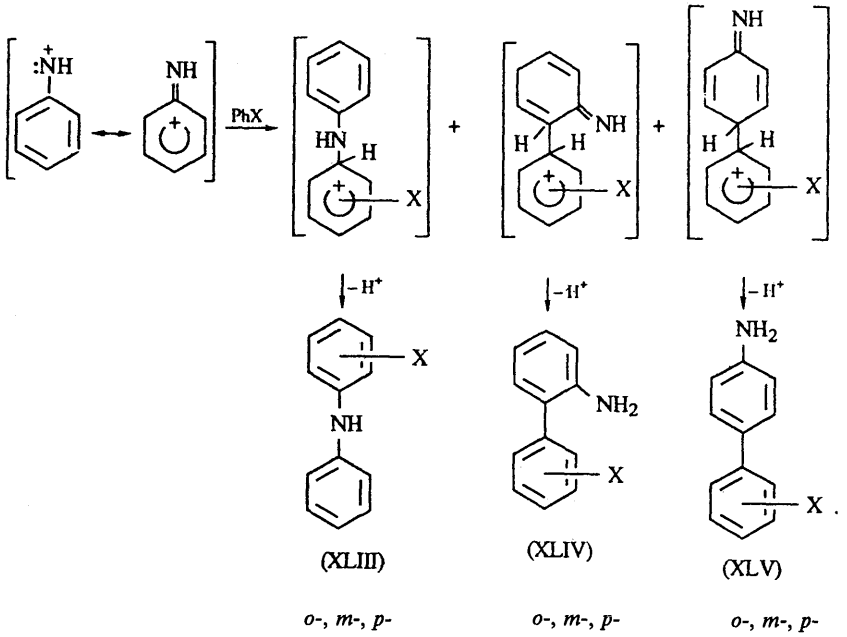
b) Reactions of phenylnitrenium ions with olefins. The reaction of phenylnitrenium ions obtained from azides in the presence of TFAA with aliphatic and cyclic olefins on their double bond results in the formation of addition products both on the N-cation [route (a)] and C-cation [route (b)] sites of the phenylnitrenium ions according to Scheme 9.[41]

Scheme 9





Scheme 10



In the absence of steric hindrance a mixture of products (XXXVIII)–(XLII) is always formed through reaction of the phenylnitrenium ion with aliphatic olefins as shown above. Only their ratio varies according to the reaction conditions. The reaction of a phenylnitrenium ion by route (*a*) occurs via the substituted aziridine cation (A) as an intermediate. The yields of reaction products depend on both the structure of the olefins and the concentration of TFAA. The main reaction product is the *N*-phenyl-β-hydroxylamine (XXXVIII). As the concentration of TFAA is increased, the yield of main product usually decreases, which is due to a side reaction involving polymerisation of the initial alkene.

With cyclohexene the reaction is stereospecific and the *trans* isomer is formed. The unsaturated compounds (XXXIX), (XLI), and (XLII) are isolated as by-products in the reaction with cyclohexene. Product (XXXIX) results from the addition of phenylnitrenium ion to the nitrogen site, while products (XLI) and (XLII) are formed as a result of the reaction of phenylnitrenium ion on a carbon site of the benzene ring. In the latter case the reaction occurs via the cation complex (B).

Products of C-substitution are not formed in the reaction of *cis*- and *trans*-4-methyl-2-pentene with the phenylnitrenium ion. Takeuchi et al.[41] assume that intermediate complex (B) is not formed because of steric hindrance.

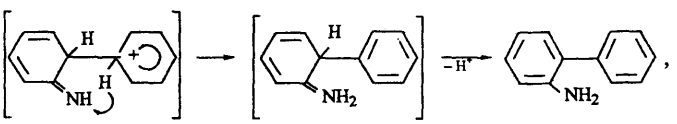
In the reaction of the phenylnitrenium ion with *cis*-4-methyl-2-pentene not only product (XXXIX) but also (XL) is isolated, which corroborates the mechanism put forward by the authors.

The by-product (XXXIX) is not formed at all with methyl acrylate.

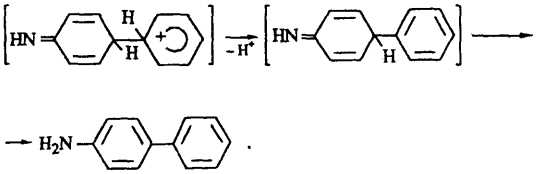
c) Reactions of phenylnitrenium ions with aromatic hydrocarbons. The reactions of phenylnitrenium ions with aromatic compounds have been studied in the greatest detail. These are reactions involving the electrophilic substitution of hydrogen in a benzene ring (S_E) which are complicated by the presence of four cation sites in phenylnitrenium ions.

Reaction of the latter with benzene, depending on the nature of the medium, leads either exclusively to N-substitution products[47,158] or to preferential attack on the carbon atoms of the phenylnitrenium ion,[81] and more frequently to both products with preferential substitution on nitrogen.[37,39,72,159] In this case the *ortho*- and *para*-isomers of aminobiphenyls (C-substitution products) are formed in almost equal proportion.

It is interesting to compare the results of the reactions of benzene and phenylnitrenium ions obtained by classical methods with the reactions of free phenylnitrenium ions generated by the nuclear chemical method.[30] In the absence of specific media that are capable of suppressing the nitrogen or carbon cation sites of the phenylnitrenium ions, the free nitrenium ion on reacting with benzene behaves to an almost equal extent as a nitrenium ion (55%) and a carbocation (45%). At the same time the ratio of *ortho*- to *para*-isomers—the C-substitution products (XLIV) and (XLV) in Scheme 10—was 8 : 1, which is probably due to a difference in the rate of proton transfer in the intermediate σ-complexes. In the case of the *ortho*-isomers this is a rapid direct intramolecular process



while for the *para*-isomer intermolcular deprotonation occurs:



In the reaction of phenylnitrenium ions with toluene, the formation of six products (XLIII, *o*, *p*-), (XLIV, *o*, *p*-), and (XLV, *o*-, *p*-) is possible, according to the classical orientation rules (see Scheme 10). However, Takeuchi et al.[37,39,47] detected only the N-substitution products (XLIII, *o*-, *p*-) and the ratio of *ortho*- to *para*-isomers varied in relation to the method of generating the phenylnitrenium ion (from pyridinium salts or azides) in TFAA. On conducting this reaction, Parish and Whiting[81] isolated all six isomers with a twofold or greater excess of C-substitution products. Differences in the reaction conditions may account for these findings.

In the reaction of toluene with free phenylnitrenium ion generated by the nuclear chemical method, the sole product was 4-methyldiphenylamine (XLIII, *p*-) (Scheme 10).[31] The results of other studies[82] also show that the reaction mainly occurs on nitrogen.

In the reactions of nitrenium ions with other substituted benzenes (RPh, where R = Pr, Cl, Ph) and with naphthalene there is a tendency for preferential substitution on the nitrogen atom to occur.[37,39] Only when special media are used, as demonstrated by Parish and Whiting,[81] is there a marked increase in the yields of C-substitution products.

On reaction of phenylnitrenium ions in TFMSA with a substrate having an electron-withdrawing substituent (for example, nitrobenzene), products of the aminophenylation of nitrobenzene were not detected.[39]

The reactions of *para*-substituted phenylnitrenium ions (p-$RC_6H_4\overset{+}{N}H$, where R = Me, OMe, CN, NO_2) with benzene and toluene have been studied by Takeuchi et al.[43] It was established that the phenylnitrenium ions with electron-withdrawing groups (CN, NO_2) solely undergo aromatic N-substitution. On the other hand, the positive charge of phenylnitrenium ions with electron-donating groups is preferentially delocalised on the carbon atoms of the ring as a result of the positive mesomeric effect of the substituent. Prolongation of the lifetime in this type of resonance effect can lead to the coexistence of both the triplet and singlet states, which results in an increase in the yields of products of hydrogen removal.

Studies were carried out by Takeuchi et al.[39] on the reactions of naphthylnitrenium ions obtained from 1-azidonaphthalenes in the presence of TFMSA with benzene. 1-Amino-4-phenylnaphthalene—a C-substitution product—is formed as a result of this reaction. No N-substitution products were detected. This results from the preferential localisation of positive charge in the naphthylnitrenium ion at the *para* position of the ring rather than on the nitrogen atom.

Thus it may be concluded from the above information that in the organic reactions of nitrogen-containing compounds monitoring the behaviour of nitrenium ions meets with certain difficulties. The fact that these species are formed at intermediate stages has usually been established from the final reaction products. However, the ratio of final products depends on the nature of the specific media in which these reactions are occurring.

It is evident that the most reliable data on the chemical nature and properties of the intermediate species may be obtained when there is the possibility of generating them in a free state and studying their reactions in the absence of extraneous substances (counterions, catalysts, etc.). The nuclear chemical method of generating nitrenium ions opens up considerable possibilities in this respect. This non-traditional approach to the study of reactive intermediate species can assist in the interpretation of the mechanisms of classical organic reactions.

---o0o---

The review of studies on the properties and reactions of nitrenium ions presented here indicates the increased interest shown in these species by scientists from different countries. This is mainly because a study of these reactive intermediate species is closely related to the development of general theoretical problems in organic chemistry. In particular, a study of the properties and reactions of nitrenium ions is necessary for an understanding of the reaction mechanisms and development of synthetic methods for organonitrogen compounds. In this respect the new methods for obtaining and studying the reactions of free nitrenium ions that have been developed during the last ten years are of particular significance.

It follows from several original publications[49–53] that an important part is played by these species in carcinogenetic and mutagenetic processes. Therefore, a study of nitrenium ions is of paramount importance in finding a solution to specific problems in oncology, genetics, and ecology.

Conjunction in organic compounds of silicon-subgroup elements

A N Egorochkin
Institute of Organometallic Chemistry, Russian Academy of Sciences, Nizhnii

ABSTRACT. The existing theoretical ideas concerning the intramolecular interactions in organic compounds of silicon-subgroup elements are examined in relation to the results of experimental studies. It is shown that the overall resonance effect of organoelement substituents includes acceptor (joint influence of unoccupied *nd* and antibonding σ^* orbitals) and donor (σ,π conjugation, σ,π^* conjugation, and σ,n conjugation) components. The relative contributions of these components to the resonance effect are analysed as a function of the type of central element, the organic groups linked to it, and the reaction centre.

The bibliography includes 161 references.

I. Introduction

The problem of intramolecular interactions is of key importance in theoretical and applied organoelemental chemistry. A steady trend in recent years has involved the appearance of new ideas and improvement of the methods of study of this still inadequately elucidated problem (see, for example, Refs. 1–10). The aim of the present review is to analyse the experimental data and the existing theoretical ideas about the intermolecular interactions and especially about the effects of conjugation in silicon-subgroup compounds.

Group IVB organoelemental compounds constitute unusual model systems in the chemistry of non-transition [main Group] elements.[3,11,12] Typical difficulties, arising in the solution of the problem of intramolecular interactions where alternative but inadequately supported views are put forward about a number of its important aspects, are manifested clearly for the given compounds. Under the conditions of a growing stream of information, which requires the development of a general theoretical standpoint for its consideration, one has to adopt a critical attitude to extreme views claiming universality—not only to attractively simple ideas but also to hypotheses seemingly disproving them which are applicable in reality only to a limited number of facts. The overall concept must, firstly, include these polar ideas as special limiting cases and, secondly, must be based on large sets of correct experimental data, must explain them without contradictions, and must possess predictive power, at least in principle.

Unfortunately this entirely evident methodology has been frequently infringed in the study of conjugation in compounds of silicon-subgroup elements despite the availability in the literature of a constructive basis for the avoidance of such errors.[13] Since the available data on the subject of the review are contradictory, the reivew has been constructed in accordance with the following scheme to elucidate the causes of the contradictions and to seek ways for their elimination: the choice of a general theoretical concept most consistent with the available set of experimental data and intramolecular interactions: the elucidation on its basis of "score" points in the literature data; comparison of the possibilities of the concept employed and of alternative ideas for the explanation of experimental facts; establishment of the limits of applicability of the chosen concept.

In the present review, preference is given to the consideration of (1) studies of fundamental importance for the elucidation of the given subject and (2) the most thoroughly investigated compound of tetracoordinate silicon-subgroup elements. The review does not deal with data, which are of specialised interest, concerning the relationship between intramolecular interactions and reactivity (see, for example, Refs. 2, 11, 12 and 14) and also compounds of pentacoordinate elments.[12,15–19]

II. Theoretical ideas concerning conjugation

1. Separation of the inductive, resonance and steric effects

In the first place, it is necessary to make a series of general remarks which will explain the approaches used in the review to the analysis of literature data. The absolute majority of publications on the subject of the review presuppose the use in an explicit or implicit form of two important principles of physical organic chemistry: the linear relation between free energy changes (LFE) and the independence and additivity of the influences of the inductive, resonance, and steric effects on the free energy change. An enormous number of studies have been devoted to the verification of these semiempirical principles (see, for example, Refs. 6, 20, and 21), which indicate a high degree of their generality. At the same time, a number of difficulties arise in the theoretical justification and practical use of these principles. These have been analysed in greater detail in a number of other communications.[6,20,21] We shall consider briefly the essential features of the above principles.

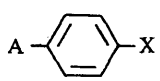
The most concise formulation of the LFE principle is the familiar Hammett equation $\lg K - \lg K_0 = \rho\sigma$,[22] which relates the rate or equilibrium constants K (a spectroscopic or other physical parameter having the significance of the Gibbs free energy can also be used as $\lg K$ [20,23]) for substituted and unsubstituted compounds to σ constants characterising the substituent. The reaction constant ρ characterises the sensitivity of the reaction centre (for chemical

reactions) or the indicator centre (for physical parameters) to the electronic effects of the substituents. The quantity σ is a constant only for constant properties of the medium (temperature, solvent, etc.).[6,22] For compounds of the type $A-B-ER_3$, the value of σ for an organoelement substitutent ER_3 (here and henceforth E is a silicon subgroup element, i.e. Si, Ge, Sn, or Pb) can generally speaking depend on the nature of the conducting fragment B of the molecule and on the type of the reaction (indicator) centre A.[6,24,25] The latter factor necessitates, on the one hand, a cautious approach to the use of σ constants as universal characteristics of the electronic effects of organoelement substituents, but, on the other hand, it can be used in the study of the dependence of intramolecular substituent–reaction centre and substituent–conducting fragment interactions on the nature of the varied A and B.[6,24,25]

In practice, when the LFE principle is used it is necessary in the majority of cases to take into account yet another principle, whose essential feature consists in the possibility of representing the Gibbs free energy change ΔG (in chemical processes or in the correlation of physical properties) by the sum of independent and additive components, i.e. $\Delta G = \Delta G_I + \Delta G_R + \Delta G_S$, determined by the influence of the inductive, resonance, and steric effects. The LFE principle must then be applied not to the overall quantity ΔG but to each of the three components separately.[20,22] The development of the LFE principle on this basis leads to three new σ constants: σ_I, σ_R, and E_S (there are also other designations), characterising the above effects. We shall mention briefly the problems arising in attempts at a theoretical justification of the principle of independence and additivity and of its practical application.[20–22]

Among the three components of ΔG, only the inductive component can be characterised with an adequate degree of approximation by a set of universal constants σ_I of the substituents.[20] The nature of the inductive effect (the field and/or bond polarisation effect) remains controversial.[26–28] Both factors are apparently significant for substituents EX_3 with electronegative groups X.[6] In highly excited electronic states, where there is appreciable charge separation under the influence of the inductive effect, the universality of the constants σ_I may break down.[29]

The constants σ_R of organic and organoelement substituents are used to characterise the change in ΔG under the influence of the resonance effect. The values of σ_R depend on the type of reaction centre.[6,20,21] Thus the constants σ_R^+ *and* σ_R^- have been widely used[6,22] as a quantitative measure of the resonance effect of substituents X (organic and organoelement) in the systems



in the presence of positive and negative charges on the reaction centre A respectively.

The resonance effects of two substitutents are not in general additive, which follows from theoretical analysis,[20,30,31] quantum-chemical calculations,[32] and experiment (for example, a wide variety of spectroscopic studies).[5,25,33,34] It has been established[5,20,25,30–34] that the non-additivity makes an appreciable contribution only when there is a large difference between the donor– acceptor properties of the two substituents or when both substituents are typical resonance electron donors.

The problem of isolating the component ΔG_R due to the influence of conjugation effects is unduly complex only at first sight. Experiment shows that the successive application of methods of correlation analysis with adequately representative selections of objects makes it possible to convert the above complications into their opposite, i.e. into an instrument for the study of fine details of resonance interactions in organoelement compounds. In particular, the important role of hyperconjugation effects in organoelement compounds was established in this way. It will be considered in greater detail below.

The isolation of the steric component ΔG_S constitutes a complex problem, since the influence of steric effects cannot be characterised by a standard set of universal constants invariant in relation to the system investigated. Steric constants of the type E_S, v, and their derivatives[35] are of limited applicability, especially in the study of intermolecular and intramolecular interactions with participation of Group IVB organoelement compounds.[36] Furthermore, the electronic and steric aspects of intramolecular interactions are interrelated in many instances (the stereoelectronic effect—see, for example, Egorochkin[3,36]). Generally speaking, a dual approach to the elucidation of the presence or absence of a dependence of ΔG_S on the nature of the varied substituents is possible. Firstly, there are several versions of computational schemes estimating with different degrees of approximation the shielding of the reaction (indicator) centre by substituents.[37–40] Secondly, the role of the component ΔG_S can be estimated by carrying out a correlation analysis of representative sets of experimental data of the kind mentioned above for ΔG_R. The significance of steric factors then becomes evident if the impossibility of explaining the influence of substituents (at least bulky ones) by electronic effects alone is observed explicitly.

An independent and extremely important approach to the study of intramolelcular interactions, one which has as yet been inadequately developed for organoelement compounds, is based on quantum-chemical methods. The principal results will be examined below.

Thus fairly stable ideas have arisen in the literature concerning the possibilities and limitations of the experimental methods for the study of intramolecular interactions in organic and organoelement compounds. The principle of maximum consistency with these ideas has been the main criterion for the selection of correct literature data on intramolecular interactions in Group IVB organoelement compounds.

We shall now consider the problem of the selection of a general theoretical concept satisfying the experimental data to the greatest extent.

2. Characteristic features of conjugation in organoelement Group IVB compounds

The long trial and error procedure followed in the study of intramolecular interactions in compounds of the silicon-subgroup elements has still not reached completion. The evolution of views on conjugation, frequently reflected in review communications,[6,13,41–46] is especially contradictory. We shall consider briefly the main stages of this evolution.

The first stage was based on the idea that unoccupied $3d$ orbitals of the silicon atom may participate in the formation of multiple bonds ($d_\pi-p_\pi$ conjugation).[47] This idea was invoked to account for the small length of the silicon–oxygen and silicon–halogen bonds.[48] A series of symbols are used to designate the conjugation of the atoms E with π- and n-electron substituents, among which the most concise are d,π and d,n respectively.

The hypothesis of unoccupied nd orbitals was subsequently applied to the interpretation of an enormous number of experimental facts obtained in the study of virtually all types of organoelement Group IVB compounds with the aid of chemical and physical methods (see the relevant reviews[41,42,49–51]). This hypothesis proved

to be extremely effective for the explanation of a most important difference between compounds of the elements E and carbon—the existence of π-acceptor properties in the atoms of E. It was established that these properties weaken with increase in the atomic number of E and that there is a close analogy between them and the conjugation effects in organic chemistry.[42]

Although the *nd*-orbital hypothesis agrees qualitatively with general quantum-chemical ideas, numerous attempts to obtain quantitative information about the involvement of *d*,π orbitals by means of approximate semiempirical methods were always open to criticism, since they did not lead to unambiguous, correct conclusions.[42,46,52] Such dual role of the approximate quantum-chemical methods left a strong imprint on the second stage of the evolution of ideas about conjugation in silicon-subgroup compounds.

The second stage was prepared for by the vigorous development with the aid of various chemical and physical methods[3,10,54–56] of the initial idea of Nesmeyanov and co-workers[53] concerning the more important role of hyperconjugation in organoelemental compounds than in organic compounds. A study by Pitt,[57] in which the author concluded without adequate justification that only hyperconjugatin occurs in silylacetylenes and that there is no need to resort to the idea of *d*,π conjugation, can apparently be regarded as the start of the second stage. Although subsequently Pitt corrected his ideas signifcantly,[13] his initial study[57] actually stimulated a series of publications (see, for example, Ponec and Chvalovsky[58,59]), whose authors considered hyperconjugation as an alternative to *d*,π conjugation in α,β-unsaturated compounds of the elements E. Despite the erroneous nature of the initial postulate, these studies have also played a constructive role, because they promoted the recognition of the complexity of the overall effect of conjugation in organoelemental Group IVB compounds.

The next stage of the evolution of views on conjugation, which arose almost simultaneously with the second, was the attempt to explain the electron-accepting properties of the atoms E not by the presence in them of *nd* orbitals but by the involvement of the antibonding σ* orbitals of the E–X bond in hyperconjugation.[7,9,60–65] Different versions of hyperconjugation interactions were proposed as alternatives to the *d*-orbital hypothesis (and sometimes as an addition to it—see, for example, West and Wadsworth[66,67]): (1) the interaction of σ*(E–C) orbitals with the π-electrons of the substituents Y in the C–E–Y fragments, where Y = aryl,[68] ethenyl,[69] ethynyl,[69] furyl, or thienyl;[70] (2) the interaction of the σ*(Si–C) and σ*(Si–H) orbitals with the lone pairs (LP) of Y in the (H)C–Si–Y fragments, where Y = NR_2, OR, SR, SeR, or F (R = organic and organosilicon groups);[7,64,65,71] (3) the interaction of the σ*(Si–H) orbitals with the carbanionic centre in $H_3SiCH_2^-$.[61,72] The qualitative aspects of the hyperconjugation interactions involving the antibonding orbitals of the bonds formed by elements of the Second and Third Periods were examined in the study of the anomeric effect[7,9,64] and other stereoelectronic effects.[9,73–75] The general approach to the problem of the involvement of antibonding orbitals will be examined below. Here we may note the possibility of invoking the concept of antibonding orbitals in the study of hypervalent bonds[15] in atranes (see, for example, Arshinova[9]) and in certain other compounds,[76,77] especially SiH_5^-.[78]

It is noteworthy that none of the three systems of views on conjugation presented above contains rigorous evidence for the erroneous nature of alternative ideas. In the search for such evidence, fundamental difficulties apparently arise inevitably owing to the complexity of the conjugation effects in organoelemental Group IVB compounds. Therefore views constituting the basis of the general theoretical concept which satisfies best the experimental facts must not exclude but supplement one another.

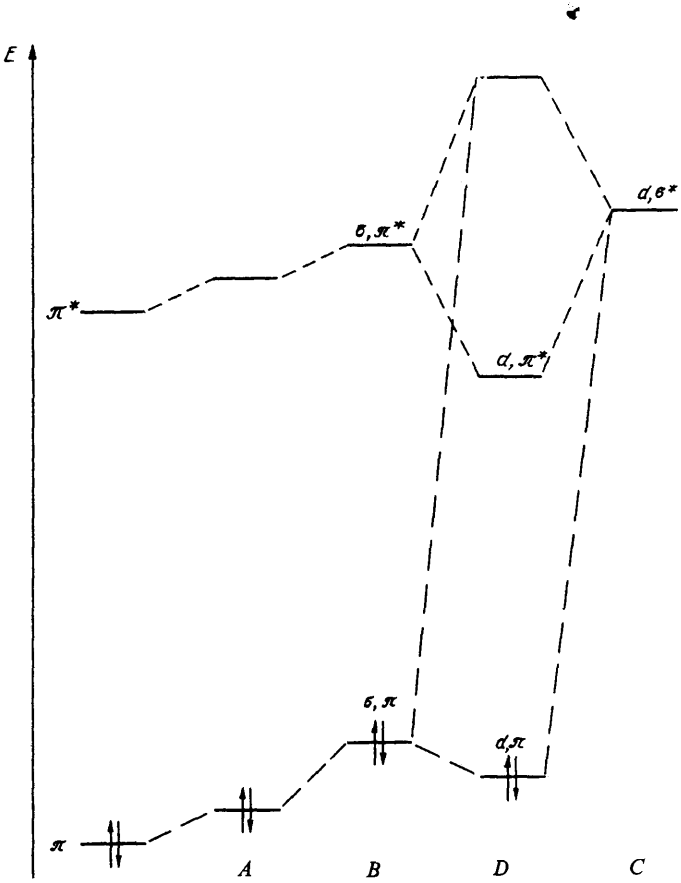


Figure 1. The influence of the substituents $E(CH_3)_3$ on the energies of the frontier orbitals π and π* of unsaturated hydrocarbons (according to Pitt's data[13]). Stage A—inductive +*I* effect of $E(CH_3)_3$; Stage B—σ,π and σ,π* conjugation; Stage C—mixing of σ*(E–C) orbitals of the substituent $E(CH_3)_3$ with the *nd* orbitals of the E atoms (a mixed *d*,σ* orbital with a lower energy is illustrated); Stage D—mixing of the *d*,σ* orbitals with σ,π* and σ,π; the formation of HOMO (*d*,π) and LUMO (*d*,π*) in the molecule.

Such a unifying concept was proposed by Pitt[13] in the fourth stage of the evolution of views on conjugation. Following Pitt, we shall consider this concept in relation to the change in the energy levels of frontier π and π* orbitals of substituted unsaturated hydrocarbons under the influence of the substituents $E(CH_3)_3$ (Fig. 1), i.e. as a result of the intramolecular interactions in compounds of the type $YE(CH_3)_3$, where Y = C_6H_5, $CH_2=CH$, etc. To facilitate the treatment, we shall represent arbitrarily the overall electronic effects of the substituents $E(CH_3)_3$ by several components.[13] In conformity with the ideas described in the first

part of Section II, the differentiation of the inductive and resonance components of the influence of the $E(CH_3)_3$ group then becomes entirely evident. As regards further subdivision of the overall resonance effect of $E(CH_3)_3$ into components, this problem is close in its significance to that solved in physical organic chemistry in estimations of the contributions of the hyperconjugation component to the overall conjugation effect of organic substituents.[20,22]

Stage A. The inductive effect. The inductive donor–acceptor properties of the substituents EX_3 depend on the nature of the groups X. The substituents $E(CH_3)_3$ have a positive inductive $+I$ effect (inductive electron donors), so that their influence results in an increase in the energy (destabilisation) of the orbitals π and π^*. On the other hand, if X are electronegative groups, then the substituent EX_3 is an inductive electron acceptor ($-I$ effect).

Stage B. Hyperconjugation of the σ,π and σ,π^* type [mixing of the $\sigma(E-C)$ orbitals of the substituent $E(CH_3)_3$ with the π and π^* orbitals of the fragment Y after taking into account the change in the energies of the initial orbtials under the influence of the inductive effect in stage A]. We may note certain key postulates and conclusions in Pitt's study.[13] From the linear combination of three $\sigma(E-C)$ orbitals, it is possible to obtain three wave functions, one of which, namely $\psi(\sigma)$, has π-type symmetry and can therefore interact with the $p_z(\pi)$ wave functions of the $Y-\psi(\pi)$ fragment. According to the perturbation molecular orbital theory,[13,30] the energy of the initial orbitals $E(\sigma)$ and $E(\pi)$ changes by the following amount after σ,π mixing:

$$\delta E(\sigma) = -\delta E(\pi) = \pm\sum[(4P^2(\pi\sigma) + \Delta E^2)^{1/2} - \Delta E] / 2, \quad (1)$$

where $P(\pi,\sigma)$ is the $\psi(\pi)P\psi(\sigma)d\tau$ perturbation operator and $\Delta E = E(\pi) - E(\sigma)$. If $\Delta E = 0$, then $\delta E = P(\pi\sigma)$ and if $\Delta E \gg P(\pi\sigma)$ (the case most often encountered), then Eqn. (1) becomes

$$\delta E = \pm P^2(\pi\sigma) / \Delta E. \quad (2)$$

Since $P(\pi\sigma) = a(\pi)a(\sigma)P$, where $a(\pi)$ and $a(\sigma)$ are respectively the p_z orbital coefficients of the carbon atom of the fragment Y and of the E atom in the σ orbital of the E–C bond while P is the perturbation integral of the $C(p_z)-E(p_z)$ bond, Eqn. (2) can be written in the form

$$\delta E = \pm a^2(\pi)a^2(\sigma)P^2 / \Delta E. \quad (3)$$

The perturbation integral in Eqn. (3) is related to the overlap integral $S(\sigma\pi)$ by the expression

$$P = -KS(\sigma\pi)[I(\sigma) + I(\pi)] / 2,$$

where I is the ionisation potential of the σ and π orbitals.

In hyperconjugation of the σ,π and σ,π^* types, the substituents $E(CH_3)_3$ behave as resonance electron donors in relation to the π system of the fragment Y, which results in further (in relation to that induced by the inductive effect) increase in the energy of the frontier orbitals, the latter acquiring a mixed character. It is significant that the degree of mixing of the σ,π^* type is smaller than that of the σ,π type owing to the smaller value of the overlap integral $S(\sigma, \pi^*)$ and the larger value of $\Delta E = E(\pi^*) - E(\sigma)$ compared with $\Delta E = E(\pi) - E(\sigma)$. Therefore conjugation of the type considered results in a greater destabilisation of the highest occupied molecular orbital (HOMO) compared with the lowest unoccupied molecular orbital (LUMO).

The ideas described above in connection with the consideration of stages A and B are sufficient, after slight modification, for the complete description of the electronic effects of the substituents in the benzyl derivatives $C_6H_5CH_2E(CH_3)_3$ and allyl derivatives $CH_2=CHCH_2E(CH_3)_3$, but are fundamentally inadequate for further analysis of compounds of the type $C_6H_5E(CH_3)_3$ and $CH_2=CHE(CH_3)_3$, since the electron-accepting properties of the substituents $E(CH_3)_3$ in relation to the π system cannot be explained on their basis. A constructive basis for the understanding of the causes of the above electron-accepting properties is the concept combining the hypotheses of the *nd* orbitals and antibonding σ^* orbitals. Using this concept as a guide, we shall consider stages C and D.

Stage C. The mixing of the $\sigma^*(E-C)$ orbitals of the substituent $E(CH_3)_3$ with the *nd* orbitals of the atom E. Although this stage was taken into account in the qualitative schemes for the consideration of the electron-accepting properties of $E(CH_3)_3$ as early as 20 years ago,[13,79] the authors of certain publications (see, for example, Giordan and Moore[68,69]) devoted to it unjustifiably little attention or actually neglected it. On the other hand, a number of considerations support the involvement of *nd* orbitals in conjugation. Thus it follows from Eqns. (1)–(3) that, in the absence of symmetry prohibition, the mixing of orbitals is greater, other conditions being equal, the smaller the difference between their energies. On the basis of this principle, Giordan and Moore[69] explained the electron-accepting properties of the substituents $E(CH_3)_3$ exclusively by the hyperconjugation interaction of the $\sigma^*(E-C)$ orbtials with the π^* orbitals of benzene, ethylene, and acetylene, whereas for thiophene and furan derivatives[70] the mixing of the $\sigma^*(E-C)$ and *nd* orbitals was not ruled out. Nevertheless, on the basis of the above principle, a real possibility of the mixing of the $\sigma^*(E-C)$ orbitals not only with the π^* orbitals of the fragment Y but also with the atomic *nd* orbitals of E for all the π systems enumerated follows from a simple consideration of the orbital energies.

Fig. 2 presents the experimental energies of the $\sigma^*(E-C)$ [68] and π^* [69,70] orbitals in the compounds YEX_3 determined by electronic transmittance spectroscopy. The energy of the unoccupied *nd* orbitals of the atom E (for the silicon atom as an example) was estimated by two procedures. Calcualtions by the Hartree–Fock self-consistent field method yield about –2 eV for the energy of the 3*d* orbitals of the silicon atom.[80–82] According to approximate estimates using a series of spectroscopic data for unsaturated compounds containing the $Si(CH_3)_3$ substituents, the 3*d* orbitals of silicon have a higher energy than the π^* orbitals of the fragment Y;[83] this view gained fairly wide currency (see, for example, Refs. 41, 50, and 79). Thus the orbitals $\sigma^*(E-C)$, *nd*, and π^* were found to have comparatively similar energies. There exists therefore a real possibility of the mixing of the $\sigma^*(E-C)$ orbitals with both π^* and *nd* orbitals. Following Pitt,[13] we shall arbitrarily select the mixing of $\sigma^*(E-C)$ and *nd* orbitals as the initial stage of the interaction between the three orbtials. This results in the formation of two mixed orbitals—with greater and smaller (presented in Fig. 1 and designated by *d*, σ^*) energies. Thus an unoccupied orbital arises in stage C with a lower energy than those of the $\sigma^*(E-C)$ and *nd* orbitals of the atoms E.

Certain comments must be made concerning the mixing of the orbitals in stage C. Fig. 2 presents only approximate energies of the orbitals $\sigma^*(E-C)$ and π^*. The exact energies of the initial orbitals

σ*(E−C) and π* could be obtained only after taking into account the influence of the inductive effect. Thus, for the calculation of the energy $E(\sigma^*)$, it is necessary to know the form of the dependence of $E(\sigma^*)$ for the fragment $E(CH_3)_3$ on the inductive effect of the substituent Y in $(CH_3)_3EY$ (Y = C_6H_5, $CH_2=CH$, etc.) while for the calculation of $E(\pi^*)$ account must be taken of the inductive effect of of $E(CH_3)_3$ and Y. Such calculations are so far lacking in the literature.

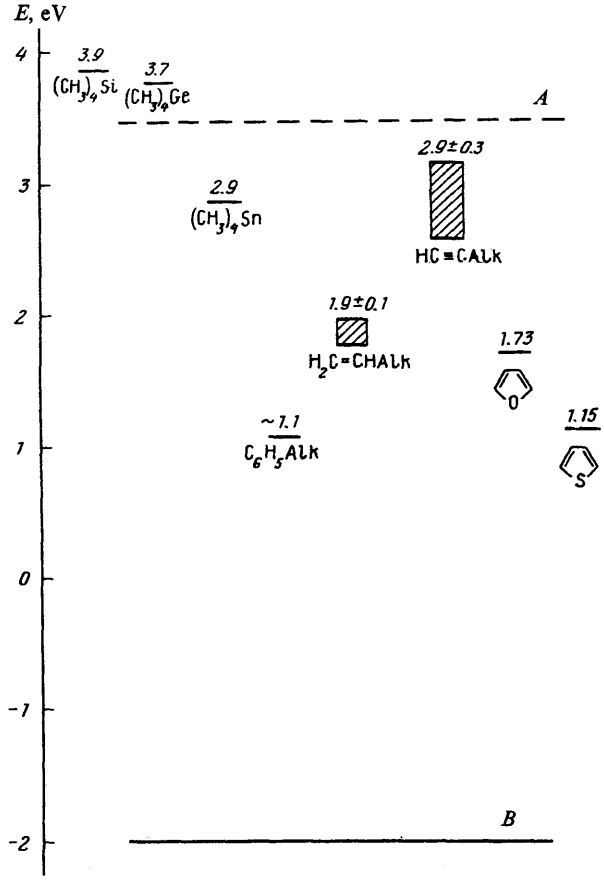

Figure 2. The energies of the σ*(E−C) orbitals in $E(CH_3)_4$,[68] the π* orbitals in certain unsaturated compounds,[69,70] and the unoccupied 3*d* orbtials of the silicon atom [(*A*) approximate estimate;[83] (*B*) calculated values[80−82]].

The problem of the exact energies of the *nd* orbitals *E*(*d*) is even more complex. This problem, as well as a number of others arising in the study of conjugation involving *nd* orbitals (their energy in isolated atoms E and molecules, the size and amplitude of *nd* orbtials, the charge on the atom E and the population, polarisation corrections in quantum-chemical calculations or real involvement of *nd* orbitals in bond formation) have been examined in a number of reviews.[41,42,46,49,51,84] Here we shall merely note yet again the absence of fundamental prohibition of the involvement of the *nd* orbitals of the atoms E in conjugation from the standpoint of quantum chemistry, but the results of even non-empirical calculations depend greatly on the choice of the basis set (see, for example, Res. 46, 85−88). Therefore, in estimating the correctness of such results, it is essential to exercise reasonable scepticism and caution.

One should also note that the π-bonds, formed with participation of the *nd* orbitals of the atoms E, are not analogous to those existing in unsaturated organic compounds.[84] As frequently mentioned in reviews,[3,6,36,42] the involvement of *nd* orbitals is only partial. Under these conditions, one cannot as yet estimate reliably the contributions of the atomic *nd* orbitals to the molecular orbitals. The self-evident nature of this assertion can be seen if only from the consideration of stage C above and the discussion of the data presented in Fig. 2.

Stage D. The mixing of the orbitals *d*,σ* and σ,π* formed in stages C and B, involving the formation of two new orbitals — with greater and lower (presented in Fig. 1 and designated by *d*,π*) energies. Similarly, on mixing of the *d*,π* and σ,π* orbitals, two orbitals are also produced [the orbital with a smaller energy (HOMO) is presented in Fig. 1 and is designated by *d*,π]. The orbital *d*,π* is stabilised i.e. its energy is reduced compared with the energy $E(\sigma,\pi^*)$ to a much greater extent than for the orbital *d*,π; this is caused by the sharp difference between the energies of the π* and π orbitals (10−15 eV [8,68−70]).

It follows from the foregoing that the orbtials σ*(E−C), *nd*, and π* are comparatively close to one another although they are not rigorously defined as regards energy. Therefore, the differentiation of stages C and D in the mixing of these three orbitals is purely arbitrary.

It follows from the consideration of stages C and D that attempts at an *a priori* quantum-chemical estimation of the relative role of each of them can at best claim to yield merely qualitative conclusions. At the same time, as quantum-chemical methods have improved, data have accumulated for the simplest organoelemental compounds, which can, on the one hand, be interpreted, at least in principle, on the basis of the scheme presented above and, on the other, they can serve as a justification of the individual stages (especially B) of this scheme. These data will be invoked in the third Section of the review together with the consideration of experimental studies in stages A−D and on conjugation as a whole.

III. Comparison of theoretical ideas with experiment

The consideration of the relevant data in this review is based predominantly on the methodology involving the separation of electronic effects adopted in physical organic chemistry, whose principles have been described in Section II. The separate stages of the intramolecular interactions with the substituents EX_3 and CH_2EX_3 as well as groups with a more complex structure having centres of not only π type but also *n* type are analysed. The arbitrary nature of the separation of the overall electronic effect of the above substituent into individual stages was considered in Section II.

1. The inductive effect

The differentiation of the inductive component ΔG_I from the overall electronic effect ΔG of organoelemental substituents constitutes, generally speaking, a standard procedure. Taking into

account certain limitations (see Section II as well as literature data[6,10]), the constants σ_I and their derivatives, tabulated, for example, by Egorochkin and Razuvaev[6] and Hansch et al.,[21] serve as a universal characteristic of the $\pm I$ effect. The possibile presence of a variable hyperconjugation component (σ,σ conjugation) constitutes in this connection a still inadequately elucidated problem. Although the contribution of this component is as a rule insignificant (except in special cases, for example, in compounds with chains of highly polarisable atoms E [3]), it can nevertheless depend on the type of centre to which the substituent is linked.[6]

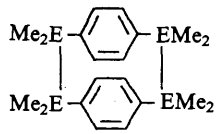
2. Hyperconjugation of the σ,π and σ,π^* type

This type of hyperconjugation has been studied in especially great detail (with the aid of physical and chemical methods) in the compounds YCH_2EX_3, where Y = phenyl, vinyl, ethynyl, furyl, thienyl, etc. In a number of reviews[3,6,10,55,89,90] and subsequent communications,[25,91–96] it was established that the substituents $CH_2E(CH_3)_3$ always behave as resonance electron donors in relation to the π systems of the fragment Y. This is indicated, in particular, by the negative values of their resonance constants σ_R^0, σ_R, and σ_R^+ as quantitative characteristics of conjugation respectively in the electronic ground state (NMR, IR spectroscopy), under the conditions of direct polar conjugation (IR spectroscopy of the hydrogen bond),[24] and in the presence of a positive charge on the π system (UV spectroscopy of charge-transfer complexes). The frontier orbitals formed on interaction of CH_2EX_3 with the π system of Y are of the σ,π and σ,π^* type. The HOMO energy increases (according to quantum-chemical calculations and photoelectron spectroscopic data) under the influence of the substituents $CH_2E(CH_3)_3$, while the LUMO energy is less sensitive to the effect of substituent.

With an increase in the atomic number of E (other conditions being equal), an enhancement of the σ,π conjugation is observed. Hyperconjugation also increases following the appearance of a positive charge on the π system. Thus the negative values of the resonance constants of the substituent $CH_2E(CH_3)_3$ increase in the sequence $\sigma_R^0 < \sigma_R < \sigma_R^+$. The magnitude of the effect of the σ,π conjugation depends on the nature of the groups X in CH_2EX_3 and on the substituent Z bound to the π system. The enhancement of the electron-accepting properties of X in CH_2EX_3 is accompanied by a weakening of the σ,π conjugation, whereas under conditions favouring direct polar conjugation between the substituents $CH_2E(CH_3)_3$ and Z via the π system [for example in the case of $(CH_3)_3SnCH_2C{\equiv}CSi(CH_3)_3$ [97]], σ,π conjugation intensifies with enhancement of the electron-accepting properties of Z.

In organotin and organolead compounds, especially in the presence of a positive charge on the π system, σ,π conjugation is a powerful resonance electron-donating effect, which exerts a strong influence on the reactivity of these compounds.[2,54]

Hyperconjugation of the σ,π and σ,π^* type depends significantly on stereoelectronic effects. The maximum σ,π conjugation therefore occurs only under favourable steric conditions, which has been considered in detail in a number of studies.[3,10,36,55,89,95] In σ,π conjugation with the π systems of a double bond, a triple bond, and benzene and naphthalene rings, substituents containing the E–E′ groups also participate. Here E and E′ represent different combinations of identical or different elements (Si, Ge, Sn).[3,55,98–101] Thus, as a consequence of the parallel disposition of the E–E bridges and the p_π ring orbitals, the σ,π conjugation in cyclophanes of the type



(E = Si, Ge)

is stronger than in the corresponding acylclic compounds.[102] On the other hand, the σ,π conjugation with participation of the groups $-Si-Si(CH_3)_3$ constitutes an appreciably weaker resonance electron-donating effect than the conjugation involving the substituent $CH_2Si(CH_3)_3$.[3] This finding can be explained by the existence in the disilyl substituent of two opposite resonance effects — the electron-donating effect [σ,π conjugation is apparently stronger than in the substituent $CH_2Si(CH_3)_3$ because of the greater polarisability of the Si–Si bond compared with Si–C [93]] and the electron-accepting effect [d,π conjugation, which is absent in the $CH_3Si(CH_3)_3$ group].[3]

According to the results obtained by different methods,[6,41,42,50,51] the substituents SiX_3 containing any organic groups X exert an overall resonance electron-accepting effect in relation to the π system, which follows, for example, from the positive resonance constants σ_R.[6,21] An alternative interpretation of the resonance effects of the substituents SiX_3 is formally permissible: either (a) these substituents manifest only electron-accepting properties or (b) the overall effect includes a weaker electron-donating component (σ,π conjugation) and a stronger electron-accepting component. Evidence in support of the second view, obtained in a general theoretical study (see Section II as well as the literature[103–105]) until recently had not received convincing experimental confirmation. Unambiguous proof of the presence of an electron-donating component (σ,π conjugation) in the overall resonance effect of the substituents EX_3 (E = Si, Ge, Sn, Pb) and $E'X_n$ (E′ = Hg, B, P, As, Sb, Bi) was obtained in the joint analysis of the constants σ_p abd σ_p^+ of phenyl derivatives with the above substituents and the benzyl derivatives $C_6H_5CH_{3-n}[E(CH_3)_3]_n$.[93] The principal factor determining the enhancement of the σ,π conjugation following the appearance of a positive charge on the aromatic ring in both phenyl and benzyl series is the polarisability of the chemical bonds of the substituent.[93] Under these conditions, the hyperconjugation is enhanced more the greater the atomic number of E in EX_3 and $CH_{3-n}[E(CH_3)_3]_n$.[93]

Yet another feature of the σ,π conjugation is its dependence on the type of the π system to which the organoelement fragment is linked. Thus systematic studies by different methods of benzene and acetylene derivatives with different substituents $EAlk_3$ [6,24,25,57,89,97,106] established, in particular, that the enhancement of the σ,π conjugation on passing from substituted benzenes to acetylenes is greater the higher the atomic number of the element E in the substituent $EAlk_3$ attached to the π system.[24] The idea that the σ,π conjugation between $E(CH_3)_3$ and π systems intensifies with increase in the atomic number E was also confirmed in other studies.[107–109]

Semiempirical quantum-chemical methods are used in the vast majority of cases in studies on σ,π conjugation, so that the conclusions reached with their aid are only qualitative. The existence of both electron-donating (σ,π conjugation) and electron-accepting effects in the substituents EX_3 and of only hyperconjugation in CH_2EX_3 has been established for benzene,[13,103,104,110] ethylene,[10,52,88,95,111,112] acetylene,[13,52,89,113,114] and furan[105,115]

derivatives and also for π systems of more complex structure.[116,117] Non-empirical calculations for vinylsilanes and their radical-cations,[118,119] silylacetylenes,[120,121] stannylacetylenes,[122] as well as the cyclopentadienyl[123] and naphthyl[101] derivatives of silicon provide better evidence. The joint application of modern quantum chemistry and photoelectron spectroscopy proved especially effective.[8,89]

3. Hyperconjugation of the σ,*n* type

The development of ideas about the dual nature of the overall resonance effect of substituents EX_3 in relation to π systems, which includes electron-donating (σ,π conjugation enhanced as E varies in the sequence Si < Ge < Sn) and electron-accepting components, was accompanied by the accumulation of facts concerning the effects of these substituents in relation to the groups Y comprising atoms with lone pairs in the α-position relative to the E atom. Pauling's initial concept,[48] according to which the substituents EX_3 exhibit exclusively an electron-accepting resonance effect in relation to Y ($d_\pi-p_\pi$ conjugation) was subsequently given a deeper content. This was based on numerous data obtained by various physical and chemical methods, which, although to a large extent indirect, nevertheless generated a consistent system of views concerning the presence of not only electron-accepting but also of electron-donating properties in the substituents $E(CH_3)_{3-n}X_n$ linked to Y.[3,124–128]

Initially (see, for exmaple, Egorochkin and co-workers[3,129]) the electron-donating properties of the substituents in the H–C–E–Y fragments were interpreted as the σ,σ conjugation of the H–C and E–Y bonds (like the conjugation of the E–C bonds in compounds with E–C–C–E atomic groups[130]). However, such interpretation is doubtful bearing in mind the weaker hyperconjugation in the H_3C-Si fragments than in H_3C-C.[131] On the basis of orbital approaches, the treatment of the resonance electron-donating properties of $E(CH_3)_3$ relative to Y as the σ,*n* mixing of the initial unperturbed σ orbitals of E–C with the *n* orbitals of the lone pairs of Y, which have a higher energy, appears more adequate.

The same procedures of the perturbation theory are applicable to the consideration of the σ,*n* conjugation as for σ,π conjugation. The rigorous allowance for the influence of the inductive effect on the energies of the initial orbitals gives rise to an appreciable complication under these conditions (see, for example, Baidin et al.[132]). Only qualitative estimates of the σ, *n* conjugation in the compounds $(CH_3)_3EX$ (X = OAlk, SAlk, Cl, Br) and $[(CH_3)_3E]_2X$ (X = O, S) are therefore available at the present time.[133–135] The effect of σ,*n* conjugation intensifies as E and X are varied in the sequences Si < Ge < Sn < Pb, S < O, and Br < Cl. On passing from the compounds $(CH_3)_3EX$ to $[(CH_3)_3E]_2X$, the σ,*n* conjugation is enhanced for X = O and is weakened for X = S, which is due to stereoelectronic factors determining the directions assumed in space by the interacting orbitals.[134]

Thus the effects of the σ,π and σ,*n* conjugation of the substituents $E(CH_3)_3$ linked to π or *n* systems intensify with increase in the atomic number of the E atom and depend on the type of each of the systems indicated. The effect of the σ,*n* conjugation in $(CH_3)_3EY$ intensifies as the atomic nubmer of the atoms with the lone pair in the α-position relative to the E atom diminishes. Within the framework of the phyiscal-organic chemical concept of the separation of the effects of substituents, adopted in this review, these facts have provided in recent years much evidence in support of the idea of the resonance effects of the groups $E(CH_3)_3$ as effects combining electron-donating and electron-accepting properties.

After the rigorous allowance for the inductive effects of the groups $E(CH_3)_3$, it was shown that the resonance electron-accepting effect of these groups is not enhanced but is actually weakened with increase in the atomic number of the E atoms, in contrast to σ,π and σ,*n* conjugation. On the other hand, both σ,*n* conjugation and the resonance electron-accepting effect weaken with increase in the atomic number of the Group VI or VII elements linked to E.[6,42,133,135] Thus the overall resonance effect of the groups $E(CH_3)_3$ relative to centres of the π and *n* type, representing the result of the combination of two opposed components, is a typical electron-accepting effect for organosilicon compound and a weak electron-accepting effect (and sometimes an electron-donating effect) for organotin compounds. In the case of organogermanium compounds and also in systems with weak resonance interactions, situations frequently arise which are difficult to predict. Therefore in the analysis of experimental data in early reviews[41,49–51] the interpretation of the overall resonance effect (traditionally given the term $d_\pi-p_\pi$ conjugation) on the assumption that $E(CH_3)_3$ has electron-accepting properties only encountered a number of difficulties. It is essential to note also the significantly different sensitivities of the research methods and indicator centres to the influence of resonance effects to which special attention has been drawn recently.[10]

The idea of dual donor–acceptor resonance properties of the substituent $E(CH_3)_3$ examined above was confirmed by non-empirical quantum-chemical calculations for the compounds $(CH_3)_{4-n}SnCl_n$ (n = 1, 2, 3), $[Sn(CH_3)_3]_2X$ and $[(CH_3)_2SnX]_3$ (X = S, Se).[136,137] The fragments $CH_3-\underset{|}{\overset{|}{Sn}}-$ exhibit in relation to chlorine atoms both resonance electron-accepting properties (the involvement of 5*d* orbitals of Sn in bonding) and electron-donating properties [σ,*n* mixing of the σ(Sn–C) orbitals and *n* orbitals of the lone pair of chlorine]. σ,*n* conjugation apparently predominates in the reonance interaction between the $Sn(CH_3)_3$ group and the sulphur (selenium) atom, which agrees, in particular, with the present author's experimental data.[133,134] The same type of conjugation is evidently responsible for the low values of the first ionisation potentials of compounds with the Si–C–S groups.[138,139]

Thus experimental data and non-empirical quantum-chemical calculations indicate, in conformity with the theoretical ideas described in Section II, a dual nature of the resonance interactions of substituents of the $E(CH_3)_3$ type with π and *n* systems. The electron-donating properties of these substituents are caused by their involvement in σ,π conjugation, σ,π* conjugation, and σ,*n* conjugation and possibly also in other versions of hyperconjugation, which have so far been scarcely investigated.

We shall now analyse the question to what extent experimental studies on the resonance electron-accepting properties of $E(CH_3)_3$ agree with the general approach to this problem (stages C and D in Section II of the review).

4. Resonance electron-accepting properties of the substituents $E(CH_3)_3$

We shall consider the simplest case, that of the compound $(CH_3)_3EY$, where only one group Y, having π electrons or a lone pair in the α-position relative to E, is linked to the E atom. In this situation, the overall electron-accepting effect of E in relation to Y diminishes with increase in the atomic number of the elements E

(i.e. from Si to Ge and Sn) and Y (in the sequences N > P, O > S > Se, and F > Cl > Br > I). The relative capacity of the substituents Y for conjugation with silicon or germanium atoms (i.e. the overall electron-donating effect of the conjugation of Y with E) is correlated with the resonance constants σ_R of the groups Y. These conclusions were reached from data obtained by NMR and IR spectroscopy.[6,42]

Here one should note that the energies of the initial orbitals E(E−C), $E(\pi)$, and $E(n)$, which are extremely significant for σ,π and σ,n conjugation [see Eqns. (1)−(3)] are not explicitly decisive for the resonance electron-accepting effect (designated as $d,\bar{\pi}$ or d,n conjugation in Section II).[134] The effects of the σ,n and d,n conjugation (as well as σ,π and d,π conjugation) can depend in different ways on the type of substituents X in X_3EY.

The influence of X on d,n conjugation for E = Si and Ge has been studied in fair detail.[42] The enhancement of electron-accepting properties increases the effective positive charge on E,[41,49,84,140] which induces, according to a widely held hypothesis,[41,42,51] the contraction of the diffuse unoccupied *nd* orbitals of E and hence improves the conditions for d,π or d,n conjugation in the molecule. Linear relations are known between experimental quantities characterising the charge on the E atom and the resonance electron-accepting effect of EX_3 (i.e. d,π or d,n conjugation under conditions where it clearly predominates over σ,π or σ,n conjugation): variation of the charge on E ensures the variation of the resonance electron-accepting properties of ER_3 within wide limits.[42]

On the other hand, the dependence of σ,π or σ,n conjugation on the nature of X in X_3EY is extremely complex. The enhancement of the electron-accepting properties of X (i.e. an increase in the charge on E) should increase the absolute energies E(E−C), $E(\pi)$, and $E(n)$. However, there are no grounds for the expectation that the form of the dependences of E(E−C), $E(\pi)$, and $E(n)$ on the charge on E is the same. Therefore, the relation between the charge on E and the values of ΔE [Eqns. (1)−(3)] as well as other quantities characterising the σ,π and σ,n conjugation is virtually unpredictable.[134]

The effects of σ,π and σ,n conjugation are determined by the interaction of the orbitals with the energies $E(\pi)$, $E(n)$, and E(E−C) leading to the formation of the HOMO. Therefore the methods based on the analysis of the orbital characteristics (photoelectron spectroscopy, UV spectroscopy of charge-transfer complexes[3,6]) are most effective for the study of hypoconjugation. The effects of d,π and d,n conjugation are maximum for E = Si and depend greatly on the charge on E; the π- or n-donor properties relative to $E(CH_3)_3$ (E = Si, Ge) are determined by the σ_R constants of Y.[6,42] Therefore the effective and sensitive methods for the study of d,π and d,n conjugation are based on the analysis of charge characteristics, for example, the intensities of the E−H (E = Si, Ge) bands in the IR spectra of Alk_2HEY (the effects of σ,π and σ,n conjugation are then comparatively small, i.e. the electron-donating component of the overall resonance effect of Alk_2HE relative to Y in Alk_2HEY is small). It must be emphasised that d,π and d,n conjugation undoubtedly affects the energy of HOMO and other orbitals (see, Section II and Fig. 1), but such dependence is complex, since the antibonding σ^* orbitals of E−C also participate in conjugation of this type together with *nd* and π (or n) orbitals [this was taken into account more than 20 years ago (see, for example, Pitt et al.[79])]. As regards the *nd* orbitals of the E atoms, they are stabilised under the influence of the electronegative substituents linked to E, i.e. their energy diminishes.[41,49,81,84] This last finding justifies the assumption that the *nd* orbitals are located between the π and π^* orbitals, i.e. their energy approaches that of the n orbitals; ultimately this should enhance d,π and d,n conjugation.

Thus all the foregoing considerations concerning the complexity of the resonance electron-accepting properties of the groups $E(CH_3)_3$ cast doubt on the legitimacy of the simplified view on these properties. Such a simplified approach can be encountered in many studies during the last decade (typical examples can be found in Refs. 65, 68−71, and 141 and in reviews[2,11,12,56]). In these studies, sometimes regarded as an alternative to the *nd* orbital hypothesis, the resonance electron-accepting properties of $E(CH_3)_3$ relative to Y are explained exclusively by the mixing of the antibonding σ^*(E−C) orbitals with π or n orbitals of Y. The only argument in support of this choice is the smallness of the *nd* orbital contributions according to the results of certain non-empirical quantum-chemical calculations.[60−63,65,72,141,142]

However, this argument is open to objection. Firstly, there have been non-empirical calculations[136,143−145] in which the involvement of the *nd* orbitals was found to be significant not only in silicon but also in tin derivatives. Secondly, in quantum-chemical studies[63,72,87,142] involving a rigorous approach to the problem of conjugation the necessity for further investigations for a correct assessment of the role of *nd* orbitals has been pointed out. The importance of these studies has been noted in a review.[46] Thirdly, even in non-empirical calculations for resonance interactions between systems and organic substituents not containing the atoms of Third Period elements, the results depend on the choice of the basis sets.[106] The current interest of this problem increases greatly on passing from organic[88] to organoelement[46,77,86,87] compounds. In non-empirical calculations for the latter, the authors of many investigations have noted an improvement of the agreement between the calculated and experimental data when *d* functions are included in the basis set.

For the reasons indicated, there are at present no well-founded grounds for the simplification of the idea, examined in Section II of the present review, that the resonance electron-accepting effects of the substituents $E(CH_3)_3$ relative to centres of the π or n type are complex. Therefore, in particular the overall resonance effect of the substituents $E(CH_3)_3$ on the HOMO and LUMO energies in benzene, ethylene, acetylene, thiophene, and furan derivatives[68−70] and on the HOMO energy in silyl ethers and siloxanes[141−146] as well as the effect of SiH_3 on the ionisation potentials of the lone pairs in $Y(SiH_3)_n$ (Y = N, O, S, and Se) [71] can be interpreted with greater justification not on the basis of hyperconjugation interactions with participation of the σ^*(E−C) and σ^*(Si−H) orbitals but as a result of the simultaneous operation of the electron-donating effect of the σ,π (or σ,π^*) as well as σ,n conjugation and the electron-accepting effect of the d,π (or d,π^*) as well as d,n conjugation. The large Si−O−C bond angles in compounds of the type $(CH_3)_3Si-O-Aryl$ and $(CH_3)_2ClSi-O-Aryl$ (where the oxygen atom has long been known[42] to participate in resonance interactions with both substituents) also cannot be accounted for within the framework of the concept of the electron-accepting properties of the Si−C and Si−Cl σ^* orbitals,[147] which casts doubt on the application of this concept by Reed et al.[65] to compounds with a related structure.

5. Electronic effects of the substituents $E(CH_3)_{3-n}X_n$

It was shown above that the substituents $E(CH_3)_3$ in the simple compounds $(CH_3)_3EY$ exhibit, together with the electron-donating inductive $+I$ effect in relation to π or n systems, also resonance electron-donating (σ,π or σ,n conjugation intensifies in the sequence Si < Ge < Sn < Pb) and electron-accepting (d,π and d,n conjugation weakens in the sequence Si > Ge > Sn) properties. We shall now consider the more complex systems $(CH_3)_{3-n}X_nEY$, where two or three groups X and Y having π electrons or lone pairs in the α-position relative to E, are linked to the latter.

The enhancement of the electron-accepting properties of X and/or the increase in the number of groups X is accompanied by a change in the sign and increase in magnitude of the I effect of $E(CH_3)_{3-n}X_n$ compared with $E(CH_3)_3$. Thus, for any element E, the groups EHal are typical $-I$ inductive σ-acceptors.[6,21]

The resonance interactions between $E(CH_3)_{3-n}X_n$ and Y are distinguished by a greater variety [compared with those in $(CH_3)_3EY$], since they depend not only on the nature of E and Y but also on the type and number of the groups X. Only the simplest versions of these interactions have been investigated hitherto. We shall now consider the main ideas formulated in this field.

1. Judging from the values of the constants σ_R, the overall resonance effect of the substituents $(CH_3)_{3-n}X_nE$ in benzene, ethylene, and acetylene derivatives intensifies with enhancement of the electron-accepting properties of the groups X and their number.[6] In the study of silane and germane derivatives $(CH_3)_{3-n}X_nEH$ by IR spectroscopy, where the situation at the indicator centre (E–H bonds) is determined predominantly by the charge characteristics (see Section III. 4), it was shown that the overall resonance interactions in the EX_n fragments are regulated by the effective charge on the silicon or germanium atom, which depends in its turn on the inductive and mesomeric effects of X.[42,148,149] In the analysis of the integral intensities of the E–H bands in the IR spectra, which was especially sensitive to the effect of conjugation, linear relations were established between the overall resonance effect in the EX_n fragments and the positive charge on the E atom (Si or Ge).[42,150]

2. The groups $E(CH_3)_{3-n}X_n$ for any X possess not only an electron-accepting component (which decreases in the sequence Si > Ge > Sn) but also an electron-donating component of the overall resonance effect. Unambiguous proof of the existence of the electron-donating component has been obtained both for the substituents $E(CH_3)_3$ (see Section III. 2) and for $E(CH_3)_{3-n}X_n$ in the analysis of the constants σ_p and σ_p^+ characterising the overall electronic effect (inductive and resonance) respectively in the absence and presence of a positive charge on the benzene ring to which these substituents are linked.[93]

The difference between the constants σ_p and σ_p^+ is caused by the enhancement of the electron-donating component (i.e. σ,π conjugation) of the overall resonance effect when a charge appears on the ring. Such enhancement is determined by the polarisability of the E–C and E–X bonds in $E(CH_3)_{3-n}X_n$. Thus the SiF_3 acceptor ($\sigma_p = +0.66$), which is strongest among silicon-containing acceptors, does not lose its electron-accepting properties appreciably in the presence of a positive charge on the ring in $C_6H_5SiF_3$ because of the low polarisability of the Si–F bonds. However, the electron-accepting properties of the substituent $GeCl_3$ ($\sigma_p = +0.79$) diminish sharply ($\sigma_p^+ = +0.33$) owing to the high polarisability of the Ge–Cl bonds.

Other features of the σ,π conjugation with participation of the groups $E(CH_3)_{3-n}X_n$, for example the enhancement of the effect, other conditions being equal, in the sequence Si < Ge < Sn, have been examined in detail.[6,93] Although the ratio of the resonance electron-donating and electron-accepting properties of these substituents, bound to the benzene ring, varies within wide limits as a function of the type and number of the groups X in $E(CH_3)_{3-n}X_n$ (the values of σ_p and σ_p^+ can differ not only in magnitude but also in sign), the electron-accepting resonance effect predominates in the groups $EHal_3$.[6,21,104] This predominance evidently persists also in those cases where the groups $EHal_3$ are linked to other reaction centres, for example to a double bond.[151] The strong resonance electron-accepting properties of the $SiCl_3$ group at the iron atom in $(\eta^5\text{-}C_5H_5)Fe(CO)_2SiCl_3$ are caused, according to the authors,[152] by both the antibonding σ^*(Si–Cl) orbitals and the d orbitals of silicon.

The electronic effects of the substituents $E(CH_3)_{3-n}X_n$ with groups X of the same type were examined above. If the atoms X or X and Y, having lone pairs in the α-position relative to E, are of different types in $(CH_3)_{3-n}X_nEY$, then an additional conjugation channel arises in the molecule. In compounds with the O–E–Cl and N–E–Cl fragments, the occurrence of additional resonance interactions can be observed by NQR [3,153–155] and IR spectroscopic[3,51,156] methods.

Initially, such interactions were established in carbon compounds with F–C–Cl [157] and X–C–Cl (X has a lone pair in the α-position relative to C)[158] groups and were explained by σ,p conjugation.[157] A modern interpretation of this effect, close in its significance to that of Lucken,[157] in the X–A–Y (A = Be, Mg, B, Al, C, N, P, O, S) or X–O–Y systems is based on the idea of the n,σ^* interaction (negative hyperconjugation) of the lone pair of the atom X with electron-accepting σ^*(A–Y) [7,9,64,65] or σ^*(E–Y) orbitals.[7,64,65]

The significant role of n,σ^* conjugation is indicated by quantum-chemical[7,9,64,65] and experimental studies using indicator centres sensitive to charge[3] and especially orbital interactions.[7,9,64,77,159] In view of the appreciable influence of the n,σ^* interaction in silicon, phosphorus, and sulphur compounds and the less definite situation involving nd orbitals, the contributions of the latter to conjugation have been altogether denied in certain quantum-chemical studies[64,65,160] or are believed to be relatively insignificant. However, this view appears to be insufficiently supported by arguments, in view of the simplification of the complex pattern of electronic effects, for the following reasons.

Firstly, the effect of n,σ^* conjugation cannot serve as an alternative to the nd orbital hypothesis, since it occurs, for example, in carbon and nitrogen compounds,[7,9] while the contribution of the nd orbitals can be neglected *a priori*. Secondly, the ambiguity of the quantum-chemical conclusions concerning the involvement of nd orbitals has already been examined above (see Section III. 4). Nevertheless, we may note that non-empirical calculations for hypervalent compounds indicate an appreciable role of the nd orbitals of phosphorus, sulphur, and chlorine.[77] Thirdly, application of the standard procedure[20,22,31,158] adopted in the interpretation of experimental data[3,153,155,156,161] by the methods of correlation analysis to the separation of electronic effects indicates a significant difference between the resonance interactions in compounds containing X–E–Y fragments with groups X and Y of the same or different types. For X and Y of the same type, the above interactions include the inductive effect as well as d,n and σ,n conjugation. For X and Y of different types, the interpretation

of the experimental data becomes impossible without invoking the idea of the additional effect of n,σ^* conjugation.

IV. Conclusion

The analysis in this review of the available theoretical ideas in the literature concerning conjugation in organic compounds of the silicon-subgroup elements and their comparison with experiment permits a series of general conclusions.

None of the existing theoretical concepts (Pauling's *d*-orbital hypothesis, hyperconjugation as an alternative to this hypothesis, the involvement of the antibonding σ^* orbitals of the E–C or E–X bonds in conjugation), invoked to account for the nature of the resonance π-acceptor properties of the substituents $E(CH_3)_{3-n}X_nE$, where E = Si, Ge, or Sn, withstands criticism both from the standpoint of demonstrating the inadequacy of alternative systems of views and as regards the possibility of an exhaustive interpretation on their basis of the entire set of experimental data accumulated hitherto. The general theoretical concept in which the resonance electron-accepting properties of the groups $E(CH_3)_{3-n}X_n$ are treated from the standpoint of the joint involvement in conjugation of the *nd* orbitals of E and also of the antibonding orbitals $\sigma^*(E-C)$ and/or $\sigma^*(E-X)$ is consistent with experimental data most completely and with least contradiction. The ratio of these two contributions to the overall electron-accepting effect remains, however, obscure and reliable quantum-chemical approaches to its estimation are so far lacking. It has apparently been finally demonstrated merely that the transition of the E atoms to the sp^3d or sp^3d^2 hybridised state does not occur and the involvement of *nd* orbitals constitutes a special case.

Systematic comparative studies on the resonance electron-accepting properties of the groups $E(CH_3)_{3-n}X_n$ in the electronic ground and excited states have not so far been carried out.

Together with electron-accepting properties, the substituents $E(CH_3)_{3-n}X_n$ possess also resonance electron-donating properties in relation to π systems (σ,π conjugation) and groups containing an atom with lone pairs in the α-position relative to E (σ,n conjugation). Whereas the resonance electron-accepting effect is diminished as E is varied in the sequence Si > Ge > Sn, the σ,π- and σ,n-conjugation effects are actually enhanced with increase in the atomic number of E.

The resonance electron-donating and electron-accepting properties of the substituents $E(CH_3)_{3-n}X_n$ are responsible for the significant dependence of the relative contributions of these properties on the type of reaction centre. Therefore the variation of the nature of the latter (for example, the appearance of a positive charge) can lead not only to a change in the overall resonance effect of the substituents but also to a change in its sign. Such inversion of the donor–acceptor properties of the substituents $E(CH_3)_{3-n}X_n$ is of fundamental importance in the study of the reactivities of systems with these groups. It appears that accumulation and systematic treatment of facts and a deeper consideration of the characteristic features of the changes in the donor–acceptor properties of $E(CH_3)_{3-n}X_n$ compared with the behaviour of the substituents $(CH_3)_{3-n}X_nECH_2$, which do not have resonance electron-accepting properties, will make it possible in the future to avoid speculative constructions in the analysis of reactivity. Instead experimentally tested elements of the theory being created will be invoked.

It is essential to note also the fruitfulness of the orbital ideas, which are being used to an increasing extent in the organoelement chemistry of Group IVB elements. A complex organoelement molecule contains as a rule several indicator centres sensitive in different experiments, the application of physical research methods to charge and/or orbital interactions. The accumulation and analysis of such data together with non-empirical quantum-chemical calculations is important for the development of concepts concerning the charge and orbital control of reactions with participation of organoelement compounds and for the more active incorporation of the principle of hard and soft acids and bases in its modern interpretation. In its turn, progress on these lines will promote the improvement of our knowledge about conjugation effects in organic compounds of silicon-subgroup elements.

Aggregation of dye molecules and its influence on the spectral luminescent properties of solutions

V I Yuzhakov
Faculty of Physics, Lomonosov Moscow State University

ABSTRACT. The principal results of studies carried out in recent years on the molecular aggregation of organic dyes and pigments in solutions are examined and surveyed in the present review. Attention is concentrated on the influence of association on the photoenergetics of the dye molecules. Theoretical studies on the spectral-luminescent spectroscopic characteristics of the molecular aggregates are briefly considered. Studies on the anisotropy of the absorption and on the emission from the associated species are described. Investigations of the concentration depolarisation and concentration quenching of the fluorescence of dye solutions are subjected to a critical analysis. The results of studies of the mixed association of dye molecules and of its influence on the lasing characteristics of the solutions are presented. The physicochemical conditions affecting the efficiency of the association process are examined.

The bibliography includes 251 references.

I. Introduction

The wide-scale employment of organic dyes in science and engineering has stimulated research into the photophysical and photochemical properties of their molecules. Since dyes are most often used in liquid and solid solutions, where their spectral luminescent characteristics are complicated by intermolecular interactions, studies on the associated molecular forms of such compounds have become important. One may point out several aspects responsible for the interest in molecular association. This is in the first place the necessity to create a non-contradictory theory of the liquid state and solutions. The study of the photoenergetics of dye solutions always requires the knowledge of the spectral-luminescent characteristics of their molecular aggregates in order to be able to isolate in a pure form the optical manifestations of various intermolecular interactions, which are frequently complex and varied. It is impossible to overestimate the importance of studies on molecular association for the investigation and modelling of biological processes at the molecular level since under these conditions the molecules, functioning as reaction centres, are usually associated.

The employment of dye solutions as the lasing media in lasers has given rise to interest in problems such as that of the influence of solvents and various additives on the development of molecular association, which has a negative effect on the lasing efficiency. The application of dye solutions in quantum electronics as passive modulators, optical filters, shutters, etc., when appreciable absorption in the absence of luminescence is required, has given rise to additional interest in their associated molecular forms. Under these conditions, the appreciably different spectral-luminescent properties of the associated dye molecules and their monomeric forms can serve as a factor expanding their application in this field. The idea of a shift from the set of elements used in electronics to the molecular level will greatly expand the research into the problem of the molecular dye aggregates which is thus related to a number of fundamental aspects. Since the association of dye molecules lead as a rule to the quenching of the luminescence, it is essential to know the physicochemical factors inducing association or reducing its effectiveness. On the other hand, luminescent associated species can be used in concentrators of light energy, which requires conditions for the intensification of the association process. It is virtually true that whatever aspect of the study or use of dyes is considered (the study of relaxations of different kinds, Langmuir-Blodgett films, micellar systems, etc.), the problem arises of molecular association and its luminescence-spectroscopic manifestations. This is in fact why the number of studies devoted to the association of dye molecules and their spectroscopy has been continuously increasing. The previous review devoted to this problem[1] no longer reflects the current state of research in this field. The development of the spectroscopic techniques and the use of quantum-chemical modelling methods have made it possible to obtain a series of new luminescence-spectroscopic effects, arising on dimerisation of organic dye and pigment molecules. This review is based on studies published during the last 15 years.

II. Theoretical study

The luminescence-spectroscopic properties of the molecules of organic compounds in aggregates are a result of their collective interaction and are caused by the change on association of the oscillator strengths for optical transitions and selection rules and by

the manifestation of vibronic interactions. They involve the splitting of spectral bands, the displacement of electronic spectra, and changes in the intensity and anisotropy of absorption and emission and in molecular vibration frequencies, and the appearance of new vibrational transitions.

As regards their theoretical aspect, many of these problems have still not been solved even in a general form and for this reason there has been no weakening of interest in the theoretical description of the optical spectra of molecular aggregates (absorption, luminescence, and circular dichroism spectra), attention being concentrated on the effects of vibronic interaction.[2] The following aspects of the theoretical study of the molecualr aggregates have yielded most results: (1) the classical theory of the polarisability of bound oscillators; (2) the study of the exciton–phonon interaction as a stoichastic process which depends on time and the potential; (3) numerical calculation of the positions of the lines and intensities on the basis of a simple microscopic model; (4) the application of the sums rule as the theorem of moments for a vibronic band.

However, the quantitative application of theoretical methods to real systems remains problematical and the optical characteristics of associated species are calculated only for ordered structures, for example, sandwich type structures.

The most significant results have been obtained using the theory of excitons. The shape of the absorption bands of molecular dimers has been predicted with the aid of the model of incoherent exciton scattering.[3] The Hamiltonian of the dimer is represented by the sum of the Hamiltonians of the monomers and of the intermolecular interaction operator, whose matrix elements are expressed in terms of the eigenfunctions of the monomers. The energy levels and the matrix elements of the dipole moments of the dimer have been calculated in this way. The absorption coefficient and the absorption contours are expressed in terms of these quantities for different molecular interaction energies. The form of the absorption spectrum of the dimer depends on the relation between the nuclear relaxation and the exchange energy between the monomers. As an example, the absorption spectrum of the 9-chloroanthracene dimer was calculated and was found to be close to the experimental spectrum.

Allowance for the exciton effects, the electron–phonon interaction, and the local disorder among phosphor molecules made it possible to calculate the form of these individual transitions in the vibronic spectra of the molecular aggregates.[4] Best agreement between calculation and experiment was then achieved for pseudocyanine on the assumption that the aggregates contain eleven molecules arranged helically.

The same workers proposed a method for calculating the electronic absorption spectra of aggregates permitting the separate description of the vibrational structure of the non-uniform broadening.[5] The applicability of the method was demonstrated for the *J*-aggregates of 1,1-diethyl-*N*,*N*′-isocyanine chloride in water. It was found that the aggregate consists of six monomers.

A new approach to the calculation of the optical properties of molecular aggregates is based on allowance for the non-uniform spectra broadening caused by the non-equivalence of the environments of phosphor molecules comprising the molecules of the medium.[6] One considers an assembly of chemically identical aggregates in an isotropic medium (liquid, glass, etc.) in which it is necessary to take into account the distribution of non-equivalent states and to average out the form of the spectral lines with respect to the distribution. The functional form of the Hamiltonian corresponding to each six system is uniform but the magnitude of the parameter can differ from system to system. In this model, the medium is characterised by vibrations (modes) which can be divided into strong and weak in terms of their interaction with the aggregates. Strong modes are regarded as the usual exciton–phonon interaction and weak modes are responsible for the statistical non-uniformity. The Hamiltonian is constructed as follows:

$$H = \sum_i \varepsilon_i A_i^+ A_i + \sum_n \omega_n B_n^+ B_n +$$
$$+ \sum_j \sum_i \sum_n g_{ij}^n \omega_n \left(B_n + B_n^+\right) A_i^+ A_j ,$$

where ε_i are the electronic energy levels of the aggregates, A and B are operators of the exciton–phonon formation and annihilation, and g_{ij}^n is the parameter of the exciton–phonon coupling for a separate mode on transition between levels i and j. The vibrational modes ω_n of the solvent and the molecule are grouped in the last two terms. Non-uniform local perturbations of any of the parameters (ε, ω, g) can differ for different species in the ensemble, but it is postulated that during the absorption of a photon the parameters are constant. Calculation showed that even in simple systems dimer spectra can be completely different from the monomer spectrum (depending on the vibronic and non-uniform contributions to the line width and the variation of any one parameter). The possibility of applying these theoretical results to real molecular systems, in which individual vibronic lines are not resolved, has been discussed in a study,[7] where analytical expressions were obtained for the form of the absorption and circular dichroism bands of the dimer.

The study of exciton–nuclear interactions in aggregates showed[8,9] that such interactions predominate in real dimers. The parameters used in this case were obtained by adjusting the theoretical spectra to agree with the experimental spectra of solutions of xanthene dyes (rhodamine B, pyronines B and Y).

The dimers of eosin Y have been investigated.[10] The visible absorption spectrum of its monomers refers to a single electronic transition, but includes several different vibration bands. The spectra of the dimers are therefore regarded as a result of their exciton interaction between vibronic levels. The difficulties in the interpretation of the experimental spectra proposed by Jones, et al.[11] are indicated and an approximation, constituting a further development of the exciton theory, is proposed for the analysis of the spectra of the dimers. It is suggested[10] that such spectra be considered on the basis of exciton interactions between vibronic states.

The electronic transitions between the split components of the electronically excited dimers have been analysed using perturbation theory.[12] It was shown that the one-photon transition between the ground state and one of the components of the excited state is prohibited for dimers in the case where the transition moments of the monomers constituting the associated species are parallel. However, the components forbidden in a one-photon transition can be manifested in a two-photon process. The theoretical treatment adopted in the above study[12] is equivalent to the strong bond limit.

The properties of the electronic states of metalloporphyrin dimers have been investigated by quantum-chemical methods.[13,14] Calculations have been carried out for the sandwich dimer, where the centres of the monomers are located on the axis perpendicular to the molecular plane.[13] The singlet and triplet states of the dimers of this compound have been obtained[14] for structures where the molecules are in one and in different parallel planes. Quantitative

agreement with experiment were not always obtained but the parameters of the structure attributed to the dimers agree with EPR data.

The dimers of a series of porphyrins[15] with different geometries[16] were investigated by this method. The energy changes and the orbital nature of the excited electronic states of the xanthene dyes during their dimerisation were established by direct quantum-chemical calculation,[17] dimers with a sandwich structure being considered.

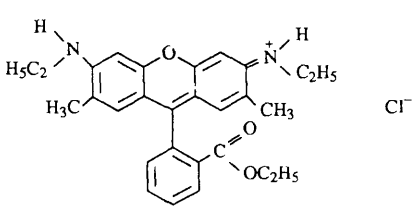
The results obtained when the theoretical parameters are determined from experimental data are of interest.[9,10,18] Not only the form of the electronic spectra of the dimers but also quantities such as the association constant, the quenching constant etc. are then obtained. Thus, using the method of least squares and the experimental spectra of Acridine Orange in the hydrochloride form, the dimerisation constant and the molar exctinciton coefficients of the dimers were obtained.[19] However, in their analysis the authors had to assume that the dye solutions consists only of monomers and dimers.

The approach to the description of the contours of the electronic bands of associated dye molecules, based on the hypothesis that the total absorption spectrum consists of "elementary" spectra (uniform relaxation components), has been proposed.[20] The initial postulate is that the line width and the probability of the transition between two electronic states are functions of the transition frequencies only. With the aid of the expression obtained for the description of the spectra of associated species and the experimental spectra, the parameters of the absorption spectra of the associated species were determined by minimising the corresponding function. No temperature dependence of the width of the Lorentzian component of the spectra of the associated species was observed for rhodamine 6G, in contrast to the monomers where such a dependence exists.

The optical properties of aggregates of chromophores have been studied theoretically using the incoherent dynamics model in the theory of Green's functions.[21]

III. The photoenergetics and structure of the associated species

Aggregates are molecular objects which occupy an important place in traditional spectroscopic research whose aim is the elucidation of spectral-luminescent changes occurring on association, the influence of this process on photophysical phenomena in solutions of dyes (the quenching of luminescence, the migration of energy), the influence on the lasing properties of solutions etc. The association of dye molecules alters significantly the probabilities of their vibronic transitions. The redistribution of the radiative and non-radiative transitions in associated rhodamine 6G species, occurring when their structure and composition are altered, has been investigated.[22,23]

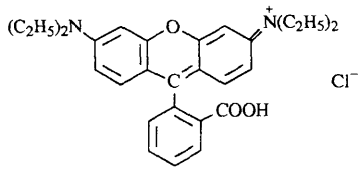


Rhodamine 6G

Earlier studies on aggregates of this compound have already been reviewed.[24] Different degrees of association of the dye were obtained in mixtures of polar and non-polar sovlents. The associated species are arbitrarily divided into "simple" and "complex" (the simple species arise when the content of the non-polar component is up to 90% of the volume of the mixture and the complex species arise when its content is higher). The luminescence with λ_{max} - 570 nm (20% of ethanol and 80% of CCl_4) was attributed to type *P* slow fluorescence due to the triplet–triplet annihilation of the simple associated species. For a higher CCl_4 content the intensity of the above glow falls and a new band arises with a maximum in the region of 620 nm, which is attributed to slow type *E* fluorescence due to the thermal activation of the associated triplet molecules to the excited singlet state with subsequent emission. For complex rhodamine 6G associated species, the $S_1 - T$ splitting is ~ 1500 cm^{-1}. The association of the molecules of this dye in binary mixtures takes place with participation of the anion[23] and the latter behaves as a heavy atom accelerating the intersystem crossing processes in the simple associated dye species.

The luminescence maximum at $\lambda = 670$ nm is attributed[22,23,25] to the phosphorescence of the rhodamine 6G associated species.

The absence of sensitised phosphorescence or slow fluorescence of stilbene has in fact been explained by the aggregation of rhodamine 6G following its adsorption from aqueous solution on the surface of a stilbene crystal.[26] This is associated with the fact that the *T* level of stilbene lies above the S_1 level of the rhodamine 6G aggregates. The aggregation of the molecules of rhodamines B and 3B, adsorbed on crystals (SnO_2, ZnO, etc.)[27–29] and on amorphous quartz,[30] is responsible for the anomalous spectroscopic-kinetic effects and the electron and hole injection in such systems.



Rhodamine B

Comparison of the optical properties of the associated species formed under different conditions can allow conclusions about their structure and the nature of the forces inducing association. The comparison for rhodamine 6G showed[31] that in dye solutions with $c \simeq 10^{-4}$ M and with a non-polar component content up to 90%, associated species are formed with a geometry such that they are incapable of luminescence. An increase in the content of the non-polar component (to 98–99%) increases the degree of association of the dye molecules and alters the geometry of the associated species (the angle between the planes of the molecules becomes less than 90°), whereupon the associated species fluoresce. More complex associated species, which do not fluoresce, are formed in virtually non-polar media. The fluorescence spectra of the rhodamine 6G associated species, formed in alcoholic solutions at –150 °C and in a binary mixture with a 99% content of the non-polar component, are identical.[31,32]

A more complete study of the optical properties of the luminescent associated species formed in cooled highly concentrated alcoholic solutions of dyes with different molecular structures (rhodamine 6G, Neutral Red, Crystal Violet, and Methylene Blue) showed that there is a definite qualitative agreement between the

luminescence-spectroscopic characteristics of the associated species of these dyes, despite the fact that the optical characteristics of the monomeric forms differ significantly.[32] Thus the fluorescence quantum yield of the associated species of the dyes investigated is low even at 77 K ($\sim 10^{-2}$), while the phosphorescence yield is lower still by 2–3 orders of magnitude. The electronic spectra of Neutral Red in ethanol at $c = 3 \times 10^{-2}$ M, where the dye molecules are almost all associated, are presented in Fig. 1, while Table 1 lists the wavelengths of the maxima in the spectra of the different types of luminescence, their quantum yields, and the phosphorescence decay times. The luminescence excitation spectra of the associated species have an appreciable maximum on the long-wavelength edge of the absorption band where the extinction coefficient is extremely low. Studies have shown[32] that complex associated species with non-uniformly broadened electronic spectra luminesce.

