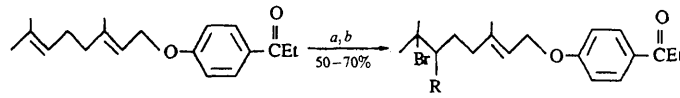
The introduction of a halogen atom, a hydroxy or an alkoxy group into the terpene portion of the molecule did not change significantly the biological activity of the initial geraniol ether (Scheme 32).[114]

Scheme 32

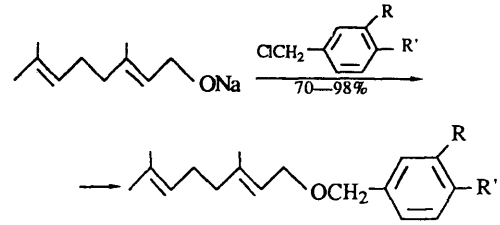


R = OH, OMe, iso-Pr;

a: NBS; *b*: ROH.

Benzyl ethers of geraniol proved to be less active than phenyl ethers (Scheme 33).[115,116]

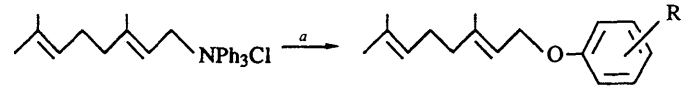
Scheme 33



R = H, OH, Cl; R' = H, CMe_3, OMe, OEt, SMe, SEt, Cl, Br.

The method proposed for obtaining the phenyl ethers of geraniol is the reaction of the appropriate alkali metal phenoxide with geranyltriphenylammonium chloride (Scheme 30).[111,112]

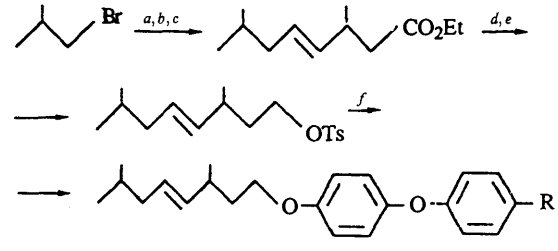
Scheme 30



R = 3-Me, 4-Me, 4-Et, 3,4-Me_2, 4-iso-Pr, 2-iso-Pr, 5-Me, 2-OMe, 3-OMe, 4-NO_2, 4-Cl;

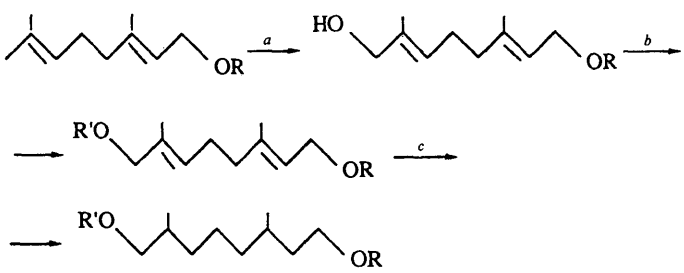
a: 
Juvenoid activity is increased significantly for the phenoxyphenyl ethers (Scheme 31).[113]

Scheme 31



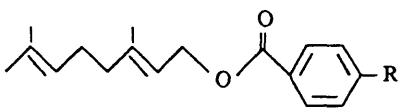
The diethers of (2*E*, 6*E*)-3,7-dimethyl-2,6-octadiene-1,8-diol and their tetrahydro derivatives shows high activity in relation to mosquitoes and the red cotton stainer bug (Scheme 34).[117]

Scheme 34



R = Me, Et, Ph, Bz, 4-MeC_6H_4; R′ = Me, Et, Ph, 4-ClPh, Bz, 4-MeC_6H_4; *a*: SeO_2; *b*: R′Hal – NaH; *c*: H_2/PtO_2 – Et.

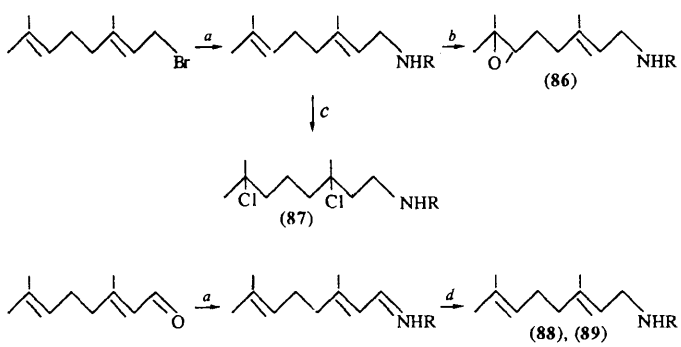
The geranyl esters of 4-substituted benzoic acids display high activity.[118]



R = OMe, Cl, NO_2.

The derivatives of geranylamine (**86**)–(**89**) have been investigated as potential juvenoids. However they proved to be less active than the corresponding oxygen-containing analogues (Scheme 35).[73,119]

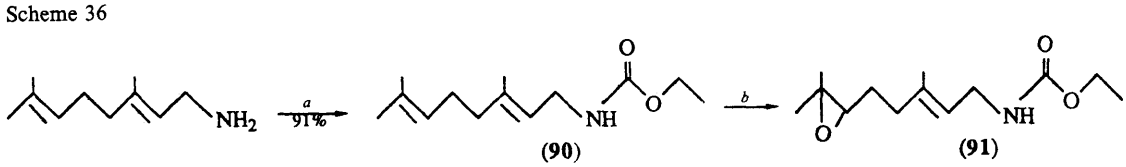
Scheme 35



R = C_nH_{2n+1} (n = 1 to 9) (**86**), (**87**); 4-$(EtO_2C)C_6H_4$ (**88**), 4-(HO_2C).C_6H_4 (**89**);
a: RNH_2; *b*: 3-$ClC_6H_4CO_3H$; *c*: HCl; *d*: KBH_4.

On the other hand the geranyl derivatives of carbamic acid (**90**) and (**91**), obtained by the reaction of ethyl chloroformate with geranylamine,[120] display high juvenoid activity in relation to the yellow meal worm (*Tenebrio molitor*) (Scheme 36).[120]

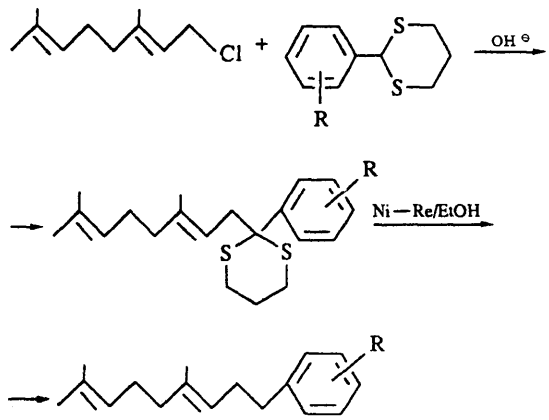
Scheme 36



a: $ClCO_2Et$; *b*: 3-$ClC_6H_4CO_3H$.

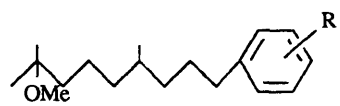
The reaction of geranyl chloride with dithiianes of substituted benzaldehydes and subsequent reduction of the dithiiane group gave geranyl benzyl derivatives (Scheme 37).[121]

Scheme 37



R = 3-Br, 4-Br, 4-F, 4,5-Cl_2, 4-CN, 4-CO_2Et, 4-NMe_2.

The methoxy substituted tetrahydro derivatives of the series (**92**)–(**94**) display high juvenoid activity against the house-fly.[122] Compound (**94**) proved to be the most active.

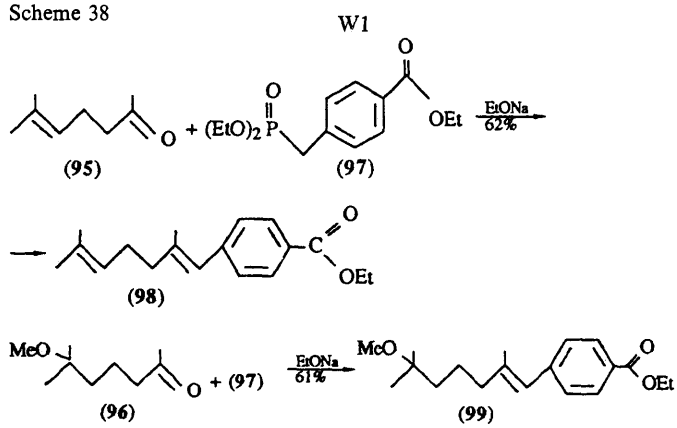


(**92**)—(**94**)

R = Et (**92**), Pr (**93**), iso-Pr (**94**).

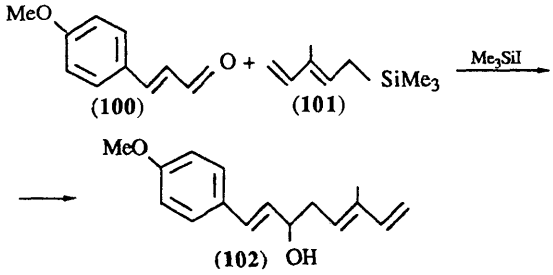
Compounds (**98**) and (**99**), obtained from ketones (**95**) and (**96**) and the phosphonate (**97**), display selective JH activity in relation to *Diptera* (Scheme 38).[123]

Scheme 38



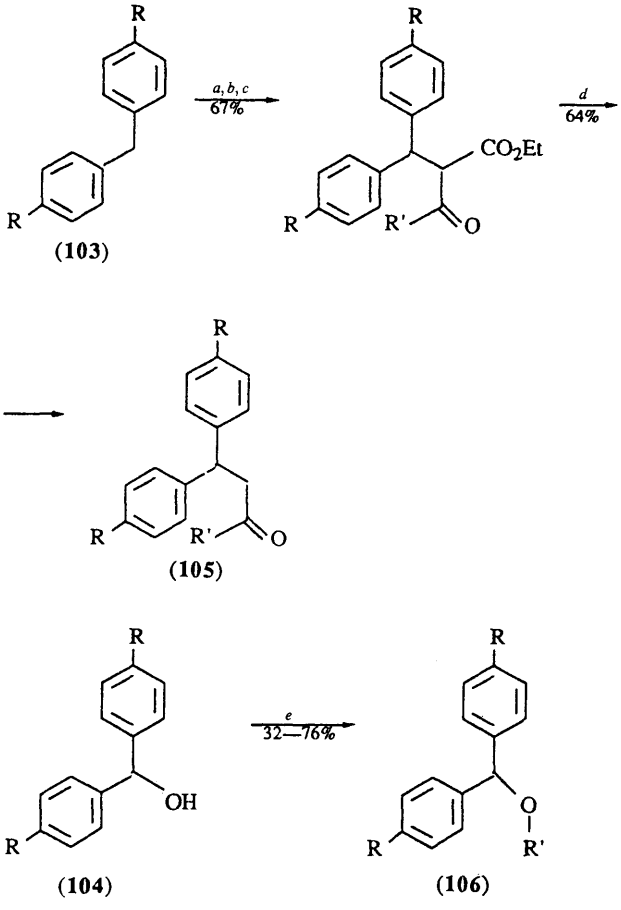
The product (**102**) from the reaction of 4-methoxycinnamaldehyde (**100**) and the allylsilane (**101**) shows juvenoid activity (Scheme 39).[124]

Scheme 39



The activity of the substituted diarylmethanes (**105**) and (**106**), synthesised[12] from the symmetrical diphenylmethanes (**103**) and (**104**), depends on the length of the alkyl chain R'. Compounds with eight carbon atoms in the side chain have the highest JH activity (Scheme 40).

Scheme 40



R = Cl, CO_2Me; R' = Me, Et, iso-Pr, iso-Bu, $COCCl_3$, $COCH_2CHMe_2$, $Me_2C{=}CH(CH_2)_2CH(Me)(CH_2)_2$;

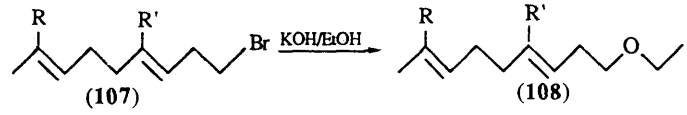
b) Oxa and aza derivatives

The interesting results obtained for geranyl ethers stimulated the search for active JH analogues in other compounds of the ether type referred to as oxa analogues of JH in the literature.[16] The oxa-AJH (**108**) were synthesised from the homologues of geranyl bromide (**107**) (Scheme 41).[126]

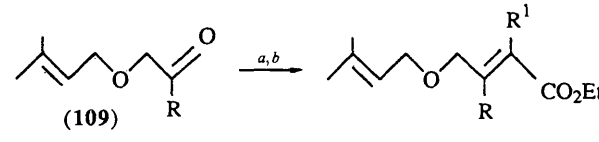
Scheme 41



R, R' = Me, Et, Pr.