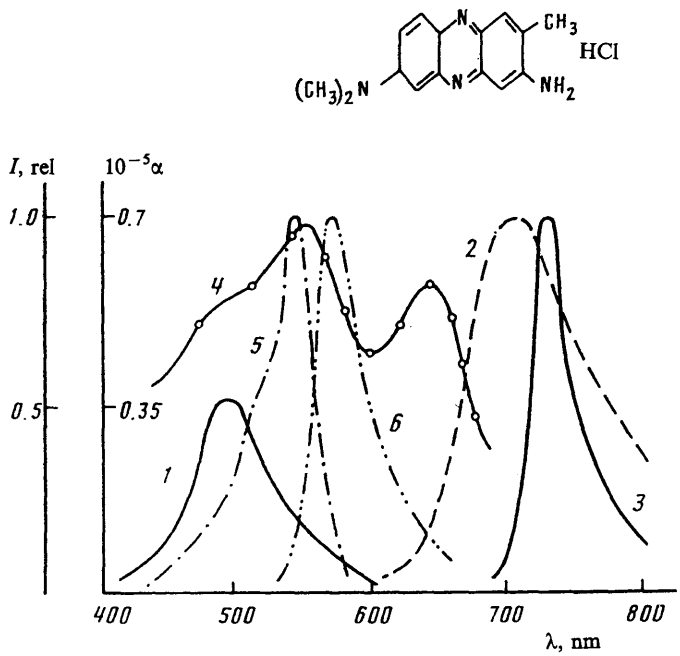


Figure 1. Electronic absorption (α) (curve *1*), fluorescence (curve *2*), phosphorescence (curve *3*), and excited fluorescence (*I*) (curve *4*) spectra of Neutral Red associated species in ethanol at 77 K; curves *5* and *6*—absorption and fluorescence spectra of the monomeric form at 77 K.[32]

It is essential to note that in binary mixtures of polar and non-polar solvents, the structure of the dye aggregates and the composition of their solvation shells vary non-linearly with the ratio of the solvent components.[33] This is related to the fact that the macroproperties of the binary solvent differ appreciably in the majority of instances from its microproperties, which exert a decisive influence on the spectral-luminescent characteristics of the phosphor molecules.[34] The polarisation characteristics of the luminescence and the axial moments of inertia of the rhodamine 6G assocated species give grounds for the assumption that in such mixtures their geometry is either of the "house of cards" or sandwich type.[33] The same geometry has been postulated for rhodamine B dimers in aqueous solutions. The separate aggregation of this dye in the neutral and cationic forms has been considered.[35] The energy of the exciton interaction (~ 560 cm^{-1}) and the angle between the dipole moments of the monomers ($\sim 70°$) of both forms are virtually identical, but the greater tendency towards the association of the neutral form is due to the electrostatic interaction between the carboxy- and xanthene groups of the monomers. The monomeric molecular forms of rhodamine B in water have also been investigated.[36]

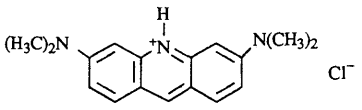
Table 1. The wavelengths of the maxima in the absorption (λ_a), fluorescence (λ_{fl}) and phosphorescence (λ_{ps}) spectra, the fluorescence (B_{fl}) and phosphorescence (B_{ps}) quantum yields, and the phosphorescence decay times (τ_{ps}) of associated dye species in ethanol and $T = 77$ K.[32]

Dye	λ_a, nm	λ_{fl}, nm	λ_{ps}, nm	B_{fl}	B_{ps}	τ_{ps}, ms
Rhodamine 6G	502 534	628	695	$3 \cdot 10^{-2}$	$2 \cdot 10^{-6}$	1200
Crystal Violet	584 592	732	745	$5 \cdot 10^{-3}$	$4 \cdot 10^{-4}$	345
Neutral Red	514	715	732	$8 \cdot 10^{-4}$	$1 \cdot 10^{-6}$	200
Methylene Blue	569	700	-	$3 \cdot 10^{-2}$	-	-

The maxima in the induced absorption spectra of the rhodamine 6G and B associated species in aqueous solutions are respectively at $\lambda \simeq 430$ and 510 nm, while the lifetimes of the excited states are $\tau \simeq 160$ and 120 ps.[37] Smirl, et al.[38] obtained $\tau = 100$ ps for rhodamine B.

The formation of associated species of different types has been established for ethanol solutions of Arcridine Orange at 77 K[39] and the total emission spectra undistorted by reabsorption were obtained for different concentrations of the solutions. The authors were able to isolate four fluorescence bands of different aggregates, characterised by different durations τ of the afterglow, with maxima at $\lambda = 535$ nm ($\tau = 12$ ns), which is attributed to the dimers, $\lambda = 572$ nm ($\tau = 24$ ns), $\lambda = 605$ nm ($\tau = 42$ ns), and $\lambda = 645$ nm ($\tau = 33$ and 25 ns); τ for the monomers was 6 ns. It was proved that the higher aggregates do not phosphoresce. The increase in the average lifetime of the excited states for more complex aggregates implies an increase in the forbiddeness for the lowest sublevel, i.e. the approach of the angle between the molecular planes of the dye in the associated species to 90°. We observed an increase in the yield and duration of the luminescence of the associated species of acridine compounds also in polymer matrices at room temperature.[40] It was found[41] that $\tau = 4.2$ ns for Acridine Orange monomers in alcoholic solutions and $\tau = 14.7$ ns for the aggregated forms.

The study with the aid of Stark modulation spectroscopy of the aggregation of rhodamine 6G,[42] acriflavin, and Acridine Orange[43] in polymer matrices also confirmed that the structure of the dimers is of the house of cards type, but in Acridine Orange the molecular planes are almost parallel.



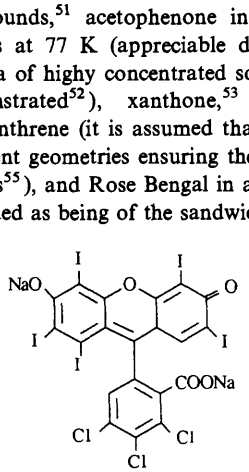
Acridine Orange

It was established that the dipole moments of the associated species of the compounds investigated change by less than a factor of 2 on electronic excitation as compared with monomers. Theoretical study within the framework of the simple exciton theory of the Stark effect in the aggregates confirmed this.[44]

Despite the fact that, in the first approximation of the theory, the triplet states of the aggregate should not differ from the monomer states in the case of large aggregates the T_1 states differ signifciantly. The phosphorescence band of Acridine Orange with λ_{max} = 680 nm has been atttributed[45] to the luminescence of large aggregates, while the phosphorescence band with λ_{max} = 615 nm, which virtually coincides with the phosphorscence spectrum of the monomers, was attributed to simple associated species. The long-wavelength phosphorescence quantum yield is ~0.05 and τ = 0.3 s (smaller by a factor of 15 than for the monomers).

The conclusions reached concerning the structure of the associated species of xanthene dyes, based on optical spectroscopy, have been confirmed also by NMR spectroscopy.[45,47] The molecular pattern in the associated species of azo-dyes in water and their micro-environment have been established by this method.[48,49]

The structures of the dimers in aqueous solutions of benzothiazole[50] (distance between the molecules 3.8 Å, angle between the molecules 18–25°, bond energy 5 kcal mol^{-1}), β-dicarbonyl compounds,[51] acetophenone in methylcyclohexane and isopentane glasses at 77 K (appreciable deformations in the phosphorescence spectra of highy concentrated solutions of this compound have been demonstrated[52]), xanthone,[53] thionine in H_2O and D_2O,[54] phenanthrene (it is assumed that the dimers of this compound have different geometries ensuring the stacking interaction of the chromophores[55]), and Rose Bengal in aqueous and methanol solutions[56] are regarded as being of the sandwich type.



Rose Bengal

It is believed[57] that the aggregation of Rose Bengal in aqueous solutions containing added KNO_3 develops in two stages: a neutral complex is formed initially between the dye anion and the K^+ ion, which is followed by the reaction between the neutral complex and a second dye anion. Multistage association with increase in concentration has also been proposed for vat dyes, which give rise to dimers and trimers in aqueous solutions.[58] The concentration variations of the absorption spectra of stilbene in a water–dioxane mixture have shown that association takes place directly between the molecules of this compound by virtue of van der Waals forces.[59] Certain aggregation parameters for dyes in solutions, obtained in the studies quoted above, are listed in Table 2.

Table 2. The dimerisation constants K, bond energies ΔH, the angles θ, and the distances R between the molecules in the associated species.[18,35,48,49,54,57,59]

Dye	Solvent	K, litre mol^{-1}	ΔH, kcal mol^{-1}	θ, deg	R, Å

The photoenergetics of associated dye species and its relationship with structure can be understood by studying the aggregates of other compounds with a similar molecular structure, for example, porphyrins. The photophysics of the aggregates of these compounds has been thoroughly investigated.[60–70] From the standpoint of the problem considered in this review, the principal results of these studies reduce to the following.

Aggregation does not alter the probability of fluroescence per molecule, while the probability of intersystem crossing increases. There is a significant increase in the probability of internal conversion, while the probability of intersystem deactivation of the triplet state hardly changes on aggregation. The relative positions of the molecules in the associated species and the distances between them play an important role in altering the probability of non-radiative transitions. The electronic spectra of chemical dimers are determined by the exciton interaction of the dipole moments of the transitions of the monomers and by the intermolecular vibronic interaction. However, such interactions do not cause significant changes in the probability of non-radiative deactivation processes involving singlet and triplet excited states compared with the monomers and the main pathway to the deactivation of excitation in vibrationally linked dimers is interconversion to the T state. The overlap of the π-conjugated systems plays a significant role in the spectroscopic and energetic properties of the associated species. The

structure of the dimers was established and the oscillator model of the interacting chromophores was justified on the basis of spectroscopic-polarisation studies, data for the linear dichroism of oriented polymer films, and ^{1}H NMR data.

A series of covalently bonded Zn—H_2 porphyrin dimers have been investigated.[71] Two representatives of porphyrin dimers joined via the benzene ring have been studied by resonance Raman spectroscopy,[72] whilst in another study,[73] the photoelimination of the dip in the absorption spectra of aetioporphyrin in organic glasses showed that in the case of dimers the phase and energy relaxation of the excited electronic state are faster than for the monomers.

Both hypsochromic and bathochromic band shifts are observed in the electronic absorption spectra on formation of physical dimers of porphyrin compounds. The structure of the associated species is determined by the nature of the solvent and the substituents in the porphyrin ring.[74,75] The quantum yield of the luminescence of the dimers of certain porphyrins [for example, *meso*-tetrakis(*N*-methyl-4-pyridyl)porphin] is similar to the yield of the monomeric forms which aggregate at very low concentrations (10^{-7} M).[76] In contrast to the monomer, the aetioporphyrin I dimers exhibit optical activity and their fluroescence yield is 0.9 of the yield of the monomer.[70] Tetra(4-aminophenyl)porphin and its derivatives exhibit a high tendency to associate in solutions and in films.[77–79] The form of the associated species, having their own characteristic features of deactivation of the electronic excitation, depends greatly on the conditions in the association process and on the nature of the solvent. Thus in dimethylformamide the associated species of this compound exhibit, in addition to the fluorescence with a maximum at λ = 702 nm, a broad luminescence band with $\lambda_{max} \simeq 1000$ nm.[80] The pathways to the deactivation of the excitation of porphyrin associated species depend to a considerable extent on their structures and on the characteristic features of the interaction of the monomeric molecules in them. These questions have also been discussed in other communications.[81,82]

The structure of the associated species indicated by the appreciable influence of the properties of the solvent affects very greatly their spectra and energetics. However, hitherto there has been no unanimous view concerning the nature of the spectral changes in the association of dye molecules. In a number of studies,[83–91] this problem was solved taking into account the solvation of phosphor molecules. It was shown that the change in the absorption spectra on association of the same dye molecules can be various depending on the composition and structure of the sovlation shells. The concentration-induced changes in the absorption spectra of rhodamines, anthracene, erythrosine, trypaflavin, and other compounds have been investigated in various solvents and their mixtures at different temperatures of the solutions. The authors initial postulate was that, when the dye molecules are in the immediate vicinity of one another, the deformation of their electronic absorption spectra is caused by resonance interactions. For an intermolecular distance of ~10 Å, the molecules in the associated species are surrounded by individual solvation shells whose structures are not the same and are dynamic in character as a consequence of the thermal motion of the solvent molecules. On the other hand, a change in the immediate environment of the phosphor molecules infringes the resonance conditions and leads to an increased role of dispersion forces. Therefore, it is suggested in the above studies that the main cause of the hypsochromic effect on association is the dispersion interaction between the molecules in the aggregate when each monomeric molecule of the latter has its own solvation shell. Associated species having a common solvation shell give rise to a splitting in the absorption spectrum. The conditions have been examined for the occurrence and the spectroscopic manifestation of aggregation, wheruepon associated species of both types (contact and solvent separated) may be formed in the solution.[87]

It is noteworthy that the question of the solvation of the aggregates is extremely complex and has been solved only in a broad outline.

Studies of mixed solutions of rhodamine 6G, Bromothymol Blue, and benzopurpurine 4B,[88] showed that the nature of the distortions of the electronic absorption spectra on association of dye molecules of different kinds is similar to that for homogeneous associated species.

The study of this problem for ultraviolet absorpt on spectra[91] showed that the nature of the distortion of such spectra on association is the same.

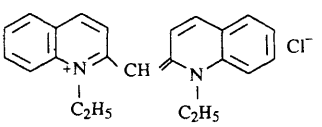
Thus the wide variety of concentration-induced changes in the absorption and luminescence spectra of dye solutions have been explained[83–91] from a single standpoint postulating the possibility of the formation of associated complexes differing in the nature of the solvation processes.

IV. Polymethine dyes

Until recently, the association of polymethine dyes was investigated in polar, mainly aqueous, solutions.[92–95] Attention was concentrated on *J*-aggregates (Scheibe aggregates).[96–100] The study of these compounds in weakly polar media is hindered by their sparing solubility and the problem is solved by introducing "aliphatic" groups into their molecules. Such cyanine dyes with long alkyl chains readily form Langmuir—Blodgett layers,[101–105] which have found extensive applications in various branches of science and engineering.[106]

J-Aggregation occurs not only in solutions but also in adsorption on the surfaces of microcrystals,[107,108] on oppositely charged polymer units,[109] and in adsorption of dyes from solution to give monolayers[110,111] or porous bilayers.[112,113] Cyanine dyes without long alkyl chains form *J*-aggregates at the air-water interface[110,114] if they are moderately soluble in water. In Langmuir—Blodgett films, the occurrence of aggregation has been established not only for cyanine dyes but also for other compounds, for example spiropyrans[115] and pyrene.[116]

The development of the spectroscopic technique has made it possible to obtain additional data about the development of the aggregation of cyanine dyes. A new model of aggregation and a critical discussion of earlier concepts concerning such aggregation have been described in a study[117] where aqueous solutions of pseudoisocyanine (PIC) were considered, while the *J*-band (the sharp peak at λ = 573 nm at room temperature and $c \simeq 10^{-3}$ M) was measured with a high spectral resolution (~5 cm^{-1}) on excitation by a dye-based laser.



Pseudoisocyanine

It has been established that the PIC monomers exist only at a very low concentration and at fairly high temperatures. As the temperature of the solution is reduced (the concentration is increased), dimers of the above dye are formed with a bond energy of ~ 1.8 kcal mol^{-1} and an angle between the monomeric transition moments of about 70°. Before the *J*-band appears in the spectrum, virtually all the molecules are in the dimeric state.[118] A further decrease in temperature leads to aggregation, the constant position of the *J*-band indicating a rapid growth of large aggregates with a narrow distribution of *n*-meric species, which are highly extended with their dipole moments parallel to the long axis. By studying the long-wavelength edge of the *J*-band for very low absorption coefficients, Kopainsky, et al.[117] established that the aggregates have an intrinsic absorption "tail" and that the *J*-band is to a large extent non-uniformly broadened.[119] Aggregation at very low concentrations ($\sim 10^{-6}$ M) has been demonstrated for solutions of furocoumarins.[120] The authors believe that only aggregated forms of furocoumarins exhibit an appreciable fluorescence, but these conclusions are rather tentative and require a more rigorous experimental justification.

It has been established by non-linear spectroscopic methods that the PIC *J*-aggregates have a fluorescence lifetime of 600–800 ps, but, for high intensities of the exciting light, it diminishes to 15 ps.[121] The emission time has been established for PIC bromide *J*-aggregates in ethylene glycol and water glasses with the aid of the photon echo method (~ 14 ps).[122] The luminescence lifetime of the 1,1-diethyl-2,2-cyanine bromide *J*-aggregates in water is 20 ps, while for the monomers it is 300 ps[123] and for microcrystals adsorbed on AgBr it amounts to 230 ps.[108]

At the same time, the question of the architecture of the *J*-aggregates and of its influence on the fluroescent properties remains open.[124] Aggregation numbers both ranging from 4 to 100 molecules[121] and amounting to 500 molecules[122] have been quoted for PIC. The effectiveness of the association of cyanine dyes can be increased by adding certain compounds to the solution.[125] The question of the structure of Scheibe aggregates can be of fundamental importance in the practical use of such systems. For example, when a thiacyanine dye is introduced into a monolayer of an oxacyanine dye organised into *J*-aggregates and present at a concentration greater by a factor of 10^4, an anomalously pronounced transfer of excitation energy from the "host" to the "guest" is observed,[126] its effectiveness depending greatly on the temperature of the system. The determination of the degree of association of naphthalocyanines in water, toluene, and acetone, showed that the associated species are either dimers or trimers.[127–130]

The influence of association on the spectral-luminescent properties of polymethine dyes with one chromophore as a function of their structure in mixtures of polar and non-polar solvents has been investigated.[131–134] The increase in the content of the non-polar solvent (hexane) to 90% induces a sharp fall in the intensity of the long-wavelength absorption band and an increase in the short-wavelength band. The latter is then narrower than the band in the spectrum of the solution in pure chloroform and undergoes a hypsochromic shift, whilst the long-wavelength band undergoes a bathochromic shift. These spectroscopic changes are accompanied by the quenching of fluorescence. The spectroscopic effects noted above depend on the characteristics of the molecular structure of the dyes and on the nature of the anion. On the basis of electronic and NMR spectra, it has been established that polymethine dyes whose molecules contain no bulky substituents form ion pairs with a sandwich structure. In weakly polar media, the structure of these associated species is more stable since the cations of their constituent molecules are rigidly fixed at both ends by anions as a consequence of the electrostatic attraction of unlike charges. Owing to the dissociation of the dyes, in polar solutions the counterion does not participate in association, which takes place as a result of dispersion interactions. The same cationic cyanines form different types of associated species in media of different polarity depending on the electronic and steric structures of the dye molecules.

The aggregation of cyanines with two chromophores was first examined by Herz,[96] but the chromophores of the test compounds were not rigidly linked, so that the spectroscopic changes were caused not only by aggregation but also by the change in the angle between the chromophores. Depending on the molecular structure of biscyanines with rigidly fixed chromophores, their association leads to the appearance of new short-wavelength or long-wavelength absorption and luminescence bands.[135,136] The effects in the absorption spectra occuring with increase in the content of the non-polar component depends on the nature of the anion. The results of these studies confirmed the marked dependence of the spectral-luminescent characteristics of the associated species on the nature of their solvation.[83–86] In contrast to cyanines with one chromophore, biscyanines exhibit a considerable tendency to associate.[137,138]

The form of the absorption bands of polymethines in a polymeric matrix is determined by the capacity of their ion pairs for association.[139] This process can be consistently regulated by introducing bulky substituents into the heterocyclic residues and the polymethine chain and also by altering the polarity of the polymeric medium.

The study of the molecular **aggregates of dyes in polymers** has become important, because such systems are used as scintillators,[140] radiation converters,[141] carriers for the recording of holograms,[142,143] laser media,[144,145] materials for the recording of information,[146] etc. The dye molecule association processes in polymeric media and its influence on the spectral-luminescent characteristics of these systems were analysed in a review.[147] Here we may note that dye molecules usually associate in polymers less effectively than in liquids, but the photophysical properties of the associated molecules can differ appreciably from the monomeric ones. For example, the associated species of Golden Yellow vat dye (dibenzopyrenequinone) in poly(vinyl alcohol) are more photostable than the monomers[148] and the sensitising effect in such a system depends on the ratio of the molecular and associated forms and on the operation of factors inducing the deaggregation of the dye. The fluorescence quantum yield of the dimers of a series of acridine dyes in polymers is higher than the yields of the monomeric molecules[149] but more complex associated species formed at $c > 2.5 \times 10^{-3}$ M have a low fluorescence yield.

In such systems, it is difficult to determine the degree of association of phosphor molecules. This has been done[150] for acridines and rhodamines in poly(vinyl alcohol) films, where the equilibrium constants of monomers and dimers were also determined. However, no account was taken in the above study of complex aggregates. The concentrations of the dimers and complex associated species of acridines were determined in our study[149] and their absorption spectra were identified ($\lambda_{max} = 470$ nm for the dimers and 435 nm for complex associated species), while in another study[40] their fluorescence spectra were identified and the decay times were estimated (8.0 and 2.0 ns respectively). The study of the kinetics of the polarisation of the fluorescence of these compounds showed that, in contrast to the monomeric forms, in poly(vinyl

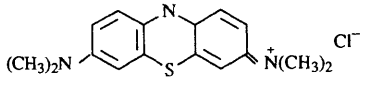
alcohol) the associated species of acridine compounds do not rotate after their photoexcitation.[151]

The association of dye molecules exerts a significant influence on the activity of the systems employed. Thus the polymeric lattices with incorporated dyes used in biotechnology and medicine undergo a change in their properties[152] and the diffraction efficiency of gelatine grids activated by Methylene Blue is impaired at high dye concentrations.[153]

V. Mixed association

Mixed association is the aggregation of the molecules of different dyes. In the literature, this is referred to as heterogeneous association. The study of mixed association processes has become important in connection with the fact that mixtures of different dyes are used as working media in dye lasers,[155] in radiation converters,[141] and in other systems based on the phenomenon of sensitised luminescence.[156] The study of heterogeneous association is complicated because it occurs against the background of homogeneous association which as a rule takes place more efficiently.

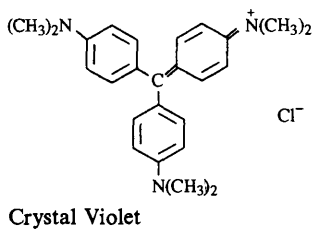
Heterogeneous association is manifested in the study of the electronic excitation energy migration processes in mixed solutions of dyes. In the study of the concentration dependences of the yield of the luminescence and of its polarisation,[157] it was noted that the main role in the quenching of the luminescence of rhodamine 6G is played by associated species comprising this dye and benzopurpurine 4B. It has been shown by absorption spectroscopy[83,88] that, on formation of mixed associated species of these compounds, there is an appreciable diminution of the absorbing capacity of the solutions. The procedure has been proposed[157,158] for the determination of the degree of heterogeneous association based on the measurement of the luminescence characteristics of the dye solutions. Thus the degree of heterogeneous association for an aqueous solution of rhodamine 6G ($c = 2 \times 10^{-6}$ M) and Methylene Blue ($c = 1 \times 10^{-4}$ M) at room temperature was found to be 0.33.



Methyl Blue

The bond energies in such associated species (4.6 kcal mol^{-1}) are smaller by a factor of ~2 than the bond energy in homogeneous rhodamine 6G associated species in water.[159]

The heterogeneous association of the same compounds as well as Crystal Violet, Methylene Red, Brilliant Yellow, and Methylene Orange in water has been studied[160] and the absorption spectra of such aggregates have been identified. The splitting of the absorption band characteristic of homogeneous associated species is absent from such spectra.

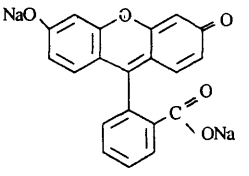


Crystal Violet

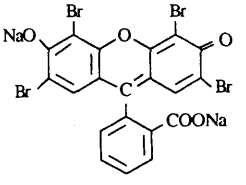
This can be understood bearing in mind that the splitting of the electronic levels on association is induced by resonance interactions which are impossible for molecules of the individual compounds. It was concluded[160] that heterogeneous associated species are formed as a result of dispersion interaction forces. The stability of such aggregates may depend on the addition of electrolytes to the solution.[161] Mixed associated species comprising rhodamine 6G and oxazine 17 are formed also in polar organic solvents.[162] The solvents apparently exert their main influence on the heterogeneous association of dye molecules through their microproperties, i.e the properties of solvent molecules in the solvation shells and the composition of the latter. This conclusion was reached[163] in a study of the spectroscopic characteristics of mixtures of rhodamine dyes with Methylene Blue in various solvents (water, glycerol, ethanol, formamide), the effectiveness of mixed asociation depends on the parameter which reflects the ability of the solvent to form hydrogen bonds. The major role of the nature of the solvent in mixed association of dyes has been pointed out also by Dzhumadinov, et al.[164] However, like homogeneous association, heterogeneous association is most effective in binary mixtures of polar and non-polar solvents. In such media, it was possible to record not only fluorescence but also slow fluorescence and phosphorescence for mixed associated species of rhodamines with Methylene Blue.[165,166] Since the singlet level is appreciably lowered and the energy gap between the S_1 and T_1 levels diminishes in such association, this leads to the quenching of the fluorescence and the excitation of slow fluorescence. It has been established with the aid of IR spectrosocpy that mixed associated species of these compounds are formed via hydrogen bonding.

The heterogeneous association of rhodamines and Methylene Blue has been studied in solutions of polyelectrolytes[167,168] and in aqueous solutions of surfactants[169,170] but an unambiguous interpretation of its spectral-luminescent manifestations in such systems is difficult. The mixed association of Methylene Blue and organic anions (naphthalene-1-disulphonate, etc.) in water has been detected with the aid of absorption and luminescence spectra, which undergo a bathochromic shift under these conditions.[171] The thermodynamic quantities and equilibrium constants were determined for such complexes and it was concluded that they arise in the reaction between the Methylene Blue cation and the aromatic ring of the organic anion. At high concentrations of the polyanion (naphthalene-2,7-disulphonate) such complex formation predominates over the dimerisation of the dye.

The formation of mixed sandwich dimers in aqueous solutions of a number of basic dyes has been established.[172,173] Such aggregation in the presence of natural or synthetic polymers occurs at lower concentrations.[174] The temperature dependences of the absorption and fluorescence spectra of mixtures of Na-fluorescein Na-eosine, trypaflavin, and Acridine Orange showed that the mixed associated species are formed by those dyes whose molecules are capable of being linked by a hydrogen bond.[175]



Na-Fluorescein



Na-Eosine

Mixed aggregation has been observed also for cyanine dyes in Langmuir–Blodgett monolayers.[176] For a certain combination of Na-octadecyl-substituted cyanines in films formed from the solution, mixed *J*-aggregates are produced, whose single absorption and luminescence bands occupy, in spectroscopic terms, an intermediate position between the spectra of *J*-aggregates of the individual components of the dyes. It was established that the appearance of such aggregates requires a very particular compatibility of the molecules, since even slight structural changes in them disrupt the mixed association. Thus the dyes 1′methyl-3-octadecylthia-2′-cyanine and 1-methyl-3-octadecylselena-2′cyanine form mixed aggregates with 1′-methyl-1-octadecyl-2,2′-cyanine but not with 1′-methyl-3-octadecyloxa-2′-cyanine. The luminescence spectra of such mixed *J*-aggregates undergo a slight Stokes shift, while the homogeneous *J*-aggregates exhibit resonance fluorescence.

The formation of mixed associated species has been demonstrated for many dyes, but the available data on their photoenergetics are in the main qualitative. These systems require much attention by investigators using modern methods. Thus it has been established by differential spectrosocpy that the absorption spectrum of mixed associated species of rhodamine 6G and Crystal Violet in poly(vinyl alcohol) matrices contains four maxima,[177] which agrees fully with the general pattern in the electronic absorption spectra of dye dimers.[178]

VI. Polarisation studies

According to the exciton theory, the oscillators of the sandwich dimers, referring to different absorption bands, should be mutually perpendicular and hence should be polarised in different directions. This is also indicated by the theory of the circular dichroism of aggregates.[179] However, there are virtually no theoretical data on the characteristics of the polarisation of the luminescence of the aggregates and the experimental data are not numerous and are contradictory. This is associated with the fact that the degree of polarisation of the emission by the dye associate species has different causes (both the structure of the emitter and the depolarising factors).[180]

An attempt has been made to devise a theory of the polarised luminescence of dimers with the aid of the non-linear Schrödinger equation.[181] The donor–acceptor pair of identical molecules, whose transition dipole moments are either located in a single plane or are mutually perpendicular, was adopted as the dimer model. The average degree of polarisation of the fluorescence of the dimers was calculated as a function of the parameter characterising the non-linearity of the interaction of the molecules, which was varied from 0.7 to 0.776. However, the applicability of the results for practical purposes is extremely problematical.

The depolarisation of the fluorescence of molecular aggregates as a result of energy transfer between the molecules within the framework of the model of a randomly arranged pair of electronically linked molecules[182] has been investigated in a study[183] where the theory was compared with experiment for chlorophyll and phaeophytin. As the author himself notes, analysis of the equations obtained is difficult. Nevertheless, using experimental results together with the equations, it is possible to obtain a number of parameters characterising the energy transfer in the associated species.

At the same time, the polarisation methods for the investigation of aggregation make it possible to extract valuable information, which is frequency difficult to obtain by other methods. Thus by investigating the polarisation fluorescence and circular dichroism of covalently linked ethylene–bisporphyrin dimers in viscous solvents in a magnetic field, it was established that electronic-vibrational exchange with participation of both totally symmetric and non-totally symmetric vibrations is intensified in such dimers. Such exchange smoothes out the polarisation spectra of the dimers, while the changes in the circular dichroism spectra in the region of the Soret band are due to exciton effects.[63]

It has been shown with the aid of absorpton-polarisation measurements that the absorption spectra of the rhodamine 6G associated species in poly(methyl methacrylate) matrices have four absorption bands with maxima at λ = 491, 512, 547, and 561 nm, the bands of the short-wavelength doublet having identical amplitudes and being polarised at right angles to one another.[184,185] Since the dimer contour of the short-wavelength doublet is retained at different dye concentrations, the authors concluded that the rhodamine associated species consists of many molecules in the form of a polymer chain with a dimeric unit cell in which the exciton and vibronic interactions determine the nature of the splitting in the absorption spectrum. The energy of the exciton interaction between the molecules and the associated species has been estimated as 430 cm^{-1}. A similar absorption spectrum of the associated species has been observed also for rhodamine B in aqueous solutions at low temperatures.[186]

Measurements of the polarisation characteristics of the fluorescence and dichroism makes it possible to determine the structure of the associated species. This method has been demonstrated on alcoholic solutions of rhodamine 6G.[187] It has thus been shown that the hydrogen-bonded dimers of pyrromethenone amides have a nearly coplanar structure.[188] Polarisation measurements and the use of the Levshin–Perren formula[180] made it possible to determine the composition of the associated species of asphaltenes.[189] The effect of the association of the molecules of rhodamine dyes, eosine, and erythrosine in aqueous glycerol solutions on the polarisation of the fluorescence has been investigated.[190–193] The increase in the degree of polarisation of the long-wavelength luminescence of the solution with increase in the concentration of the dyes was explained by the formation of their luminescent associated species but no evidence was adduced to show that the associated species in the test solutions are capable of luminescing. The increase in the degree of polarisation of the fluorescence can apparently be explained in this case by the non-uniform broadening of the electronic spectra and by directional energy transfer (the Weber effect).[194] Furthermore, calculation showed that the degree of polarisation of the luminescence of the dimers is smaller than that of the monomers.[195] It has been established[196] that the degree of polarisation of the fluorescence of different forms of *p*-(dialkylamino)benzylidenemalononitrile in poly-(vinyl acetate) matrices diminishes in the sequence monomer (0.5) > dimer (0.2) > complex associated species (0.03). However, it has been found for a series of dyes in frozen ethanol solutions that the degree of polarisation of the luminescence of the associated species can be both smaller and greater than the degree of polarisation of the luminescence of their monomeric forms.[32]

VII. Concentration-induced depolarisation and the quenching of luminescence

When dyes are used in different systems, the problem of the quenching of the luminescence is of primary importance. Numerous studies have established that the concentration-induced quenching in solutions of organic dyes is associated with molecular association,[1] whilst the concentration-induced depolarisation of the fluorescence is associated with electronic excitation energy transfer.[180,197] Until recently, it was assumed that the associated dye molecules do not fluoresce under the usual conditions.[1] However, modern experimental techniques make it possible to record the luminescence of associated species for which the luminescence quantum yield is very low.[198–200] The luminescence of associated species of rhodamine dyes in alcoholic[201] and aqueous[202] solutions at room temperature was observed. The luminescence spectrum of the associated dye molecules is appreciably displaced towards longer wavelengths relative to the spectra of the monomers.

The question of the contribution to the concentration-induced quenching of luminescence by the migration of the electronic excitation energy between the monomers remains controversial. It has been shown for rhodamine dyes in various solvents and for different degrees of association, taking into account the diffusion of molecules, that non-radiative energy transfer between identical monomeric molecules does not lead to the quenching of luminescence.[203,204] Energy is transferred without losses from acriflavin to rhodamine B.[205] The energy transfer between the molecules of different dyes can lead to non-radiative deactivation in the molecules of an acceptor dye and the effectiveness of such losses depends on the spectral luminescent characteristics of the test dyes.[206] The migration of excitation between the monomeric molecules under the conditions of spectral non-uniformity of the systems can induce the quenching of fluorescence.[207–212]

The problem of the concentration-induced depolarisation of fluorescence has been solved for solid solutions by assuming that the probability of transfer is isotropic.[213] The influence of fluctuations in the concentration of the luminescing molecules on the anisotropy of the emission has been examined in a study[214] where an expression was obtained for the anisotropy as a function of the concentration of the molecules, which was identical with the formula derived by Bodunov.[213] These problems were examined in detail by Gaisenok and Sarzhevskii.[180]

The expression for the concentration induced depolarisation of the fluorescence of non-viscous solutions, examined on the basis of Boyarskii's theory[1,215] and the Levshin–Perren formula,[180] has been obtained[216] (in terms of the anisotropy of the emission r):

$$r/r_0 = d_m/d_d,$$

where r_0 is the anisotropy of the "frozen" highly dilute solution in the absence of acceptor associated species and d_m the depolarising factor due to the transfer of excitation both between the monomers and from monomers to the associated species:

$$d_m = (1-\alpha\left[1+\frac{1}{2}\frac{(\alpha f)^2}{1-\frac{3}{4}(\alpha f)^2}\right],$$

$$f\sqrt{\pi}\gamma\exp(\gamma^2)\left[-\frac{2}{\sqrt{\pi}}\int_0^{\gamma}\exp(-t^2)dt\right],$$

$$\alpha = \alpha_0\left[\frac{\gamma_m}{\gamma_m+\gamma_a}\right],\ \gamma = \gamma_m+\gamma_a = \frac{\sqrt{\pi}}{2}\left(\frac{c_m}{c_{0m}}+\frac{c_a}{c_{0a}}\right),$$

where c_m, c_{0m}, c_a, and c_{0a} are the concentrations and critical concentrations of the monomers and associated species, α_0 is the probability that the excitation energy is not degraded during migration between the monomers, and d_d is the rotational depolarising factor:

$$d_d = 1-\frac{3}{2}<\sin^2\theta>$$

(θ is the angle between the directions of the moments of the transition when the molecule is excited and deactivated).

The averaging procedure was carried out[217] and reabsorption and secondary emission, which exert a significant influence on r at high concentrations, were taken into account in another study.[218]

The above expressions were confirmed experimentally for aqueous glycerol solutions of rhodamine 6G.[219] At high concentrations of dyes, the theoretical relations indicated an increase in anisotropy, which was in fact observed experimentally for both Stokes and anti-Stokes excitation.

On the assumption of a multistep non-radiative energy transfer from the monomers to the associated species, an expression was obtained for the relative decay time τ of the fluorescence of phosphors:[220,221]

$$\frac{\tau}{\tau_0} = \frac{1+\gamma^2-(1.5+\gamma^2)f(\gamma)+\alpha_0\alpha f(\gamma)\left[f(\gamma)+\gamma^2-0.5\right]-\alpha_0\alpha\gamma^2}{[1-f(\gamma)]\,[1-\alpha_0\alpha f(\gamma)]}.$$

It was tested experimentally for rhodamine dyes in solutions where the dye molecules exhibit different tendencies to associate.[222–224]

A critical analysis of the above formulae was carried out by Bodunov and co-workers.[225] Using the graphical method proposed by Loring, et al.,[226] theoretical expressions were obtained for the anisotropy r and the yield B of the luminescence, with the aid of which it is possible to analyse the experimental data:

$$\frac{r}{r_0} = 1+\frac{\pi}{2\sqrt{2}}q^{0.5}\gamma_m+0.1887q\gamma_m^2+(0.3832-\delta)q\gamma_m\gamma_a,$$

$$\frac{B}{B_0} = q\frac{r_0}{r},$$

$$q = \left\{-\frac{\pi}{4}\gamma_a-\frac{\pi}{4\sqrt{2}}\gamma_m+\left[1+\left(\frac{\pi}{4}\gamma_a+\frac{\pi}{4\sqrt{2}}\gamma_m\right)^2-\right.\right.$$

$$\left.\left.-0.5258\gamma_m^2-(0.13716-\delta+\beta)\gamma_m\gamma_a\right]^{0.5}\right\}[1\text{-}0.371\gamma_a^2-$$

$$-0.1887\gamma_m^2-(0.13716-\delta+\beta)\gamma_m\gamma_a],$$

$$\gamma_{m(a)} = \frac{c_{m(a)}}{c_{0m(a)}}.$$

δ and β have been tabulated.[226]

The above formulae agree with the exact theoretical results obtained previously[180] in the corresponding limiting cases.

For an experimental test of the above formulae, it is essential to know the degree of association (the fraction of the associated dye molecules) and the order of the association (the number of molecules in the associated species) of the solutions. These characteristics permit the determination of the concentration of the monomers and associated species in dye solutions. A number of methods for their

determination have been described.[1] The dimerisation constant has been calculated from the quenching of the fluorscence of rhodamine and acridine compounds in poly(vinyl alcohol) matrices[150,227] and a method for the determination of the degree of association has been proposed.[228]

At the same time, the formulae quoted above can be used to determine the degree of association (the concentration of associated molecules). For this purpose, it is essential to obtain experimentally the concentration variations of r/r_0, B/B_0, and τ/τ_0. The numerical solution of the resulting equations makes it possible to determine the degrees of association for different concentrations of the solutions. The concentration dependence of the degree of association of rhodamine 6G molecules in poly(vinyl alcohol) matrices was obtained by this method[229] and is illustrated in Fig. 2 (curve *4*). The same figure presents the experimental concentration dependences of the anisotropy of the emission (curves *1*), the quantum yield (curve *2*), and the lifetime of the fluorescence (curve *3*). Curve *1* in Fig. 2 shows that, at high concentrations of rhodamine 6G, an increase in the relative anisotropy of the emission r_{rel} is observed.

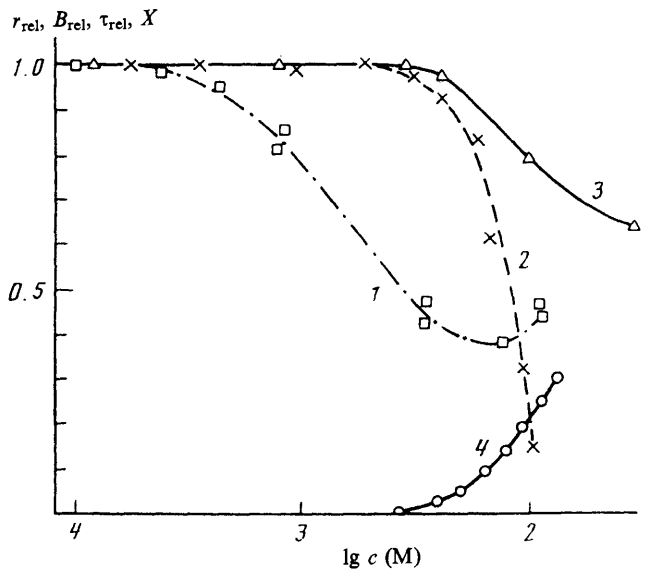


Figure 2. Concentration variation of the relative anisotropy of the emission (curve *1*), relative quantum yield (curve *2*), and relative decay time (curve *3*) of the fluorescence of rhodamine 6G in poly(vinyl alcohol) films; curve *4*—fraction of associated rhodamine 6G molecules (X).[229]

Comprehensive analysis of the association processes and of the concentration-induced quenching of fluorescence in different media linked to them has been performed for dyes widely used in science and engineering. The structural aspects of the fluoroescein aggregates in water have been examined in a study[18] where the association constants were determined by absorption spectroscopy and the absorption spectra of the dimers and trimers of this dye were identified. The calculated exciton parameters for the dimers satisfy two different geometrical models ("sandwich" and "jointed"). The trimers appear at $c \simeq 10^{-1}$ M. The authors suggest that the exciton theory predicts an increase in the trimerisation constant. The quenching of the fluorescence in water occurs up to limiting concentrations ($\sim 3 \times 10^{-1}$ M) and is due both to the migration of excitation between monomeric molecules and to energy transfer to aggregates, quenching by trimers being more effective.[230]

The aggregation of coloured neutral and cationic forms of rhodamine B in aqueous solutions has been studied.[35,231] The greater effectiveness of the association of the neutral form is caused by the electrostatic attraction between the carboxyl and xanthene groups of the monomers. The thermodynamic characteristics of the dimerisation of both forms are similar.

The quenching of the luminescence of rhodamine 6G in ethanol and water takes place starting from concentrations of $\sim 5 \times 10^{-3}$ M and 2×10^{-4} M respectively.[232,236] The quenching is attributed to the formation of dimers and trimers and to the transfer to them of excitation energy from their monomers via the Forster mechanism. However, the authors believe that in the case of ethanol solutions energy is transferred also via an exchange mechanism and that molecular diffusion plays a major role. Quenching by trimers is more effective as a consequence of their greater size compared with dimers, while migration of excitation via monomers does not lead to quenching.[18,237] For aqueous solutions of rhodamine 6G, the collision mechanism does not play a role. The association and quenching processes involving rhodamine 19 have been examined by Arbeloa, et al.,[238] while the mechanisms of the concentration-induced quenching of the luminescence of sulphorhodamine,[101] encapsulated in phospholipid vesicles, has been examined by Plant,[239] who investigated the influence of concentration on the fluorescence lifetime, which becomes shorter for higher concentrations owing to energy transfer to complexes and the collisions between dye molecules.

It is noteworthy that, in the study of the lumienscence of dye solutions, the above investigators[230–238] did not take into account the role of the inactive absorption by associated species in this process. The considerations which they have put forward concerning the formation of dye trimers and the quenching effect of the migration of excitation energy between monomers are not very convincing.

VIII. Association and lasting properties of the solutions. Factors influencing the effectiveness of association

The association of the molecules of laser dyes leads to an appreciable impairment of the lasing properties of their solutions. Polar organic solvents are usually employed for laser dyes. They prevent the development of the self-association of their molecules. However, as noted above, associated species are formed at high concentrations also in such media. Numerous studies have been devoted to the influence of association on the lasing characteristics of dye solutions.[162,240–243] It was established that an increase in dye concentrations in a series of lasing systems entails a fall in the laser energy and shifts of the laser emission spectrum. The spectral shifts are particularly notable in the case of two-component solutions.[162] At the same time lasing by rhodamine 6G associated species has been noted in aqueous solutions[202] in which the associated species do not luminesce under the conditions of stationary excitation. The wavelength of the laser radiation is 640 nm and, although the lasing

efficiency is not high it is nevertheless almost the same as the efficiency of the monomers in aqueous solutions of rhodamine 6G.

The effectiveness of the association process in dye solutions depends on many factors and it is not always a simple problem to determine whether it occurs or not. Association is determined by the molecular structure of the dyes and the nature of the solvents. It increases for molecules containing groups capable of forming hydrogen bonds and also for weakly polar solvents where the dye molecules are not surrounded by a solvation shell which prevents their mutual approach.

The association fof dyes is also prevented by the addition of detergents to the solutions.[41,244,245] In the case of aqueous solutions, the addition of electrolytes diminishes the degree of association of dye molecules,[246] while in the case of alcoholic solutions salts (electrolytes) do not affect the association process[247] but induce an additional orientational broadening of the spectrum. For rhodamine 6G in mixtures of polar and non-polar solvents, the addition of salts to the solution disrupts the complex associated species into monomers, which shows that the association of the molecules of this compound in weakly polar media involves the formation of ion pairs.[137,248] A decrease in the degree of association of dyes is observed after the addition of cyclodextrins and water-soluble polymers to the solution.[249] Data indicating an increase in the association of rhodamine dyes at high (up to kbar) pressures have been published.[250,251]

- - - o0o - - -

Investigators working in the field of quantum electronics, spectroscopy, photochemistry, molecular biology, etc. have devoted much attention at the present time to the molecular aggregation of dyes and its physicochemical manifestations. This is related both to the wide-scale application of dyes and to the good prospects for the use of individual organic molecules and their aggregates as information processing elements, high speed memory devices, etc. The study of the photonics of the molecular aggregates of dyes will make it possible in the future to regulate the radiative and non-radiative relaxation of the excited states of organic molecules at the structural level.

Definite views based on a series of theories, which agree to some extent with experimental data, have arisen in the literature as regards the spectral luminescent manifestation of aggregation. The influence of aggregation on the probabilities of various transitions in molecular systems has been established for many compounds. The view that, together with dimers, complex associated species with characteristic optical properties are formed under certain conditions has been generally accepted. The problems of the influence of the solvent microenvironment on the structure of the aggregates and on their spectral luminescent characteristics have been solved in broad outline. Vigorous studies have been initiated on associated molecules in polymeric media. The problem of the concentration-induced depolarisation and quenching of the luminescence of dye solutions can be regarded as solved in broad outline taking into account molecular aggregation. Extensive data are available on the development of the association process in solutions of a large series of dyes and of the influence of various factors on it.

However, despite the availability of numerous experimental data, there is so far no unanimous view on the nature of the changes in the spectroscopic characteristics of molecules during their association. The elucidation of this process would make it possible to solve the converse problem—the determination of the nature and energetics of intermolecular interactions in the aggregation of dye molecules. The cause of the loss of capacity for luminescence by aggregates and the structure and photochemical properties of complex dye species (including those of dimers) need to be elucidated. For this purpose, it is essential to determine the orbital structure of the excited electronic states of the associated molecules. One should note that, despite the elucidation of the general characteristics of the optical manifestations of aggregation, the individual properties of compounds frequently play a decisive role in such manifestations. It is therefore so far impossible to carry out a sufficiently complete analysis of the results of studies on aggregation in terms of classes of dyes, since many problems (the influence of the medium, of the structural characteristics of dye molecules, of the nature of the counterion, etc.) have been investigated sporadically. The relations between the structure of aggregates and their spectral-luminescent characteristics have been established mainly only for dimers and ordered *J*-aggregates, while for complex associated species this problem still has to be solved. The establishment of these relations will make it possible to use organic dyes more effectively and studies on the aggregation of their molecules and of its influence on the spectral-luminescent properties of their solutions therefore still remain of current interest.

Silylation in polymer chemistry

R D Katsarava, Ya S Vygodskii
Institute of Molecular Biology and Biophysics, Academy of Sciences of Georgia
Nesmeyanov Institute of Organoelement Compounds, Russian Academy of Sciences

ABSTRACT. The review is devoted to the formation and other reactions of macromolecules using silylated monomers and reagents. The methods of synthesis, reactivities, and other properties of silylated monomers of different classes are examined. Polycondensation and polyaddition processes, on the one hand, and polymerisation processes leading to the formation of macromolecules, on the other, are analysed. Reactions in the chains of polymers involving silylated monomers and reagents are also described.

The bibliography includes 165 references.

I. Introduction

The replacement of an active hydrogen atom in a wide variety of organic compounds by tris(hydrocarbyl)silyl (usually trimethylsilyl) groups makes it possible to solve effectively many synthetic problems. Silylation proved useful in peptide synthesis for the acylation of the amino-groups of α-aminoacids (the formation of an amide linkage), for the protection of carboxy- and hydroxy-groups, and also for the preparation of a wide variety of agents—acyl group donors, silylated reagents used to remove an N-protecting group, and condensing agents.[1–7] The use of silylating agents for the synthesis of esters[8] and nitriles,[9] the oxidation of alcohols in the silylated form to carbonyl compounds,[10] the synthesis of acid chlorides under neutral conditions,[11] the preparation of acyl isocyanates and isocyanates using phosgene and in a phosgene-free scheme employing CO_2,[12] and the synthesis of a wide variety of heterocycles[13] and tetra-substituted polymethylenediamines and cyclic triamines.[14] Cyclic disilazanes are used to protect amino-groups,[15] the disilyl protecting group being readily removed in an acid or alkaline medium.

Volatile liquid silylated derivatives of solid substances are convenient in analysis, for example, for the gas-chromatographic separation of a mixture of aminoacids.[16–18]

The use of silylated monomers and reagents gives rise to new possibilities also in macromolecular chemistry. Certain characteristic features of processes leading to the formation of both known and new polymers with a high molecular weight have been examined.[1,19–25] In the present review, we attempted to survey critically the available data and we supplemented them by new ones, including those concerning both polycondensation and polymerisation reactions as well as reactions in polymer chains.

II. Synthesis of silylated monomers and their properties

Synthesis of silylated Monomers

The silylation of organic compounds containing a wide variety of functional groups has been described in detail in a number of reviews.[1,2,5] Chlorotris(hydrocarbyl)silanes, usually chlorotrimethylsilane (CTMS), are common and effective silylating agents. Silylation using these compounds proceeds under mild conditions in organic solvents and with high yields. However, hydrogen chloride, capable of catalysing side reactions, is evolved in these processes, which necessitates the employment of an acceptor—a tertiary amine (B_N):

$$R-XH + Me_3SiCl \xrightarrow[-B_N\cdot HCl]{B_N} R-X-SiMe_3,$$

where X = NH†, O, etc. and B_N is a tertiary amine.

Chlorotrimethylsilane is used successfully for the preparation of silylated diamines,[26–28] diols (usually bisphenols and aromatic hydroxyacids,[29–39] bisthiophenols,[40] and bis-*o*-aminophenols.[41,42]

Dialkyl(trialkylsilyl)amines (usually Me_3SiNMe_2 and Me_3SiNEt_2) are convenient silylating agents. Silylation with their aid can be carried out without an organic solvent with evolution of the readily removable volatile dialkylamines:

$$RXH + Me_3SiNR'_2 \longrightarrow RXSiMe_3 + HNR'_2,$$

where R′ = Me or Et.

The silazanes indicated are used to silylate diamines.[43] They are especially conveneient in the treatment of aliphatic diamines in a salt form;[4] the role of the acid acceptor in such processes is assumed by the evolved dialkylamine:

$$R-NH_2\cdot HCl + Me_3SiNR'_2 \longrightarrow RNHSiMe_3 + HNR'_2\cdot HCl\downarrow.$$

Diethyl(trimethylsilyl)amine proved to be effective also in the silylation of bisaminophenols.[45–47]

Hexamethyldisilazane, evolving gaseous ammonia during the reaction, is a readily available silylating agent. However, it is not a very active donor of the trimethylsilyl group and for this reason it is

† In the case of primary aromatic amines, only one hydrogen atom is substituted by the trimethylsilyl group under the conditions indicated (see below).

particularly useful in the silylation of compounds containing an acid proton, for example, phenol and carboxylic acids:[48,49]

$$HOArOH + Me_3SiNHSiMe_3 \longrightarrow Me_3SiOArOSiMe_3 + NH_3\uparrow$$

or

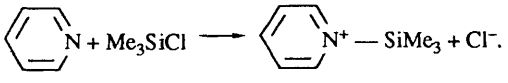
$$HOOCRCOOH + Me_3SiNHSiMe_3 \longrightarrow Me_3SiOCORCOOSiMe_3 + NH_3\uparrow.$$

O-Trimethylsilyl *N*-trimethylsilylcarbamate, in the reaction of which with alcohols gaseous side products are evolved, is an effective silylating agent of hydroxylated monomers:[50,51]

$$2ROH + Me_3SiNHCOOSiMe_3 \longrightarrow 2ROSiMe_3 + CO_2\uparrow + NH_3\uparrow.$$

N,O-Bis(trimethylsilyl)amides of carboxylic and carbonic acids [especially *N,O*-bis(trimethylsilyl)trifluoroacetamide], which are powerful donors of the trimethylsilyl group, are also promising.[2]

We may note that in many instances the silylation of monomers, particularly aromatic diamines, is carried out in solutions in inert organic solvents using a wide variety of catalysts [for example, $(NH_4)_2SO_4$,[2,43] acids, etc.[2]]. Pyridine, forming with chlorosilane a quaternary silylammonium complex (a silyl group donor), also exhibits a catalytic acitivty:[2]



Imidazole and heterocycles of similar structure are also effective agents for the transfer of the silyl group.[2]

It is essential to bear in mind that the silylation of aliphatic diamines proceeds so readily that exhaustive silylation of primary amino-groups is possible. This can lead in its turn both to the deactivation of the amino-groups and to the breakdown of stoichiometry in polycondensation (because disilylated amino-groups may be present in an indefinite amount) and to the formation of cross-linked polymers (see below).

The introduction of a second silyl group into aromatic amines (in contrast to aliphatic amines) constitutes a fairly difficult problem, which can be solved, for example,[52] using the corresponding lithium derivatives:

$$Ar-NH-SiMe_3 \xrightarrow[-C_4H_{10}]{C_4H_9Li} Ar-\underset{\displaystyle Li}{\underset{|}{N}}-SiMe_3 \xrightarrow[-LiCl]{Me_3SiCl} Ar-N(SiMe_3)_2.$$

Ethylmagnesium bromide can also be used for this purpose:[47]

$$Ar-NH_2 \xrightarrow[-2C_2H_6]{2C_2H_5MgBr} Ar-N(MgBr)_2 \xrightarrow[-MgBr_2,\ MgCl_2]{2Me_3SiCl} Ar-N(SiMe_3)_2.$$

Sodium iodide is used as the catalyst in the synthesis of silylated enolic forms of carbonyl compounds (silyl ethers of phenols—polymerisation monomers):[53]

$$CH_3-CO-R + Me_3SiCl + NaI \xrightarrow{CH_3CN} CH_2=\underset{\displaystyle O-SiMe_3}{\underset{|}{CR}}.$$

Properties of silylated monomers

The majority of silylated bisnucleophiles are liquid or comparatively low-melting substances which can be readily purified by vacuum distillation or (more rarely) recrystallisation. Silylation improves the solubility of the monomers, which significantly facilitates the choice of the solvent and polycondensation at high solution concentrations.

The silylated monomers, especially diamines, are resistant to the action of light and atmospheric oxygen.

In the condensed phase, the silylated monomers are fairly resistant also to atmospheric moisture, which may be due to their hydrophobic nature. However, in solutions in a polar organic solvent they readily split off the silyl group in the presence of traces of water (or impurities containing an active hydrogen atom). This leads to the "self-drying" and "self-purification" of the reaction system, which is important in some cases, for example in polycondensation in the vapour phase with silylated monomers of especially active biselectrophiles (acid dichlorides, bischloroformates, dianhydrides, etc.), which are capable of entering into side reactions with hydrogen-containing impurities. This is apparently one of the advantages of the silylated monomers in polycondensation ("silylated polycondensation"). On the other hand, in polymerisation silylation makes it possible to carry out processes which are difficult to achieve using the initial hydrogen-containing precursors.

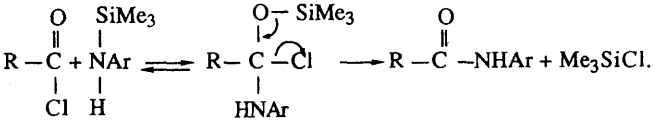
The introduction of a trimethylsilyl group into amino-groups of both aromatic and aliphatic amines lowers their electron-donating activity, which is attributed to the $(d-p)_\pi$ interaction via the Si–N bond.[54–56] An increase in the number of trimethylsilyl groups at the nitrogen atom lowers the basicity of amines still further.‡[57]

The decrease in the electron-donating activity of the silylating amino-groups together with the steric factors due to the replacement of the hydrogen atom by the bulky dimethylsilyl group lead to a decrease in the nucleophilic reactivity of aliphatic amines.[58]

On the other hand, an increase in reactivity has been noted for heterocycles, aromatic amines, and acid amides (the so called silyl activation of the nitrogen atom), at any rate in relation to acid chlorides,[1,13,59–62] which, however, requires more rigorous proof with the aid of kinetic measurements.§

The increase in the reactivity of aryl-*N*-dislylamines is attributed to a two-stage addition-elimination mechanism:[61]

Scheme 1

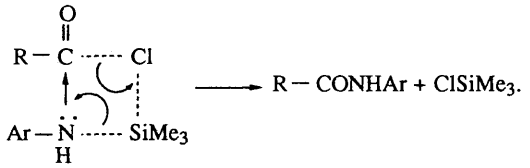


‡We may note that, in the determination of the basicity of silylamines by the titration method, special care must be excercised, because the silyl group can be transferred to the acid under the influence of protic acids, which has been indicated in particular by the results of NMR studies.[43]

§This is valid at least for monosilylated arylamines. One of the authors has established that the introduction of a second trimethylsilyl group actually entails a decrease in the activity of the amine to such an extent that it no longer reacts at an appreciable rate with benzoyl chloride on heating to 100 °C.

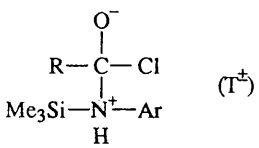
This uneconomical two-stage mechanism of the reaction occurring in the elimination stage with formation of a four-membered transition complex, is unlikely.¶ From our point of view, a single-stage concerted mechanism, similar to that proposed by Birkofer et al.,[60] is more likely. It involves the formation of a Cl–Si bond in the first stage [taking into account the increase in the reactivity of the functional groups in which the heteroatom–silicon bond is sufficiently loosened—$ArNH-SiMe_3$ and $ArS-SiMe_3$ (see below)] and further propagation of the reaction via the following transition state:

Scheme 2



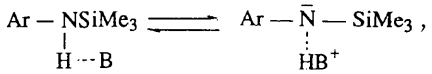
This mechanism of the reaction with acid chlorides may be supported indirectly by, for example, the lower, compared with free bases, reactivity of silylated alkylamines in relation to activated ethers.[58] In this case, the reaction apparently proceeds via the "traditional" pathway with formation of a tetrahedral zwitter-ionic intermediate or via a "reactant-like" transition state.[63,64] Under these conditions, silylation leads to a steady decrease in the nucleophilic reactivity of the amines

The formation of the silylated tetrahedral zwitter-ionic intermediate on interaction of arylsilylamines with acid chlorides, i. e.

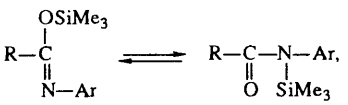


(the formation of $T^{\pm}$ is postulated in the interaction of arylamines with acylating agents[63]), which can subsequently rearrange to the neutral *O*-silylated tetrahedral intermediate see Scheme 1), is also unlikely because of steric factors.

The increase in the reactivity of the silylated primary arylamine can also be associated with the increase in the mobility of the NH proton[1] due to the effect of the electron-accepting silyl group and hence the increase in the nucleophilicity of the nitrogen atom in the presence of a proton acceptor:



¶ Bearing in mind the high oxygen affinity of silicon, in the operation of such a reaction mechanism one would expect the elimination of HCl (especially in a proton-accepting medium[1]) and the formation of a silylated amide:



which according to certain data either does not occur[62] or occurs extremely rarely.[64]

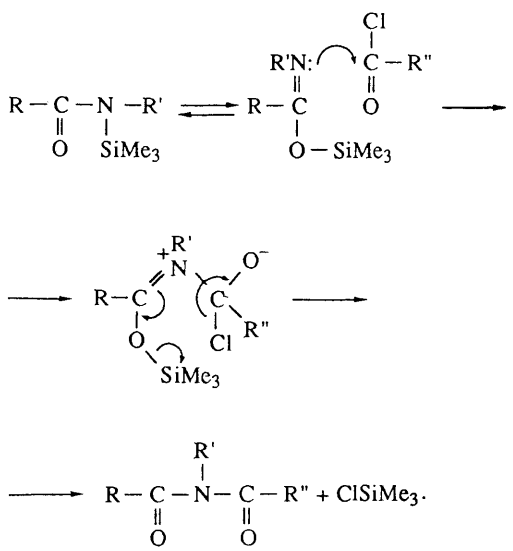
where B is the proton acceptor (solvent molecules, the amine itself, etc.).

In order to make finally sure about the "silyl activation" of aromatic amines and to give preference to one of the mechanisms examined, it is useful to compare the kinetics of the interaction of arylamines and their silylated analogues with acid chlorides and other electrophiles not containing a halogen (acid anhydrides, activated ethers, isocyanates, etc. in various media—proton-accepting and proton-inert).

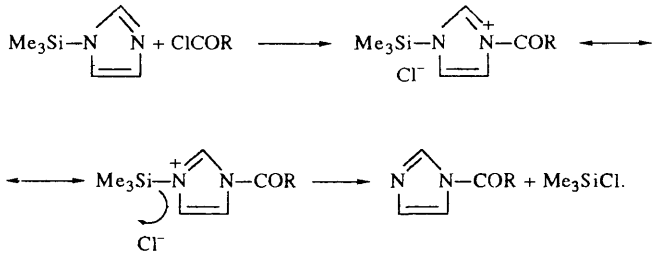
The "silyl activation" of the amide (urea) linkage has been convincingly demonstrated in a number of studies.[1,59,62] In this case there is no need for direct kinetic investigations, because the usual amides are hardly acylated by acid chlorides in the absence of tertiary amines, while silylated amides readily give rise to the corresponding acyclic imides.

The nature of the "silyl activation" of amides is in all probability somewhat different and is associated with the involvement in the reaction of the tautomeric *O*-silylated form of the amide:†

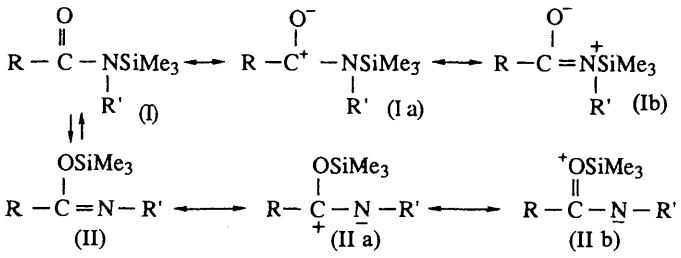
Scheme 3



† The tautomeric mechanism operates, for example, in the alkylation of heterocycles in the silylated imidol [hydroxyimide?] form.[1] It may be that a complex mechanism also underlies the "silyl activation" of the imidazole nitrogen atom and heterocycles of similar structure:[60]



It is known that silylated amides can exist in two tautomeric forms[2] (p. 63):



When R′ = alkyl, the *N*-silylated form (I) is thermodynamically preferable owing to the amide resonance [varieties (Ia) and (Ib)]. On the other hand, if R′ is capable of stabilising the negative charge on the nitrogen atom [for example in the case where R = CH_2=CH, Ph, etc.; varieties (IIa) and (IIb)], then the contribution of the *O*-silylated form (II) increases appreciably. We believe that the latter is kinetically more significant in amide acylation reactions.

The silylation of hydroxy-groups has different effects on their reactivity depending on the nature of the adjoining group. Whereas silylated alcohols readily interact with acid chlorides under mild conditions,[1,29,30] the corresponding phenols react only above 100–140 °C.[30] On the other hand, the reactivity of S-containing analogues—silylated thiophenols—approaches that of silylated amines.[40] This fact may indicate the importance of the effect of the degree of loosening of the heteroatom–silicon bond on the reactivity of the silylated nucleophile. Thus, when the nucleophilicity of the functional groups is reduced, it is possible to introduce electrophilic substituents into the molecule. For example, it is possible to obtain stable aliphatic diamines containing alkyl ester groups or hydroxyl-containing compounds with acid chloride groups, to carry out reactions with a high selectivity, etc. (see below), and, if necessary, to carry out the selective desilylation of the alcoholic and phenolic hydroxy-groups.[65]

III. Synthesis of polymers

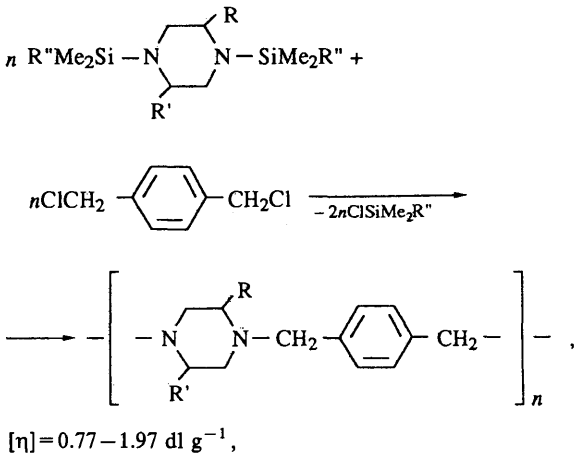
The polycondensation processes involving monomers with N–Si and O(S)–Si bonds are analysed separately below. Next to be considered are polycondensation processes *in situ* in the presence of silicon compounds, including silicon-containing condensing agents as well as polymerisation processes with participation of silylated initiators and monomers. Finally, examples of the modification of macrochains by their silylation are presented.

(a) Polycondensation

The new polycondensation methods of synthesis of polymers are based mainly on nucleophilic substitution reactions (or reactions of the type of nucleophilic substitution) with participation of silylated bisnucleophiles.

Syntheses Based on Monoers with a N–Si Bond

Polyamines. One of the first heterochain polymers synthesised using silylated monomers were polyamines obtained by Klebe[26] by the reaction of *N,N′*-disilylated piperidines with *p*-xylylene dichloride in bulk at 100 °C:

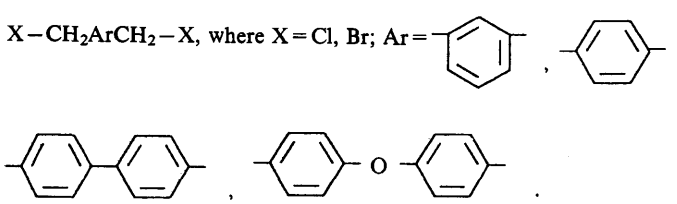


$[\eta] = 0.77 - 1.97$ dl g^{-1},

where R = R′ = H or Me or R = H and R′ = Me; R″ = Me or Ph.

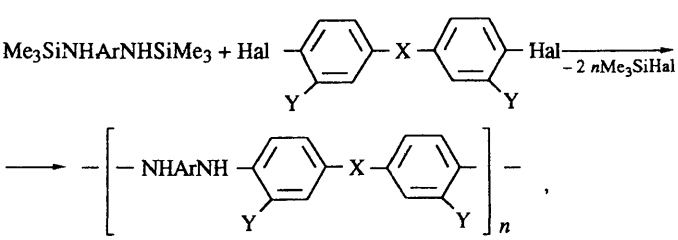
The polyamine with the highest molecular weight (M_n = 40 000—determined by osmometry), soluble in organic solvents, was obtained with R = H, R′ = Me, and R″ = Ph. It was shown that the reaction is accelerated (by a factor of 5–10) in the presence of ammonium salts and (to a lesser extent) tetramethylene sulphone (sulpholan).

Klebe[26] used in this process silylated *N,N′*-dimethylethylenediamine and alkylene halides:



Quaternisation of the polyamines synthesised with methyl iodide afforded polyelectrolytes soluble in polar solvents and water, while quaternisation with diiodopropane yielded cross-linked membranes insoluble in water.

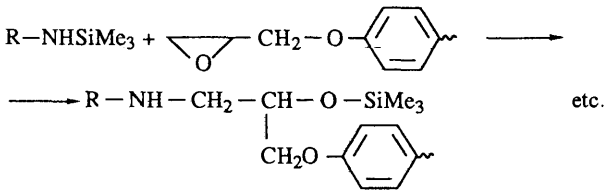
An aromatic nucleophilic substitution reaction with similar essential features has been used[66,67] to synthesise aromatic polyamines ($\eta_{init} \leqslant 0.93$ dl g^{-1}):



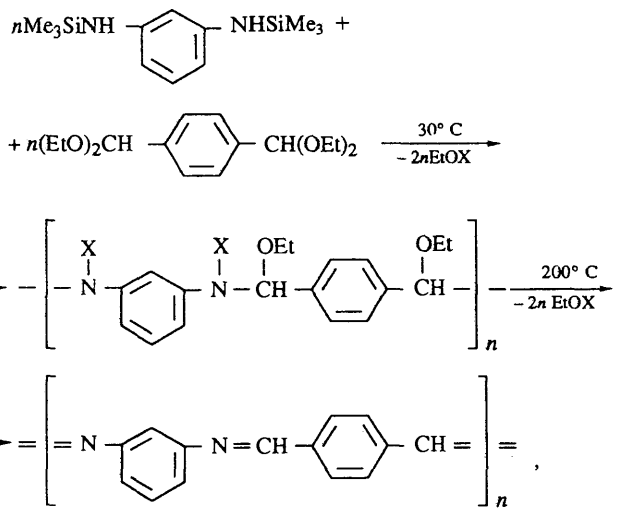
where X = NO_2 or CO, Hal = Cl or F, and Y = H or NO_2. The reaction was carried out in dimethyl sulphoxide (DMSO) at 150 °C.

The authors established that only fluorides are reactive and that the process is catalysed by CsF. Aromatic chlorides (Hal = Cl) are passive in the reactions but are appreciably activated after the introduction of a nitro-group in the *ortho*-position (Y = NO_2).

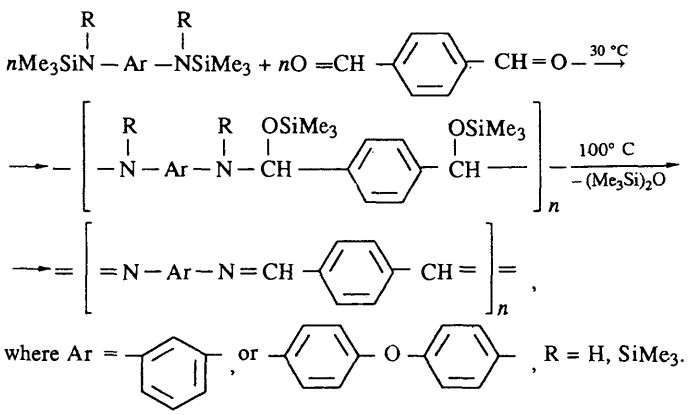
Silylamines can also be alkylated with the aid of oxiranes.[68] This process has been used to harden epoxide resins:[69,70]



Polyazomethines. Using silylated diamines as the initial monomers, high-molecular-weight polyazomethines were obtained, which made it possible to overcome difficulties associated with the insolubility and infusibility of their forms unsubstituted in the aromatic ring.[71,72] Either diacetals[71] or directly the dialdehydes[72,73] were used as the biselectrophiles:



where X = H or $SiMe_3$;

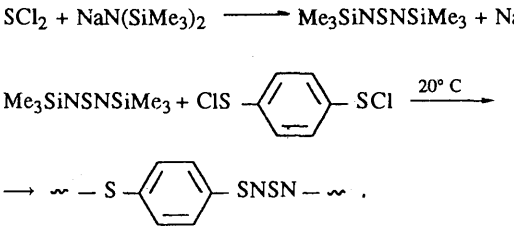


where Ar = , or , R = H, $SiMe_3$.

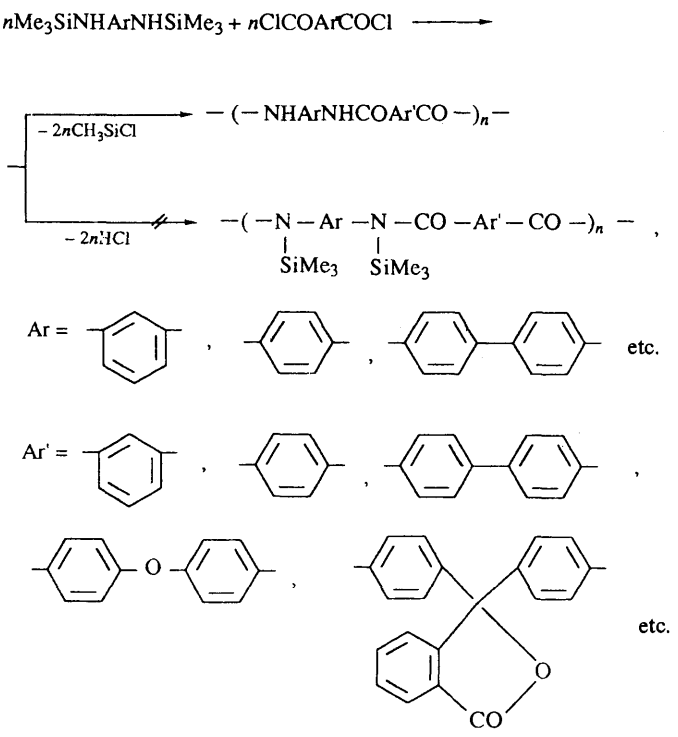
and R = H or $SiMe_3$.

The soluble film- and fibre-forming polymers formed in the first stage are converted into insoluble polyazomethines as a result of thermal β-elimination. It is of interest that in the second version fully silylated diamines were used together with *N,N'*-bistrimethylsilylated primary diamines in the reaction with the dialdehyde. As mentioned above, such fully silylated diamines should be appreciably less reactive. However, the lack of information about the molecular weights of the polyazomethines synthesised makes it impossible to decide that a particular silylated form of the diamine is preferable.

Polythiazyls. A polyconjugated electrically conducting poly-*p*-phenylenethiazyl was synthesised by a reaction similar to that for the formation of polyamines (see above).[74] Using Na-silylamide, a monomer was formed initially and was then used in polycondensation with *p*-phenylenebissulphenyl chloride in an inert solvent:



Polyamides. Since the beginning of the 1970's, silylated diamines began to be used also for the synthesis of polyamides.[75] High-molecular-weight arylamides were obtained by the polycondensation of silylated aromatic diamines with acid dichlorides in amide solvents under mild conditions:[75,76]



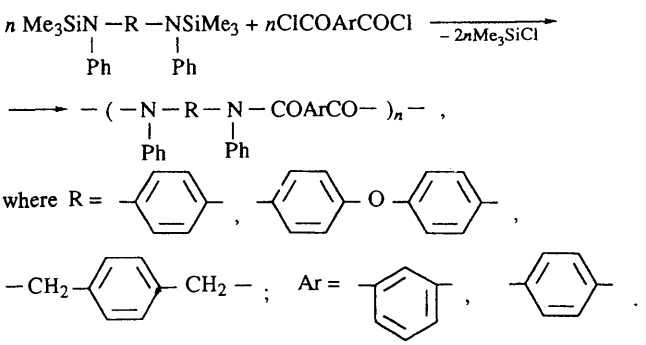
It was shown that the reaction proceeds virtually with elimination of Me_3SiCl and the formation of a "normal" polyamide. The absence of silicon from the polyamides and their solubility in organic solvents (i.e. the absence of intermolecular cross-links—see below) indicate that the alternative pathway involving the elimination of HCl and the formation of a silylated polyarylamide hardly operates.‡

Bearing in mind the increased solubility of the silylated monomers in the solvent used, it is possible to carry out the polycondensation in more concentrated solutions.[75] An advantage of this polyamide formation scheme is that it leads to the formation of polyamides with higher molecular weights ($\eta_{log} \leqslant 7.4$ dl g^{-1}) than in the case where free diamines are used ($\eta_{log} \leqslant 3.0$ dl g^{-1}).[76]

It is believed[76] that this is associated with the higher reactivity of the silylated diamine and hence with the higher rate of polycondensation, characterised by the time variation of the viscosity of the polyamides. However, these data are insufficient to draw unambiguous inferences about the rate of the process and it is essential to carry out direct kinetic studies, particularly since analysis of the numerous results of the investigation of the low-temperature polyamide formation does not provide grounds for such a conclusion. The formation of polyarylamides with higher molecular weights may be due to the following factors: (1) the greater purity and resistance to oxidation of the silylated aromatic diamines; (2) the absence of salt formation (protonation of the amino-group by HCl); (3) "self-purification" of the reaction system (see above). In the absence (more precisely on sharp reduction) of the contribution of side reactions, the rate of increase in the viscosity of the polyamides rises.[78]

The possibility of carrying out the process in inert solvents ($CHCl_3$, CH_3CN, $PhNO_2$), which do not exhibit a proton-accepting activity (this is essential in the formation of polyamides using free aromatic diamines), should be included among the advantages of the "silyl polyamide formation".

The "silyl polyamide formation" reaction has also been used to obtain high-molecular-weight ($\eta_{log} \leqslant 2.21$ dl g^{-1}) *N*-phenylated polyamides[27,79] from relatively unreactive bisphenylenediamines:[80]



‡It is known that chlorosilane is split off in an inert medium, while in the presence of a proton acceptor (triethylamine) the elimination of HCl and the formation of a silylated amide is actually observed.[1] In weak bases (forming, however, strong hydrogen bonds[77]), this pathway is nevertheless probably possible (see below). Apparently the silylated arylamides formed do not interact with terminal acid chloride groups and are readily desilylated by traces of moisture or HCl, which is not bound to the amide solvent quite so strongly as to triethylamine.

The reaction was carried out in sulpholan at elevated temperature (80–200 °C depending on R).

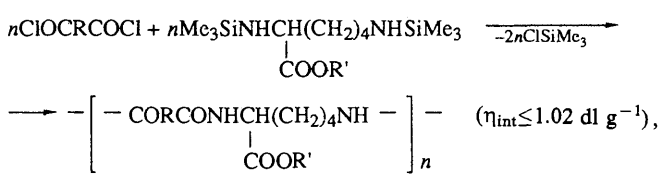
We may note that the ability of the system to undergo "self-purification" and the use of an acid solvent are especially important in the synthesis of *N*-phenylated arylamides, because the reaction proceeds under fairly severe conditions and *N,N*-diaryl-substituted polyamides, which belong to the category of "activated amides",[81] can interact destructively with a wide variety of impurities, especially basic ones.

Silylation has been successfully used for the synthesis of polyamides from other relatively unreactive monomers—the weakly electrophilic perfluroisophthaloyl chloride[82] and the sterically hindered perfluoro-*m*-phenylenediamine.[83] This clearly indicates the silyl activation of aromatic amino-groups, although we repeat that direct kinetic measurements are essential for final conclusions.

The formation of high-molecular-weight polyamides with participation of weakly basic highly sterically hindered silylated secondary aromatic diamines, where direct lateral attack[84] on the carbonyl carbon atom with formation of a tetrahedral intermediate (Scheme 1) is unlikely, may serve as evidence in support of an alternative mechanism (see Scheme 2).

In order to obtain fine arylamide film coatings, the relatively high volatility of silylated aromatic diamines in their reaction with acid dichlorides involving deposition from the gas phase has been used successfully.[85] The advantage of the silylated diamines over the free bases consists in this case also in the ease of removal of the neutral, volatile chlorotrimethylsilane.

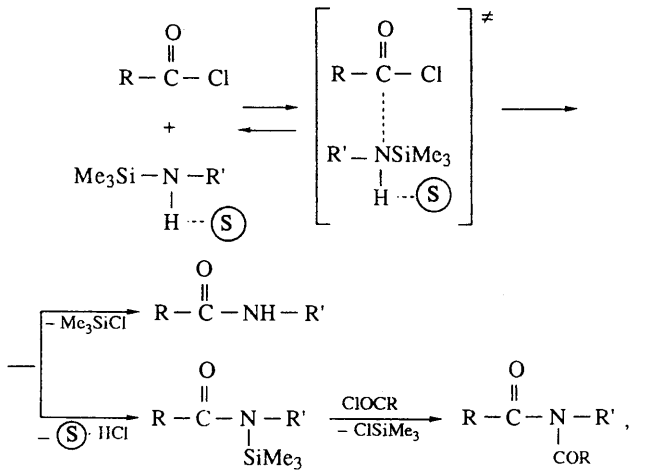
High-molecular-weight polyamides with functional group substituents have been obtained by the reaction of acid dichlorides with alkyl esters of N^{α},N^{ε}-bis(trimethylsilyl)lysine in an organic solvent:[44]



where R = $(CH_2)_4$ or  ; and R′ = Me or Et.

It is essential to note that this reaction is accompanied by the formation of a cross-linked polymer (particularly vigorous in the case of an aliphatic acid dichloride), which may be due to the partial formation of a trimethylsilylated amide in a solvent capable of forming strong hydrogen bonds [dimethylacetamide (DMA),

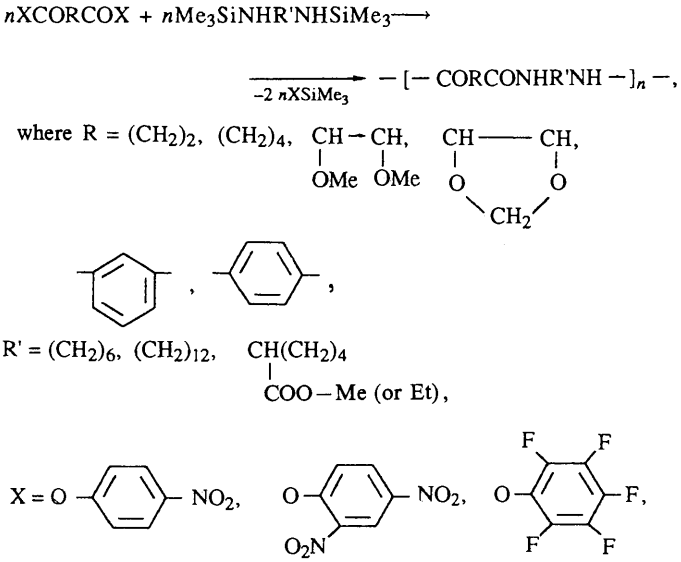
hexamethylphosphoramide (HMPA)] (see above) and its subsequent interaction with the acid chloride group:



where (S) = solvent molecule.

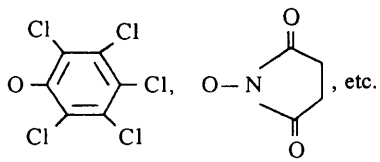
The proposed mechanism of the formation of intermolecular bonds is supported by the synthesis of a cross-linked polyamide also in the case of an aromatic acid dichloride, which, in contrast to aliphatic acid dichlorides[86] with a "normal" amide linkage, does not react under the conditions investigated. The reaction using an aromatic acid dichloride at a reduced temperature (−10 − 0 °C) leads to the formation of a soluble polyamide.

Yet another piece of evidence is the synthesis of soluble polyamides from an aliphatic acid dichloride and an alkyl ester of N^{α},N^{ε}-bis(trimethylsilyl)lysine in solvents with a weak proton-accepting capacity (acetonitrile, dichloroethane). Apart from acid dichlorides, a wide variety of activated dicarboxylic acid diesters react vigorously with trimethylsilyated aliphatic diamines. Such interaction under mild conditions in a wide variety of organic solvents, including inert ones, leads to the formation of high-molecular-weight (of the order of 40 000 − 60 000) polyamides:[44,87–90]



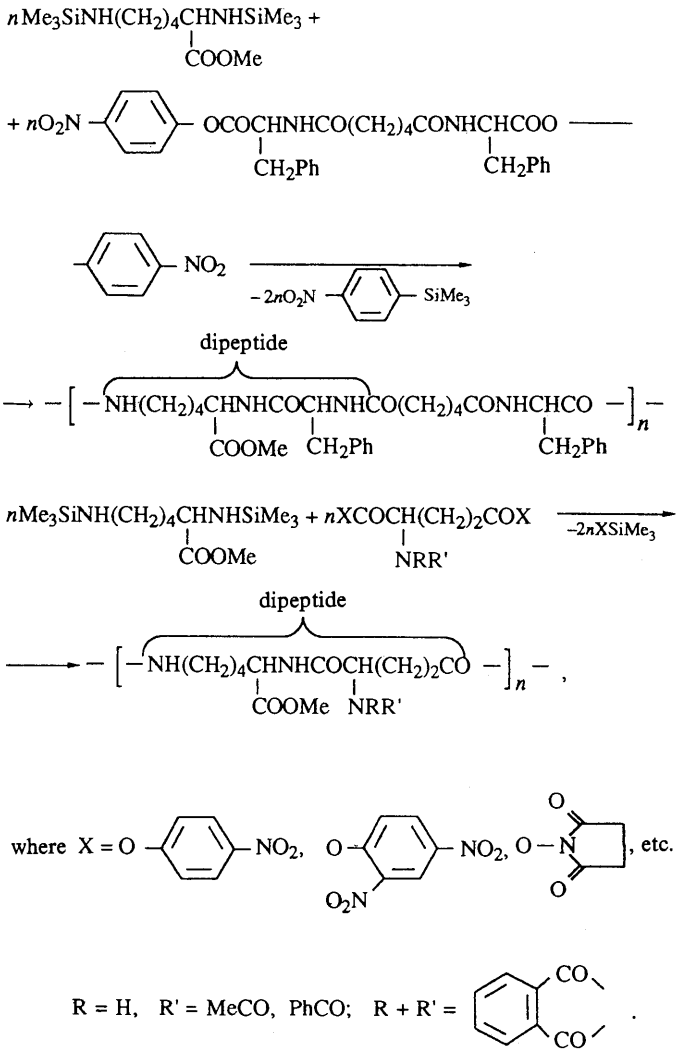
where R = $(CH_2)_2$, $(CH_2)_4$,

R' = $(CH_2)_6$, $(CH_2)_{12}$,



In this case, the role of the desilylating agent at different stages of the reaction can be fulfilled by the evolved acid hydroxylated compound HX[58,91] — a vigorous acceptor of the trimethylsilyl group,[2] which leads to the synthesis of the "normal" polyamide. This factor appreciably facilitates the synthesis of linear polyamides based on silylated aliphatic diamines.