However, compounds containing a Δ^2-double bond conjugated with the ester group were more promising. Compounds of this class with oxygen at various positions in the chain were synthesised. The 5-oxa analogues of JH were obtained, for example, by the Reformatsky reaction from the ketoethers (**109**) and α-haloacids with subsequent dehydration of the resulting β-hydroxyesters (Scheme 42).[127]

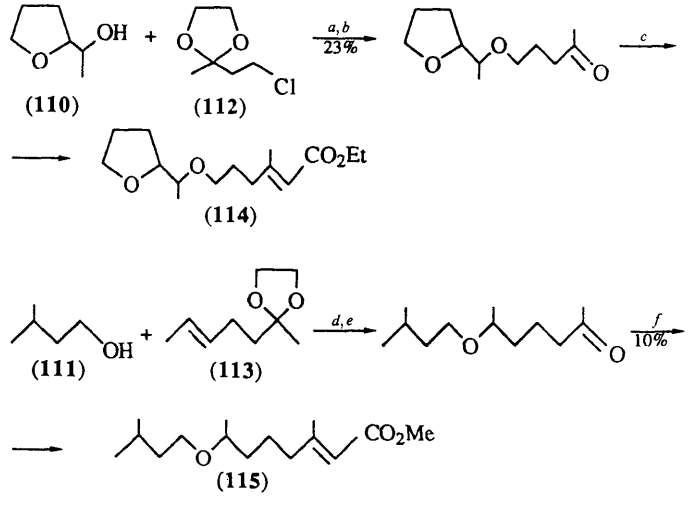
Scheme 42



R, R^1 = Me, Et, Pr;
a: $R^1CH_2(Br)COOEt$; *b*: $POCl_3$.

Compounds (**114**) and (**115**) were obtained by the reaction of the alcohols (**110**) and (**111**) with the acetals (**112**) and (**113**) respectively with subsequent Horner olefination (Scheme 43).[128,129]

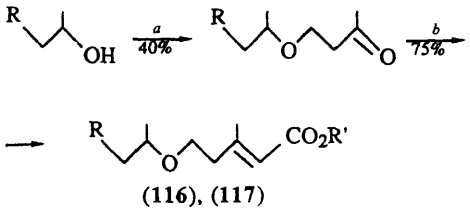
Scheme 43



a: NaOH; *b*: H_3O^+; *c*: $(EtO)_2P(O)CHCO_2Et$; *d*: $NaBH_4$; *e*: TsOH;
f: $(MeO)_2P(O)CHCO_2Me$.

The key step in the synthesis of esters of the 6-oxa derivatives of (2*E*)-3,7-dimethyl-2-alkenoic acids (**116**) and (**117**) is the addition, catalysed by mercuric oxide and boron trifluoride etherate, of alcohols to methyl vinyl ketone with subsequent Horner olefination of the resulting ketones (Scheme 44).[130,131]

Scheme 44



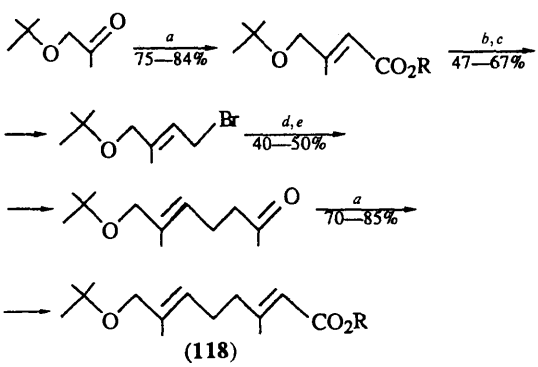
(**116**), (**117**)

(**116**): R = , R' = Me; (**117**): R =  , R' = Et;

a: , $HgO/BF_3.Et_2O$; *b*: $(EtO)_2P(O)CHCO_2R'$.

9-Oxa derivatives of (2*E*,6*E*)-2,6-undecadienoic acid (**118**) have been synthesised using two olefination stages (Scheme 45).[132,133]

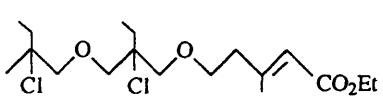
Scheme 45



(**118**)

R = Me, Et, iso-Pr;
a: $Ph_3P{=}CH_2CO_2R$; *b*: $LiAlH_4$; *c*: PBr_3; *d*: $MeC(O)CH(Na)CO_2Et$; *e*: Δ.

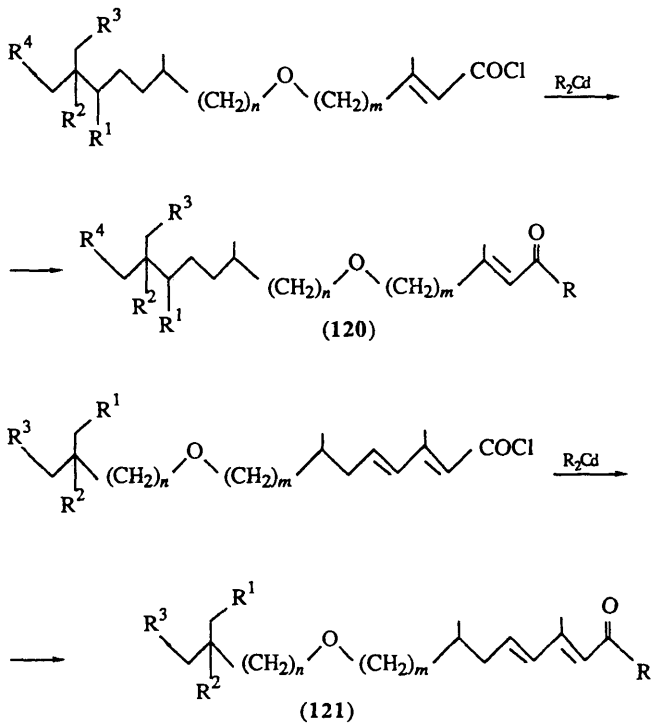
The juvenoid activity of compounds (**114**)–(**118**) proved to be less than that of the corresponding deoxy derivatives.[134] However some oxa derivatives show a selective action on particular species. Thus the ethyl ester of (2*E*)-8,12-dichloro-8-ethyl-12-methyl-6,10-dioxa-2-tetradecenoic acid (**119**) is an effective juvenoid in relation to *Dysdercus cingulatus*. The dose of compound enabling 50% intermediate forms to develop under standard conditions (specimens with part-larva part-pupa features) (UD_{50}) was 0.06 μg per specimen.[84]



(**119**)

Several mono- (**120**) and dienoketones (**121**) containing an oxygen atom in the main chain show high juvenoid activity towards the yellow meal worm, the domestic fly and *Eurygaster integriceps*.[135,136] These compounds were obtained by the reaction of the acid chlorides of the appropriate carboxylic acids with organocadmium compounds (Scheme 46).

Scheme 46



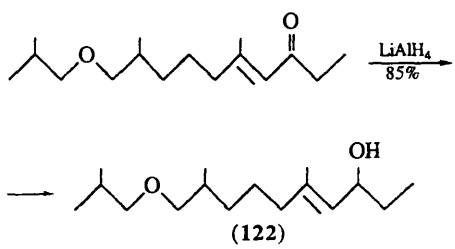
(**120**)

(**121**)

R, R^1, R^2, R^3, R^4 = H, Me, Et, Pr; *m* = 1,2; *n* = 0,1.

The oxa compound (**122**), obtained by reduction of the corresponding α,β-unsaturated ketone, displays high JH activity on the same insect species (Scheme 47).[137]

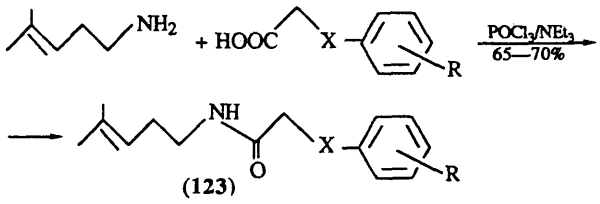
Scheme 47



(**122**)

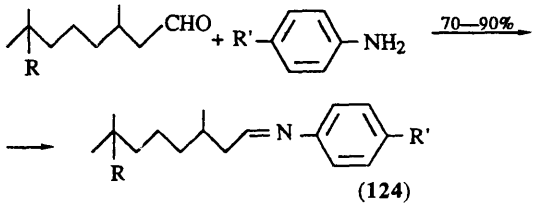
It was discovered that compounds (**123**)–(**128**), containing a nitrogen atom in the chain, display low juvenoid activity (Scheme 48).[138–140]

Scheme 48



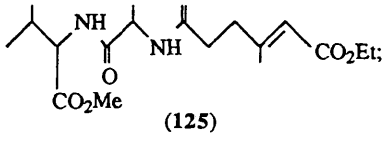
(**123**)

X = O, S; R = H, 4-Me, 4-Et, 2-Cl, 4-Cl, 4-Br.

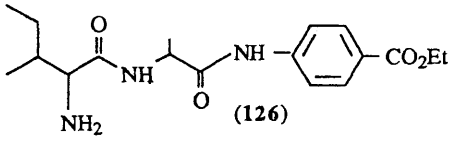


(**124**)

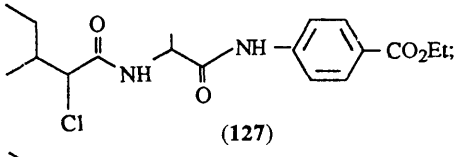
R = OH, OMe; R' = H, Me, Cl, CO_2H, NO_2.



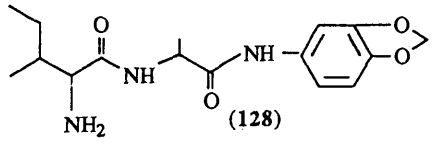
(**125**)



(**126**)



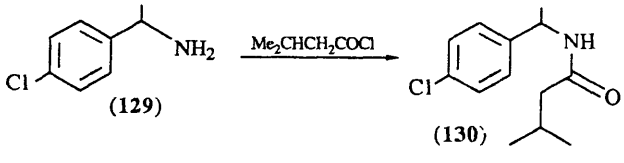
(**127**)



(**128**)

It was however established that the aza analogues of juvabione[141] display selectively high activity in relation to *Dysdercus fasciatus*. The most active proved to be compound (**130**) obtained by the acylation of the amine (**129**) (Scheme 49).

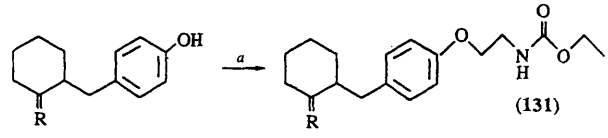
Scheme 49



(**129**) (**130**)

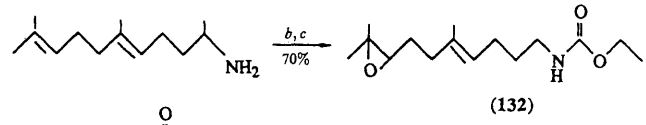
The compounds (**131**) and (**132**), containing oxygen and nitrogen atoms in the chain, display selective activity towards termites (Scheme 50).[142,143]

Scheme 50



(**131**)

R = O (50%); OCH_2CH_2O (23%)

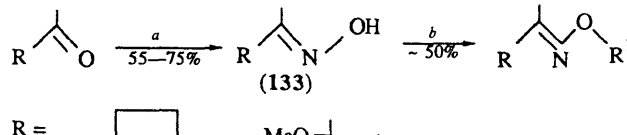


(**132**)

a:  ; *b*: $ClCO_2Et$; *c*: $3\text{-}ClC_6H_4CO_3H$.

The reaction of oximes (**133**) and (**134**) with the appropriate halogen derivative[144–151] or chloroformate ester[143] may serve as an efficient method of obtaining juvenoids containing two heteroatoms, nitrogen and oxygen, in the same structure (Scheme 51).

Scheme 51



(**133**)

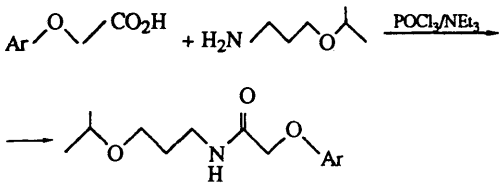
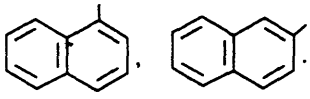
Amides of unsaturated carboxylic acids with an oxygen atom in the chain, obtained by the reaction of acids with amines in the presence of $POCl_3$, display high JH activity in relation to the yellow meal worm (Scheme 52).[152–156]

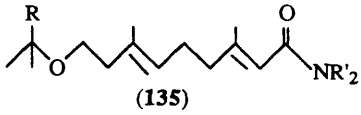
Scheme 52



Ar = 4-EtC_6H_4, 2-FC_6H_4, 2-ClC_6H_4, 3-EC_6H_4, 4-ClC_6H_4, 4-BrC_6H_4,



The JH activity of compounds of the (135) series is ~0.01 μg per specimen.[157]

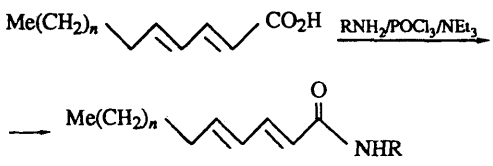


(135)

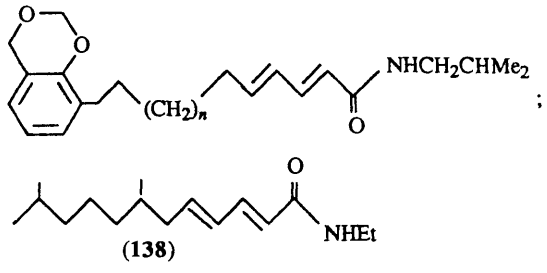
R, R′ = C_1–C_5-alkyl or C_2–C_5-alkenyl.