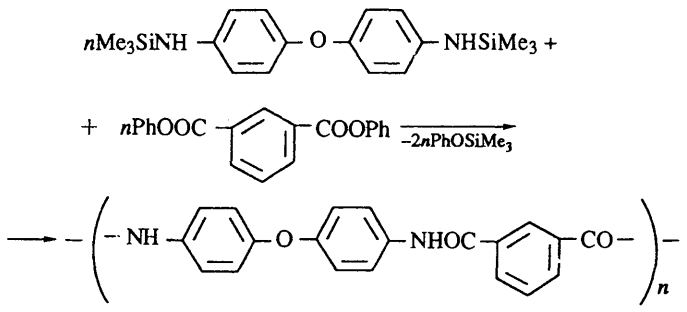
"Activated silylated" polycondensation has been used successfully to obtain polyamides with functional-group substituents from lysine[44] and can be useful for the introduction into the macrochain of fragments carrying additional functional groups, for example dipeptide units capable of undergoing enzymic cleavage:[92,93]



where X = O

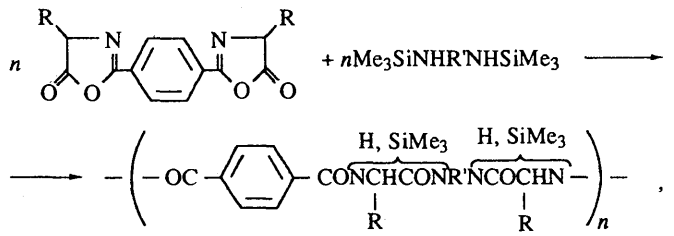
R = H, R' = MeCO, PhCO; R + R' =

We may note that under more severe conditions (100 °C) the non-activated diphenyl isophthalate enters into the reaction with the silylated diamine (even a comparatively unreactive aromatic diamine):[94]



(η_{log} = 0.43 dl g^{-1} in DMA).

High-molecular-weight ($\eta_{init} \leqslant 0.68$ dl g^{-1}) film-forming polyamides have also been synthesised by the reaction of silylated diamines with bisazlactones in DMA (in a number of instances in the presence of 5% of LiCl) at 70–100 °C:[95]



where R = Me, $(CH_2)_2Me$, $CH(Me)_2$, $(CH_2)_3Me$, $CH_2CH(Me)_2$, CH(Me)Et, $(CH_2)_2SMe$, CH_2Ph;

R' = $(CH_2)_6$, $CH(CH_2)_4$ (COOMe (or Et)).

This polyadditive scheme, leading to silylated polymers (cf. the synthesis of polyurethanes described below) has been used to obtain dipeptide-containing polyamides from L-lysine. Such polymers are promising as biodegradable temporary implants capable of undergoing bioerosion.[96]

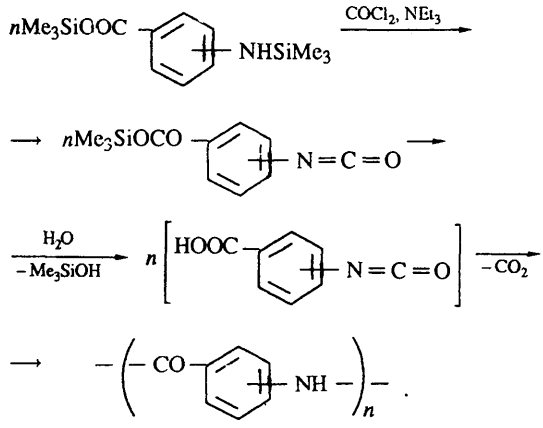
A novel method of synthesis of polyamides (with yields up to 94%) has been proposed by Kozyukov et al.[97] It consists in the high-temeprature AB-polycondensation in solution in *N,O*-disilylated aminoacids (glycine, *p*-aminobenzoic acid):

$$n\text{Me}_3\text{SiNHRCOOSiMe}_3 \xrightarrow[\text{DMF}]{150\ ^\circ\text{C}} -(-\text{NHRCO}-)_{\bar{n}} + n(\text{Me}_3\text{Si})_2\text{O},$$

where R = CH_2,  .

The process takes place in a polar medium and is catalysed by Lewis acids. This factor is apparently in fact responsible for the possibility of obtaining and purifying by vacuum distillation at fairly high temperatures disilylated aminoacids without appreciable self-condensation.

An alternative method, proposed by the same authors, involves the preliminary treatment of the *N,O*-disilylated monomer with phosgene:[98]



An essentially similar process has been used also in AA–BB-polycondensation to obtain a high-molecular-weight polyamide-6,6 without the intermediate formation of a salt AX;[99] under these conditions, one of the monomers can be used in the non-silylated form:

$$n\text{YHN}(CH_2)_6\text{NHY} + n\text{Y'OCO}(CH_2)_4\text{COOY'} \xrightarrow{220\text{–}250\ ^\circ\text{C, in bulk}}$$

$$\longrightarrow -(-\text{NH}(CH_2)_6-\text{NHCO}-(CH_2)_4-\text{CO}-)_n-,$$

where (a) Y = H and Y' = $SiMe_3$, (b) Y = $SiMe_3$ and Y' = H, and (c) Y = Y' = $SiMe_3$.

Polyurethanes. The processes leading to the formation of polyurethanes using silylated diamines are in many respects similar to those involved in "silylated polyamide formation".

Film-forming ($\eta_{int} \leqslant 0.48$ dl g^{-1}) linear polyurethanes have been obtained by the polycondensation of a silylated diamine with bischloroformates in dimethylacetamide (DMA) under mild conditions (0–20 °C):[100]

$$n\text{Me}_3\text{SiNH}(CH_2)_6\text{NHSiMe}_3 + n\text{ClCOOAlkOCOCl} \xrightarrow{-2\ \text{Me}_3\text{SiCl}}$$

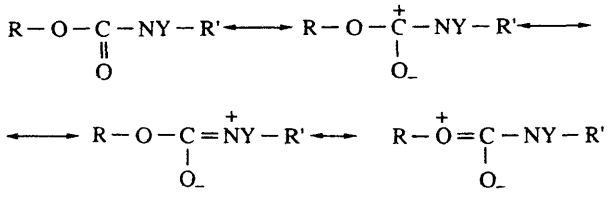
$$\longrightarrow -(-\text{NH}(CH_2)_6\text{NHCOOAlkOCO}-)_n -$$

Alk = $(CH_2)_3$, $(CH_2)_2CH(Me)$, etc.

The reaction of silylated diamines and bischloroformates, which occurs effectively in solution under mild conditions, leads to interesting possibilities in the synthesis of one of the most important classes of heterochain polymers. Since the neutral chlorotrimethylsilane and not HCl is evolved under these conditions, there is no need to use an acid acceptor (a tertiary amine), which interacts vigorously with chloroformates, such reaction involving the termination of the growing polymer chain. A side reaction of this kind is known[101] to limit significantly the application of the chloroformate method in the synthesis of polyurethanes in solution.

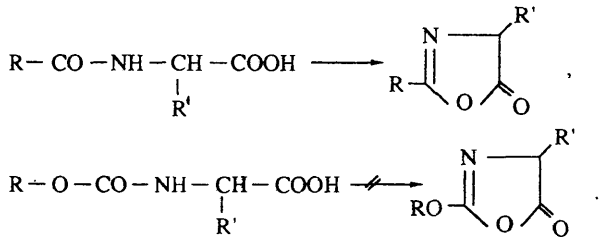
It is essential to note that in the interaction of silylated diamines with bischloroformates, in contrast to their reaction with aliphatic acid dichlorides, the formation of a cross-linked polymer was not observed even in a proton-accepting medium. This finding can

support the tautomeric mechanism of the acylation of a silylated amide examined above (see Scheme 3). Urethanes (and apparently also their silylated forms) showed a smaller tendency to undergo tautomeric transformations—they do not enter into reactions with participation of the tautomeric form of the NH–CO linkage. This may be associated with the greater loss of "resonance energy" because the carbonyl group in urethanes is conjugated with both nitrogen atoms and with the oxygen atom:

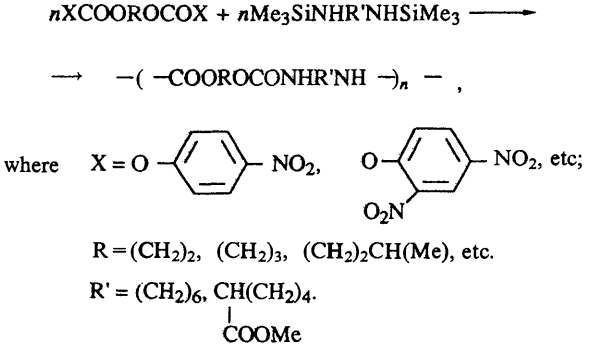


(Y = H, $SiMe_3$).

For example, in contrast to *N*-acyl-α-aminoacids, *N*-alkoxycarbonyl-α-aminoacids do not cyclise to the corresponding azlactones:[102]



High-molecular-weight polyurethanes ($\eta_{init} \leqslant 0.7$ dl g^{-1}) are formed readily on polycondensation of silylated diamines with activated diol biscarbonates—promising monomers for the synthesis of linear polyurethanes under polycondensation conditions in solution:[103]

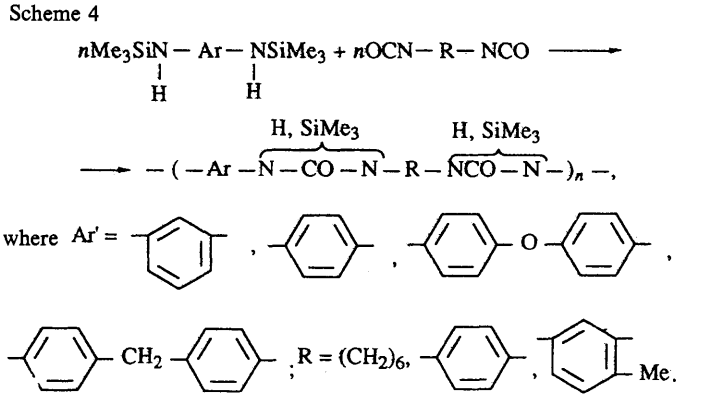


The polyurethane formation reactions using silylated diamines are convenient for the synthesis of polyurethanes with functional-group substituents, for example those based on L-lysine.[104]

Polyureas. One of the first representatives of heterochain polymers, synthesised using silylated diamines, were polyureas together with polyamines.

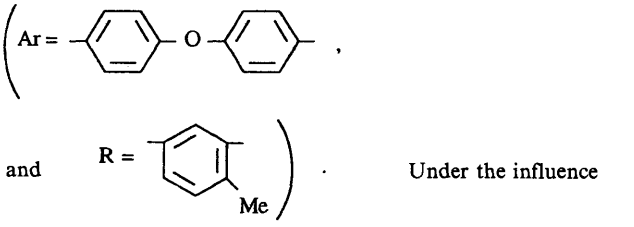
Klebe[105] achieved the synthesis of polyureas by the reaction of diisocyanates with silylated aromatic amines in tetrahydrofuran (THF), benzene, toluene, or their mixture:

Scheme 4



It is remarkable that the silylated secondary amine, containing no NH proton, reacts vigorously with the diisocyanate via a polyadditive mechanism with evolution of heat. In contrast to silylated primary diamines, a polyurea with a fixed N–Si bond is formed under these conditions.

Polyureas in which 50% of the NH protons have been substituted by the silyl groups exhibit an increased solubility in organic solvents. The fully silylated piperazine-based polymer is soluble in benzene and toluene, which may be associated, apart from the absence of intermolecular hydrogen bonds, with the presence of the bulky phenyl substituents in the silyl group. The silylated polyureas are also characterised by lower melting points, which (in contrast to non-silylated analogues) are lower than the decomposition temperatures. This greatly facilitates the formation of articles from them. Strong films have been obtained via Scheme 4 from silylated polyurea ($\overline{M}_W$ 120 000, light scattering)



Under the influence of atmospheric moisture, slow desilylation takes place in such films, which is significantly reflected in their properties (Table 1). Polyureas are rapidly desilylated when methanol is added to the final solution.

The reaction of diisocyanates with silylated diamines in DMA has been used successfully to obtain polyureas with functional-group substituents from natural carboxylic diaminoacids:[106]

$$n\mathrm{OCNRNCO} + n\mathrm{Me_3SiNHR'NHSiMe_3} \longrightarrow$$

$$\longrightarrow -(-\mathrm{COHNRNHCONHR'NH}-)_n-,$$

where R,R' = $\mathrm{CH(CH_2)_3}$ (COOEt), $\mathrm{CH(CH_2)_4}$ (COOEt), $\mathrm{CHCH_2}$ (COOEt), $\mathrm{SS-CH_2CH}$ (COOEt).

The difference from the scheme proposed by Klebe[105] consists in the fact that a diamine desilylated ina preliminary step participated in the reaction. The diamine was desilylated by introducing an equimolar amount of methanol.

Table 1. Properties of films of silylated urea and of its hydrolysed analogue.

Properties	Initial polyurea	Film after 30% surface hydrolysis
Tensile strength, kg cm^{-2}	560	450
Elongation at rupture, %	30	150

*The film was maintained for several weeks at room temperature in air. The hexamethyldisiloxane formed on hydrolysis and remaining in this film played the role of a plasticiser.

One of the authors of this review established that the reactions between aliphatic monomers proceed vigorously with evolution of heat also without preliminary desilylation. Thus the reaction of hexamethylene diisocyanate with *N,N'*-bis(trimethylsilyl)hexamethylenediamine in DMA results in the formation of a viscous solution of a 50% silylated polyrea:

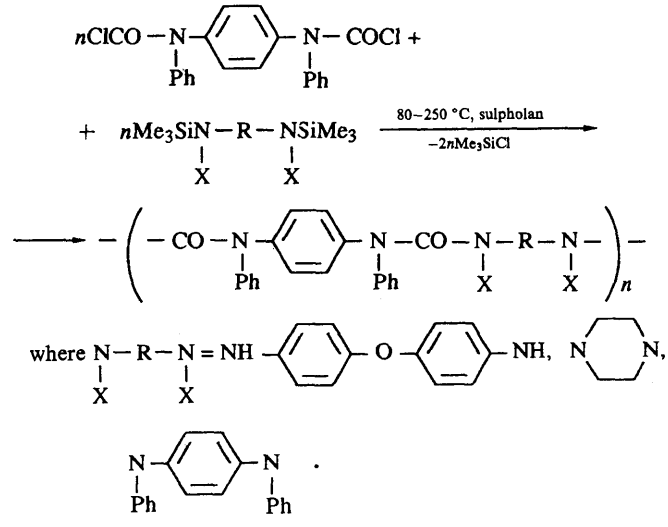
$$(n/2)\mathrm{OCN(CH_2)_6NCO} + (n/2)\mathrm{Me_3SiNH(CH_2)_6NHSiMe_3} \longrightarrow$$

$$\longrightarrow -\left[-(\mathrm{CH_2})_6-\overbrace{\mathrm{N-CO-N}}^{\mathrm{H,\ Me_3Si}}-\right]_n- \xrightarrow{\mathrm{MeOH}}$$

$$\longrightarrow -\left[-(\mathrm{CH_2})_6\mathrm{NHCONH}-\right]_n- .$$

After the addition of methanol to the reaction solution, a polyrea in the H-form is rapidly precipitated. It contains in all probability intermolecular cross-links, because it is insoluble in trifluoroacetic and sulphuric acids [a polyurea having a similar structure, obtained in a different way (see below), does not dissolve in DMA but is soluble in the acids indicated]. We may note that a tendency towards the rapid exchange of the trimethylsilyl group leads to interesting possibilities for the use of silylated polyreas as polymeric reagents—effective donors of the silyl group and especially convenient for the separation of the reaction products.

Polyureas have been synthesised by the reaction of *N*-phenylbiscarbamoyl chloride [*N,N'*-bis(chloroformyl)-*p*-dianilinobenzene] with silylated diamines, including secondary diamines:[28]



The viscosity of polyureas ($\eta_{\log} \leqslant 0.35$ dl g^{-1}), obtained in accordance with this scheme, is higher than that of the analogous specimens obtained by the reaction of *p*-dianilinobenzene with the corresponding diisocyanate ($\eta_{\log} \leqslant 0.18$ dl g^{-1});[107] best results were achieved using a piperazine derivative as the amine component.

High-molecular-weight polyureas are formed in the reaction of silylated diamines with phosgene:[108]

$$n\mathrm{COCl_2} + n\mathrm{Me_3SiNH-R-NHSiMe_3} \xrightarrow[-2n\mathrm{Me_3SiCl}]{}$$

$$\longrightarrow -(-\mathrm{CONH-R-NH}-)_n- .$$

Diphosgene and triphosgene, which are experimentally more convenient, are also used in this reaction instead of phosgene. The employment of other sources of the CO group—crystalline activated carbonates—likewise proved fruitful:[108]

$$n\mathrm{XCOX} + n\mathrm{Me_3SiNH-R-NHSiMe_3} \xrightarrow[-2n\mathrm{XSiMe_3}]{}$$

$$\longrightarrow -(-\mathrm{CONHRNH}-)_n-,$$

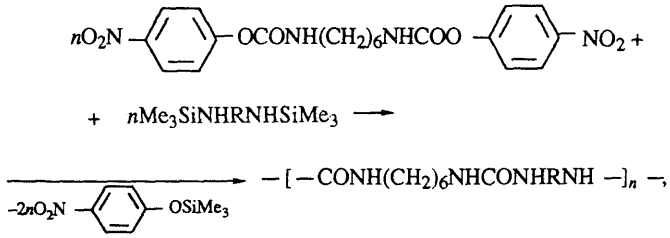
where X = O, NO_2; O, O_2N, NO_2; R = $(\mathrm{CH_2})_6$, $\mathrm{CH(CH_2)_4}$ (COOEt) etc.

The interaction of activated carbonates and silylated diamines takes place at room temperature in DMA. However, in many instances the temperature is raised to 90–100 °C and LiCl is added in order to homogenise the solution and complete the reaction

(under heterogeneous conditions, the polyurea chain propagation stops). Polyureas with $\eta_{int} \leqslant 0.95$ dl g^{-1}, soluble in organic solvents and possessing film- and fibre-forming properties, have been synthesised under such conditions.

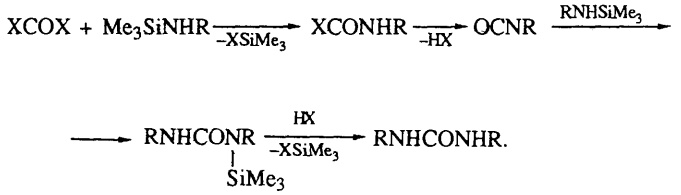
This scheme is particularly convenient in the synthesis of L-lysine-based polyureas with functional-group substituents.[104,108] A polymer with a microstructure in which symmetrical "head-to-head" and "tail-to-tail" triads predominate (with a microheterogeneity coefficient[109] $K_m = 0.6$) are formed in accordance with this scheme, while a polyurea with a normal statistical distribution of triads (with a slight predominance of the "head-to-tail" triads having $K_m = 1.1$) formed[110] in accordance with the isocyanate scheme presented above.[106]

The polycondensation of silylated diamines by reaction with an activated carbamate also leads to the synthesis of high-molecular-weight polyureas;[111]

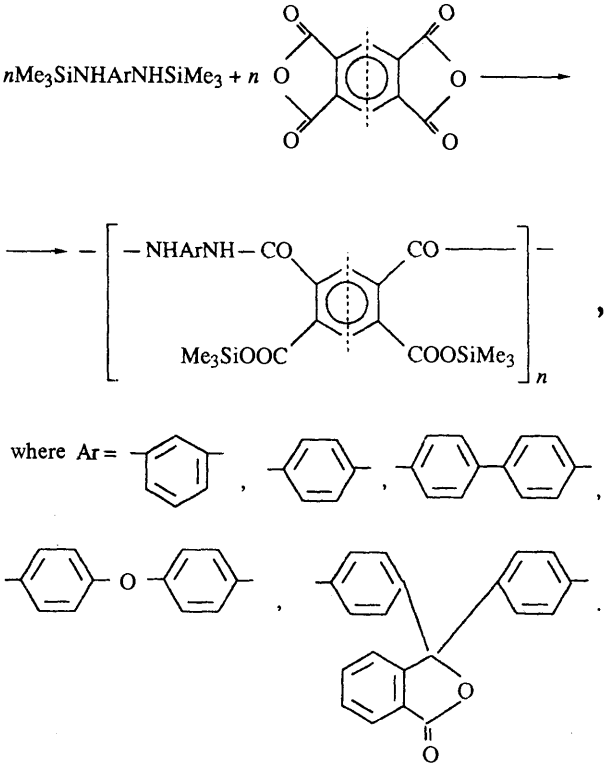


This scheme is also effective in the synthesis of L-lysine-based polyureas with functional-group substituents.

In contrast to polyamide and polyurethane formation processes, the synthesis of polyureas using phosgene and its derivatives proceeds via the intermediate formation of an isocyanate;[108]

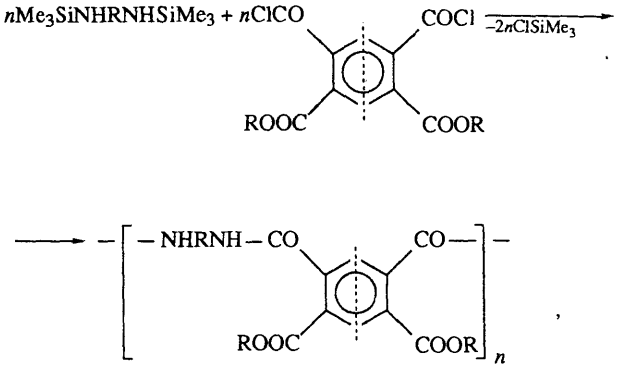


Polycycloimides. *The two-stage method.* The possibility of synthesising polymides via silylated diamines was first examined by Klebe.[1,112] In the polycondensation of cyclic anhydrides with trimethylsilylated aromatic diamines, trimethylsilyl esters of polyamidoacids (Si-PAA) are formed under mild conditions. The Si-PAA differ from the free PAA by their stability in inorganic solvents. For example, the viscosity of Si–PAA does not change during 120 days at room temperature in DMA,[113] which may also be a consequence of the "self-purification" of the system (see above):[1,94,112–117]



An interesting feature of these processes is that the $COOSiMe_3$ group "departs" in the reaction and a Si-PAA is formed.

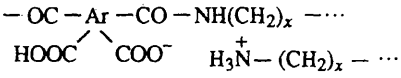
Precursors of the polyimides can be synthesised via an alternative scheme involving a reaction similar to that described above (see "Polyimides") between silylated diamines and tetracarboxylic acid diester dichlorides:



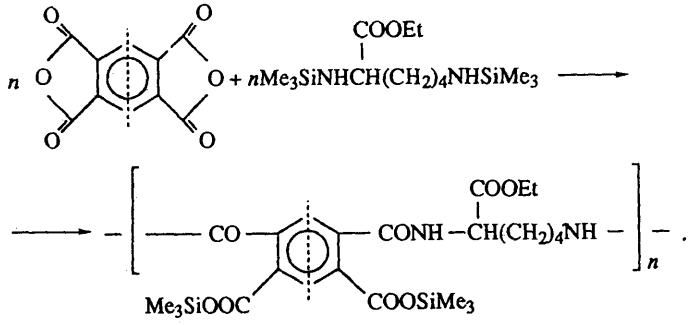
where R = Me, Et, etc.

An advantage of the formation of polyamides from silylated aliphatic diamines using cyclic acid dianhydrides is the formation of high-molecular-weight Si-PAA ($\eta_{log} \leqslant 1.0$ dl g^{-1}). When the corresponding free polymethylenediamines are employed, low-molecular-weight PAA are also obtained ($\eta_{log} \leqslant 0.2$ dl g^{-1}), which

is due to the strong inhibition of the process as a result of the formation of stable salts by highly basic aliphatic amines with the carboxyl side groups of the PAA, the salts precipitating:§ [118]



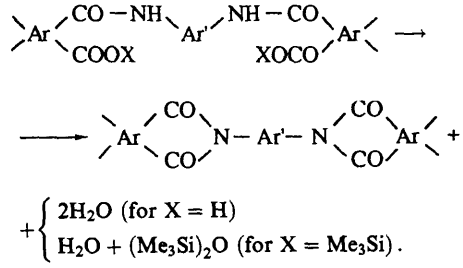
The interaction of silylated diamines with dianhydrides has been used for the synthesis of L-lysine-based polyamides with functional-group substituents:[115,116]



We may note that silylated forms of PAA are stable in the reaction solutions. During isolation by precipitation using an excess of a precipitant, they are readily desilylated (apparently by traces of moisture). Si-PAA can be maintained in an intact form only when the solvent (DMSO) is removed by lyophilising the solutions.

The thermal cyclisation of Si-PAA proceeds extremely effectively (according to certain data, it is faster than the cyclisation of free PAA) with formation of the target polyimides having a high molecular weight and basic properties identical with those of the polyimides obtained by the traditional method.[117]

It is significant that hexamethyldisiloxane and an amount of water smaller by a factor of 2 than in the conversion of PAA into the imide form are produced in the thermal cyclisation of Si-PAA:

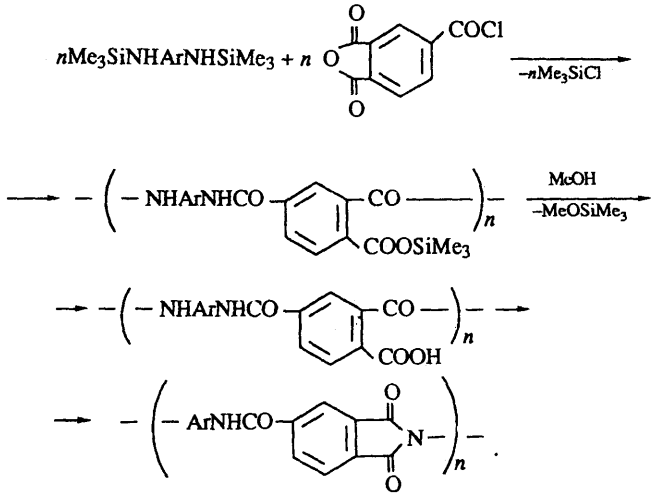


Water is formed in the case of Si-PAA on condensation of two molecules of trimethylsilanol, in all probability in the gas phase, which protects the PAA from hydrolysis (degradation).

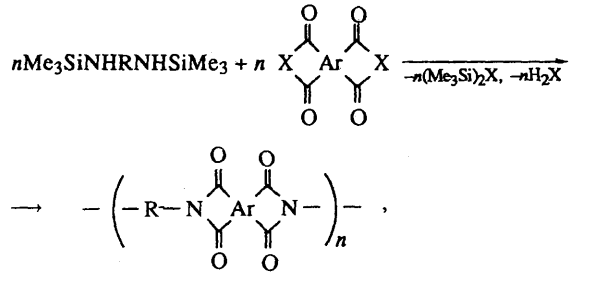
Si-PAA also undergo readily chemical cyclisation in the presence of a pyridine–acetic anhydride (or acetyl chloride) mixture with intermediate formation of a mixed anhydride. This process can apparently be achieved in the absence of the organic base, because it is known that the silyl esters of carboxylic acids form anhydrides fairly readily on treatment with the acyl group donors indicated above:[1]

where X = Cl or MeCOO.

The advantages of the "silylated polyamide formation reaction" using cyclic dihydrides were taken into account in the synthesis of copolyimides (aliphatic and aromatic diamines were used as the comonomers), the microstructure of the chains of which was regulated (by means of degradative and exchange processes) in the stages involving the formation of Si-PAA and their cyclisation.[114] We may note that high-molecular-weight copolyimides were obtained both from the Si-alkylenediamine/Si-arylenediamine pair despite the possible exchange of the silyl group in the latter case and the appearance in the system of free aliphatic amino-groups. The combination in the first stage of the acid chloride and anhydride "silylated polyamide formation reactions" made it possible to synthesise high-molecular-weight polyamidoimides based on 4-chloroformylphthalic anhydride:[117]



The single-stage method. Using Si-diamines of different nature and cyclic dianhyrides (including dithioanhydrides[119]), high-molecular-weight polyimides were obtained in a single stage in solution at elevated temperatures:[114,119,120]



where X = O or S. It was established that there is no appreciable difference between the reactivities of diamines and their silylated analogues both in the single-stage polyimide formation reactions and in the reactions involving the aminolysis of polyimides.[120]

§ The polymeric salt based on the dianhydride of oxydi(3,4-dicarboxybenzene) and dodecamethylenediamine is insoluble in polar solvents even after prolonged heating at 100 °C.

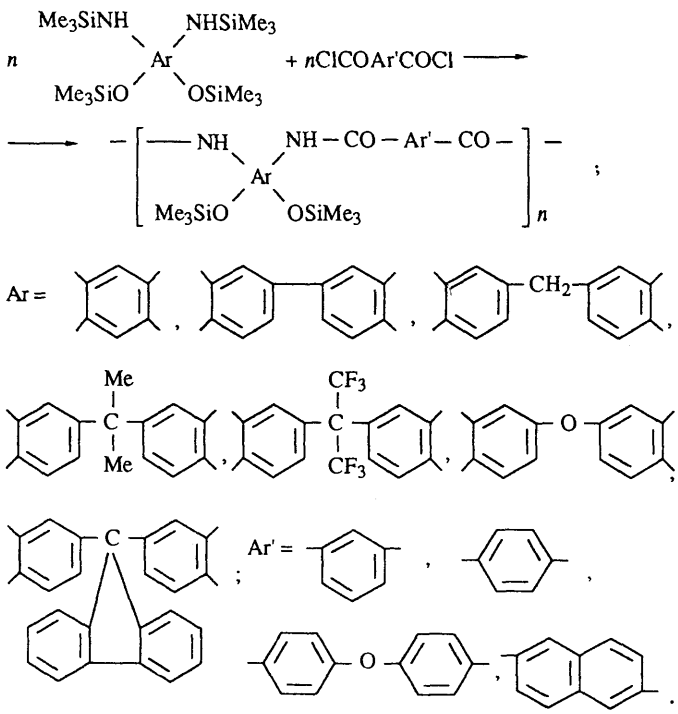
Acyclic linear polyimides. The "trimethylsilyl activation" of the amide nitrogen, which was discussed above, has been used successfully to acylate acid amides i.e. to synthesise acyclic analogues of polyimides:[62]

$$n(Me_3Si)_2NH + \tfrac{n}{2}ClCORCOCl \rightarrow \tfrac{n}{2}Me_3SiNHCORCONHSiMe_3 \rightarrow$$
$$\xrightarrow{\frac{n}{2}ClCORCOCl} -(-COR - CONHCO - R - CONH)_{n/2} - .$$

A characteristic feature of this reaction is that the primary amine behaves as a bifunctional reactant. Disilylated primary monoamines $(SiMe_3)_2NR'$ can apparently be used also under analogous conditions.

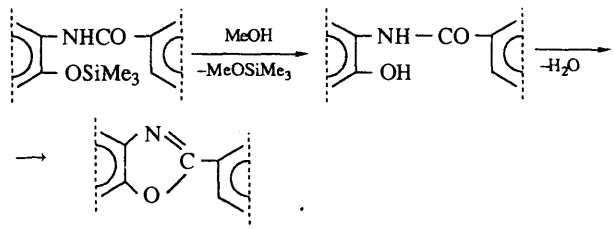
Like polyanhydrides,[121–123] the polyimides examined are of potential interest as rapidly degradable polymers for medical-biological purposes, especially since both R and R′ can carry different functional groups.

Polybenzazoles. The use of silylated monomers also for the synthesis of polybenzoxazoles by a two-stage method proved fruitful:[24,25,42,94,124–129]

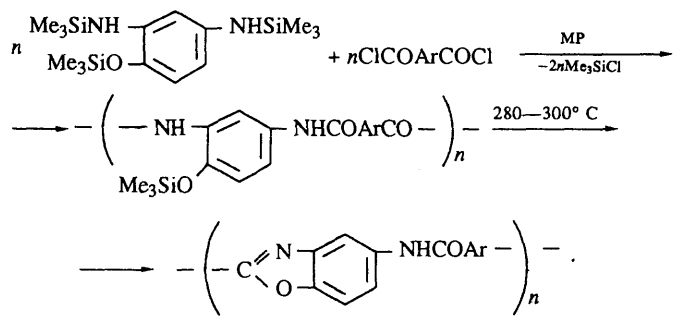


Higher-molecular-weight poly-*o*-hydroxyphenylamides ($\eta_{log} \leqslant 0.64$ dl g^{-1}) can be obtained from silylated bis-*o*-aminophenols[41] than from the free bases ($\eta_{log} \leqslant 0.33$ dl g^{-1}).[42] Here one can assume that the reaction proceeds with participation of the silylated amino-groups, because the silylated hydroxy-groups do not interact with acid chlorides under the conditions of low-temperature polycondensation (see below).

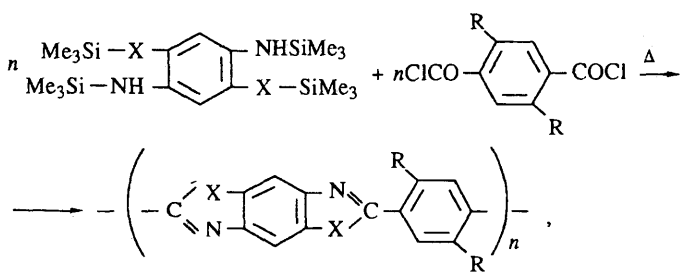
In order to facilitate the second reaction stage (cyclisation to the target benzoaxole), the hydroxy group is desilylated by treating the polymers with methanol:



Imai and co-workers[1] synthesised film-forming polyimidobenzoxazoles ($\eta_{log} \leqslant 1.49$ dl g^{-1}) in *N*-methylpyrrolidinone (MP) in accordance with the following scheme:

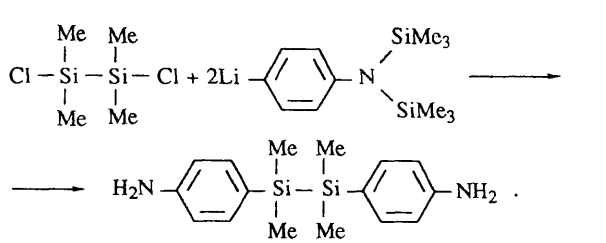


Kricheldorf and co-workers[24,25,128] obtained rod-like polybenzoxazoles and polybenzothiazoles with the aid of "silyated polycondensation":



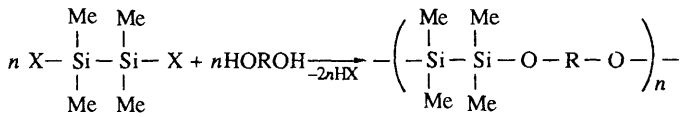
where X = O or S. According to the authors, the minimal contribution of side reactions is an advantage of this method.

Photosensitive polymers. An interesting study designed to create photo-sensitive (photodegradable) polymers has been carried out.[130–132] 1,2-Bis(*p*-aminophenyl)tetramethyldisilane was synthesised by the reaction of 1,2-dichlorotetramethyldisilane with 4-[*N*,*N*-bis(trimethylsilyl)amino]phenyl-lithium:

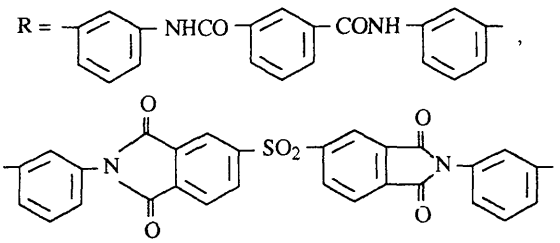


Polyamides ($\eta_{log} \leqslant 0.7$ dl g^{-1}) and polyimides ($\eta_{log} \leqslant 0.84$ dl g^{-1}), which undergo photodegradation on UV illumination, were synthesised by the polycondensation of the above diamine with dicarboxylic acid dichlorides[130] and the dianhydride of di(3,4-dicarboxyphenyl) sulphone[131] respectively.

The same workers proposed also an alternative method of synthesis of photo-sensitive polyamides and polyimides ($\eta \leqslant 0.59$ dl g^{-1}), in which the silylated amino-groups are directly involved in the chain propagation process:[132]

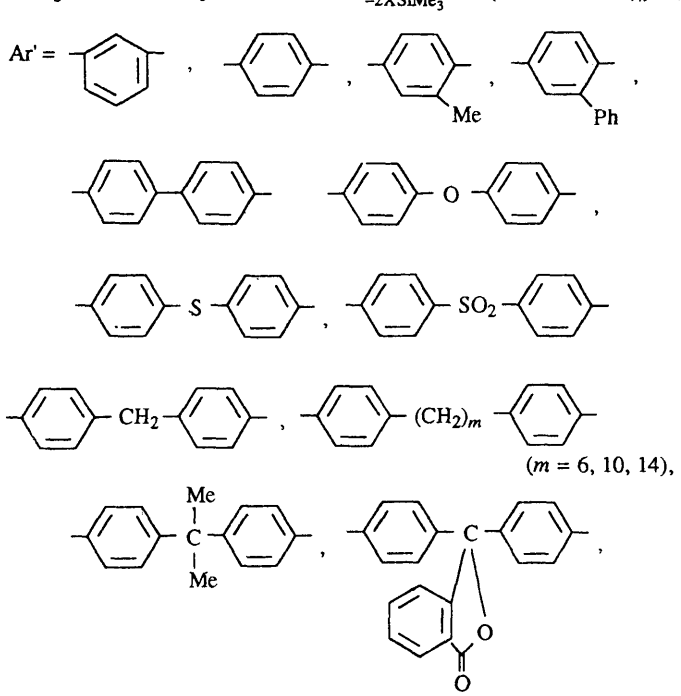


where X = NEt_2, HN−Ph;

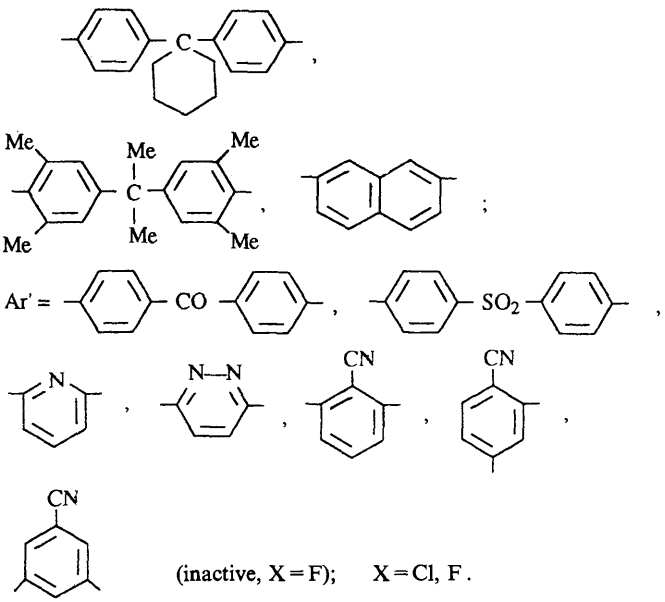


Polymers based on monomers with a O(S)−Si bond

Polyethers. Kricheldorf and co-workers obtained high-molecular-weight ($\overline{M}_W \leqslant 2 \times 10^5$) simple homopolymers and copolymers by the reaction of silylated bisphenols with activated (with the aid of a heterocycle or the electron-accepting CO_2 and SO_2 groups) aromatic difluoro(chloro)-compounds:[24,25,31,35,38,39,48,133–136]



(*m* = 6, 10, 14),



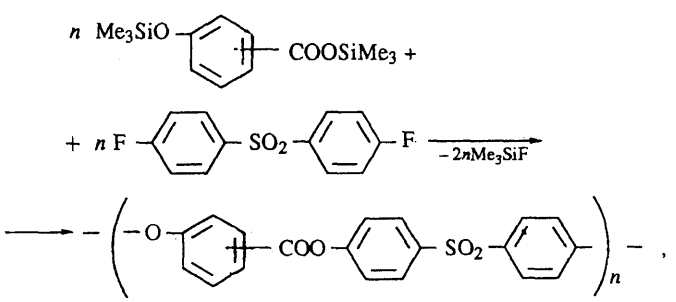
(inactive, X = F); X = Cl, F.

The polycondensation of silylated bisphenols with activated aromatic difluoro-compounds proceeds at elevated temperatures ($\leqslant$340 °C) in bulk. The silylated oxygen in bisphenols can be activated by inorganic anions (F^-, Cl^-, CO_3^{2-}), the use of fluorides (KF, CsF) producing the best results.

Polycondensation with participation of activated aromatic chloro-compounds also proceeds in solution in methylpyrrolidinone in the presence of K_2CO_3. On the whole, in the reactions indicated aromatic fluoro-compounds are much more reactive than their chloro-analogues, as in the reactions with alkali metal phenoxides.[137,138]

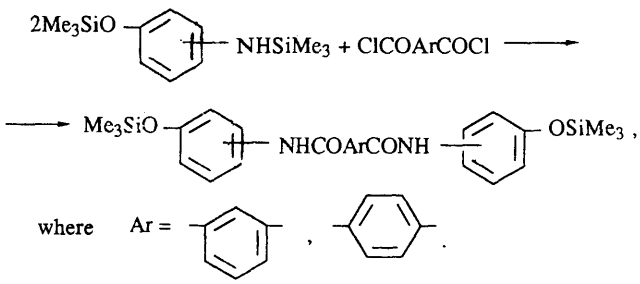
The proposed methods of synthesis of aromatic polyethers, involving the evolution of volatile products (Me_3SiF, Me_3SiCl), have advantages over the traditional method of their synthesis by the polycondensation of alkali metal bisphenoxides with activated aromatic dihalo-compounds in solution (in DMSO, methylpyrrolidinone, etc.).[137,138] The main disadvantage of the traditional method consists in the necessity to eliminate large amounts of metal salts (low-molecular-weight polycondensation side products) from the polyethers.

Polymers containing ether and ester linkages in the main macromolecular chains have been obtained by the reaction of silylated *m*- and *p*-hydroxybenzoic acids and di(4-fluorophenyl) sulphone:[48]



$\bar{M}_n \leq 20\,000$.

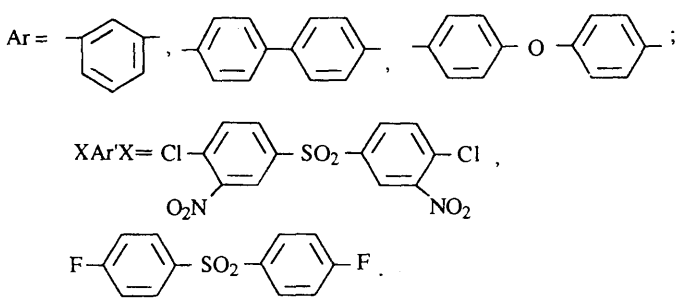
Using the different reactivities of *O*- and *N*-silylated functional groups, regular polyamides containing ether linkages have been synthesised.[139] Silylated diphenyldiamides were obtained initially by the reaction of *N,O*-bis(trimethylsilyl)-3-(or 4-)aminophenol with acid dichlorides under mild conditions. The diamides were then condensed with activated aromatic difluoro-monomers:



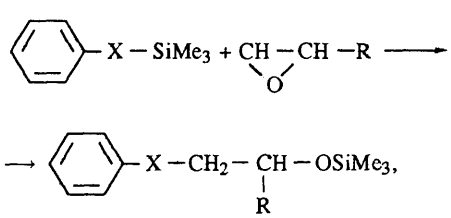
Polysulphides have also been synthesised by the reaction of *S,S'*-bistrimethylsilylated dithiophenols with aromatic dihalo-compounds:[140]

$$n\,Me_3Si-SArS-SiMe_3 + n\,XAr'X \xrightarrow[-2nMe_3SiX]{} -(-SArSAr'-)_n-,$$

where



We may note that silylated phenols and thiophenols may be alkylated also with the aid of epoxy-compounds. The oxiran ring is then inserted (and opened) between the Si and O(S) atoms:[68]



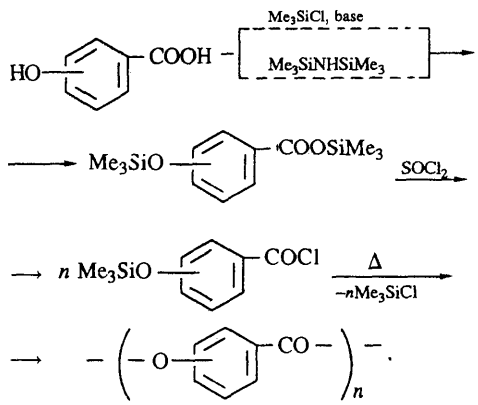
where X = O or S.

Polyesters. Kricheldorf and co-workers[30,32–34,49,141] developed a method of synthesis of polyarylates which serves as an alternative to the procedure for the arylation of silylated acids described above. It consists in the interaction of silylated phenols with acid chlorides at elevated temperatures in bulk or in a high-boiling solvent:

$$\sim ArOSiMe_3 + ClCOAr'\sim \xrightarrow{200-300^\circ C} \sim ArOCOAr'\sim ,$$

According to the authors, "silylated polyesterification" is especially useful in the synthesis of AB-polyesters, because monomers are partly volatilised in the AA–BB polycondensation, which leads to the breakdown of stoichiometry.

The silylated aromatic OH groups are inert to acid chlorides in a neutral medium and at moderate temperatures. This made it possible to synthesise the chlorides of trimethylsiloxybenzoic acids:

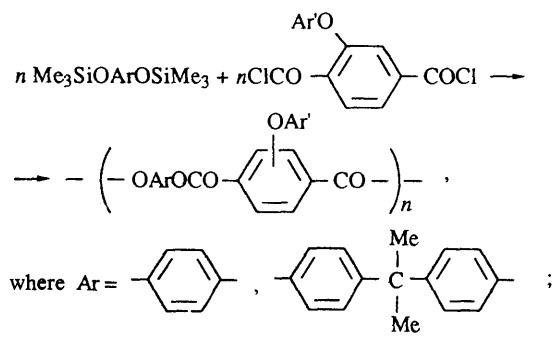


The polycondensation of trimethylsiloxybenzoic acid in bulk in the temperature range 200–300 °C leads to the synthesis of polyesters with $\overline{M}_n$ = 12 000–13 000; in solution in the presence of pyridine (a nucleophilic catalyst), much worse results are achieved ($\overline{M}_n \leqslant 2300$).[33]

The new scheme for the synthesis of aromatic AB-polyesters also has an advantage over the thermal polycondensation of acetoxybenzoic acids[30] and over direct polycondensation in the presence of phosphorus compounds as condensing agents.[33]

By selecting appropriate conditions (redistilled trimethylsilyl ester of *p*-trimethylsiloxybenzoic acid in the persence of an excess of $SOCl_2$, polycondensation in Marlotherm S), it was possible to increase $\overline{M}_n$ for the polyester to 200 000.[34]

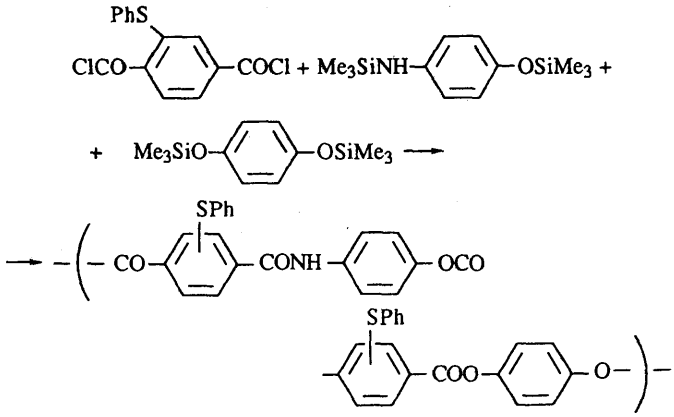
Using the silylated polyesterification method, thermotropic polyarylates were synthesised from aryloxyterephthalic acid:[52,72,146]



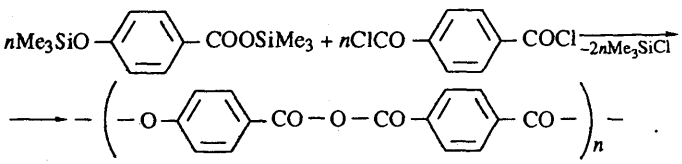
Ar' = Ph, PhOPh, $PhOC_6H_4Cl$, $PhOC_6Cl_5$.

Polyarylates with higher viscosities were obtained by the above method in many instances than in the traditional low-temperature polyesterification of bisphenols by acid dichlorides in the presence of pyridine or in the high-temperature polycondensation of aryloxy-terephthalic acids with acetylated bisphenols. The advantage of the new scheme is the small contribution of the anthrone formation side reaction.[24,49,141]

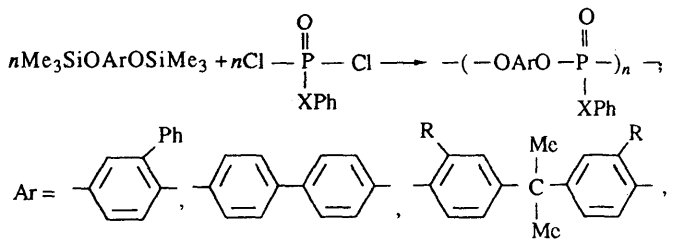
Using silylated 4-aminophenol as the comonomer, thermotropic polyamidoesters have been synthesised:[24]



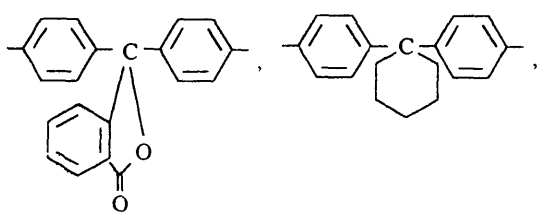
The polycondensation of terephthaloyl chloride with a silylated hydroxyacid afforded thermotropic polyester anhydrides:[24]



Stepwise heating of silylated bisphenols with phenyl phosphorodichloridate and phenyl phosphonodichloridate in the presence of benzyltriethylammonium chloride as the catalyst afforded fire-resistant poly(phenyl phosphates) and poly(phenyl phosphonates) with $M_n \leqslant 20\,000$:[36,37]

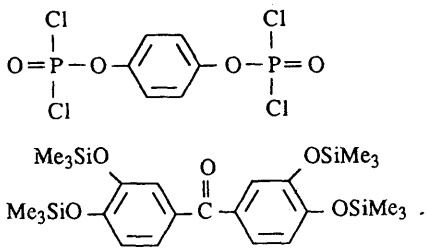


(R= H, Me, Cl, Br),



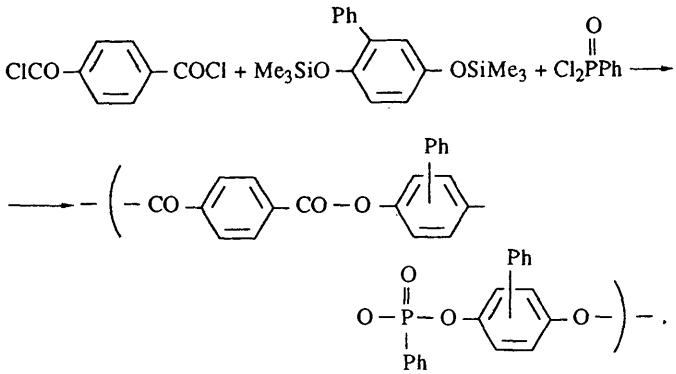
X = bond, O.

"Cross-linking" tetrafunctional compounds have also been used in the synthesis of phosphorus-containing polyesters, but the reaction yielded polymers with lower viscosity characteristics:

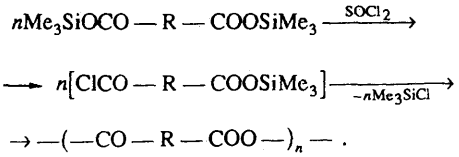


According to the author,[37] this is associated with the involvement of the tetrafunctional monomers in side reactions.

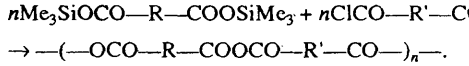
Thermotropic copolymers of terephthalic and phenylphosphonic acid have been synthesised:[24]



Polyanhydrides. The synthesis of polyanhydrides ($\eta_{int} \leqslant 0.6$ dl g^{-1} in chloroform) by the polycondensation of bistrimethylsilylated dicarboxylic acids with $SOCl_2$ in the presence of benzyltriethylammonium chloride as the catalyst has been described:[142]



Polyanhydrides can also be synthesised by the reaction of bistrimethylsilylated dicarboxylic acids with acid dichlorides, similarly to the synthesis of polyester anhydrides described above:



The "silylated polyanhydrides formation" reactions can be useful for the synthesis of new polyanhydrides promising as biodegradable polymers.[121–123]

Polyesterurethanes. Under certain conditions, silylated alcohols and phenols react with carboxylic acid chlorides whilst remaining inert to isocyanate groups. This feature has been used[29] to synthesise diesterdiisocyanates in accordance with the scheme

$$2OCN(CH_2)_mCOCl + Me_3SiOROSiMe_3 \longrightarrow$$

$$\longrightarrow OCN(CH_2)_mCOOROCO(CH_2)_mNCO;$$

R = $(CH_2)_4$,  ; m = 2, 3, 5.

Polyesterurethanes with a regular structure have been synthesised from diesterdiisocyanates. We may note that the above monomers are of interest for the synthesis of regular polyesterureas and polyamidoesters.

Polycondensation *in situ*

Polycondensation reactions in which the silylating agent is added directly to a mixture of the biselectrophile and bisnucleophile are examined below. Under these conditions, one of them gives rise to a silylated derivative, which then reacts *in situ* with the monomer of the opposite kind.

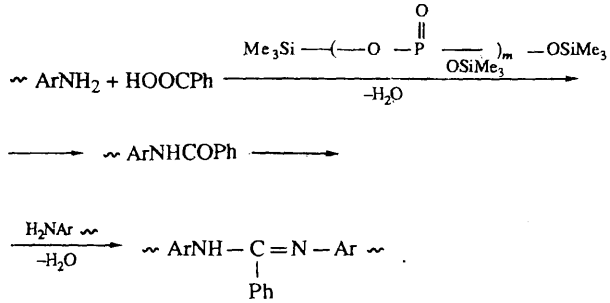
Modification of the bisnucleophile. Kaneda and co-workers[143,144] proposed a simplified method of synthesis of polyamides which does not require the preliminary synthesis and purification of silylated diamines. The diamine is subjected to polycondensation with an acid dichloride in amide solvents (HMPA, DMA, methylpyrrolidinone) at 0 °C in the presence of Me_3SiCl. This entails the silylation of the amino-groups of the diamine, which reacts *in situ* with the acid chloride. The addition of Me_3SiCl makes it possible to obtain polyamides with higher molecular weights ($\eta_{log} \leqslant 6.68$ dl g^{-1}) than in the case where salts such as LiCl ($\eta_{log} \leqslant 3.9$ dl g^{-1}) or $CaCl_2$ ($\eta_{log} \leqslant 4.48$ dl g^{-1}) (polyamides based on 3,9-diaminophenanthridinone and terephthaloyl chloride) are used.

Direct polycondensation. A method of synthesis of polyamides by the polycondensation of diamines and dicarboxylic acids or *p*-aminobenzoic acids in the presence of $SiCl_4$ as the condensing agent has been proposed (in this case both the biselectrophile and the bisnucleophile may be activated simultaneously):[145–147]

$$n H_2NArNH_2 + n HOOCAr'COOH + {}^n/_2 SiCl_4 \rightarrow$$
$$\rightarrow -(-NHArNHCOAr'CO-)_n- + (SiO_2)_{n/2} + 2n HCl.$$

It is of interest that SiO_2 is formed in these processes as a side product. This leads to the prospect of obtaining filled materials directly during synthesis.

Poly(trimethylsilyl phosphate) has also been used as the condensing agent:[148]



This agent exerts such a powerful dehydrating effect that an amidine bond is formed from the amide and amine groups. The interaction of diamines with benzoic acid (which behaves as a bifunctional monomer in the processes indicated) yielded polyamidines.

The syntheses described in this Section illustrate a variety of direct polycondensation—a new promising method of synthesis of heterochain polymers.[149,150]

(b) Polymerisation

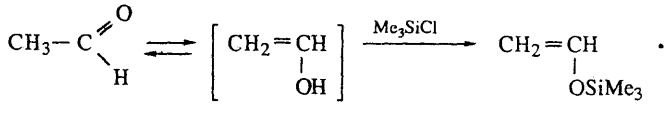
Polymerisation of heterocycles

The silyl protecting group has been used in the synthesis of polycarbohydrates by polymerisation with the opening of the ring in the corresponding anhydro-sugars. For example, the reaction of t-butylchlorodimethylsilane and 1,5-anhydro-β-D-xylofuranose afforded 1,5-anhydro-2,3-di-*O*-(t-butyldimethylsilyl)-β-D-xylofuranose, whose polymerisation in the presence of BF_3 or $SbCl_5$ yielded high-molecular-weight polymers containing the 1,5-α- and 1,5-β-furanose fragments.[151] A polysaccharide with free hydroxy-groups, capable of further polymer-analogue transformations, was obtained by the desilylation of the polymer indicated.

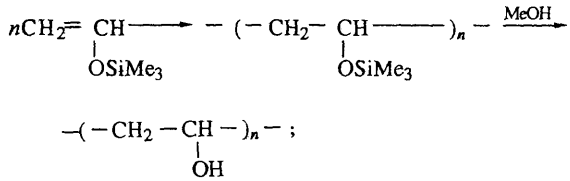
N-Trimethylsilylated lactams have also been used in the synthesis of polymers. In particular, it has been established that *N*-trimethylsilyl caprolactam  accelerates the anionic polymerisation of ε-caprolactam.[152]

Timethylsilated compounds are also effective as catalysts of the polymerisation of heterocycles. It has been shown[153] that trimethylsilylated acids, in particular, trimethylsilyl triflate ($CF_3{=}SO_3SiMe_3$) and bistrimethylsilyl sulphate ($Me_3SiOSO_2OSiMe_3$) initiate the polymerisation of lactones. Polycaprolactone with a molecular weight of 60 000 (degree of conversion 70–90%) has been obtained by treatment with trimethylsilyl triflate in 1,2-dichloroethane at 50 °C.

Polymerisation of silyl ethers of enols. An elegant method of synthesis of poly(vinyl alcohol) from acetaldehyde has been proposed.[154] The *O*-trimethylsilyl derivative of the enolic form of acetaldehyde was synthesised initially and then trimethylsiloxyethylene was obtained:

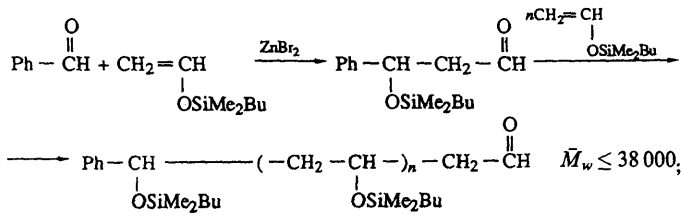


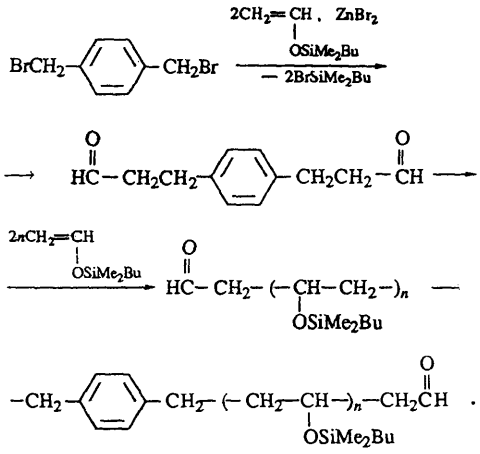
The polymersiation of the latter afforded silylated poly(vinyl alcohol). It was desilylated by adding methanol;



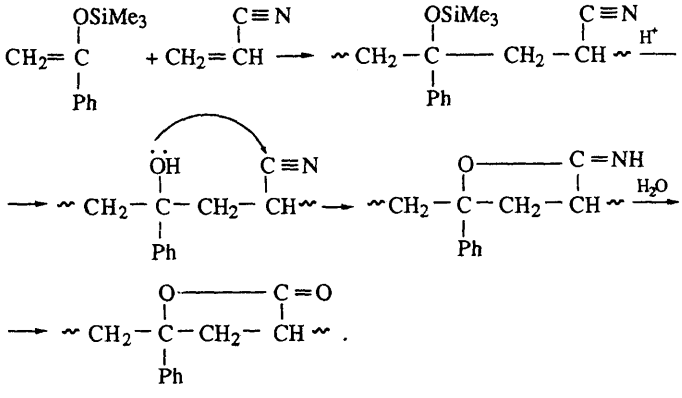
$$[\eta]^{30}_{H_2O} \leq 0.6 \text{ dl g}^{-1}.$$

This interesting procedure was developed in a study[53] whose authors achieved the synthesis of silylated poly(vinyl alcohols) in accordance with one of the schemes presented below (the polymer formation process proceeds via the mechanism of aldol condensation):



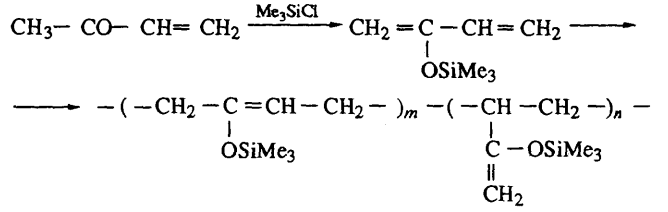


α-Trimethylsiloxystyrene, its polymers, and its copolymers with styrene[155] and acrylonitrile[156] were synthesised from acetophenone. In the latter case, in the presence of a proton, there is possibility of cyclisation with formation of a five-membered lactone:

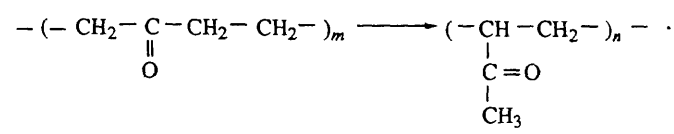


Lactone-containing polymers are of intereest, for example, as carriers for the covalent immobilisation of various substances. In this case, there is no need for the additional activation of the polymer, because it is known that five-membered lactones exhibit an enhanced reactivity and readily interact with aliphatic amino-groups.[157]

An interesting method of synthesis of polyolefins containing ketone groups in the main and side chains of the macromolecules has been proposed.[158] 2-Trimethylsiloxybuta-1,3-diene was obtained initially by silylating methyl vinyl ketone and its polymerisation or copolymerisation with unsaturated monomers led to polymers with 1,4- and 3,4-units:



Desilylation of the polymers by treatment with HCl or NBu_4F results in the formation of polyketones:



These are of interest, for example, as photodegradable materials.

Interesting examples of the use of silyl compounds as initiators of the polymerisation of unsaturated compounds exist. Thus metallo-derivatives of silylamines $(Me_3Si)_2NM$ (where M = Li or Hg) catalyse the polymerisation of vinyl monomers,[1] lithium derivatives exhibiting a high catalytic activity; the catalytic activity of the corresponding amide complex of mercury is less marked. Polymers resistant to fungi have been obtained using the above initiators.

Silyl compounds can also be used to protect catalytic systems. For example, silylamines having the general formula

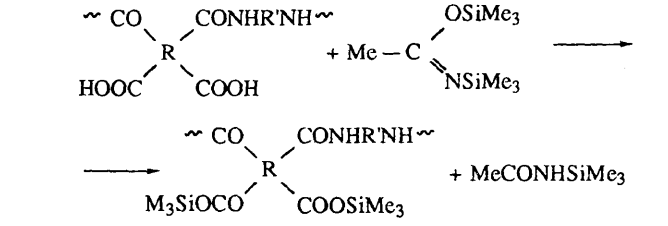
$$R_aSiH_b(NR^1R^2)_c,\ a=1,\ 2,\ 3;\ b=0.01;\ c=1,\ 2;\ a+b+c=4$$

are used as additive neutralising compounds which poison the anionic polymerisation of unsaturated compounds.[160]

Silylation is used to block functional groups (phenolic hydroxyls) present in the monomer itself and capable of inhibiting polymerisation, for example, the polymerisation of 4-allyl-2,6-dimethylphenol.[161]

IV. Reactions in polymer chains

An alternative method of synthesis of Si-PAA, by polymer-analogue reactions in accordance with the scheme



(apart from the silylating agent indicated in the scheme, other donors of the $SiMe_3$ group have been used) is of undoubted interest as regards the employment of the advantages of silylated polycondensation in the synthesis of polymides. Carboxylic acids are silylated more readily than the initial arylenediamines. However, such treatment of PAA at room temperature results in an effective

imide formation reaction.[75]¶ As can be seen from Table 2, best results are then achieved using *N,O*-bis(trimethylsilyl) acetamide.

An advantage of silylating agents in imide formation processes is that, in contrast to, for example, carboxylic acid anhyrides and tertiary amines, which are effective only when used in combination with one another, there is no need for a second agent when silazanes and silylamides are employed. In addition, the cyclisation of PAA takes place successfully in the presence of equivalent amounts of silazanes. Whereas the attainment of optimum results with mixtures of anhydrides and tertiary amines requires an appreciable excess of the components of the catalytic system. The silylation of polyamide chains has also been achieved.[163]

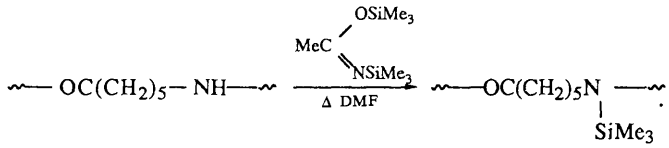


Table 2. Synthesis of polyimides by cyclising PAA in the presence of silylating agents.[75]

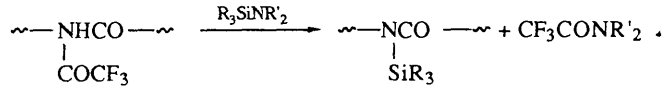
PAA base	η_{lg} for PAA, dl g^{-1}	Silylating agent	η_{lg} for the polymide dl g^{-1}
p-Phenylenediamine and 3,3-bis(3',4'-dicarboxyphenyl)phthalide	1.22	*N,O*-bis(trimethylsilyl)acetamide	0.95
	0.99	$Me_3SiCl+NEt_3$(1 : 1)	0.32
Anilinofluorene and bis(3,4-dicarboxyphenyl) oxide	1.10	*N,O*-bis(trimethylsilyl)acetamide	0.90
	0.64	$Me_3SiCl+NEt_3$ (1 : 1)	0.21

As a result of sharp decrease in the number of intermolecular hydrogen bonds, silylated polyamides are soluble in many organic solvents and are suitable for conversion into various articles and for studies by the gel-chromatographic methods. They can be regarded also as polymeric reagents—effective donors of the silyl group.

The conversion of polyamides into a soluble form by silylation has advantages over another known method—chain trifluoroacetylation, because certain *N*-trifluoroacetates, for example those of poly-α-aminoacids, are readily degraded.[164]

We may note that the polyamide derivatives indicated can undergo interconversions. For example, *N*-trifluoroacetyl derivatives of polyamides, which are effective trifluoroacetyl group transferring agents, can be converted into the corresponding silylated derivatives on treatment with silazanes:



¶ It is not clear why Greber and Darms[162] nevertheless obtained Si-PAA under analogous conditions, although they do note that the cyclisation of the latter takes place more readily than that of PAA.

Instances of the use of silylated amines instead of free bases in polymer-analogue reactions of polymers are known. Thus, in order to suppress aldol condensation, trimethylsilylated amines were used[165] to convert poly(methyl methacrylate) into the corresponding amide by the aminolysis of ester side groups.

V. Conclusion

There is evidently no need to conclude the review by listing anew and discussing the advantages and characteristics of the employment of the silylation method in polymer chemistry. One can only draw the reader's attention to the steady and extremely marked enhancement of interest in this approach, which has been expressed both by an increase in the number of publications and reviews on this question and also by the application of silylation to the synthesis of new poymers which are relatively difficult to obtain by means of traditional polymer formation reactions. At the same time, it is essential to note that so far the "silyl" method has not reached the stage of its industrial use as regards its application to polymers. This is apparently partly due to the fact that a successful compromise between the chemical, technological, economical, and ecological problems arising when silylated monomers and reagents are employed in the synthesis of polymers has not been found. However, one may assume that, as the process is improved and some kind of unique possibilities of the latter are discovered, it will become more than a purely preparative method for the synthesis of monomers and polymers with a specified combination of properties.

Modern theories of chemical reactions in condensed phases

M V Bazilevskii, V I Faustov
Karpov Physicochemical Institute, Moscow
Zelinskii Institute of Organic Chemistry, Russian Academy of Sciences, Moscow

ABSTRACT. The review is devoted to theoretical studies of the dynamics of chemical reactions in condensed phases. The fundamental differences in the description of the kinetics of gas-phase and liquid-phase reactions are demonstrated. The principal approaches, developed in the theory of liquid-phase reactions, are examined in detail: numerical modelling by Monte Carlo and molecular dynamics methods; numerical and analytical study of stochastic Langevin equations, the Fokker–Planck equation, and the kinetic Bohm–Gross equation. The possibilities and limitations of the modern theory are demonstrated in relation to examples of calculations of rate constants for specific isomerisation, substitution, addition, and electron transfer reactions.

The bibliography includes 114 references.

The dynamics and kinetics of elementary chemical processes in condensed media constitute an important aspect of theoretical chemistry. It has developed vigorously during the last decade. The methodology for and calculations of potential energy surfaces and gas-phase reaction rate constants as well as dynamic calculations were developed in the previous decade on the basis of powerful computational techniques. Towards the end of the 1970's, the principal methodological aspects and problems of the gas-phase theory were exhausted and the interest of investigators shifted to the region of liquid-phase and solid-phase reactions.

This article deals with the present state of the problem. Without aiming at a complete survey of the literature, we concentrated attention on key factors in order to give the reader an idea, at an elementary level, about the advances in the theory and in its applications at the present time. Several reviews dealing with reactions in the condensed phase from current theoretical standpoints have been published.[1–7] Together with more specialised reviews, which will be quoted in the course of further exposition, they contain a complete bibliography.

Our exposition is restricted to reactions in non-ordered condensed media, primarily in molecular liquids, and only to those reactions whose dynamics can be adequately described within the framework of classical mechanics. Only processes occurring in the kinetic regime are described, i.e. diffusion kinetics are excluded. This in fact represents the situation, of fundamental importance for chemistry, where the medium influences directly the chemical step. New approaches and concepts, which are the subject of the present article, have been developed in this field.

I. Distinctive features of the dynamics of liquid-phase reactions

Under the influence of the medium, the rates of reactions can vary within a wide range. There exist fairly numerous chemical systems in which the interaction with the medium is weak. As a rule, these are reactions which occur in non-polar solvents under the usual conditions (room temperature, normal pressure). As a typical example, we shall quote data on the dimerisation of cyclopentadiene. Table 1 shows that different solvents hardly alter the Arrhenius parameters determined for the gas phase. There exist extensive experimental data also for other reactions. The established point of view is that, in the absence of polar effects, the liquid-phase reactions are usually faster by a factor of 2–5 compared with the gas phase and these slight differences between the rate constants are insufficient to detect reliably differences between the Arrhenius parameters in the gas phase and in solution and also when different non-polar solvents are compared.

One may quote an example of the opposite kind. For ionic reactions in polar solvents, i.e. for systems with a strong interaction, the rate constant is sometimes smaller by 10–20 orders of magnitude compared with the gas phase. There are well known S_N2 nucleophilic substitution reactions (Fig. 1) where the unusual gas-phase two-well PES profile is converted for an aqueous solution into a potential curve with a barrier (free energy profile),[10] which is familiar to chemists, while the activation energy increases from several units to 10–20 kilocalories per mole. However, the last example illustrates merely a change in the energetics of the elementary chemical process and at first sight does not require a revision of the principles governing its theoretical description. This aspect is not very interesting from the standpoint of the present review, whose subject is new approaches and concepts. S_N2 reactions will be examined below from new idealogical standpoints.

The transition state (TS) theory provides the standard method for the theoretical description of gas-phase reactions. The expression for the rate constant is

$$K = \kappa \frac{kTF^{\neq}}{hF^{(0)}} \exp(-\Delta U^{*}/kT), \qquad (1.1)$$

where k and h are the Boltzmann and Planck constants, T is the absolute temperature, $F^{\neq}$ and $F^{(0)}$ are the partition functions of the transition state and the reactants, and $\Delta U^{\neq}$ is the activation energy, usually identified with the height of the potential barrier on the PES.

Table 1. Experimental Arrhenius parameters and rate constants for the dimerisation of cyclopentadiene.

Medium	T, K	lg A (litre mol^{-1} s^{-1})	E_a, kcal mol^{-1}	lg$K$ (25 °C)
Gas phase	353–423	6.11	16.7	
	393–467	4.93	14.9	
	405–455	6.77	16.9	
Non-polar solvents				
C_6H_6	258–358	6.10	16.4	6.06
CCl_4	273–328	6.70	17.1	6.15
	273–295	5.90	16.2	6.00
paraffin	273–445	7.10	17.4	6.31
CS_2	273–308	6.20	16.9	7.80
	273–295	5.57	17.7	7.43
cyclopentadiene	271–308	5.80	16.2	7.90
	273–331	5.57	16.8	7.82

Note. The original literature on gas-phase reactions is quoted by Hynes[1] and the literature on liquid-phase reactions is quoted by Denisov.[9]

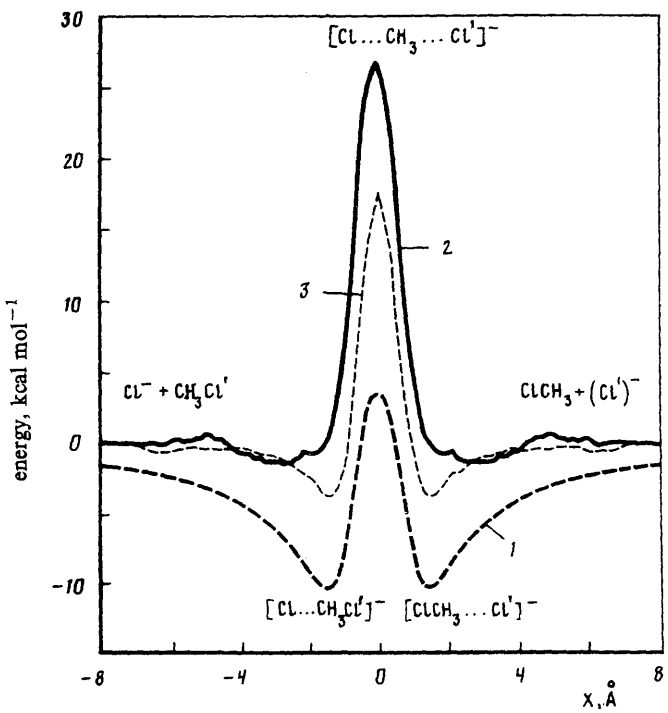

Figure 1. The calculated potential energy profile in the gas phase (curve *1*) and the free energy profile in water (curve *2*) and dimethylformamide (curve *3*) for an S_N2 reaction: $Cl^- + CH_3Cl'$.[10] The difference between the C–Cl and C–Cl′ distances is the reaction coordinate X.

The transmission factor $\varkappa$ cannot be calculated within the framework of the transition state theory and is usually assumed to be unity. The partition function is as a rule calculated in terms of the "harmonic oscillator–rigid rotator" approximation. It is useful to examine specially the isomerisation reactions (transition in a two-well system). Only the oscillator degrees of freedom change significantly in such reactions and, in terms of the classical approximation, the ratio of the partition functions is equal to the ratio of the products of the vibration frequencies ω at the minima for the reactants ($\omega_\nu^{\neq}$) and in the transition state (ω_ν^0) (ν = 0, 1, 2, ..., N):

$$K = \varkappa \frac{\Omega}{2\pi} \prod_{\nu=0}^{N} \frac{\omega_\nu^0}{|\omega_\nu^{\neq}|} \exp\left(-\Delta U^{\neq} / kT\right). \qquad (I.2)$$

The transition state frequencies include the purely imaginary frequency $\omega_0^{\neq} = i\Omega$. The modulus in the denominator of Eqn. (I.2) is necessary in order to eliminate the imaginary unity. A decomposition mode is known to correspond to the imaginary frequency, such modes being found by solving a standard vibrational problem in the vicinity of the saddle point on the PES.

For liquid-phase reactions with strong interaction, the harmonic approximation is inapplicable in principle.

We shall consider the S_N2 reaction already mentioned, for example:

$$\underset{\text{reactants}}{Cl^- + CH_3Cl} \rightarrow \underset{\text{TS}}{[Cl \cdots CH_3 \cdots Cl]^-} \rightarrow \underset{\text{products}}{ClCH_3 + Cl^-}. \qquad (I.3)$$

It is assumed that the reaction proceeds in the kinetic regime, i.e. the reactants in Eqn. (I.3) are in a solvent cage, their diffusion into the cage constituting a fast stage which does not affect the kinetics. Thus the reacting system is surrounded by a solvation shell consisting of a large number of molecules, the influence of which on the reaction has to be taken into account. The orientation motion of each solvent molecule is relatively free. It is found that the solvation shell has a multiplicity of configurations which correspond to different orientations of the solvent molecules. A minimum on the PES corresponds to each configuration; there is a set of minima with approximately equal energies separated by a low barrier (of the order of kT at room temperature). Rapid transitions occur between them and there are no grounds for differentiating any one of them as the "reactants minimum". Likewise in the region of the transition state there exists a set of first-order saddle points separated by higher-order saddle points whose relative height is of the order of kT and they must all be considered on an equal basis. This fundamentally anharmonic situation entails the breakdown of the usual ideas of the gas-phase theory, according to which its single minimum on the potential energy surface corresponds to the reactants and a single saddle point corresponds to the transition state.

Detailed study of each of the configuration minima of the solvation shell loses significance. The local frequencies corresponding to them have no direct bearing on the rate of the chemical reaction. An average description of the influence of the entire assembly of the configurations of the solvation shell on the reaction in the chemical subsystem (I.3) is necessary. This is formally achieved by a transition from the PES to the free energy surface (FES) with the corresponding modification of Eqn. (I.1):

$$K = \varkappa \frac{kT}{h} \exp(-\Delta G^{\neq}/kT), \qquad (I.4)$$

where $\Delta G^{\neq}$ is the height of the barrier on the FES. The use of Eqn. (I.4) presupposes the calculation of the anharmonic partition functions in Eqn. (I.1). The method for the theoretical description is then radically altered. For a gas-phase reaction, the central feature was the quantum-chemical calculation of the PES and the search for stationary points on the latter: the minima for the reactants and products as well as the saddle point corresponding to the transition state. This was sufficient to determine the activation energy as the height of the potential barrier and to establish the reaction mechanism. The dynamic calculations necessary for the evaluation of the pre-exponential factor reduced to the solution of the standard vibrational problem. After this, the dynamic calculation of the transmission factor, which is possible in principle, was assumed to be superfluous in the majority of applications. In order to find the activation energy and to establish the mechanism of reaction (I.3) in a polar medium, one has to construct the free energy profile. Thus the calculation of the anharmonic partition functions comes to the fore. As a rule this is a calculation by the Monte Carlo method.

The next stage is the calculation of the transmission factor $\varkappa$ by the method of molecular dynamics. One has to bear in mind that for a liquid-phase reaction the calculation of the transmission factor is more fundamental than for a gas-phase reaction. In the latter case, the decomposition mode, along which the reaction coordinate is directed at the saddle point on the PES, is chosen by the optimisation procedure as a result of the solution of the vibrational problem. On the other hand, the FES profile for a liquid-phase reaction is constructed as a rule along the reaction coordinate for the chemical subsystem found without taking into account the medium. When there is a strong interaction between the chemical subsystem and the medium, there are no grounds for the assumption that the coordinates of the medium (i.e. the orientation motions of the solvent molecules) do not contribute to the decompositon mode. Thus in the calculation of the FES profile the mode is not chosen by the optimum method. This constitutes an additional cause of the decrease in the transmission factor, which is characteristic only of a liquid-phase calculation.

II. Numerical modelling methods

The development of the computer technique, has made possible the direct modelling of systems comprising several hundreds of particles interacting in accordance with the laws of classical mechanics. The required values are calculated as averages over a large number of instantaneous configurations. Under certain conditions, such a model system describes successfully the properties of real microscopic objects. This is the essential feature of the method of molecular dynamics (MD).[11] The second approach in numerical modelling—the Monte Carlo (MC) method[11,12]—starts with the fundamental postulates of classical equilibrium statistical mechanics. It represents a procedure for calculating the average values $<A>$ of the observed quantity $A(\mathbf{r})$ for an equilibrium ensemble comprising n particles. Here $\mathbf{r}$ is the vector of the coordinates of the particles (r_1, r_2, r_3, ..., r_N). For example, in the case of a canonical ensemble, we have

$$<A> = \frac{\int A(\mathbf{r})\exp[-U(\mathbf{r})/kT]d\mathbf{r}}{\int \exp[-U(\mathbf{r})/kT]d\mathbf{r}}, \qquad (II.1)$$

where $U(\mathbf{r})$ is the potential function of the interaction.

A common feature of the method of molecular dynamics and the Monte Carto method is the absence of conceptual differences betweem them in the description of the interaction within the chemical subsystem, the interactions of the chemical subsystem with the molecules of the medium, and the interactions between the molecules of the medium themselves. The entire information about the system is included in the parameters of the classical particle interaction potentials and also in the masses of the particles in the method of molecular dynamics. By virtue of this factor, both methods are suitable, in principle, for the investigation of reactions occurring in any state of aggregation (gas, liquid, or solid) and for any densities and temperatures.

The test system is placed in a cell, which is frequently cubical or octahedral in shape. The system consists of molecules of the reactants and the solvent and their number ranges from several tens to several hundreds. Periodic boundary conditions are imposed on the cell, i.e. it is assumed that it is surrounded on all sides by exact copies. If in the course of modelling any one particle leaves the cell through one of its walls, then a similar particle from a neighbouring cell enters it through the opposite wall in the same direction (and with the same momentum in the method of molecular dynamics). This approach reduces to a minimum the edge effects and when the calculations are performed for a comparatively small number ($\sim 10^2$) particles, makes it possible to model successfully the properties of macroscopic systems containing $\sim 10^{23}$ particles.

The observed quantities are calculated as averages over a large number ($\sim 10^5 - 10^6$) of instantaneous configurations of this system. In the Monte Carlo method, the configuration is determined by the set of coordinates $\mathbf{r}$, while in the method of molecular dynamics it is determined by the set of coordinates $\mathbf{r}$ and the momenta $\mathbf{p}$ of the particles (the molecules of reactants and the medium) in the cell. Both methods were developed and have been widely used in relation to equilibrium chemical systems and have begun to be employed only recently in the study of the dynamics of chemical reactions. Studies on equilibrium chemical systems have shown that, despite the serious simplifications characteristic of the molecular dynamics and Monte Carlo methods (the ergodic hypothesis and the restrictions imposed on the number of particles in the cell and on the modelling time), both methods make it possible to calculate with satisfactory accuracy, using only the microscopic characteristics of the system (the interparticle interaction potentials and the masses of the particles), the equilibrium macroscopic characteristics of real chemical systems (heat capacity, density, equilibrium constants, etc.). Calculations by the Monte Carlo method are more economical as regards computer time than modelling of the same system by the method of molecular dynamics. On the other hand, the Monte Carlo method is applicable, because of its very nature, only to equilibrium systems. Therefore, in the study of the dynamics of chemical reactions in condensed phases the FES characteristics are calculated in the first stage by the Monte Carlo method and the rate constant is determined within the framework of the equilibrium transition state theory, while the transmission factor $\varkappa$ is calculated (but not always) in the second stage by the method of molecular dynamics. We shall consider both methods in greater detail, emphasising their applications to the dynamics of chemical reactions.