It was noted that the juvenoid activity of the amides was reduced in the series NR_2 > NHR > NH_2 (R = Alk, Ar)[9,158] and tertiary arylamides are more active than aliphatic amides. The amides of 2,4-dienoic acids are more active than the corresponding derivatives with isolated double bonds. A series of dienoates (136)–(138) was prepared, the action of which on *Callosobruchus maculatus*[159] and *Boophilus decoloratus*[160] exceeds that of methoprene (Scheme 53).

Scheme 53



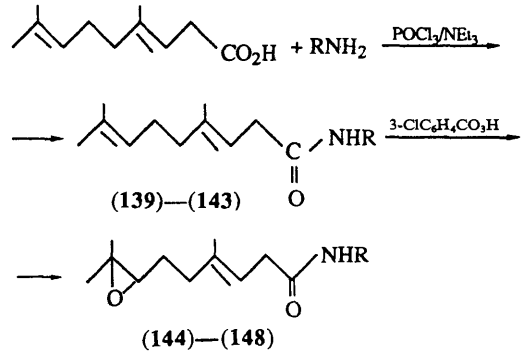
R = Me, Et, Pr, iso-Pr; n = 4 to 6.



(136), n = 5; (137), n = 3.

It was established that the epoxy derivatives (144)–(148) are more active than the initial amides (139)–(143) (Scheme 54).[155]

Scheme 54



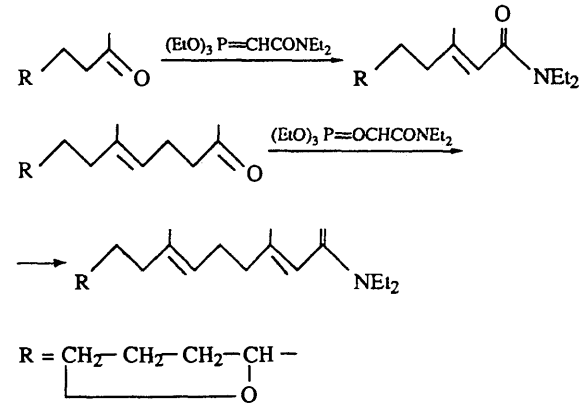
(139)—(143)

(144)—(148)

R = Ph (139), (144); 4-MeC_6H_4 (140), (145); 4-$MeOC_6H_4$ (141), (146); 4-$EtOC_6H_4$ (142), (147); 4-ClC_6H_4 (143), (148).

The Horner reaction is used for the synthesis of the α,β-unsaturated amides (Scheme 55).[152,153]

Scheme 55



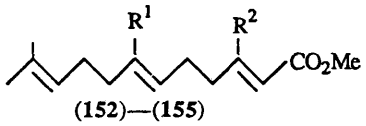
R = CH_2–CH_2–CH_2–CH(O)–

Highly active juvenoids of the amide type were obtained by the reaction of the corresponding alcohols with isocyanates,[161] or of amines with a chloroformate ester.[143,162] Compounds (149)–(151) display high activity towards the yellow meal worm (UD_{50} = 0.1 μg per specimen) but their activity in relation to *Dysdercus cingulatus* exceeds that of methoprene (UD_{50} = 0.008 and 0.04 μg per specimen respectively) (Scheme 56).

c) Derivatives of isoprenoid acids

Comparison of the methyl ester of farnesenic acid (152) and its C(3) and C(7) methylated analogues (153) and (154)[163] showed that the presence of the substituent at C(7) has little effect on juvenile hormone action but the absence of a methyl group at C(3) leads to an attenuating effect as indicated by the low activity of compound (154). On the other hand a stronger juvenoid is obtained by replacement of the methyl group at C(3) by trifluoromethyl [compound (155)].[164] It was also established that activity is increased in a series of farnesenic acid esters from methyl to propyl: CO_2Me < CO_2Et < CO_2Pr.[165,166] Replacement of the ester group

by amide reduces the juvenoid action of the obtained compound on *Bombyx mori* while the susceptibility of the yellow meal worm is increased.[167]

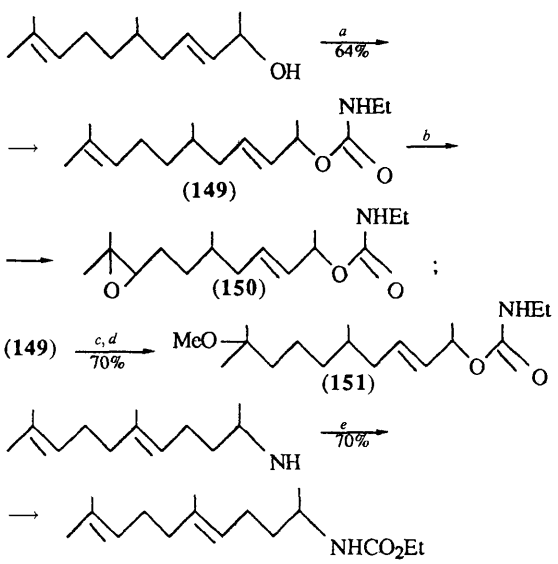


(152)—(155)

R^1 = H (153); Me (152), (154); CF_3 (155);
R^2 = H (154); Me (152), (153).

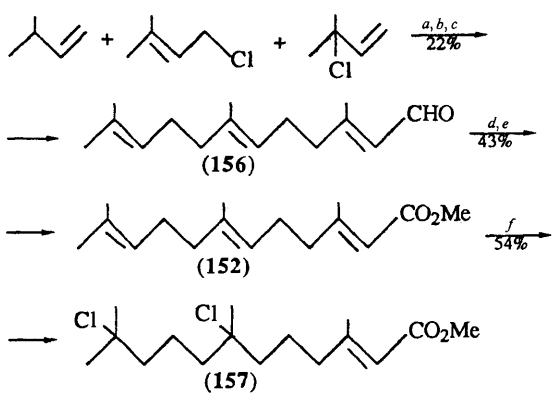
Methyl farnesenate (**152**) may be obtained mixed with other compounds by the telomerisation of isoprene, 1-chloro-3-methyl-2-butene and 3-chloro-3-methyl-1-butene with formaldehyde and subsequent oxidation of the aldehyde (**156**).[168] On treatment with hydrogen chloride the dichloride (**157**) is given and proved to be 1000 times more active in relation to *Antheraea polyphemus* than the natural JH (Scheme 57).[169]

Scheme 56



a: EtN=C=O; *b*: 3-$ClC_6H_4CO_3H$; *c*: $Hg(OAc)_2$; *d*: $NaBH_4$/NaOH; *e*: $ClCO_2Et$.

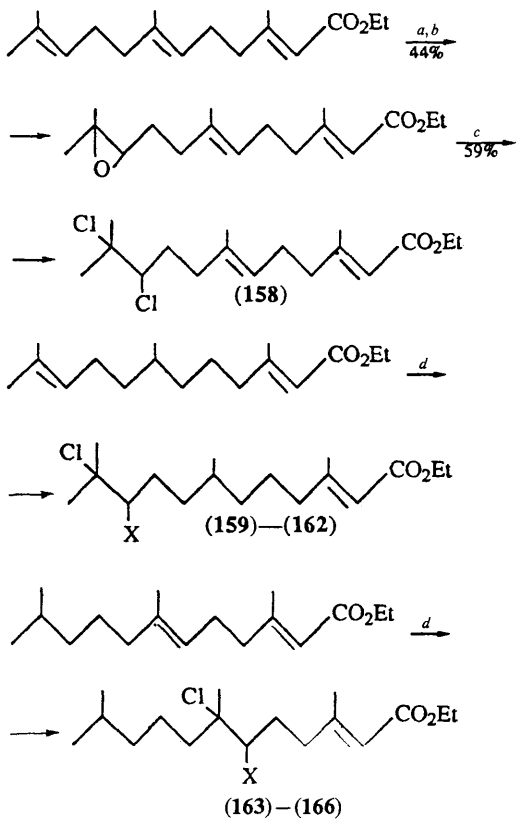
Scheme 57



a: $SnCl_4$; *b*: urofropin; *c*: CH_2O; *d*: $AgNO_2$; *e*: Me_2SO_4; *f*: HCl/MeOH.

It was shown that of the compounds (**159**)—(**166**) the activity of the 10,11-dichloro derivative (**158**) towards *Eurygaster integriceps* was greater than that of the 6,7- (**163**) and 7,11- (**157**) dichlorides. The thio analogues (**160**), (**161**), (**164**) and (**165**) were less active than the corresponding dichlorides (Scheme 58).[168,170]

Scheme 58



X = Cl (**159**), (**163**); SMe (**160**), (**164**); SPh (**161**), (**165**); 4-ClC_6H_4 (**162**), (**166**).
a: NBS; *b*: K_2CO_3; *c*: CCl_4/Ph_3P; *d*: $CuCl_2$/MeCN or RSCl.

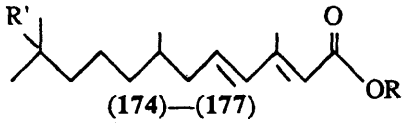
According to literature data[171] the presence of a fluorine atom in an organic compound inhibits its oxidative metabolism. This stimulated the synthesis of the fluorinated analogue (**169**) of JH-III. The fluorine-containing ester (**167**) served as starting material and was converted into the ester of 6-fluorogeranic acid (**168**) by a Claisen—Cope rearrangement. Further transformations led to the desired compound (**169**) (Scheme 59).[172]

The antipodes of the optically active juvenoids (**172**) and (**173**), which were obtained from the nitrile (**170**), possess different juvenoid activity in relation to *Dysdercus cingulatus*.[173,174] The racemic secondary alcohol (**171**), formed by the reaction of the nitrile (**170**) with propylmagnesium bromide was resolved into optical antipodes by Sharpless asymmetric epoxidation. Depending on whether (+) or (−) diisopropyl tartrate was used either the (*S*)-(−)- or the (*R*)-(+)-alcohol (**171**) respectively react and the unreacted (*R*)-(+) or (*S*)-(−) (**171**) enantiomer is isolated. The optical purity of the (*R*)-(+)-(**171**) and (*S*)-(−)-(**171**) alcohols was 88 and 74%

respectively. A Claisen rearrangement with an alkyl orthoformate in the presence of propionic acid[175] gave the juvenoids (172) and (173) of the (*R*) or (*S*) configuration (Scheme 60).[174]

Analogues of farnesenic acid of similar structure are comparable in juvenoid activity to the natural JH.[176–185] For example, a significant growth in JH activity was detected for esters of (2*E*,4*E*)-3,7,11-trimethyl-2,4-dodecadienoic acid on changing from the α,β-enoates to the corresponding 2,4-dienoates.[1,186]

Compounds with very high juvenoid activity were found among the esters of (2*E*,4*E*)-3,7,11-trimethyl-2,4-dodecadienoic acid. The ethyl ester (174) (hydroprene) and the propargyl ester (175) (kinoprene) are amongst these. The introduction of a methoxyl group at the 11 position of the isopropyl ester (176) gave an increase of almost one order of magnitude in juvenoid activity. Methoprene proved to be non-toxic to warm blooded animals and man. On the other hand this compound displayed high juvenoid activity towards the house ant *Monomorium pharaonis*,[187] the mosquito *Culex nigripalpus*,[188] the house-fly and the dung fly and also towards many agricultural pests of the orders *Lepidoptera* and *Hemiptera*.[13,189] The addition of 0.01% methoprene to bird feed led to 99% destruction of flies on poultry farms. Hydroprene (174)[189,190] and kinoprene (175)[189,191] are also of practical use.



(174)—(177)

R = Et (174); $CH_2C{\equiv}CH$ (175); $CHMe_2$ (176), (177);

The key stage in the synthesis of the 2,4-dienoates is usually the Emmons modification of the Wittig reaction (Scheme 61).[134,186,192–196]

A review[13] has been devoted to the synthesis and properties of methoprene (**177**). Hydroprene (**174**), as a mixture of the (2*E*,4*E*) and (2*Z*,4*E*) isomers, was synthesised for the (2*E*) unsaturated ketone (**178**) and ethyl bromoacetate by the Reformatsky reaction,[197] using the Iotsich–Preobrazhenskii reagent[198] or by the reaction with acetic acid di-anion.[199]

The individual (2*E*,4*E*) isomer of the methyl ester (**181**) was obtained by elimination of acetic acid from the homoallyl acetate (**180**), which was itself obtained by the reaction of tetrahydrocitral (**179**) with the di-anion generated from 3-methyl-3-buten-1-ol (Scheme 63).[200]

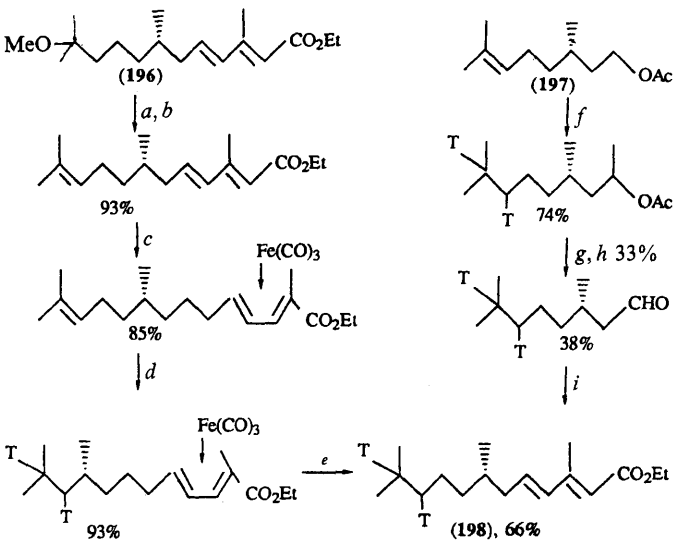
It is known that the (7*S*)-(+) enantiomer of hydroprene (**174**) displays higher activity than the (7*R*)-(−) antipode.[209] Enantiomerically enriched hydroprene (**174**) (enantiomeric excess ~50%) is obtained from dihydromyrcene (**191**) through (*S*)-(+)-3,7-dimethyloctanal (**192**) which was treated with allyl- or methallylmagnesium chloride and gave the alcohols (**193**) or (**194**), each of which was converted into the conjugated ketone (**195**) then transformed by the usual route into the desired (*S*)-(+)-hydroprene (Scheme 68).[210]

The synthesis of 10,11-ditritiohydroprene (**198**), used for investigating the metabolism of juvenoids *in vivo*, was effected from the (*S*)-(+)-dienoate (**196**) in which the Δ^{10} double bond was tritiated after protecting the diene system as the iron carbonyl complex. Another route is based on tritiation of the double bond of (*S*)-(+)-citronellyl acetate (**197**) before constructing the diene system (Scheme 69).[211]

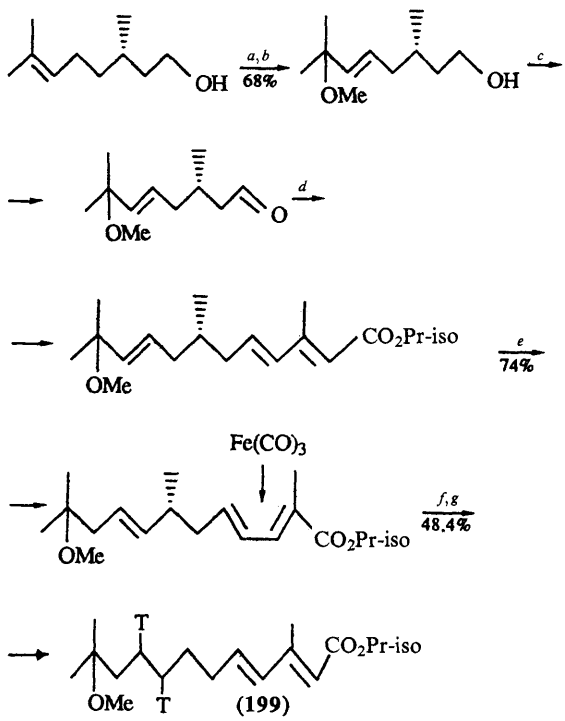
Scheme 69



a: NaOEt/EtOH; *b*: H_2SO_4; *c*: $Fe_3(CO)_{12}$; *d*: $T_2/Ph[Ph_3P]_3Cl$; *e*: $(NH_4)_2Ce(NO_3)_2$; *f*: T_2/Pd; *g*: NaOH/MeOH; *h*: CrO_3/Py; *i*: $Et_2.OCCH=C(Me)CH_2P(O)(OEt)_2$.

A similar approach was used in the synthesis of 8,9-ditritiomethoprene (**199**) used as a tracer for characterising protein receptors in insects (Scheme 70).[212]

Scheme 70

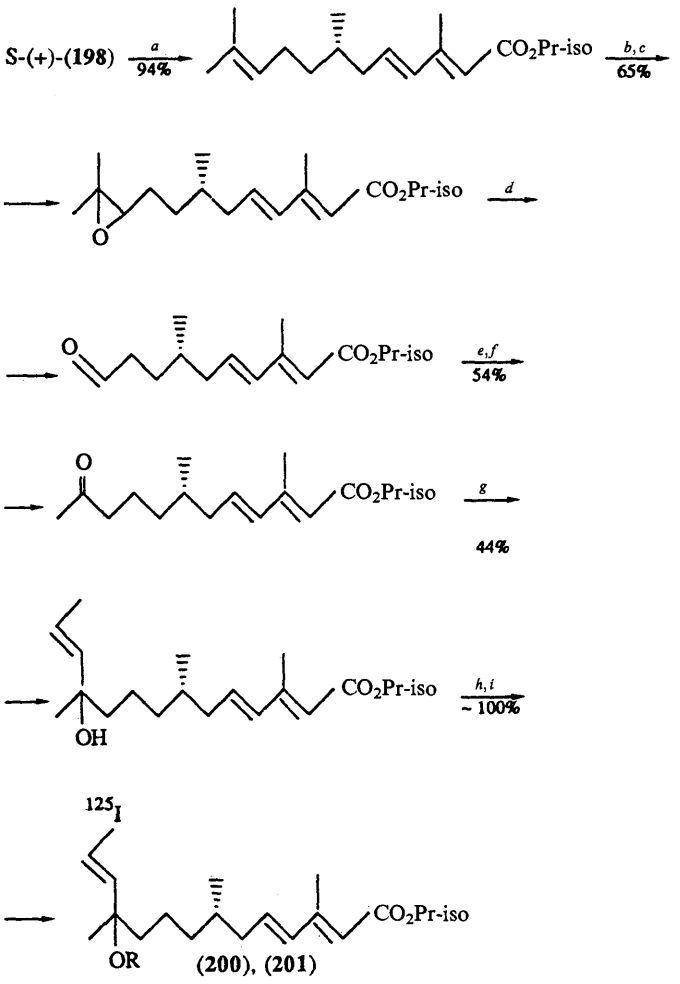


a: NBS/MeOH; *b*: $Ph_3CK/CH_2(OMe)_2$; *c*: $Py.CrO_3.HCl$; *d*: $(iso\text{-}PrO)_2P(O)CH_2CH(Me)=CHCO_2Pr\text{-}iso$; *e*: $Fe(CO)_{12}$; *f*: $T_2/Rh-C$; *g*: $Ce(NH_4)_2(NO_3)_2$.

In order to study the mechanism of binding juvenoids to protein, an iodomethyl group labelled with radioactive ^{125}I, which is stable to metabolism, was introduced into the methoprene molecule

[compounds (200) and (201)].[213] The resulting analogue (201) proved to be four times as active as methoprene (Scheme 71).

Scheme 71

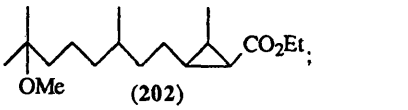


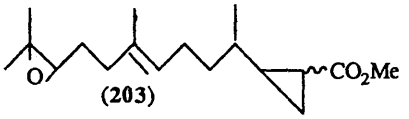
R = H(200), Me (201);
a: H_2SO_4; *b*: NBS; *c*: K_2CO_3; *d*: H_2IO_6; *e*: $Ph_3P=C(Me)OMe$; *f*: $H^{\oplus}$/MeOH; *g*: (*E*)-$Bu_3SnCH=CHSnBu_2$, BuLi/THF; *h*: $Na^{125}I/H_2O_2$/AcOH; *i*: $NaHSO_3$.

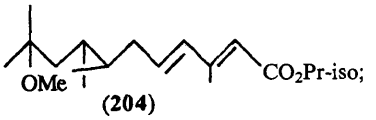
2. Juvenoids containing cyclic residues in the carbon chain

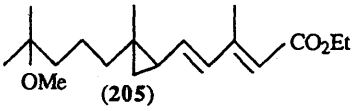
a) Juvenoids containing carbon rings

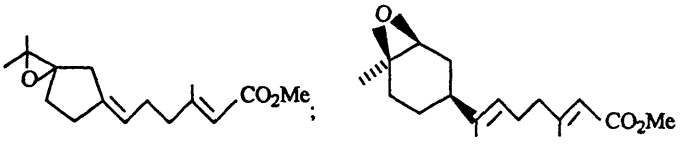
Compounds containing cyclic residues in various parts of the carbon chain of the AJH molecule have been synthesised with the aim of studying the mechanism of action and of searching for new active juvenoids. It was established that the introduction of a cyclopropane ring into the head portion of the molecule [compounds (202), (203)[214,215]] or its heart [compounds (204), (205)[216,217]] did not change the biological activity while the presence of an alicycle in the tail portion of the molecule [compounds (206)–(209)] reduces JH activity compared with the corresponding compounds containing no cyclic fragments.[218–221]

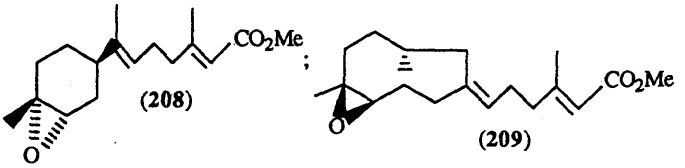






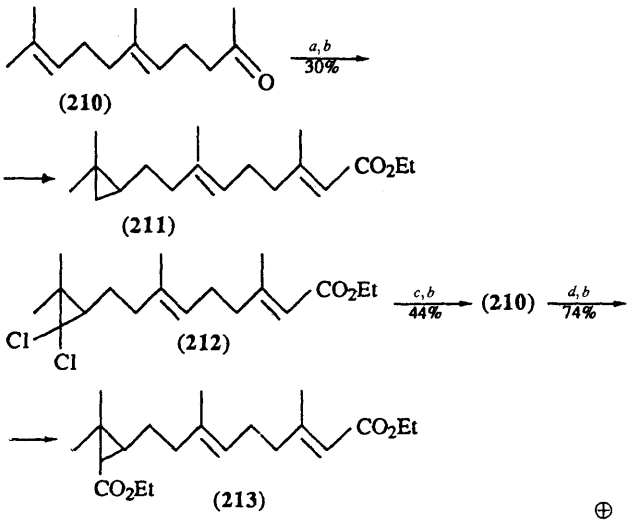






Compounds (211)–(213) were obtained by the cyclopropanation of geranylacetone (210) and subsequent Horner olefination (Scheme 72).[221]

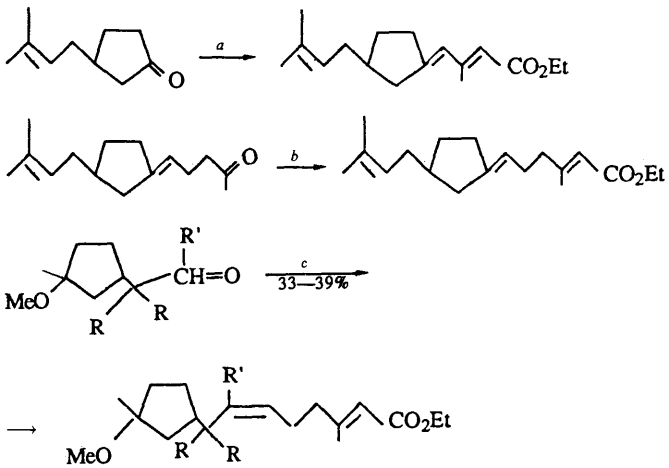
Scheme 72



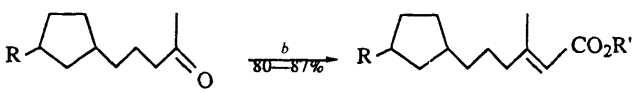
a: $CH_2I_2/Zn/CuO$; *b*: $(EtO)_2P(O)CH_2CO_2Et$; *c*: $CHCl_3/Et_3BuNCl^{\ominus}$; *d*: $EtO_2CCH_2N_2$.