1. The Monte Carlo method

A random sequence of configurations of the system $\{\mathbf{r}_j\}$ is used in the Monte Carlo method.[11,12] Their energies obey the Boltzmann distribution $\exp[-U(\mathbf{r}_j)/kT]$ and Eqn. (II.1) is replaced by the average over the configurations realised:

$$<A> = \frac{1}{M}\sum_{j=1}^{M} A\{\mathbf{r}_j\}, \qquad \text{(II.2)}$$

where M is the number of configurations. The random sequence $\{\mathbf{r}_j\}$, sometimes called the trajectory of the Monte Carlo method, is generated with the aid of the Metropolis algorithm. The Metropolis algorithm and the details of the Monte Carlo method in relation to equilibrium chemical systems have been described in detail.[7,11,12] The texts of the Fortran and Basic programs, which employ the Monte Carlo method for equilibrium[13,14] and non-equilibrium[12] systems, have been published.[12–14] We shall consider below only the versions of the Monte Carlo method applicable to calculations for chemical reactions. The majority of the points on the Monte Carlo trajectory correspond to the configurations with energies close to the minimum value, precisely the configurations which make the main contribution to the partition functions used in the calculations of the equilibrium characteristics of the system. This approach is relatively ineffective in the calculation of the free energy of activation $\Delta G^{\neq}$.

We are interested in the free energy changes along the reaction coordinate x. In principle, they can be determined by averaging the probability of realising different values of x along the Monte Carlo trajectory. The distribution function $g(x)$, which yields the dependence of the free energy on x to within an additive constant C, is usually calculated:

$$G(x) = -kT\ln[g(x)] + C. \qquad \text{(II.3)}$$

The quantity $G(x)$ defined in this way is sometimes referred to as the average force potential. In order to achieve satisfactory statistics of the values in the vicinity of the transition state with a coordinate $x = x^{\neq}$ and a relative potential energy $\Delta U^{\neq}$, the Monte Carlo trajectory must pass fairly frequently through regions of the configuration space whose energies relative to the reactants minimum are close to $\Delta U^{\neq}$. The probability of the occurrence of such configurations for points on the Monte Carlo trajectory is proportional to $\exp(-\Delta U^{\neq}/kT)$ i.e. it is negligible when $\Delta U^{\neq} \gg kT$. In the usual version of the Monte Carlo method, it would therefore be either necessary to generate an extraordinarily long sequence of configurations or to be content with a very rough estimate of $G(x)$. There are two main ways of obviating this difficulty. The first is called the method of importance sampling[10,12] and the second is referred to as the statistical theory of perturbations.[10,13]

The method of importance sampling involves the imposition of an artificial external potential V, which "forces" the Monte Carlo trajectory to remain for most of the time in the region with the value of x in which we are interested. The potential V usually has a constant negative value within the range $(x - \Delta/2, x + \Delta/2)$ and is zero outside it. A sequence of configurations with a non-Boltzmann distributon of probabilities $\exp[-(U + V)/kT]$ is then generated and most of the points on the resulting Monte Carlo trajectory correspond to the range $(x - \Delta/2, x + \Delta/2)$. Within the range indicated, the relative probabilities of different values of V obey the Boltzmann distribution.

The imposition of the external potential V creates, as it were, a "window" which makes it possible to see the distribution of the probabilities of the values of x along the given section of the reaction coordinate. By carrying out a series of Monte Carlo calculations with window potentials V_j centred on different sections of the reaction coordinates which must partly overlap, we find for each window i its own distribution function $g_i'(x)$. The true distribution function $g(x)$ in the ith interval $(x - \Delta/2, x + \Delta/2)$ is related to distribution function in the corresponding window by the formula $g(x) = C_i g_i'(x)\exp(V_i/kT)$, where C_i is a normalised constant. The constants C_i are determined from the condition of the continuity of $g(x)$. By joining together the functions $g_i'(x)$ calculated for different intervals i, we obtain a single function $g(x)$ embracing the entire range of variation of x—from the reactants to the transition state.

An alternative to the importance sampling method is the statistical perturbation theory.[10,12,15] It is based on the formula:

$$G(H_0 + H_1) - G(H_0) = -kT\ln <\exp(-H_1/kT)>_0, \qquad \text{(II.4)}$$

where H_0 is the Hamiltonian of the initial system, H_1 is the perturbation, and the averaging $<\ldots>_0$ is carried out with respect to the distribution of the initial system. When applied to the Monte Carlo method, this means that trajectories corresponding to the Hamiltonian H_0 are generated. The expansion of the exponential function $\exp(-H_1/kT)$ in Taylor's series corresponds to the thermodynamic perturbation theory. In the calculation of the free energy profile, the configuration of the reactants minimum might be adopted as the initial system assuming that the non-equilibrium configurations along the reaction coordinate up to the transition state are perturbed systems. Eqn. (II.4) yields the exact computational algorithm, but, if the perturbation H_1 is large, the calculations converge slowly. The calculation is therefore carried out by scanning along x in several stages, so that in each step an acceptably small perturbation is achieved. The calculation requires careful optimisation of the length of the step and is refined in each step by the alternate replacement of the initial and final configurations.

The practical execution of the program for the evaluation of the free energy of activation in solution throughout the entire volume has been achieved for the simplest S_N2 substitution reaction [Eqn. (I.3)][16] and for the nucleophilic addition of OH^- to $H_2C{=}O$.[17] We shall consider the principle stages in the calculations and we shall discuss the results in relation to reaction (I.3).

1. The gas-phase reaction pathway corresponding to the potential energy minimum in the cross-section, i.e. the gas-phase reaction coordinate, was determined in the first stage with the aid of non-empirical quantum-chemical calculations. The parameters of the empirical analytical potential, describing the interaction in the chemical system along the reaction coordinate x, were selected.

2. Quantum-chemical calculations for the interaction of the reacting system with a single solvent molecule were carried out in the second stage for different values of x and the parameters of the solvent–reacting system interaction potentials were evaluated as functions of x. The potentials of the interaction between the solvent molecules had been calibrated previously.

3. The one-dimensional average force potential was calculated in the third stage by the importance sampling method and the activation energy $\Delta G^{\neq}$ was calculated with its aid.

Specific calculations have been carried out for two polar solvents—water and dimethylformamide (DMF).[16] The potential and free energy curves obtained are presented in Fig. 1. Evidently the section through the FES calculated for an aqueous medium has little in common with the gas-phase potential energy curve. On passing from the gas phase to the aqueous solution, the minima corresponding to the pre-reaction and post-reaction ion–dipole complexes vanish almost completely and the height of the activation barrier increases from 4 to 26 kcal mol^{-1}. For the reaction in DMF, the differences from the gas phase are not so large. The activation barrier increases to 18 kcal mol^{-1} and, in addition, in DMF there are distinct although not quite so deep as in the gas phase, minima for the ion–dipole complexes. The latter factor is important, since it requires a revision of the traditional ideas concerning the single-stage mechanism of the S_N2 reactions in solutions occurring without the formation of intermediates.

Similar results have been obtained[18,19] for the S_N2 reaction in a polar medium using semiempirical quantum-chemical approaches in the stage involving calculations for the interactions in the chemical subsystem and partly the interactions between the chemical subsystem and the solvent molecules in combination with the statistical perturbation theory in the stage involving the calculation of the free energy.

2. The method of molecular dynamics

Despite the apparently self-evident nature of the molecular dynamics method and the simplicity of the underlying idea, the theoretical aspects of its numerical application merit examination. It is known[20] that the differential equations of motion in the method of molecular dynamics with the intermolecular interaction potentials normally employed are locally unstable. This means that the solutions corresponding to similar initial conditions can differ very greatly. The numerical solution of the equations of motion inevitably introduces an error, which can be treated as a change in the initial conditions. It is therefore important to analyse the dependence of the results of the modelling on the characteristics of the system and on the selected algorithm for the solution of the dynamic equations. In estimating the errors of numerical methods, one usually compares the results of computer calculations carried out with the accuracy of the arithmetical operations and with twice such accuracy.

In the case of molecular dynamics, it is possible to estimate directly the accuracy of the method on the basis of the invariance of Newton's equations relative to changes in the sign of the time. The calculated trajectories for a specific time interval with subsequent inversion at the final point of the signs of the momenta of all the particles and the calculation of the trajectory of the reverse motion should lead to the initial point in the phase space. In reality, numerical calculation does not lead to the return to the exact starting point and the differences obtained between the initial and final points constitute an estimate of the accuracy of solving the equations of motion.

Systematic studies[20] on the forward and reverse trajectories for systems with a short-range interaction potential (Lennard-Jones) have led to a series of important conclusions concerning the errors in numerical modelling by the method of molecular dynamics. Analysis of the accumulated errors led to the conclusion that the results of the molecular dynamic experiment resemble in many respects the solutions of the stochastic Langevin equation, which will be examined in detail in the next Section. For short modelling times, the standard errors of the coordinates and momenta of the particles vary linearly with time, the duration of the linear interval depending on the algorithm for the solution of the differential equations, in particular on the degree of the equation fitted to the function to be integrated. With increase in the modelling time, the system becomes stochastic and the error of the calculation is found to depend solely on its physical characteristics and not on the numerical application of the method of molecular dynamics. The error is expressed in this case in terms of the entropy of the system by the Krylov–Kolmogorov procedure.[20]

The existence of errors in the method of molecular dynamics leads to a randomly migrating trajectory in a layer with a thickness ΔE resembling the trajectory of the Monte Carlo method. This means that the modelling in the method of molecular dynamics, formally carried out for a microcanonical ensemble taking into account the random scatter of the values of ΔE, possesses features of averaging with respect to a canonical ensemble. Thus the numerical application of the method of molecular dynamics introduces a series of fundamental factors which infringe the deterministic nature of the initial equations and which render the method of molecular dynamics similar to other approaches used in the modelling of multiparticle systems—the Monte Carlo method and stochastic equations. It is useful to bear these considerations in mind in comparing the results of various approaches to the description of the kinetics of chemical reactions in a condensed phase.

3. Calculation of the transmission factor by the reaction flux method

We shall consider how the complete dynamic theory, free from the limitations of the approximation of the transition state theory, is formulated within the framework of classical dynamics.[12,21] The idea of a "critical surface" in the configuration space, separating regions of the reactants and products, is introduced as a basis. The reaction coordinate x is normal to the surface. If this coordinate is known, then the equation of the surface in the vicinity of the transition state can be formulated as follows:

$$x = x^{\neq}. \tag{II.5}$$

The simplest and commonest is the selection of the top of the barrier on the FES profile as the coordinate $x^{\neq}$.

Another important factor is the introduction of the characteristic function

$$\eta[x(t)] = \begin{cases} 1 \text{ when } x(t) > x \\ 0 \text{ when } x(t) < x^{\neq} \end{cases} \tag{II.6}$$

i.e. η is a power function. It is a function of time and a functional of the classical trajectory $x(t)$. The starting point of the trajectory at $t = 0$ is selected on the critical surface. The distribution of the initial conditions is assumed to correspond to equilibrium. In particular, the initial rates $\dot{x}(t = 0)$ are taken from the equilibrium (Maxwell) distribution. In the course of dynamic evolution, the trajectory can intersect repeatedly the critical surface but ultimately, at $t \to \infty$, it always remains either in the reactants region or in the products region. In the former case

$$\eta[x(t)] = 1 \text{ when } t \to \infty, \tag{II.7}$$

while in the latter

$$\eta[x(t)] = 0 \text{ when } t \to \infty. \tag{II.8}$$

The conditions (II.7) and (II.8) can hold only in a multidimensional system (strictly speaking a macroscopic system), since otherwise even at $t\to\infty$ transitions from the reactants to the products region and conversely are inevitable on a two-well FES.

The classical rate constant is calculated from the equation

$$K = \lim_{t\to\infty}\left\langle \delta\left(x - x^{\neq}\right)\dot{x}(t=0)\,\eta\left[x(t) - x^{\neq}\right]\right\rangle. \qquad \text{(II.9)}$$

The angular brackets denote averaging with respect to the equilibrium distribution i.e. correspond to the equilibrium initial conditions on the critical surface. It can be shown that in the limit $t\to 0$ this average value reduces to the rate constant in terms of the approximation of the transition state theory:

$$K_{TS} = \lim_{t\to 0}\langle \delta(x^{\neq} = x)\,\dot{x}(t=0)\eta[x(t) - x^{\neq}]\rangle =$$

$$= \langle \delta(x = x^{\neq})\,\dot{x}(t=0)\eta\,\dot{x}(t=0)]\rangle .$$

We used the fact that $x(t) - x = t\dot{x}(t = 0)$ when $t\to 0$. Consequently the transmission factor $\varkappa$ is

$$\varkappa = \frac{\lim_{t\to\infty}\langle \delta(x = x^{\neq})\dot{x}(t=0)\eta[x(t) - x^{\neq}]\rangle}{\langle \delta(x - x^{\neq})\dot{x}(t=0)\eta[\dot{x}(t=0)]\rangle} . \qquad \text{(II.10)}$$

In fact, the calculation of the transmission coefficient reduces to studying an ensemble of the trajectories $x_i(t)$ with equilibrium initial conditions on the critical surface. In calculating the contributions of the trajectories to the transmission factor, one should take into account correctly their direction and the sign of the initial rate. Various recipes have been proposed for this purpose.[5,21–25] We shall consider one of them. For all the trajectories, the initial rate $\dot{x}(t = 0) = \dot{x}$ is positive. The trajectories extend both into the future ($t > 0$, $t\to\infty$) and into the past ($t < 0$, $t\to-\infty$). The evolution of each trajectory can be traced for a fairly long time (in practice for ~3 ps). After this, a characteristic multiplier Q_i is attributed to each trajectory $x_i(t)$:

$$Q_i = 1, \text{ when } t>0 \;\; x_i > x^{\neq} \text{ at } t\to\infty ,$$

$$Q_i = -1, \text{ when } t<0 \;\; x_i > x^{\neq} \text{ at } t\to-\infty , \qquad \text{(II.11)}$$

$$Q_i = 0 \begin{cases} \text{when } t>0 \; x_i < x^{\neq} \text{ at } t\to\infty , \\ \text{when } t<0 \; x_i < x^{\neq} \text{ at } t\to-\infty . \end{cases}$$

The trajectories with $Q_i = 1$ are reaction trajectories, while those with $Q_i = 0$ are non-reaction trajectories. The trajectories with $Q_i = -1$ may be called anti-reaction trajectories since their contribution is subtracted from the total reaction flux. One can write for the transmission factor

$$\varkappa = \frac{\Sigma_i W_i \dot{x}_i Q_i}{\Sigma_i W_i \dot{x}_i} , \qquad \text{(II.12)}$$

where W_i is the Maxwellian weighting factor.

4. Examples of calculations by the method of molecular dynamics

The first reaction in a condensed phase for which it was possible to carry out direct calculations of the rate constant by the method of molecular dynamics was the *gauche–trans* isomerisation of n-butane in liquid CCl_4.[26] The molecular dynamics calculations were performed for a unit cell containing a n-butane molecule and 122 CCl_4 molecules. The modelling conditions corresponded to a temperature of ~300 K. The interactions of the solvent molecules with one another and with the solute were described by the Lennard-Jones potentials. The CCl_4 molecules were assumed to be spherically symmetrical, while the n-butane molecule was assumed to consist of a chain of four Lennard-Jones spheres rotating about the central axis.

The calculations were performed for two models of the medium: a liquid solvent with moving CCl_4 molecules and a "frozen" vitreous solvent, in which the positions of the CCl_4 molecules were fixed in one of the equilibrium configurations obtained by the Monte Carlo method. The time variation of the rate of reaction $K(t)$ and the transmission factor $\varkappa = K(t)/K(0)$ were calculated by the reaction flux method using the formula (II.12).[21] Here $K(0)$ is calculated in the initial instant and, as shown above, agrees with the rate constant in the transition state theory.

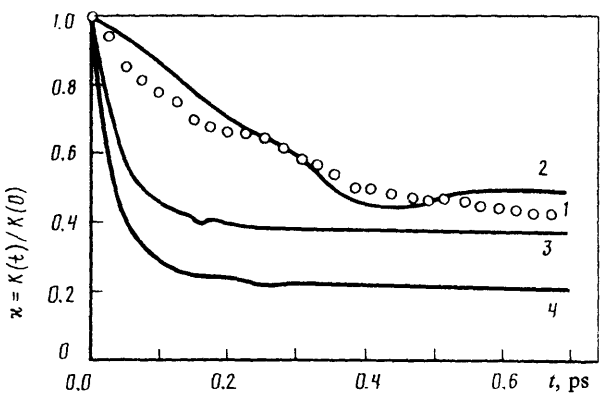

Figure 2. Time variation of the transmission factor $\varkappa = K(t)/K(0)$ calculated from Eqn. (II.12) by the method of molecular dynamics (curve *1*) and the method of stochastic dynamics (curves *2–4*) based on the kinetic Bohm–Gross equation (see text) for the isomerisation of n-butane in liquid CCl_4:[28] (*2*) $\nu = 0.2 \times 10^{13}$ s^{-1}; (*3*) $\nu = 4.0 \times 10^{13}$ s^{-1}; (*4*) $\nu = 10.0 \times 10^{13}$ s^{-1}.

The calculated relations are presented in Fig. 2. The points were obtained by numerical modelling and the continuous lines are a result of the solution of the stochastic equation (subsection II.5). The form of the curves obtained for the liquid and vitreous solvents is completely analogous. In both cases the $K(t)/K(0)$ curve reaches a plateau almost at the same time. The existence of the plateau makes it possible to consider the existence of a rate constant for the given reaction. The transmission factor in the region of the plateau for the liquid solvent ($\varkappa = 0.361$) does not differ greatly from the value $\varkappa = 0.276$ obtained for the vitreous solvent. This can be

partly explained by the fact that the mass of the solvent molecules is much greater than the mass of the n-butane units: $m_{CH_4}/m_{CCl_4} = 0.11$. The small molecules therefore move much more slowly than the methyl groups of n-butane.

One of the problems for the solution of which the application of the method of molecular dynamics is most fruitful is that of testing the applicability of the approximate models describing the influence the medium on the rate of reaction. Calculations for the chair–boat type of isomerisation of cyclohexane are instructive in this sense.

It was observed at the beginning of the 1980's[28,29] that the rate of isomerisation of cyclohexane increases with increase in pressure. The experimental pressure dependence of the free energy of activation, which determines the pressure dependence of the rates within the framework of the transition state theory, proved to be too weak to account for the observed relation. Calculation[30] by the method of molecular dynamics within the framework of the stochastic model (see the next Section) reproduced the observed effect.

The reason for the discrepancy between the predictions of the transition state theory and the stochastic calculation was elucidated by the Monte Carlo and molecular dynamic methods.[31] The modelling was carried out for the cyclohexane molecule in a cell containing 250 CS_2 molecules. An empirical intermolecular potential, which satisfactorily reproduced the geometry and conformational properties of the cyclohexane, was used. The solvent–solvent and solvent–cyclohexane intermolecular interactions were described by Lennard-Jones potentials. The energy of the system corresponded to a temperature of 300 K and the density (ρ = 1.0, 1.3, 1.4, and 1.5 g cm^{-3}) corresponded to the experimental pressure range. The calculations of the free energy of activation $\Delta G^{\neq}$ by the Monte Carlo method using window potentials showed that an increase in density from 1.0 to 1.5 g cm^{-3} does not alter $\Delta G^{\neq}$ to within the accuracy determined by the statistical scatter. A more detailed allowance for the influence of the medium at ρ = 1.5 g cm^{-3} yielded a positive contribution of solvation to the activation barrier, amounting to 0.08 $\pm$ 0.02 kcal mol^{-1}. This means that, according to the transition state theory, the rate of reaction should diminish only slightly with increase in pressure. The molecular dynamic calculation demonstrated that, on the contrary, the transmission factor $\varkappa$ increases from 0.34 to 0.47 with increase in density, which in fact produces an increase in the rate of reaction.

The establishment of the theory of gas-phase reactions, in particular the transition state theory, was in many respects based on theoretical and experimental studies of the substitution reaction:

$$A + BC \rightarrow AB + C, \qquad (II.13)$$

which is the simplest chemical reaction in which bonds are simultaneously ruptured and formed. Reactions (II.13) proved to be suitable for the elucidation of the mechanism of the elementary chemical step and the fundamental concepts of theoretical chemical kinetics were in fact first formulated in relation to these processes as an example. An enormous amount of experimental data, obtained in the gas and liquid phases, has accumulated for substitution reactions, indicating a wide variety of their mechanisms. These factors explain the interest in the study of reactions (II.13) by various theoretical methods, including the method of molecular dynamics.[32–34]

In the initial version,[32] the hypothetical reaction

$$X + X_2 \rightarrow X_2 + X \qquad (II.14)$$

was modelled in a cell containing 100 atoms of the medium [an inert gas (He, Ar, or Xe) with the density corresponding to the liquid state]. The interaction in the chemical subsystem X_3 was described by the London–Eyring–Polanyi–Sato (LEPS) potential, usually employed in theoretical studies on the gas-phase reactions involving triatomic sytems.

Three series of calculations were performed with the parameters of the LEPS potential corresponding to barrier heights of 20, 10, and 5 kcal mol^{-1} and frequencies of the decomposition mode at the top of the barrier of 419, 288, and 168 cm^{-1} respectively. The chemical subsystem–solvent and solvent–solvent interactions were described by the Lennard-Jones potentials. In calculations with high gas-phase activation barriers (20 and 10 kcal mol^{-1}), not one case of a repeated intersection of the critical surface by trajectories was observed. All the trajectories starting from the critical surface at velocities directed towards the reactants appeared at the reactants minimum, while all the trajectories with initial velocities directed towards the products appeared at the products minimum. This is a result of the weakness of the interaction of the X_3 system with a medium comprising a liquid inert gas. Only for a low barrier (5 kcal mol^{-1}) with a small curvature in the vicinity of the transition state did individual trajectories reintersect with the critical surface. In this case transmisison factors $\varkappa$ of 0.97, 0.91, and 0.91 were obtained respectively for the reactions in He, Ar, and Xe. Thus calculations by the method of molecular dynamics for reaction (II.14) in a system interacting weakly with the medium showed that, for sufficiently high barriers, the transition state theory constitutes a satisfactory approximation for the calculation of the rate constant. This estimate agrees with the conclusion known from the gas-phase theory.

In order to elucidate the limits of the applicability of the transition state theory, it is desirable to investigate chemical reactions by the method of molecular dynamics under the conditions of strong interaction with the medium. A good example is provided by the ionic version of the substitution reaction (II.14)–an S_N2 (I.3) reaction occurring in a polar medium.

The $Cl^- + CH_3Cl$ reaction in an environment comprising 64 H_2O molecules has been modelled[33,34] by the method of molecular dynamics. A potential of the LEPS type was adopted for the $Cl^- + CH_3Cl$ system. In the one-dimensional case, it reproduced the principal characteristics of the potential used in a study[16] of this reaction by the Monte Carlo method. The potential of the interaction of the solvent molecules with the chemical system depended on the charge distribution in the latter, which varied continuously along the reaction coordinate. The calculations yielded a transmission factor $\varkappa$ = 0.55.

The main qualitative result consisted in the description of the dynamic events occurring in the vicinity of the barrier. The outcome of the reaction is usually determined in the course of the first 0.02 ps after the start of the trajectory from the top of the potential barrier. This period is much shorter than the reorientation time of the solvent molecules. For a sufficiently high potential barrier, the reaction in the vicinity of the transition state is determined by the potential generated by the configuration of the solvent "frozen" in this state, which was the equilibrium configuration at an earlier stage but is a non-equilibrium configuration in relation to the transition state.

The presence or absence of ternary points on the trajectory depends on the configuration of the solvation shell in the initial instant. Having been selected at random this configuration makes an additional contribution to the potential barrier which is

asymmetric relative to the gas-phase top of the barrier. Whether the reaction occurs or not depends on the direction in which the given trajectories starts relative to this fluctuation barrier. The average picture corresponds to an effective decrease in the curvature of the potential barrier in the vicinity of the transition state, which reduces the transmission factor.

The situation described can be reproduced at the phenomenological level with the aid of the stochastic theory, which will be examined in detail in the succeeding Sections of the present review. Using the trajectories calculated by the method of molecular dynamics, the correlation function for a random external force acting on the variable reaction coordinate has been determined.[34] The principal dynamic characteristic of the corresponding generalised Langevin equation (GLE)—the friction kernel—is expressed directly in terms of this correlator.[33,34] The transmission factor, obtained as a result of the solution of the GLE by a standard approximate method (The Grote—Hynes method), agrees satisfactorily with the result of the direct dynamic calculation.

The dynamic study considered above constitutes undoubtedly an outstanding computational achievement. It demonstrates not only the possibilities of modern methods of the computer modelling of reactions but also their limitations. Thus the qualitative picture of the dynamics of the trajectories in the vicinity of the barrier, described in detail above, is incorrect or at least is only partly correct. The point is that in the method of molecular dynamics, which is applied using simplified potentials (atom—atom potentials) because of computational limitations, one cannot take into account the polarisation of the electrons of solvent molecules caused by the dynamic charge redistribution in the chemical subsystem in the course of evolution along the molecular dynamic trajectory. This, so called non-inertial polarisation, is almost instantaneously adjusted to the current charge distrubution, in contrast to the orientation polarisation associated with the motion of heavy molecular fragments, which, as shown above, remains frozen in the course of the reaction. Since the non-inertial polarisation is known to constitute not less than 40% of the total polarisation of the medium by the chemical subsystem, one may conclude that the inference concerning the "frozen" medium, which is undoubtedly valid within the framework of the given molecular dynamic study, cannot be extended to the real development of events in an S_N2 reaction.

In conclusion we may note that the problem of calculating the absolute rate constant for reaction (I.3) has not been fully exhausted. The point is that the calculation by the Monte Carlo method described above (subsection II.1) was carried out for a one-dimensional set of rigid configurations of the chemical subsystem located along the reaction coordinate. The corresponding free energy profile takes into account only the contribution of solvent molecules to the partition function. The contribution of the motions of the chemical subsystem to the pre-exponential factor has not so far been calculated. Thus the Arrhenius exponential function (the calculation of $\Delta G^{\neq}$ [16] yields the activation energy) and the transmission coefficient $\varkappa$ have been found,[33,34] but the contribution to the pre-exponential factor, calculated within the framework of the usual transition state theory, has not been determined. The difficulty is associated with the estimation of the corresponding partition functions for the chemical subsystem in solution. A well-founded solution of the problem requires an extremely complex calculation by the Monte Carlo method taking into account the configurations of the reactants with complete allowance for their interactions (and their internal structure) with solvent molecules on different bases.

5. Application of the method of molecular dynamics in the modelling of chemical kinetics by stochastic equations

The stochastic theory, which provides the most general and natural methods for the description of many-particle systems, is widely used in the study of the influence of the medium on chemical reactions. In the subsequent Sections of the present review, it is discussed in detail at a qualitative level. The direct numerical solution of stochastic equations constitutes a more complex problem, which can be solved by the method of molecular dynamics within a certain range of dynamic parameters. Calculations of the trajectories (the reaction flux method) have been used[35–39] to extract kinetic information from the Langevin equation (LE) and the generalised Langevin equation.

Here we shall describe in greater detail an alternative stochastic model based on the kinetic Bohm—Gross equation.[41] In this model, the phase point $(\mathbf{r}, \dot{\mathbf{r}})$ of a system comprising N particles evolves subject to the potential $U(\mathbf{r})$ in conformity with Newton's equations. At a random instant t', the velocity of the ith particle $\dot{r}_i$ changes abruptly to $\dot{r}'_i$. The evolution then continues until the time t'', when the velocity of the jth particle (this can be any particle including the ith particle) changes abruptly to $\dot{r}''$, and so on. The velocities $\dot{r}'$, $\dot{r}''$, ... are selected at random from the Maxwell distribution. The time intervals t' after which the velocities of the particles become stochastic are statistically independent and obey the Poisson distribution:

$$P_n(t) = \frac{(\nu t)^n}{n!} \exp(-\nu t),$$

where ν has the significance of the collision frequency. This algorithm is equivalent to the solution of the kinetic Bohm—Gross (BG) equation[36] for the distribution function $f(\mathbf{r}, \dot{\mathbf{r}}; t)$

$$\left[\frac{d}{dt} + \hat{L}\right] f(\mathbf{r}, \dot{\mathbf{r}}; t) = \hat{D}(\nu) f(\mathbf{r}, \dot{\mathbf{r}}; t), \qquad \text{(II.15)}$$

where $\hat{L}$ is the Liouville operator describing the evolution of the system in the absence of collisions and $\hat{D}(\nu)$ is an integral operator taking into account the influence of collisions. One may point to the relation between this approach and the stochastic theories discussed below. The Langevin equation can be reduced by a standard procedure to the Fokker—Planck equation.[42] On the other hand, the latter differs from Eqn. (II.15) only by its right-hand side: the corresponding collision operator describes the diffusion process subject to the external forces potential.

The solution of the Bohm—Gross equation (II.15) with the aid of the Laplace transformation makes it possible to write formal expressions for the correlaton functions in terms of which the rate of the chemical reaction is expressed.[40,43] Analytical studies on the expressions obtained have been carried out for two limiting cases corresponding to low and high collision frequencies ν. In the diffusional limit for high values of ν, Eqn. (II.15) reduces to the Smoluchowski equation with a coefficient of friction ν/m [the equivalent of the intense friction limit in the Langevin equation (see sub-section III.2).

Within the framework of this technique, the reaction flux method (see sub-section II.3) was first applied to the study of chemical reaction kinetics.[40] The simplest unimolecular reactions were considered—conformational isomerisation of alkanes in a non-polar solvent.[27,40] The interaction with the medium was described by a single parameter—the collision frequency ν. In specific calculations a value with the same order of magnitude as the average collision

frequency in the modelling of the solvent by the method of molecular dynamics using the hard sphere potential was adopted as ν. The dependence of the result of the calculations on ν when the latter was varied in the range $(2-300) \times 10^{12}$ s^{-1} has been studied in detail.[27,40]

Fig. 2 presents the time variations of the rate constant $K(t)$ for the *trans–gauche* isomerisation of n-butane obtained by the reaction flux method[21] within the framework of the Bohm–Gross model[27] and by the method of molecular dynamics.[26] The values of $K(t)/K(0)$, where $K(0)$ is the rate in the initial instant equal exactly to the rate constant in the transition state theory, were plotted along the ordinate axis. After the initial transition period, the duration of which depends on the parameter ν, the value of $K(t)$ reaches a plateau, as in the usual molecular dynamics calculation. The quantity $K(t)/K(0)$ in the region of the plateau represents the transmission factor $\varkappa$. With increase in the collision frequency ν, the system reaches the plateau sooner and there is a simultaneous decrease in the transmission factor $\varkappa$, in agreement with the result derived from the Kramers theory in the high friction limit (see subsection III.2).

Fig. 2 shows that the results of calculations by the methods of stochastic and molecular dynamics agree best for $\nu = 2 \times 10^{12}$ s^{-1}, which agrees in terms of order of magnitude with the collision frequency in liquid CCl_4 for which the molecular dynamics calculation was carried out. Using certain assumptions, it is possible to determine for specific systems the $\nu(p, T)$ relation (p is the pressure and T the temperature) and thus to determine the dependence of the rate of reaction on the thermodynamic parameters of the system. It has been found[14] that, in the isomerisation of n-butane under normal conditions (T = 300 K, p = 1 atm), the change in the activation barrier $\Delta E^{\neq}$ owing to collisions is very small, while the contribution of collisions to the change in the activation volume $\Delta V^{\neq}$ is approximately an order to magnitude higher than follows from the transition state theory. Several calculations have been devoted to the study of the influence of pressure on the isomerisation of cyclohexane.[27–30]

III. Stochastic dynamics

1. Simplest stochastic equations

In the dynamic theory, an enormous number of coordinates of the medium have to be studied. An effective way of obviating this difficulty is to eliminate most of them from the equation of motion, leaving only significant dynamic variables. Among "significant variables", one includes the internal coordinates of the chemical subsystem and in the first place the reaction coordinate. It is sometimes necessary to examine explicitly one or several coordinates of the medium. This happens in those cases where the reorganisation of the medium is an important or even fundamental condition for the chemical reaction, as happens, for example, in electron transfer processes. The examples presented below illustrate the choice of significant coordinates.

The coordinates which have not been taken into account explicitly (these usually include all the coordinates of the medium with a few possible exceptions) are referred to as the thermostat. The explicitly considered significant coordinates interact (exchange energy) with the thermostat, forming a thermodynamically open system. The dynamics of open systems is described by stochastic equations. The simplest of these, the Langevin equation, deals explicitly with a single dynamic variable:

$$m\frac{d^2x}{dt^2} + \gamma\frac{dx}{dt} = -\frac{dU(x)}{dx} + (\text{random force}). \qquad \text{(III.1)}$$

The first terms on the left-hand and right-hand sides of this equation represent the usual Newtonian contributions: the kinematic term proportional to the acceleration (m is the mass) and the regular force $-dU(x)/dx$. The frictional force added to the left-hand side is proportional to the velocity (γ is the coefficient of friction)†. It describes the dissipation of energy as a result of the interaction of the dynamic variable x with the thermostat. The random force describes the irregular effect of the thermostat on the variable x. In the modelling of a chemical reaction by Eqn. (III.1), the random force ensures the thermal activation of the substrate which is necessary to overcome the potential of the barrier. Its intensity is related to the coefficient of friction in such a way that the joint effect of the random and dissipative forces leads to the establishment of the Boltzmann equilibrium for the variable x during a time significantly exceeding its relaxation period.

For chemical applications, it is necessary to examine a more complex stochastic equation—the so called generalised Langevin equation:[44,45]

$$m\frac{d^2x}{dt^2} + \int_{-\infty}^{t} f(t-\tau)x(\tau)d\tau = -\frac{dU(x)}{dx} + (\text{random force}). \qquad \text{(III.2)}$$

It differs from the Langevin equation (III.1) by a more complex structure of the term describing the dissipative force. The corresponding integral expression depends in each instant t on the entire preceding evolution of the dynamic variable $x(t)$. The quantity $f(t-\tau)$ is called the relaxation kernel or the memory kernel. Dynamic systems with such properties are referred to as non-Markov systems in contrast to the Markov systems in which the frictional force is local in terms of time, i.e depend only on the current instant t. Eqn. (III.2) is obtained when the linear response theory is applied to continuous dynamic models of the medium.[46]

An alternative form of the formulation of the generalised Langevin equation, where the integral term contains the velocity $\dot{x}(t)$ and not the coordinate $x(t)$, is also commonly used:[44]

$$m\frac{d^2x}{dt^2} + \int_0^t \beta(t-\tau)\,\dot{x}(\tau)d\tau = \frac{d\,\bar{U}(x)}{dx} + \text{random force}. \qquad \text{(III.3)}$$

The quantity $\beta(t)$ is called the friction kernel. The different lower integration limit compared with Eqn. (III.2) is in most cases insignificant. To within this difference, Eqns. (III.2) and (III.3) are mathematically equivalent and the integral kernels $f(t-\tau)$ and $\beta(t-\tau)$ as well as the potentials $U(x)$ and $\bar{U}(x)$ are linked by the relations:[44]

$$f(t) = d\beta/dt;\ \bar{U}(x) = U(x) + \frac{\beta(0)x^2}{2}. \qquad \text{(III.4)}$$

The Langevin equation (III.1) can be obtained both from Eqn. (III.2), when the memory kernel is the derivative of the Dirac delta function:

$$f(t) = \gamma\delta'(t), \qquad \text{(III.5)}$$

† The quantity γ/m is sometimes referred to as the coefficient of friction.[42–45]

and from Eqn. (III.3) if

$$\beta(t) = \gamma\delta(t). \tag{III.6}$$

The intensity of the random force on the right-hand side of Eqn. (III.2) is linked to the kernel $f(t)$ by the relation called the fluctuation-dissipative theorem (FDT). We shall designate the random force by $F(t)$ and its autocorrelation function by $<F(t)F(0)>$ [the averaging is over instances of the random process $F(t)$]. The Fourier transform of the autocorrelation function is designated by

$$\left(F^2\right)_\omega = \int_{-\infty}^{+\infty} \langle F(t)F(0)\rangle \exp(i\omega t)\mathrm{d}t.$$

Then FDT assumes the form[45–47]

$$(F^2)_\omega = -\frac{2kT}{\omega}\,[\mathrm{Im}f(\omega)], \tag{III.7}$$

where $f(\omega)$ is the Fourier transform of the kernel $f(t)$:

$$f(\omega) = \int_{-\infty}^{+\infty} f(t)\exp(i\omega t)\mathrm{d}t. \tag{III.8}$$

It can be shown that the imaginary component of $f(\omega)$ is always negative.

In the case of Eqn. (III.3), the FDT is written in the following form:[44,45]

$$<F(t)F(0)> = kT\beta(t). \tag{III.9}$$

The two forms of the FDT, namely Eqns. (III.7) and (III.9), are equivalent, which can be readily established using Eqn. (III.4). The FDT ensures the establishment in the system of a Boltzmann equilibrium for times exceeding the relaxation period. The analogous relation for the Langevin equation (III.1) mentioned above is a special case of the FDT.

Henceforth we shall always assume that the random force $F(t)$ is Gaussian.[43–45] In this case, it is fully determined by its autocorrelation function. If the friction kernel has been specified, then the FDT fully determines the Gaussian random force. This factor permits the description of the dynamics of the medium by only one friction kernel in a phenomenological study of reactions in a condensed medium. The Langevin equation was first used for the description of Brownian motion of colloidal (i.e. macroscopic) particles. In applying it in the theory of elementary chemical processes, it is essential to remember that the coordinate x in Eqn. (III.1) characterises the changes in the chemical subsystem and is a microscopic variable. Therefore the interpretation of γ as a macroscopic coefficient of friction is illegitimate although it is frequently used. The quantity γ as well as the integral kernels $f(t)$ and $\beta(t)$ should be regarded as phenomenological characteristics of the interaction between the chemical subsystem and the medium. Their microscopic interpretation is discussed below.

2. Extraction of kinetic information from stochastic equations

If the potential (more precisely the free energy profile) is represented by a two-well curve, then such equations decribe the dynamics of the transition through the barrier and can model the chemical reaction (Fig. 3). The corresponding frequencies (the frequency at the top of the barrier $\omega^{\neq}$ is imaginary) are:

$$\omega_0^2 = \lambda_0/2m, \qquad (\omega^{\neq})^2 = -\lambda^{\neq}/2m.$$

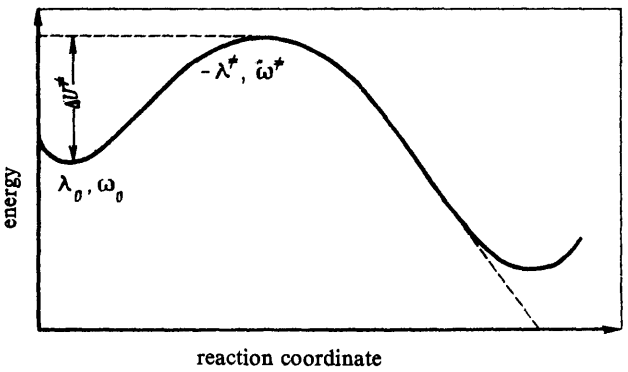

Figure 3. Potential curve (free energy profile) for a chemical reaction in a condensed medium; $\Delta U^{\neq}$ is the height of the barrier, λ_0 and $-\lambda^{\neq}$ are the force constants at the reactants minimum and at the top of the barrier ($\lambda_0 > 0$, $\lambda^{\neq} > 0$) and ω_0 and $\omega^{\neq}$ are the corresponding frequencies. In the Kramers theory, the presence of the second well is ignored (dashed straight line).

The rate constant in Eqn. (III.1) has been calculated by Kramers.[48] If the condition

$$\gamma/m\omega_0 >> 1, \tag{III.10}$$

has been fulfilled, then

$$K = \frac{\Omega}{2\pi}\sqrt{\lambda_0/\lambda^{\neq}}\exp(-\Delta U^{\neq}/kT),$$
$$\Omega = \sqrt{(\gamma/2m)^2 + (\omega^{\neq})^2} - \gamma/2m. \tag{III.11}$$

When

$$\gamma/2m\omega^{\neq} >> 1 \tag{III.12}$$

the expression for the rate constant assumes a simpler form:

$$K = \frac{\omega_0\omega^{\neq}m}{2\pi\gamma}\exp\left(-\frac{\Delta U^{\neq}}{kT}\right). \tag{III.13}$$

This is the so called high friction limit in the Kramers theory, where the rate constant is inversely proportional to the coefficient of friction. If Eqn. (III.11) is extended to the region of low friction, formally ignoring the limitation (III.10), then the well known result

$$K = \frac{\omega_0}{2\pi}\exp(-\Delta U^{\neq}/kT) = K_{\mathrm{TS}}, \tag{III.14}$$

is obtained, which is equivalent to the application of the transition state theory without taking into account the influence of the medium.

The condition (III.10) defines the regions of intermediate and high friction. In the region of very low friction, where

$$\gamma/m\omega_0 << kT/\Delta U^{\neq}, \tag{III.15}$$

a different expression is valid for the rate constant. It differs from Eqn. (III.11) by the pre-exponential factor, which is directly proportional to the coefficient of friction. In this region the kinetics are limited by the thermal activation of the chemical system. The rate constant increases in proportion to the intensity of the random force ensuring activation, which is proportional to γ according to the FDT.

The overall dependence of the rate constant on γ, predicted by the Kramers theory, is presented in Fig. 4. Between its two-branches, corresponding to the increase and decrease in K, there is a transition region; in order to find the solutions in this region, use is made of numerical methods for the solution of the generalised Langevin equation.[3,5–39] The exact value of the constant K is always less than that calculated by Eqn. (III.14) obtained in the primitive transition state theory without taking into account the influence of the medium.

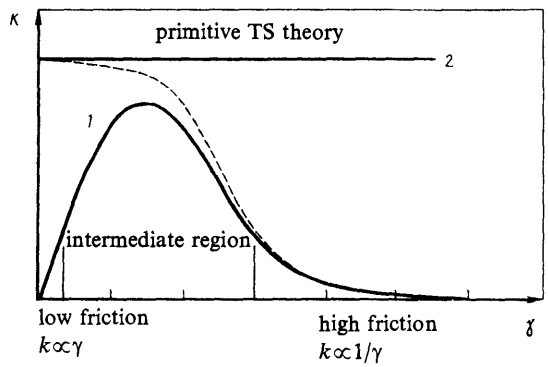

Figure 4. Dependence of the rate constant K on the coefficient of friction γ in the Kramers theory (curve *1*) and in the primitive transition state theory (curve *2*). The regions of high and low friction are described by simple formulae. Dashed curve—calculation by Eqn. (III.11). Upper horizontal line (primitive transition state theory)—calculation by Eqn. (III.14).

It is sometimes assumed that the quantity γ is proportional to the hydrostatic viscosity of the medium. The Kramers theory stimulated the experimental search for the relation between the reaction rates and the viscosity‡.[49,50] The decrease in K with increasing viscosity has been observed in a number of cases. On the other hand, the question of the existence of a kinetic regime for which the rate of reaction increases with increasing viscosity still remains open. The point is that the thermal activation of a fairly complex chemical subsystem can be achieved not only through the interaction with the medium but also as a result of energy exchange within the subsystem itself. This effect, which is not taken into account within the framework of the simple model (III.1), is independent of the viscosity and can render the Kramers model insignificant in the region of very low friction [Eqn. (III.15)].

‡ This concerns the effect of the viscosity on the kinetics of an elementary chemical process and not its trivial effect, which is always observed for diffusion-controlled reactions.

For the generalised Langevin equation (III.3), the rate constant for a system with a two-well potential was calculated by Grote and Hynes.[51] It has the form of Eqn. (III.11) with a modified expression for the decomposition frequency Ω. This quantity is determined as the single positive root of the characteristic equation

$$m\Omega^2 + \Omega\beta(\Omega) + \lambda^{\neq} = 0,$$

where

$$\beta(\omega) = \int_0^{\infty} \beta(t)\exp(-\omega t)dt$$

represents the Laplace transformation of the kernel $\beta(t)$.

The characteristic equation for the generalised Langevin equation (III.2) assumes the form:[2,9]

$$m\Omega^2 + f(i\Omega) + [\lambda^{\neq} - f(\omega = 0)] = 0, \qquad \text{(III.17)}$$

where $f(\Omega)$ is the Fourier transform of the kernel $f(t)$ defined in Eqn. (III.8). If Eqn. (III.4) holds, then Eqns. (III.16) and (III.17) yield the same decomposition frequency Ω and the same rate constant K. The Grote–Hynes equation for the rate constant is obtained on the same assumptions as those underlying the derivation of the Kramers formulae (III.11). For the reactions occurring in complex chemical subsystems, these postulates are found to be justified in many cases. Eqns. (III.11), (III.16), and (III.17) are widely used in modern literature and are known as the Kramers–Grote–Hynes (KGH) approximation.

An alternative formulation of the KGH theory, in which the characteristic equation (III.17) plays a key role, is also possible. It can be conveniently rewritten by introducing the notation $\omega = i\Omega$:

$$\begin{aligned} -m\omega^2 + f(\omega) + [\lambda^{\neq} - f(\omega = 0)] = 0, \\ -m\omega^2 + f(\omega) + [\lambda_0 - f(\omega = 0)] = 0. \end{aligned} \qquad \text{(III.18)}$$

The second equation analogous to the first, was formulated for the reactants minimum. We shall consider all the roots of these equations, designating them by $\Omega_{\nu}^{\neq}$ and $\Omega_{\nu}^{(0)}$ (ν = 0, 1, ..., N) respectively. For the first equation, the decomposition frequency is

$$\Omega_0^{\neq} = i\Omega; \quad \Omega > 0. \qquad \text{(III.19)}$$

All the remaining roots $\Omega_{\nu}^{\neq}$ and $\Omega_{\nu}^{(0)}$ are complex and have negative imaginary components. This fact implies that the characteristic equations (III.18) describe decaying oscillations, whose energy is dissipated. It follows from the property of causality of the core $f(t)$.[45,47] The rate constant can now be represented in the form[52]

$$K = \frac{\Omega}{2\pi}\left(\left|\prod_{\nu=0}^{N}\frac{\Omega_{\nu}^{0}}{\Omega_{\nu}^{\neq}}\right|\right)^{1/2}\exp\left(-\Delta U^{\neq}/kT\right). \qquad \text{(III.20)}$$

This formulation corresponds to the generalised transition state theory, because, as in the usual harmonic transition state theory [Eqn. (I.2)], it uses only the energies and characteristic frequencies at stationary points. It also has a deeper significance, based on the equivalence of the KGH and transition state theories, which is discussed in the next Section. Here one considers of course the transition state theory taking into account the influence of the medium, in contrast to the primitive version of this theory which completely ignores the medium [see Eqn. (III.14)].

3. Relation between the dynamic and stochastic descriptions. Generalised transition state theory as a multidimensional extrapolation of the KGH approximation

Hitherto, in speaking of dynamics, we had in mind the study of equations of motion, both classical Newtonian and stochastic Langevin equations. In this Section, the dynamic systems will be understood as conservative systems retaining the total energy and obeying the equations of classical mechanics. In contrast to them, stochastic systems, being open, dissipate energy, exchanging it with the thermostat.

Stochastic systems permit an abbreviated description of dynamic systems with a large number of degrees of freedom (ideally a macroscopically large number). They can be obtained rigorously from Newtonian equations formulated for the complete dynamic system, differentiating one or several "significant" variables for explicit examination, excluding all others in succession. The exclusion of "insignificant" variables represents a mathematical procedure, the application of which results in the subdivsion of the initial dynamic system into a subsystem having a small number of dynamic degrees of freedom and the thermostat interacting with it.[44,45,53] We shall consider the result of the application of this procedure to the model dynamic system "coordinate x + set of harmonic oscillators q_j with linear interaction in terms of q_j. The system Hamiltonian is

$$H = \frac{p_x^2}{2m} + U(x) + \sum_{j=1}^{N}\left\{\frac{p_j^2}{2\mu_j} + \frac{\mu_j}{2}\left[\omega_j q_j + \frac{C_j}{\mu_j\omega_j}x\right]^2\right\}, \quad \text{(III.21)}$$

where m is the mass of a "one-dimensional particle" x, $U(x)$ its potential, and p_x its momentum. The oscillator variables q_j are characterised by masses μ_j, frequencies ω_j, and momenta p_j ($j = 1, 2, ..., N$). The interaction of the dynamic variable x with the oscillator variables q_j has the form of the linear combination $x\sum_{j=1}^{N} C_j q_j$, where C_j are coupling constants. In essence one considers harmonic oscillators the equilibrium positions of which depend linearly on x.

The equation of motion for the variable x, obtained as a result of the exclusion of the oscillator variables,[54] reduces to the generalised Langevin equation (III.3) with the friction kernel.

$$\beta(t) = \sum_{j=1}^{N}\frac{C_j^2}{\mu_j\omega_j^2}\cos(\omega_j t). \quad \text{(III.22)}$$

The random force is determined by the initial conditions for oscillator variables and satisfies the FDT.

For a continuous medium, $N\to\infty$ and the set of oscillators is characterised by a spectral density defined as follows:[55]

$$J(\omega) = \frac{\pi}{2}\sum_{j=1}^{N}\frac{C_j^2}{\mu_j\omega_j}\delta(\omega - \omega_j), \quad \text{(III.23)}$$

$$\beta(t) = \frac{2}{\pi}\int_{-\infty}^{+\infty}\frac{J(\omega)}{\omega}\cos(\omega t)d\omega. \quad \text{(III.24)}$$

Eqns. (III.23) and (III.24) specify the mutually single-valued correspondence between the phenomenological generalised Langevin equation, specified by the friction core $\beta(t)$, and the dynamic system described by Eqns. (III.21) and (III.23). This correspondence permits a deeper understanding of the significance of the KGH approximation. If $U(x)$ is a one-dimensional two-well potential, then the Hamiltonian (III.21) describes transitions in a model two-well system. By applying to it the canonical transition state theory, it is possible to calculate the rate constant defined by Eqns. (I.2). Here one observes that, if the friction core satisfies Eqns. (III.22) and (III.24), the result agrees with the rate constant based on the KGH theory. Thus the following general assertion is valid:[56–59] the KGH approximation for the generalised Langevin equation (III.3) is equivalent to taking into account the medium within the framework of the dynamic model (III.21) to which the canonical transition state theory has been applied.

However, as mentioned in Section I, the medium is in principle anharmonic. The application of the oscillator model therefore requires explanation. We shall consider a completely different method for the microscopic modelling of the generalised Langevin equation (III.3) on the basis of a dynamic system of equations. For a real medium, having a PES with a complex anharmonic structure with a multiplicity of shallow (with a depth of $\sim kT$) minima, it is possible to construct a smooth free energy profile along a "significant" variable, which we designate by x. It corresponds to the two-well curve of stochastic models. Then, on the basis of the complete system of dynamic equations, it is possible to calculate the friction kernel for the generalised Langevin equation, which is achieved by statistical mechanical methods within the framework of the linear response theory.

The molecular-dynamic calculation permits the study of the fluctuating force $F(t)$ acting on the variable x and, in particular, permits the calculation of the autocorrelation function $\langle F(t)F(0)\rangle$. Then, having identified $F(t)$ with the random force included in the generalised Langevin equation, and applying the FDT [Eqn. (III.9)], we obtain the friction kernel $\beta(t)$ for the generalised Langevin equation (II.9).[33,34,60] Thus, when the methods of molecular dynamics and the FDT are used jointly, the generalised Langevin equation can be fully reproduced for a specific dynamic model reaction in the given medium. Having compared the Hamiltonian (III.21) with the generalised Langevin equation obtained, one can now show that the oscillator variables included in it have no direct microscopic interpretation. They arise on transition, within the framework of the linear response theory, from the strongly anharmonic microscopic PES to the smooth FES, because the dissipative force in the generalised Langevin equation is linear in x. This is only one of the indirect methods for describing the influence of the medium on the variable x. It is not essential to resort to it, because all the results are obtained by studying the phenomenological generalised Langevin equation without employing a particular interpretation.

We obtained two important corollaries from the above discussion. Firstly a practical recipe has been formulated for the microscopic evaluation of the friction kernel. Secondly, the assertion that the KGH approximation is a version of the transition state theory with allowance for the medium has acquired a profound significance. We demonstrated that the KGH method permits the extrapolation of the harmonic version (I.2) of the transition state theory to the description of fundamentally anharmonic models within the framework of the linear response theory.

In chemical applications, one cannot restrict the treatment to one-dimensional stochastic equations (III.1)–(III.3). It is frequently necessary to examine explicitly several "significant" variables, whose dynamics are described by a system of stochastic equations. An equivalent of the Kramers theory for a system of Markov–Langevin

equations of type (III.1) as well for a system of non-Markov equations of type (III.3) is known.[63–66] An alternative solution of the problem[52] is provided by employing the generalised transition state theory in the form defined by Eqn. (III.20). This universal expression for the rate constant is independent of the dimensions of the system. It can be obtained by applying the canonical transition state theory to the oscillator Hamiltonian of type (III.21) containing any number of oscillator variables $x_1, x_2, \ldots$ At the phenomenological level, these variables evolve on a multidimensional two-level FES $U(x_1, x_2, \ldots)$ in conformity with the specified system of generalised Langevin equations.

In order to apply the generalised transition state theory, it is necessary to find initially the reactants minimum and the saddle point on the FES. The difference between their energies yields the activation energy $\Delta U^{\neq}$ in Eqn. (III.20). The force constants matrices are then calculated at both points. The linearisation of the system of generalised Langevin equations in the vicinity of the stationary points makes it possible to obtain two systems of linear integrodifferential equations, whose coefficients are the matrices of masses, friction kernel (they are assumed to be known), and the calculated force constants. Two characteristic equations are derived from these quantities by a standard method. They are analogous to Eqn. (III.18), whose roots are the characteristic frequencies for the reactants and the transition state. The roots are complex and have the same properties as the roots in the one-dimensional case. The pre-exponential factor in Eqn. (III.20) is derived from the frequencies obtained. This method makes it possible to obtain the rate constant in terms of an approximation analogous to the one-dimensional KGH approximation for systems of any complexity.

An alternative method of calculating the rate constant in a multidimensional stochastic system is also known.[63–66] It reduces the calculation to the one-dimensional expression (III.11), the ratio of the two force constants is replaced by the ratio of the corresponding determinants, and the decomposition frequency Ω is calculated from the multidimensional characteristic equation. The result is equivalent to the calculation by Eqn. (III.20).

IV. Examples of the application of stochastic models

1. Charge transfer reactions. Formulation of the continuous model of the medium in relation to outer-sphere electron transfer

The electron transfer between the donor D and the acceptor A in a polar solvent

$$D^- + A \rightarrow D + A^- \qquad \text{(IV.1)}$$

is the simplest chemical process in which the specific features of the influence of the medium are fully manifested. The kinetics of a multiplicity of reactions (IV.1), in which D and A are transition metal complexes, organic substrates, and fragments of biomolecules, have now been investigated. The term "outer-sphere electron transfer" presupposes that the internal coordinates of the chemical subsystem do not change in the rate-limiting stage of the reaction. Changes occur in the configuration of the solvation shell surrounding the reaction complex. The solvation shell is adjusted to the charge distribution in the chemical subsystem, which changes significantly during the reaction. The rearrangement of the solvation shell for a fixed geometry of the chemical subsystem occurs mainly as a result of the orientation motions of the solvent molecules. The study of reaction (IV.1) makes it possible to investigate in relation to a specific example and in a pure form the dynamic behaviour of the coordinates of the medium in the chemical process.

We shall designate the coordinates of the solvent by Q_v. It is necessary to examine the dependence of the free energy $G(Q_v)$ on these coordinates. In the continuous model of the medium, one introduces as Q_v not the elementary orientation motions of individual solvent molecules but collective modes describing concerted combinations of a large number of elementary displacements. This approach permits, in principle, the differentiation of one or several collective coordinates significant for the description of the reaction and the restriction of the treatment to their explicit study.

In a purely electrostatic interaction of the medium with a donor–acceptor pair, the inertial polarisation $P(r)$, i.e. the part of the total polarisation of the medium from which the polarisation due to electrons has been excluded, may be conveniently adopted as the variable.[67,68] The inertial polarisation varies from point to point in the three-dimensional space. Its values at each point are independent variables. Such quantities are referred to as field variables. A field variable actually represents a three-dimensional continuum of variables of the usual type. For a given charge distribution $\rho_a(r)$ in the pair $[D + A]^-$, one may consider the dependence of the FES on the variable $P(r)$ modelling the collective motions of the solvent molecules. This dependence is quadratic: the FES represents a paraboloid, with an infinite number of dimensions, in the polarisation space. Its minimum corresponds to the polarisation $P^{(a)}(r)$ adjusted by an equilibrium procedure to the charge ρ_a. For a different charge distribution $\rho_b(r)$, the minimum in the FES paraboloid shifts to another point in the polarisation space $P^{(b)}(r)$. If, during the reaction, the charge distribution in the substrate changes from ρ_a to ρ_b, then the FES has the form of two intersecting paraboloids. It describes the reorganisation of the polar solvent taking into account only electrostatic forces and has an activation barrier whose height is

$$\Delta U^{\neq} = (E_r + Q)^2/4E_r. \qquad \text{(IV.2)}$$

This is the familiar Marcus formula,[67,68] where Q is the difference between the free energies of the products and the reactants (it is assumed that $Q < 0$ for exothermic reactions) and E_r is the so called solvent reorganisation energy (an important parameter characterising the change in the FES on passing from the ρ_a to the ρ_b charge distribution). It is assumed that $|Q| \leqslant E_r$.

The interaction between the donor and the acceptor is introduced into the theory within the framework of the two-level model. A matrix Hamiltonian of the following type is considered:

$$H = \begin{pmatrix} H_{aa} & H_{ab} \\ H_{ba} & H_{bb} \end{pmatrix}. \qquad \text{(IV.3)}$$

The diagonal matrix elements depend parametrically on the polarisation $P(r)$:

$$H_{aa} = \alpha_a - \frac{1}{2} f_0 \int [P_a^2 - (P - P_a)^2] \mathrm{d}^3 r,$$
$$H_{bb} = \alpha_b - \frac{1}{2} f_0 \int \left[P_b^2 - (P - P_b)^2\right] \mathrm{d}^3 r. \qquad \text{(IV.4)}$$

The electronic matrix elements α_a and α_b characterise the intrinsic energy of the chemical subsystem in the states "a" and "b" without taking into account the interaction with the inertial polarisation. The effects of the polarisation of the electrons of the medium (non-inertial) are assumed to be implicitly included in α_a and α_b. The non-diagonal matrix element is a parameter of the electronic interaction:

$$H_{ab} = H_{ba} = \beta. \tag{IV.5}$$

The coefficient $1/f_0$ is called the Pekar multiplier:[69]

$$\frac{1}{f_0} = \frac{1}{4\pi}\left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0}\right), \tag{IV.6}$$

where ε_0 and ε_∞ are the static and optical dielectric constants. The quantity f_0 is the coefficient of the linear response for the inertial polarisation (response)—induction field (external force) pair:

$$f_0 P(r) = D(r). \tag{IV.7}$$

In particular, one may consider the equilibrium induction fields D_a and D_b related to the charges ρ_a and ρ_b by the Poisson equation.

We shall consider the adiabatic theory in greater detail. The lowest eigenvalue of the matrix H plays the role of the FES in it:

$$U[P] = -\sqrt{\alpha^2/4 + \beta^2} + \alpha/2 + H_{aa}. \tag{IV.8}$$

Here $\alpha = H_{bb} - H_{aa} = Q + E_r - X$, where

$$Q = \alpha_b - \alpha_a - \frac{1}{2}f_0\int(P_b^2 - P_a^2)\mathrm{d}^3r, \qquad E_r = \frac{1}{2f_0}\int(D_b - D_a)^2\mathrm{d}^3r,$$
$$X = X[P] = \int(P - P_a)(D_b - D_a)\mathrm{d}^3r. \tag{IV.9}$$

The free energy of the reaction Q and the reorganisation energy E_r were discussed above. The quantity X is a variable of the usual type (a non-field variable), which is a functional of the field variable $P(r)$.

The quantity $U[P]$ is called the free energy functional. It depends on $P(r)$ solely via the usual variable X, which makes it possible to obtain a closed dynamic equation for this variable.

The dynamic properties of the continuous model are specified phenomenologically through the complex dielectric constant $\varepsilon(\omega)$.[70,71] This function of the frequency ω is determined experimentally from the relation between the variable periodic electric field $E(\omega)$ and the induction $D(\omega)$. The form of $\varepsilon(\omega)$ usually employed in practice is the Debye approximation:

$$\varepsilon(\omega) = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + i\tau_D\omega}, \tag{IV.10}$$

where the parameter τ_D (the Debye time) characterises the time scale of the relaxation processes determined by the polarisation of the medium. The renormalised quantity

$$\tau_L = \tau_D(\varepsilon_\infty/\varepsilon_0), \tag{IV.11}$$

called the longitudinal relaxation time, is frequently employed subsequently.

The dynamic theory starts with the equation of motion for polarisation. In the absence of external charges, it assumes the following form for the Debye model:[71]

$$(\tau_L f_0 \frac{\mathrm{d}}{\mathrm{d}t})P = -f_0 P + \text{random force}, \tag{IV.12}$$

where $f_0 P$ is a regular force generated by the change in the intrinsic energy of the polarisation field. In the presence of external charges, the regular force is modified. It can be found[46] as the variational derivative of the functional $U[P]$ [Eqn. (IV.8)]. The following equation is obtained as a result:[72]

$$\tau_L f_0 \frac{\mathrm{d}}{\mathrm{d}t}(P - P_a) = -f_0(P - P_a) + G(X)(D_b - D_a) + \text{random force}, \tag{IV.13}$$

where

$$G(x) = \frac{1}{2}[1 - \alpha/\sqrt{\alpha^2/4 + \beta^2}\,].$$

We have to determine the reaction rate constant from Eqn. (IV.13).

2. Kinetics of the outer-sphere electron transfer within the framework of the stochastic continuous model

The principal concepts of the continuous model of a polar solvent in relation to the simplest charge transfer reaction—the outer-sphere electron transfer—were introduced in the previous subsection. This is an essential preparatory stage before proceeding to the kinetic problems proper. For a number of reasons, the theory of such processes has nowadays advanced further than others and is essentially complete. It is useful to trace, in relation to this example, the logical structure of the complete dynamic theory of an elementary chemical process in a condensed phase.

A simplifying factor, characteristic of the two-level model described by Eqns. (IV.8) and (IV.9), is the dependence, mentioned above, of the free energy functional $U[P]$ on the field variable P through the coordinate X of the usual type. By virtue of this, the stochastic equation (IV.13) for the field variable P reduces to the incomparably simpler equation of X:[72,73]

$$\tau_L f_0 \frac{\mathrm{d}}{\mathrm{d}t} X = -X + 2E_r G(X) + \text{random force}. \tag{IV.14}$$

In this equation it is easy to recognise the generalised Langevin equation (III.1), from which the kinematic term, containing the acceleration (mass equal to zero), has been omitted. The first two terms on the right-hand side of the equation are functions of X representing the regular force. The corresponding one-dimensional potential $U(x)$ is represented by a two-well curve over a wide range of parameters§. The positions of the reactants minima and of the top of the barrier as well as the force constants are calculated for this potential. After this, it is possible to apply immediately the Kramers formula (III.11). Furthermore, since the inequality (III.12) is valid for $m = 0$, it is sufficient to use the high friction approximation (III.13). In this case the rate constant is given by:[46,72,73]

$$K = \frac{1}{2\pi\tau_L}\left(\frac{E_r}{2|\beta|}\right)^{1/2}\left(1 - \frac{Q^2}{E_r^2}\right)^{3/4}\exp(-\Delta U^*/kT), \tag{IV.15}$$
$$(E_r >> |\beta| >> kT;\ |Q| \leqslant E_r).$$

§ More precisely, the condition $2|\beta|/E_r < 1$ should hold. If it is infringed, the two-well potential becomes a one-well potential.

The activation energy $\Delta U^{\neq}$ is given by Eqn. (IV.2) in the zeroth approximation; it can be refined by subtracting $|\beta|$ from it. An important feature of Eqn. (IV.15) is the presence in the pre-exponential factor of a dynamic characteristic of the medium—the relaxation time τ_L.

Hitherto we have considered the adiabatic theory. It is valid subject to the condition

$$2|\beta|/kT \gg 1. \qquad \text{(IV.16)}$$

The numerator contains the minimal energy splitting of the two electronic terms of the two-level model described by Eqns. (IV.3)–(IV.5). The condition (IV.16) means that thermal fluctuations (i.e. the random force in the stochastic model are incapable of populating effectively the electronically excited state. If the condition (IV.16) has broken down, it is necessary to solve the electronic-non-adiabatic problem, which involves the consideration of a coupled system of two stochastic equations.[74] The dynamics of the outer-sphere electron transfer was first considered by Levich and Dogonadze[4,68,75] precisely within the framework of the non-adiabatic approach. Their calculations were based on perturbation theory. Current studies[74,76,77] were able to overcome this serious limitation. [It is noteworthy that the collective variable X, defined by Eqn. (IV.9), first appeared as a significant element of the dynamic theory in Zusman's study[74] within the framework of the non-adiabatic approach.] The expression recommended on the basis of the modern non-adiabatic theory for the rate constant has the Arrhenius form with an activation energy described by Eqn. (IV.2). The pre-exponential factor is usually formulated thus:

$$A = \frac{\beta^2}{\hbar}\sqrt{\frac{\pi}{E_r kT}}\,\frac{1}{1+\beta^2\tau_L B}. \qquad \text{(IV.17)}$$

The quantity B differs somewhat in the studies of different workers.[74,76–81] We shall quote the simplest (albeit not the best founded) version of the definition of B:[79]

$$B = 4\pi/\hbar E_r. \qquad \text{(IV.18)}$$

If the electronic matrix element β is sufficiently small in absolute magnitude, then the well known result based on perturbation theory in the classical limit is obtained from Eqn. (IV.17).[4,75] However, one can show directly that in the opposite limiting case where $\beta^2\tau_L B \gg 1$, Eqn. (IV.17) does not reduce to the correct Eqn. (IV.15) of the adiabatic theory. The approximate non-adiabatic theory, underlying Eqn. (IV.17), describes only cases of weak and intermediate linkages between the diabatic terms H_{aa} and H_{bb} in the two-level mode (IV.3). Thus Eqns. (IV.15) and (IV.17) supplement one another.

In conformity with the criterion (IV.16), the question of the mechanism, adiabatic or non-adiabatic, involved in electron transfer reduces to the estimation of the matrix element β. On the basis of the results of published calculations and their discussion,[82–83] one may conclude that the adiabatic condition in intermolecular electron transfer holds in many cases, while in intramolecular transfer it holds in all cases. In the study of more complex charge-transfer reactions, where internal motions of the chemical subsystem play a significant role (see subsection IV.3), the application of the adiabatic theory is natural and promising.

The scheme described for the outer-sphere electron transfer involves simplifications which are undesirable in the solution of specific problems. The most serious of them is the homogeneous medium approximation, on which the electrostatic formulae of subsection (IV.1) are based. A more realistic approximation is called the Born–Kirkwood–Onsager (BKO) model, it involves the cutting out of a cavity in the continuous medium in which the chemical subsystem is placed. The dielectric constants within and outside the cavity are different. In the dynamic theory, the complex dielectric constant has two values:

$$\varepsilon = \begin{cases} 1 \text{ (within the cavity)}, \\ \varepsilon(\omega) \text{ (outside the caivity)}. \end{cases} \qquad \text{(IV.19)}$$

In the static theory $\varepsilon(\omega)$ outside the cavity is replaced by the static constant ε_0.

The introduction of an inhomogeneity in the form of a cavity complicates the theory, but its structure remains the same as before.[84] The inhomogeneity leads to the renormalisation of the parameters: the expressions for the energy effect Q, the reorganisation energy E_r, and the principal dynamic variable X in Eqn. (IV.9) are altered. In particular, the reorganisation energy is[4,67,85]

$$E_r = \frac{1}{2f_0}\int_{V_e}(\nabla\varphi_b - \nabla\varphi_a)^2 d^3r, \qquad \text{(IV.20)}$$

where V_e is the volume outside the cavity and $\varphi_a(r)$ and $\varphi_b(r)$ are the vacuum potentials ($\varepsilon = 1$) generated by the diabatic charge distributions $\rho_a(r)$ and $\rho_b(r)$ and calculated from the Poisson equation. The general expressions (IV.15) and (IV.17) for the rate constant remain in force.

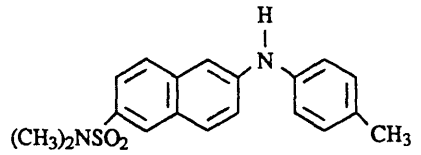
On going outside the framework of the Debye model of the solvent described by Eqn. (IV.10), a dynamic equation is arrived at in the adiabatic approximation,[46] which differs from Eqn. (IV.13) by its left-hand side: instead of the derivatives dP/dt, a linear integral operator acting on the polarisation variable P appears. This dynamic equation is the generalised Langevin equation (IV.2). A similar rate constant, defined by Eqn. (IV.15), can be calculated in terms of the KGH theory [Eqns. (III.11), (III.17), and (III.20)]. A non-adiabatic version of the non-Debye theory has also been formulated.[76,77,86]

Allowance for the internal degrees of freedom of the chemical subsystem, i.e. the extension of the treatment outside the framework of the outer-sphere model, means in essence that electron transfer is regarded as a reaction with charge redistribution in the chemical subsystem. We shall consider such processes in the next Section. Finally, the question of the extension of the treatment outside the framework of the two-level model (IV.3)–(IV.5) by improving the wave function describing the chemical subsystem has been discussed recently.[84,87,88] The wave function of the two-level model is linear and consists of two terms, i.e. contains only one variational parameter. In many cases this is insufficient. The problem is of current interest in applications of the theory to intramolecular processes in complex chemical substrates.

Experimental kinetic studies have confirmed the dependence of the rate constant for the outer-sphere electron transfer on the longitudinal relaxation time τ_L [see Eqns. (IV.11) and (IV.15)]. The distinct inverse proportionality observed for organic radical-ion donors and acceptors[89,90] constitutes convincing evidence in support of the adiabatic process mechanism. For a reaction involving

ruthenium complexes in different aliphatic alcohols and glycerol, a weaker relation $K \propto \tau_L^{-0.6}$ was observed.[91] This result can be explained in different ways: either on the basis of the non-adiabatic formula (IV.17),[92,93] or within the framework of the non-Debye approximation for $\varepsilon(\omega)$,[93,94] or by including in the dynamics the internal degrees of freedom of the chemical subsystem.[52]

The correlation between the kinetic measurements and the quantity τ_L is complicated by the fact that, together with τ_L, other factors change in different solvents, and their effect on the kinetics cannot be excluded. We may mention in the first place the change in solvent polarity, which is capable of altering the potential barrier in the reaction. In this respect, the study of intramolecular electron transfer in systems of the type



is instructive. The reaction was investigated in aliphatic alcohols in the temperature range 168–338 K.[95] Comparison of the temperature variations of the reaction rate constants and of the quantity τ_L itself in the same solvent (the influence of the change in polarity is excluded) demonstrated quite convincingly the transition of the kinetics from the regime in which there is no dependence on τ_L to one where it does obtain. The authors identified these two regimes as "non-adiabatic" and "adiabatic". However, we may note that, for the systems investigated, the electron transfer is accompanied by an appreciable change in intramolecular geometry, i.e. can be hardly classified as a purely outer-sphere process. Allowance for the internal degrees of freedom would make it possible to describe both regimes within the framework of the two-dimensional adiabatic model examined in the next subsection.

Thus the uncertainty in the interpretation of the experimental results within the framework of stochastic theories is difficult to overcome at the present time.

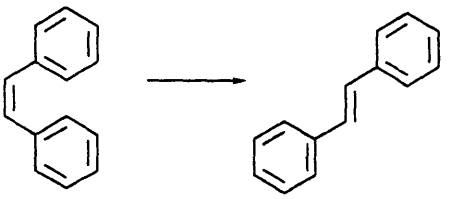
3. Reactions in polar and non-polar media

Transition to chemical reactions implies explicit study of the variables of the chemical subsystems together with the variables of the medium. For example, for charge transfer reactions in a polar solvent, one introduces the free energy functional $U[x_i, P(r)]$, which is a functional in relation to the variables of the medium [i.e. the polarisation $P(r)$] and is a normal function of the chemical variables x_i. We shall formulate the corresponding system of dynamic equations for the case of a single coordinate x[52] and the Debye approximation for $\varepsilon(\omega)$:

$$\tau_L f_0 \mathrm{d}P/\mathrm{d}t = -\delta U/\delta P + \text{random force}, \qquad m\mathrm{d}^2x/\mathrm{d}2t = -\mathrm{d}U/\mathrm{d}x. \tag{IV.21}$$

The functional $U[x_i, P(r)]$ plays the same role in the adiabatic theory of reactions in a condensed medium as the potential energy surface in the theory of gas-phase electronically adiabatic reactions. The variational derivative $\delta U/\delta P$ plays the role of the regular force. The rate constant for the system of Eqns. (IV.21) can be calculated on the basis of the generalised transition state theory [Eqn. (III.20)].[52]

Such a consistent theoretical programme of study, ranging from the construction of the energetic functional to the calculation of the rate constants for specific reactions in the medium, has not so far been realised. Fully phenomenological models are commonly used nowadays. The simplest of these arises from the Kramers Eqn. (III.1) and the corresponding expressions (III.11) and (III.13) for the rate constant. The isomerisation of cyclohexane[29,30] and the *cis–trans* isomerisation of stilbene and of its analogues in an excited state[49,50,96] have been frequently discussed at this theoretical level:



(IV.22)

In reaction (IV.22), the coordinate x of the Kramers model is identified with rotation about the central bond and a macroscopic quantity, directly proportional to the viscosity of the medium η and inversely proportional to the diffusion coefficient D, is used as the coefficient of friction γ. In order to observe the dependence of the rate constant on the viscosity, systematic studies have been carried out on the reaction kinetics in the gas phase and in non-polar liquids over a wide pressure range.[49,50] The observed relation is illustrated in Fig. 5. The right-hand side of this figure reveals a decrease in the rate constant with increasing viscosity, which is slower than would follow from the Kramers relation in the region of high friction. Considerable efforts have been made to observe the branch of the Kramers solution which ascends with increasing viscosity. Fig. 5 shows that its presence has not been convincingly confirmed. In this connection, one must recall the limitations of the Kramers model in the region of low friction when it is applied to complex molecular systems which were discussed in Section III.

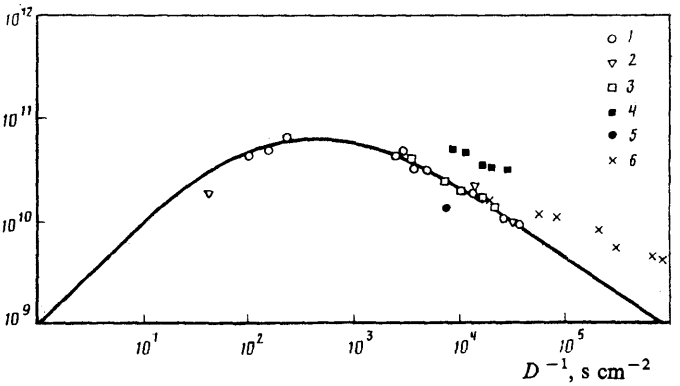


Figure 5. Correlation between the rate constant K for the photochemical isomerisation of stilbene and the reciprocal of the diffusion coefficient D^{-1}.[49] Experimental points obtained in the gas and liquid phases over a wide pressure range at 298 K: *1*, ethane; *2*, propane; *3*, CO_2; *4*, xenon; *5*, SF_6; *6*, n-hexane. Continuous curve — calculation based on the Kramers theory.

The phenomenological approach based on the Kramers equation encounters fundamental difficulties. We have seen that the role of the medium does not reduce only to the introduction of stochastic elements (the dissipative and random forces) into the description but

also involves the modification of the regular force. The interaction of the chemical system with the medium, superimposed on the intrinsic potential surface of the latter can distort appreciably both the height of the potential barrier and its shape (see, for example, Fig. 1). In the study of the role of friction, this side effect must be excluded, which requires accurate calculation of the interaction potential. For systems of type (IV.22), serious calculations have never been performed and the change in barrier height has been taken into account using an empirical method.[49]

Finally, in many cases the application of the one-dimensional generalised Langevin equation (III.1) as a model of the reaction in the given medium cannot be regarded as justified. In particular, using the hydrodynamic viscosities as a means of estimating the coefficient of friction γ, one frequently postulates a macroscopic description of the interaction in the spirit of the hydrodynamic Stokes formula

$$\gamma \sim \eta l, \qquad \text{(IV.23)}$$

where l is the characteristic distance over which the benzene rings migrate in reaction (IV.22).

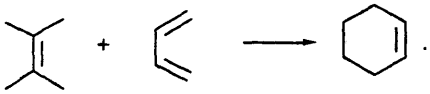
An attempt has been made to refine the dynamic description of isomerisation reactions with the aid of a two-dimensional stochastic model.[97,98] It was postulated that the process actively involves two angular variables with two different coefficients of friction. A study was made of the dynamic behaviour of the system as a function of the ratio of these parameters. The corresponding system of stochastic equations was solved in the high friction limit for both variables, where the kinematic contributions to the dynamics (proportional to the acceleration) are insignificant.

A consistent microscopic description of reactions in a given medium leads to a different two-dimensional dynamic model, in which the roles of both dynamic variables are fundamentally different:

$$m\mathrm{d}^2x/\mathrm{d}^2t + \mathrm{d}U/\mathrm{d}x = 0,$$
$$\gamma\mathrm{d}Q/\mathrm{d}t + \mathrm{d}U/\mathrm{d}Q = \text{random force}. \qquad \text{(IV.24)}$$

The chemical coordinate x, obeying Newtonian dynamics, and the medium coordinate Q, the dynamics of which are introduced at the level of the simplest version of the Kramers theory (the high friction limit in which the kinematic term, proportional to the mass, has been omitted), are considered explicitly. The two variables are linked by the interaction included in the regular two-well potential $U(x, Q)$. By specifying this potential, it is possible to take into account the microscopic interaction explicitly. The significant factor is that in the two-dimensional model the coefficient γ characterises the interaction of the differentiated medium coordinate Q with the remaining degrees of freedom of the medium (thermostat) and its interpretation in the spirit of Eqn. (IV.23) is not open to objection.

We shall illustrate the application of the model (IV.24) in relation to the study of the pressure dependence of the Diels–Alder reaction.[8] For a typical reaction of this type



(IV.25)

dienophile diene adduct

The distance between the reactants is adopted as the chemical coordinate x. This leads to the simple model illustrated in Fig. 6. The chemical subsystem x is placed at the centre of a cylindrical cavity with a cross-section σ_0 and a length L. The medium coordinate Q is identified with the quantity L. During the reaction, the distance x diminishes and this entails also the diminution of the cavity. The dynamics is described by Eqns. (IV.24). An advantage of the two-dimensional model is the possibility of taking into account non-equilibrium solvation, i.e. the situation in which there is insufficient time for the medium coordinate Q to become adjusted to the change in the coordinate x, which is assumed to be faster. This effect can be described only by considering explicitly both coordinates—x and Q. The corresponding kinetic theory goes beyond the framework of the KGH approximation and the generalised transition state theory. It will be examined in Section V.

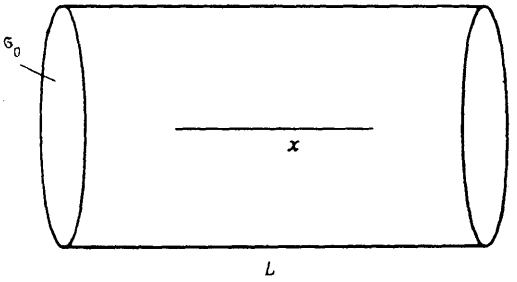


Figure 6. Model of the addition reaction in a condensed medium. x = distance between reactant molecules (reaction coordinate), L = coordinate of the medium; σ_0 = cross-section.

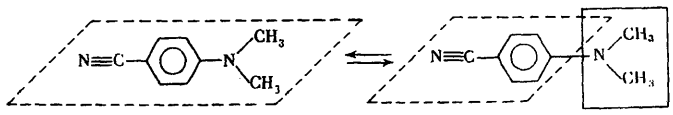
The experimental kinetic characteristics obtained for reaction (IV.25), investigated in the pressure range 0–6 kbar, have been interpreted[8] in terms of the non-equilibrium theory based on Eqns. (IV.24) and the reaction scheme adopted in Fig. 6. It was found that the majority of reactions can be regarded as reversible and that the rare anomalies in the pressure dependence of the rate constant could be interpreted as non-equilibrium effects.

Adopting the two-dimensional theory [Eqns. (IV.24)], we emphasised the difference between isomerisation reactions (IV.22) and addition reactions (IV.25). In the former case, the volume of the cavity hardly changes but its shape is altered. The latter case is characterised by a sharp decrease in the volume of the cavity during the elementary process. Accordingly, pressure affects addition reactions to an incomparably greater extent than isomerisation reactions. In the latter, the influence of the pressure is manifested mainly indirectly—through a change in the coefficient of friction γ.[28,29] The construction of a two-dimensional theory of isomerisation reactions would require the specification of a special medium coordinate the changes in which should model the change in the shape of the cavity. Without an explicit representation of coordinates x and Q, it is impossible to derive the energetic functional $U(x, Q)$.

Among charge-transfer reactions in polar media, photochemical isomerisation and nucleophilic substitution processes have been discussed in the literature. In the typical isomerisation reaction,[99]



planar structure perpendicular structure

(IV.26)

the molecule is excited to the first singlet state and there is rotation about the central C–C bond by 90° with alteration of the relative orientations of the terminal fragments. This conformational transition is accompanied by a strong polarisation of the molecule: according to a quantum-chemical calculation, its dipole moment increases from 6 to 16 D. A consistent dynamic description of reaction (IV.26) must include at least the angle of the conformational rotation and the polarisation of the medium as the dynamic variables.

It would also be necessary to examine the photochemical *cis–trans* isomerisation of non-polar conjugated molecules of the type of stilbene [reaction (IV.22)] when the latter occurs in a polar solvent, because it is known that the corresponding intermediate structures are highly polarised. However, all such reactions have been discussed theoretically hitherto at the elementary level of the one-dimensional Kramers model.[96,99,100] As in the electron transfer reaction, the coefficient of friction γ was assumed to be proportional to the relaxation time τ_L.

Methods for the explicit introduction of the medium coordinates into the two-dimensional model have been discussed in connection with the S_N2 reaction (I.3). In this case the antisymmetric motion in the complex

$$[Cl \cdots CH_3 \cdots Cl]^-$$

in the vicinity of the transition state is assumed to be the reaction coordinate. The form of the medium coordinate is determined by the form of the functional $U(q, P]$. One can imagine two limiting versions of the structure of this functional in the vicinity of the saddle point. In the first case, the section along x contains a barrier, while the section along the medium coordinate in the polarisation space consists of a paraboloid. This version corresponds to an insignificant modification of the gas-phase reaction coordinate in the presence of the polar solvent. A discrete coordinate corresponds to it:[101]

$$Y = \frac{\int D'(r)[f_0 P - D(r,\tilde{x})]d^3r}{\int [D'(r)]^2 d^3r}. \qquad (IV.27)$$

It is postulated that the regular electrostatic force $D(r,x)$, (the induction field which depends on the chemical coordinate x), has been linearised in the vicinity of the point $x = \tilde{x}$—for example, $\tilde{x}$ can correspond to the reactants minimum or to the saddle point of the potential $U[x, P(r)]$:

$$D(r, x) = D(r, \tilde{x}) + D'(r)(x - \tilde{x}),$$

$$D'(r) = \left.\frac{\partial D(r, x)}{\partial x}\right|_{x=\tilde{x}}.$$

In the second case, the section along x is a fragment of a parabola and that in the polarisation space is a two-well curve. In the vicinity of the transition state, the reaction proceeds mainly as a rearrangement of the medium, i.e. via the same mechanism as the outer-sphere electron transfer discussed above. The use of the variable X [Eqn. (IV.9)], which occurs in the electron transfer theory, as the reaction coordinate is most justified. Both variables, X and Y, correspond to the homogeneous medium approximation. The improvement of this simplest model by introducing a cavity would require the modification of both variables.[84]

Yet another procedure for the introduction of the medium variable, designed for a two-level electron transfer model, is possible. We designate by $P_a(r)$ and $P_b(r)$ the equilibrium polarisation of the medium corresponding to the reactants and reaction products. The current polarisation $P(r)$ can be specified by a linear interpolation:[67]

$$P(r) = \lambda P_a(r) + (1 - \lambda)P_b(r), \quad 0 < \lambda < 1. \qquad (IV.28)$$

This relation defines λ as the medium coordinate. It has been used for an S_N2 reaction[102] on the assumption of a one-well parabolic dependence of the free energy on λ. Such a scheme is not free from contradictions, since Eqn. (IV.28) was initially designed for a two-well model of the potential of the type which occurs in the electron transfer reaction.