A typical route for the synthesis of juvenoids containing a carbocyclic residue is the olefination of cyclic ketones or ketones and aldehydes containing a cyclic fragment in the carbon chain (Scheme 73).[222–232]

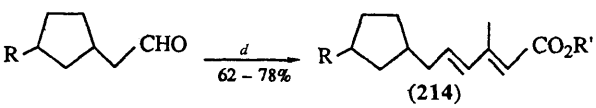
Scheme 73



R = H, Me; R' = H, Me;

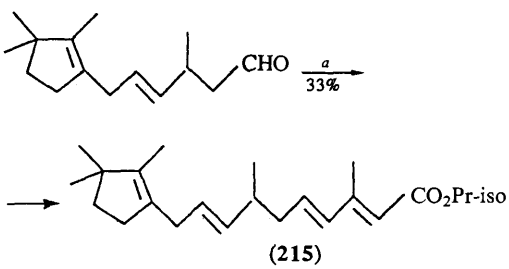


R = $CH(Me)_2$; $C(Me)_3$; $HOCMe_2$; R' = Et, $CHMe_2$;

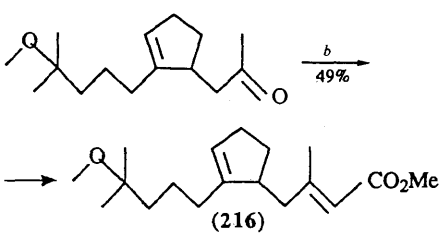


(214)

R = OAc, $MeC(OMe)-CH_2-CH_2$; R' = Et, Pr-iso;



(215)



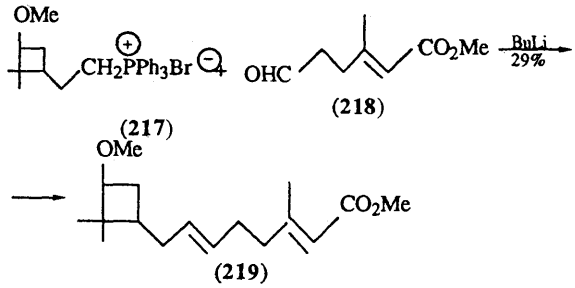
(216)

a: $(EtO)_2P(O)CHC(Me)=CHCO_2Et$, *b*: $(EtO)_2P(O)CHCO_2Et$;

c: Ph_3P  CO_2Et; *d*: $Br^{\ominus}(Ph_3)PC$ $CO_2R'/BuLi$

The juvenoid (**219**) was obtained by the reaction of the aldehyde (**218**) with the phosphonium salt (**217**) containing a cyclobutane residue (Scheme 74).[233]

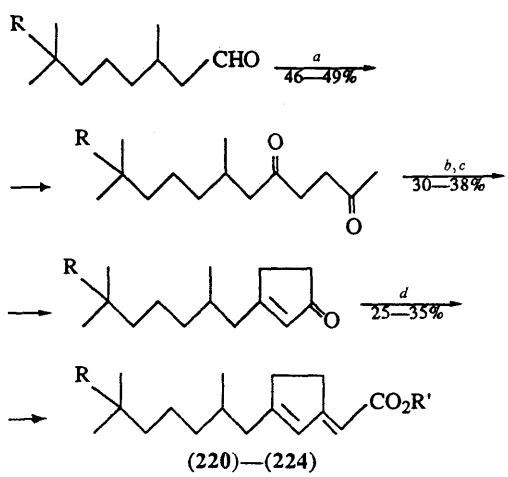
Scheme 74



It may be concluded from the existing literature data that AJH containing an alicyclic residue possess lower juvenoid activity than compounds without these fragments. The dienoates (**214**) do not have significant advantages over the unconjugated or α,β-unsaturated esters. The presence of a double bond in a cyclopentane ring does not increase biological activity [compounds (**215**), (**216**)]. Juvenoids containing cyclobutane rings proved to be selectively active towards *Tribolium costaneum*.[233,234]

The ethyl bridge between atoms C(3) and C(5) in the 2,4-dienoates (**220**)–(**224**) leads to high morphogenetic activity, two to three times greater than the activity of methoprene (**177**) and hydroprene (**174**) on the pupa of the Cabbage White butterfly (*Pieris brassicae*).[235–237] The methoxy derivatives of the 2,4-dienoates of this series are selectively active towards *Diptera*, while compounds without the methoxy group display higher activity towards *Lepidoptera* (Scheme 75).[236]

Scheme 75



(220)—(224)

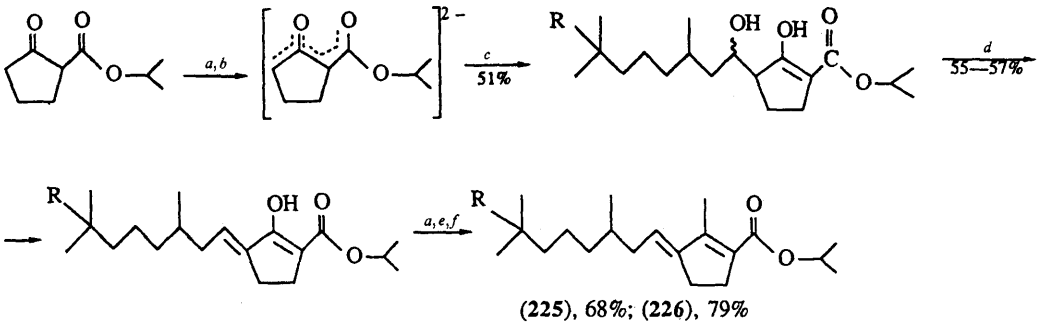
R = H (**220**), (**221**); OMe (**222**)—(**224**); R' = H (**220**), (**222**);

$CHMe_2$ (**221**), (**223**); $CH_2C{\equiv}CH$ (**224**);

a: $H_2C=CHC(O)Me/HO$  ; *b*: iso-$PrNH_2$; *c*: NaH;

d: $Me_3SiCH_2CO_2R'$ or $(R^1O)_2P(O)CH_2CO_2R^1$.

Scheme 76



(225), 68%; (226), 79%

R = H (225), OMe (226);

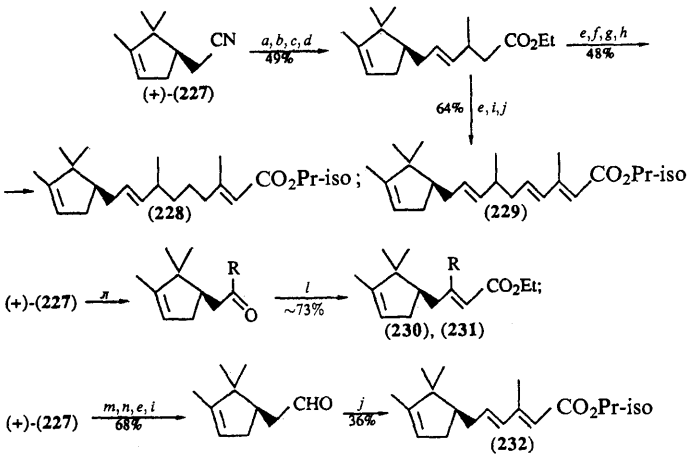
a: NaH; *b*: AlkLi; *c*:  ; *d*: HCl; *e*: Et_2PCl; *f*: $LiCuAlk_2$.

The following route is proposed for the synthesis of 2,4-dienoates (**225**) and (**226**) with an ethylene bridge between the C(2) and C(4) atoms (Scheme 76).[238]

The optically active compounds (**228**)–(**232**), obtained from (+)-1-cyanomethyl-2,2,3-trimethyl-3-cyclopentane (**227**), displayed higher juvenoid activity than the corresponding racemates (Scheme 77).[239,240]

Juvenoids of medium activity (**234**) and (**235**), containing a cyclobutane ring, were obtained by the partial ozonolysis of caryophyllene (**233**) (Scheme 78).[241]

Scheme 77



R = Me (230), Et (231);

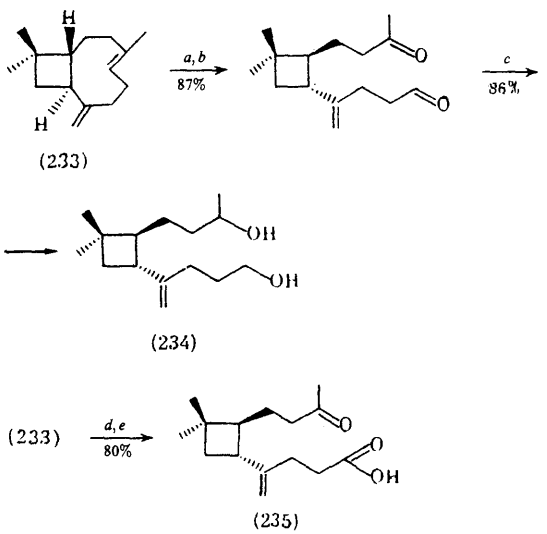
a: $CH_2=CHMgBr$; *b*: $Et_3N/EtOH$; *c*: iso-BuAlH; *d*: $MeC(OEt)_3$;

e: $LiAlH_4$; *f*: PBr_3; *g*: $AcCH(Na)CO_2Et$; *h*: $(EtO)_2P(O)\overset{\ominus}{C}HCO_2Pr$-iso;

i: $Py.CrO_3.HCl$; *j*: $(EtO)_2P(O)$  CO_2Pr-iso; *k*: RMgX;

l: $(EtO)_2P(O)\overset{\ominus}{C}HCO_2Et$; *m*: KOH/H_2O; *n*: TsOH/EtOH.

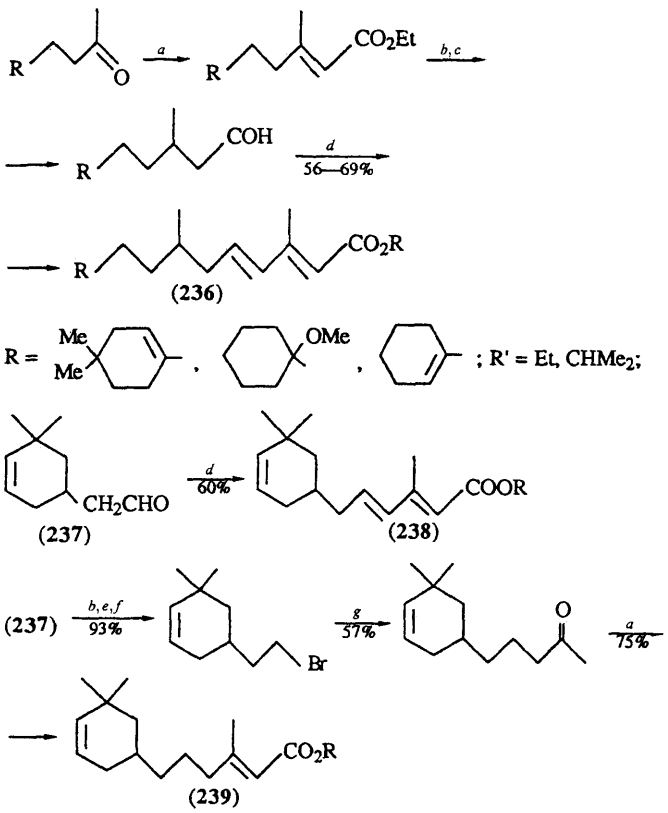
Scheme 78



a: O_3/MeOH; *b*: H_2/Pd.$CaCO_3$.PbO; *c*: $NaBH_4$; *d*: O_3/AcOH; *e*; AcOH/AcONa.

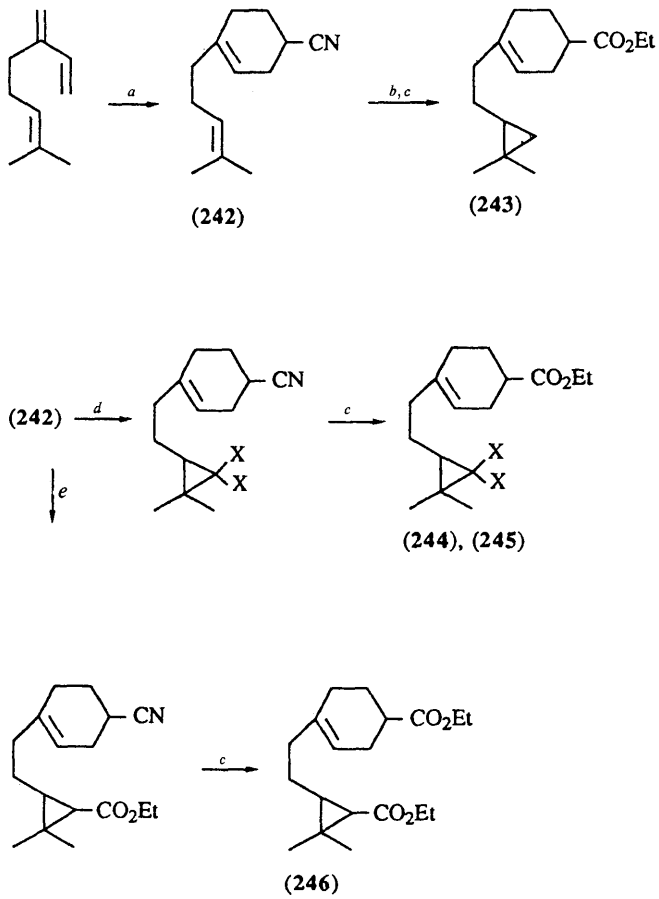
The juvenoids (**236**) with a six-membered ring, like the related compounds (**238**)–(**241**) obtained from the aldehyde (**237**), are not active towards the yellow meal worm and are ten times less active than their acyclic analogues towards *Dysdercus cingulatus* (Scheme 79).[123,217,242–245]

Scheme 79



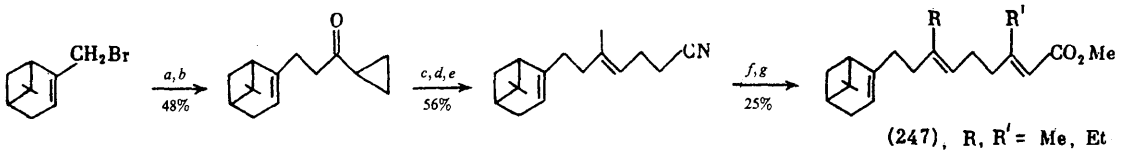
The compounds (**243**)–(**246**) obtained from compound (**242**) and containing cyclohexene and cyclopropane fragments proved to be active towards *Dysdercus koenigii* (Scheme 80).[246]

Scheme 80

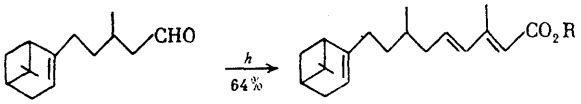


Several AJH have been synthesised with pinene (**247**) and (**248**) and norbornene (**249**) bicyclic fragments.[217,247–249] The AJH (**251**)–(**253**) were synthesised from camphene (**250**) (Scheme 81).

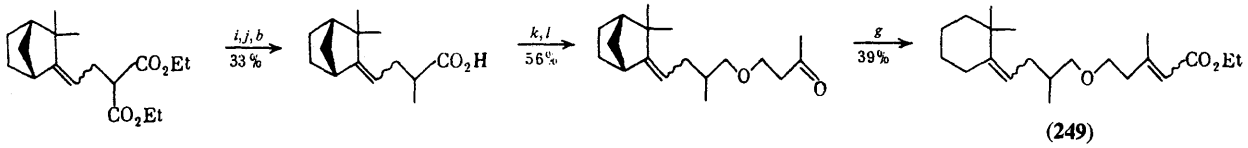
Scheme 81



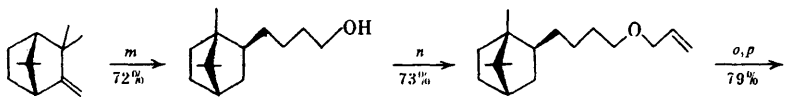
(247), R, R' = Me, Et



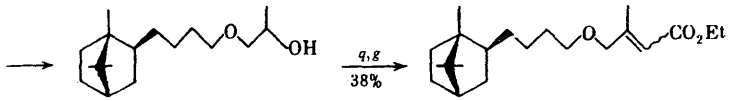
(248), R = Et, $CHMe_2$



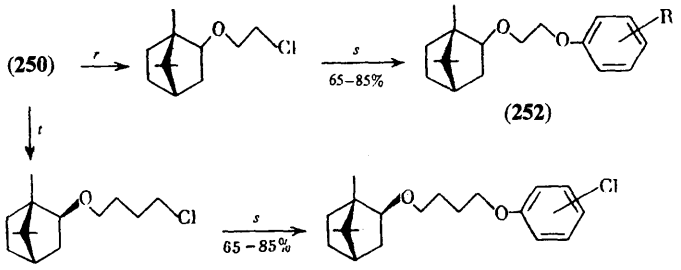
(249)



(250)



(251)



R = 4-Et; 2-iso-Pr; 2-Me; 4-iso-Pr; 2-Me; 4-Ac; 4-Cl; 4-Br; 2,4,6-Cl_3; 4-NO

a: $EtO_2CCH_2\overset{O}{\overset{\|}{C}}/EtONa$; *b*: Δ; *c*: RMgI; *d*: HBr; *e*: NaCN; *f*: R_1MgBr;

g: $(EtO)_2\overset{\ominus}{P}(O)CHCO_2Me$; *h*: $(EtO)_2\overset{\ominus}{P}(O)CH-C(CH_3)=CHCO_2R$;

i: Na/MeI; *j*: $OH^{\ominus}$; *k*: $LiAlH_4$; *l*; $CH_2=CH-C(O)-Me$;

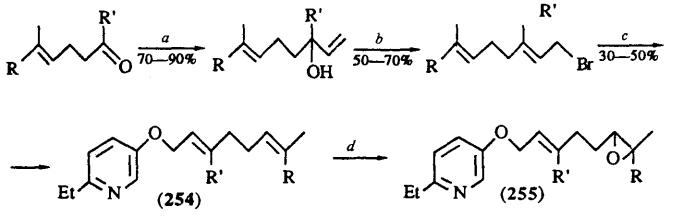
m: $HO(CH_2)_3OH/HClO_4$; *n*: $CH_2=CH-CH_2I$; *o*: $Hg(OAc)_2$;

p: $NaBH_4/OH^{\ominus}$; *q*: CrO_3/Py; *r*: $HO(CH_2)_2Cl/HClO_4$; *s*: 
t: $HO(CH_2)_4Cl/HClO_4$.

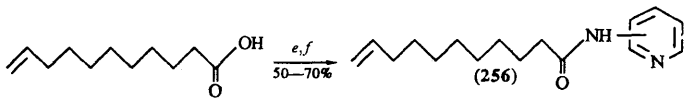
b) Juvenoids containing heterocycles

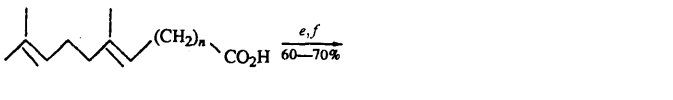
Compounds containing heterocycles have been investigated as AJH. The AJH (**254**)–(**257**) have been obtained with a pyridine ring in the molecule and also compound (**258**) containing a pyrrolidine ring as well (Scheme 82).[250–252]

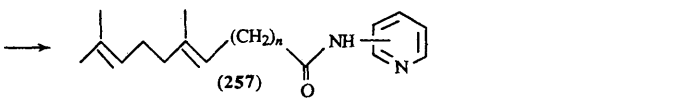
Scheme 82



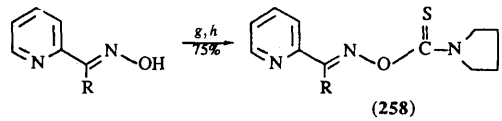
R = $Me(CH_2)_2$, $Me(CH_2)_3$; R' = Me, Et;







n = 0,1



R = Me, Me_2CH;

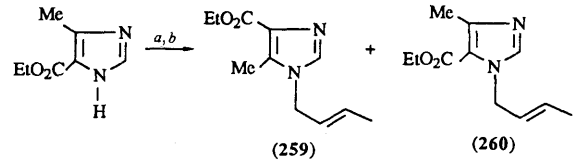
a: $CH_2=CHMgBr$; *b*: HBr; *c*:  ; *d*: $3\text{-}ClC_6H_4CO_3H$; *e*: $SOCl_2$;

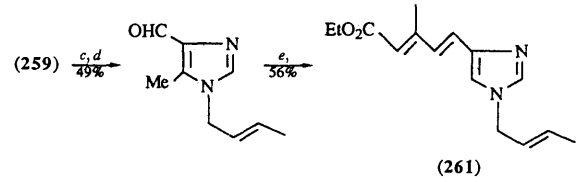
f: ; *g*: $CSCl_2/Et_3N$; *h*: .

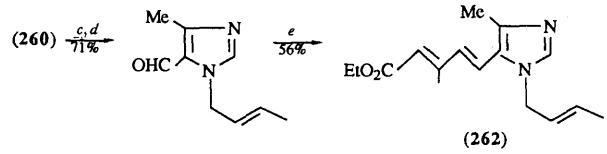
It was established that the introduction of a pyridine ring reduced JH activity significantly. A similar result was obtained for the imidazole derivatives (**261**) and (**262**) synthesised from compounds (**259**) and (**260**) (Scheme 83).[157,253]

Highly active AJH have been discovered among compounds (**263**)–(**266**) containing oxygen in the heterocycle and also for compounds (**267**) and (**268**) containing both nitrogen and oxygen in the rings (Scheme 84).[254,255]

Scheme 83

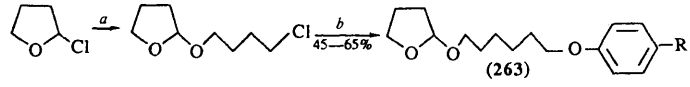




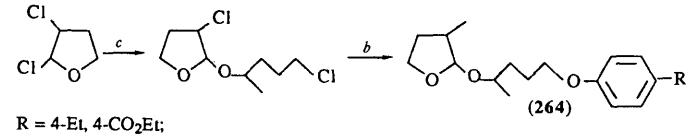


a: NaH; *b*: $Me_2C=CH-CH_2Cl$; *c*: $LiAlH_4$; *d*: MnO_2; *e*: $(EtO)_2-\overset{\ominus}{C}H.-C(Me)=CHCO_2Et$.

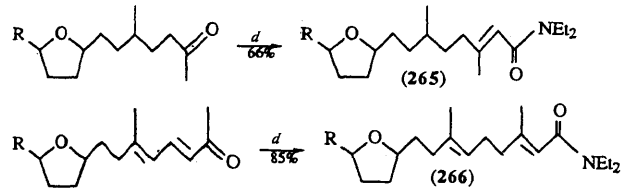
Scheme 84



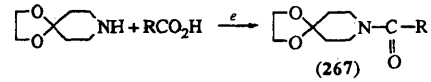
R = 4-H, 3-Me, 4-OMe, 4-SMe, 4-COMe, 4-COEt, 4-CO_2Me, 4-CO_2Et, 4-Cl, 4-NO_2.

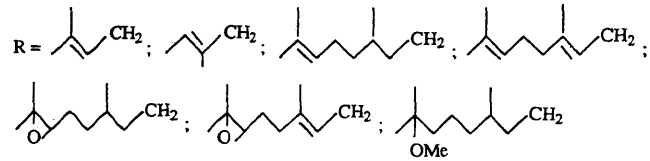


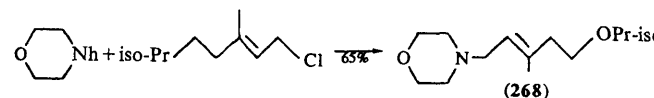
R = 4-Et, 4-CO_2Et;



R= H, Me;



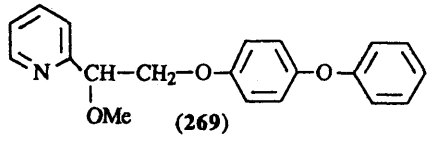




a: $HO(CH_2)_4Cl$; *b*: R-  ; *c*:  ; *d*: $(EtO)_2P(O)\overset{\ominus}{C}HCONEt_2$;

e: $Ph_2P(O)Cl$.