The examples quoted in this Section show that theoretical studies on chemical reactions in a solvent are in their initial stage. The importance of the explicit consideration of the coordinates of the medium and their specific character has now been recognised. For reactions in non-polar media, these coordinates characterise the size or shape of the cavity in which the chemical subsystem is enclosed. In a polar solvent, the medium variables are represented by a particular functional of the inertial polarisation. In any version, such variables are collective modes, i.e. are concerted combinations of elementary motions of a large number of solvent molecules. The specific form of such a collective variable is defined within the framework of a particular model. Ultimately it follows from the concrete form of the energetic functional, just as the form of the usual vibrational modes is determined by the nature of the PES in the vicinity of its stationary points. In particular, in order to achieve a consistent solution of the problem of the medium coordinate in charge-transfer reactions, one has to establish the form of the cross-section of the functional $U[x, P]$ in the vicinity of the transition state. This requires the development of a method for quantum-chemical calculations with allowance for the effect of the medium.

V. Dynamics of multidimensional stochastic systems. Non-equilibrium solvation and its kinetic consequences

We shall consider in greater detail the equation of motion (IV.24) describing the stochastic dynamics of a system with two degrees of freedom. One of them, the Newtonian coordinate x, refers to the motion within the chemical subsystem. The second, the stochastic coordinate Q, is one of the modes of the medium. These variables are related via the potential $U(x, Q)$, which corresponds to the simplest version to a harmonic model with a quadratic term containing a linear combination of x and Q:

$$U(x, Q) = V(x) + \frac{\lambda}{2}(Q - ax)^2, \qquad (V.1)$$

where $V(x)$ is a one-dimensional two-well potential characterising a gas-phase reaction. The second term of Eqn. (V.1), containing the coordinates Q, corresponds to a harmonic oscillator with a force constant λ and an equilibrium position which depends linearly on x.

The two-dimensional equation (IV.24) is the simplest model suitable for the description of non-equilibrium solvation. In order to extend the treatment beyond kinetics under non-equilibrium conditions, it is necessary to abandon the KGH approximation. We shall introduce two characteristic periods τ_x and τ_Q related to the time scales of the motions of the corresponding variables. The period τ_x is assumed equal to the reciprocal of the frequency for two reactant wells subject to the one-dimensional potential $V(x)$. In certain cases, τ_x is determined in terms of the residence time of the system near the barrier. The period τ_Q characterises the relaxation of the variable Q; it is proportional to the coefficient of friction γ. If the time scales for τ_x and τ_Q are comparable in magnitude, then the non-equilibrium effects are insignificant and the multidimensional KGH theory yields a satisfactory approximation for the rate constant. Another situation arises if τ_x and τ_Q are quantities of the same order of magnitude. We shall assume that Q is the slow coordinate, having put

$$\tau_x/\tau_Q << 1. \qquad (V.2)$$

Then in the course of an elementary process, there is insufficient time for the coordinate Q to become adjusted to the changes in the faster coordinate x, which in fact entails non-equilibrium effects.[86,103] The mathematical situation described by the inequality (V.2) is treated by averaging the system of Eqns. (IV.24) over the period of fast motion ν_x.[103–105] As a result of the averaging, the two-dimensional potential function is converted into a one-dimensional effective potential $\tilde{U}(Q)$, which governs the motion of the slow variable of the medium Q. The kinetic evolution of Q is expressed in terms of the Fokker–Planck equation for the distribution function $R(Q, t)$:[103–107]

$$\frac{\partial R}{\partial t} = D_Q \frac{\partial^2 R}{\partial Q^2} + \frac{D_Q}{kT}\frac{\partial}{\partial Q}\left[R\frac{\partial}{\partial Q}\tilde{U}(Q)\right] - K(Q)R. \qquad (V.3)$$

Here the first two terms on the right-hand side describe diffusion subject to a potential U with a diffusion coefficient D_Q. The last term on the right-hand side describes the departure of the particles from the reactants region at each point Q with a rate constant $K(Q)$, i.e. a chemical reaction subject to a two-well potential, which is represented by the section along the variable x through the two-dimensional potential $U(a, Q)$ [Eqn. (V.1)] parametrically dependent on Q. The local rate constant is given by

$$K(Q) = \frac{\omega(Q)}{2\pi}\exp\left(-\frac{\Delta U(Q)}{kT}\right). \qquad (V.4)$$

The frequency in the pre-exponential factor and the height of the barrier are functions of Q. Under these conditions, the diffusion coefficient D_Q is proportional to τ_Q^{-1} and the frequency $\omega(Q)$ is proportional to τ_x^{-1}. Eqn. (V.3) gives rise to a range of kinetic regimes.[107–109] Even more varied kinetics are generated by the initial system of Eqns. (IV.24), from which Eqn. (V.3) is obtained in the limit represented by Eqn. (V.2). Each kinetic regime operates in a different range of parameters of Eqn. (IV.24) and can be derived within the framework of a particular approximate model.

Fig. 7 represents the regions of applicability of different approximate descriptions of the kinetics of reaction (IV.24) as a function of the ratio τ_Q/τ_x. For a fixed τ_x, the above parameter increases with increase in τ_Q and is therefore proportional to the coefficient of friction γ and inversely proportional to the diffusion coefficient D_Q. The exact solution of Eqn. (IV.24) would make it possible to cover the entire range of values of the parameter τ_Q/τ_x.

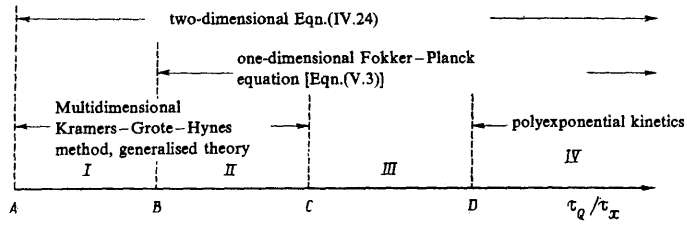


Figure 7. Schematic illustration of the changes in kinetics with increasing viscosity of the medium in the two-dimensional model of the reaction (IV.24). Points *A*, *B*, *C*, and *D* represent the conventional boundaries of different kinetic regimes.

The point B constitutes the left boundary of the region of applicability of the average quasi-one-dimensional equation (V. 3). To the left of this point, the solution is significantly two-dimensional (region I). Here τ_x and τ_Q are of the same order of magnitude and the two-dimensional KGH theory[94] or, what amounts to the same thing, the generalised transition state theory [Eqn. (III.20)] is applicable in this case. The next section of the horizontal axis (region II) corresponds to the situation where the quantity τ_Q/τ_x is now so large that the averaging of Eqn. (IV.24) is legitimate, but the KGH theory is still applicable. The rate constant in this region constitutes the quasi-one-dimensional limit of the two-dimensional KGH theory, is independent of γ, and is given by the simple Arrhenius expression

$$K_e = \frac{\omega_e}{2\pi}\exp\left(-\Delta U^{\neq}/kT\right), \qquad (V.5)$$

where ω_e is the frequency determined by the parameters of the two-dimensional potential.

The approximate solution of Eqn. (V. 3), which represents the equilibrium distribution $R_e(Q)$ and is obtained for fixed values of τ_Q and D_Q in the limit $\Delta U^{\neq}/kT \gg 1$, also corresponds to Eqn. (V. 5). The maximum in the reaction flux, described in Eqn. (V.3) by the term $K(Q)R(Q)$, is then found at the point $Q = Q^{\neq}$, i.e. the saddle point on the surface specified by the function (V.1). At the point $Q^{\neq}$, the quantity $K(Q)$ is a maximum and the reaction passes through the saddle point.

On passing to the region III, the distribution $R(Q)$ ceases to correspond to equilibrium. Movement along the coordinate Q becomes so slow that it has insufficient time to compensate for the decrease in the density of particles owing to the reaction in the vicinity of the point $Q^{\neq}$. The maximum in the reaction flux therefore shifts to the region $Q < Q^{\neq}$, the shift being extended further the greater the ratio τ_Q/τ_x. This increases the effective

potential barrier, which now depends on the coefficient of friction and temperature. A viscosity-dependent rate constant K with a non-Arrhenius temperature variation is thus obtained[103,104] and we then always have

$$\kappa = K/K_e < 1. \quad (V.6)$$

The non-equilibrium rate constant is always smaller than the equilibrium constant and there exists a range of parameters of the potential where the ratio (V.6) is extremely small ($\kappa \simeq 10^{-3}$ and less).[104,109]

Region IV is particularly interesting. Here the kinetics are of a polyexponential type; in other words, they cannot be described with the aid of a single rate constant.[107,108] The extreme case of polyexponential kinetics represents the "frozen" medium limit ($\tau_x/\tau_Q \to \infty$, $D_Q \to 0$) in which the rate of reaction is

$$Q(t) = \int \exp[-K(y)]R(y, 0)dy,$$

where $R(y, 0)$ is the distribution in the initial instant (it is determined by the conditions in the preparation of the reaction system). The dependence of the rate of reaction on the initial distribution is a distinctive property of the polyexponential regime. Eqn. (V.7) means that at each point on the Q axis a chemical reaction is generated with its own rate constant $K(Q)$ and the initial concentration of the reactants at each point is specified by the initial distribution $R(y, 0)$. Polyexponential kinetic regimes, especially the limit (V. 7), have been frequently observed in media with a low mobility. For example, they are typical for low-temperature chemistry.[110] Thus the simple two-dimensional model (IV.24) gives rise to a whole range of kinetic regimes, which are observed experimentally. In this respect, it is incomparably more elaborate than the primitive one-dimensional model (III.1). It can apparently be usefully employed as the phenomenological basis of the description of reactions in condensed media.

The description of effects due to the non-equilibrium nature of the medium is possible in a highly simplified form within the framework of a unique generalised Langevin equation.[34,60,111] We shall consider the dissipative term of Eqn. (III.3):

$$\int_0^t \beta(t - \tau)\dot{x}(\tau)d\tau.$$

Suppose that the time interval $\bar{\tau}$ during which the friction kernel $\beta(t)$ decays is sufficiently long compared with the reciprocal of the decomposition frequency Ω^{-1} [Ω is the solution of the characteristic equation for (III.3)]:

$$\bar{\tau}\Omega >> 1. \quad (V.8)$$

The multiplier $\beta(t-\tau)$ can then be taken outside the integral sign at the point $\tau = t$. This yields the additional term $\beta(0)x(t)$ in the expression for the regular force $(-\partial U/\partial x)$ in Eqn. (III.3), which effectively diminishes the absolute magnitude of the negative force constant in the transition state region. Such description is fully equivalent to the "frozen" medium picture mentioned in Section II.4 in connection with the calculation for the S_N2 reaction by the reaction flux method. Indeed, according to the inequality (V.8), the characteristic relaxation time of the medium $\bar{\tau}$ is much longer than the characteristic time of the motion of the chemical system in the vicinity of the barrier Ω^{-1}. In the other limiting case $\beta(t-\tau) = \delta(t-\tau)$, one obtains the usual Kramers equation; the intermediate case is characterised by a gradual change in the type of kinetics as a function of the ratio of the characteristic times indicated. In this abbreviated description many important results of the more complete two-dimensional theory are lost—for example the polyexponential kinetic regime.

VI. Certain problems and prospects

According to standard textbooks of chemical kinetics concerned with gas-phase reactions,[112,113] the calculation of the reaction rate constant is preceded by three stages:

1. calculation of the potential energy surface;
2. dynamic calculation on this surface;
3. calculation of the distribution function of the initial conditions in the reactants region with the aim of incorporating such conditions in the dynamic calculation.

After this, the rate constant is obtained by averaging the reaction flux in the reactant region on the basis of the initial conditions found.

The transition state theory eliminates the last two stages (dynamic and statistical) using the reaction flux in the region of the saddle point (i.e. the transition state) with the equilibrium distribution function. Modern gas-phase dynamic calculations involve as a rule the first two stages using the hypothesis of the equilibrium Boltzmann distribution in order to average the initial conditions.

Theoretical studies on the kinetics of reactions in condensed media have introduced significant modifications into the programme of operations indicated. In its numerical application, all its three stages are closely intertwined and their artificial separation is undesirable. Thus the calculation of the FES by the Monte Carlo method already involves the equilibrium estimate of the rate constant, which is more or less consistent with the transition state theory. In the stage involving the calculation of the transmission coefficient (i.e. the correction to the Monte Carlo calculation) by the method of molecular dynamics, the dynamic (calculation of reaction trajectories) and statistical (correction of the equilibrium distribution function) stages are virtually inseparable.

A similar situation occurs also in stochastic models: the search for the distribution function for a system of stochastic dynamic equations (we have in mind classical theories) reduces to the solution of the corresponding Liouville (or Fokker–Planck) equation, in which the dynamic and statistical aspects have merged into one.

Research has confirmed the striking vitality of the transition state theory. It was unexpectedly reborn in a generalised form, taking into account the medium, as the multidimensional KGH theory. After such radical modification, its application to a wide variety of kinetic chemical and biological problems promises to be fruitful.

From the standpoint of the development of the theory of chemical kinetics, it is of interest to go beyond the framework of the transition state and KGH methods, i.e. to investigate non-equilibrium effects. This concerns the small transmission factors $\kappa \ll 1$ in classical systems where tunnelling effects are ruled out. The search for the corresponding chemical objects constitutes a special task and this confirms yet again the advantages of the transition state theory in relation to reactions with thermal activation.

At the microscopic level, highly non-equilibrium situations have not so far been observed under thermal conditions. It is sufficient to point out that the calculation for an S_N2 reaction,[33,34] described in subsection II.4, which constitutes a record as regards the thoroughness and volume of computations, yielded only $\kappa = 0.55$ as

the transmission factor. However, even this quantity can be almost completely reproduced within the framework of the KGH theory,[34,60] i.e. it has no bearing on true non-equilibrium effects.

A general study of a model microscopic chemical system[114] showed that it is hardly possible to obtain $\varkappa < 10^{-1}$ retaining the hypothesis, usual for gas-phase reactions, that the initial distribution function in the reactants region corresponds to equilibrium. However, pronounced non-equilibrium effects arise naturally in the phenomenological description of the kinetics in the language of stochastic equations. Two examples were examined above: the region of low friction in the one-dimensional Kramers theory (subsection III.2) and the region of high friction in the two-dimensional stochastic model [Eqn. (IV.24)] (Section IV). Both cases are characterised by the breakdown of the Boltzmann distribution in the reactants zone, which is in fact the source of the disequilibrium.

Thus the next task to be tackled involves the calculation of the distribution functions for thermal reaction systems, under conditions where they deviate markedly from the Boltzmann equilibrium, and the experimental search for the corresponding natural objects. In this connection, we may note that the existing versions of the molecular dynamics calculations are unsuitable for such purposes. They are designed specially for the calculation of transmission factors close to unity under the conditions of small deviations from equilibrium in the transition state region. A converging (i.e. attaining a plateau) calculation of a low transmission factor within the framework of this method is impossible.

An evident aspect of theoretical studies is the application of the approaches already developed to specific chemical and biological systems. The next task on these lines is the development of continuous stochastic models for systems with non-electrostatic interaction by analogy with electron transfer theory. A promising procedure involves the combination of continuous models with numerical approaches: with Monte Carlo and molecular dynamic methods for the determination of the parameters of stochastic equations and with quantum-chemical methods for the calculation of interaction potentials. Finally, it is essential to develop quantum stochastic theories and their numerical application. Without such an instrument, it is impossible, for example, to investigte seriously electron transfer in a polar environment. Studies in this field are nowadays developing vigorously,[55,59] but their discussion is outside the framework of the present review.

Solvent effect on the kinetics of crystal growth

E B Treivus
St. Petersburg University

ABSTRACT. Experimental data for the solvent effect on the kinetics of crystal growth are summarised. The common analytical method based on the concept that crystallisation in solutions occurs essentially through random addition of particles to the crystal surface (normal growth mechanism) and the means for estimating the contribution of this mechanism are critically examined. The conclusion is made that the role of such a mechanism is overstated. A theory is formulated that enables the solvent effects pertaining to layered facial crystal growth to be estimated.

The bibliography contains 52 references.

I. Introduction

Solvent effects on crystallisation are interesting for a number of reasons. Solvent exchange is a useful method of studying mechanisms of chemical reactions in solutions, in particular, the growth of crystals. Finding the principles underlying this area is also worthwhile for applications since the current trend is toward expanding the number of solvents (organic liquids, metal melts, inorganic salts and oxides) used to grow crystals from solutions. The choice of solvent is important to various sectors of the chemical industry (processing crude petroleum, production of mineral fertilisers, reagents, pharmaceuticals, etc.) owing to the need to promote crystallisation and the desire to gain a greater yield and to change the shape of the crystallites in the required direction. In particular, the caking of a substance, the effectiveness of its separation from the mother liquor, its pharmaceutical efficacy, etc., depend on this shape. A review of studies in this area was published abroad more than 10 years ago.[1] Analogous publications have not appeared in the domestic literature.

II. Treatment of experimental data within the framework of the normal growth mechanism

The solvent was known to affect crystal shapes, i.e., the ratio of growth rates of their various faces, even at the start of the present century. Thus, the solvent affected the habit of crystals of urea, sulphur, etc.[2] According to Orlov,[3] these facts were related to the change of surface tension of the various faces since shortly before this the well-known Gibbs–Curie principle about the minimum surface energy of an equilibrium crystal had been formulated. It is now evident that this principle is inapplicable to nonequilibrium crystal shapes. How the concept of the role of surface energy in the kinetics of crystal growth has up to now been transformed will be clear from the following exposition.

Orlov[3] discovered that the facetting of NaOH crystals becomes complicated on going from aqueous solution to formamide and also on going to a mixture of water with certain hydroxy-acids. According to his viewpoint, the shape of crystals changes if the dissolved substance reacts chemically with the solvent. He saw signs of this in the high dielectric constant of formamide and in the structural features of the solvents used. A specific interaction with different crystal faces of complexes of the crystallising species and solvent species that have a variable structure in different solutions can change the crystal habit.[3] Apparently, this study was the first in which the possible role during crystallisation of a change in solution structure owing to a solvent change was pointed out.

Wells[4] pointed out the significance of a specific solvent interaction with different crystal faces. He illustrated this using resorcinol as an example. Certain opposing faces of resorcinol crystals have different structures. According to Wells, the faces terminating in hydroxyl groups are blocked by water molecules. This leads to preferential development of these faces during formation of resorcinol crystals. The nonpolar solvent benzene does not affect this selective adsorption. The crystal grows symmetrically in opposite directions.

Both these ideas are expanded upon or confirmed in subsequent studies. Kleber and Raidt[5] discovered that salol crystals in nonpolar solvents (CCl_4, C_6H_6) and in acetone have a shape corresponding to their symmetry type $2/mm$. The external symmetry is reduced to 22 if polar solvents (CH_3OH, C_2H_5OH, C_3H_7OH) are used. This phenomenon was related[5] to the solution structures. In nonpolar solvents, salol molecules are associated; in polar, they are not associated. However, it is not clear how this is related to the external crystal facetting. The concept of specific solvent adsorption has been developed.[6] The formation of a new face on $Hg(CN)_2$ crystals in CH_3OH solution was explained by epitaxy on this face of the complex $Hg(CN)_2.CH_3OH$. The similarity of the atomic distributions in planes of the growing faces of $Hg(CN)_2$ and $Hg(CN)_2.CH_3OH$ crystals confirms that epitaxy occurs.

Thus, the position was in essence taken[6] that solvent is specifically adsorbed if there are epitaxial relationships between faces of the crystallising substance and the solvent (a compound with it is a particular instance). The scale of the dimensional fit is an important condition and significant sign of the extent of specific solvent adsorption. It is noteworthy that, apparently, Petrov[7] first expounded the idea of selective epitaxial solvent adsorption on different faces of a single crystal and its role in their growth features.

Then, this idea was directly confirmed[8] by results of ice crystal formation on different faces of sodium bromate crystals.

This short synopsis is necessary, in particular, because the domestic studies are not mentioned in the previous review.[1]

According to Berkovitch-Yellin,[9] polar faces preferentially adsorb polar solvent molecules. Nonpolar ones are solvated by nonpolar solvents. The solvent effect should be especially distinctly evident for crystals of those substances for which the different faces have considerably different polarities. By the polarity of a face is meant the degree of contrast in its electrostatic relief that is quantitatively characterised by the difference of the positive and negative peaks in the map of the electrostatic potential of this face. Such maps have been presented[9] for different crystal faces of benzamide, benzoic acid, α-glycine, E-cinnamide and succinic acid. The maxima of the positive and negative potentials are given. Within the framework of his hypothesis, Berkovitch-Yellin qualitatively explains the crystal shape of these compounds obtained from different solutions. Certainly this hypothesis helps the problem to be understood and possesses a certain predictive capability. However, the importance of dimensional fits is ignored in it.

According to Chan et al.,[10] hexamethylmelamine (an anti-tumour drug) crystals become most anisometric with increasing supersaturation on crystallisation from polar media. Crystals formed in polar media are less sensitive to a change of supersaturation. The spectroscopic features of solutions of this compound in both types of solvents are the same. The crystallisation of two organic compounds was used[10] to demonstrate that relatively well formed isometric crystals are formed from solutions that differ in ideal solubility. Needle-like crystals grow in other solutions. These studies are attempts to find common features of the solvent effect on crystal growth.

The solvation of different faces was quantitatively estimated for saccharose crystals in aqueous solution from the change of surface tension.[12]

For all studies up to the middle of the 1960s, and for many earlier ones including those mentioned above, a qualitative approach and the lack of control of the supersaturation and temperature was characteristic. It was noted in the best instances at what supersaturation, high or low, the experiments were conducted. The temperature was approximately indicated. The results of similar studies are dubious since they may be due not to a solvent effect but to the factors mentioned above. Furthermore, these data are not always reproducible. The first quantitative measurements of the growth rates in different solutions with accurately controlled conditions were described in 1967.[13] It was found that the growth rate of glyceryltripalmitate and glyceryltristearate (measured for one crystal direction) crystals is much higher in CCl_4 solution than in glyceryltrioleate solution. This is consistent with the noticeably higher solubility of these tristearides in the first solvent than in the second. This feature was not noted.[13] However, it then turned out that it is fundamental.

It has been discovered[14] that the growth rate of urotropine crystals from aqueous, ethanol and aqueous-acetone solutions directly depends on its solubility in these media. The solubility of biphenyl in toluene is almost 20 times greater than in CH_3OH (in mole fractions). The growth rate of biphenyl crystals from toluene solution is also almost 20 times greater than from CH_3OH.[15] The kinetics of KNO_3 crystal growth from a series of five solvents and four of their binary mixtures obey the same rules.[16] The growth rate of succinic acid crystals[17] with solubility expressed in molality or molarity also directly depends on its solubility in water and isopropanol although an inverse dependence is obtained if the solubility is expressed in mole fractions. The growth rates of separate faces of hexatriacontane crystals are directly proportional to the solubility of this paraffin in heptane, decane, pentane and petroleum ether.[18]

Table 1. Growth rate of *para*-xylene crystals V at various relative supersaturations σ (0 °C, 30 mass% solvent).[20]

Solvent	m_0	σ	10^4V, cm sec^{-1}	$10^2\beta$, cm sec^{-1}
Ortho-xylene	21,7	0,014	1,0	0,71
Toluene	21,7	0,012	0,7	0,58
Meta-xylene	21,8	0,009	0,6	0,67
Benzene	21,8	0,006	0,8	1,3
Ethylbenzene	21,9	0,002	2,2	11,0

Note. The concentration of the saturated solution m_0 in molality was calculated by us.

Table 2. Thermodynamic and kinetic parameters for growth of urea crystals (25 °C).[21]

Solvent	m_0	ΔH_{cr}, kJ mol^{-1}	α_2	α_3		$10^6\beta_2$, mol cm^{-2} sec^{-1}	
				(100)	(011)	[100]	[001]
Propanol	0,52	27	7,9	3,3	5,0	0,43	1,3
Ethanol	1,04	20	5,9	3,2	4,7	0,26	3,6
Ethyleneglycol	7,45	12	3,6	2,4	3,5	0,38	0,89
N-Methylformamide	7,45	11	2,9	2,4	3,6	1,5	3,5
Formamide	8,79	10	3,2	2,4	3,6	0,70	8,2
Water	20,0	12	3,2	2,4	3,7	43	140

The same was observed for growth rates of individual faces of stearic acid crystals in hexane, decane, dodecane and octane.[18,19] The crystallisation of *para*-xylene (Table 1), which was studied in connection with the problem of separating the precipitate from the mother liquor, and urea (Table 2) can also be used as examples. The kinetic coefficient β appears in both tables as a parameter characterising the growth rate. In the first instance, it is calculated by us from original data presented in Table 1 using the equation $\beta = V/\sigma$. In other words, it is assumed that the growth rate is linearly dependent on the supersaturation. In fact, this function is nonlinear and β is therefore somewhat high. In the second instance, β was determined using the equation $\beta = V/(\sigma - \sigma_{cr})$, where σ is the total supersaturation of the solution and σ_{cr} is the critical supersaturation within which the face does not grow. The quantity σ_{cr} is unique for different solutions. It is zero for aqueous and formamide solutions of urea. The quantity α (Table 2) is discussed below.

In general, the correlation between the crystal growth rate and the solubility is considered to be firmly established although there are exceptions. For example, an inverse dependence is observed for the growth rate of stearic acid crystals from butanone and octane-2-one solutions (Table 3). It is noteworthy that the described feature contradicts the old Van't Hoff rule,[25,26] according to which the rate constant is inversely proportional to the solubility of the reagents.

Table 3. Data for growth of *B*- and *C*-modifications of stearic acid crystals.[22–24]

Solvent	m_0 (25 °C)	ΔH_{cy}, kJ mol^{-1} (25 °C)		V, rel. units		$E^{\neq}$, kJ mol^{-1}	
		B	*C*	*B*	*C*	*B*	*C*
Butanone	0.16	78	74	2.4	2.9	180	105
Octane-2-one	0.37	72	67	1	1	110	73

Note. The activation energy $E^{\neq}$ for growth in butanone solution is found for the (110) face at 13–25 °C; from octane-2-one solution, 16–29 °C. The solubility in molality is calculated by us using previous data.[22,24]

The features of crystal growth from various solvents were analysed using the so-called "entropy factor" (α-factor, Jackson–Temkin factor, roughness factor or parameter),[1,27–30] which was first introduced to analyse growth of crystals from the melt. Small α-factors indicate small differences between the bond energy of species in the crystal and that of the same species with solvent or similar entropies for the crystal and dissolved substance. In other words, these α-factors reflect the strong solvation of the crystal faces, characterised by a low interfacial surface tension. Hence, atomic species should add randomly at small α to the crystal surface at any point (so-called "normal" or "continuous" crystal growth). As a result, the face should be "atomically rough". It is noteworthy that the term "atomically rough" has two meanings. These are the morphological one, as here, and the energetic one. In the second instance, the atomic roughness is the source of normal growth and not its consequence.

For certain intermediate α values, where the surface tension of a face and, consequently, the end of an atomic layer on it, is comparatively small, layered growth of an ideal (defect-free) face is possible owing to formation on it of two-dimensional nuclei even at low supersaturations. Further increasing α should indicate the necessity of large supersaturations for two-dimensional nucleation. At low supersaturations at these α values, the ideal face should not grow at all. At relatively high α values (large surface tension), layered growth is possible that is caused only by dislocations in the crystals. Dislocational growth becomes more significant as α increases. In other words, higher α values indicate that the face is atomically smooth.

The difference between an atomically rough surface and an atomically smooth (singular) one is illustrated in Fig. 1, in which free-energy activation barriers to transfer of an atomic species from solution onto the crystal and its migration along the face are presented for both instances. The barrier (solid line) to direct transfer into the crystal, characterised by the quantity of $\Delta\overleftarrow{G}_0^{\neq}$, is also shown in Fig. 1. This barrier is higher than the previous one since it is accompanied by more extensive desolvation. All points on an atomically rough surface are equivalent for adding atoms to it. They have identical energies for adding atoms to kinks in a step on the crystal surface. The dashed line in Fig. 1*b* outlines the barrier to diffusion along an atomically rough surface, which is also rather high compared with an atomically smooth surface. There should be intermediate instances since it is assumed that the contribution from the normal growth mechanism can vary.

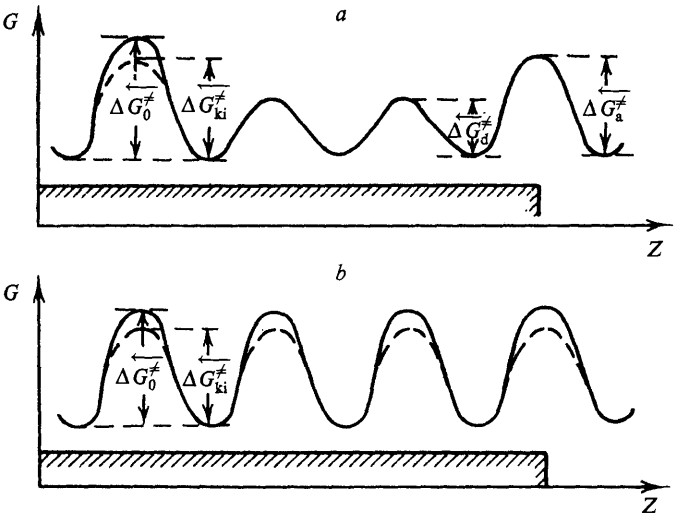

Figure 1. Free energy as a function of position of an atomic particle on a crystal surface (the crystal surface is hatched): an atomically smooth face ($\alpha \gtrsim 3$) (*a*) and an atomically rough face ($\alpha \lesssim 3$) (*b*). The quantity z is the reaction coordinate, $\Delta\overleftarrow{G}_a^{\neq}$ is the free energy of activation for transferring particles from solution into the adsorbed layer on the face (this transfer is accompanied by incomplete desolvation of the crystallising particles), $\Delta\overleftarrow{G}_d^{\neq}$ is the activation energy for surface diffusion of adatoms, $\Delta\overleftarrow{G}_{ki}^{\neq}$ is the activation energy for transfer from the adsorbed layer on a face into a kink on a step accompanied by further partial desolvation (the corresponding barrier is shown as a dashed line).

Thus, a phase transition characterised by low α values should have a high growth rate with a linear dependence on supersaturation and poorly facetted, more or less isometric crystals. Increased growth rates for the normal mechanism are the result of a high density of growth sites on the crystal surface. Crystallisation at high α values should be accompanied by the nonlinear dependences of the growth rate on supersaturation that are typical of layered growth and formation of well formed crystals with a more distinct anisometry than for normal growth, according to the structure of a given crystal. The correlation between α and the crystal-growth features are well observed for melts.

Computer modelling demonstrated (see also previous theoretical estimates[31]) that surface roughness, normal growth and a linear dependence of rate on supersaturation occur for α less than a critical $\alpha_{cr} \approx 2.5$ (Ref. 1) or 3 (Ref. 28). For the range $2.5 \lesssim \alpha \simeq 4$ (Ref. 1) [according to other estimates from 3 to 5 (Ref. 28)], two-dimensional nuclei form comparatively easily and the dependence of growth rate on supersaturation begins to acquire a nonlinear nature. At larger α in a relatively broad range of supersaturations, growth is possible only if dislocations are present and the faces are atomically smooth. These results were obtained by modelling a Kossel crystal (a crystal consisting of closest packed cubes) and considering interactions only between nearest neighbours. For actual crystals differing in structure, types of chemical bonds and shapes of the species comprising them, α values indicating one crystallisation mechanism or another possibly will greatly vary.

The following equations are proposed for calculating α for solutions

$$\alpha_1 = \zeta \frac{\Delta H_{cy}}{RT_{cy}} = \zeta \frac{\Delta S_{cy}}{R}, \quad (1)$$

$$\alpha_2 = \frac{4\gamma_{1a}}{RT_{cy}}, \quad (2)$$

$$\alpha_3 = \zeta \left(\frac{\Delta H_f}{RT_f} - \ln x \right). \quad (3)$$

Here ζ is the crystallographic anisotropy factor that depends on the actual face (ratio of bond energy of the crystal building block within an atomic layer parallel to the given face to the total bond energy or, to a first approximation, the ratio of the number of nearest neighbours in an atomic layer to the coordination number), ΔH_{cy} is the heat of crystallisation, ΔS_{cy} is the entropy of crystallisation, γ_{1a} is the surface tension of an end of an atomic layer on the given crystal face, ΔH_f is the heat of fusion, T_{cy} is the crystallisation temperature, and T_f is the melting point (m.p.). The quantity x has been given different meanings in various studies.[15,17,28] At present, solubilities of substances in mole fractions are preferred for x.

Calculations of α using Eqn. (1) have been shown to be unreliable[1] although this expression is used with ΔH_f and ΔS_f for melts. It is well known that the heat and, therefore, the entropy of crystallisation sometimes have negative values. This makes calculation of α using Eqn. (1) meaningless. Unjustifiably small α are obtained for athermal solutions that have low ΔH_{cy} although they are far from ideal. Furthermore, Eqn. (1) does not consider the individual solvation of different faces. A calculation using Eqn. (1) and ΔS_{cr} for growth of urotropine crystals from aqueous solution (apparently ignoring the sign of ΔS_{cy} since the heat of crystallisation of urotropine from aqueous solution is negative) gave $\alpha = 0.9$.[27] This should indicate that poorly facetted crystals grow. However, urotropine crystals from aqueous solution form typical regular rhombododecahedra and usually capture inclusions of solution. This is characteristic of growth under conditions of "diffusional depletion" (but not of normal growth). Eqn. (1) is not used much anymore. However, the correlation between the growth rate and heat of crystallisation cannot be invalidated (see Table 2), although there may be extenuating circumstances.

Eqn. (2) has previously been applied.[21,27,32,33] Calculations for urotropine using Eqn. (2) and surface tension values of the surface γ_s obtained from the kinetic data for crystal nucleation with subsequent conversion to γ_{1a} gives $\alpha = 0.1$.[27]

Thus, urotropine crystals from aqueous solution should be poorly facetted and rounded according to these calculations. This contrasts with their actual shape. The quantity γ_{1a} for Rochelle salt ($\alpha = 5.2$, well facetted crystal) was calculated[32] on the basis of the empirical correlation between γ_s and ΔH_{cy} known from the literature. The quantity γ_{1a} was analogously determined for urea crystals.[21] The α values (see Table 2) agree with the regular shape of these crystals. This correlation is not accurate enough to calculate α. It loses meaning for solutions with $\Delta H_{cy} < 0$ and for athermal solutions. The quantity γ_{1a} for octogen crystals was calculated[33] on the basis of experimental stability data for supersaturated solutions. Such determinations give γ_s close to the true values. However, these are evidently not accurate enough to calculate γ_{1a}. Furthermore, if the crystal has complicated facetting and this method is used, averaged γ_s are obtained for the crystal as a whole and not for an actual face. For octogen crystals formed from dimethylsulphoxide solution, $\alpha = 0.26$. For such an α value, the crystals of this compound should grow by the normal mechanism, be poorly facetted, and have a linear dependence of rate on supersaturation. However, they were regularly shaped and the dependence of growth rate on supersaturation was distinctly nonlinear.[33]

For octogen in cyclohexane, the agreement of theory and experiment was satisfactory. Thus, $\alpha = 0.6$, the crystals are poorly facetted, and the growth rate depends linearly on supersaturation. According to the literature,[33] the process is diffusion limited, evidently, owing to the fast growth rates. The diffusion limit should be the reason for this linear dependence. However, the fact that the growth rates are fast should argue in favour of a normal mechanism.

The quantity γ_s was converted to γ_{1a} by assuming that the surface tensions of a face and an end of an atomic layer are identical.[27,33,1] This can be disputed by considering the differences in the number of dangling chemical bonds for the species located on the smooth face and on the end of an atomic layer. Furthermore, the symbol of a step end may not coincide with that of the given face if the crystal has complicated facetting. Even for the instance where the crystal has simple facetting, the symbol of the layer end may not correspond to the symbol of this shape (for example, the crystal is cubic and the layer is oriented along [110]). However, it is well known that the surface tension of a layer end depends on its orientation.

Eqn. (3) is used most. This apparently is due to the fact that calculations using it are the easiest. The calculations are contradictory. Obviously, this equation gives small α values for a given substance the greater its solubility. Since the solubility and growth rate are correlated, a systematic inverse correlation between α calculated using Eqn. (3) and the crystal growth rate is observed (an example can be found in Table 2). The two following examples concerning the relationship between α and the crystal shape are interesting.

The entropy factor for biphenyl crystals growing from CH_3OH and toluene solution were calculated using Eqn. (3) (Table 4). The α_{cr} values for different faces were also determined. As it turned out, the faces (001) and (110), for which $\alpha > \alpha_{cr}$, are planar. The face $(20\bar{1})$, for which $\alpha \lesssim \alpha_{cr}$, is rounded. The other two faces, which have comparatively high α_{cr}, are practically unobserved in the facetting. This is quite natural in view of their fast growth rates characteristic of a normal mechanism.

The second example involves crystallisation of naphthalene[34] from solutions in biphenyl and phenanthrene at the eutectic temperatures. It can be seen from Table 5 that the face (001) has the highest σ values. Thus, this face is planar and dominates in crystals at all studied supersaturations. The crystal is platelike along this face.

The smallest α are seen on $(20\bar{1})$. This face has the fastest growth rates and becomes rounded at $\Delta T > \Delta T_{cy}$. The face (110) has an intermediate α value. In biphenyl solution, the eutectic temperature of which is comparatively far from the m.p. of naphthalene, ΔT_{cy} for (110) is much greater than for $(20\bar{1})$. For crystallisation from the eutectic with phenanthrene, the temperature of which is close to the m.p. of naphthalene, ΔT_{cy} for both faces are similar (the approach of the crystallisation temperature to the m.p. neutralises the individual features of the different faces).

Table 4. The α-factor for biphenyl crystals at 30 °C.[15]

Face	CH_3OH	Toluene	α_{kp}
(001)	7.8	6.4	2.6
(110)	4.3	3.5	2.8
$(20\bar{1})$	3.1	2.5	2.7
$(11\bar{1})$	3.5	2.9	3.4
(110)	2.7	2.2	3.0

Table 5. Parameters for growth of naphthalene crystals from biphenyl (x = 0.44, 39.4 °C) and phenanthrene solutions (x = 0.98, 78.9 °C).[34]

Face	ζ	Biphenyl		Phenanthrene	
		α	ΔT_{cy}	α	ΔT_{cy}
(001)	0.820	5.78	–	5.13	–
(110)	0.409	2.94	1.1	2.62	0.3
$(20\bar{1})$	0.380	2.74	0.3	2.43	0.2

The growth of naphthalene crystals has been studied in detail.[35] It was found that rounded surfaces growing by a normal mechanism are formed in solutions of those solvents that have benzene or similar rings in their structure (benzene, toluene, pyridine, etc.). Fully facetted crystals are formed in solutions of solvents that do not have aromatic rings or are elongated or spherical (hexane, CH_3OH, $CHCl_3$, etc.). Elwenspoek et al.[35] suggest that the solvent in the first instance forms an oriented ordered adsorption layer on the naphthalene crystal surface and that the surface tension of the crystals in these solvents is relatively low. In the second instance, there is no such ordered layer and the surface tension is relatively high.

Let us illustrate examples where the observations and calculations using Eqn. (3) do not agree. The dependence of growth rate on supersaturation for the triglycerides mentioned above that is found for CCl_4 solution is much more nonlinear than for glyceryltrioleate solution although α = 2.8 in CCl_4 and α = 4.5 in trioleate.[13] For succinic acid in water and in isopropanol (Table 6), $\alpha_{(010)} > \alpha_{(001)}$; however, $V_{(010)} > V_{(001)}$. The habit changes from platelike along (001) in water to prismatic along [100] in isopropanol. This is in no way predicted on the basis of the α values. These discrepancies between theory and experiment were explained for succinic acid[17,28] as the result of solvation by isopropanol of the ends of atomic steps on the crystal faces. However, this only means that Eqn. (3) is unsatisfactory for calculating α. All varieties of interactions of the compound with the solvent are taken into consideration in Eqn. (3) only through the solubility. The individual features of the solvation of the different faces are ignored. The correction coefficient in Eqn. (3) that reflects the individual interaction of actual solution species and has previously been given[36] is difficult to calculate in practice.

Table 6. Parameters of succinic acid crystallisation.[17]

Face	ζ	Water		Isopropanol	
		α	10^6V	α	10^6V
(010)	0.67	7.8	15	8.0	1.0
(001)	0.5	5.8	4.0	6.0	0.1

Note. The growth rate is in cm sec^{-1} at σ = 0.015.

The data described suggest that in general application of α to solutions is problematical. Eqn. (3) is interesting for calculating an approximate α. Eqn. (2) is most general although it is difficult to use in practice owing to the complexity of determining the surface tension of the end of an atomic layer. The conversion to a rough surface at certain small but finite γ_{st} has been confirmed.[36,37] This contradicts the common viewpoint[31] according to which a condition for the conversion to a rough surface is the reversion of γ_{st} to zero. Regardless of the end construction (degree of roughness), the atomic step is an interface. Therefore, γ_{st} cannot revert to zero.

The method for analysing crystallisation from solutions that depends on use of α is counterposed to the method[28] based on direct analysis of solvation of a face and that[9] based on an analysis of solvation and its relation to the activational barriers. Such contrast is unfounded in view of the auxiliary nature of α. Its significance is to indicate the features of a phase transition on a crystal surface. If both methods contradict each other, α is calculated using an inaccurate formula.

Direct determinations of the activation energy during crystallisation from various media are rare. It has been established that the increase of solubility and growth rate of hexatriacontane in the series decane–heptane–pentane is accompanied by a decrease of activation energy, which equals to 205, 146 and 121 kJ mol^{-1}, respectively.[28] The increased solubility of stearic acid crystals (see Table 3) is also accompanied by a decrease of activation energy and heat of crystallisation.

In general, the examples of normal growth of crystals from solutions are selective and include organic compounds at formation temperatures that differ little from the m.p. Facetted growth is characteristic for crystals in solution. Faces develop owing to expansion of layers on them. Therefore, features of crystallisation from solutions should be theoretically explained by first examining layered facetted growth.

III. Experimental data analysed within the framework of the layered growth mechanism

1. Kinetic equation for the phase transition of an individual atomic species.

The known equation from the activated-complex theory[25,26,38] is usually used to describe the elementary step of crystallisation:

$$V = 0.5\nu\kappa \exp\left(-\Delta G^{\neq}/RT\right)\Pi\alpha_i^{\nu_i}. \quad (4)$$

Here ν is a frequency factor, κ is a transition coefficient, $\Pi a_i^{\nu_i}$ is the product of the activities of the starting reagents taken to powers equal to the stoichiometry coefficients ν_i of the reactants, and $\Delta G^{\neq}$ is the free energy of activation. The factor 0.5 reflects the possibility that the activated complex can decompose in the forward and reverse directions. The quantity $\Delta G^{\neq}$ consists of two terms:

$$\Delta G^{\neq} = \Delta G_{st}^{\neq} + \Delta G_{solv.}^{\neq}. \quad (5)$$

Here $\Delta G_{st}^{\neq}$ is the standard free energy of activation, $\Delta G_{solv}^{\neq}$ is the solvation energy of the activated complex determined from the expression $\Delta G_{solv}^{\neq} = RT\ln\gamma^{\neq}$, and $\gamma^{\neq}$ is the activity coefficient of the activated complex.

The coefficient κ is invariably omitted in studies on crystal growth as is the factor 0.5. Concentrations are used instead of activities. The quantity $\gamma_{st}^{\neq}$ is also ignored. Thus, $\Delta G_{st}^{\neq}$ are used although this is not always noted. In other words, an ideal systems are examined. Such simplifications are inadmissable in analysing crystallisation from solutions. Evidently, $\Delta G_{st}^{\neq}$ at these temperatures and pressures is independent of solvent, supersaturation, and the presence of impurities. Therefore, there is no basis with such an approach to make any assumptions about a change of activation barrier under the influence of these factors.

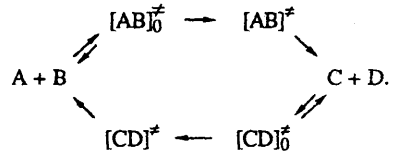
Activated-complex theory has often been criticised[39–43] (see also references in Ref. 26) mainly because the complex is postulated to be in thermodynamic equilibrium with the starting species. However, provisions are made for the further development even in the basic theory. It was noted that κ can substantially differ from unity for reactions in both gases (Ref. 25, p. 280) and in solutions (Ref. 25, p. 415). The necessity to differentiate the activated complex itself and the transition state has been pointed out (Ref. 25, pp 274–278). According to Glasstone et al.,[25] this is the reason that the transmission coefficient characterising the probability of a transfer through the activation barrier differs from unity. This idea was then further developed. According to Shakhparonov,[38] the formation of an activated complex does not imply its immediate decomposition. After it forms, there follows a fluctuating energy redistribution within it and formation of the transition state itself that ensures decomposition in the forward direction.

A detailed kinetic theory of chemical reactions in solutions that supplements the classical approach by taking into account the theory of fluctuations has been published.[38,44] The first question that arises is that of the correctness of using the Boltzmann equation, which is known to be valid only for systems with a rather large number of particles. The following considerations are relevant to this.

The activated complex during crystallisation from solutions includes the solvation sphere since the elementary step in solutions involves desolvation. The theory of fluctuations "often leads to good quantitative agreement with experiment" up to sizes of 10 nm. For smaller dimensions, it agrees qualitatively with experiment (Ref. 45, p. 129). The size of the activated complex including the solvation sphere apparently is of this order. Methods for estimating the sizes of such regions have been discussed.[40]

The refined kinetic equation for a phase transition of a separate atomic species during crystallisation from solutions is similar to that given before[38,44] for homogeneous chemical reactions in liquids. It is obtained as follows.

The chemical reaction is written in the form



Here $[AB]_0^{\neq}$ are the activated complexes in equilibrium with the starting compounds A and B, $[CD]_0^{\neq}$ are activated complexes in equilibrium with the reaction products C and D, and $[AB]^{\neq}$ and $[CD]^{\neq}$ are their respective transition states. The activated complexes in the transition state are not in thermodynamic equilibrium with other species. However, the transition states $[AB]^{\neq}$ and $[CD]^{\neq}$ are indistinguishable whereas $[AB]_0^{\neq}$ and $[CD]_0^{\neq}$ are distinguishable since they are not in thermodynamic equilibrium with each other.

The activated complex in the transition state, which includes the solvation sphere, is considered as a subsystem and the solution surrounding it, the system. According to the Boltzmann equation, the concentration of these subsystems is

$$m^{\neq} = m_0^{\neq}\exp\left(-\frac{\Delta G_{fl}^{\neq}}{RT}\right), \quad (6)$$

where $\Delta G_{fl}^{\neq}$ is the difference between the free energy of the system containing one mole of activated complexes in the transition state and its free energy in the absence of these complexes. Let us recall that this equation also forms the basis for the more expanded kinetic theory of nucleation.

The pre-exponential factor $m_0^{\neq}$ is equal to the concentration of the subsystems consisting of activated complexes for which $\Delta G_{fl}^{\neq} = 0$, i.e., in thermodynamic equilibrium with the starting compounds. The chemical potential of such complexes is

$$\mu^{\neq} = \mu_{st}^{\neq} + RT\ln\left(\gamma^{\neq}m^{\neq}\right), \quad (7)$$

where $\mu_{st}^{\neq}$ is the standard potential of the activated complexes.

Using Eqn. (7), $m_0^{\neq}$ can be expressed in terms of the activity of the starting components

$$m_0^{\neq} = K^{\neq}\frac{\Pi a_i^{\nu_i}}{\gamma^{\neq}};\ K^{\neq} = \exp\left(-\frac{\Delta G_{st}^{\neq}}{RT}\right), \quad (8)$$

where $K^{\neq}$ is the equilibrium constant of the activated complexes.

The rate of the elementary step of the reaction is determined by $V = 0.5\nu m^{\neq}$.

Substituting Eqn. (6) and taking into account Eqn. (8) we obtain

$$V = 0.5\nu\exp\left(-\frac{\Delta G_{fl}^{\neq}}{RT}\right)\exp\left(-\frac{\Delta G_{st}^{\neq}}{RT}\right)\frac{\Pi a_i^{\nu_i}}{\gamma_0^{\neq}}. \quad (9)$$

The quantity $0.5\exp(-\Delta G_{fl}^{\neq}/RT)$ can be treated as the coefficient κ. Methods for estimating it have been examined.[38] Possible methods for estimating $\gamma_0^{\neq}$, i.e. $\Delta G_{solv}^{\neq}$, have also been discussed.[46]

For this approach, the free energy of activation is

$$\Delta G^{\neq} = \Delta G_{st}^{\neq} + \Delta G_{solv}^{\neq} + \Delta G_{fl}^{\neq}. \quad (10)$$

Taking into account Eqn. (10), Eqn. (9) acquires the form

$$V = 0.5\nu\exp\left(-\frac{\Delta G^{*}}{RT}\right)\Pi a_i^{\nu_i}. \qquad (11)$$

This expression is of interest to us. It provides broad possibilities for analysing the effect on the rate of the solution composition (solution concentration, supersaturation, solvent). In a non-equilibrium process, the free energies of activation of the forward and reverse reactions are not equal: $\overrightarrow{\Delta G^{\neq}} \neq \overleftarrow{\Delta G^{\neq}}$. At equilibrium, $\overrightarrow{\Delta G_0^{\neq}} = \overleftarrow{\Delta G_0^{\neq}}$.

2. Rate equation for advance of an individual atomic step.

The rate of addition of atomic species to a step of monatomic height [mol (unit length)$^{-1}$ sec^{-1}] is defined on the basis of Eqn. (11) by

$$\vec{V}_{st} = 0.5\nu \sum_{i=1}^{3} \exp\left(-\frac{\overrightarrow{\Delta G_i^{\neq}}}{RT}\right) a_i a[M], \qquad (12)$$

where $\Delta G_i^{\neq}$ is the free energy of activation of the forward reaction for an atomic growth site i on the step and a_i is the activity of the corresponding site (mole fractions per unit length). The index of a site is 1,2,3 (isolated atom at the end of a step, an atom in a kink and at a smooth site). The index is simultaneously equal to the number of chemical bonds to nearest neighbours in the plane of the (100) face for a Kossel crystal. The variable a is the activity of the crystallising substance in solution (for simplicity, the formation of an unhydrated crystal in the absence of a chemical reaction was used). The quantity [M] is a coefficient introduced so that the dimensions of both parts of the equation are equal (omitted from here on).

It is assumed that the heights of the activation barriers $\overrightarrow{\Delta G_i^{\neq}}$ and the concentrations of different types of sites, i.e., a_i, do not change with a departure from equilibrium. Generally speaking, this is incorrect. However, this is not significant for finding the principal relations between the rate of advance of a step and the most important macroscopic parameters characterising it. Combining all quantities in Eqn. (12) except for a into a single rate coefficient for the forward reaction $\vec{k}_{st}$, we obtain

$$\vec{V}_{st} = \vec{k}_{st} a. \qquad (13)$$

It is also assumed that the removal rate of atoms from a step $\overleftarrow{V}_{st}$ is constant and equal at all supersaturations to the rate of the forward reaction at equilibrium:

$$\overleftarrow{V}_{st} = \vec{V}_{st} = \vec{k}_{st} a_0, \qquad (14)$$

where a_0 is the activity of a compound in the saturated solution.

For the step propagation rate V_{st} taking into account that $a/a_0 = \exp(\Delta\mu/RT)$, where $\Delta\mu$ is the difference of chemical potentials of the crystallising substance in the supersaturated and saturated solutions, we obtain

$$V_{st} = \vec{V}_{st} - \overleftarrow{V}_{st} = \overleftarrow{V}_{st}\left(\exp\frac{\Delta\mu}{RT} - 1\right). \qquad (15)$$

The rate of the reverse reaction $\overleftarrow{V}_{st}$ on the basis of Eqn. (11) is written

$$\overleftarrow{V}_{st} = 0.5\nu \sum_{i=1}^{3} \exp\left(-\frac{\overleftarrow{G_i^{\neq}}}{RT}\right) a_i, \qquad (16)$$

where $\overleftarrow{\Delta G_i^{\neq}}$ is the free energy of activation for removal of particles from i sites at equilibrium.

It follows from Eqn. (16) that the rate of the reverse reaction is determined by $\overleftarrow{\Delta G_i^{\neq}}$ and a_i. It is noteworthy that we are interested in crystal growth in a narrow range of supersaturation near equilibrium that corresponds to supersaturations greater than the saturation temperature by 1–3 °C. Such supersaturations are typical of bulk crystallisation and single-crystal growth. The change of thermodynamic driving force in this range of supersaturations does not exceed fractions of a kilojoule. Therefore, it is assumed to be insignificant compared with the expected activation barriers. The change of position of the upper point of the barriers should be close to that for the change of driving force. Thus, the activation barriers in the range of supersaturations usually used should be practically constant. The concentrations of various types of sites on a step and, consequently, a_i, change at the same supersaturations within narrow limits.[48] The assumption made above that the rate of the reverse reaction is constant are based on these considerations.

Let us express a_i and $\overleftarrow{\Delta G_i^{\neq}}$ for atoms at different positions on the step in terms of the corresponding value for atoms in a kink according to the scheme in Fig. 2.

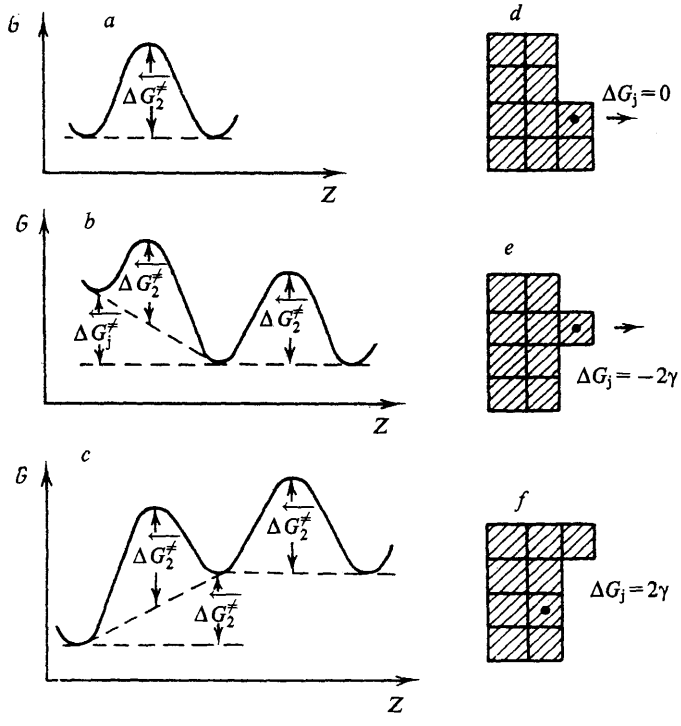


Figure 2. Free-energy activation barrier G (a–c) for transfer of atomic particles at different positions (d–f) from sites on a step into solution (from left to right).[47] The particles being removed are shown by dots.

The chemical potential of particles in solution at equilibrium μ_0 is equal to the chemical potential of particles located in a kink at the end of the step.[31] The chemical potential of an isolated particle on a step is 2γ greater than that of a particle in a kink (see Fig. 2) (γ is the specific free surface energy calculated per area of one atom at the end of a step). On the other hand, the chemical potential of a

particle at a smooth site is 2γ less than that of a particle in a kink since its removal will increase the surface energy of the step (i.e., the whole system) by 2γ. Thus,

$$\mu_{ki}(\mu_2)=\mu_0;\ \ \mu_1=\mu_{ki}+2\gamma;\ \ \mu_3=\mu_{ki}-2\gamma. \tag{17}$$

Setting the standard chemical potential of particles at all points of the step equal to the standard chemical potential of the compound in solution, we obtain from Eqn. (17)

$$a_2(a_{ki})=a_0;\ \ a_1=e^{2\gamma}a_2=e^{2\gamma}a_0;\ \ a_3=e^{-2\gamma}a_2=e^{-2\gamma}a_0. \tag{18}$$

It is noteworthy that a_i are related by the Gibbs–Duhem equation:

$$\sum_{i=1}^{3}x_i d\ln a_i=0.$$

Here x_i are the concentrations of particles at different positions on the end of a step in fractions of the total number of sites:

$$\sum_{i=1}^{3}x_i=1.$$

The quantities $\overleftarrow{\Delta G_i^{\neq}}$ are related as follows (see Fig. 2):

$$\overleftarrow{\Delta G_1^{\neq}}=\overleftarrow{\Delta G_2^{\neq}}-\gamma;\ \ \overleftarrow{\Delta G_3^{\neq}}=\overleftarrow{\Delta G_2^{\neq}}+\gamma. \tag{19}$$

Substituting Eqn. (16) into Eqn. (15), we obtain taking into account Eqns.(18) and (19):

$$V_{st}=0.5\exp\left(-\frac{\overleftarrow{\Delta G_2^{\neq}}}{RT}\right)a_0\left(2\cosh\frac{3\gamma_{st}}{RT}-1\right)\left(\exp\frac{\Delta\mu}{RT}-1\right). \tag{20}$$

The following points are noteworthy. According to Eqn. (20), the growth rate of a step should increase with increasing surface energy. At first glance, this seems paradoxical. However, it is just as paradoxical that the rate of advance of a step is greater the greater the rate of removal of particles from it according to Eqn. (15).

On going to nonequilibrium and increasing the supersaturation, the number of kinks and single atoms on the step increase.[48] Thus, the number of atomic particles belonging to the smooth parts of the step decreases. This means that the activities of the kinks a_2 and single particles a_1 increase whereas the activity of atomic particles at the smooth sites a_3 decreases. Thus, besides increasing the position of the free-energy minimum for particles in solution, the position of the minimum for various types of particles on the step increases or decreases (see Fig. 2). It can be assumed that the position of the minima for the latter changes to a lower value than for particles in solution. The position of the free-energy maxima (tops of the activation barriers) also changes with a change of supersaturation. However, it is not clear to what value it changes. There is no basis to think that they decrease by $\Delta\mu/2$ for the forward and increase by $\Delta\mu/2$ for the reverse reaction, as previously assumed.[47,49] These effects, as already noted above, are ignored here.

3. Rate equation for growth of a crystal face.

Dislocations, as a rule, are the source of growth layers on faces during formation of crystals from solutions. A two-dimensional nucleus can predominate only during growth of perfect crystals from carefully purified solutions. During crystallisation under ordinary conditions, it begins to contribute to growth of faces only at rather large supersaturations. The presence of dislocations ensures that steps are always present on a face, even where the crystal is in equilibrium with the medium. Therefore, the face growth rate is

$$V=V_{st}B, \tag{21}$$

where B is the total length of dislocation steps of atomic height per unit area of face at a given supersaturation.† Let us substitute Eqn. (20) into Eqn. (21) and find a linear approximation to Eqn. (21) near equilibrium (i.e. the first term in the expansion of the latter equation in a Maclaurin series):

$$V=0.5v\exp\left(-\frac{\overleftarrow{\Delta G_{ki}^{\neq}}}{RT}\right)B_0\left(2\cosh\frac{3\gamma_{st}}{RT}-1\right)a_0\sigma. \tag{22}$$

Here B_0 is the density of dislocation steps at equilibrium. The supersaturation is $\sigma\approx\Delta\mu/RT$. Introducing for simplification the parameter B_0, we obtain, according to Eqn. (22), an expression for the kinetic coefficient β, which determines the slope of the curve for the growth rate at zero coordinates:

$$\beta=\beta_0B_0\exp\left(-\frac{\overleftarrow{\Delta G_{ki}^{\neq}}}{RT}\right)\left(2\cosh\frac{3\gamma_{st}}{RT}+1\right). \tag{23}$$

The parameter β is calculated in practice (see Section II). According to the resulting equation, the solution composition affects the growth rate through B_0, the free energy of activation $\overleftarrow{\Delta G_{ki}^{\neq}}$ and the specific free surface energy of a step γ_{st}. The density of steps depends on the crystal imperfection, which in turn is determined by the impurities in solution. Two other quantities reflect the degree of solvation of crystallising particles and the solvation of the actual crystal face.

Thus, at large departures from equilibrium we have:

$$V=\beta\frac{\Delta\mu}{RT}\cong\beta\frac{\Delta a}{a}\cong\beta\sigma. \tag{24}$$

This means that if the driving force is represented as $\Delta\mu/RT$ (i.e., $\Delta a_0/a_0$ or σ), then the kinetic coefficient is equal to the rate of reverse reaction $\overleftarrow{V}$ at equilibrium [mol (unit area)$^{-1}$)]. If the driving force is represented as the difference of the activities, then

$$V=\overleftarrow{k}_0\Delta a, \tag{25}$$

where $\overleftarrow{k}_0$ is the rate constant of the forward reaction at equilibrium. Thus, $\beta=\overleftarrow{k}_0a_0$. Since a_0 = const regardless of the solvent, then β and $\overrightarrow{k}_0$ in all solutions for a single substance at a given temperature differ only by a constant factor.

The apparent Arrhenius activation energy of the reverse reaction is found as usual from the temperature dependence of β

$$\partial\ln\beta/\partial(1/T)=-\overleftarrow{E}^{*}/R. \tag{26}$$

The Arrhenius activation energy of the forward reaction is found from the temperature dependence of $\overrightarrow{k}_0$:

$$\partial\ln\overrightarrow{k}_0/\partial\ (1/T)=-\overrightarrow{E}^{*}/R. \tag{27}$$

The free energy of activation in Eqn. (23) is determined using the known equations

$$\overleftarrow{\Delta G_{ki}^{\neq}}=\Delta\overrightarrow{G}_{ki}^{\neq}=\overleftarrow{\Delta H_0^{\neq}}-T\Delta\overleftarrow{S}_0^{\neq}=\Delta\overrightarrow{H}_0^{\neq}-T\Delta\overrightarrow{S}_0^{\neq}, \tag{28}$$

where $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are the enthalpy and entropy of activation for the forward and reverse reactions. The subscript

† The possibility that atomic and larger steps may be present on the crystal faces is ignored. They form through consolidation of atomic steps, like other cooperative effects arising between steps, owing to impurities and solvent diffusion. These factors are peripheral to our examination. Furthermore, these factors at small supersaturations have a comparatively weak effect on the growth of steps.

zero indicates that these quantities refer to equilibrium conditions. The activation energy $\vec{E}^{\neq}$ is evidently related to $\Delta H^{\neq}$; $\overleftarrow{E}^{\neq}$, to $\Delta H^{\neq}$.

The quantity B_0 should be practically constant if crystals of a given compound obtained under identical conditions are used as seeds to grow crystals from various solvents. This occurs because the dislocation density in them in all instances will be about the same. It is even better if the same crystals are used as seeds in the experiments, as was previously done.[21] Thus, the solvent effect can change only the parameters of $\Delta G^{\neq}$ and γ_{st}. These quantities are related to the enthalpy of crystallisation. Let us examine first the relation of $\Delta H^{\neq}$ to ΔH_{cy}.

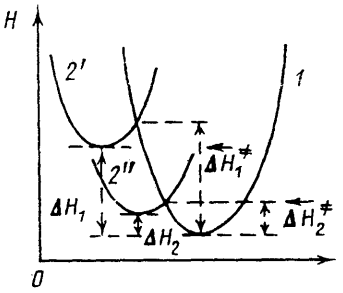

Figure 3. Enthalpy of a crystal–solution system as a function of coordinates of crystallising particles.

Suppose, in analogy with the previous potential curves,[46] that line *1* in Fig. 3 is the curve for the enthalpy change of the system after a position change of an atomic particle belonging to the crystal along the reaction coordinate z (calculated per mole of substance). Obviously, the minimum on this curve does not depend on solvent. Intermediate steps (position of the particle on a step on the face, adsorbed on the surface) are not considered. The line *2'* is the curve for the enthalpy change of the system after a position change of a dissolved particle in solvent 1; line *2''*, the same after a position change of a particle in solvent 2. The quantities ΔH_1 and ΔH_2 are the enthalpies of the phase transition in the first and second instances. The quantity $\Delta H_1 > \Delta H_2$. Therefore, the activation enthalpy of the reverse reaction is greater in the first instance than in the second. Thus, the heat of crystallisation and the enthalpy of activation of the forward reaction are directly correlated. In exactly the same way, the heat of the process and the enthalpy of activation of the forward reaction should be directly correlated since β and $\vec{k}_0$ are related by a constant factor. This means that the minimum on curve *2* in Fig. 3 must shift along the z axis on going from one solvent to another (the reaction radius changes). If the curve does not shift, then the activation energy of the forward and reverse reactions should change in opposite directions on going from one medium to another, which is impossible.

This theory was previously used[21] to explain the features described in Section II.

It is well known that an increase of the free energy of activation owing to an increase of the enthalpy of activation is usually accompanied by a decrease due to an increase of the entropy of activation (the so-called "compensation effect") since the change of the enthalpy and entropy of activation, as a rule, have the same sign. This was also confirmed for crystallisation.[50] However, the enthalpy of activation still plays the dominant role. Thus, there should be an inverse correlation between the heat of crystallisation and the growth rate. This is observed for urea (see Table 2). Furthermore, it is also possible that the entropy of activation (more accurately, the term $T\Delta S^{\neq}$) in Eqn. (28) changes more than the enthalpy of activation $\Delta H^{\neq}$. As a result, despite the decrease of activation energy, the crystal growth rate will decrease. It has been pointed out[26] that situations are also possible where the enthalpy and entropy of activation change differently.

The heat of crystallisation in solutions is determined using the known equation,[51] according to which, to a first approximation, $\Delta H_{cy} \sim m_0^{-1}$. This explains the direct correlation between the growth rate and the solubility of a given substance in the series of solvents described in Section II.

The specific surface free energy of crystals and their solubility are inversely correlated.[52] Thus, if the role of surface energy were to dominate over the effect of growth, then the increase of solubility would lead, in agreement with Eqn. (22), to a reduction of growth rate. However, as a rule, the opposite is experimentally observed. This means that the role of surface energy in the solvent effect on facetted growth of crystals is second-order compared with the role of activation barriers. Special instances ($\Delta H_{cy} < 0$) and isolated examples of a rate reduction with an increase of solubility require special investigations.

We emphasise that the described examination of the crystallisation is limited to layered dislocation growth. Its signature is the formation of well formed crystals with stable growth layers centered on the faces. The skeletal nature of the growth faces is not consistent with the normal mechanism and is only an indication of unequal diffusion of a substance to the faces (diffusional depletion due to a rate that is too fast). Rounding of the faces (antiskeletal growth) is not an unambiguous indication of the normal growth mechanism since it can be the result, like in the known example of KH_2PO_4 crystallisation, of layered growth that is hindered by trace impurities adsorbed on the faces.

I. Introduction

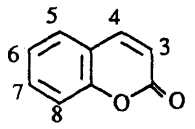
Superb luminescence in the blue-green part of the spectrum is characteristic of the majority of coumarin derivatives. By virtue of this property, coumarins have found extensive applications as optical bleaching agents,[1] in the creation of active media for tunable lasers,[2] and as luminescence labels.[3] Furocoumarins or psoralens are epidermal photosensitisers and are used in the phototherapy of skin diseases.[4] Coumarin derivatives are also of interest for the creation of photochromic materials.[5] Numerous studies devoted to the synthesis, properties, and applications of compounds of this class have been published recently. The principal methods of synthesis, reactivities, and lasing characteristics of 7-aminocoumarins have been recently reviewed.[6] Since the main applications of coumarins involve the transformation of radiation, photochemical studies are of decisive importance in the search for their new more effective and photostable derivatives. The luminescence-spectroscopic properties of coumarins are briefly analysed in the present review and a systematic account is given of data on their photochemistry, mainly those published in the literature during the last ten years.

II. Spectra and excited states

1. Absorption and fluorescence spectra

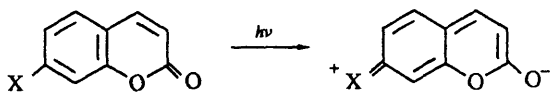
Our aim was not to carry out an exhaustive survey of the luminescence-spectroscopic properties of all the known coumarin derivatives.[7–11] We shall confine ourselves to the most general features of their dependence on the structure of the dye.

The luminescence-spectroscopic properties of coumarins are determined by the relative positions of the lowest electronically excited states of the $n\pi^*$ and $\pi\pi^*$ type. The unsubstituted coumarin does not fluoresce—it has a singlet lowest excited state of the $n\pi^*$ type with an energy of 3.4 eV.[12]



Coumarin

The most common phosphors among the compounds considered are 7-amino- and 7-hydroxy-derivatives. The introduction of an electron-donating substituent in the 7-position in coumarin has only a slight effect on the energies of the $S_{n\pi^*}$ and $T_{n\pi^*}$ states, while the energies of the $S_{\pi\pi^*}$ and $T_{\pi\pi^*}$ states diminish appreciably under these conditions as a consequence of the conjugation of the electron-donating substituent with the aromatic system and they become the lowest states[12] with a considerable contribution by the state with intramolecular charge transfer owing to the promotion of an electron from the electron-donating substituent to the carbonyl group:



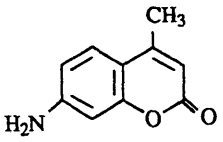
X = NR_2, OR.

The polarisation of the molecule on excitation is also indicated by the greater bathochromic shift of the fluorescence bands of 7-aminocoumarins relative to the absorption bands with increase in solvent polarity.[7] The estimated change in the dipole moment on excitation to the S_1 state is $\Delta\mu$ = 6.84 and 8.02 D for 7-amino and 7-diethylamino-4-methylcoumarins respectively.[13]

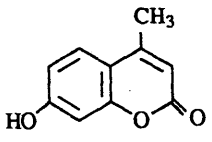
The data presented in Table 1 for certain coumarins illustrate the following characteristics of the influence of structural factors on the electronic absorption and fluorescence spectra. In comparing the spectroscopic parameters, account must be taken of the fact that the methyl group in the 4-position of the 4-pyrone ring does not affect the positions of the long-wavelength bands.

1. It has been demonstrated in relation to aminocoumarins with different positions of the amino-group in the molecule (Table 1) that the maximum bathochromic shift of the absorption spectra is observed when an electron-donating substituent is introduced in the 6 and 7-positions (the effect of substitution in the 6-position is

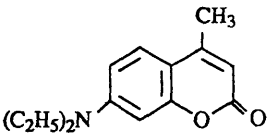
greater[20]) as a consequence of the greater stabilisation of charge transfer on excitation.



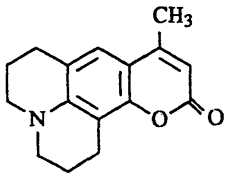
Coumarin 120



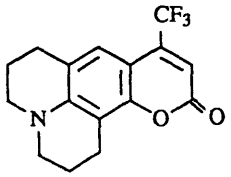
4-Methylumbelliferone



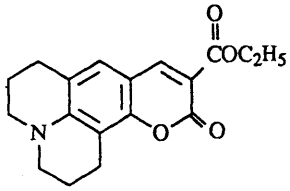
Coumarin 1



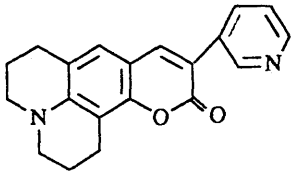
Coumarin 102



Coumarin 153



Coumarin 504



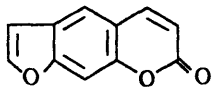
Coumarin 510

2. The bathochromic shifts of the absorption and fluorescence spectra depend on the electron-donating properties of the substituent. Thus the amino-group is a stronger electron donor than the hydroxy-group and has a greater effect than the latter on the energy of the S_1 state of coumarin. Alkylated amino-groups intensify the electron-donating properties of the substituent and lead to a further successive shift of the absorption and fluorescence bands of coumarins 120, 1, and 102 to the long-wavelength region.

3. The introduction of an electron-accepting substituent, for example, the trifluoromethyl, ethoxycarbonyl, aryl, heteroaryl, and other groups, into the pyrone fragment of the molecule induces an even greater shift of the absorption and fluorescence maxima into the red region as a consequence of the further enhancement of the degree of charge transfer. This conclusion is confirmed by the spectroscopic data presented in Table 1 for coumarin 102, on the one hand, and for coumarins 153, 504, and 510, on the other. The introduction of electron-donating substituents into the pyrone fragment of 7-aminocoumarins results in the opposite effect.[21]

The above features refer to the influence of structural factors on the absorption and fluorescence of neutral forms of coumarin derivatives, the acid–base reactions of which make it possible to expand considerably the spectral range of luminescence.[22–25]

Furocoumarins (derivatives of psoralen), exhibiting a photo-therapeutic effect, are of considerable interest.



Psoralen

The absorption spectra of the majority of furocoumarins are similar to that of psoralen, the lowest excited $S_{\pi\pi^*}$ state of which lies somewhat below the $S_{n\pi^*}$ state.[4]

Table 1. The luminescence spectroscopic parameters of coumarins in ethanol.

Coumarin	Wavelength, nm		Fluorescence quantum yield	Refs.
	in absorption	in fluorescence

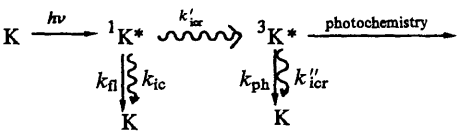
2. The fluorescence efficiency

The fluorescence quantum yields of compounds of the coumarin series are determined both by internal factors (non-radiative internal conversion to the ground state and the intersystem crossing to the triplet state) and by external factors (interaction of the excited molecules with other molecules).

We shall consider the role of internal factors, which include the processes leading to the deactivation of excited states presented in Scheme 1.

Scheme 1



where K, $^1K^*$, and $^3K^*$ are coumarin derivatives in the ground, first excited singlet, and triplet states, k_l, k_{ph}, k_{ic}, and k_{icr} are the rate constants for fluorescence, phosphorescence, internal conversion, and intersystem crossing respectively.

It follows from Scheme 1 that a low fluorescence yield is observed in the case of predominant deactivation of the excited singlet state in non-radiative processes involving internal conversion to the ground state (k_{ic}) or intersystem crossing to the triplet state (k_{icr}^{i}).

Theoretical calculations for 7-aminocoumarin derivatives showed that they belong to the fifth luminescence type of molecules with heteroatoms having higher energies of the $S_{\pi\pi^*}$ states relative to the triplet states of the $\pi\pi^*$ type.[12] Since the intersystem transition between these states is forbidden,[26] the population of the triplet levels (the main pathway leading to the loss of the energy of the fluorescent state of heteroaromatic compounds) is small in the case of 7-aminocoumarins (the quantum yield of the excited triplet states is $\varphi_T < 0.05$).[19]

The probability of intersystem crossing is determined, apart from the nature of the excited singlet and triplet states, also by the energy gap between them, increasing with decrease in the $S-T$ splitting. The energy gaps between the S_1 state and the triplet state closest to it have been calculated[12] for a series of 7-aminocoumarin derivatives. It was shown that, for compounds of the coumarin series, a relation is observed between the fluorescence quantum yields and the relative positions of the singlet and triplet states, in agreement with the ideas described.

The non-radiative deactivation via internal conversion is the second important pathway leading to the loss of the energy of the fluorescence states — it takes place mainly as a result of transitions between the vibronic levels of the S_1 and S_0 states and via hydrogen bonds. Comparison of the fluorescence quantum yields of coumarin 1 and coumarin 102 (Table 1) confirms the conclusion[27–29] that the fixation of the alkyl amino-group as a result of the incorporation of the alkyl substituent in a ring makes it possible to diminish the non-radiative excitation energy losses on rotation of the amino-groups in the excited state and permits a significant increase in the fluorescence quantum yield.

The deactivation of the fluorescent state via the hydrogen bond between 7-aminocoumarin and the solvent has been postulated to account for certain experimental data,[7,29] but it is apparently less effective than other pathways leading to the dissipation of excitation energy. Thus detailed studies have been made[13,19,27,30] of the dependences of the positions of the fluorescence bands, quantum yields, and lifetimes on the solvent polarity. It was found that in the case of 7-alkyl-aminocoumarins with a free amino-group, anomalously weak fluorescence, displaced to the red region, is observed in polar solvents. This phenomenon also occurs in solvents which do not form hydrogen bonds.[30] On the basis of these observations for 7-alkylaminocoumarins with a free amino-group, the following new model of the non-radiative deactivation of the excitation energy has been proposed. Two excited states with intramolecular charge transfer are postulated — a planar state which emits with a high efficiency and a "twisted" state, the degradation of the excitation energy of which is achieved mainly by a non-radiative pathway.[13,19,30,31] The activation barrier to the transition from the emitting planar state to the "twisted" state diminishes with increase in solvent polarity. For 7-aminocoumarins with a bound amino-group (coumarins 102, 153, etc.), only the planar excited state with intramolecular charge transfer can exist. With increase in solvent polarity, the fluorescence of such compounds shifts towards longer wavelengths and the efficiency and lifetime of the fluorescence change little under these conditions. In the case of 7-amino-coumarins with a free amino-group, there is a possibility of the formation of a non-luminescent "twisted" excited state in polar solvents, which is manifested by a significant decrease in the fluorescence efficiency and lifetime and its displacement towards longer wavelengths with increase in solvent polarity. For 7-amino-coumarins with a bound amino-group, the formation of a "twisted" non-luminescent excited state with intramolecular charge transfer is possible when the molecule contains other substituents capable of rotation.[32] It is noteworthy that the concept, developed in a number of studies,[13,19,30,31] that there are two types of excited states in coumarins with a free amino-group has not been confirmed experimentally in studies on the induced absorption and emission spectra of these compounds by picosecond spectroscopy.[33]

For coumarin derivatives with close lowest $\pi\pi^*$ and $n\pi^*$ states, the probability of non-radiative deactivation increases sharply as a consequence of vibrational interactions leading to a displacement of levels (the "proximity effect"). The effective non-radiative degradation of the excitation energy of 4-methylumbelliferone in aprotic media[18] and of furocoumarins[34] has been interpreted in terms of these ideas.

The fluorescent state energy deactivation processes, determined by external factors, including the interaction of the excited molecules with the molecules of quenching agents, are also extremely important. The oxygen present in solution, which induces the intersystem crossing to the triplet state by exchange interaction, is usually the cause of the quenching of the fluorescence of dyes of different classes.[35] Fletcher and co-workers[36] determined the relative fluorescence quantum yields (φ_{fl}) for a series of coumarin dyes in ethanol as a function of oxygen concentration. They established that the fluorescence of all the test compounds diminishes significantly in the presence of oxygen. For example, in the case of coumarin 1 the quantum yields φ_{fl} were 0.57, 0.79 and 0.85 in ethanol saturated with oxygen, air, and argon respectively.[36] Shakhverdov, et al.[35] noted high values of the constants for the quenching of the fluorescence of 7-aminocoumarins by oxygen ($k \geqslant 10^{10}$ litre mol^{-1} s^{-1}) accompanied by low rate constants for their intersystem crossing ($k_{cr} = 0.3 \times 10^7$ and 0.4×10^7 s^{-1} for coumarins 1 and 102), which is inconsistent with the quenching of the fluorescent state via the mechanism involving the oxygen-induced intersystem crossing to the triplet state. On the other hand, the rate constants for the quenching of the fluorescence of coumarin by oxygen agree with the relative positions of the states involving charge transfer from the dyes to oxygen.[35] On the basis of this relation, Shakhverdov, et al.[35] concluded that the mechanism of the quenching of the fluorescence of coumarin dyes by oxygen is based on donor–acceptor interactions.

The quenching of the fluorescence of umbelliferone derivatives by inorganic ions has been investigated.[37–40] Since the results could not be explained by the heavy atom effect,[39] the most probable mechanism in this instance is believed to involve[39] quenching via electron transfer. The methyl group in the 4-position in the pyrone ring provides a partial shield to the quenching of the fluorescence of coumarin by halide ions.[39]

The rate constants for quenching by electron donors and acceptors increase with decrease in the free energy of electron transfer with participation of 7-aminocoumarins in the excited singlet state, and for donors with $E_{1/2}^{ox} < 1.0$ V and acceptors with $E_{1/2}^{red} > -1.5$ V (relative to the saturated calomel electrode) the rate constants for the quenching of 7-aminocoumarins in the S_1 state are close to diffusion rate constants.[41]

3. Excited triplet states

The triplet–triplet absorption spectrum of unsubstituted coumarin in ethanol, measured in several studies,[42–44] revealed the occurrence of an intense long-wavelength transition $T_1 \rightarrow T_3$ with a

maximum λ_{max} = 459 nm and a molecular extinction coefficient ε_T = 13000 litre mol^{-1} cm^{-1}. This transition is polarised in the molecular plane along the long axis of the molecule. A weak $T_1 \rightarrow T_2$ transition occurs at lower frequencies. The intersystem crossing quantum yield in water and the energy of the first triplet state of coumarin are φ_T = 0.054[45] and 262 kJ mol^{-1} [46] respectively. According to a theoretical study,[47] a strong polarisation of the bond between the third and fourth carbon atoms is characteristic of the T_1 state of coumarin. The lifetimes of the excited triplet states of both coumarin and its derivatives, which are in the microsecond range,[19,45,48] depend on the solution concentration. At low concentrations, the excited triplet states are degraded via a first-order process. For example, in the case of unsubstituted coumarin, the rate constant for this process in benzene is 2.6 × 10^5 s^{-1}.[45] With increase in coumarin concentration, τ_T diminishes as a consequence of the quenching of the triplets by interaction with the ground state and the rate constant for quenching via a second-order reaction is 1.5 × 10^8 litre mol^{-1} s^{-1} for coumarin in benzene.[4]

Laser-type 7-aminocoumarin has low yields of intersystem crossing to the excited triplet state (φ_T < 0.05;[19] for coumarin 1 in ethanol, φ_T = 0.006[49]). The phosphorescence lifetimes of these compounds at 77 K are in the range corresponding to several seconds,[42] which is characteristic of excited triplet states of the $\pi\pi^*$ type.

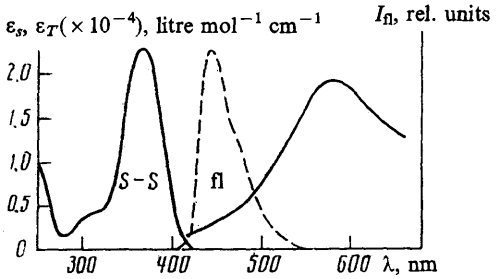


Figure 1. The $S-S$ and $T-T$ absorption and fluorescence spectra of coumarin 1;[42] I_{fl} = fluorescence intensity.

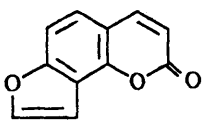
Fig. 1 illustrates the absorption spectrum of coumarin 1 in the excited triplet state obtained by pulsed laser photolysis.[42] Similar spectra have been obtained for a series of other 7-substituted coumarins. It is seen (Fig. 1) that the $T-T$ absorption of these compounds is represented by a broad band whose short-wavelength slope overlaps the luminescence spectrum. In order to estimate the loss of lasing energy in absorption by triplet levels, the molecular extinction coefficients for the $T-T$ absorption have been determined[50] in the region corresponding to the luminescence of the most important lasing coumarin dyes in ethanol.

As in the case of $S_0 \rightarrow S_1$ transitions, the methyl group in the 4-position in the pyrone ring does not alter the position of the maximum in the $T-T$ absorption spectrum, whereas the introduction of electron-donating substituents in the 7-position shifts the spectral maxima to the low-frequency region.[42] The characteristics of the $T-T$ absorption spectra of certain lasing coumarin dyes are[λ_{max}^{T-T}, nm (ε_T, litre mol^{-1} cm^{-1})]: coumarin 1—570 (15050),[51] coumarin 102—580 (14000),[48] coumarin 153 in benzene—580 (10000),[52] and 7-hydroxycoumarin in frozen alcohol—510 (18500).[44] The energies of the triplet levels determined by the energy transfer method using various triplet donors and acceptors are 240, 240, 210, and 217 kJ mol^{-1} for coumarins 1, 102, and 153 and 7-diethylamino-4-trifluoromethylcoumarin respectively.[48,51,52] As in the case of excited singlet states, the energies of the triplet levels of 7-aminocoumarins are lowered when the CH_3 group is replaced by the electron-accepting CF_3 group in the pyrone part of the molecule and T_1 therefore has the character of a state with charge transfer.