It turned out that the JH activity of compound (**269**) exceeded that of methoprene (**177**) in relation to *Aedes aegypti, Galleria mellonella, Tenebrio molitor* and *Musca domestica*.[256]

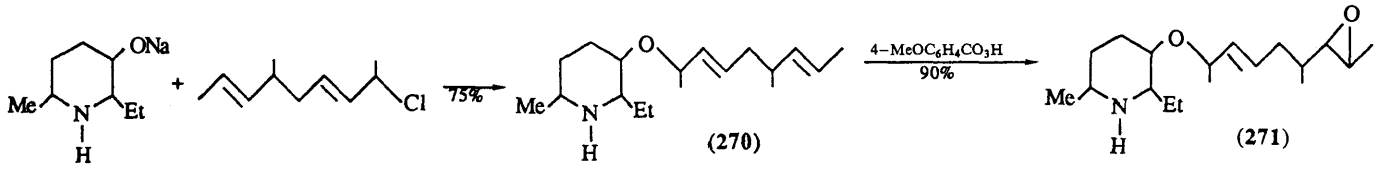


(**269**)

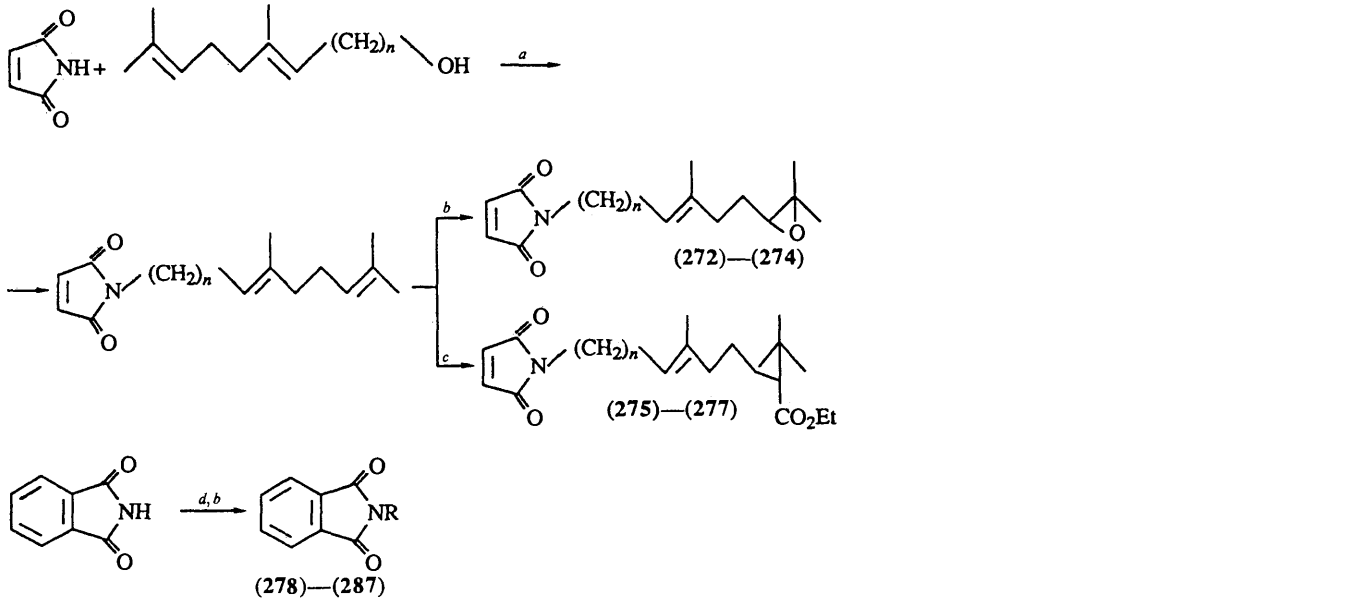
Oxa-AJH containing a piperidine ring (**270**) and (**271**) displayed selective activity towards *Coleoptera* (Scheme 85).[257]

Of the other AJH containing nitrogen heterocycles it is necessary to mention the derivatives of maleimide (**272**)–(**277**) and phthalimide (**278**)–(**287**).[258,259] Compounds (**278**)–(**287**) were tested for JH activity against *Dysdercus koenigii* and proved to be 1.5–2 times more active than methyl faranesenate (**152**). Compounds (**283**)–(**287**), containing an epoxy group in the isoprenoid group R, display higher activity (Scheme 86).

Scheme 85



Scheme 86

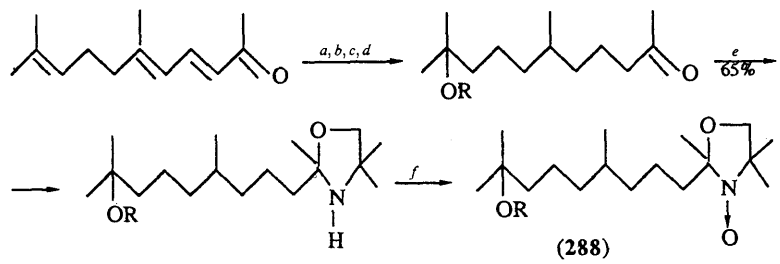


n = 1 (**272**), (**275**); 2 (**273**), (**276**); 3 (**274**), (**277**);

R =  (**278**), (**279**), (**280**), (**281**), (**282**), (**283**), (**284**), (**285**), (**286**), (**287**);

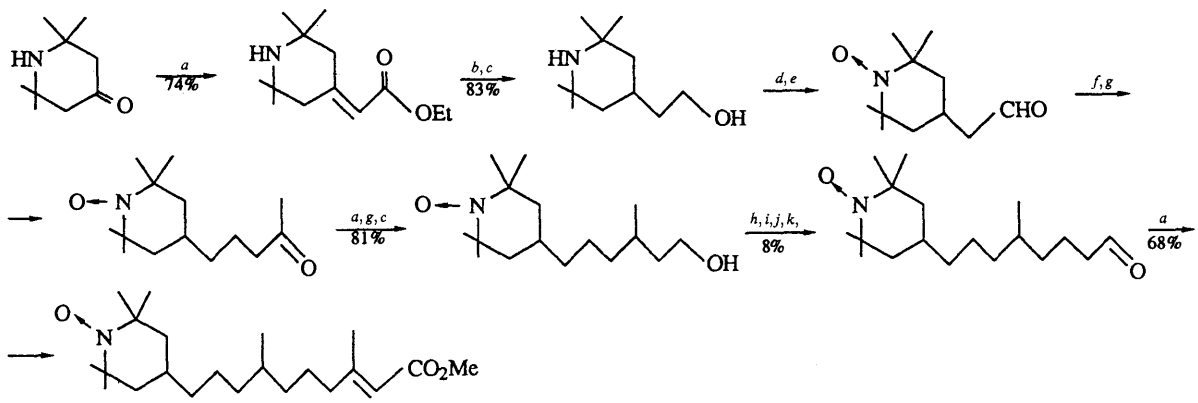
a: $PhP/N_2(CO_2Et)_2$; *b*: $3\text{-}ClC_6H_4CO_3H$; *c*: $N_2C(CO_2Et)_2$; *d*: ROH/PPh_3; $N_2(CO_2Et)_2$.

Scheme 87



(288)

R = Me, Et;
a: Ni–Re; *b*: $Hg(OAc)_2/ROH$; *c*: $NaOH/NaBH_4$; *d*: CrO_3; *e*: $Me(NH_2)_2C-CH_2OH$; *f*: $3\text{-}Cl-C_6H_4CO_3H$.

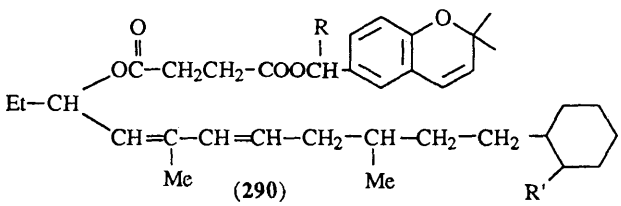


(289)

a: $(EtO)_2P(O)^{\ominus}CHCO_2Et$; *b*: $H_2/Ni-Re$; *c*: $LiAlH_4$; *d*: H_2O_2; *e*: CrO_3/Py; *f*: $Ph_3P=CHCH_2C(O)Me$; *g*: $H_2/Pd-BaSO_4$; *h*: TsCl/Py; *i*: NaI/. .acetone; *j*: $MeC(O)CH_2CO_2Et$; *k*: Δ.

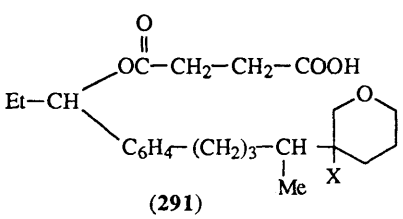
AJH with stable nitroxyl radicals in oxazolidine (**288**)[260] or piperidine (**289**)[261] rings have been synthesised and display high juvenoid activity (Scheme 87).[260,261]

The mixed succinic acid esters (**290**) and (**291**) proved to be active analogues of JH.[262,263]



(290)

R = Me, Et, Pr; R′ = H, Me, Et, Pr, iso-Pr:



(291)

X = H, Cl

To date, stereospecific methods of synthesising the natural juvenile hormones have been developed. Active analogues of the juvenile hormones, such as farnesal, methyl farnesenate, echinolone and juvabione, have been isolated from natural sources. The discovery in nature of JH analogues has stimulated investigation of the synthesis and study of the biological activity of compounds of various structures. Highly active juvenoids have become apparent in various classes of organic compounds. The most active juvenoids were found among the isoprenoid 2,4-dienoates and the aryl ethers of geraniol. The search for highly active and readily available JH analogues has been actively pursued since juvenoids are already recommended as effective and ecologically safe agents for regulating the insect population and an extension of their use for this purpose must be expected.

The chemistry of perfluoroalkyl-substituted dicyanoethylenes

A V Fokin, V Yu Tyutin, N D Chkanikov
A N Nesmeyanov Institute of Heteroorganic Compounds, Russian Academy of Sciences

ABSTRACT. Fundamental data on the means of obtaining and on the reactivity of perfluoroalkyl-substituted dicyanoethylenes are correlated. The principal ways of using these compounds in organic synthesis are shown. Examples are given of the practical application of perfluoroalkyl-substituted dicyanoethylenes and of the compounds derived from them.

The bibliography contains 72 references.

I. Introduction

The needs of medicine, agriculture and various modern technologies for new organic compounds possessing specific properties have enabled organofluorine chemistry to be integrated into organic chemistry in recent years. An important route for such an amalgamation is the use of synthons, which contain a perfluoroalkyl group at a multiple bond, in syntheses of organic compounds of more complex structure modified by perfluoroalkyl groups.[1] Direct analogy with reactions of unfluorinated unsaturated compounds usually fails since the presence of a perfluoroalkyl group at a multiple bond significantly affects reactivity. The present review considers the features of the chemical behaviour of perfluoroalkyl-substituted dicyanoethylenes in traditional conversions of organic synthesis.

Perfluoroalkyl-substituted dicyanoethylenes combine the properties of perfluoro-olefins,[2] polyfluorocarbonyl compounds[3,4] and their acylimines,[5] and also unfluorinated polycyanoethylenes,[6,7] the chemistry of which is widely represented in appropriate reviews. The chemistry of fluorine-containing dicyanoethylenes has not been reviewed. By filling this gap the authors hope that their work will enable bridges to be built between organofluorine chemistry and classical organic synthesis.

II. Methods of synthesis of perfluoroalkyl-substituted dicyanoethylenes

Three basic methods exist for the synthesis of fluorine-containing dicyanoethylenes. The first method described for obtaining 1,2-dicyano-1,2-bis(trifluoromethyl)ethylenes (Ia, b) and their analogues was the pyrolysis of chlorosulphite derivatives of perfluoroalkyl- and fluorohaloalkyl-cyanomethanes in the presence of sulphur.[8]

$$R_F(NC)CH-OSOCl \xrightarrow{200-800^\circ C} R_F(NC)C{=}C(R_F)CN \quad (Ia, b)$$

This method is similar to the preparation of tetracyanoethylene by chlorination–dehydrochlorination of dicyanomethane.[9] The mechanism probably includes the formation of appropriate intermediates of the carbene type in both cases. Dimerisation of these intermediates leads to the ethylene derivative. In the pyrolysis of the chlorosulphite derivative of (trifluoromethyl)cyanomethane a mixture is formed of the *cis*- and *trans*-1,2-dicyano-1,2-bis(trifluoromethyl)ethylenes (Ia, b), the quantitative ratio of which is not reported. The isomeric mixture may be separated by GLC. The *cis*-isomer (Ia) is transformed readily into *trans*-1,2-dicyano-1,2-bis(trifluoromethyl)ethylene (Ib) by treatment with triethylamine.[10]

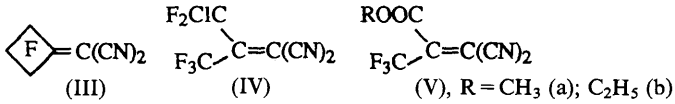
The synthesis of the initial chlorosulphite derivatives[8,10] was effected in the following way:

$$CF_3CH(OH)_2 \xrightarrow{P_2O_5/H_2SO_4} CF_3CHO \xrightarrow[C_5H_5N]{HCN} CF_3CH(CN)-OH \xrightarrow{SOCl_2} CF_3CH(CN)-OSOCl$$

The second method is based on the use of the Knoevenagel reaction under somehat modified conditions. Dicyanomethane and perfluoro- or fluorohaloketones are condensed in the presence of catalytic quantities of zinc chloride. The resulting alcohol is dehydrated with phosphorous pentoxide in the liquid phase or by passing the vapour over silica gel at 100–300 °C.[11–16] For example, the condensation of dicyanomethane and hexafluoroacetone with subsequent dehydration of the adduct with P_2O_5 leads to 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) in 50% yield.[14]