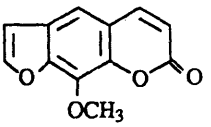
Table 2. Characteristics of the excited triplet states of furocoumarins in benzene.[34,53]

Furocoumarin	$\varphi_T \pm 10\%$	λ_{max}^{T-T}, nm	ε_T, litre mol^{-1} cm^{-1}	E_T, kJ mol^{-1}
Psoralen	0.03	450	8100	278
Angelicin	0.03	430	5500	–
8-Methoxypsoralen	0.01	480	10000	270
4,5',8-Trimethylpsoralen	0.21	450	7750	–
6,4,4'-Trimethylangelicin	0.13	450	6300	–
3-Ethoxycarbonylpsoralen	0.30	410	11500	271
3-Acetoangelicin	0.54	430	13200	–

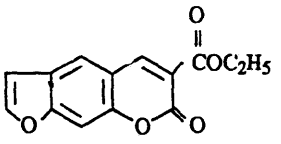
Like many aromatic carbonyl-containing compounds, furocoumarins or psoralens, which is another important group of coumarins, have $n\pi^*$ levels which are close to the lowest excited states of the $\pi\pi^*$ type.[34] This phenomenon, the so called "proximity effect", leads to intense non-radiative degradation of the excitation energy involving its transfer to both the ground and excited triplet states. The dependence of the efficiency of the non-radiative degradation on the relative positions of the levels is used to explain the characteristic features of the influence of the structure of furocoumarin on the quantum yield of the intersystem crossing, which are illustrated by examples in Table 2. The photophysical and spectroscopic parameters of the excited triplet states for a wide range of furocoumarins have been published in the literature.[34,54] The quantum yields of the intersystem crossing of furocoumarins vary within wide limits as a function of their structure—from 0.01 for 8-methoxypsoralen to 0.54 for 3-acetylangelicin (Table 2).



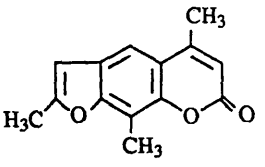
Angelicin



8-Methoxypsoralen



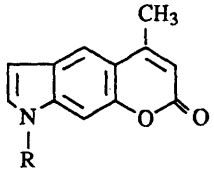
3-Ethoxycarbonylpsoralen



4,5',8-Trimethylpsoralen

The introduction of a methyl group increases φ_T. For example, φ_T = 0.21 for 4,5′,8-trimethylpsoralen, whereas the intersystem crossing yield for unsubstituted psoralen is much lower, amounting to 0.03. Similarly, 6,4,4′-trimethylangelicin has φ_T = 0.13, while angelicin itself has φ_T = 0.03. The yields φ_T increase also when an additional carbonyl group is introduced into the furocoumarin molecule. Thus the intersystem crossing quantum yield increases from φ_T = 0.03 to φ_T = 0.30 and 0.54 when the hydrogen atom in the 3-position in psoralen and angelicin is replaced by the ethoxycarbonyl and acetyl groups respectively. The molar extinction coefficients also increase on passing to furocoumarins containing an additional conjugated carbonyl group. The energies of the triplet levels of furocoumarins decrease when both electron-donating substituents and groups containing a carbonyl moiety conjugated with the aromatic system are introduced into the molecule (Table 2).

The pyrrolocoumarins (I) and (III), which have been synthesised recently,[55] are structurally similar to psoralenes.



R = H(I), CH_3(II), C_2H_5(III)

The photophysical behaviour of these two groups of compounds also has much in common. Whilst exhibiting only a weak fluorescence ($\varphi_{fl} \simeq 10^{-2}$), pyrrolocoumarins phosphoresce intensely in the range 480–600 nm. The triplet–triplet absorption spectrum of compound (I) contains bands with maxima at λ_{max}^{T-T} = 380, 500, and ~600 nm.[55] The lifetimes of the excited triplet states of pyrrolocoumarins are typical for coumarins and amount to ~5 μs. Experimental data[55] indicate an intense intramolecular charge transfer on excitation of compounds (I)–(III) as a consequence of the pronounced electron-donating properties of the pyrrole ring.

4. Generation of singlet oxygen

An important characteristic of coumarins is the quantum yield in the generation of singlet oxygen by these compounds. It has been suggested that the phototherapeutic effects of furocoumarins, which are epidermal photosensitisers and are used in the phototherapy of many skin diseases, may be partly due to the formation of $^1\Delta_g$ singlet oxygen ($^1O_2$).[56,57] The lasing 7-aminocoumarins are oxidised by singlet oxygen via a self-sensitised oxidation mechanism.[58,59] For the quantitative estimation of the efficiency of both the processes listed above as well as others occurring with participation of $^1O_2$ generated by coumarins, it is essential to know the quantum yield of singlet oxygen ($\varphi_{^1O_2}$).

$^1O_2$ is usually formed when excitation energy is transferred from the T_1 level of the sensitiser (coumarin) to oxygen in the triplet ground state:

$$^3K^* + {}^3O_2 \rightarrow K + {}^1O_2 .$$

The energies of the triplet levels of coumarin and its derivatives (see above) exceed the energy of $^1\Delta_g$ singlet oxygen (94.4 kJ mol^{-1}), so that the energy transfer process considered is feasible. The quenching of the excited triplet states of coumarin by oxygen proceeds, like that of the majority of other compounds, with rate compounds close to the diffusion-controlled limit and leads to the formation of $^1O_2$.[60]

$\varphi_{^1O_2}$ for unsubstituted coumarin, which has been determined by a comparative method from the luminescence of the singlet oxygen generation, is ~0.015 in D_2O and 0.03 in CH_3OH.[61] Knox, et al.[34] determined the quantum yields in the generation of $^1O_2$ for a series of furocoumarins in benzene. The yields $\varphi_{^1O_2}$ for some of them are presented in Table 3, which shows that the efficiency of the generation of $^1O_2$ by furocoumarins may be various. It has been established that $\varphi_{^1O_2}$ is determined not only by the quantum yields of the excited triplet states of furocoumarins but also by the probability of the formation of $^1O_2$ when their T_1 states are quenched by oxygen ($\theta_{^1O_2}$), which varies in the range 0.1 to 1 for many of the furocoumarins investigated (Table 3).

Table 3. Characteristics of the generation of singlet oxygen by furocoumarins in benzene.[34]

Furocoumarin	$\varphi_{^1O_2}$ ±10%	$\theta_{^1O_2}$ ±25%
Psoralen	0.01	0.33
Angelicin	0.01	0.33
8-Methoxypsoralen	0.004	0.40
5,8-Dimethoxypsoralen	0.004	0.10
4,5′,8-Trimethylpsoralen	0.08	0.38
6,4,4′-Trimethylangelicin	0.02	0.16
3-Ethoxycarbonylpsoralen	0.30	1.00
3-Acetoangelicin	0.40	0.73

The quantum yields in the generation of $^1O_2$ by the lasing 7-aminocoumarins are low — the values for coumarins 1 and 102, determined using rubrene as the trapping agent for $^1O_2$, are 0.08–0.025 in benzene.[62]

III. Photochemical properties

1. Electron and proton phototransfer

The phototransfer of an electron is postulated as the primary elementary step in many photochemical reactions of coumarin derivatives. This aspect of the problem will be dealt with in the corresponding Sections of the review.

As noted above, the excited singlet[37–41] as well as triplet[41] states of coumarins are quenched by electron donors and acceptors. The acceleration of the destruction of coumarin and psoralene triplets in the presence of thymine and other DNA bases as well as aminoacids, in particular tryptophan, has also been interpreted as quenching via an electron transfer mechanism.[45] However, the attempts to detect coumarin radical-ions as the products of the total electron transfer were unsuccessful in these experiments.[41,45] Only in the study of the quenching of the excited triplet states of coumarin and 4′,5′-dihydropsoralen by tryptophan using pulsed laser photolysis was a relatively long-lived absorption detected and was tentatively

assigned to absorption by the mixture of the coumarin radical-anion and the tryptophan radical-cation.[45]

Reliable data for the absorption spectra of the radical-ions of coumarin derivatives were obtained by the pulsed radiolysis method.[45,53,63] The electronic absorption spectra of the radical-anions of coumarins and psoralens in water show an intense absorption peak in the vicinity of 360 nm and a broad structureless band in the wavelength range above 500 nm with a diffuse maximum near 600 nm ($\varepsilon \simeq 2000$ mol litre^{-1} cm^{-1}).[45,53] The radical-cations of coumarins absorb at shorter wavelengths: $\lambda_{max}^{abs} = 460$ nm for the coumarin 153 radical-cation in cyclohexane[63] and $\lambda_{max}^{abs} = 480-500$ nm for the radical-cations of psoralen and its derivatives in aqueous solution.[53]

Proton phototransfer has been investigated for many, mainly lasing, coumarin dyes. New ionic forms formed in this process exhibit an effective luminescence in a whole series of instances, which makes it possible to plan significantly the laser tuning range. The spectra and structures of photoprotolytic forms have been identified and the kinetics of the proton phototransfer reactions have been investigated for 7-hydroxycoumarin[22,64,65] and its 4-methyl[22,64] and 4-trifluoromethyl derivatives[23] as well as esculin (6,7-dihydroxy-coumarins to the S_1 state intensifies sharply the acid properties of the hydroxy-group and the basic properties of the carbonyl oxygen, which determines the direction of the proton phototransfer. Whereas the CH_3 substituent in the 4-position in the pyrone ring does not alter the efficiency of the formation of the various protolytic forms, the CF_3 group has a marked influence on this reaction with abstraction, addition and transfer of a proton in hydroxycoumarins. By virtue of the inductive effect of the trifluoromethyl group, in the excited singlet state there is an appreciable increase in the probability of the abstraction of a proton from the hydroxy-group, but its addition to the carbonyl group is hindered. In the case of 3-hydroxycoumarin, there is insufficient time for the attainment of the protolytic equilibrium in the excited state owing to the rapid degradation of the excitation energy.[67]

The acid–base forms of aminocoumarins luminesce much less effectively than the neutral forms.[14,25] We shall consider the characteristics of the photocatalytic reactions of the familiar lasing dye coumarin 102. On protonation of the coumarin 102 molecule, the amino group is the first to be protonated in the ground state and is followed by the carbonyl group.[24] In the fluorescent S_1 state, the proton-accepting capacity of the carbonyl group increases appreciably and the order in which the groups are protonated changes. It has been suggested[24] that, during the lifetime of the excited state in acidified solutions of coumarin 102, a proton is abstracted from the nitrogen atom of the amino-group and is added to the oxygen atom of the carbonyl group after transfer through the surrounding medium.

7-Aminocoumarins have been divided into three groups in terms of their photoprotolytic properties:[25] (1) coumarins 102 and 120 as well as others in which a proton adds adiabatically to the carbonyl oxygen; (2) 7-aminocoumarins containing a CF_3 substituent in the 4-position in the pyrone ring, where the proton phototransfer is accompanied by the loss of excitation; (3) 7-alkylaminocoumarins whose photoprotolytic forms do not luminesce owing to the disruption of the planar configuration of the cation by the mobile alkyl groups attached to the nitrogen atom.

It is noteworthy that the proton phototransfer reactions are fully reversible: the loss of excitation is accompanied by the rapid conversion of the dye into the initial form.

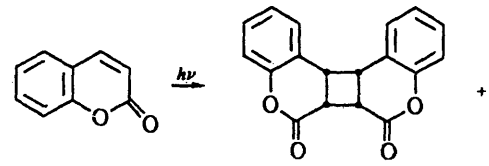
2. Phototransformation of the chromophore

Photochemical reactions leading to the disruption of the benzo-pyrone fragment, which serves as the chromophore in compounds of the coumarin type, are included among the phototransformations of the chromophore. The absorption and luminescence in the visible and near UV regions of the spectrum disappear under these conditions. This part of the review will deal with the reactions involving the opening of the pyrone ring, the photochemical reduction, as well as reactions involving the [2 + 2]photocyclo-addition to the double bond between the third and fourth carbon atoms, which are extremely characteristic of coumarins.

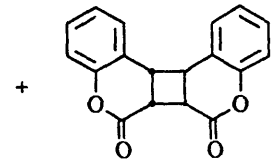
(a) [2 + 2]Photocycloaddition reactions

Photodimerisation. Coumarins, which are cyclic esters [lactones?] of α,β-unsaturated carboxylic acids, show an extremely great tendency to undergo reactions involving photocycloaddition to the 3,4-bond of the pyrone ring, in which cyclobutane adducts are formed. Such reactions include photodimerisation. The photo-dimerisation of coumarin has been the subject of numerous investigations.[68–71] The principal conclusions reached in such studies can be formulated as follows.

Mainly two out of the four possible stereoisomers are formed as the products of the photodimerisation of coumarin in solution:



(IV)



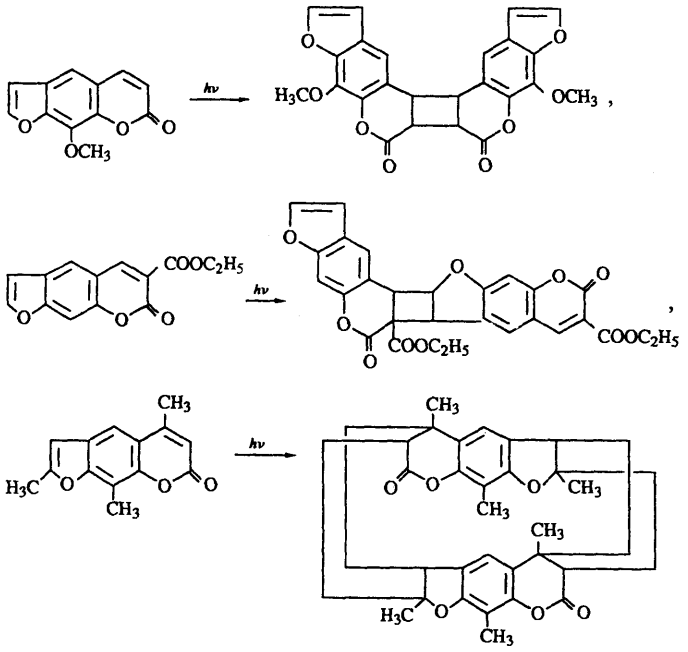
(V)

The "head to head" *endo*-dimer (IV) is the main product of the extremely inefficient reaction of coumarin in the excited singlet state ($\varphi \simeq 10^{-3}$ in water at a coumarin concentration of 0.01 M and $\varphi < 10^{-5}$ in methanol and benzene[70]). The "head to head" *exo*-adduct (V) is formed from the excited triplet state with an average efficiency ($\varphi \simeq 0.1$ on sensitisation with benzophenone[69]). The reaction in the excited singlet state is catalysed by Lewis acids. Thus the quantum yield of the *endo*-dimer in dichloromethane (coumarin concentration 0.2 M) increases from 10^{-3} to 0.16 in the presence of BF_3.[71]

The *endo*-orientation of the product obtained from the excited singlet state and the *exo*-orientation of the product obtained from the excited triplet state in the photodimerisation reaction persist also for substituted coumarins. Studies have been performed in relation to compounds containing alkyl, alkoxy-, acetoxy-, chloro-, phenyl, and cyano-substituents in the 3-, 4-, 6-, and 7-positions.[72,73] Depending on their structure, coumarin derivatives dimerise via both excited singlet and triplet states. Thus, whereas in the case of 4-substituted derivatives the photoreaction takes place via the triplet on direct excitation, the multiplicity of the reactive excited state of coumarins substituted in the 7-position depends on the nature of the

substituent. A dual behaviour is characteristic of 4,7-di-substituted derivatives—the reaction proceeds simultaneously via states of different multiplicity.[72–74] The methyl group in the 4-position in the pyrone ring does not prevent photodimerisation,[72,75] but the familiar lasing dye 7-diethylamino-4-methylcoumarin (coumarin 1) does not dimerise under the reaction conditions, undergoing another photochemical transformation involving the photochemical oxidation of the diethylamino-group.[75] 3,4-Disubstituted coumarins do not form dimeric cyclobutane photoadducts, probably as a consequence of steric hindrance.[75] In aqueous micellar solutions, the nature of the products has not changed but a decrease in the rate of photochemical reaction is observed for coumarin itself,[70] whereas in the case of its substituted derivatives the rate increases.[72]

Furocoumarins can dimerise via both the pyrone and furan fragments[76–79] to form dimers of different types, for example:

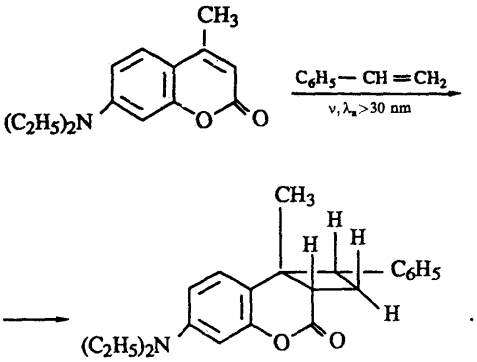


In contrast to the liquid phase, in the solid state coumarin exhibits a fairly high photostability and does not form dimeric cyclobutane adducts on irradiation.[80] A characteristic feature of the solid-phase reaction is the restriction of the movement of the molecules and a greater influence of their disposition in the crystal on the course of the process. The packing in individual crystals unfavourable for photodimerisation can be modified in mixed crystals, for example, with phenanthrene or antipyrine.[80] In mixed crystals, photodimerisation of this kind becomes geometrically feasible and a mixture of the photodimers (IV) and (V) is formed, containing mainly the "head to head" *endo*-dimer (IV).

The relation between the structure of the crystals and reactivity was investigated for a series of coumarin derivatives.[81,82] The limiting distance between the centres of the reaction bonds in the photoreactive crystals is 4.2 Å.[81] For small deviations from the disposition of molecules favourable for photodimerisation, of the kind which occur, for example, in the case of 7-chlorocoumarin where the distance between the reacting bonds in the crystals is 4.454 Å or 7-methoxycoumarin in the crystals of which the reacting bonds have been rotated by 65° relative to one another, the topochemical reaction can proceed with a high yield (~90%).[82]

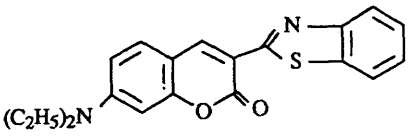
The photodimerisation of coumarin is reversible: on irradiation with short-wavelength light, the dimers are reconverted into the initial compounds, while on exposure to polychromatic sunlight a photostationary equilibrium is established between coumarin and its dimer.[83]

Photocycloaddition of olefins. The [2 + 2]photocycloaddition of olefins to coumarins usually takes place more effectively than the photodimerisation of the latter. In the presence of olefins, the photodimerisation can be actually inhibited as a consequence of the preferential reaction with olefins.[84] 7-Aminocoumarins, which do not tend to form photodimers,[75] react with olefins to form cyclobutane adducts.[85–88] As a result of the reaction occurring regiospecifically via the excited singlet state, mainly "head to tail" cyclic [2 + 2]adducts are formed. For example, coumarin 1 reacts with styrene in acetonitrile at reactant concentrations of 10 and 0.08 M respectively to form a "head to tail" type isomer with the *endo*-disposition of the phenyl substituent,[86] the quantum yield being 0.041:



The presence of an electron-donating group in the 4-position accelerates the process.[87,88] These results as well as the data of other workers concerning the reactivity of 4-hydroxycoumarin[89] and 3-acetylcoumarin[90] show that the substituents in the 3- and 4-positions in the pyrone ring do not prevent the formation of [2 + 2]photoadducts with olefins.

The lasing dye coumarin 6 in solutions in the presence of diphenylpolyenes generates stimulated radiation under the influence of a light pulse and is simultaneously decolorised in the [2 + 2]photocycloaddition reaction.

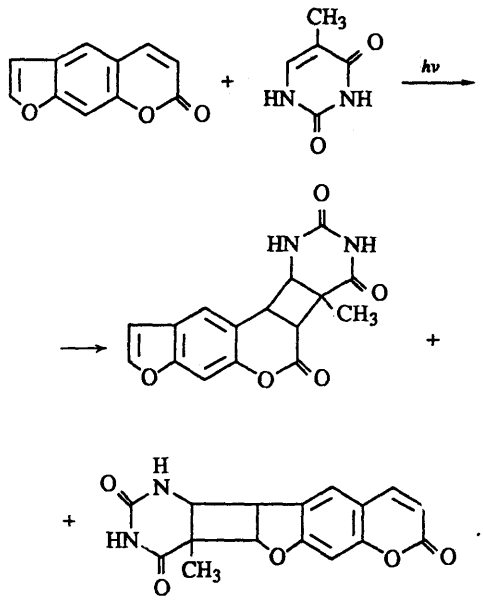


Coumarin 6

Active media having this composition have been proposed for lasers of a new type operating in the decolorisation wave regime with the lasing zone moving in the solution.[91]

Furocoumarins also form photoadducts with olefins,[92] while in biological systems they add under the influence of light to thymine in nucleic acids, to unsaturated acids, and to lipids and proteins,[93–96] and the reaction can involve not only the pyrone but also the furan

ring. Thus both types of psoralene–thymine monoadducts have been isolated:[97–99]



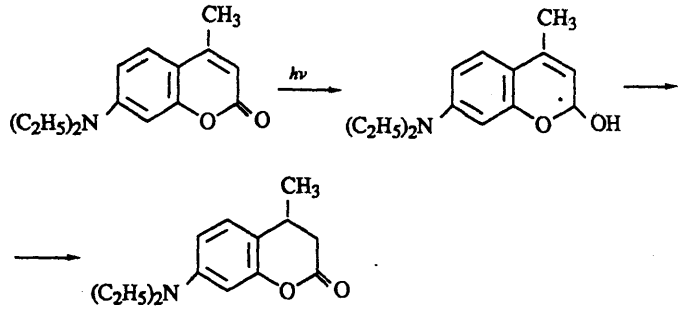
It is nowadays generally accepted that the therapeutic action of furocoumarin combined with irradiation by near UV light is due to the photochemical formation of interstrand cross-links in DNA via the successive cycloaddition of the furocoumarin to the pyrimidine bases of two DNA strands. The presence of such cross-links suppresses the hyperactive synthesis of DNA associated with psoriasis.[4] The breakdown of conjugation in the psoralen molecule on formation of a monoadduct via the pyrone ring induces a marked hypsochromic shift of the absorption, whereas the product of the addition of thymine to the furan ring absorbs radiation in almost the same way as psoralene—up to 380 nm.[97,98] Accordingly, it is clear that the interstrand cross-linking of DNA is possible only under the conditions of the initial addition of psoralene to the furan fragment, since only then can the system retain its ability to be activated by near UV light. It is noteworthy that in solution the reactivity of furocoumarins in the photocycloaddition reaction is much higher for the double bond of the pyrone ring than for that of the furan ring.[92] Since furocoumarins add to DNA in the opposite order in biological systems, it has been suggested that the mode of photocycloaddition is determined in this instant by non-valence interactions.

The [2 + 2]photocycloaddition of olefins to coumarins can occur, like the photodimerisation of the latter, both via the excited singlet and excited triplet states, depending on the structure of the substrate. Thus experimental data show that in the case of 7-aminocoumarins the excited singlet state is reactive,[85–87] while in furocoumarins it is the excited triplet state.[92,100]

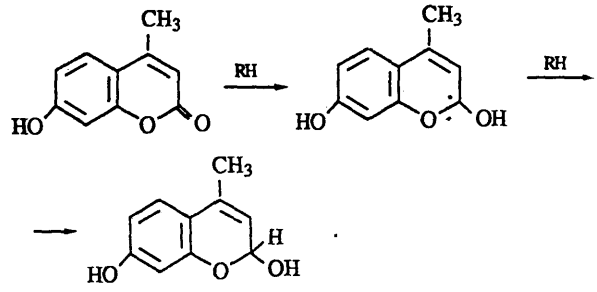
The similarity between the [2 + 2]photocycloaddition of olefins and [2 + 2]photocyclodimerisation is also manifested by the fact that both reactions are reversible—under the influence of short-wavelength light the cyclic adducts are reconverted into the initial compounds.[95,98]

(b) Other photochemical reactions of the chromophore

There are few data on the photodegradation of the chromophore in coumarin dyes in photochemical reduction reactions. When coumarin 1 is irradiated in deoxygenated acetonitrile, the product of the hydrogenation of one of the double bonds is formed, judging from mass-spectrometric data, in a low yield as a side-product.[49,101] Jones and co-workers[49,101] suggested that the 3,4-bond of the pyrone ring is reduced. In their view, the photochemical reaction proceeds via the excited singlet state by a bimolecular mechanism, which includes the ketyl radical disproportionation stage:

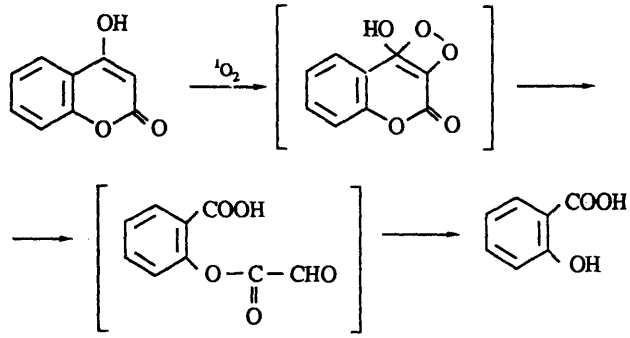


On the other hand, the reduction of the carbonyl groups has been postulated[102] for the analogous product of the photolysis of 4-methylumbelliferone:



The different views concerning the mode of photochemical reduction of the chromophore in coumarin derivatives indicate that the process has been studied inadequately and that a detailed analysis of the products is necessary in order to elucidate their structure unambiguously.

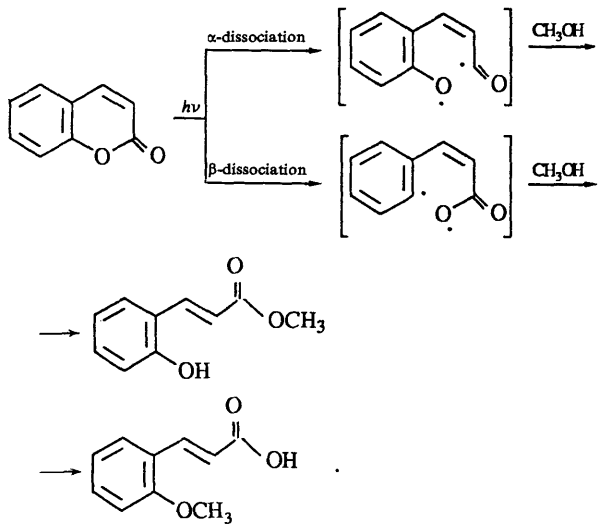
The photodegradation of the heterocycle with participation of singlet oxygen is known to occur for coumarins containing a hydroxy-group in the 4-position:[103]



The electron-donating hydroxy-group in compounds of this type activates the 3,4-double bond in reactions with $^1O_2$, which is particularly necessary for coumarins containing a carbonyl group, a powerful electron acceptor, next to the double bond. The hydroxy-group in the 3-position does not activate coumarin, since it forms an intramolecular hydrogen bond with the carbonyl oxygen. Like other

substituted derivatives, 3-hydroxycoumarins, with the exception of those containing a hydroxy-group in the 4-position, are not oxidised by singlet oxygen.[103]

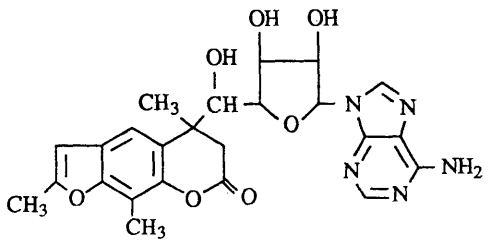
The opening of the pyrone ring can be initiated by the α- and β-dissociation of the C—O bond (relative to the carbonyl group).[104] The final products are formed in the reactions of biradicals with solvent molecules:



The α- and β-dissociation products are formed via states of different multiplicity—singlet and triplet respectively, α-dissociation being more probable.

The analogous ring opening reaction in derivatives of 3,4-dihydrocoumarin proceeds via α-dissociation. The quantum yield of this photochemical reaction is high and amounts to, for example, $(7.4 \pm 0.5) \times 10^{-2}$ for unsubstituted 3,4-dihydrocoumarin.[105]

The only known example of photoaddition to coumarins without the formation of cyclobutane derivatives is the photoaddition of adenosine to trimethylpsoralene.[106] The photoadduct has the following structure:

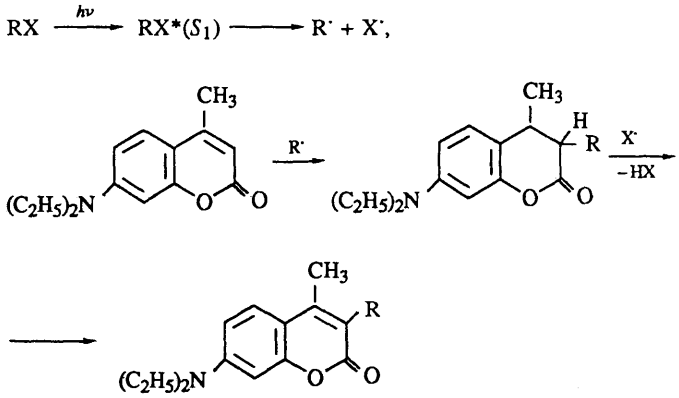


3. Photochemical reactions of the substituting groups

It was noted above that unsubstituted coumarin does not fluoresce and that the best phosphors of the coumarin series have electron-donating substituents in the 7-position. Other groups usually cause a shift of the fluorescence to the required spectral region and increase solubility, photostability, affinity for fibres, etc. In the light, the substituting groups can enter into various photochemical reactions. We shall consider the most important of these.

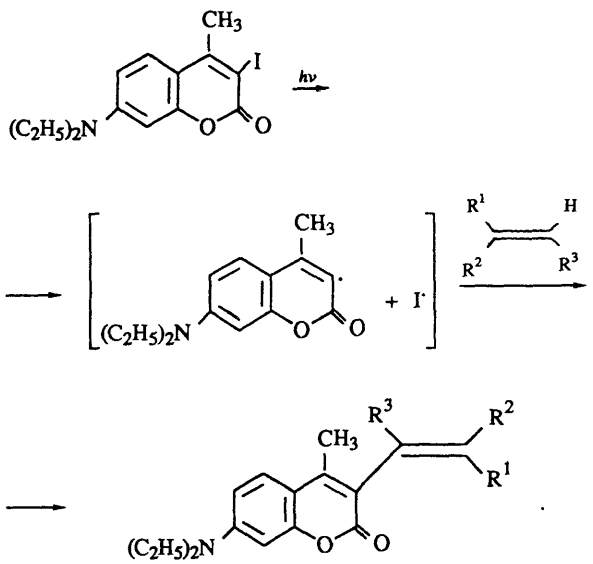
(a) Photosubstitution

The photosubstitution reactions of coumarin derivatives have been investigated in relation to the most readily available dye coumarin 1. Photosubstitution via a radical mechanism involves the 3-position when coumarin 1 is irradiated in the presence of reagents containing photolabile chemical bonds (alkyl and aryl halides, dioxane pyroxide, nitromethane):[107]



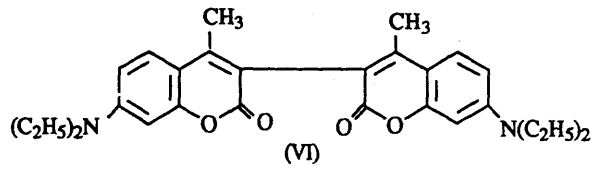
The yields of the photochemical reaction products are 10—30%. In conformity with the bond energies in the series of alkyl or aryl halides. the use of iodo-derivatives is most effective for substitution reactions. The study of the influence of the nature of the substituent in the 4-position in the pyrone ring showed that both electron-donating and electron-accepting substituents accelerate the process, apparently stabilising the radical centre in the intermediate.[108]

When 3-iodocoumarins containing the photolabile C—I bond were used in the presence of substituted benzene derivatives as well as olefins, a series of new 7-aminocoumarins were obtained containing an aryl[109] or unsaturated substituent[110] in the 3-position. The photochemical reaction proceeds via the excited singlet state of the substrate in accordance with the following most probable mechanism:



The reactions with monosubstituted benzenes result in the formation of *ortho*- and *para*-isomeric products, the efficiency of the photosubstitution decreasing on passing from electron-donating to electron-accepting substituents.[109]

The biscoumarin (VI) was obtained from coumarin 1 and its 3-iodo-derivative under similar conditions.[107]



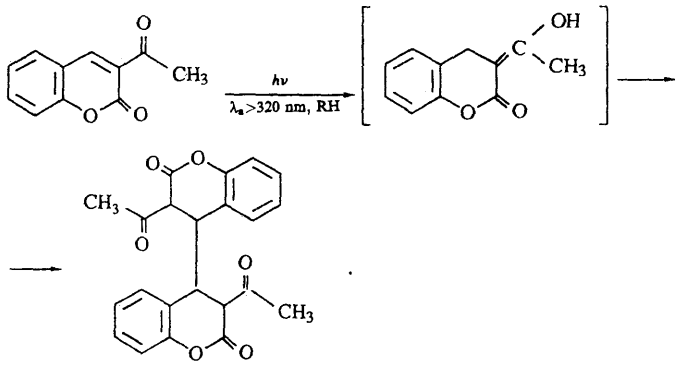
(VI)

On irradiation of 7-aminocoumarins in chlorine-containing solvents, 3-chloro-substituted derivatives are also formed via the radical photosubstitution mechanism with participation of chlorine atoms, which attack the unoccupied 3-position in the substrate molecule.[111]

Photosubstitution of coumarins by the radical-ion mechanism has not been investigated. According to preliminary data,[107] it is not selective and involves not only the 3-position but also other positions subjected to attack by the radical-ion.

The formation of a 3-hydroxy-derivative from coumarin 120 in the reactions of the latter with singlet oxygen has been postulated.[112,113]

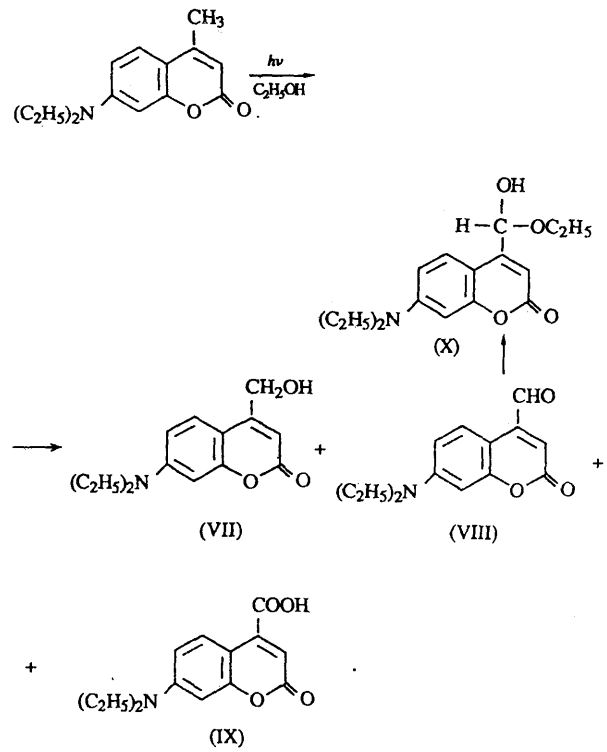
In connection with the discussion in this Section of the review of the mechanism of the formation of the biscoumarin (VI), we may note that 3,3'-diacetyl-3,3',4,4'-tetrahydro-4,4'-biscoumarin is formed in accordance with an unusual mechanism via the reduction of a substituent and the isomerisation and recombination of radicals:[90,114]



(b) Photochemical oxidation of alkyl substituents

Many coumarin phosphors contain a methyl group in the 4-position in the pyrone ring. Compounds of this type include coumarins 1 and 102, which have found extensive applications in the laser technique.

Winters, et al.[115] established for the first time that, when active lasing media based on alcoholic solutions of coumarin 1 are irradiated with light from pulsing pumping lamps, the methyl group in its structure is oxidised to the corresponding alcohol, aldehyde, and acid:

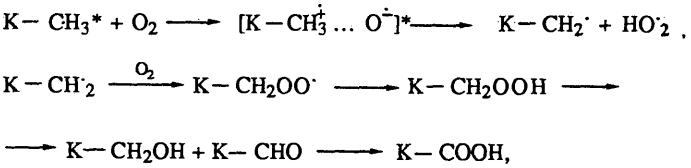


(VII) (VIII) (X) (IX)

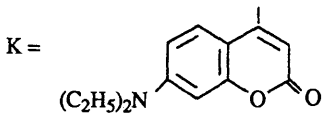
The accumulation in the solution of the products of the photochemical oxidation of the methyl group leads to an increase in the absorption by the lasing medium in the region corresponding to the luminescence of coumarin 1 and the impairment of lasing parameters. However, in alcohol only 4-carboxy-7-diethylamino-coumarin (IX) among the photoproducts (VII)–(IX) absorbs appreciably in the region corresponding to lasing by coumarin 1.[116] The aldehyde (VIII) likewise makes a significant contribution to the photoinitiated increase in the optical density of the active medium in the long-wavelength region, but subsequent interaction of compound (VIII) with the solvent leads to the formation of the hemiacetal (X), which does not absorb the luminescence radiation, is responsible for the dark relaxation of the optical density in the lasing region (Fig. 2), and determines the lasing energy in irradiated alcoholic solutions of coumarins.[116]

In order to seek ways of increasing the photostability of lasing media based on 4-methylcoumarins, the mechanism of the photochemical oxidation of these compounds was investigated by several groups of workers.[59,117–120] In air-saturated ethanol, the quantum yield of the photochemical reaction is 5×10^{-4}, is independent of the dye concentration, and in the range $10^{-4}-10^{-2}$ M the reaction constitutes the principal photodegradation pathway.[117] The efficiency of the photochemical oxidation of the methyl group increases with enhancement of the electron-donating properties of the substituent in the 7-position. The process is sensitised by triplet sensitisers and is almost independent of the energy of the absorbed quantum in the wavelength range 254–365 nm. The oxidation

reaction proceeds via a free-radical mechanism and is initiated by the bimolecular reaction between the excited coumarin and oxygen:[117]



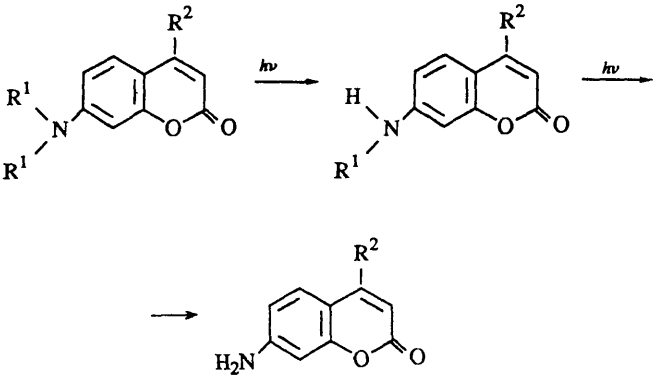
where



The study of the photochemical processes occurring in solutions of coumarins containing a methyl-group in the 4-position revealed the following pathways leading to the expansion of the stock of available active lasing media: removal of oxygen from the solution by bubbling the latter with an inert gas;[121,122] the use of coumarins not containing a CH_3 group[123] or containing the non-oxidisable CF_3 group in the 4-position'[124] inhibition of the radical oxidation reactions by photostabilisers;[125] adsorption of 4-carboxy-7-diethylaminocoumarin on the Al_2O_3 filter in the laser pumping system.[115]

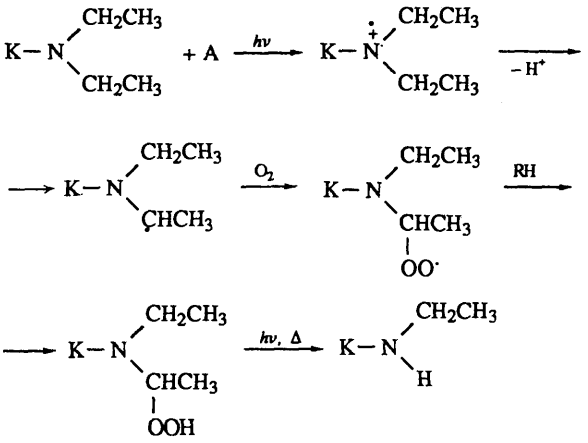
(c) Photochemical reactions of alkylamino-groups

The most numerous group of coumarin phosphors contain an amino- or alkylamino-group in the 7-position. 7-Alkylaminocoumarins are dealkylated under the influence of radiation, the dealkylation products being formed with a greater or small probability virtually under any photolytic conditions. They were first isolated and identified by Winters, et al.[115] after irradiating coumarin 1 in ethanol. In the latest studies,[59,101] it has been shown that the process is common to all 7-alkylamino-coumarins:

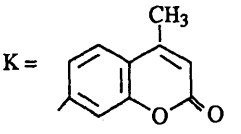


$R^1 = CH_3,\ C_2H_5;\quad R^2 = CH_3,\ CH_2OH,\ CF_3.$

7-Alkylaminocoumarins are dealkylated in accordance with the same mechanism as other tertiary and secondary amines—via α-aminoalkyl radicals, which are formed when electron acceptors abstract a hydrogen atom or an electron and a proton according to the following most probable scheme:



where



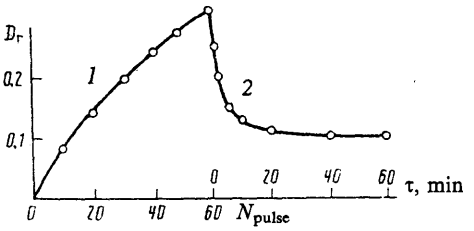


Figure 2. Variation of the optical density of an ethanol solution of coumarin 1 ($c = 10^{-3}$ M, $L = 5$ cm) in the lasing region at a wavelength of 460 nm during irradiation by light pulses (N_{pulse}) from an IFP=2000 lamp at a frequency of 0.3 Hz (curve *1*) and during the subsequent dark process (curve *2*).[116]

Various oxidants, for example aromatic nitro-compounds,[126] the solvent,[111] another coumarin molecule in an excited state,[49,127,128] and singlet oxygen,[58,59,62] can also function as electron (hydrogen atom) acceptors.

The role of the photochemical oxidation by singlet oxygen, which is extremely common in organic photochemistry, in the photodegradation of coumarins has been investigated in fair detail. It has been established[59,62] that the interaction of 7-alkylaminocoumarins with $^1O_2$ leads to the oxidative photo-*N*-dealkylation and does not usually involve the 3,4-bond in the pyrone fragment. With the exception of the 4-hydroxy-derivative,[103] coumarins without amino-groups do not react on treatment with $^1O_2$.

On direct photolysis in a number of solvents, the photo-*N*-dealkylation proceeds according to the self-sensitised photochemical oxidation mechanism, which consists in the initial activation of oxygen by the transfer to the latter of the excitation energy from the triplet level of coumarin and the formation of singlet oxygen, which oxidises the dye in the electronic ground state:

$$K \rightsquigarrow {}^3K^*,$$

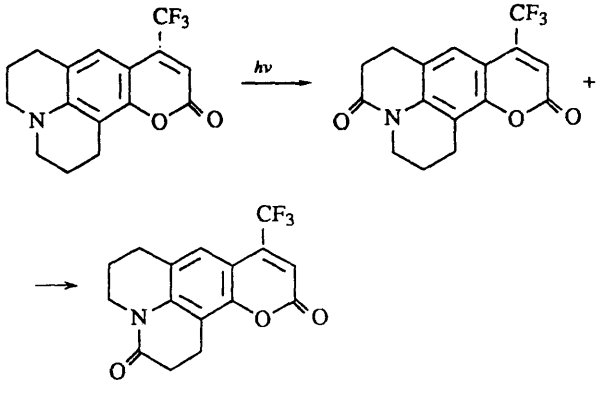
$${}^3K^* + {}^3O_2 \rightarrow K + {}^1O_2,$$

$$K + {}^1O_2 \rightarrow N\text{-dealkylation products}.$$

For example, in benzene the photo-*N*-dealkylation of coumarin 1 (the main photochemical reaction) via the mechanism of the self-sensitised photochemical oxidation by singlet oxygen proceeds to an extent greater than 70% for a $^1O_2$ generation quantum yield of ~ 0.1 and an overall rate constant for the physical and chemical quenching of singlet oxygen by coumarin of 10^6 litre mol^{-1} s^{-1}.[62] The formation of the clathrate complex between coumarin 1 and β-cyclodextrin increases the stability of the dye as regards the action of $^1O_2$ in aqueous solutions by an order of magnitude.[128]

On passing from dilute to concentrated ($c > 10^{-2}$ M) solutions, the mechanism of the photo-*N*-dealkylation changes to a bimolecular mechanism, which includes the abstraction of an electron (hydrogen atom) by an excited coumarin molecule from an unexcited one ($k = 10^7$ litre mol^{-1} s^{-1} in ethanol[128]). In this connection, one should note that in alcoholic solutions at low concentrations the main photochemical reaction of 7-dialkylamino-4-methylcoumarins is the photochemical oxidation of the methyl group, whereas at high concentrations the bimolecular photo-*N*-dealkylation predominates.

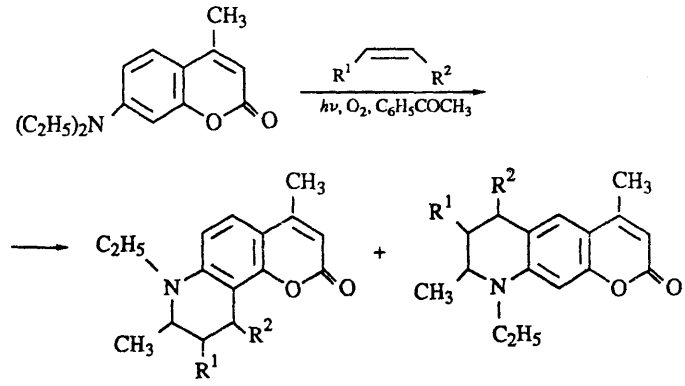
The formation of amides in the photochemical oxidation of alkylaminocoumarins has been reported in a number of communications.[59,101] Thus two isomeric amides are formed on irradiation of coumarin 153 in air-saturated acetonitrile:[102]



Evidently amides are formed as products of photo-*N*-dealkylation on oxidation of the intermediate α-aminoalkyl radicals by oxygen.

In deoxygenated solutions, the radicals undergo other dark reactions — they recombine with solvent molecules[129] and give rise to oligomers.[49,101] The role of radicals in the photodegradation of deoxygenated solutions has been confirmed by the inhibition of the reaction by divalent sulphur compounds.[127]

The heterocyclisation of alkylamino-groups in the 6- and 8-position in the coumarin ring is of interest. On photoirradiation in the presence of olefins containing more than one electron-accepting substituents, 7-aminocoumarins do not give rise to adducts resulting from the [2 + 2]cycloaddition to the 3,4-bond, but in the presence of acetophenone, a triplet sensitiser, they afford heterocyclisation products in a quantum yield of 0.01:[130]



The mechanism of the photochemical reaction proposed by Kirpichenok, et al.[130] involves the participation of acetophenone in the T_1 state as the oxidant in the formation of the α-aminoalkyl radical and the addition of the latter to the olefin.

It follows from the data presented in this Section of the review that the photochemical reactions involving the alkylamino-group are initiated by the formation of α-aminoalkyl radicals, the different dark reactions of which determine the nature of the final product.

- - - o0o - - -

The results considered show that during the last decade our knowledge about the photochemical reactions of coumarin derivatives has greatly expanded. Various photochemical reactions of compounds of this class have been investigated, but the available information about certain aspects of the photolysis, for example, about the irreversible photodegradation of the chromophore, is inadequate. Nevertheless, on the basis of the known values it is possible in many instances to predict the behaviour of coumarin derivatives on photoirradiation. The results described determine to a large extent the course of future studies, which will have to be carried out in the search for effective ways of increasing the photostability of the organic phosphors in this important class.

The electronic structure and reactivity of alkenes

V G Barabanov, A V Golovin, A A Rodin, A A Ustenko
State Institute of Applied Chemistry, St. Petersburg, St. Petersburg State University,
Patrice Lumumba University of Friendship Among Peoples, Moscow

ABSTRACT. The modern methods for the calculation of the electronic structures of alkenes are examined. The photoelectron spectra of alkenes are analysed and the relation between the properties of molecules and their orbital structure is discussed on the basis of experimental data and quantum-chemical calculations. The corresponding structural parameters of alkenes are systematically compared with their reactivities. The ionisation energies of alkenes are presented.

The bibliography includes 86 references.

I. Introduction

The method for the investigation of the electronic structures of molecules which yields most information is nowadays photoelectron spectroscopy (PES). As it developed, it became possible to test experimentally the adequacy of quantum-chemical calculations within the framework of the molecular orbital (MO) theory. On the other hand, quantum-chemical calculations play an important role in the interpretation of photoelectron spectroscopy data.

The aim of the present review was to survey the studies on the electronic structures of alkenes with the aid of quantum-chemical calculations and photoelectron spectroscopy and to compare the parameters of the electronic structures of alkenes with their reactivities, which are determined mainly by the presence of the π-bond.

II. Approximations used in the analysis of the electronic structures of alkenes

1. Approximations of the molecular orbital method

Since exact quantum-chemical calculations of the electronic structures of polyatomic molecules are impossible, it is necessary to carry out significant simplifications and approximations depending on the complexity of the system investigated, the nature of the problem, and the possibilities of the computer technique. In the development of computational methods, one usually begins with the stationary Schrödinger equation for a polyatomic molecule. The fact that the mass of electrons is significantly smaller than the mass of nuclei while the forces acting on nuclei and electrons are of the same order of magnitude makes it possible to separate approximately the motions of the nuclei and electrons in the wave function (the Born–Oppenheimer approximation), while in the analysis of the photoelectron spectrum one can consider separately the positions of the bands in the spectrum (they are determined by the electronic subsystem) and the band contours (they are determined by the nuclear subsystem).[1,2]

The next approximation usually introduced involves allowance for the Coulombic interaction between electrons in the form of an effective potential acting on an isolated electron in the molecule. The set of eigenfunctions of the one-electron equation is usually referred to as molecular orbitals. The wave function of a many-electron system is represented in terms of this approximation by a linear combination of derivatives of one-electron wave functions.

A set of a finite number of basis functions, for which one usually selects functions centred on the atoms in the molecule, is used as an approximation to one-electron wave functions. The molecular orbitals are then represented by linear combinations of atomic orbitals (the LCAO-MO approximation). Only $1s$ atomic orbitals (AO) are used for hydrogen atoms, while s, p_x, p_y, and p_z atomic orbitals are used for carbon and other atoms.

For planar molecules, the molecular orbitals can be subdivided in accordance with the principle of their transformation on reflection in a plane. The π MO change sign on reflection in a plane, while σ MO do not. π MO are formed mainly from the p_z atomic orbitals, where the z axis is perpendicular to the symmetry plane of the molecule. Molecular orbitals of another type, frequently manifested in photoelectron spectra in the form of narrow bands, are the orbitals of the lone electron pairs of the heteroatoms. Such orbitals are mainly localised on heteroatoms and the removal of electrons from them does not lead to significant changes in the molecular geometry.

The molecular orbitals of the molecules are classified in accordance with the characteristics of the irreducible representations of the point group to which the equilibrium configurations of the molecule refer.[3] For example, in the ethylene molecule, which belongs to the D_{2h} symmetry group, eight types of symmetry of the molecular orbitals are distinguished: A_g, A_u, B_{1g}, B_{1u}, B_{2g}, B_{2u}, B_{3q}, and B_{3u}. In order to determine the symmetry type of a specific molecular orbital, it is essential to discover in terms of which irreducible representation the LCAO coefficients of the given molecular orbital are transformed for different symmetry operations. Here one uses standard tables of characters of irreducible representations.

The molecules of the class of alkenes can belong to the D_{2h}, C_{2h}, C_{2u}, C_2, and C_s symmetry groups. These groups contain only one-dimensional irreducible representations and in alkene molecules there is therefore no degeneracy of molecular orbitals in terms of symmetry. Doubly degenerate molecular orbitals are encountered only in cumulenes with an even number of double bonds (molecules of the type of allene $H_2C=C=CH_2$) which belong to the D_{2d} symmetry group incorporating a two-dimensional irreducible representation.

The knowledge of the LCAO coefficients for occupied molecular orbitals makes it possible to analyse the electronic populations of atoms and bonds, i.e. to discover the electronic structure of the molecule. The partial charges on atoms, calculated as the difference between the number of electrons in the isolated atom and its population in the molecule, are usually quoted. The total charges on atoms, as well as their σ and π components, are used as quantitative characteristics of the inductive and mesomeric effects of substituents in alkenes. Comparative analysis of the populations of bonds makes it possible to infer their relative strengths.

In discussing the effect of substituents in alkenes and also the reactivities of alkenes, use is frequently made of Fukui's theory of frontier orbitals (this theory has been most fully described by Hochstrasser[3] and Fukui[4]), in which only the interactions between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of the molecular fragments are considered. Here one analyses characteristics of frontier orbitals such as their energy, symmetry, bonding or antibonding character, and their overlap in space. For clarity, one frequently uses energy diagrams of orbital interactions for reacting systems. The approximation of frontier orbitals constitutes a simplified qualitative theory, which works successfully in alkenes, provided that the HOMO have energies appreciably different from those of the remaining molecular orbitals. In other cases, for example in HFC=C=CHF, where the HOMO and the occupied molecular orbital which follows it have the same energies,[5] it is essential to take into account several highest occupied or lowest unoccupied molecular orbitals. In those cases where the conclusions reached from the theory of frontier orbitals do not explain the experimental results, it is assumed that the given interaction is subject to charge and not orbital control.

In a qualitative description of alkenes with a complex structure, use is made in a number of instances of the model of group orbitals,[6–8] according to which the orbitals of individual fragments (methylene and methyl groups, amino-groups, etc.) can be transferred from molecule to molecule, and thus to construct the molecular orbitals of large molecules from the orbitals of these fragments. Here correlation diagrams for the orbital energies of the molecule and its fragments, referred to as Walsh diagrams, are widely used. The employment of the orbitals of fragments in discussing the effects of substituents proves to be extremely fruitful. For highly polar molecules, the predictions of this simple model may be of the usual kind.

In discussing the molecular orbital stabilisation or destabilisation effects under the influence of substituents, Dewar's theory of perturbations of molecular orbitals is sometimes invoked.[9] It makes it possible to estimate the contributions of the inductive and mesomeric effects of the substituents and also of hyperconjugation.

2. Non-empirical and semiempirical calculations within the framework of the molecular orbital method

In the theory of molecular orbitals, the orbitals are obtained as functions minimising the electronic energy of the molecule in terms of the fixed nuclei approximation. Here one solves a system of equations in which the interelectron repulsion is taken into account in the form of the interaction between the electron in the given orbital and the average field of the remaining electrons. This approach, known as the self-consistent field (SCF) method, leads to an unduly high electron repulsion energy because the electron in fact moves in the instantaneous and not the average field of the remaining electrons. The difference between the true energy of the molecule and the energy obtained in terms of the SCF approximation is called the correlation energy.

The overall estimate of the interelectron repulsion energy in the SCF method is approximately constant for each type of electron pairs and therefore has little effect in the study of processes where the number and type of electron pairs (bond electrons, lone pairs) are conserved. In processes accompanied by the separation of electron pairs (ionisation, dissociation), failure to take into account the correlation energy can lead to serious errors.

Both non-empirical (*ab initio*) and semiempirical methods are widely used in quantum-chemical calculations.

In non-empirical calculations, account is taken of all the electrons of the atoms and of all the molecular integrals encountered in the SCF equations. The accuracy of calculations of this type depends on the choice of the basis set of atomic orbitals for the construction of the molecular orbital. In calculations for alkenes, both minimal and extended sets are encountered. Minimal basis sets include only the Slater type orbitals (STO) which are necessary for the construction of the complete atomic shell. Each Slater atomic orbital is represented by the sum of several Gaussian functions (GF) the use of which simplifies the calculation of molecular integrals. The STO-3G minimal basis sets in which three Gaussian functions are used to represent each Slater atomic orbital has come to be most widely used. The minimal basis set, frequently employed for the optimisation of the molecular geometry, has the advantage that it requires relatively small amounts of computer time in the calculations. Non-empirical calculations for alkenes in terms of the STO-3G basis set have been carried out in a number of studies.[11–15] A significant deficiency of the minimal basis set consists in the absence of the possibility of altering the size of the atomic orbitals as a function of the molecular structure because the same set of atomic orbitals is used for all types of molecular orbitals. This deficiency is eliminated in the extended basis sets, such as 4-31GF, where the core orbitals are fitted by four Gaussian functions while the valence orbitals are divided into two components—the compact component comprising three Gaussian functions and the diffuse component represented by a single Gaussian function. The 4-31G basis set has been used in calculations for alkenes.[13,14,16] Further expansion of the basis set is achieved by including polarisation *d* orbitals for heavy atoms and *p* orbitals for hydrogen atoms, as is done in basis sets of type 6-31G (in calculations for haloethylenes[17]). Two-exponent function (double-zeta) basis sets have also been used in calculations for alkenes.[5,10,18–22] Other basis sets can also be encountered, for example, basis sets consisting of Hartree–Fock atomic orbitals (i.e. obtained for individual atoms by the SCF method).[22]

Non-empirical calculations by the SCF method, in which the electronic wave function of the molecule is represented by a single determinant made up of occupied molecular orbitals, do not permit allowance for the electronic correlation energy, as stated above. Therefore in a number of calculations for alkenes, the correlation correction is taken into account additionally using different methods—the configuration interaction,[10] perturbation theory,[5] and

many-particle Green's functions.[17,23] The number of such studies is relatively small, since allowance for the electronic correlation by the above methods constitutes a laborious computational procedure and requires the consumption of much computer time.

In non-empirical calculations, use is also made of the discrete-variational X_α method,[22] which, however, has not so far become quite so common in the quantum chemistry of alkenes as the molecular orbital method.

Together with non-empirical methods, semiempirical computational methods, in which account is taken only of the electrons of the valence shells of atoms, have found extensive application in calculations for alkenes. The use in these methods of the null differential overlap (NDO) approximation makes it possible to neglect all three- and four-centre two-electron integrals as well as most of the two-centre integrals encountered in SCF equations, which significantly accelerates the computational procedure. Such reduction in the accuracy of the treatment of the problem is compensated by the introduction of a series of empirical parameters for each type of atoms, the numerical values of which are calibrated against the experimental characteristics of the compounds, such as dipole moments, heats of formation, and ionisation energies.

The earliest semiempirical methods employing the NDO approximation, namely CNDO, INDO, and NDDO, were developed by Pople and co-workers.[24] In the simplest of these, the CNDO (complete neglect of differential overlap) method, all the two-electron integrals in which different atomic orbitals are encountered on a single centre are rejected. The INDO method (incomplete neglect of differential overlap) has an additional feature involving allowance for the exchange integrals between the atomic orbitals of the same atom. The most complete allowance for two-electron integrals is achieved in the NDDO method (neglect of diatomic differential overlap). There exist versions of these methods in spectroscopic parametrisation which are designed to reproduce the electronic absorption spectra (CNDO/S,[35] INDO/S [36]) or photoelectron spectra (SPINDO [25]). Subsequently Dewar proposed a modified version of the INDO method, namely MINDO/3,[26] in which one-centre repulsion integrals are not evaluated analytically (as in the initial INDO version) but are regarded as parameters. The MINDO/3 method has come to be widely used in the calculation of molecular geometries. However, it has been noted that the method greatly underestimates the repulsion of lone pairs. Subsequently, Dewar developed on the basis of the NDDO approximation the improved MNDO method,[27] which makes it possible to avoid a series of systematic errors of the MINDO/3 method and which yields more accurate values of the geometrical parameters, heats of formation, and ionisation energies of molecules. One of the important advantages of the MNDO method over MINDO/3 is that the former involves only the parameters of individual atoms, while the latter contains also the parameters of pair combinations of atoms (in recent years, Dewar also developed the AM1 (*Austun Model* 1) method,[28] which is based, like the MNDO method, on the NDDO approximation and which eliminates the inability of the MNDO and MINDO/3 methods to reproduce the properties of hydrogen bonds.

The simplest semiempirical valence approximation method, in which the interelectron repulsion is fully neglected, is the extended Hückel method (EHM),[29] which was used in earlier studies on alkenes[5,10,46] and was subsequently displaced by improved methods. A version of the NDO approximation, which takes into account only π electrons and which is applicable only in the case of systems with conjugated bonds, is used in the Pariser–Parr–Pople (PPP) method.[30]

In contrast to non-empirical methods, in semiempirical methods the problem of correlation energy has been partially solved as a result of the optimisation of parameters on the basis of experimental data. Therefore in many cases methods such as MINDO/3, MNDO, and AM1 yield more reliable results than non-empirical calculations even when extended basis sets are used in the latter. Nevertheless the MNDO/C method,[31] where correlation corrections are evaluated (and the parametrisation takes into account such corrections), is used in certain problems. When account is taken of correlation in semiempirical methods with the aid of configuration interaction, the relative values of the calculated energies in a series of similar compounds and not their absolute values are of interest.

Semiempirical methods require much less computer time than non-empirical methods and are therefore widely used in the study of alkenes having fairly complex structures.

In non-empirical calculations, the geometry is usually optimised in terms of the STO-3G basis set, whilst in semiempirical calculations different methods can be used for this purpose. The procedure for the optimisation of the geometry of alkenes is sometimes carried out by methods of molecular mechanics (see, for example, Werstiuk and Timmins[32]). The standard values of bond lengths and bond angles are also frequently used to specify the geometries of large molecules.[22,33]

3. Koopmans' theorem

In the case of molecules with closed shells, where each molecular orbital in the one-determinant wave function is occupied by two electrons, the molecular orbital theory yields a simple method for the calculation of the ionisation energy (IE). According to Koopmans' theorem,[34] the ionisation energy is equal to the energy ε_i of the corresponding occupied molecular orbital with the sign reversed ($\varepsilon_i < 0$):

$$IE_i = E_{ion} - E_{mol} = -\varepsilon_i. \quad (1)$$

Koopmans' theorem was obtained subject to the condition that the molecular ion formed on ionisation has the same geometrical parameters as the initial molecule. Eqn. (1) is therefore used to estimate the vertical ionisation energies and is inapplicable to adiabatic ionisation energies. Furthermore, in the derivation of Koopmans' theorem, it was assumed that during the removal of an electron the molecular orbitals remain unaltered (the "frozen orbitals" approximation), i.e. that the electron shell of the molecular ion is described by the same orbitals as that of the initial molecule. Thus Eqn. (1) does not take into account the effect of the reorganisation (relaxation) of the electron shell of the molecular ion, which reduces the energy of the ion by $-\Delta E_{reorg}$ ($\Delta E_{reorg} > 0$).

Since the molecular orbital method does not take into account the electronic correlation effects, in Eqn. (1) account must be taken also of the correlation energy of both the molecule and the ion, the correlation correction reducing the energy of the molecule to a greater extent than that of the ion, which contains one electron less. Thus the difference between the correlation energies of the ion and the molecule ΔE_{cor} is positive. When account is taken of both corrections (ΔE_{reorg} and ΔE_{cor}), Eqn. (1) becomes

$$IE_i = -\varepsilon_i - \Delta E_{reorg} + \Delta E_{cor}. \quad (2)$$

Evidently the corrections taken into account enter Eqn. (2) with opposite signs. In the case of the ionisation of valence electrons, ΔE_{reorg} and ΔE_{cor} are similar in absolute magnitude and therefore partly cancel out, which justifies the application of Koopmans' theorem to valence electrons. In the case of the ionisation of inner

electrons, ΔE_{reorg} can exceed ΔE_{cor} by a factor amounting to several tens and in this case the Koopmans' theorem is inapplicable.

Attempts have been made in recent years to improve the accuracy of the estimation of the ionisation energies within the framework of Koopmans' theorem. Thus an approach has been developed[37] to take into account the correlation correction to the orbital energies of the molecule based on the use of natural molecular orbitals, which are obtained on diagonalisation of the density matrix. The applicability of this approach, which the authors called the extended Koopmans' method, has been demonstrated in the calculation of the ionisation energies for a series of atoms[38] and the accuracy of the extended Koopmans' method has been analysed.[39] However, this method has not so far found applications in calculations for organic molecules.

The approximations used in the derivation of Koopmans' theorem impose fundamental limitations on its applicability. Firstly, Eqn. (1) is valid only for molecules with closed electron shells where there are no unpaired electrons. In the case of open shells, where the ground state of the molecule has a radical character (a doublet or triplet state), molecular Coulombic and exchange integrals must be included in Eqns. (1) for the orbitals forming part of the open shell.[40] In alkenes, ground states with an open shell are not encountered. Secondly, Koopmans' theorem is valid only for one-electron ionisation and is inapplicable when the ionisation process is of a many-particle kind. Thirdly, Koopmans' theorem ceases to be applicable if the excited state formed on ionisation of the molecular ion cannot be described in terms of the orbital model of the ionisation and its description requires the mixing of several configurations of identical symmetry within the framework of configuration interaction.[17] Finally, Koopmans' theorem does not hold if there is a vibronic interaction between the states of the molecular ion manifested in the photoelectron spectra, which is observed, for example, in the case of fully deuteriated ethylene,[41] tetrafluorobutatriene,[10] and certain allenes,[11, 13, 42–44] One should also note that, in the SCF X_α method, Koopmans' theorem does not hold because direct comparison of the one-electron energies obtained in this method with photoelectron spectroscopic data lacks significance.[45]

The wide scale employment of Koopmans' theorem, despite its approximate nature, can be explained by its evident advantage: within the framework of one SCF calculation for the molecule, all the ionisation energies are obtained at once. At the same time, studies may be encountered where the ionisation energies of alkenes have been calculated as differences between the total energies of the ground state of the molecule and the radical cation states, for each of which its own SCF calculation is performed.[21] The geometry of the ground state of the molecule is then retained for the calculated states of the cation. This method of calculation of ionisation energies, called the ΔSCF method, includes, in contrast to Koopmans' theorem, allowance for the reorganisation energy of the electron shell of the cation. However, it has been noted that convergence of the iterative SCF procedure cannot be achieved for all the states of the cation considered.[21]

The agreement between the ionisation energies obtained within the framework of Koopmans' theory and experimental data depends on the chosen method of calculation. The difference between IE_{exp} and IE_{theor} can vary in different calculations from a few to several tens of electron-volts. In some investigations,[6,11] the results of calculations of ionisation energies by different methods have been compared and it has been noted that the greatest differences between the calculated and experimental ionisation energies are observed when the minimal STO-3G basis set and the semiempirical CNDO/2 methods are used. Linear relations between the experimental ionisation energies and the ionisation energies calculated by the Koopmans' theorem have been considered in a number of studies:[20,47,48]

$$IE_{exp} = K \times IE_{calc} + a, \quad (3)$$

and the correlation coefficients K for these relations have been determined. In comparing the results of the calculation with experiment, some workers[17,49] shift the spectrum of the calculated IE_{calc} in such a way that the ionisation energy of the HOMO agrees with the first ionisation energy.

III. Results of quantum-chemical calculations of the electronic structures and ionisation energies of alkenes

The simplest alkenes, ethylene and its derivatives with different substituents at the double bond, will be considered initially, then the homologues of the polyene series with different numbers of double bonds, and finally cumulenes of different structure.

1. Ethylenes

The electronic structure of the ethylene molecule has been studied in fair detail both experimentally and theoretically and the results of these investigations have been included in earlier reviews and monographs.[1,2] We shall therefore refer only to a study[50] in which the most complete and accurate non-empirical calculations have been carried out for the ethylene molecule and its cation taking into account the correlation corrections and the reorganisation energy of the electron shell. The calculation was performed using an extended two-exponent basis set supplemented by polarisation d functions and Rydberg s and p functions of carbon as well as diffuse d functions centred on the midpoint of the C–C bond (altogether 52 basis functions). The correlation energy of the ground state of the molecule was taken into account using the formalism of the cluster expansion of the wave function with subdivision in terms of symmetry. The ionised states of ethylene were calculated in terms of the configuration interaction approximation taking into account doubly, triply, and quadruply excited configurations. The vertical ionisation energies, calculated as differences between the energies of the cation and the molecule, were evaluated for the experimental geometry of ethylene in the ground state. The difference between the calculated and experimental ionisation energies does not exceed 0.3 eV and the calculated intensities of the bands in the photoelectron spectrum also agree well with experimental data. The study of high-energy ionised states of ethylene revealed the presence of a large number of low-intensity satellite peaks in the range 23–33.5 eV, the majority of which correspond to ionisation processes accompanied by excitation from the σ and π bonding molecular orbitals with $1b_{3u}$ symmetry to the antibonding π molecular orbital $2b_{2g}$. The results obtained by earlier non-empirical calculations for ethylene, carried out taking into account the electronic correlation, were also compiled in the above study.[50]

Among ethylene derivatives, fluoroethylenes have been studied in greatest detail.[51–53] According to ideas established at the present time, the influence of fluorine on the electronic properties of olefins can be explained by the inductive and mesomeric effects. The inductive effect is associated with the greater electronegativity of the fluorine atoms and consists in the strong polarisation of the σ skeleton of the olefin. The mesomeric effect reduces to the repulsive

interaction of the lone pair of fluorine with the π system arising as a result of $p-\pi$ conjugation. The competing influence of these two effects is manifested, in particular, by the fact that substitution by fluorine of one or several hydrogen atoms located in the nodal plane of the π system of the alkene does not lead to a significant shift of the ionisation energies of the π orbitals but does induce an appreciable shift (up to 4 eV) of the ionisation energies of the σ orbitals. This phenomenon, which has been called the perfluoro-effect, can be explained by the fact that the stabilisation of both σ and π orbitals by the inductive effect of fluorine is compensated in the case of π orbitals by the destabilising mesomeric effect.

The results of non-empirical and semiempirical calculations for fluoroethylene published up to 1986 have been discussed critically in detail in a monograph[52] and we shall therefore confine ourselves to listing the studies of this period, concentrating attention on later investigations.

Attempts at the interpretation of the photoelectron spectra of fluoroethylenes with the aid of non-empirical methods have been undertaken.[14,18,20,54] For this purpose, calculations have been performed in terms of a two-exponent basis set for monofluoro-ethylene[18] as well as tetrafluoroethylene without[20] and with[54] optimisation of the geometry. Calculations have also been performed for monofluoroethylene using the STO-3G and 4-31G basis sets.[14] The ionisation energies of fluoroethylenes have been calculated by semiempirical SCF methods in a number of studies.[19,49,55,56] The first ionisation energies have been calculated[19] by the PPP method for mono-, di-, and tri-fluoroethylenes, while for tetrafluoroethylene calculation by the CNDO/S method has been carried out.[49] The ionisation energies of all the fluoroethylenes have been calculated in terms of the CNDO and INDO approximations[55,56] and the CNDO/2 method has also been used in a study[57] where it was noted that this procedure yields a satisfactory agreement with experiment only for the first two ionisation energies of fluoroethylenes.

The most complete non-empirical calculation for the entire series of fluoroethylenes has been performed in a study[21] where a two-component basis set was used and a complete optimisation of the molecular geometry was carried out. The vertical ionisation energies have been determined in two ways—within the framework of Koopmans' theorem and by the SCF method, i.e. as the difference between the energies of the molecule and the cation adjusted for self-consistency. In the latter case, a separate SCF calculation was performed for the ground and each of the excited states of the cation (with retention of the molecular geometry) and thus account was taken of the reorganisation energy of the electron shell. The ionisation energies obtained by means of Koopmans' theorem are found to be higher and those calculated by the SCF method are lower than the corresponding experimental values. The final ionisation energies were therefore determined as arithmetical means of the above two theoretical values, whereby a better agreement with experiment was achieved. The bands in the photoelectron spectra of fluoroethylenes were reliably assigned[21] on the basis of the calculated results as well as the data obtained in a more detailed investigation of these compounds by photoelectron spectroscopy.[57]

The first band in the photoelectron spectra of fluoroethylene arises, according to both calculated and experimental data, as a result of the removal of an electron from the HOMO, which is a π(C=C) orbital with an antibonding contribution by fluorine atoms. In monofluoroethylene, IE_2 refers to the highest occupied σ MO, which is antibonding for the C–C and C–F bonds and bonding for the C–H bonds, while IE_3 refers to the bonding σ MO localised on the C–C and C–H bonds. This assignment agrees with the conclusions drawn from the analysis of the photoelectron spectrum of this compound.[57] According to calculated data, none of the molecular orbitals in $CHF=CH_2$ has the character of a pure lone electron pair of fluorine.

In 1,1-difluoroethylene, IE_2 corresponds to the bonding σ MO localised on C–H bonds. It was concluded that the third band, whose assignment gave rise to difficulties in early studies, arises from two molecular orbitals: the bonding σ(C–C) orbital a_1 and the orbital b_2, which can be regarded as a combination of the lone pairs of fluorine atoms. On the basis of calculated data, the fourth band was assigned to the π MO a_2, which represents the antibonding combination of p_π orbitals of fluorine atoms. The region of the fifth band includes two ionisation transitions, one of which corresponds to the σ MO a_1, which is antibonding for the C–C bond and bonding for the C–F and C–H bonds, while the second corresponds to the bonding π MO with a contribution by fluorine atoms.

The *cis*- and *trans*-isomers of 1,2-difluoroethylene are characterised by a close similarity of the photoelectron spectra (the ionisation energies obtained from these spectra agree within the limits of experimental error, except for the IE_3, which differ by 0.2 eV). Only the vibrational structure of the second band exhibits characteristic differences. As postulated by Cell and Kupperman,[57] it is formed in both isomers by two molecular orbitals. However, Heaton and El-Talbi[21] concluded that, whereas this band does indeed correspond to two σ MO a_1 and b_2 in the spectrum of the *cis*-isomer, in that of the *trans*-isomer it corresponds to only one σ MO a_g. With the aid of the analysis of the bond populations, which reveals the bonding or antibonding character of these molecular orbitals, it was then possible to account for the differences in the vibrational structure of the second band in the spectra of the isomers. According to calculated data, IE_2 and IE_3 correspond in both isomers to two σ MO involving respectively antibonding contributions by the C–F and C–C bonds. IE_4 in the *cis*-isomer and IE_5 in the *trans*-isomer correspond to the antibonding π(C=C) orbital with a bonding contribution from fluorine atoms, while IE_4 in the *trans*-isomer and IE_5 in the *cis*-isomer correspond to the σ MO, which is bonding for the C–F and C–H bonds and antibonding for the C–C bond; IE_6 corresponds in both isomers to the bonding π MO. As in the case of monofluoroethylene, none of the molecular orbitals of 1,2-difluoroethylene can be rigorously assigned to the lone pair of fluorine.

In the case of trifluoroethylene, the Koopmans' theorem and the ΔSCF method lead to different orbital assignments of the bands in the photoelectron spectrum (the ionisation energies obtained by the ΔSCF method agree better with experimental data). The nature of the bands is therefore not discussed and only the sequence of the molecular orbital energies is quoted, according to which IE_2 and IE_4 correspond to two σ MO—bonding in the case of IE_4 and with an antibonding contribution due to the C–F bonds in the case of IE_2. IE_3 corresponds to an antibonding combination of the lone pairs of the fluorine atoms of the CF_2 fragment; IE_5 and IE_6 correspond to π MO with main contributions by fluorine atoms.

In the photoelectron spectrum of tetrafluoroethylene, the experimental assignment is available only for the first band,[57] while the interpretation of the nature of the remaining bands without invoking calculations is made difficult by the presence of a large number of close ionisation transitions. For $CF_2=CF_2$, Koopmans' theorem and the ΔSCF calculation yield identical orbital assignments of the ionisation energies. According to these data, IE_2 corresponds

to the σ MO a_g with an antibonding contribution by the C–F bond and IE_3 and IE_4 have been assigned respectively to the σ MO b_{3g} and b_{2u}, which can be regarded, with some approximation, as a combination of the lone pairs of the fluorine atoms; IE_5 and IE_6 are associated with π MO consisting of the p_π orbitals of fluorine.

A semiempirical calculation for fluoroethylenes (except $CF_2=CH_2$) has been carried out in a study,[58] where the MRINDO/S method was used. This is a modified version of the INDO/S approximation, in which the one-centre exchange integrals are taken into account only in the valence atomic orbitals and are rejected for the Rydberg 3*s* and 3*p* atomic orbitals. The sequence of the π and σ MO obtained is the same as in the study of Heaton and El-Talbi.[21] The difference between the calculated and experimental first ionisation energies is 0.5–1.1 eV. The remaining ionisation energies were not discussed.

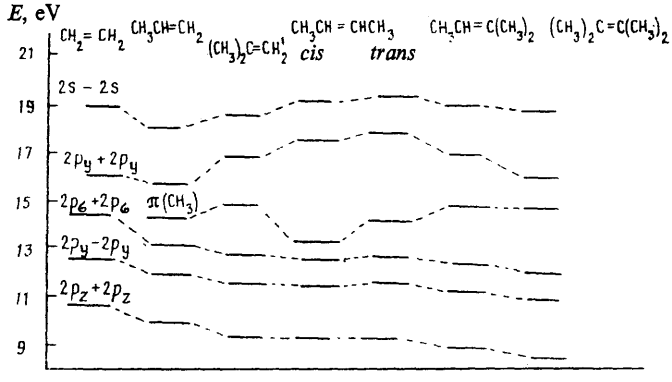

Figure 1. Correlation energy level diagram for the molecular orbitals of alkenes.

A theoretical study of the photoelectron spectra of chlorofluoroethylenes was undertaken in a study[17] where the 6-31G basis set, including the 4*s* and 4*p* atomic orbitals of Cl, the 3*s* and 3*p* atomic orbitals of C, and the 2*s* atomic orbital of H, was used in the non-empirical calculations for $CH_2=CFCl$, $CF_2=CHCl$, $CF_2=CFCl$, and $CF_2=CCl_2$. The experimental or optimised molecular geometry was employed. The ionisation energies were determined by means of Koopmans' theorem, the scale of the calculated ionisation energies being displaced for each molecule in such a way that the theoretical and experimental ionisation energies coincide. The ionisation energies thus obtained agree well with experiment. The ionisation energies of all the molecules for which calculations were made correspond to the highest occupied π MO having an antibonding contribution from the p_π atomic orbitals of chlorine atoms (the involvement of Cl in the formation of the HOMO has been confirmed by the analysis of the vibrational structure of the first band). IE_2 corresponds to the highest occupied σ MO localised on the C–C and CCl bonds, while IE_3 corresponds to a combination of the p_π atomic orbitals of chlorine atoms. An orbital assignment was given also for the remaining ionisation energies, calculated up to 22 eV. It was concluded that the ionisation of the inner electrons of haloethylenes in the range 20–75 eV cannot be described in terms of the orbital model.

The photoelectron spectra of mono-, di-, tri-, and tetra-methylethylenes have been compared in a study[7] where a quantum-chemical calculation by the method of group orbitals was carried out in order to assign the ionisation energies. The results of the calculation are presented in the form of a correlation energy level diagram for the molecular orbitals (Fig. 1), from which it is seen that the introduction of one methyl substituent into ethylene destabilises the ethylene molecular orbitals, which is associated with the transfer of electron density from the CH_3 group to these molecular orbitals.

A further increase in the number of substituting CH_3 groups intensifies this destabilising effect for the first three ionisation energies. In terms of the approximation of group orbitals, the fourth ionisation energy was assigned in all the methylethylenes to the π level of the CH_3 group. The nature of the change in the fifth and sixth ionisation energies under the influence of substitution was found to be more complex than for the first three ionisation energies.

The effect of the cyano-group on the first ionisation energy in ethylene has been examined in a study[46] where the Hückel approximation was used for the analysis of the nature of the HOMO of mono-, di-, tri-, and tetra-cyanoethylenes. The successive increase in the number of CN groups (*n*) induces an additive increase in the first ionisation energy, which is described satisfactorily by the relation

$$IE = 10.52 + 0.32n.$$

The effect of the cyano-group on IE_1 can be explained by the joint manifestation of both the inductive effect, where this group functions as an electron acceptor, and the conjugation effect, which has been shown to arise as a result of the mixing of the HOMO of ethylene with the π LUMO of the C≡N group. The mechanism of the joint effect of the methyl substituent and the cyano-group on IE_1, manifested by the fact that β-methylation of monocyanoethylene (acrylonitrile) causes a more marked decrease in IE_1 (by 0.69 eV) than α-methylation (0.55 eV), has also been explained. The point is that the orbitals of the CH_3 group interact more strongly with the π system in the β-position, since the HOMO coefficient is greater for the β-carbon atom than for the α-carbon atom. On the other hand, the effect of the introduction of the second cyano-group is greater in the α-position (0.46 eV) than in the β-position (0.23 eV), which can be explained by the smaller sensitivity of the inductive effect (compared with hyperconjugation) to the value of the HOMO coefficient at the substituted carbon atom. The destabilising effect of the acetyl group on the position of the HOMO has been demonstrated in relation to crotononitrile.

The influence of the mesomeric and inductive effects of substituents on the first ionisation energy of ethylene has been investigated[59] in relation to mono- and 1,2-di-substituted ethylenes with π-donor substituents [F, Cl, Br, I, OCH_3, SCH_3, $Si(CH_3)_2$] and monosubstituted ethylenes with π-acceptor substituents (CHO, $COCH_3$, CN, NO_2). The approximation of group (fragment) orbitals (LCFO-MO), in which the HOMO of the substituted ethylenes is represented by a linear combination of the HOMO of ethylene and either the π or *p* orbital of the substituent X, was used:

$$\Psi_{CH_2=CHX} = a_1\Psi_{CH_2=CH_2} + a_2\Psi_X.$$

The coefficients a_1 and a_2 characterise the contributions of the π MO of ethylene and the π MO of the substituent to the combined orbital. In this representation, the mesomeric effect (i.e. π conjugation) of the substituent is taken into account automatically. The inductive effect of the substituent X on the ionisation energy is

treated[59] as a result of the electrostatic interaction of the positive charge, delocalised over the π-system and arising when an electron is removed from the molecule, with the dipole of the C–X fragment. The vertical ionisation energy of the compound HX was used as the parameter characterising the inductive effect of the substituent X. The ionisation energies calculated in this way for mono- and di-substituted ethylenes differ from the experimental values by not more than 0.2 eV. It was concluded that the resonance effect of the nitro-group may be neglected because of the considerable difference between the HOMO and LUMO energies of this group and the HOMO energy of ethylene.

The influence of the σ–π conjugation, the inductive effect, and the $p_\pi - d_\pi$ interaction on the first ionisation energy in monosubstituted ethylenes with the organosilicon substituents SiH_3, $SiH(CH_3)_2$, $Si(CH_3)_3$, CH_2SiH_3, and $CH_2Si(CH_3)_3$ has been studied.[60] The ionisation energies were calculated in accordance with the Koopmans' theorem by the semiempirical CNDO/2 method using *sp* and *spd* basis sets. The contribution of the σ–π conjugation ($\delta IE_{\sigma,\pi}$) to the change in the ionisation energy of ethylene under the influence of the substituent (ΔEI) was estimated on the basis of the perturbation theory and the contribution of the $p_\pi - d_\pi$ interaction ($\delta IE_{p,d}$) was found from the difference between the HOMO energies of the substituted molecule calculated in terms of the *spd* and *sp* basis sets (in the calculation using the *sp* basis set, the influence of the *d* orbitals is not taken into account). The contribution of the inductive effect was determined from the residual, having subtracted $\delta IE_{\sigma,\pi}$ and $\delta IE_{p,d}$ from ΔIE. It was concluded that in the majority of ethylene derivatives σ–π conjugation predominates over other effects. The extent of the $p_\pi - d_\pi$ interaction diminishes in the sequence $SiH_3 > SiH(CH_3)_2 > Si(CH_3)_3$, i.e. with increase in the number of CH_3 groups at the silicon atom. The extent of the σ–π conjugation diminishes in the sequence $C(CH_3)_3 > Si(CH_3)_2 > CH_3 > SiH_3$, while the inductive effect diminishes in the sequence $Si(CH_3)_3 > SiH_3 > CH_3 > C(CH_3)_3$, which agrees with the concept of the electronegativity of the substituents.

A number of theoretical studies have been devoted to ethylenes with cyclic substituents.[33,61–64] The influence of the substituents F, Cl, CH_3, and OCH_3 in the *meta*- and *ortho*-positions on the ionisation energies of styrene has been studied[61] with the aid of photoelectron spectra and calculations by the CNDO/2 method. The calculations were performed using the standard bond lengths and bond angles. The photoelectron spectra of styrene and its derivatives exhibit in the range 8–11 eV three well resolved bands, which correspond, according to the calculated data, to the π MO arising as a result of the interaction of one of the two degenerate benzene molecular orbitals of the e_{1g} type and the π MO of the vinyl group (π_1 and π_3 MO) and to the second degenerate molecular orbital of benzene e_{1g}, which does not interact with the vinyl group (π_2 MO). The influence of the inductive effect of the substituents has been investigated on the basis of the change in IE_2 corresponding to the ionisation of π_2 MO, which is not involved in conjugation with the π-system of the vinyl group; the maximum inductive effect is manifested by the F atom; IE_1 and IE_3 are acted upon by both the inductive and resonance effects. The difference $IE_3 - IE_1$ varies about 1.93 eV, which indicates the similarity of the effects of substituents on the π_1 and π_3 MO. The resonance effect of substituents was estimated from the difference between IE_1 and IE_2. For *para*-substituted styrenes, this difference is greater than for the *meta*-substituted derivatives; the greatest resonance effect is observed for the OCH_3 substituent.

The effect of Cl, NH_2, and NO_2 on the ionisation energies of *trans*-2,2-disubstituted stilbenes has been studied.[62] Derivatives containing identical substituents in the *ortho*-positions of the phenyl fragment were examined. The presence of the NH_2 group leads to an appreciable decrease in all the ionisation energies of stilbene (by 1.0 eV for IE_1), while the presence of the NO_2 group entails an appreciable increase in all the ionisation energies (by 0.9 eV for IE_1), which can be explained by the strong inductive effect of these substituents. The presence of Cl leads to some decrease in the ionisation energies of stilbene (by 0.2 eV for IE_1). The assignment of the photoelectron spectra based on calculations of ionisation energies by the Hückel method made it possible, in particular, to identify bands referring to the ionisation of the lone pairs of the chlorine atoms in 2,2-dichlorostilbene (11.19 and 11.53 eV) and in 2-amino-2-chlorostilbene (11.03 and 11.52 eV).

The INDO/S semiempirical method has been used[33] to interpret the photoelectron spectra of stilbene, α-cyanostilbene, 2-styryl-thiophene, and α-cyanostyrylthiophene. An idealised geometry was specified for the phenyl fragment and the experimental geometry was used for the thienyl fragment. Calculation showed that the first five ionisation energies of these compounds are associated with molecular orbitals consisting of a combination of the π orbital $1e_{1g}$ of benzene, the π orbitals $1a_2$ and $2b_1$ of thiophene, and the π MO of ethylene with a perturbing effect of the cyano-group. The doubly degenerate π MO of the C≡N group have energies which are too low and they do not enter into this combination, so that the influence of the cyano-group reduces to the inductive and steric effects. The first band in the photoelectron spectra of the cyano-derivatives and 2-styrylthiophene is generated on ionisation of the delocalised π MO, which is an antibonding combination of the b_1 MO of benzene and π MO of ethylene. The second band corresponds to three molecular orbitals localised on benzene rings. The third band corresponds to the π MO of the ethylene bond. The calculation reproduces satisfactorily the difference between IE_1 and IE_2.

3-Methyl-3-vinylcyclopropene (I) as well as its α-methyl and β-methyl derivatives [compounds (II) and (III)] have been investigated[63] with the aid of the semiempirical AM1 method. The calculation was performed with complete optimisation of the geometrical parameters for different values of the dihedral angle θ between the planes of the ethylene and cyclopropene fragments (θ = 0°, 60°, 90°, 120°, and 128°). One minimum was observed on the potential curve as a function of θ for compound (III) and two minima were observed for compounds (I) and (II). According to the calculated data, the ionisation energy of compound (I) corresponds to the ionisation of the cyclopropene π(C=C) MO whereas the ionisation energies of compounds (II) and (III) correspond to the ionisation of the ethylene bond. The presence of the methyl substituent at the ethylene bond lowers IE_1, the effect of one CH_3 group introduced in the α-position proving to be stronger than the effect on IE_1 of two CH_3 groups introduced in the β-position.

2. Polyenes

Numerous theoretical studies have been devoted to the electronic structure and the photoelectron spectra of polyenes. Some of them dealt with individual compounds—butadiene,[65,66] hexatriene,[66] and octatetraene,[12] whilst others were concerned with the general characteristics of the polyene series.[22,67] The influence of substituents has been traced in relation to monomethyl- and polymethylbutadienes[8,32,67] and decapentaene with different substituents at the C(5) and C(6) atoms.[68]

According to the results of a non-empirical calculation in terms of a grouped two-exponent basis set, the first band in the photoelectron spectrum of butadiene corresponds to the π HOMO b_g, whilst the second band corresponds to the second occupied π MO a_u.[66] The same result has been obtained in terms of a two exponent basis set supplemented by two diffuse *p* functions of carbon.[65] In both calculations, the first two ionisation energies agree with the experimental values to within 0.05–0.2 eV. The same assignment of the bands is given by the semiempirical SPINDO method.[67] The first three ionisation energies of hexatriene have also been calculated[66] (differing from the experimental values by −0.1 eV) and it was concluded that the first three bands in the photoelectron spectrum of this compound refer to π-type molecular orbitals, but, according to the calculation by the SPINDO method, the third band refers to σ-type molecular orbitals.[67] A comparative analysis of the orbital structures of the *cis*- and *trans*-isomers of hexatriene has been carried out (using the SPINDO method). The geometry of the *trans*-isomer (with C_{2h} symmetry) was specified on the basis of electron diffraction data, while in the *cis*-isomer (C_{2v}) the same bond lengths were used as in the *trans*-isomer. A satisfactory agreement with experiment was obtained for all the nine calculated ionisation energies. In the *cis*–*trans* transition, the energies of all three occupied π MO hardly change (like the experimental ionisation energies). A different picture is observed for this transition in the three highest occupied σ MO $9b_2$, $10a_1$, and $9a_1$, the energies of two of which ($10a_1$ and $9a_1$) increase, whilst that of the third ($9b_2$) falls, which leads to an appreciable narrowing of the energy range in which these orbitals are located in the *trans*-isomer. This result of the calculation made it possible to explain the differences in the shape of the photoelectron spectra of the hexatriene isomers in the region of 12 eV, where a broad gap is observed between the bands in the case of the *cis*-isomer (the σ MO lie within a wide range), being absent from the spectrum of the *trans*-isomer (the σ MO lie within a narrow range). It was concluded that the shift of the energies of the σ MO in hexatriene isomers is caused by the interaction through space between the C–H and C–C σ-bonds, which stabilises the orbitals with the a_1 symmetry and destabilises b_2 orbitals in the *cis*-isomer. Calculations by the non-empirical method using the minimal STO-3G basis set and by the SPINDO method led to the conclusion that the first three ionisation energies in octatetraene refer to π-type molecular orbitals.[12]

Calculations have been carried out for the polyenes $C_{2n}H_{2n+2}$ with $n = 1-6$ by the discrete-variational X_α method using a two-exponent basis set and a basis set comprising Hartree–Fock atomic orbitals.[22] The experimental geometry was used for the first members of the polyene series ($n = 1-3$), while for the remaining molecules the idealised geometry was employed. The first ionisation energies of butadiene, hexatriene, and octatriene, obtained in terms of a two-exponent basis set, differ from the experimental values by not more than 0.2 eV (photoelectron spectroscopic data are lacking for $C_{10}H_{12}$ and $C_{12}H_{14}$). The deviations of the remaining ionisation energies from the experimental values are on average ~0.5 eV for the two-exponent basis set and ~1 eV for the Hartree–Fock basis set. According to the calculations, the highest σ-type level (a_u or b_g) in all polyenes is close to the π-type level (a_u or b_u). It was suggested that for long polyene chains one may expect either a slight overlap of the σ and π zones in the photoelectron spectrum or these zones can be separated by a small gap amounting to several tens of electron-volts.[22,69]

For the theoretical study of the effect of methyl substituents on the π bands in the photoelectron spectra of polyenes, Beez et al.[67] used a model in which the π MO of the polyene is represented by a linear combination of the bonding orbitals (LCBO) of individual π-bonds (it was shown that the mixing of the bonding and antibonding orbitals of π-bonds leads to incorrect results in the calculation of ionisation energy), while the effect of the methyl substituent on the π-system of the polyene is considered as an inductive and hyperconjugation perturbation within the framework of the Hückel method. In this procedure, the CH_3 group is described by two degenerate pseudo-π orbitals made up of the σ orbitals of the C–H bonds. This simple and clear model makes it possible to reproduce the π-orbital ionisation energies with a satisfactory accuracy (to within not more than 0.1 eV for hexatriene, for example) and leads naturally to the sums rule, according to which the sum of the changes in all the π-orbital ionisation energies ($\sum_i \delta IE_i^\pi$) in the polyene under the influence of the CH_3 group is constant for the entire polyene series and is equal to δIE for ethylene (0.78 eV). The validity of the sum rule has been demonstrated in relation to monomethyl-substituted butadiene and hexatriene. Comparison of the experimental ionisation energies and the ionisation energies calculated within the framework of the LCBO model for mono-, di-, and tetra-methylbutadienes showed that the sums rule holds, provided that the substituting CH_3 groups are attached to different double bonds, i.e. the additivity of the effects of the CH_3 groups on the π ionisation energies holds in this case. On the other hand, if the substitution takes place at the same double bond, then the specific quantity $\sum_i \delta IE_i^\pi$, recalculated per CH_3 group, diminishes with increase in the degree of substitution—for example, we have the series $CH_2=CHCH_3$ (0.78 eV), $CH_3CH=CHCH_3$ (0.69 eV), $(CH_3)_2C=CH_2$ (0.64 eV), $(CH_3)_2C=CHCH_3$ (0.61 eV), and $(CH_3)_2C=C(CH_3)_2$ (0.55 eV). It has been shown that the terminal methyl substituents in the polyene do not alter the gap between IE_1 and IE_2. Substitution by CH_3 groups in the central positions leads to the mutual approach of IE_1 and IE_2, which can be explained, as demonstrated in relation to butadiene, by the interaction through space between the pseudo-π orbitals of the CH_3 group in the 2- or 3-position with the π orbital of the vicinal (unsubstituted) double bond. Allowance for this interaction in the LCBO model shows that it stabilises the HOMO in the polyene and destabilises the next occupied π MO. The same conclusion was reached in a study[8] where the investigation of the effect of methyl substituents was extended to non-planar cases when there is rotation about a single C–C bond in the polyene. Tetramethylbutadiene, containing one methyl group at each carbon atom, was investigated. This structure exists in the form of three isomers, namely (*E*, *E*), (*E*, *Z*), and (*Z*, *Z*), and can be regarded as two identical fragments interacting via the C(2)–C(3) single bond and rotated relative to this bond by an angle θ. Then, in terms of the first approximation of the perturbation theory, the gap $\Delta IE = IE_2 - IE_1$ depends on θ in accordance with the formula

$$\Delta IE = \Delta IE_0 - \cos\theta, \qquad (4)$$

where ΔIE_0 is the value of ΔIE for the planar case with θ = 0. This dependence of ΔIE on θ has been confirmed by a non-empirical calculation in terms of the minimal STO-3GF basis set in relation to unsubstituted butadiene. Using the ionisation energies found from the photoelectron spectra and Eqn. (4), the authors[8] obtained estimates of θ for the isomers; 0° ± 30° for (*E*, *E*), 80° ± 15° for (*E*, *Z*), and 80° ± 105° for (*Z*, *Z*). It has been shown[32] by calculations using the molecular mechanics method and the

semiempirical AM_1 method that the (*Z*)-conformer of the 1,3-disubstituted butadiene (2-methylpenta-1,3-diene) exists preferentially in the twisted form, while the (*E*)-conformer exists in a planar form. This made it possible to explain the differences between the photoelectron spectra of the (*Z*)- and (*E*)-conformers. It was noted that the AM_1 method overestimates the steric interaction between the CH_3 groups in the 1- and 3-positions and underestimates the stabilisation of the π-system due to the resonance effect.

The influence of electron-donating and electron-accepting substituents on the ionisation energies of polyenes has been studied theoretically[68] in relation to 5,6-disubstituted decapentaenes ($C_{10}H_{10}X_2$). The calculations were performed by the discrete-variational X_α method using a basis set of Hartree–Fock atomic orbitals. The idealised geometry was used for the hydrocarbon skeleton of the molecule. The geometrical parameters for the substituents and the C–X bond were selected on the basis of experimental data or the results of non-empirical calculations. In the unsubstituted polyene $C_{10}H_{12}$, the energies of the valence σ levels lie below those of the set of π levels. The introduction of lithium as a strong σ-donor does not destabilise the σ levels, which fall as a result into the region of the π levels. As a weaker σ-donor, BeH does not lead to the overlap of the σ and π sets of molecular orbitals and the energy IE_1 in the BeH-polyene is almost identical with IE_1 in $C_{10}H_{12}$. The introduction of F as a σ-acceptor lowers IE_1 by only 0.1 eV. The nature of the interaction of the NH_2 group, which is a π-donor, with the π-system of the polyene depends on its rotation relative to the plane of the polyene: the $2p_\pi$ atomic orbital of nitrogen is involved in conjugation with the π-system of $C_{10}H_{12}$ when the NH_2 group is in the plane of the polyene and interacts with the σ-system when the plane of the NH_2 group is perpendicular to that of the polyene. In the former case, the interaction indicated leads, as shown by the calculation, to a decrease in IE_1 by 1.2 eV, while in the latter IE_1 hardly changes. When BH_2, which acts as a π-acceptor, is introduced, IE_1 scarcely changes, provided that BH_2 is located in the plane of the polyene, and diminishes by 0.4 eV if the planes of BH_2 and the polyene are mutually perpendicular.

3. Cumulenes

The simplest representation of the cumulene series is allene $CH_2=C=CH_2$ where there are two mutually perpendicular π-systems between which there is no conjugation; the CH_2 groups are also located in mutually perpendicular planes. The allene molecule belongs to the D_{2d} symmetry group, which has a two-dimensional irreducible representation and gives rise to doubly degenerate molecular orbitals of the *e* type. In particular, in conformity with non-empirical[23,70] and semiempirical[15] calculations, the π HOMO 1*e* and the σ MO 2*e* which follows it are doubly degenerate in allene. The HOMO splits into two molecular orbitals, each of which is localised in one of the $CH_2=C$ fragments and represents an antibonding combination of the π orbital of the C=C bond with the pseudo-π orbital of the CH_2 group.[16] All the other homologues of the cumulene series with an even number of double bonds, for example, pentatetraene $CH_2=C=C=C=CH_2$, the π HOMO of which is likewise doubly degenerate, also belong to the D_{2d} symmetry group.[15] Analysis of the first band in the photoelectron spectra shows that the degeneracy is removed in the allene[23] and pentatetraene[15] radical-cations as a result of geometrical distortions arising in the ionisation of the molecule and reducing its symmetry (the Jahn–Teller effect). For example, the removal of the degeneracy of the HOMO in allene leads to the splitting of the first band in the photoelectron spectrum into two peaks with ionisation energies of 10.0 and 10.6 eV.[23] A simple molecular-orbital model shows that such splitting is a result of a twisting deformation which reduces the symmetry of the allene radical-cation from D_{2d} to D_2.[72] Cumulenes with an odd number of double bonds belong to the D_{2h} symmetry group and contain no molecular orbitals degenerate as regards symmetry. However, in this case ionisation may entail the appearance of a distortion in the molecule, which reduces its symmetry, as indicated, for example, by data obtained as a result of the optimisation of the geometry of the butatriene $CH_2=C=C=CH_2$ radical-cations in terms of the STO-3GF basis set.[75]

When the π-electronic structure of cumulenes is considered, the isolated ethylene-like π orbitals (2*e* in allene and $2b_{3u}$ in butatriene) and butadiene-like four-centre π MO, which are combinations of two ethylene orbitals—bonding ($1b_{2u}$ in butatriene and 2*e* in pentatetraene) and antibonding ($1b_{3g}$ in butatriene and 3*e* in pentatetraene)—are distinguished.[15] In the ethylene–allene–butadiene series, a gradual destabilisation of the isolated π MO (and a decrease in the corresponding ionisation energies) has been observed, which can be accounted for by the destabilising effect of the CH_2 group, which is in the nature of hyperconjugation.[15] This effect is manifested most strongly in butatriene, where the CH_2 groups are located in one plane and both interact with the π MO of the central C=C bond. On passing from butatriene to pentatetraene, where the isolated π MO are no longer encountered, the destabilising effect of the pseudo-π orbitals of the CH_2 group is weakened. In order to interpret the photoelectron spectra of allene, both non-empirical calculations, using the minimal STO-3GF basis set,[13,15] the 4-31GF basis set,[16] and a two-exponent basis set,[5,23] and semiempirical calculations by the SPINDO method,[15] have been resorted to. The most accurate calculation for the allene molecule using the experimental geometry, carried out in terms of a grouped two-exponent basis set with inclusion of polarisation *d* functions of carbon and taking into account the correlation corrections by the method of Green's functions, shows that the first band in the photoelectron spectrum (exhibiting Jahn–Teller splitting) corresponds to the π HOMO 1*e*. The second band (14–16 eV) is generated by the ionisation transition from two σ MO—2*e* and $2b_2$, while the third band corresponds to the σ MO $2a_1$.[23] A similar band assignment was obtained from calculations by the SPINDO method.[15]

Quantum-chemical calculations have shown[10,15,23,73] that the π-system of butatriene consists of two butadiene-like MO $1b_{2u}$ and $1b_{2g}$, the nodal plane of which coincides with the molecular plane, and the MO $2b_{3u}$ located on the central C=C bond in the molecular plane. When an attempt is made to interpret the photoelectron spectrum of butadiene with the aid of the ionisation energies obtained on the basis of Koopmans' theorem even in a very effective non-empirical calculation (two-exponent basis set with polarisation *d* functions as well as allowance for correlation corrections by the method of Green's functions),[23] a difficulty arises. It is associated with the fact that in the range 9–10 eV, where three bands are observed, there are only two ionisation processes, corresponding to the two highest π MO b_{3g} and b_{3u}. It has therefore been postulated that the middle band, with a maximum at 9.6 eV, is a satellite band. In order to elucidate the nature of the satellite band, the vibronic problem has been solved for butatriene with the aid of the formalism of Green's functions.[73] It was established that the band arises as a result of the vibronic interaction between the ground $^2B_{3g}$ state and the first electronically excited $^2B_{3u}$ state of the radical-cation, which are separated by a small gap (~0.7 eV). The intensities, calculated

taking into account the vibronic interaction, made it possible to reproduce closely the form of the first three bands in the photoelectron spectrum of butatriene. For an accurate prediction of the position of the above satellite band, the multiconfiguration SCF method has been used.[10] The geometry of the butatriene molecule was optimised in terms of the STO-3G basis set and the calculation for the molecule and the radical-cation was performed in terms of a grouped exponent basis set with inclusion of all the singly and doubly excited configurations (the excitations were considered only for π MO). It was concluded that non-empirical calculations of different types (SCF) in terms of the STO-3G and 4-31G basis sets, the method of Green's functions, and allowance for configuration interaction lead to the same conclusion, namely that the first three bands in the photoelectron spectrum of butatriene (not counting the satellite band) correspond to the ionisation of the highest π MO—b_{3g}, b_{3u}, and b_{2u} respectively.

As examples of two accumulated π-systems linked by a single bond,[6] 1,2,4,5-hexatetraene $CH_2=C=CH-CH=C=CH_2$ (I) (C_{2h} symmetry) and 1,3,4-pentatriene $CH_2=CH-CH=C=CH_2$ (II) have been investigated. Calculation of the ionisation energies in accordance with Koopmans' theorem with the aid of various semiempirical methods—EHM, CNDO/2, MINDO/3, and SPINDO—leads to the same sequence of the highest occupied π MO, namely $\pi_z - \pi'_z$ (b_g), $\pi_x - \pi'_x$ (a_g), $\pi_x + \pi'_x$ (b_u), and $\pi_z + \pi'_z$ (a_u), which are involved in the generation of the first four bands in the photoelectron spectrum of compound (I). It follows from the experimental ionisation energies that the energy splitting of the bonding and antibonding combinations for the $\pi_z - \pi'_z$ and $\pi_z + \pi'_z$ pair (π_z and π'_z are the orbitals of the allenyl fragments whose nodal plane coincides with the molecular plane) is much greater than for the $\pi_x - \pi'_x$ and $\pi_x + \pi'_x$ pair (π_x and π'_x are the orbitals of the allenyl fragments located in the molecular plane). It was noted that the best agreement between the calculated and experimental ionisation energies is afforded by the SPINDO method. In the photoelectron spectrum of compound (II), the first three bands correspond to the ionisation of the three highest occupied molecular orbitals. The study of the photoelectron spectrum and calculation of the ionisation energies of the 3-methyl derivative of compound (I) showed that the introduction of the CH_3 group has only a slight effect on the π_x type orbitals but causes an appreciable shift of the π_z-type orbitals. The effect of various substituents on the electronic structures and ionisation energies of cumulenes has been studied in a number of investigations.[5,10,11,16,57,74,75] Mono-, di-, tri-, and tetrafluoroallenes have been investigated in a study,[5] where the molecular geometry was optimised in terms of a biexponential basis set with polarisation *d* functions of carbon, which yields a correct description of the C—F bond; the ionisation energies were calculated in terms of the same basis set supplemented by the *d* functions of fluorine and the *p* functions of hydrogen, taking into account the correlation corrections by the method of perturbation theory. The high quality of the calculation is confirmed by the fact that the calculated dipole moments of the molecules reproduce satisfactorily the experimental values (the differences are on average 15%). According to the calculated data, as carbon atoms are substituted by fluorine, the negative charge on the central carbon atom increases, varying from +0.12 in allene to −0.43 in perfluoroallene; this effect is attributed to the π-donor capacity of fluorine. The calculation predicts a gradual increase in the first ionisation energy with increase in the number of substituting fluorine atoms, which agrees with photoelectron spectroscopic data (available only for some fluoroallenes). A large difference between the values of IE_1 (0.5 eV) of the difluoroallene isomers $H_2C=C=CF_2$ and $HFC=C=CHF$ has been noted. The random degeneracy in the latter compound, where the HOMO and the molecular orbital which follows it have the same energies, is striking.

The results of the non-empirical calculation in terms of the 4-31G basis set for 1,1-difluoroallene and tetrafluoroallene have been published.[16] Calculation showed that IE_1 for 1,1-difluoroallene corresponds to the π[C(1)=C(2)] orbital with an antibonding contribution by the electron pair of fluorine, while IE_2 corresponds to the π[C(2)=C(3)] orbital with a hyperconjugation contribution by the σ orbitals of the C—F bonds. The fluorine atom has only a weak effect on the energy of the π[C(1)=C(2)] HOMO, since in this case the stabilising inductive effect of fluorine is compensated by the destabilising resonance effect and lowers markedly the energy of the π[C(2)=C(3)] MO, where there is also a stabilising influence of the inductive effect and of the effect of the hyperconjugation of the CF_2 group.

The non-empirical calculation for perfluorobutatriene, carried out using a two-exponent basis set and the standard geometry of the molecule, may serve as an example of the study of the perfluoro-effect in cumulenes.[10] According to the calculated data, the first three bands in the photoelectron spectrum of this compound correspond to the ionisation of the highest occupied π MO b_{3g}, b_{3u}, and b_{2u}, while the fourth band (whose position and shape are similar to those of the corresponding band in the spectrum of tetrafluoroallene) is due to a linear combination of the unshared pairs of the fluorine atoms. All the fluorine atoms are located in the nodal plane of the HOMO b_{3g} and the orbital b_{2u}, corresponding to IE_3, and for this reason they give rise to only a slight change in the energies of these molecular orbitals compared with unsubstituted butatriene: IE_1 does not change at all, while IE_3 changes by 0.4 eV. A strong stabilising effect of fluorine is observed in the case of the molecular orbital b_{3u}, which lies in the same plane as the fluorine atoms: IE_2, corresponding to this molecular orbital, shifts by 2.6 eV on perfluorination.

Monosubstituted allenes have been investigated by Sinegovskaya et al.[74] (with substituents OAlk, where Alk = CH_3, C_2H_5, n-C_3H_7, iso-C_3H_7, n-C_4H_9, and t-C_4H_9) and by Kamphuis et al.[11] with the substituents t-C_4H_9, OCH_3, OC_2H_5, OC_4H_9-t, $N(CH_3)_2$, SCH_3, SC_2H_5, and SC_4H_9-t). Sinegovskaya et al.[74] calculated the ionisation energy of alkyl allenyl ethers by the MNDO method with complete optimisation of the geometry. IE_1 and IE_3 for allenyl methyl ether correspond to a linear combination of the π[C(1)=C(2)] orbitals with the *p* atomic orbitals of ether oxygen (in the case of IE_1, the contribution of the *p* atomic orbitals of oxygen is antibonding, while in the case of IE_3 it is bonding), IE_2 corresponds to the unperturbed π[C(2)=C(3)] orbital, and IE_4 corresponds to the almost pure *n* orbital of oxygen (n_O). It was shown that this sequence of the four highest occupied molecular orbitals in allenyl methyl ether can be readily obtained from the consideration of the Walsh correlation diagram constructed from the two highest molecular orbitals of allene and of the $(CH_3)_2O$ molecule. Successive substitution of CH_3 by C_2H_5, n-C_3H_7, and iso-C_3H_7 in allenyl methyl ether leads to a shift of IE_1 and IE_2 by 0.1—0.3 eV and of IE_3 and IE_4 by 0.3—0.8 eV towards lower values. Calculation shows that, with increase in chain length and in the degree of branching of the alkyl substituent, the efficiency of the mixing of the n_O orbital and the σ_{CC} orbitals of the substituent increases.

It has been established[11] that the effect of bulky electron-donating substituents containing alkyl groups on the photoelectron spectra of allenes is determined not only by electronic effects (inductive,

conjugation, and hyperconjugation effects) but also by conformational effects. Calculations by the MINDO/3 method with complete optimisation of the geometry showed that the radical-cations in the ground state can have a geometry differing markedly from that of the corresponding molecules. For example, in allenes with the $N(CH_3)_2$ and t-C_4H_9 substituents, the C=C=C fragment in the cations has a bent structure. For the radical-cations where the substituting OAlk or SAlk group includes CH_3 and C_2H_5, the *S-cis*-form is preferred, while in the case of OC_4H_9-t and SC_4H_9-t the *S-trans*-form is preferred. The non-planar *gauche*-form, in which there is strong $\sigma-\pi$ mixing, is preferred for the $N(CH_3)_2$ group and the effect of the substituents can no longer be interpreted in terms of separate π and σ interactions.

The influence of the CF_3 group on the ionisation energies in cumulated systems was investigated separately in a study[75] where calculations were performed by the MINDO/3 method for tetrasubstituted allenes with the CF_3, OCH_3, and OC_2H_5 substituents. It was shown that the inductive effect predominates when the CF_3 group is introduced. It is additive and stabilises the HOMO to the extent of 0.5 eV per CF_3 group.

The effect of methylation on the photoelectron spectra of more complex cumulenes was investigated in relation to mono- and dimethyl-derivatives of penta-1,2,4-triene (vinylallene).[47] The CNDO/S method used for the calculation reproduced satisfactorily the dependence of the ionisation energies on the position of the CH_3 group. The methyl group at the terminal atom of the allene fragment affects appreciably the energy of the orbital localised on the terminal allene bond and corresponding to IE_2. The methyl group bound to the central carbon atoms C(3) and C(4) interacts through space with the orbitals of the vicinal C=C bonds. This interaction stabilises the HOMO and destabilises the molecular orbital corresponding to IE_3.

IV. The reactivities of alkenes

In the study of the reactivities of alkenes in relation to electrophiles, the first ionisation energy may serve as a measure of the electron-donating capacity. The electron-accepting capacity of the alkene in reactions with nucleophiles can be characterised by the electron affinity (EA). The correlation between the rate of reaction and the ionisation energy or the electron affinity, observed in series of related alkenes, makes it possible to predict fairly accurately the reactivity on the basis of the ionisation energies or electron affinities obtained experimentally or from quantum-chemical calculations. The quantum-chemical calculations, performed within the framework of the molecular orbitals model, not only yield the numerical values of the ionisation energy and the electron affinity, determined respectively as the HOMO and LUMO energies, but also make it possible to determine the nature of the location of these frontier orbitals on individual atoms and bonds, which makes it possible in its turn to explain the regioselectivity of the electrophilic or nucleophilic reaction. The calculation also enables one to model the intermediate state generated by the reacting species in the rate-limiting stage of the reaction.

The study of the relation between the first ionisation energies and the relative rates of electrophilic addition enabled Nelson et al.[48] to separate the electronic and steric factors in alkene bromination, hydroxymercuration, and hydroboration reactions. Olefins with sterically unlike electron-donating and electron-accepting groups Alk, OAlk, SCH_3, SC_6H_5, $Si(CH_3)_3$, Cl, Br, I, CN, and OAc, which were present both at the double bond and in the alkyl chain of the olefin (altogether 21 compounds) were investigated. In the bromination reaction, the dependence of $\lg k_{rel}$ (k_{rel} is the relative reaction rate constant) on the ionisation energy is described by one linear relation (with a correlation coefficient of 0.96), embracing the compounds of the entire series, the rate of reaction being independent of the degree of substitution at the double bond. On the other hand, in the case of hydroxymercuration and hydroboration it is not possible to obtain a single linear relation with the ionisation energy: for each reaction, there are two groups of alkenes, each of which is described by its own linear relation. One group includes alkenes substituted only at one of the atoms involved in the double bond, whilst the other comprises alkenes with substituents at both atoms of this bond, i.e. each group combines sterically similar compounds, the alkenes with smaller steric hindrance reacting faster. Thus it has been possible to show that the rate of bromination of the alkene is independent of the steric factor and is determined solely by the electronic effect of the substituent, i.e. by the ionisation energy of the alkene, while in hydroxymercuration and hydroboration the steric factors predominate over the electronic factors. However, satisfactory linear correlations have been obtained between the ionisation energies and relative reactivities for both experimental ionisation energies and ionisation energies calculated by the MNDO method on the basis of Koopmans' theorem, which justifies the prediction of the reactivities of alkenes by a computational procedure. The overall rule is that the rate of electrophilic addition falls with increase in ionisation energy. Analysis of the nature of the HOMO on the basis of data obtained by the MNDO calculation makes it possible to explain the regioselectivity of the hydroxymercuration and hydroboration reactions, where Hg and B atoms add preferentially to the unsubstituted carbon atom involved in the double bond. This has been demonstrated for the compounds $H_2C=CHCH_2X$ with different substituents X. In the hydroboration reaction of these compounds, the addition of boron to the unsubstituted carbon atom of the double bond is more preferred the greater the coefficient of the HOMO at this atom compared with the substituted carbon atom. The MNDO calculation also made it possible to establish that the transition states in the rate-limiting stages of the hydroxymercuration and hydroboration reactions are similar and both differ from the transition state in the bromination reaction. The transition state was modelled by a three-centre intermediate, for which the calculation was performed with complete optimisation of the geometry.

The relation between the electron affinities and reactivities of alkenes with an electron-deficient double bond, which function as electrophiles in the Diels–Alder cycloaddition reaction as well as other reactions involving the addition of nucleophilic species, has been traced.[46] The electron affinity was regarded as a measure of the electrophilic reactivity of the alkene. Mono-, di-, tri-, and tetracyanoethylenes as well as ethylenes containing, together with the cyano-group, also another electron-accepting substituent (CF_3, OAc, CO_2, CH_3, and certain others) have been investigated. Since the experimental electron affinities are available only for a small number of the test compounds, those of alkenes were estimated from the known ionisation energies. The method used for such estimations is based on the fact that, according to data calculated by the CNDO/2 method, the HOMO and LUMO energies (characterising the ionisation energy and the electron affinity respectively) in cyanoethylenes are linearly related: an increase in the HOMO energy under the influence of the cyano-groups is accompanied by a

proportional decrease in the LUMO energy. The following linear relation then holds:

$$EA = 3.3IE - 36 \text{ (eV)},$$

from which the electron affinities were in fact determined. The reliability of the electron affinities obtained is confirmed by their correlations with the polarographic potentials for the reduction of cyanoalkenes. For the cycloaddition reaction, where the alkene and the nucleophile (for example, NH_2 of OH) form only one bond with the alkene in the intermediate, the electron affinity (or the LUMO energy) is the controlling factor only for a nucleophile with a low ionisation energy ($\leqslant 8$ eV). The reactivity of the cyanoalkene in relation to a nucleophile with a high ionisation energy ($\geqslant 12$ eV) is controlled by the maximum orbital coefficient of the LUMO, which always corresponds to the least substituted carbon atom involved in the double bond and which in fact proves to be most susceptible to nucleophilic attack. By analysing the nature of the interactions between the frontier orbitals of the alkene and the nucleophile (interactions of the type alkene HOMO–nucleophile LUMO), the authors were able to differentiate pairs of frontier orbitals which determine both the relative rate and the regioselectivity of the reaction between the alkene and the nucleophile as a function of the type of nucleophile.

It has been suggested,[61] in relation to *meta*- and *para*-substituted styrenes with the F, Cl, CH_3, and OCH_3 substituents, that the ionisation energy be used as a measure of the gas-phase affinity of an alkene for a proton or a hydrogen atom (in hydrogenation reactions). The numerical values of the ionisation energies were determined from the photoelectron spectra and by calculations in terms of the CNDO approximation.

Substituted derivatives of allene, whose molecule contains two mutually perpendicular π-systems, are interesting objects for the study of reactivity.

In order to investigate the effects of the substituent on the reactivity of the allene fragment, Taber et al.[71] carried out calculations by the EHM method for monosubstituted allenes $H_2C=C=CRX$ as well as $H_2C=C=CF_2$. The results of the calculations showed that the ionisation energy, determined on the basis of the Koopmans' theorem from the HOMO energy, decreases in the following sequence of substituents X: H > CN > F > Cl > F_2 > Br > CH_3, while the electron affinity, estimated as the LUMO energy decreases in the following sequence: CN > F > F_2 > H > NH_2 > Cl > CHO > CH_3 > Br. Analysis of the composition of the frontier molecular orbitals showed that, when X = CH_3, F, Cl, Br, and NH_2, the HOMO is to a large extent localised on the substituted double bond while the LUMO is localised on the unsubstituted double bond. In the case where X = CN and CHO, the opposite situation is observed: the HOMO and the LUMO are localised on the unsubstituted and substituted double bonds respectively. Therefore, the reaction, accompanied either by the loss of an electron (with participation of the HOMO) or the acquisition of an electron (with participation of the LUMO), can proceed, depending on the nature of the substituent, via both the substituted and the unsubstituted double bond of the allene.

In the [4 + 2]cycloaddition reaction (diene synthesis), which takes place as a result of the interaction of the HOMO of the diene (the electron-donating agent) with the LUMO of the dienophile (the electron-accepting agent), the substituted allene can function both as a diene and as a dienophile depending on the substituent and the nature of the other reactant. A number of studies have been devoted to this reaction of fluoroallenes.[5,16] Dommelsmith et al.[16] studied mono- and 1,1-difluoroallenes, for which calculations were made by the non-empirical method in terms of the 4-31G basis set. For the asymmetric substitution of hydrogen by fluorine in the allene, the degeneracy of the HOMO is removed because the fluorine atoms act differently on the two π MO, one of which is localised on the substituted C(1)=C(2) bond, while the other is localised on the unsubstituted C(2)=C(3) bond. As a result, the HOMO in the $CH_2=C=CHF$ and $CH_2=C=CF_2$ molecules is localised on the fluorinated π bond and is influenced little by the fluorine atom located in the same nodal plane. Therefore the C(1)=C(2) bond can be characterised, as in the unsubstituted allene, as an electron-enriched double bond.

The next occupied molecular orbital as well as the LUMO are localised on the non-fluorinated C(2)=C(3) bond and are strongly stabilised as a result of the inductive effect of fluorine. Thus this bond can be regarded as electron deficient. The concerted [4 + 2]cycloaddition reaction involving the enrichment of the species in electrons proceeds therefore with participation of a non-fluorinated bond in fluoroethylenes, while the non-concerted [2 + 2]cycloaddition involves the fluorinated bond. Dixon and Smart,[5] who used an expanded two-exponent basis set for the non-empirical calculation and studied mono- and 1,1-difluoroallenes as well as trifluoroallene, arrived at similar conclusions about the nature of the HOMO and LUMO in fluoroallenes and about the influence of these frontier molecular orbitals on the regioselectivity of the cycloaddition reactions.

Table 1 presents a compilation of the ionisation energies of 243 compounds with a C=C bond. The first column lists the empirical formulae of the compounds, which are arranged in order of increasing numbers of C, H, N, O, F, Si, S, Cl, Br, Sn, and I atoms. The second column presents the structural formulae (conventional representations of the carbon skeleton for complex hydrocarbons) and in some cases the names of the compounds. The third column lists the first two vertical and adiabatic (in brackets) ionisation energies. In addition, the symmetry and the nature of the corresponding ionisation energy are also indicated in brackets.

Ozonolytic transformations of labdane diterpenoids

P F Vlad, A N Aryku
Institute of Chemistry, Academy of Sciences of the Moldavian Republic, Kishinev

ABSTRACT. Information on the products of ozonolysis of labdane and *ent*-labdane diterpenoids is correlated. The effects of the ozonolysis conditions, the procedure for treating the products and the location of double bonds and other functional groups on the character of the resulting ozonolysis products are considered.

The bibliography contains 91 references.

I. Introduction

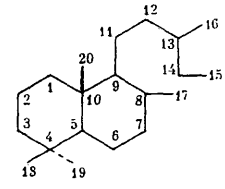
The labdane diterpenoids are bicyclic compounds based on the carbon skeleton (**1**).[1] A characteristic feature of many of them is their availability and practical value. Well known diterpenoids produced on an industrial scale (manool, sclareol, larixol, etc.) belong to this group. Raw materials for obtaining them are fairly accessible. For example, sclareol is isolated from the waste products of sage essential oil manufacture and the majority of the other compounds from the oleoresin of various coniferous plants.[2] Some of these diterpenoids display a high biological activity. For example forskolin proved to be an effective agent for the treatment of glaucoma, cardiac and other diseases[3] and sclareol displays antifungal activity.[4] However the chief practical value of the majority of the available labdanoids is that their transformation products are used in perfume manufacture as rich substitutes for the extremely precious, but unavailable at present, grey amber and in the tobacco industry for the aromatisation of tobacco products.[2]

Labdanoids are subjected to oxidative fission to obtain the indicated products. Compounds of hexavalent chromium or potassium permanganate serve as oxidising agents.[2] However these oxidising processes generally occur non-selectively and lead to a complex mixture of compounds from which the desired compounds are isolated with difficulty and in relatively low yield. Toxic aqueous effluents are formed which are difficult to purify. In addition potassium permanganate is not a readily available reagent. Consequently the development of alternative methods of obtaining the fission products of the available labdanoids using other inexpensive, more selective and ecologically clean oxidising agents is a pressing problem of both theoretical and practical interest.

Ozone is just such an oxidising agent. As is known, it is a powerful and at the same time selective oxidising agent, reacting with unsaturated compounds under mild conditions.[5–7] Thanks to this property ozone proved to be a convenient reagent to effect oxidative conversions of natural compounds in the clarification of their structures. It is perhaps used most frequently and successfully for these purposes in the terpenoid field,[8] the labdanoid diterpenoids amongst them.[1,2]

There are double bonds in the structure of the numerous known representatives of the labdanoid diterpenoid group, which most frequently occupy positions C(7), C(8)–C(9), C(8)–C(17), C(13)–C(14), C(13)–C(16) and C(14)–C(15) and only they react with ozone.[1,9] However the character of the resulting labdanoid ozonolysis products depends not only on the presence and position of the double bonds but also on such functional groups as hydroxyl and carbonyl groups.

In the present review, data on the ozonolysis of labdanoids are correlated according to the number, character and mutual disposition of functional groups in the molecule. Studies published up to 1991 are discussed. The numbering system used for the labdane carbon atoms (1) is taken from the IUPAC rules.[10]



(I)

II. Ozonolysis of labd-8-enoids without functional groups at C(13) and labda-8(17),13-dienoids

Ozone proved to be the preferred reagent for the oxidation of labdane diterpenoids with an exocyclic double bond at C(8)–C(17) to the corresponding ketones. This bond is fairly stable, for

example, to such widely used oxidising agents as potassium permanganate or compounds of hexavalent chromium. Satisfactory yields of ketones were obtained only in the two-step oxidation of labd-8(17)-enoids in which osmic acid was used in the first step,[1,2] however this reagent is expensive and available with difficulty. Ozone also oxidises these compounds efficiently. It is convenient both preparatively and for the qualitative detection of this bond. In reality the formation of formaldehyde during the process in conjunction with IR spectroscopy serves as a strict confirmation of the presence of an exocyclic double bond in labdanoids at position C(8)–C(17).

King and Jones[11] effected the ozonolysis of eperuic acid (*2*) in dichloromethane by oxidative fission of the ozonide with hydrogen peroxide and obtained the ketoester (3) in 71% yield (Scheme 1). A good yield (91%) of a mixture of ketoester (**3**) with its epimer at C(13) was also achieved on ozonolysis of a mixture of the ester (**2**) and its epimer at C(13) in ethyl acetate and reduction of the ozonolysis product with zinc in acetic acid.[12] Ozonolysis of the methyl ester of labd-8(17)-en-15-oic acid (**4**) [13] and of labdenoic acid (5) itself,[14] which are structurally close but belong to the enantiomeric series, under analogous conditions led to the keto compounds (**6**) and (**7**) respectively but in poor yield. Replacement of ethyl acetate by dichloromethane affects significantly the result of ozonolysis of methyl labdenoate (**4**) [the yield of ketoacid (**7**) after saponification of the reaction product was 46%].[15] The one-step ozonolysis of methyl labdenoate (**4**) in the presence of pyridine proceeds more smoothly [yield of ketoester (6) was 60%].[16]

(**25**) R = CH_2OAc

Chandra and collaborators[17] ozonolysed labd-8(17)-ene-3,15-diol (**8**) in chloroform and reduced the ozonide with zinc in acetic acid. The reaction product proved to be the ketodiol (**9**). The ozonolysis of oliveric acid (**10**) in dichloromethane in the presence of pyridine gave formaldehyde and the ketoacid (**11**).[18] Thus the functional groups removed from C(8) [the hydroxyl group at C(3) and the axial carboxyl group at C(4)] have no effect on the course of ozonolysis.

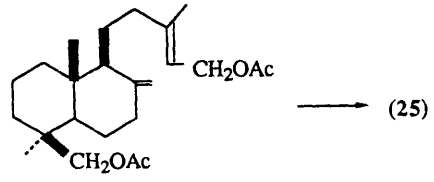
The ozonolysis of the methyl ester of labd-8(9)-en-15-oic acid (**12**) proceeds smoothly when carrying out the reaction in ethyl acetate with hydrogenation of the ozonide over palladium on calcium carbonate.[16] The yield of the diketoester (**13**) was 94%. The position of the double bond, the presence of a hydroxl group at C(13) or a hydroxyl group at C(13) and an acetoxy group at C(7) does not

affect the ozonation reaction. In fact on carrying it out in a mixture of dichloromethane and methanol (1:1) and treating the reaction product with triethyl or trimethyl phosphite, the hydroxyester (**14**) gave the hydroxydiketoester (**15**) in 76% yield[19] and the related diterpenoid (**16**) gave the polyfunctional compound (**17**) in 77% yield (see Scheme 1).[20] It should be noted that oxidation of $\Delta^{8(9)}$-labdanoids with other reagents frequently does not occur at the double bond but at position C(7),[1,2] i.e. ozonolysis is a selective process.

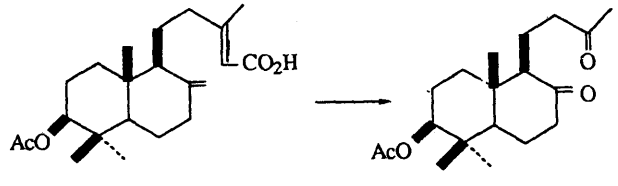
Ozonolysis also proved to be an efficient process for the oxidation of labdenoids with double bonds at C(8)–C(17) and C(13)–C(14). For example, the diketone (**19**) proved to be the sole product (74% yield) of the ozonolysis of labda-8(17),13-diene (18) in dichloromethane in the presence of pyridine.[21] Although the esters (**20**)[22] and (**21**)[23] were also ozonolysed in an aprotic solvent (ethyl acetate) the reduction of the ozonides with zinc in acetic acid led to the diketoesters (**22**) and (**23**) respectively in relatively low yield (~40%). However, the diketoacetate (**25**) was isolated in 78% yield on reduction of the ozonide obtained from 19-acetoxylabda-8(17),13-diene (**24**) in dichloromethane by the same method.[24]

The functionalisation of the carbon atom C(15) in labda-8(17),13-dienes apparently does not ease the fission of the double bond at C(13)–C(14). 15-Acetoxylabda-8(17),13-diene (**26**) is oxidised by ozone (dichloromethane solvent, reducing agent zinc in acetic acid) to the diketone (**19**) in 84% yield.[25] The latter is also formed, though in far poorer yeild (42%), on ozonolysis of labda-8(17),13-diene-15-oic acid (**27**) in ethyl acetate and reduction of the ozonide with the same reagent.[26] Additional functional groups in ring A have no effect on the ozonolysis which is evident in the example of the oxidation of the acetoxydienes (**28**)[24] and (**29**)[27] giving the corresponding acetoxydiketones (**25**) and (**30**) in identical yield (89%) (Scheme 2). In the first case the reaction was carried out in dichloromethane and the ozonide was reduced with zinc and acetic acid and in the second in ethyl acetate and the ozonide was hydrogenated over palladium on carbon.

Scheme 2



(**28**)



(**29**) (**30**)

These data show that the result of the ozonolysis of the labdanones depends significantly on the conditions, especially on the solvent. In particular ozonolysis in ethyl acetate with subsequent reduction of the ozonides with zinc in acetic acid leads to a low yield of ozonation product (Scheme 3).

(**40**) R = O

Ruzicka and collaborators[28] carried out the ozonolysis of the dimethyl ester (**31**) of agathic acid (**32**) under forcing conditions in acetic acid and, after reduction of the product by boiling in water with zinc dust, obtained a complex mixture of compounds of which the main was the labile diketoester (**23**) (20% yield). In addition an intramolecular peroxide (10%) was isolated to which the authors assigned the structure (**33**). In reality it has the structure (**34**),[5] and a ketoesteracid (**35**) was isolated from the acid fraction. Compound (**34**) is fairly stable and is not reduced by zinc dust in water. The ozonolysis of the same agathic acid (**32**) occurs less ambiguously under milder conditions. In an aprotic solvent (dichloromethane) in

the presence of pyridine it leads mainly to the diketoacid (**36**) 61% yield.[29]

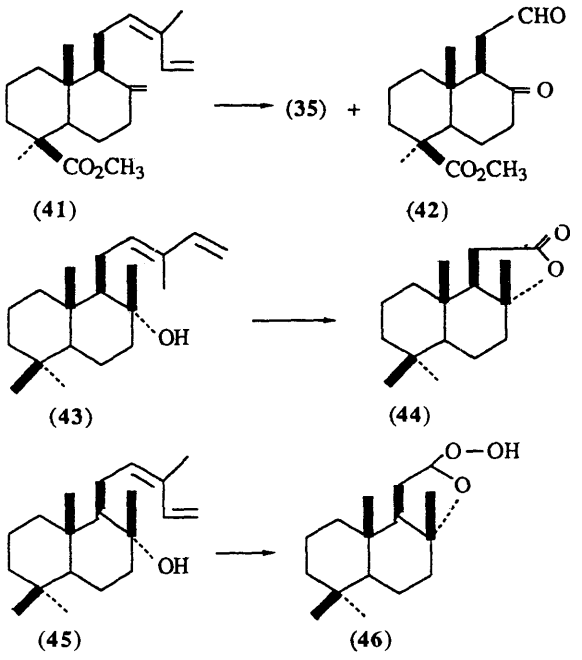
The double bond at C(8)–C(17) is norlabdanoids also reacts smoothly with ozone. Thus 14,15-bisnorlabd-8(17)-en-13-one (**37**) gives the diketone (**19**) (84%) on ozonolysis in dichloromethane in the presence of pyridine.[30] The indicated yield of diketone (**19**) was however achieved after additional treatment of the ozonolysis product with sodium iodide solution. Evidently this treatment was carried out to decompose stable peroxide compounds which were still present since it was later[31] shown from example that one of the ozonolysis products of the unsaturated ketone (**37**) was the oxonide (**38**), an analogue of compound (**34**). Its yield reached 33% if the ozonolysis product was subjected to oxidative fission with hydrogen peroxide.

The tetranorlabdene ester (**39**) is also ozonised smoothly (solvent is chloroform, reducing agent zinc in acetic acid). The sole ozonolysis product was the expected ketoester (**40**).[32]

III. Ozonolysis of labdanoids and norlabdanoids containing a functional group at C(8) and a double bond at C(9)–C(11), C(11) or C(12)

Few labdanoids with the functionalisation indicated are known. Of the compounds with a double bond at C(12) the first investigations were of the ozonolysis of the methyl ester of *cis*-communic acid (**41**) (Scheme 4).[24] The reaction was carried out in dichloromethane and the ozonide was decomposed by boiling with water or with aqueous methanol. A mixture of compounds (**35**) and (**42**) was formed in both cases. In the first case the aldehyde (**42**) predominated in the product [yields of (**35**) and (**42**) were 9 and 59% respectively] and in the second the ketoacid (69.5%) predominated [yield of ketoaldehyde (**42**) was 22.6%]. The conditions therefore affected significantly both the product ratio (6.5 : 1 and 1 : 3) and their overall yield.

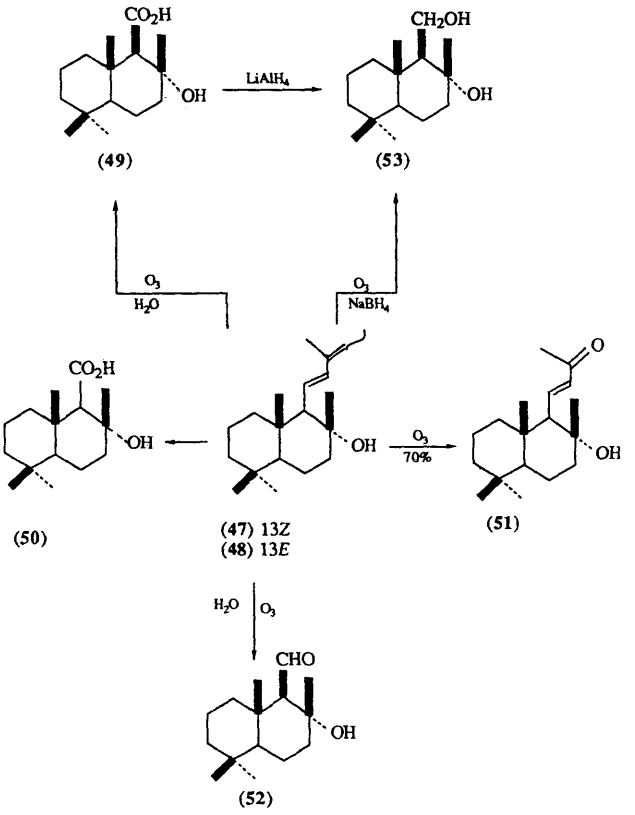
Scheme 4



Chirkova and collaborators[33] have carried out the ozonolysis of *trans*-abienol (**43**) which was isolated by them from Siberian fir and was erroneously mistaken for isoabienol.[34] Ozonolysis was effected in dichloromethane, the ozonide was decomposed by boiling with water, the product was oxidised again with potassium permanganate in acetic acid and norambreinolide (**44**) (70%) was obtained.

A compound of an altogether different nature was obtained in fairly good yield (50–70%) on ozonolysis of *cis*-abienol (**45**), which is distributed in the oleoresin of conifers, in ethyl acetate with oxidative fission of the ozonolysis product with hydrogen peroxide in acetic acid.[35] It turned out to be the epoxyhydroperoxide (**46**) which is formed by intramolecular attack of the Criegee zwitterion by the hydroxy group at C(8).[5,6] This was the first recorded case of the formation of an intramolecular alkoxyhydroperoxide in an aprotic solvent, analogous to the preparation of acyclic alkoxyhydroperoxides on ozonolysis of unsaturated compounds in alcoholic solvents.[6]

Scheme 5



A detailed investigation has been made of the ozonolysis of *cis*- and *trans*-neoabienols (**47**) and (**48**), the stereoisomeric labdanoids with a double bond at C(11) and a hydroxyl group at C(8) which are artefacts formed from *cis*-abienol (**45**) on distillation of oleoresins containing it.[36–39] The authors[36] isolated a hydroxyacid which was assigned the structure (**49**) on ozonolysis of *cis*-neoabienol (**47**) under the conditions indicated above for *trans*-abienol (**43**) (Scheme 5). However its constants differed from those described.[41] Seemingly it is an epimer of compound (**50**). The ozonolysis of a mixture of *cis*- and *trans*-neoabienols (**47**) and (**48**) has been investigated in detail.[42]

It was shown that the character of the ozonolysis products depends significantly on the quantity of oxidising agent and the method of decomposing the ozonide or peroxide. Thus on using one mole equivalent of ozone and carrying out the reaction at −60 to −70 °C in ethyl acetate in the presence of pyridine or in methanol with subsequent decomposition of the peroxide reaction products with dimethyl sulphide, the selective formation occurs of the conjugated hydroxyketone (**51**) (yield 70%), which is a component of the oleoresin of Siberian fir together with neoabienols (**47**) and (**48**).[40] On increasing the temperature the yield of the hydroxyketone (**51**) is reduced and is 55% at 0 °C. Exhaustive ozonolysis of a mixture of neoabienol in hexane with subsequent heating of the ozonide with water leads to a mixture of driman-8α-ol-11-al (**52**) (60%) and the hydroxyacid (**49**) (25%),[42] the structure of which was demonstrated unequivocally by reduction with lithium aluminium hydride to the known drimane-8α-11-diol (**53**). A mixture of the same compounds is formed on ozonolysis of a mixture neoabienols in ethyl acetate or dichloromethane in the presence of pyridine or in methanol and reduction of the peroxides with dimethyl sulphide. The acid (**49**) is the chief reaction product (yield 71%) on ozonolysis in hexane with oxidative fission of the ozonide with hydrogen peroxide. If the reaction is carried out in methanol at −75 to −78 °C and peroxides are reduced with sodium borohydride, the main reaction product is the diol (**53**) (74%) which is an important starting material for the synthesis of the natural drimane sesquiterpenoids.[43] The yield of the diol (**53**) falls with increasing temperature. The ozonolysis of the hydroxyketone (**51**) has also been investigated in detail and it was shown that there is a definite parallel between the yields of the individual products on ozonolysis under the same conditions of a mixture of neoabienols (**47**) and (**48**) and the hydroxyketone (**51**).

Japanese chemists[44] have ozonolysed sterebins E (**54**), F (**55**), G (**56**) and H (**57**) and 14,15-dinorsterebin (**58**), isolated from the leaves of *Stevia rebaudiana*, in methanol and the ozonolysis products were reduced with sodium borohydride. The tetrol (**59**) was isolated in 60–65% yield in all cases (Scheme 6).

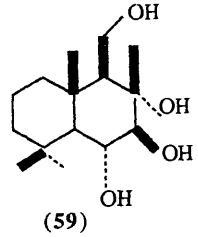
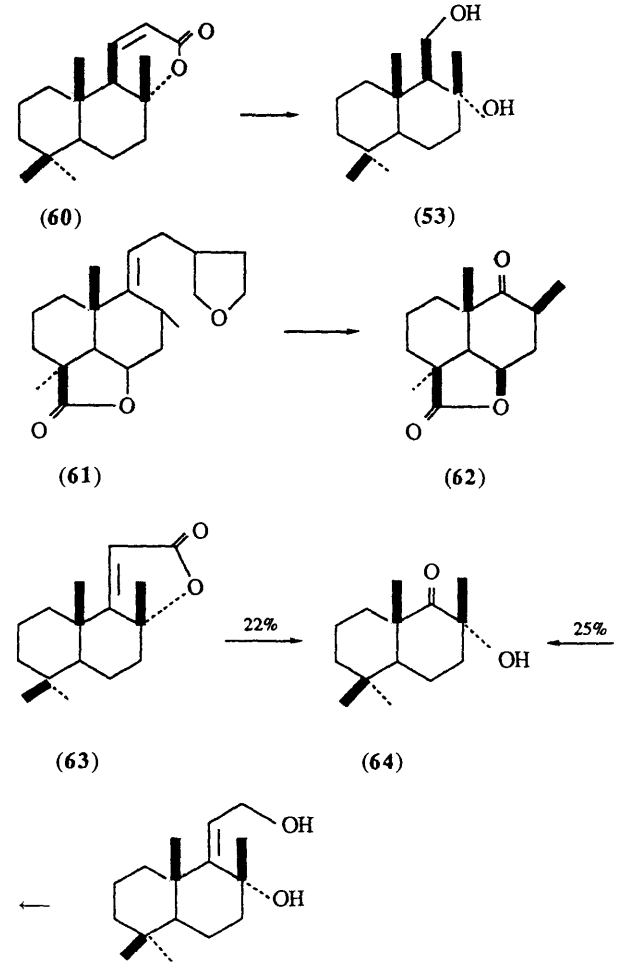
(**58**)



(**59**)



(**60**) (**53**) (**61**) (**62**) (**63**) (**64**) (**65**)

The tetranorlabdanoid Δ^{11}-dehydroabreinolide (**60**) is also smoothly ozonolysed giving driman-8α,11-diol (**53**) in 70% yield on carrying out the reaction in dichloromethane with reduction of the ozonide with sodium bis(2-methoxyethyl)aluminium hydride in benzene.[45] If the ozonide is reduced with lithium aluminium hydride in ether the yield of diol (**53**) was greater (92%).[21]

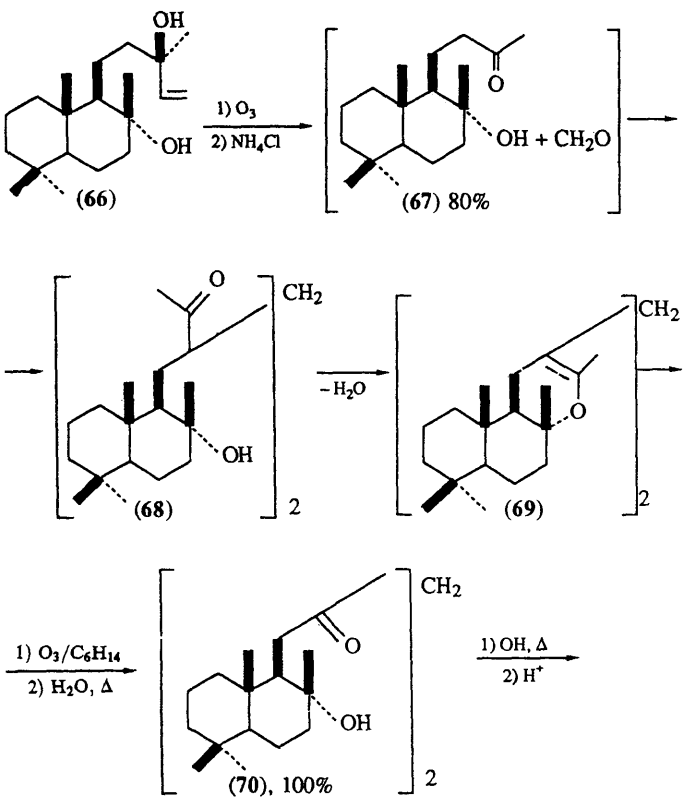
The 9,11-double bond in labdanoids and norlabdanoids is sterically hindered and reacts with ozone with difficulty. It has not as yet been detected in such compounds from natural sources.

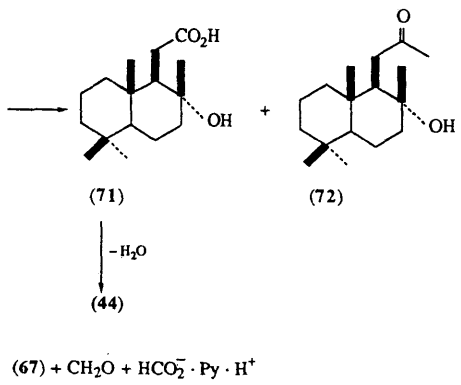
The ozonolysis of anhydrotetrahydromarrubiin (**61**) in ethyl acetate at a relatively high temperature (−5 °C) and hydrogenation of the ozonide over palladium on carbon gave the ketolactone (**62**) in only 18.5% yield.[46] $\Delta^{9(11)}$-Dehydronorambreinolide (**63**) proved to be very inert towards the action of ozone. On ozonolysis in a mixture of ethyl acetate and methanol, hydrogenation of the ozonolysis products over Lindlar catalyst and subsequent saponification with alkali, only a small quantity (22%) of the hydroxyketone (**64**) is formed, a large portion of the initial compound is recovered unchanged in spite of the use of an excess of ozone and forcing conditions.[47] An analogous result was also obtained on ozonation (methanol, hydrogenation of the peroxide over Pd/C) of the product of reduction of this lactone, viz. the diol (**65**) (see Scheme 6).[48]

IV. Ozonolysis of labdanoids with oxygen-containing functional groups at C(8) and C(13) and a double bond at C(14) or with a hydroxy group at C(8) and a double bond at C(13)–C(14)

Sclareol (**66**) was one of the first labdanoids of this type to be subjected to ozonolysis (CCl_4, fission of the ozonide by boiling with water).[49] However the product was not identified exactly. It was only recorded that is has the composition $C_{18}H_{30}O$ and was an oxide in character. On carrying out the reaction under the conditions indicated we obtained a complex mixture of products.[50] Subsequently sclareol was treated with ozone in a polar solvent (methanol) and the ozonolysis product was decomposed with ammonium chloride.[51] The epoxide (**69**) was readily isolated by crystallisation in high yield (80%) in this way. It is formed by the condensation of the primary ozonolysis products, formaldehyde and the hydroxyketone (**67**), and subsequent dehydration of the dihydroxydiketone (**68**) (Scheme 7). Compound (**69**) is either not formed or its yield is reduced significantly on using other compounds (common acids, Lewis acids, acid salts, etc.) for the decomposition of the peroxide oxidation products. Ozonation of compound (**69**) in hexane with subsequent heating of the ozonide with water leads quantitatively to the 1,3-diketone (**70**). This was decomposed with alkali to the hydroxyacid (**71**), which lactonises to norambreinolide (**44**) and to 14,15,16-trinorlabd-8α-ol-12-one (**72**),[52,53] important compounds in practice for the synthesis of perfumes. In particular, a mixture of them may be converted readily into an analogue of the known perfume ambroxide.[52]

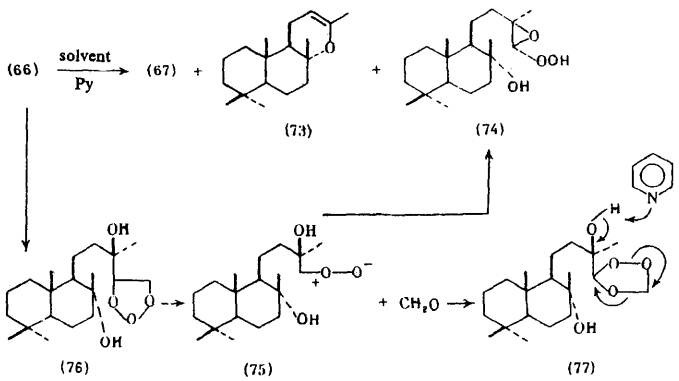
Scheme 7





(67) + CH_2O + HCO_2^- · Py · H^+

Scheme 8

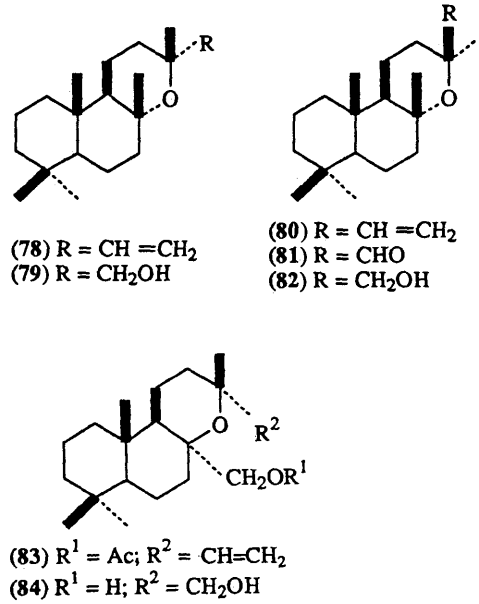


The ozonolysis of sclareol (**66**) has been investigated by other authors.[50] It was shown that on carrying it out in methanol and treating the product with dimethyl sulphide a mixture of at least six compounds is formed. Ozonolysis in dichloromethane, carbon tetrachloride, methanol or ethyl acetate in the presence of pyridine or in ethyl acetate with subsequent heating of the ozonide with water gives a mixture of the hydroxyketone (**67**), the epoxide (**73**) and the α-epoxyhydroperoxide (**74**) (Scheme 8). The latter is unstable and was characterised by spectral data and chemical conversions. Its formation is in agreement with and confirms the ozonation mechanism of allyl alcohols proposed by Everest and collaborators,[54] according to which the zwitterion (**75**), generated from the initial ozonide (**76**) of sclareol, is stabilised as the epoxyhydroperoxide (**74**). The nature of the solvent therefore has little effect on the composition of the reaction products in the ozonolysis of sclareol in the presence of pyridine. It was shown that pyridine does not react with hydroperoxide (**74**). Consequently if the ozonolysis of sclareol (**66**) occurs only by the mechanism proposed by Everest and collaborators,[54] then the presence of pyridine in the reaction mixture must have no effect on the yield and ratio of the compounds (**67**), (**73**), and (**74**). However, experimentally this is not so. This may be explained by the ozonolysis of sclareol proceeding partially according to the mechanism of Criegee[5,6] with the formation of the normal ozonide of sclareol (**77**) and its decomposition involving pyridine evidently as indicated in Scheme 8. The course of the reaction according to the latter mechanism depends to a definite extent on the solvent used.

The oxidation with ozone of those labdanoids in which the carbon atoms C(8) and C(13) are linked by an oxygen bridge, i.e. the manoyl oxides, proceeds in a different way.

The ozonolysis of manoyl oxide (**78**) (CCl_4, the ozonide was decomposed by boiling with water) was carried out for the first time by Hosking and Brandt.[55] However the nonvolatile products were not investigated by them. Later Cambie and collaborators[56] ozonised manoyl oxide (**78**) in dichloromethane in the presence of pyridine and the product was reduced with sodium borohydride giving 15-nor-8-α,13-epoxy-14-hydroxylabdane (**79**) (80%) (Scheme 9).

Scheme 9

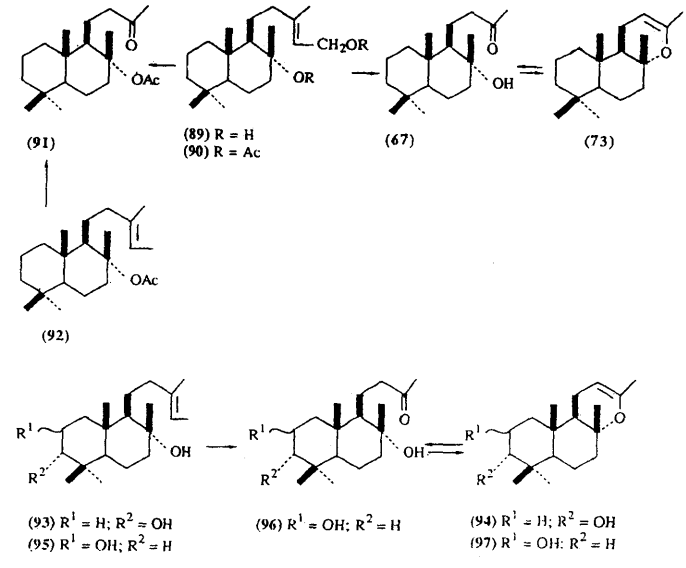


13-Epimanoyl oxide (**80**) was ozonised in carbon tetrachloride with subsequent heating of the ozonide with water. The reaction product proved to be the aldehyde (**81**) (70%).[57] On ozonising the epoxide (**80**) in dichloromethane in the presence of pyridine and reducing the product with sodium borohydride, the alcoholic epoxide (**82**), an epimer of compound (**79**), was isolated in 78% yield.[58] The ozonolysis of 8-epi-20-acetoxymanoyl oxide (**83**) to the dihydroxyepoxide (**84**) (75%) was effected fairly smoothly under the conditions indicated above.[56]

The appearance of a functional group at C(12) in manoyl oxides leads to the fission of the C(12)–C(13) bond on ozonolysis. Norambreinolide (**44**) (40%) and the acetoxyacid (**86**) (15%) were formed on ozonation of 12α-hydroxy-13-epimanoyl oxide (**85**) in chloroform followed by oxidative fission of the ozonide with hydrogen peroxide.[59]

The first of the labdanoids with a hydroxyl group at C(8) and a double bond at C(13) to be subjected to ozonation was (13*E*)-*ent*-8β,15-dihydroxylabd-13-ene (afanamixol) (**87**). The reaction was carried out in acetic acid and the ozonolysis product was reduced with metallic magnesium in hydrochloric acid. The hydroxyketone (**88**) was obtained in 88% yield.[60] The unsaturated epoxide (**73**) (75%) was isolated on ozonolysis of the antipode (**89**) of afanamixol (**87**) in a mixture of methanol and dichloromethane and reduction of the peroxide compounds with dimethyl sulphide.[61] In this case also the first reaction product is the hydroxyketone (**67**), which, as is known,[62] on heating or by the action of acid is transformed into the epoxide (**73**) with which it is in equilibrium. The equilibrium transition (**67**) ⇆ (**73**) is impossible if the hydroxy group of the starting material (**89**) is esterified. In fact the ozonation of the diacetate (**90**) [$CH_3OH-CH_2Cl_2$; $(CH_3)_2S$] leads to ketoacetate (**91**) (90%).[61] This same compound is also formed in almost quantitative yield (98%) on ozonation of the unsaturated acetate (**92**) in dichloromethane in the presence of pyridine.[21] Under the same conditions (13*E*)-3α,8α-dihydroxylabd-13-ene (**93**) gave 3α-hydroxy-8α,13-epoxy-14,15-dinorlabd-12-ene (**94**) (90%),[63] and a mixture of (13*E*)-2α- and 2β,8α-dihydroxylabd-13-enes (**95**) gave an equilibrium mixture of the 2α- and 2β,8α-dihydroxyketones (**96**) and the epoxides (**97**) (91%) (Scheme 10).[64]

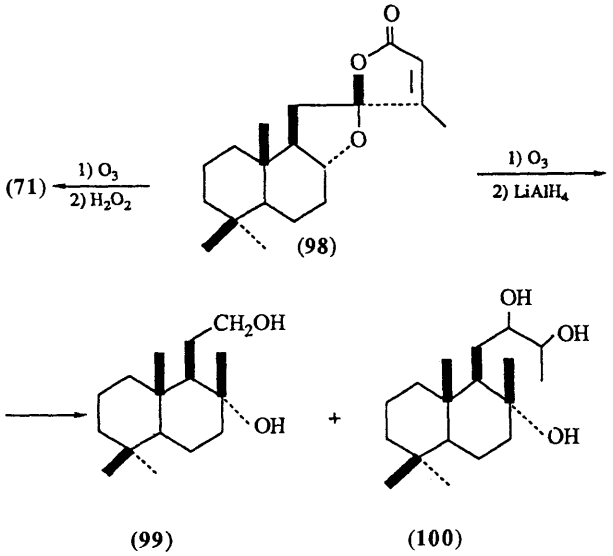
Scheme 10



If an oxygen-containing group is present at C(12) in addition to the hydroxyl group at C(8) and a double bond at C(13) in a labdanoid then depending on the conditions fission of the single

bond at C(12)–C(13) may result. The diol (**99**) (55% yield) and the triol (**100**) (~45%) were isolated on ozonolysis of α-levantenolide (**98**) in ethyl acetate and reduction of the ozonide with lithium aluminium hydride (Scheme 11). On oxidative fission of the ozonide with hydrogen peroxide the sole reaction product is norambreinolide (**44**) (78.5%).[65]

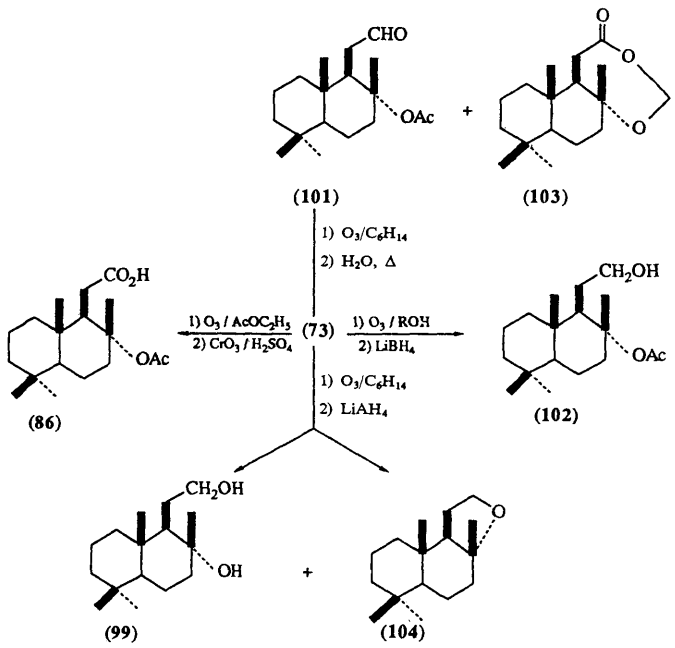
Scheme 11

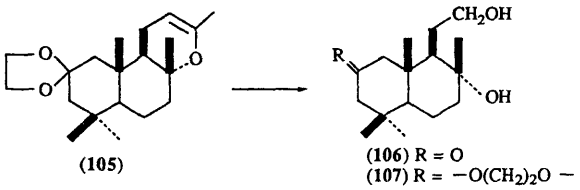


V. Products of the ozonolysis of 8α,13-epoxy-14,15-dinorlabd-12-ene and its derivatives

8α,13-Epoxy-14,15-dinorlabd-12-ene (**73**) and its derivatives are important intermediates on the route from the labdanoids to valuable perfumes,[2] consequently its ozonolysis is not solely of theoretical interest and has been investigated in detail (Scheme 12).

Scheme 12





The ozonolysis of the epoxide (**73**) was effected for the first time in hexane with subsequent treatment of the ozonide with water.[62] The acetoxyacid (**86**) was isolated in 24% yield. Later Stoll and Hinder[66] showed that if the reaction is carried out in ethyl acetate and the ozonide is decomposed with an excess of Raney nickel, then the main reaction product is the acetoxyaldehyde (**101**) (~48%), minor products being the acetoxyacid (**86**) (~3%) and the hydroxyacetate (**102**) (traces). On decomposing the ozonide by boiling with water yield of the acetoxyaldehyde was increased to 61–67% and that of the acetoxyacid (**86**) remained unchanged. A small quantity of the lactone acetal (**103**) was also isolated.[66,67] The same authors[68] ozonolysed the epoxide (**73**) in hexane and reduced the ozonide with lithium aluminium hydride. As a result the glycol (**99**) (57 to 73%) and the epoxide (**104**) (14 to 1.2%) were obtained the ratio of which depended on the conditions. Ozonolysis of the epoxide (**73**) has been repeated[58,61,69] in hexane with reduction of the ozonide with lithium aluminium hydride. The diol (**99**) was obtained in 67, 68, and 76% yield respectively but no formation of the epoxide (**104**) was observed.

A study[69] has been devoted to the search for conditions for a purpose-directed synthesis of bicyclohomofarnesane compounds from sclareol oxide. It was shown that the most convenient route to the acetoxyaldehyde (**101**) was the ozonolysis of the epoxide (**73**) in dichloromethane or ethyl acetate in the presence of pyridine or in hexane with decomposition of the ozonide by heating with water. A small quantity (13–19%) of the acetoxyacid (**86**) was formed in addition to the acetoxyaldehyde (80% yield). If the ozonide obtained in hexane was decomposed by heating with hydrogen peroxide then the reaction product was a 3:2 mixture of the compounds (**86**) and (**101**). The acetoxyacid (**86**) is the predominant product on oxidative fission of the ozonide with Jones reagent (65% yield) or on ozonolysis in cyclohexane in the presence of acetic acid and silica gel (74% yield under optimal conditions). The hydroxyacetate (**102**) (62–64% yield) was obtained on ozonolysis of sclareol oxide (**73**) in isopropanol or methanol and reduction of the peroxide products with lithium borohydride.

The ozonolysis products of the ethyleneketal of 2-ketomanoyl oxide (**105**) have also been investigated. A mixture of the dihydroxyketone (**106**) (39%) and the dihyroxyketal (**107**) (40%) was formed on carrying out the ozonolysis then reducing the ozonide with lithium aluminium hydride.[70]

VI. Products of the ozonolysis of labda-8(17),14-dien-13-ol (manool) and compounds related to it

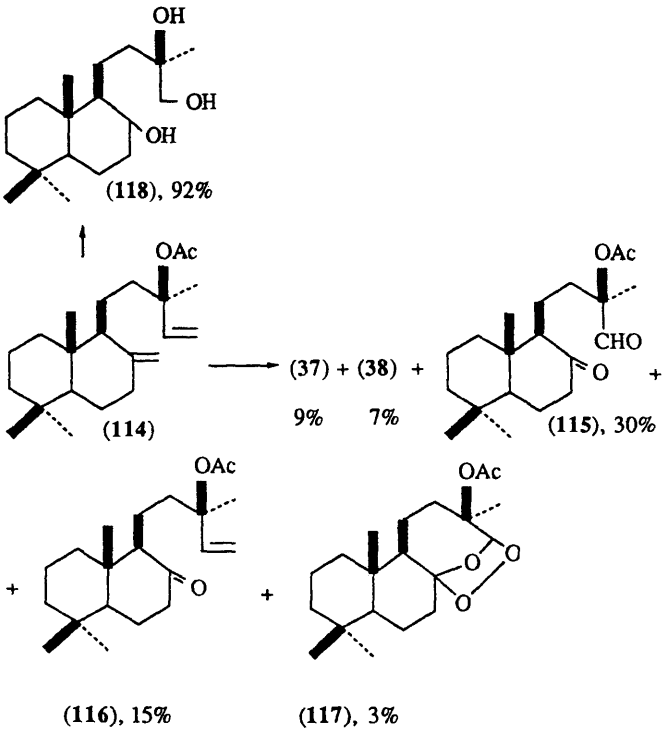
The ozonolysis of manool (**108**), one of the most important labdanoids in practice, has been investigated fairly thoroughly. It was first carried out by Hocking (CCl_4, 0 °C, decomposition of the ozonide by heating with water)[71] who identified the diketone (**19**) (34% yield). 14,15-Dinorlabd-8(17)-en-13-one (**37**) (13%) and the unsaturated epoxide (**109**) (9%) were obtained by the same

procedure for decomposing the reaction products but carrying it out under more forcing conditions in acetic acid.[72] Barltrop and collaborators[73] ozonolysed manool (**108**) in ethyl acetate, decomposed the ozonide with zinc dust in boiling water and isolated the diketone (**19**) (36%) and a product of its further transformation (**110**) (6%). A far more complex mixture of neutral products (**37**), (**38**), (**111**)–(**113**) is formed on ozonation of manool (**108**) in dichloromethane with oxidative fission of the ozonolysis products with hydrogen peroxide.[31] Compounds (**37**) and (**113**) are formed in trace amounts. The yields of the remaining product are shown in Scheme 13 under the formulae. Products of an acid character were not investigated by these authors.

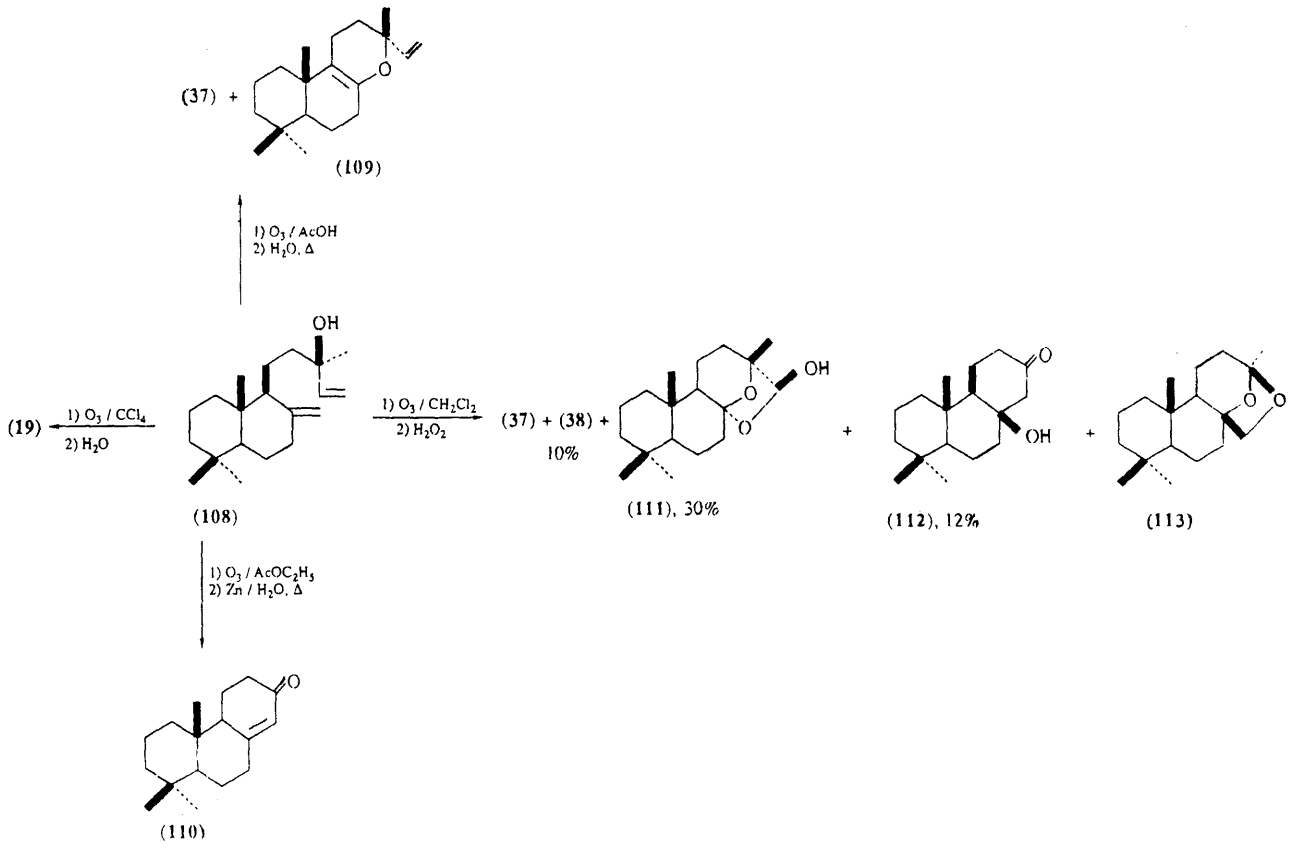
These authors[31] also investigated the ozonolysis products of manool acetate (**114**) under the same conditions. In this case also a complex mixture of products was obtained which are shown in Scheme 14 (with an indication of the yield). The cyclic products (**38**) and (**117**), called oxonides by the authors, were the unusual products of the ozonation and are unstable compounds. The ozonolysis of manool acetate (**114**) in dichloromethane in the presence of pyridine occurs in an altogether different way.[58] The triol (**118**) is isolated in 92% yield after reduction of the ozonolysis products with lithium aluminium hydride, i.e. only the double bond is broken under these conditions.

In view of the data given above it may be concluded that the ozonolysis of manool (**108**) does not as yet have any practical value.

Scheme 14

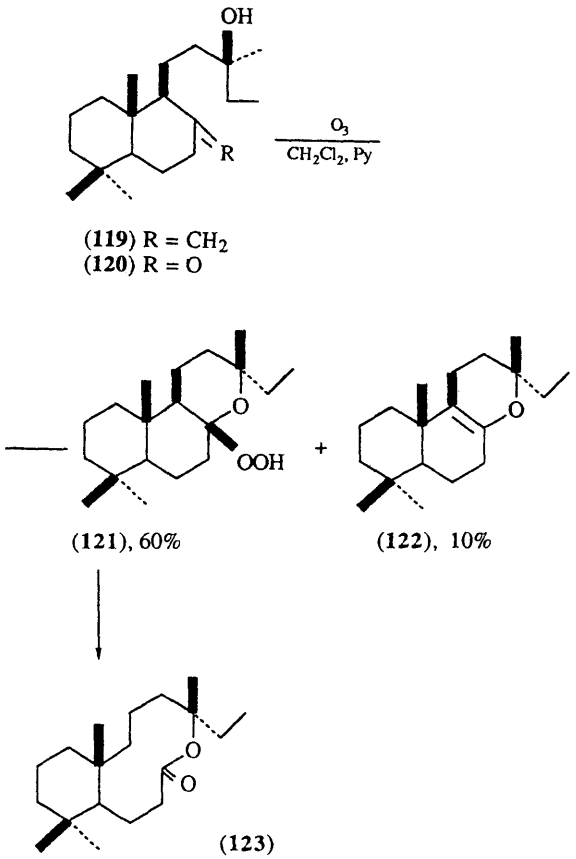


Scheme 13



The ozonolysis of dihydromanool (**119**) has also been investigated. Conducting the reaction in methanol and reducing the peroxide compounds with dimethyl sulphide leads smoothly to the hydroxyketone (**120**) (81%).[74] A mixture (6:1) of compounds (**121**) and (**122**) is formed in dichloromethane in the presence of pyridine (Scheme 15).[75] This result indicates that pyridine is ineffective as a reducing agent when hydroperoxides and not ozonides are formed as a result of the ozonolysis. The hydroperoxide (**121**) is unstable and on storage is converted into the epoxide (**122**). This hydroperoxide undergoes an interesting conversion under the action of mesyl chloride into the lactone (**123**) containing a ten-membered lactone ring. This reaction is of a general nature.

Scheme 15



(**119**) R = CH_2
(**120**) R = O

(**121**), 60% (**122**), 10%

(**123**)

Interesting results were obtained by Everest and collaborators on ozonolysis of a series of allyl derivatives of dihydromanool.[54] They found that the character of the products formed depends on the solvent used and the conditions. Anomalous ozonolysis products were formed on simple evaporation of the solvent at low temperature, and differed depending on whether an aprotic solvent or an alcohol was used. On reduction of the ozonation product either a normal or a mixture of normal and anomalous reaction products was formed. The stronger the reducing agent the greater was the quantity of the normal product. For example, ozonolysis of 7α-hydroxydihydromanool (**124**) in methanol and evaporation of the solvent gave compounds (**125**) (40%) and (**126**) (34%) but with the same treatment and in dichloromethane compounds (**126**) (26%) and (**127**) (14%) were formed. The configuration of the hydroxyl group at position C(7) is important. 7β-Hydroxydihydromanool (**128**) gave a mixture of compounds (**125**) (8%) and (**129**) (30%) on ozonolysis in methanol (Scheme 16).

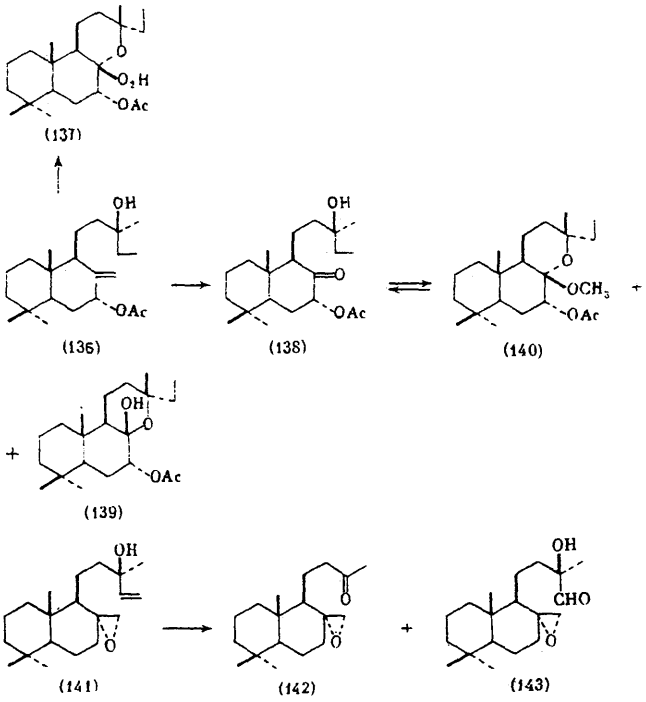
(**134**) R^1 = H; R^2CO_2H

7α-Hydroxydihydromanool 13-monoacetate (**130**) is converted on ozonolysis in methanol into a mixture of the products (**131**) (37%) and (**132**) (46%), in dichloromethane into a mixture of compounds (**133**) (40%) and (**134**) (41%) and in methanol and reduction with dimethyl sulphide into the acetoxyketone (**135**) (88%). As might have been expected only the normal product, the unstable acetoxyhydroperoxide (**137**) (67%), is formed on ozonolysis of 7α-hydroxydihydromanool 7-monoacetate (**136**) (with a protected allylic hydroxyl group) in methanol with subsequent distillation of the methanol. An equilibrium mixture of substances (**138**) and (**139**) was isolated in 60% yield on reducing the ozonolysis product of the same compound with triethyl phosphite. If dimethyl sulphide is used as the reducing agent then a small quantity (17%) of the methoxyacetate (**140**) is formed in addition to compounds (**138**) and (**139**) (58%) (Scheme 17).[74]

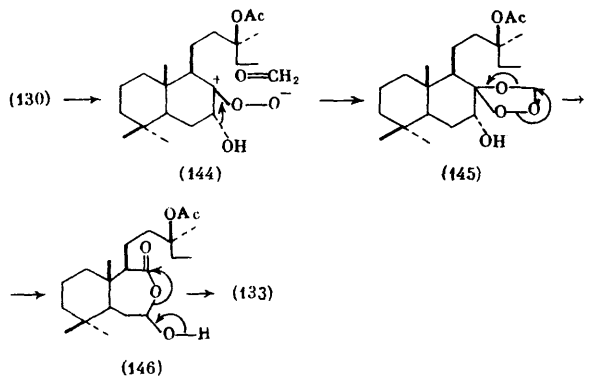
Scheme 17



The ozonolysis of 8(17)α-epoxymanool (**141**) has also been investigated.[54] The epoxyketone (**142**) (32%) was isolated on ozonolysis in methanol and evaporation of the solvent, but on reduction of the ozonolysis product with dimethyl sulphide a mixture of the epoxyketone (**142**) (15%) and aldehyde (**143**) (30%) was formed. If the same reduction is carried out with triethyl phosphite then the yields of compounds (**142**) and (**143**) are 6 and 36% respectively. Demole[76] effected the ozonolysis of the epoxymanool (**141**) in carbon tetrachloride and decomposed the ozonide with an aqueous solution of sodium bicarbonate. The ozonolysis product was subjected to further conversions without isolation, but judging by the results the yield of the epoxyketone (**142**) did not exceed 25–30%.

When analysing the above data it was concluded[54] that the mechanism proposed by Criegee for the ozonolysis of allylic alcohols[5,6] does not provide an adequate explanation. According to Criegee's mechanism the ozonolysis of compound (**130**) must proceed as in Scheme 18.

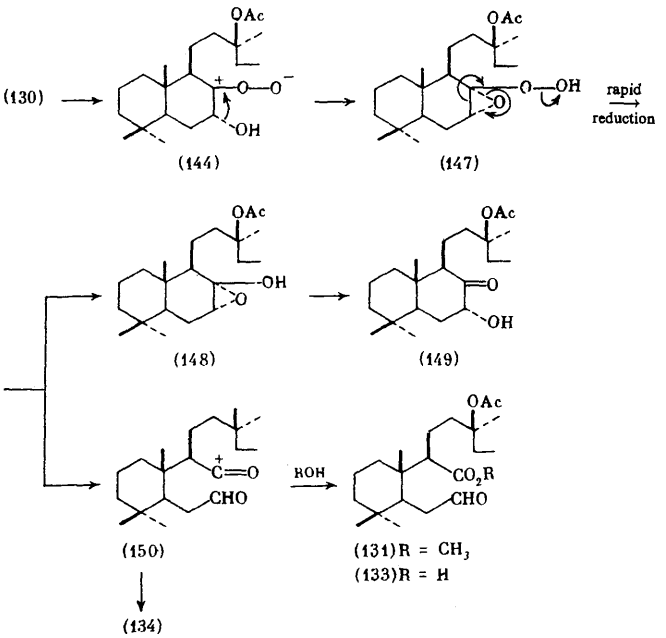
Scheme 18



If the reaction goes by this mechanism then: 1) the zwitterion (**144**) must react with methanol and give the corresponding methoxyhydroperoxide, 2) the C(9) atom, which is more electrophilic than C(7), should migrate preferentially to oxygen in the ozonide (**145**) and 3) the aldehydoacid (**133**) should be the reaction product and not its methyl ester which was in fact obtained.

Another mechanism has been proposed[54] for the ozonolysis of allylic alcohols [this is illustrated in Scheme 19 for compound (**130**) as an example] which explains all the facts mentioned above. In particular: 1) the rapid reduction of the ozonolysis product suppresses the formation of anomalous compounds, 2) carbon monoxide is evolved on ozonolysis of compounds in which there is a proton on the carbon atom bound to the carbonyl carbon atom and 3) specifically, the acids (**133**) and (**134**) are formed on ozonolysis of the unsaturated compound (**130**) in an aprotic slvent

Scheme 19

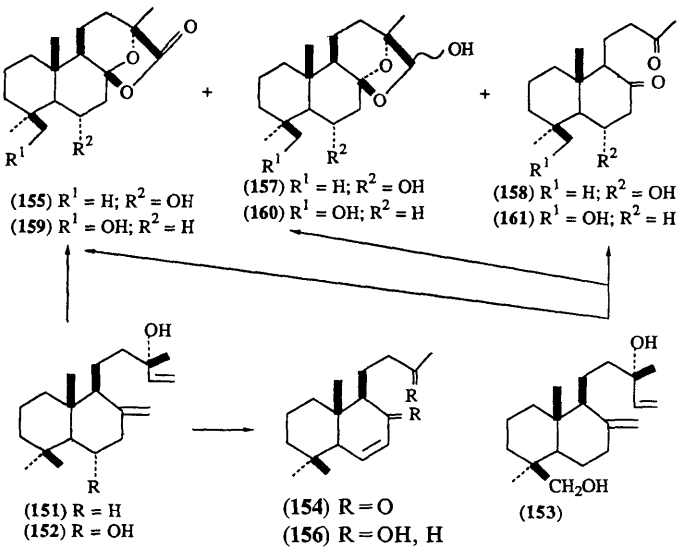


The very strained α-epoxyhydroperoxide (**147**) is spontaneously converted into the carbocation (**150**) which is neutralised by the solvent. When the grouping $-CH_2=CH-C-OH$ is present in the molecule, expulsion of proton occurs and carbon monoxide is evolved.

The ozonolysis of two derivatives of 13-epimanool (**151**) has also been investigated. These were larixol, labda-8(17),14-diene-6α,13(*S*)-diol, (**152**) and 13-epitorulosol, labda-8(17),14-diene-19,13(*S*)-diol (**153**).

The formation of a peroxide of composition $C_{19}H_{32}O_7$ of unestablished structure was recorded on ozonolysis of larixol (**152**), however, its decomposition was not carried out.[77] On carrying out the reaction in absolute methanol and treating the product with ammonium chloride a mixture was formed of no less than seven compounds among which the unsaturated diketone (**154**) and the hydroxylactone acetal (**155**) predominated (Scheme 20).[78] Other authors[79] have also ozonolysed larixol in methanol but the product was reduced with di-isobutylaluminium hydride. The diol (**156**) was isolated in low yield from the reaction products. Its structure was confirmed by X-ray structural analysis.

Scheme 20



The ozonolysis of larixol in methanol and reduction of the peroxide products with dimethyl sulphide or in dichloromethane in the presence of pyridine leads to a mixture of five compounds, identical in qualitative composition, the predominating components of which, compounds (**157**) and (**158**), were isolated and identified.[78]

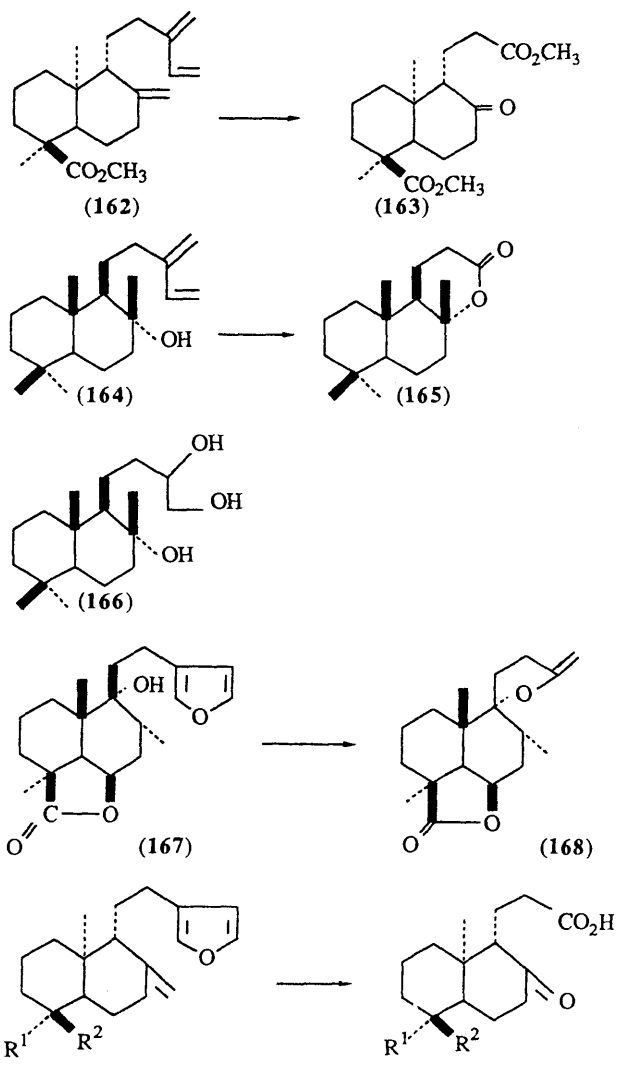
The ozonolysis of 13-epitorulosol (**153**) has been carried out under a variety of conditions: in methanol with subsequent treatment of the ozonation product with dimethyl sulphide, in a mixture of dichloromethane and pyridine and in hexane with decomposition of the ozonide by heating with water.[80] In all cases the reaction product was a mixture of three compounds (**159**)–(**161**). In the first case the hydroxylactone (**159**) predominates and in the latter the two compounds (**160**) and (**161**) predominate (Scheme 20).

The data given above indicate that the main products of the ozonolysis of larixol (**152**) and 13-epitorulosol (**153**) are formed by fission of their double bonds and the single bond at C(13)–C(14) and by the reaction of the keto group at C(8) with the hydroxyl group at C(13) and the functional group generated at C(14).

VII. Ozonolysis of labda-13(16),14-diene compounds, furanolabdanoids and labd-13(14)-enoids with oxygen-containing functional groups at C(15) and C(16)

On treating representatives of this structural group of labdanoid diterpenes with ozone the side chain is, as a rule, shortened by three carbon atoms. On ozonolysis of the methyl ester of *ent*-labda-8(17),13(16),14-trien-18-oic acid (**162**) in a mixture of acetic acid and ethyl acetate at 0 °C followed by oxidative fission of the ozonation products with alkaline hydrogen peroxide, Ourisson and collaborators[81] isolated, after methylation and diazomethane, the ketodiester (**163**) (25%) (Scheme 21). In contrast to compound (**162**) the ozonolysis of isoabienol (**164**) in absolute methanol with subsequent hydrogenation of the product over Lindlar catalyst leads to ambreinolide (**165**) (93%). The yield of ambreinolide was less (85%) on using dimethyl sulphide as reducing agent.[82] It is more convenient to carry out the ozonolysis of isoabienol (**164**) in ethyl acetate in the presence of pyridine (72% ambreinolide yield).[83] If the ozonolysis of isoabienol is carried out in methanol and the peroxide products are reduced with lithium borohydride then the triol (**166**) is the main reaction product (72%). These data show that on using dimethyl sulphide for the reduction of the peroxide ozonolysis products of isoabienol, there is an initial rearrangement with fission of the single carbon–carbon bond at C(13)–C(14) and then reduction occurs. Potassium borohydride only reduces the peroxide compounds. In view of the value of the ambreinolide for perfume manufacture[2] and the cheapness of isoabienol (it is contained in large amounts in the needles of the Scots pine[84]), the ozonolysis of the latter may be of practical interest.

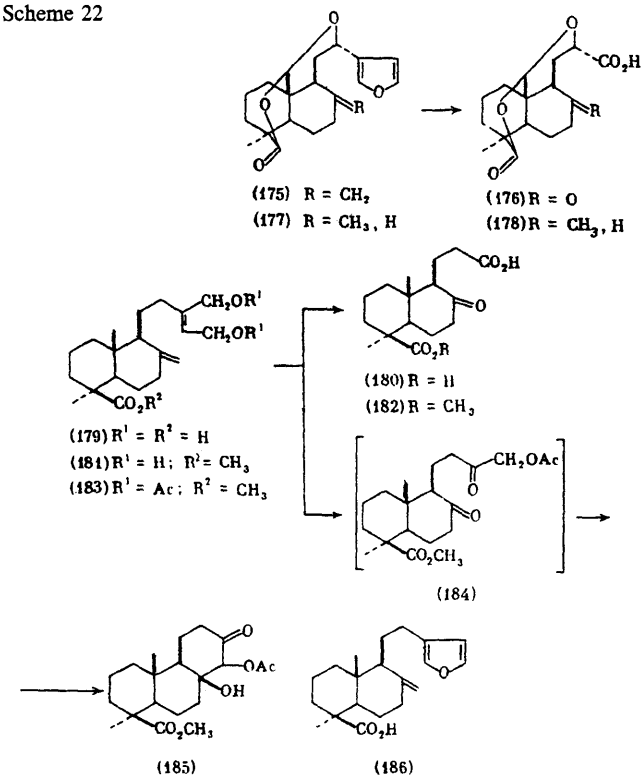
Scheme 21



Marrubiin (**167**) was one of the first of the furanolabdanoids to be subjected to ozonolysis (see Scheme 21).[85] The reaction was carried out in acetic acid and the reaction product proved to be the dilactone (**168**) (20%). Polyalthic acid (**169**) was ozonolysed in the same solvent. The ketodiacid (**170**) (17%) was isolated after treatment of the reaction product with hydrogen peroxide in alkali.[86] On ozonolysis of polyalthic acid methyl ester (**171**) in chloroform and fission of the ozonide with hydrogen peroxide, the reaction product was the monoester (**172**) (25%) of the ketodiacid (**170**). An epimer of polyalthic acid, daniellic acid (**173**), was oxidised with ozone in dichloromethane in the presence of pyridine and the product oxidised further with hydrogen peroxide in alkali. These conditions are appropriate since the yield of the ketodiacid (**174**) proved to be fairly high (66.5%).[29] Sciadin (**175**), which is more complex in structure, gave a product (**176**) on ozonolysis in chloroform in only 8.7% yield.[87] The ozonation of dihydrosciadin (**177**) to compound (**178**) proceeded with a better yield (17.4%) but in this case the products of ozonolysis were boiled with water.

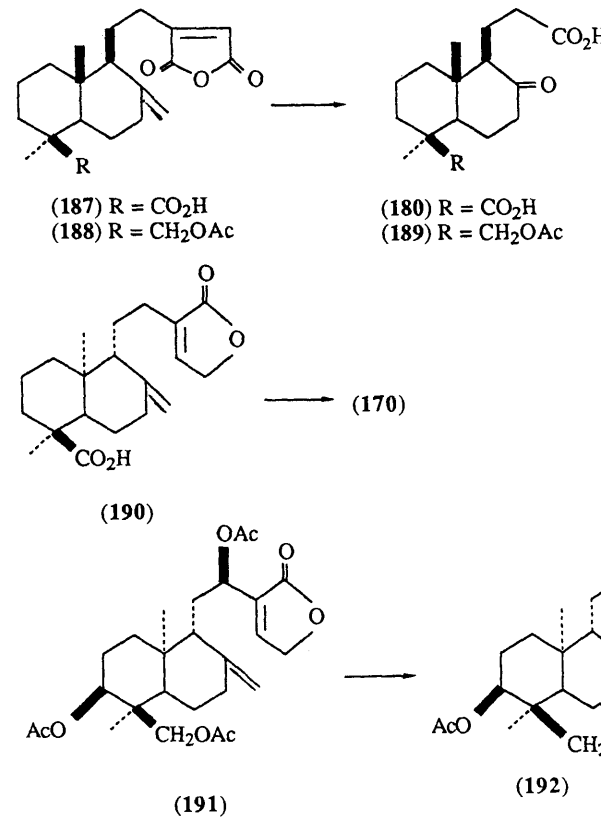
Sciadopic acid (**179**) is an example of a compound with a double bond at C(13)–C(14) and functional groups at C(15) and C(16) (Scheme 22).[84] The ketodiacid (**180**) (27%) was isolated on treating it with ozone in dichloromethane with oxidative fission of the product with hydrogen peroxide in alkali. Fission of the ozonolysis product by heating with water proved to be less effective. In such cases methyl sciadopate (**181**) was converted into compound (**182**) in only 10% yield (after alkaline saponification). The ozonolysis of the diacetoxyester (**183**) occurs in an altogether different way. The ozonolysis was carried out in dichloromethane and the product was reduced with zinc in acetic acid. The tricyclic compound (**185**) was obtained in this case in 77% yield, evidently formed by aldol cyclisation of the ozonation product, via. the diketoester (**184**) (Scheme 22).

Scheme 22



The transformation products of lambertianic acid (**186**) and the anhydrides (**187**) and (**188**) belong to the same group of labdanoids. On ozonolysis in a mixture of ethyl acetate and acetic acid with oxidative fission of the products with hydrogen peroxide the ketodiacid (**180**) (56%) and the ketoacid ester (**180**) (56%) and the ketoacid ester (**189**) (44%) respectively were obtained (Scheme 23).[89]

Scheme 23



The ozonolysis labdanoids containing an unsaturated γ-lactone grouping in the side chain, such as nivenolide (**190**), occurs in a similar manner.[90] On ozonolysis in methanol and treatment of the product with hydrogen peroxide in alkali the ketodiacid (**170**) (49%) was isolated (Scheme 23).

If there is an oxygen-containing functional group at position C(12) in a labdanoid with an unsaturated γ-lactone grouping then fission of the single bond at C(12)–C(13) occurs on ozonolysis. For example, the derivative andrographolide (**191**) gave the ketoacid (**192**) on ozonolysis in ethyl acetate and treatment of the product with hydrogen peroxide.[91]

* * *

The data accumulated show that ozonolytic transformations of labdanoids affect the carbon side chain and ring A. If there are isolated double bonds and no functional groups in the positions 4 and 5 relative to them in this structural fragment then the ozonolysis proceeds fairly unequivocally. If there are functional groups in the labdanoids at positions C(8) and C(12)–C(16) then ozonolysis leads to a complex mixture of compounds. This is a particular feature of labdanoids with an allyl structural fragment, a furan ring and an

unsaturated γ-lactone grouping. The latter two types of compound give α-dicarbonyl compounds as primary ozonolysis products.

The investigation of the ozonolysis products of the available labdanoids (sclareol, manool, abienols, etc.) and the effect of the reaction conditions on the route of the process, the clarification of the mechanism and principles of the ozonolysis reaction and the development of industrial ozonolytic processes are all problems of both theoretical and practical interest.

The synthesis of insect juvenile hormones and their analogues

V N Odinokov, O S Kukovinets, R A Zainullin, G A Tolstikov
Institute of Organic Chemistry, Urals Division of the Russian Academy of Sciences

ABSTRACT. **The methods of synthesis of insect juvenile hormones and their natural and synthetic analogues (juvenoids) are considered. Much attention is paid to juvenoids of the 2,4-dienoate class, including oxa and aza derivatives and cyclic and heterocyclic compounds, which display selective activity towards vairous forms of insect.**

The bibliography contains 263 references.

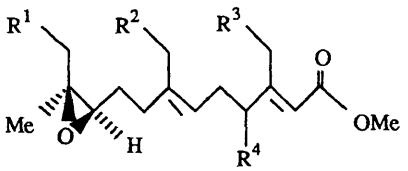
III. Synthesis of natural analogues of juvenile hormones 735
IV. Synthetic analogues of juvenile hormones 739

I. Introduction

It has been established in the last thirty years that certain terpenoid compounds, referred to as the juvenile hormones (JH), actively participate in the regulation of the development of insects at the larval stage.[1] Five native juvenile hormones have so far been isolated and identified, viz. JH-1, JH-II, JH-III, JH-0 and 4-Me-JH-I.[1–5]



JH-I ($R^1=R^2=Me$, $R^3=R^4=H$); JH-II ($R^1=Me$, $R^2=R^3=R^4=H$); JH-III ($R^1=R^2=R^3=R^4=H$); JH-O ($R^1=R^2=R^3=Me$, $R^4=H$); 4-Me-JH-I ($R^1=R^2=R^4=Me$, $R^3=H$).

The titre of JH in an insect at metamorphosis of the larva to the imago is close to zero. It was shown that the introduction of extraneous JH at this time seemingly affects the fate of a population due to disturbance of the natural cycle of insect development leading to a subsequent reduction in their number. This possible method of regulating the number of insects enables JH to be considered as insecticides of a new generation. They are ecologically safe and act exclusively upon Arthropods.

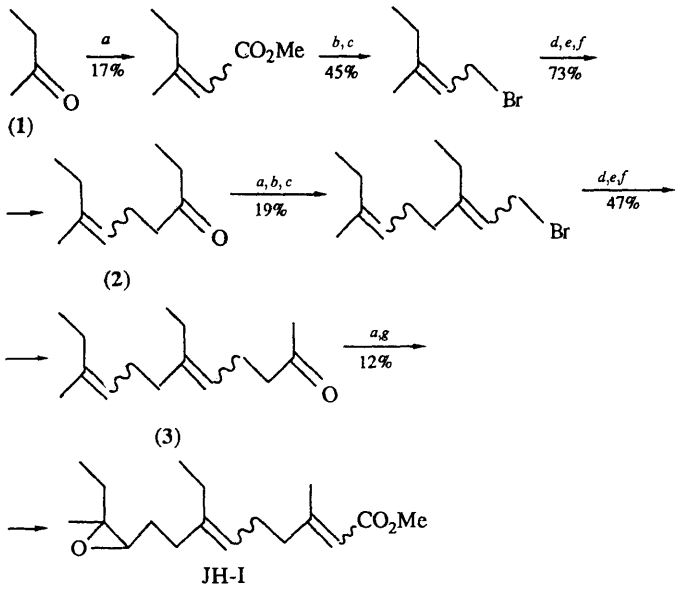
Since JH are present in insects in insignificantly small concentrations, their isolation from natural sources appears to be practically impossible and the only realistic route to obtain them is by chemical synthesis. The promise of the practical use of these regulators of insect development was marked by the discovery that JH action is possessed by certain natural compounds and by a whole series of synthetic compounds close in structure to the native JH. These analogues of the juvenile hormones (AJH) are known as juvenoids. Compounds have been discovered among the large number of AJH with JH activity significantly higher than that of the natural JH. Active juvenoids are found among compounds structurally close to the native JH and among compounds the structure of which only remotely suggests the structure of a JH.

Several monographs and reviews[6–16] have been devoted to the synthesis and study of the biological activity of JH and AJH. However they do not adequately reflect the information on the 2,4-dienoates, their oxa and aza derivatives and on the juvenoids containing hetero- and carbocycles. In addition, new reports of work in this area have recently appeared.

II. Synthesis of natural juvenile hormones

The phosphonate modification of the Wittig reaction, which is usually used to construct a trisubstituted double bond in the synthesis of JH, leads to a mixture of geometric isomers.[17,18] Thus the three-step condensation of trimethyl phosphonoacetate with the initial (**1**) and intermediate (**2**), (**3**) ketones gave JH as a mixture of (*Z*) and (*E*) isomers at the Δ^2 and Δ^6 bonds (Scheme 1).[19]

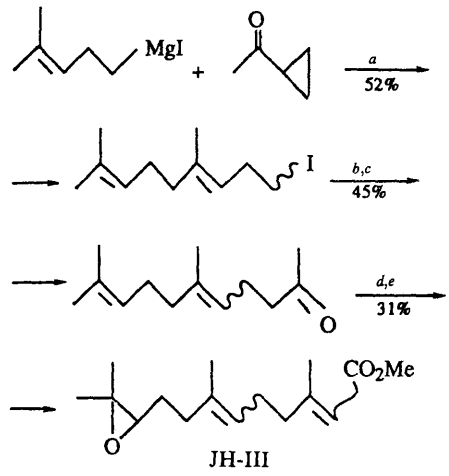
Scheme 1



a: $(MeO)_2P(O)CHCO_2Me$; *b*: $HAlH_4$; *c*: PBr_3; *d*: Mg; *e*: $MeCH_2COCH_2CO_2Et$; *f*: Δ; *g*: 3-$ClC_6H_4CO_3H$

A similar result was obtained in the synthesis of JH-III (Scheme 2).[20]

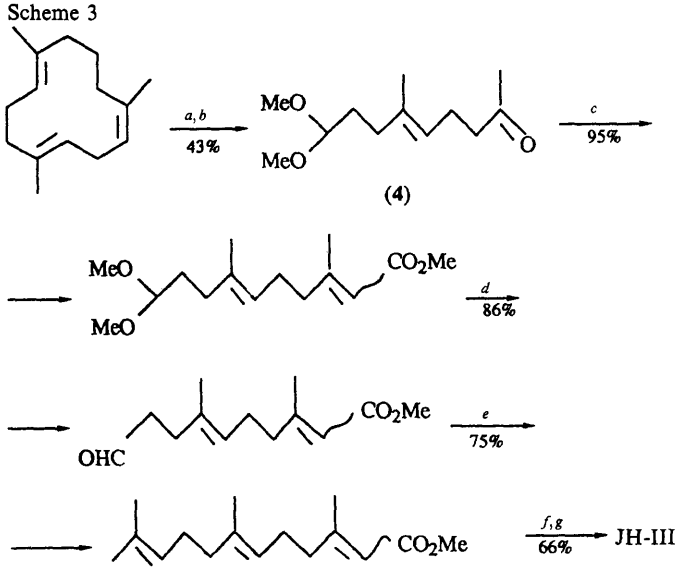
Scheme 2



a: H^+; *b*: Mg/Et_2O; *c*: Ac_2O, −70 °C; *d*: $(MeO)_2P(O)\overset{\ominus}{C}HCO_2Me$; *e*: NBS (*N*-bromosuccinimide)/K_2CO_3.

A mixture of geometric isomers at the Δ^2 bond is formed in the synthesis of JH-III via the selective ozonolysis of (1*E*, 5*E*, 9*E*)-trimethyl-1,5,9-cyclododecatriene and the Petersen reaction with the intermediate ketone (**4**) (Scheme 3).[21]

Scheme 3

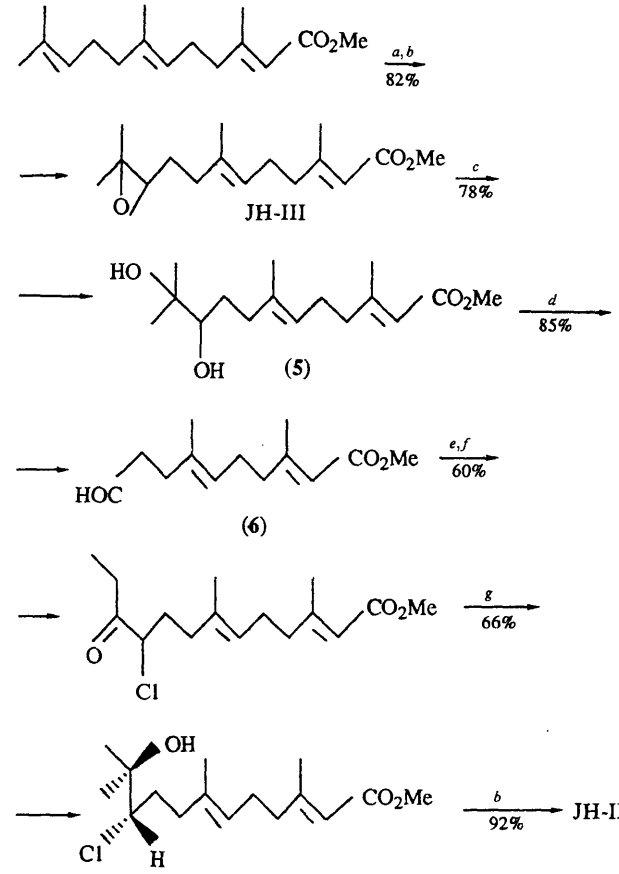


a: O_3/MeOH; *b*: MeOH/NH_4Cl; *c*: $Me_3SiCH_2CO_2Me$/iso-Pr_2NH; *d*: Py.TsOH/Me_2CO; *e*: $Me_2C{=}PPh_3$; *f*: NBS/THF; *g*: K_2CO_3/MeOH.

The individual (2*E*, 6*E*) isomers, which usually display higher activity than the other isomers,[22] were isolated by column chromatography.

Stereospecific syntheses of JH-II have been carried out from (*E*,*E*)-farnesol, methyl (*E*)-geranoate and methyl (*E*,*E*)-farnesenate [methyl (2*E*, 6*E*, 10*E*)-3,7,11-trimethyl-2,6,10-dodecanoate].[18,23] The epoxidation according to Van Tamelen[24] of the terminal double bond in methyl farnesenate gave JH-III. Subsequent opening of the epoxide to the glycol (**5**) and decomposition of the latter with sodium periodate led to the aldehyde (**6**), converted subsequently into the desired JH-II (Scheme 4).[18]

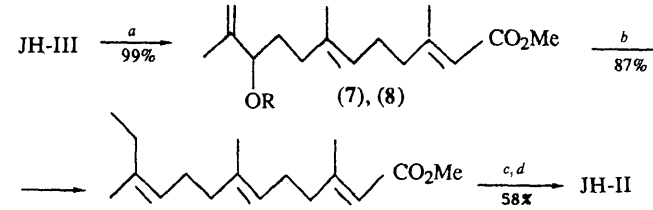
Scheme 4



a: NBS, *b*: K_2CO_3/MeOH; *c*: $HClO_4$; *d*: HIO_4; *b*: $MeCH_2C(OMe){=}PPh_3$; *f*: NCS(*N*-chlorosuccinimide); *g*: MeMgI.

It was established that on distillation JH-III is converted in high yield into the allyl alcohol (**7**), the acetate of which (**8**) is alkylated by lithium dimethylcuprate with the formation of JH-II (Scheme 5).[18,25]

Scheme 5



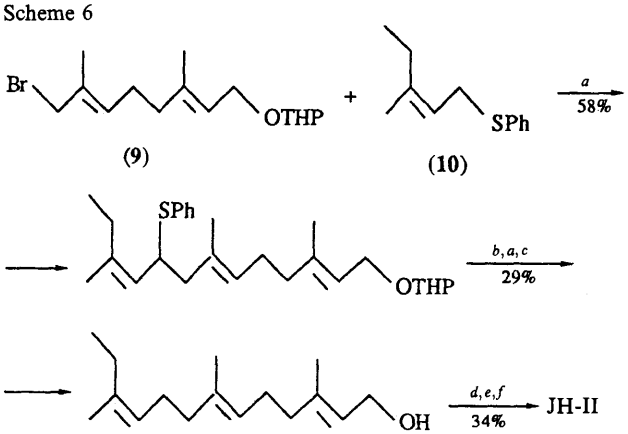
R = H(7), Ac(8).
a: Δ; *b*: Me_2CuLi; *c*: NBS; *d*: K_2CO_3/MeOH.

The syntheses of JH through alkylation of allyl substrates and the *syn*-addition of cuprates and organoaluminium reagents to acetylenes have been discussed in a review.[12] Much attention was paid in the

review to the stereospecific construction of trisubstituted alkenes using sulphur-containing intermediates in the synthesis of JH.

The key stage in one of the syntheses of racemic JH-II is the coupling of the allyl bromide (**9**) with the deprotonated allyl phenyl sulphide (**10**) (Scheme 6).[26,27]

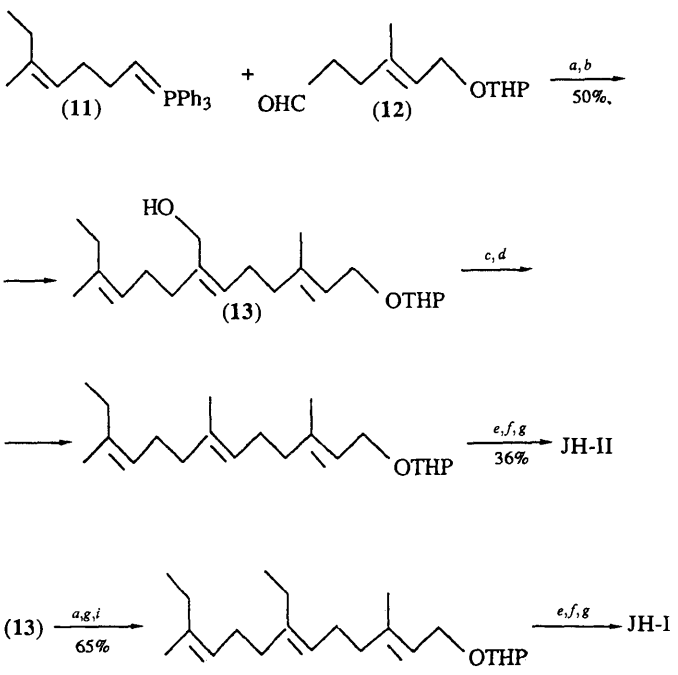
Scheme 6



THP – 2-tetrahydropyran-1-yl; *a*: n-BuLi; *b*: TsOH/MeOH; *c*: Li; *d*: MnO_2; *e*: MnO_2/NaCN/MeOH; *f*: 3-$ClC_6H_4CO_3H$.

Deprotonation of the intermediate in the reaction of phosphorane (**11**) with the aldehyde (**12**) and subsequent treatment with formaldehyde led to compound (**13**) the subsequent transformation of which gave the desired JH-II and JH-I (Scheme 7).[28]

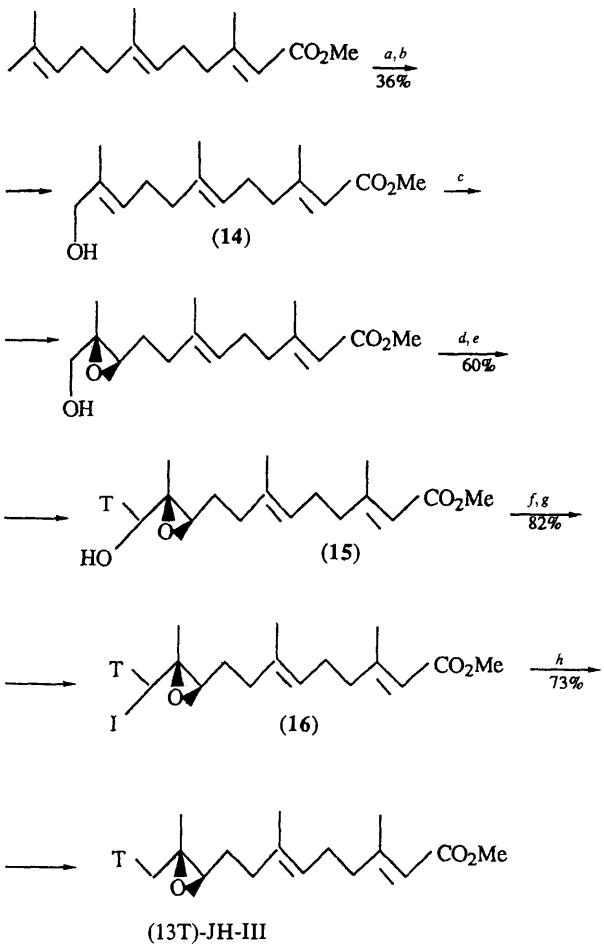
Scheme 7



a: n-BuLi; *b*: CH_2O; *c*: TsCl/Py; *d*: $LiAlH_4$; *e*: MnO_2; *f*: MnO_2/NaCN/MeOH; *g*: 3-$ClC_6H_4CO_3H$; *h*: $CH_2=PPh_3$; *i*: H_2O_2/EtOH/NH_2NH_2.

In 1970 it had already been established that the optically active natural JH have the (10*R*, 11*S*) configuration.[29] Subsequent investigations showed that the synthetic (+) enantiomers corresponding to that configuration displayed higher biological activity than the racemates.[30] One of the synthetic approaches to optically active JH is based on the Sharpless asymmetric epoxidation of allyl alcohols.[31,32] The synthesis of (10*R*, 11*S*)-JH-III containing tritium at C(13) is effected by the allylic oxidation of methyl farnesenate at the terminal position with subsequent asymmetric epoxidation of the resulting allyl alcohol (**14**). The tritiated hydroxy-epoxide (**15**) was deoxygenated via the iodide (**16**) to [13-T]-JH-III (Scheme 8).[33]

Scheme 8



a: BuOOH/SeO_2; *b*: $NaBH_4$; *c*: (iso-PrO)$_4$Ti/t-BuOOH/iso-C_3H_7.OOCCH(OH)CH(OH).$COOC_3H_7$-iso; *d*: CrO_3/Py; *e*: $NaBT_4$; *f*: TsCl/Py; *g*: NaI/Me_2CO; *h*: $NaBH_3CN$.

The asymmetric epoxidation of the triene (**18**) also served as a key stage in the synthesis of optically active (10*R*, 11*S*)-JH-I from the homoallyl alcohol (**17**). Further transformations not affecting the chiral centre led to the (10*R*, 11*S*) enantiomer identical to the

natural JH or to its (12-D, 13-D) analogue.[34] The products obtained had high optical activity (95%) (Scheme 9).

Scheme 9

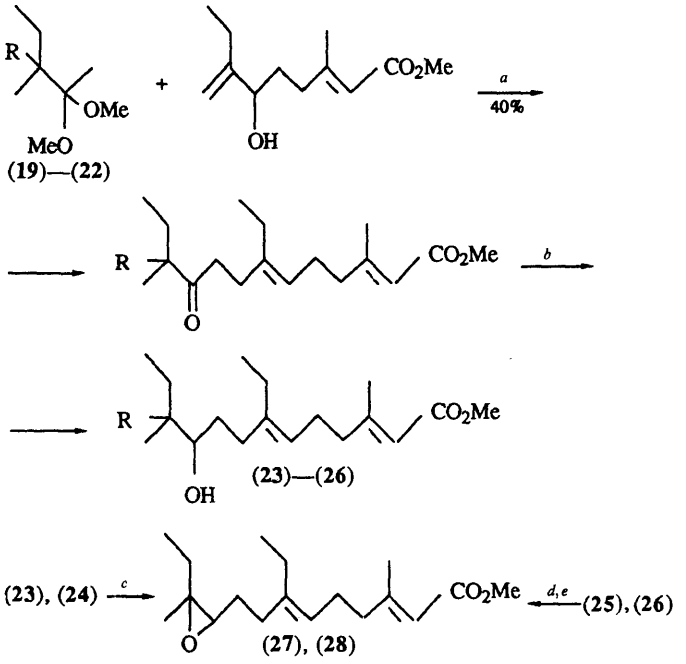
Stereospecific syntheses of the (10*R*,11*S*) (**27**) and (10*R*,11*S*) (**28**) enantiomers of JH-I were effected from the optically active 2,2-dimethoxy-3-methylpentan-3-ols (**19**), (**20**) and 3-chloro-2,2-dimethoxy-3-methylpentanes (**21**) and (**22**). The optical purity of the JH obtained in these syntheses was 80–90% (Scheme 10).[35,36]

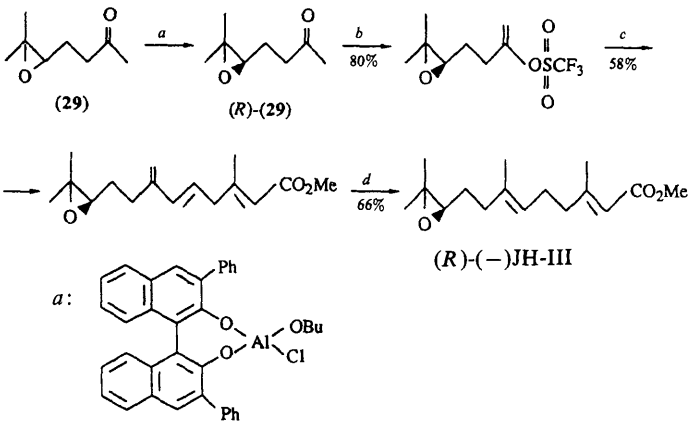
Scheme (10)



R = OH[(*R*)-(**19**), (*S*)-(**20**), (*R*,*R*)-(**23**), (*S*,*S*)-(**24**), (*R*,*S*)-(**27**)]; Cl[(*R*)-(**21**), (*S*)-(**22**), (*R*,*R*)-(**25**), (*S*,*S*)-(**26**), (*S*,*R*)-(**28**)].
a: Δ; *b*: $NaBH_4$; *c*: K_2CO_3/MeOH; *d*: TsCl/Py; *e*: MeONa/MeOH.

Kinetic resolution was used in the reaction of the racemic epoxide (**29**) with the optically active organoaluminium reagent in the synthesis of optically active JH-III.[37] Subsequent conversions of the chiral epoxide (*R*)-(**29**) led to (*R*)-(−)-JH-III (Scheme 11).[37]

Scheme 11



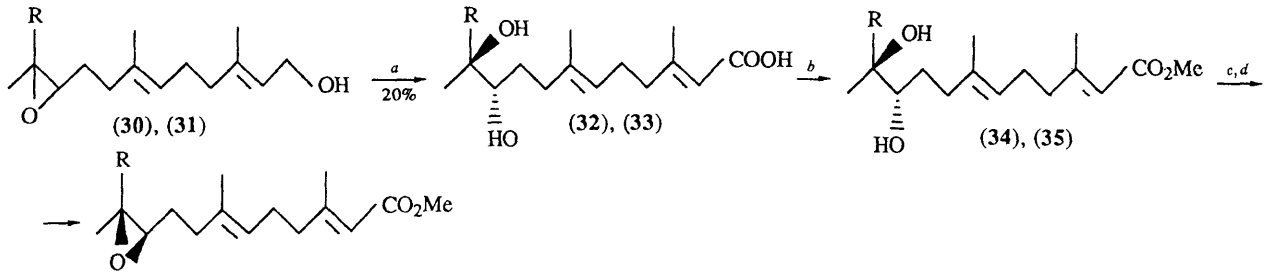
Enzymic reactions were used in the synthesis of optically active JH. Racemic 10,11-epoxyfarnesol (**30**) was converted by the action of a fungal culture of *Helminthosporium sativum* into (−)-*threo*-10,11-dihydroxyfarnesenic acid (**32**) which was then converted further into (10*R*)-JH-III through the ester (**34**).[38] Optically active (10*R*,11*S*)-JH-II was obtained similarly from homofarnesol (**31**) through the intermediates (**33**) and (**35**) (Scheme 12).[39]

The optically active (*R*)-diol (**34**) [containing < 5% (*S*)-isomer] was obtained from methyl farnesenate by treating it with the mould *Colletotrichum nicotianae*.[30] However the yield of the desired compound was low. It was more successful to synthesise enantiomerically pure JH-O, I, II, III from the chiral blocks (**38**) and (**39**) obtained by reduction of the diketones (**36**) and (**37**) with baker's yeast (*Pichia terricola*). The chiral ketones (**38**) and (**39**) were converted in eight steps into the corresponding phenylthio derivatives (**40**) and (**41**) by Baeyer-Villiger oxidation and subsequent ring opening. Further transformations of (**40**) and (**41**) led to enantiomerically pure JH (Scheme 13).[40–42]

III. Synthesis of natural analogues of juvenile hormones

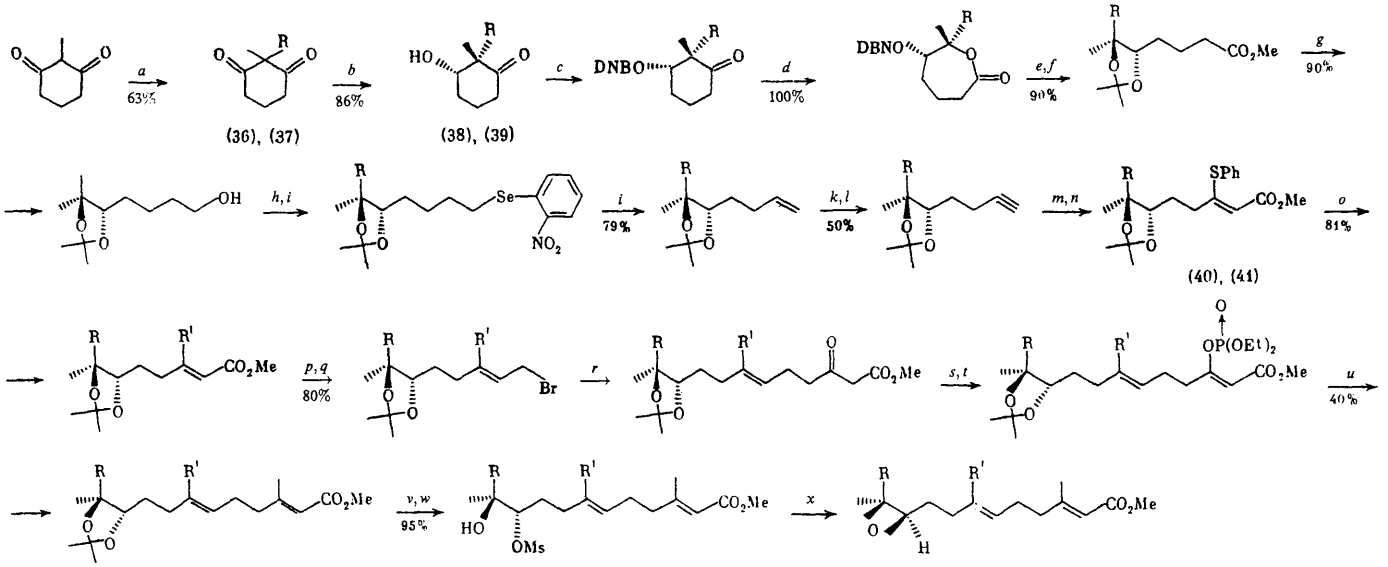
In 1975 an optically active compound was isolated from the North American rudbeckia (*Echinacea angustifolia*) which displayed juvenoid activity in relation to the yellow meal worm (*Tenebrio molitor*). This compound, called echinolone, was identified as (+)-(*E*)-10-hydroxy-4,10-dimethyl-4,11-dodecadien-2-one (**42**).[43]

Scheme 12



R = Me[(10*R*)-JH-II]; Et[(10*R*, 11*S*)-JH-II];
R = Me(**30**), (**32**), (**34**); Et(**31**), (**33**), (**35**);
a: Helm, sativum; *b*: CH_2N_2; *c*: MsCl/Py; *d*: KOH/MeOH.

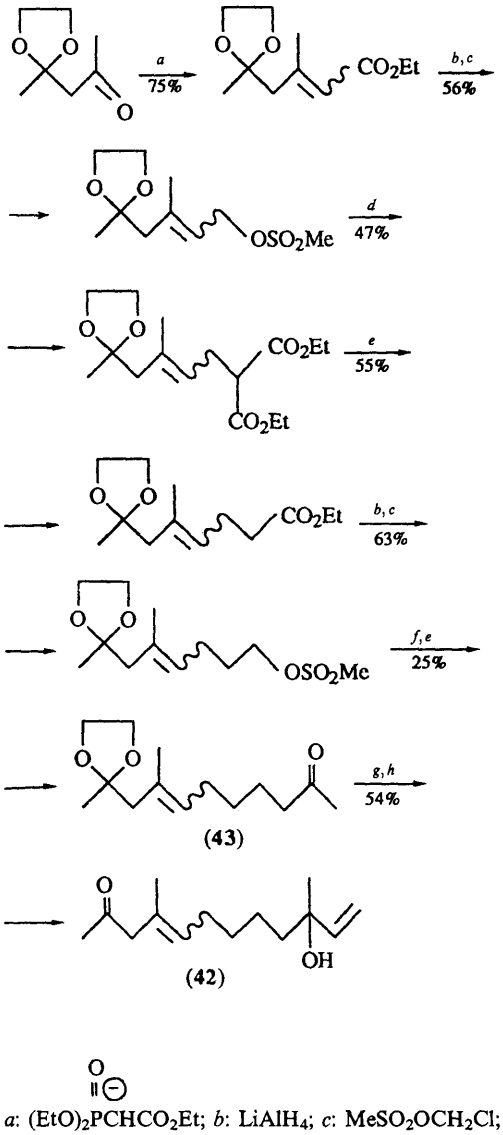
Scheme 13



DNB = 3,5-dinitrobenzoyl;
a: Rl/trilon B; *b*: Pichia tericola; *c*: DNB-Cl; *d*: $3\text{-}ClC_6H_4CO_3H/CH_2Cl_2$; *e*: K_2CO_3/MeOH; *f*: $Me_2C(ONe)_2$/TsOH; *g*: $LiAlH_4$; *h*: $o\text{-}(NO_2)C_6H_4SeCN$; *i*: $(n\text{-}Bu)_2P$; *j*: H_2O_2; *k*: Br_2; *l*: NaH_2/NH_2; *m*: $ClCO_2Me$/n-BuLi; *n*: PhSNa/MeOH; *o*: R^1MgBr/CuI/THF, −65 °C; *p*: $(iso\text{-}C_4H_9)_2AlH$; *q*: MeLi/TsCl/LiCl/HMPA; *r*: $MeCOC.HCO_2Me$; *s*: NaH; *t*: $(EtO)_2POCl$; *u*: MeCuLi; *v*: AcOH; *w*: $MsCl/Et_3N$; *x*: MeONa/MeOH.

Racemic echinolone is synthesised by a sequential build-up from the carbon skeleton of acetylacetone to the diketone monoacetal (**43**) using the Horner double bond reaction. The reaction of the ketoacetal (**43**) with vinylmagnesium bromide led to the desired (+)-echinolone as a mixture of geometric isomers (Scheme 14).[44]

Scheme 14

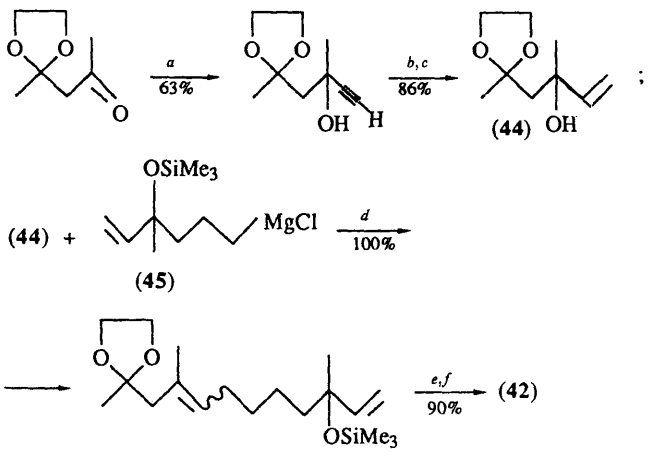


a: $(EtO)_2PCHCO_2Et$; *b*: $LiAlH_4$; *c*: $MeSO_2OCH_2Cl$; *d*: $CH_2(CO_2Et)_2$/NaH; *e*: Δ; *f*: $MeC(O)CH_2CO_2Et$/NaH; *g*: $CH_2=CHMgBr$; *h*: $H^{\oplus}$.

Another synthesis of a mixture (4:1) of the (*E*) and (*Z*) isomers of echinolone (**42**) was convergent with the key stage being the coupling of the two C_7 fragments (**44**) and (**45**).[45] The individual isomers were isolated by HPLC. It is interesting to note that the mixture of geometric isomers of echinolone proved to be more active than each of the individual isomers (Scheme 15).[45]

Schemes have been described for the synthesis of echinolone (**42**) from the unsaturated hydroxy-ester (**46**)[46] and from the ketoester (**47**) containing a cyclopropane fragment (Scheme 16).[47]

Scheme 15



a: $CH\equiv CH/NH_3/KOH$; *b*: Ac_2O; *c*: Pd/ZnO; *d*: CuI/THF; *e*: HPLC; *f*: $H^{\oplus}$.

Scheme 16

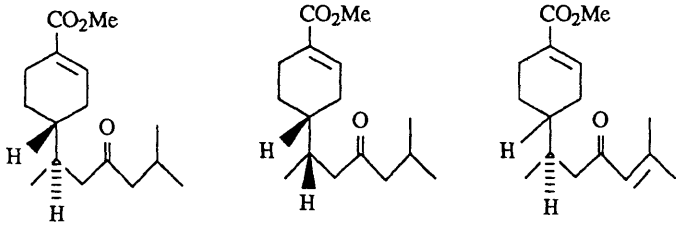
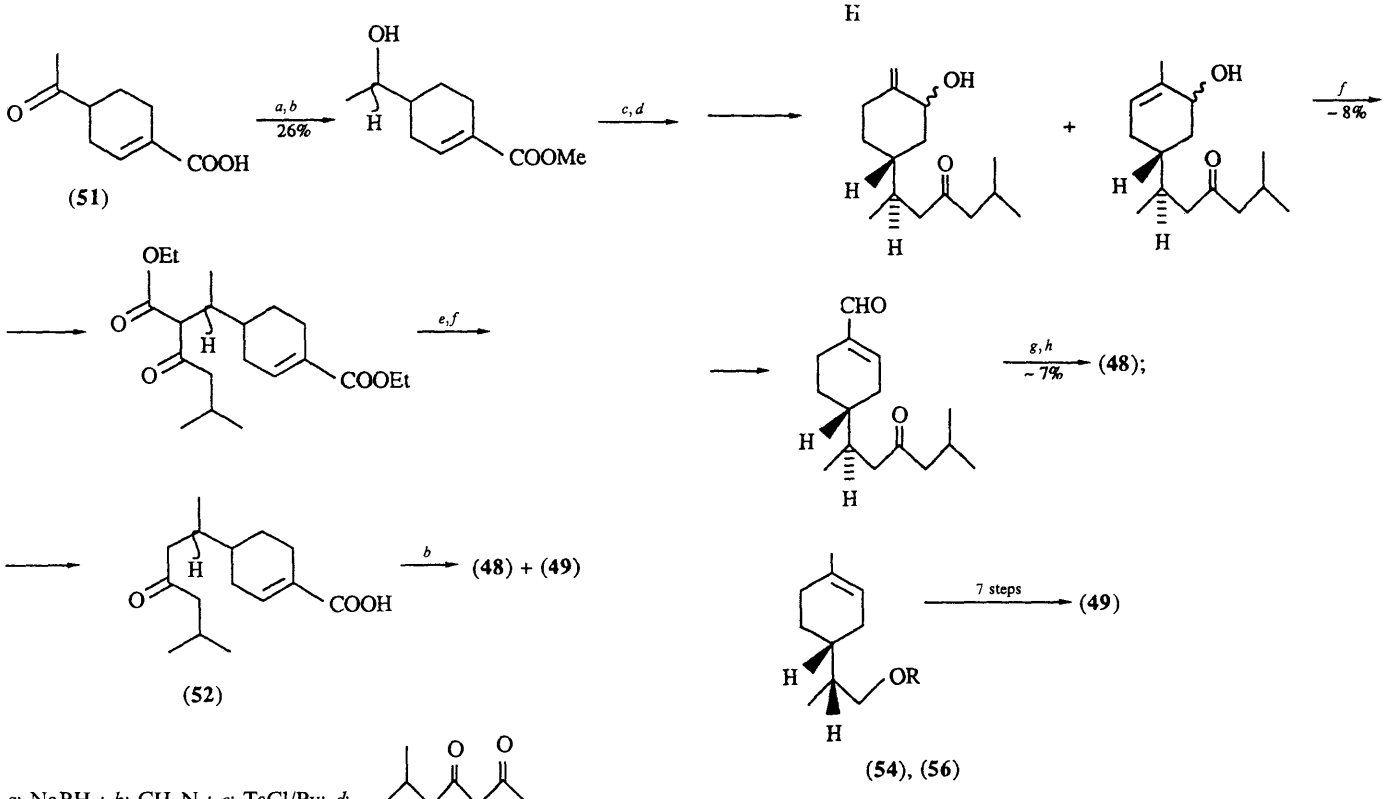
In 1965 Slama and Williams[48] discovered that paper from the wood of the balsam fir (*Abies balsamea*) possessed a JH action. The structure of the active compound proved to be identical to the methyl ester of (+)-todomatuic acid (**48**) with the (*R,R*) configuration at the asymmetric centres.[49,50] The new AJH was called juvabione. A compound of similar structure but with the (*R,S*) configuration was discovered in certain plants and was called epijuvabione (**49**).[51–53] One further active analogue, dehydrojuvabione (**50**), was isolated, together with (+)-juvabione, from Slovak fir.[54]



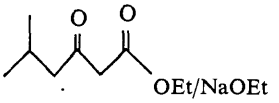
(**48**) (**49**) (**50**)

The shortest of the non-stereospecific routes proposed for synthesising a mixture of juvabione (**48**) and epijuvabione (**49**)[55–58] is that based on conversions of the methyl ester of 4-acetylcyclohexene-1-carboxylic acid (**51**) (Scheme 17).[58]

Scheme 17



a: $NaBH_4$; *b*: CH_2N_2; *c*: TsCl/Py; *d*:

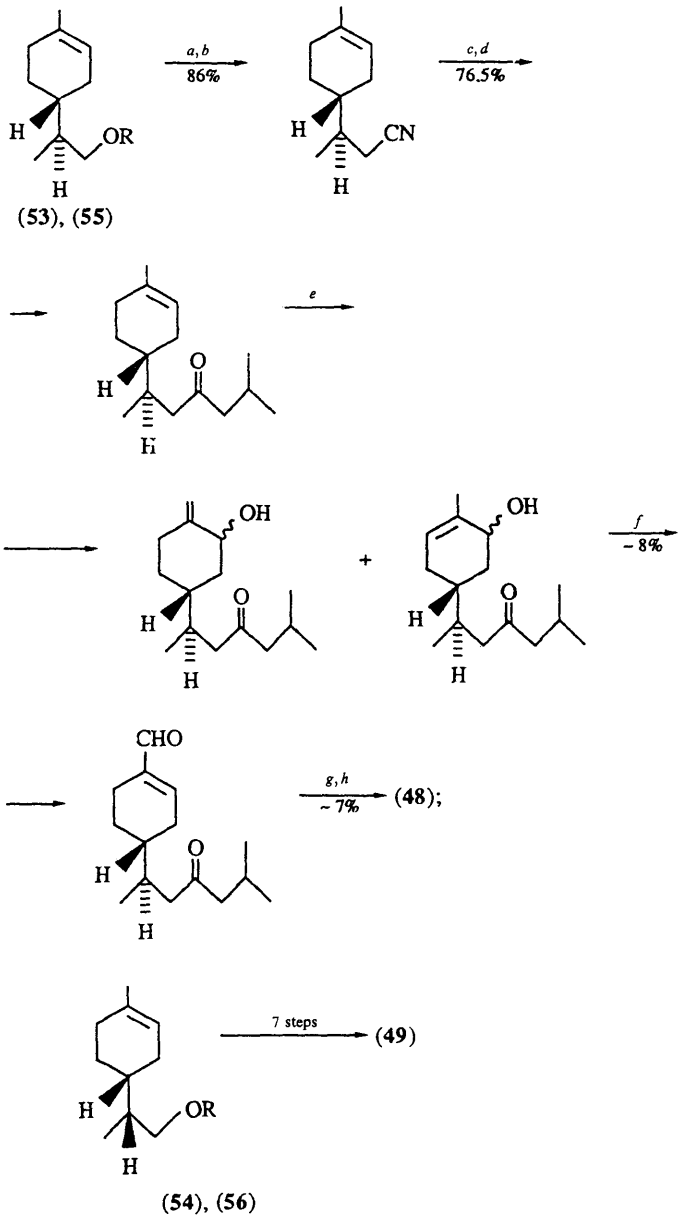


e: KOH/EtOH; *f*: Δ.

The individual epimers (**48**) and (**49**) were obtained by crystallisation of the semicarbazones of the corresponding ketoacids with subsequent esterification.[59,60]

A stereospecific synthesis of the individual (*R,R*)-(**48**) and (*R,S*)-(**49**) diastereomers of juvabione was achieved from the (*R,R*) (**53**) and (*R,S*) (**54**) alcohols, the optical activity of which was increased by fractional crystallisation of their 3,5-dinitrobenzoates (**55**) and (**56**) (Scheme 18).[61]

Scheme 18

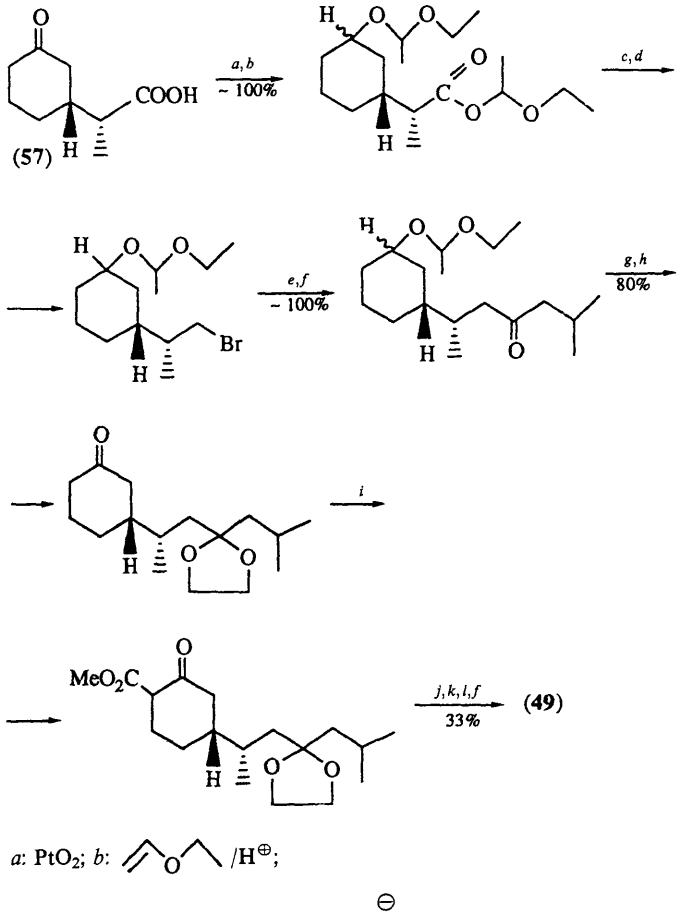


R = H(**53**), (**54**), DNB (**55**), (**56**)

a: TsCl/Py; *b*: NaCN/DMSO; *c*: $(Me)_2CHCH_2Li$; *d*: $H_3O^{\oplus}$; *e*: $O_2/h\nu$; *f*: $Na_2Cr_2O_7/H_2SO_4$/HOAc; *g*: $AgNO_3$; *h*: CH_2N_2.

Two of the stereocontrolled syntheses lead to epijuvabione (**49**).[62,63] In one of them the optically active acid (**57**) serves as starting material (Scheme 19).[62]

Scheme 19

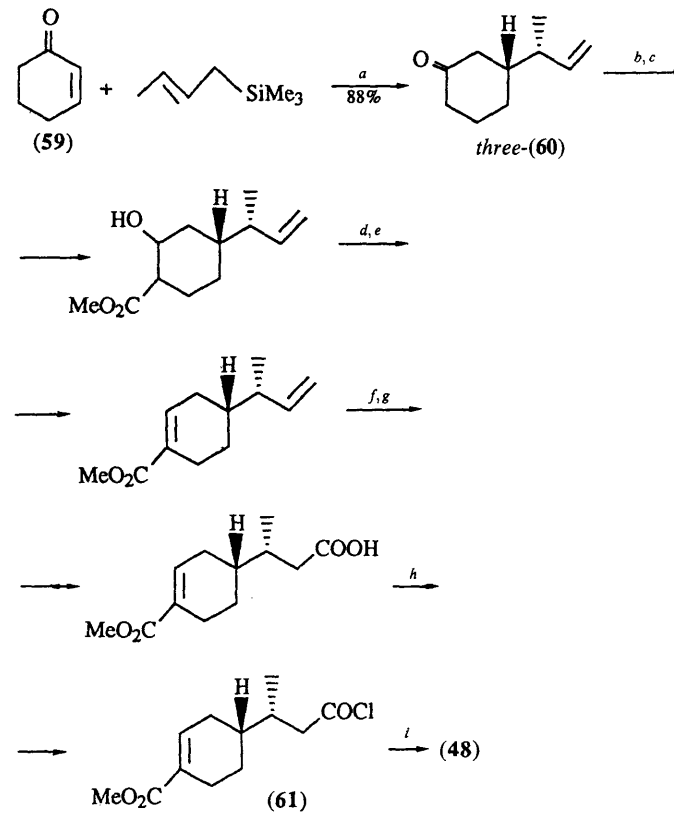


a: PtO_2; *b*: /$H^{\oplus}$;
c: $LiAlH_4$; *d*: PBr_3; *e*: $(Me)_2CH(CH_2)_2\overset{\ominus}{C}H(CN)(OH)$;
f: $H_3^{\oplus}O$; *g*: $(CH_2OH)_2/H^{\oplus}$; *h*: H_2CrO_4/Py; *i*: $(MeO)_2CO$/NaH;
j: $NaBH_4$; *k*: TsCl/Py; *l*: MeONa/MeOH.

Another approach is based on a [3,3] sigmatropic rearrangement applied to the diastereomeric mixture (**58**) with the (*R*) configuration at one of the asymmetric carbon atoms (Scheme 20).[63]

The synthesis[64] of juvabione (**48**) is based on the stereoselective condensation of the enone (**59**) with (*trans*-2-butenyl)trimethylsilane in the presence of $TiCl_4$ leading to the product (**60**) of *threo* configuration, the methoxycarbonylation of which and subsequent transformation through the acid chloride (**61**) gave juvabione (**48**) (Scheme 21).

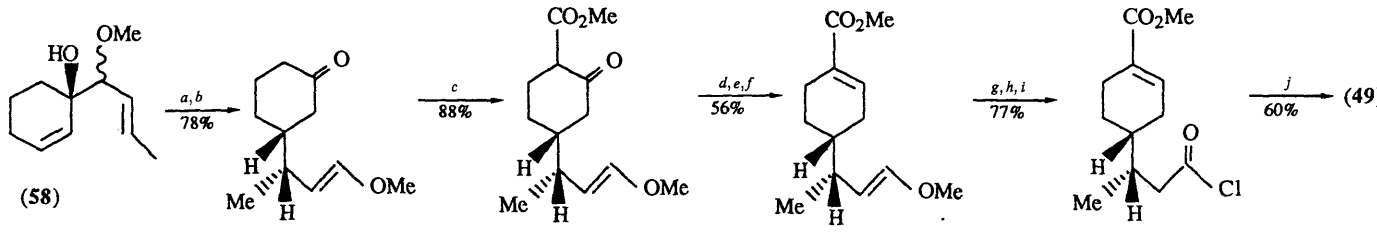
Scheme 21



a: $TiCl_4/CH_2Cl_2$; *b*: $(MeO)_2CO$/NaH; *c*: $NaBH_4$;
d: MsCl; *e*: NaOH/MeOH; *f*: $(C_6H_{11})_2BH$/THF;
g: CrO_3/H_2SO_4; *h*: $(COCl)_2$; *i*: $MeCHCH_2MgBr/Fe(acac)_2$.

The aromatic analogues corresponding to juvabione and epijuvabione have been isolated from natural sources. These are *ar*-juvabiones (**62**) and (**63**) which possess high JH activity.[65]

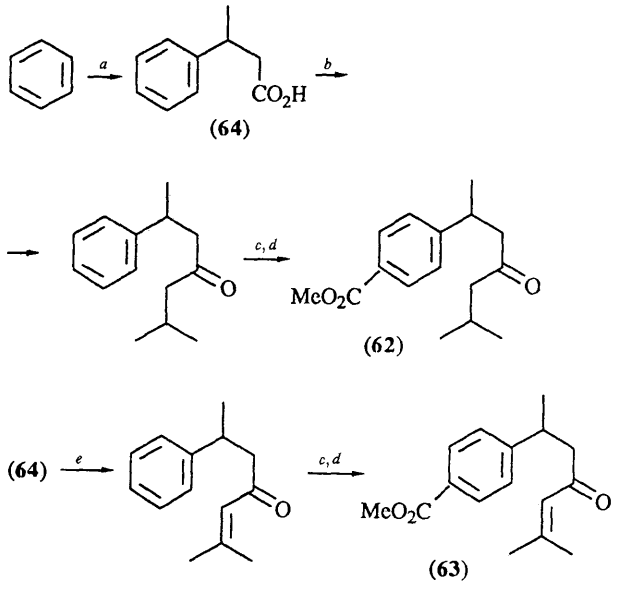
Scheme 20



a: KH, 110 °C; *b*: TLC; *c*: $(MeO)_2CO$/NaH; *d*: $NaBH_4$; *e*: MsCl; *f*: NaOMe/MeOH; *g*: $H^{\oplus}$; *h*: CrO_3/Me_2CO; *i*: $(COCl)_2$; *j*: $(iso\text{-}Bu)_2Cd$.

3-Phenylbutanoic acid (**64**) served as the key synthon in the synthesis of racemic (**62**) and (**63**) (Scheme 22).[66,67]

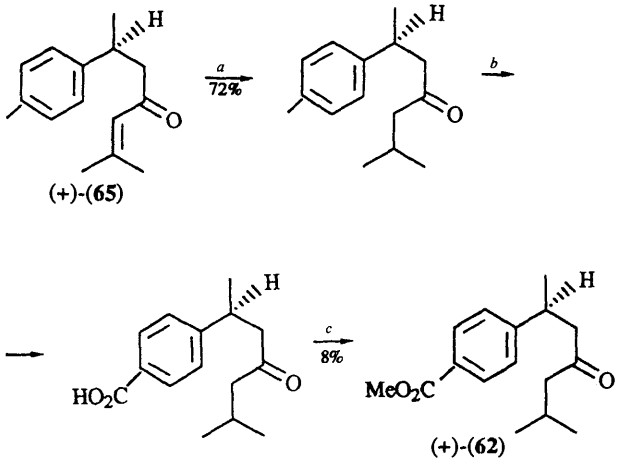
Scheme 22



a: MeHC=CHCOOH; *b*: Me_2CHCH_2Li; *c*: $(COCl)_2/AlCl_3$; *d*: MeOH; *e*: $Me_2C=CHLi$.

(+)-*ar*-Turmerone (**65**) was used for the synthesis of optically active (+)-*ar*-juvabione (**62**) (Scheme 23).[55]

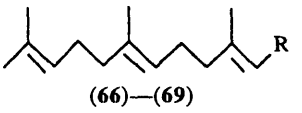
Scheme 23



a: H_2IPd-C; *b*: $CrO_3/AcOH$; *c*: MeOH/KOH/Me.

IV. Synthetic analogues of juvenile hormones

It was discovered in 1961[68] that farnesol (**66**) and farnesal (**67**) possess high juvenoid activity, comparable with that of the natural JH, but the methyl ester (**68**) and the diethylamide (**69**) of farnesenic acid proved to be even more active.[69–71]



(66)—(69)

R = CH_2OH (**66**), CHO (**67**), CO_2Me (**68**), $CONEt_2$ (**69**) .

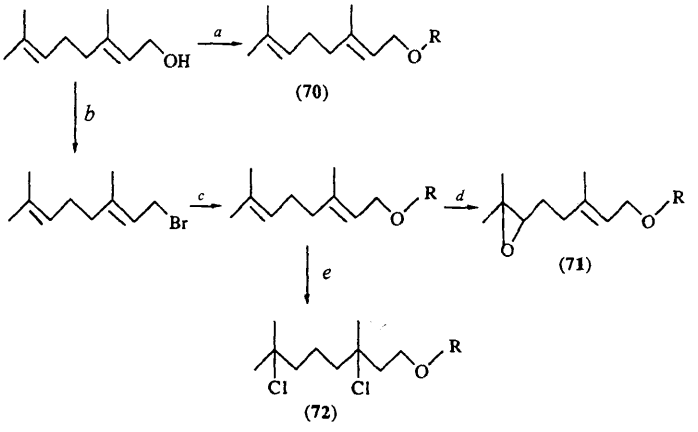
Intensive investigations then followed which were directed towards the search for active AJH and their synthesis. Several types of juvenoids emerged as a result of a widespread search. Highly active AJH were found chiefly among acyclic compounds with isoprenoid fragments in the chains, including derivatives of farnesenic acid and geraniol ethers. The most active juvenoids appeared among the esters of isoprenoid 2,4-dienoic acids (the 2,4-dienoates). Juvenoids of selective action were discovered among aliphatic compounds containing a heteroatom or a cyclic fragment in the carbon chain.

1. Acyclic juvenoids

a) Geraniol derivatives

When investigating the biological activity of alkyl ethers of geraniol (**70**), and of the epoxy (**71**) and dichloro (**72**) derivatives[72–74] in relation to the red cotton stainer bug (*Dysdercus koenigii*), it became apparent that the length of the alkyl chain (R) had considerable importance (the optimum was from four to six carbon atoms). Branching in the radical R causes a small increase in biological activity. Epoxydation of the terminal double bond in the geraniol portion of the molecule [compounds of the (**71**) series] reduces the juvenoid activity (Scheme 24).

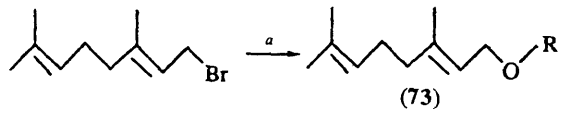
Scheme 24



R = n-Bu, CH_2CHMe_2, $(CH_2)_4Me$, $(CH_2)_2CHMe_2$, $CH_2CH=CMe_2$; *a*: $RBr/OH^{\ominus}$; *b*: PBr_3; *c*: RONa; *d*: $3\text{-}ClC_6H_4CO_3H$; *e*: HCl.

The most active were compounds with a total of 14–18 carbon atoms.[73] The geranyl ethers (**73**) or (**74**) were synthesised by the reaction of geranyl bromide with alcohols or geraniol with alkyl bromides in the presence of alkali (Scheme 25).[75–77]

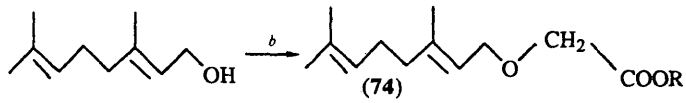
Scheme 25



(**73**)

R = $(CH_2)_2OMe$, $(CH_2)_2OCH_2Me$,

$(CH_2)_2O(CH_2)_2Me$, CH_2–CH(–)–OCH_2

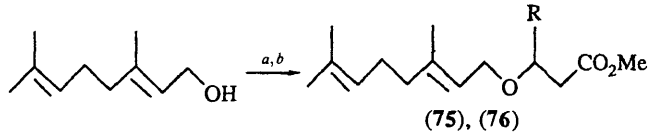


(**74**)

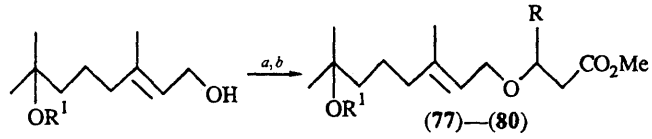
R = Me, Et, Pr, iso-Pr; *a*: $ROH/OH^{\ominus}$; *b*: $BrCH_2COOR/OH^{\ominus}$.

Catalytic addition of geraniol or of its 7-alkoxy derivatives to the activated double bond of methyl crotonate[74] or methyl 2-pentenoate[78,79] was used for the synthesis of compounds (**75**)–(**80**) (Scheme 26). It was noted that the introduction of methoxyl and ethoxyl groups at the terminal position of these compounds increases their JH activity.

Scheme 26



(**75**), (**76**)



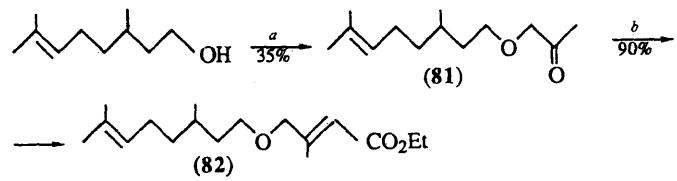
(**77**)—(**80**)

R = Me(**75**), (**77**), (**79**); Et (**76**), (**78**), (**80**);
R^1 = Me (**77**), (**80**); Et (**78**), (**79**);

a: R–CH=CH–$CO_2Me/OH^{\ominus}$; *b*: MeOH/TsOH.

An interesting approach to the synthesis of such a series of AJH is the olefination of compound (**81**), itself obtained by the reaction of citronellol with a diazoketone.[80–82] The ether (**82**), for example, was synthesised in this way (Scheme 27).

Scheme 27



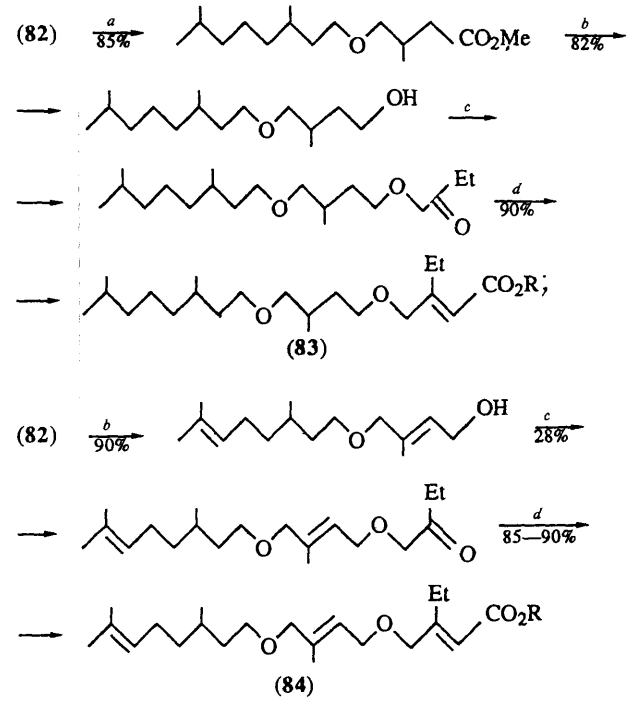
(**81**)

(**82**)

a: $MeC(O)CH_2N_2/BF_3$; *b*: $Ph_3P=CH_2CO_2Et$.

Transformations analogous to those carried out for compound (**82**) led to the ethers (**83**)[83–86] and (**84**)[84–86] with an oxygen atom in the alkyl chain of the citronellol derivative (Scheme 28).

Scheme 28

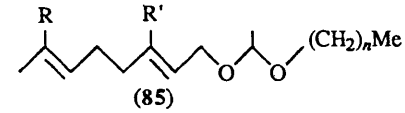


(**83**)

(**84**)

R = Me, Et, iso-Pr;
a: $H_2/Pd-C$; *b*: $LiAlH_4$; *c*: $EtC(O)CH_2N_2/BF_3$;
d: $Ph_3P=CHCO_2R$.

Some compounds of this series display a selective action. Compounds of the (**85**) series proved to be effective juvenoids in relation to the Mexican pea beetle.[87]



(**85**)

R, R' = Me, Et; *n* = 0, 1.

Juvenoids with a high morphogenetic effect were discovered in a series of phenyl ethers of geraniol and also their 6,7-epoxy, 7-hydroxy and 7-alkoxy derivatives.[9] The greatest effect on juvenoid activity was shown by substituents in the 4 and 2 positions of the phenyl group and also by hydroxyl and methoxyl groups in the 7 position of the chain.[88–110] Some of these compounds, containing for example ethyl, propyl and cyclopropyl groups in the 4 position of the phenyl ring, proved to be 100 or more times more active than the alkyl ethers of geraniol in relation to *Tenebrio molitor*, *Culex pipiens* and *Aedes aegypti*.[88,90,92,93,95] The greatest activity among

the 7-hydroxy and 7-methoxy derivatives is displayed by compounds with ring ethoxy and propoxy groups (Scheme 29).[88,93]

Scheme 29