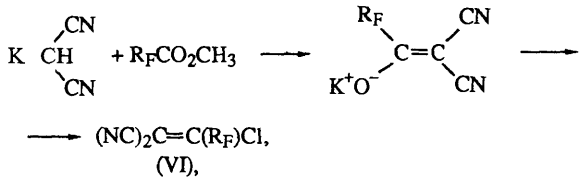
$$CH_2(CN)_2 + F_3CC(O)CF_3 \xrightarrow{ZnCl_2} H-C(CN)_2-C(CF_3)_2-OH \xrightarrow{P_2O_5} (NC)_2C{=}C(CF_3)_2 \quad (II)$$

The corresponding fluorine-containing ylidenedicyanomethanes were obtained in a similar manner from perfluorocyclobutanone[13] and chloropentafluoroacetone,[15,16] and from the methyl (Va) and ethyl (Vb) esters of trifluoropyruvic acid (III, IV, Va, b).[17]



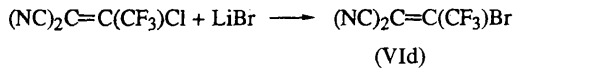
(III) (IV) (V), R = CH_3 (a); C_2H_5 (b)

At the beginning of the eighties a method was proposed for the synthesis of fluorine-containing ylidenedicyanomethanes by condensing the potassium or sodium salts of dicyanomethane with esters of perfluorocarboxylic acids with subsequent treatment of the salts of β,β-dicyano-α-(perfluoroalkyl)vinyl alcohol with phosphorus pentachloride.[13,18,19]



$R_F = CF_3$ (a), C_2F_5 (b), n-C_3H_7 (c)

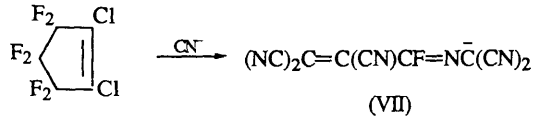
The yield of olefins (VIa–c) is increased on using $PhPCl_4$ as chlorinating agent.[19] The corresponding bromoolefin (VId) was obtained from 2-chloro-1,1-dicyano-2-(trifluoromethyl)ethylene by heating with anhydrous lithium bromide to 120 °C.[16]



(VId)

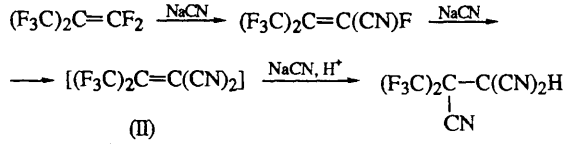
The method described for obtaining fluorine-containing ylidenedicyanomethanes has been used successfully to synthesise analogues of them containing CO_2R or CF_3 groups.[19]

While considering methods of synthesising fluorine-containing dicyanoethylenes it is impossible not to mention reactions involving the substitution of vinylic halogen atoms in perfluoroolefins and fluorohaloolefins by cyano groups. Thus the reaction of 1,2-dichloropentafluorocyclopentene with sodium cyanide leads to the formation of the 1,1,4,5,5-pentacyano-3-fluoro-2-azapentadiene anion (VII).[20]



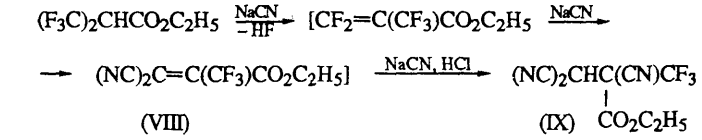
(VII)

Replacement of a vinylic fluorine by a cyano group is readily achieved in the reaction of perfluoroisobutene with sodium cyanide, though the resulting nitrile is able to react further with NaCN. It is suggested that the intermediate is 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II).[2,21]



(II)

The reaction of NaCN with hexafluoro-2-hydroisobutyric acid ethyl ester leads to 2,3,3-tricyano-2-(trifluoromethyl)propionic acid ethyl ester (IX). In this case 3,3-dicyano-2-trifluoromethyl)acrylic acid ethyl ester (VIII) is probably one of the intermediates.[21]



(VIII) (IX)

III. π-Complexes of perfluoroalkyl-substituted dicyanoethylenes with aromatic compounds

All the olefins considered form intensely coloured solutions on mixing with aromatic compounds or other π-bases. This colour indicates the formation of π-complexes which are characterised by intense absorption in the visible or near ultraviolet regions. The absorption maxima of complexes do not belong to either of the reactants and are attributed to a new molecular form. Several complexes, their absorption maxima and extinction coefficients (ε) are shown in Table 1.[14]

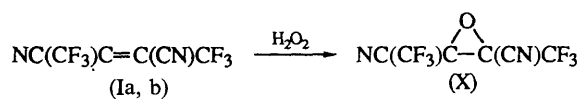
Table 1. π-Complexes of dicyanoolefins (II, III)

π-Base	π-Acid			
	(II)		(III)	
	λ, nm	ε	λ, nm	ε
Pyrene	500	3670	580	1930
Durene	386	2520	423	2430
Hexamethylbenzene	445	1060	497	1040
Benzene	316	1950	334	2170
Toluene	327	1720	358	1720

Footnote. Solvent CH_2Cl_2, temperature 24 °C.

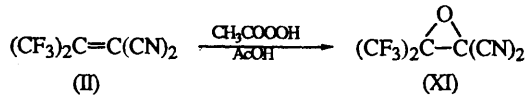
IV. Oxidation–reduction reactions of perfluoroalkyl-substituted dicyanoethylenes

1,2-Dicyano-1,2-bis(trifluoromethyl)ethylene (Ia, b) react with hydrogen peroxide with the formation of the 2,3-dicyano-2,3-bis(trifluoromethyl)oxiranes (X).[10]



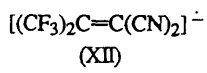
(Ia, b) (X)

Like alkenes (Ia, b), 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) and its analogues are oxidised by hydrogen peroxide or peracids to 2,2-dicyano-3,3-bis(trifluoromethyl)oxirane (XI) and its perhaloalkyl derivatives.[12,13]



(II) (XI)

Alkene (II) forms the anion radical of 1,1,-dicyano-2,2-bis(trifluoromethyl)ethylene (XII) on electrochemical reduction in dimethylformamide at 20 °C.

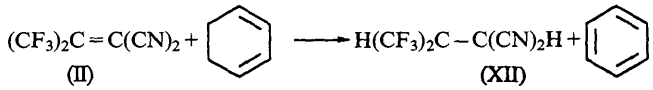


(XII)

The ESR spectrum of this anion-radical has been investigated.[22,23]

The corresponding anion-radical was obtained from *trans*-1,2-dicyano-1,2-bis(trifluoromethyl)ethylene (Ib).[22,23] The electron affinities of (Ia, b) have been estimated on the basis of experimental ionisation potentials and their photoelectron spectra were studied.[24]

1,1-Dicyano-2,2-bis(trifluoromethyl)ethylene (II) may be reduced with cyclohexadiene to the corresponding ethane derivative (XIII).[16] No traces of the [4 + 2] cyclic adduct were detected.



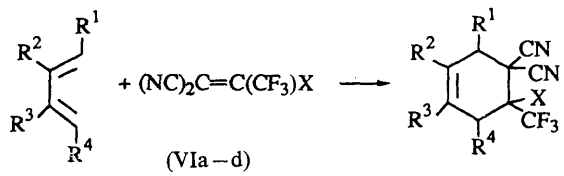
(II) (XII)

Hydrazobenzene is oxidised by alkene (II) to azobenzene.[25] Probably 1,1-dicyano-2,2-bis(trifluoromethyl)ethane (XIII) is formed in this case however it was not isolated from the reaction mixture. The dicyanoethylenes (Va, b), like the alkene (II), react with hydrazobenzene.[17]

V. Cycloaddition reactions of perfluoroalkyl-substituted dicyanoethylenes

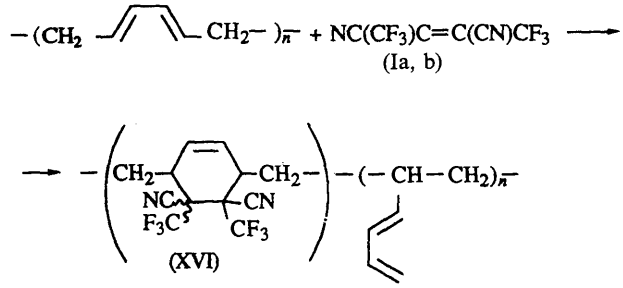
1. The Diels–Alder reaction ([4 + 2] cycloaddition)

Fluorine-containing dicyanoethylenes are reactive dienophiles in the Diels–Alder reaction. 1,1-Dicyano-2,2-bis(trifluoromethyl)-ethylene (II), 1,1-dicyano-2-(trifluoromethyl)-2-(chlorodifluoromethyl)ethylene (IV) and 1,1-dicyano-2-halo-(perfluoroalkyl)-ethylenes (VIa–d) react with 1,3-butadiene, 2,3-dimethylbutadiene, isoprene and several other linear dienes at 0–25 °C with or without a solvent giving [4 + 2] cycloaddition products (XV) in high yield.[14,16,26,27]

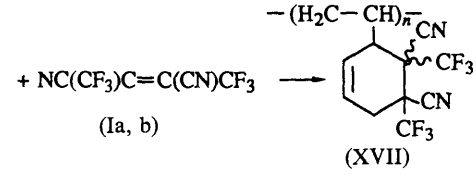


(VIa–d) (XV)

This reaction was used for the modification of various polymers of trienes. For example, polymers of 1,3,5-hexatriene, 1,3,5-heptatriene and 2,4,6-octatriene containing conjugated diene groups were modified using the Diels–Alder reaction with 1,2-dicyano-1,2-bis(trifluoromethyl)ethylene) Ia, b) at 25–80 °C in solution in benzene, toluene or tetrahydrofuran.[28,29] It was established that cyclic structures were formed in the main chain (XVI) or in the side chains (XVII) of the polymers. The conversion was from 10 to 75%.

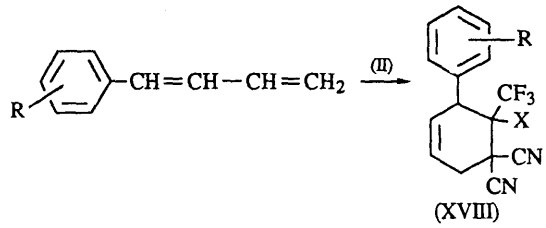


(Ia, b) (XVI)



(Ia, b) (XVII)

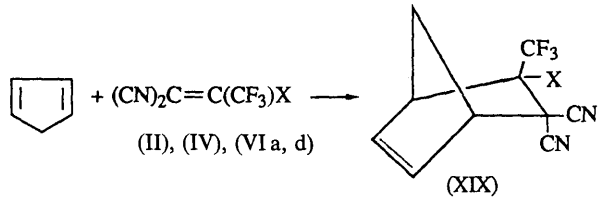
A systematic study has been made of the [4 + 2] cycloaddition reactions of alkene (II) and *trans*-1-arylbutadienes leading to the cyclohexane derivatives (XVIII).[26,27]



(XVIII)

R = *p*-$N(CH_3)_2$, *p*-OCH_3, *p*-CH_3, H, *m*-F, *m*-Cl, *m*-CF_3, *m*-NO_2

A comparison has been carried out of the relative reaction rates of various fluorine-containing dicyanoethylenes with cyclopentadiene leading to a [4 + 2] cycloaddition product (XIX).[16]

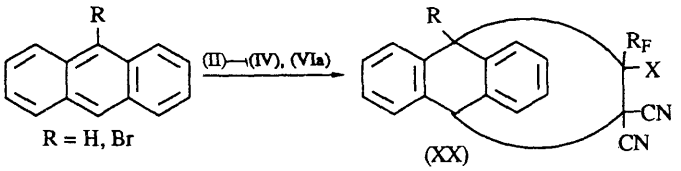


(II), (IV), (VI a, d) (XIX)

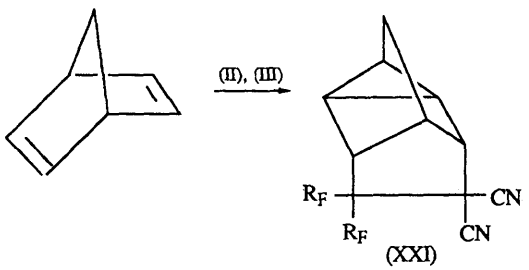
The reactivity decreases in the series $(CF_3)_2C{=}C(CN)_2$ (II) > $(CF_3)(CF_2Cl)C{=}C(CN)_2$ (IV) > $(CF_3)ClC{=}C(CN)_2$ (VIa) > $(CF_3)BrC{=}C(CN)_2$ (VId). All the alkenes considered are less reactive than tetracyanoethylene.[30]

Anthracene and certain of its derivatives may act as dienes. Dicyanomethylenehexafluorocyclobutane (III) reacts with anthracene in benzene at room temperature forming the adduct (XX) after a few minutes.[14] The reaction conditions are more forcing for alkenes (II),

(IV) and (VIa).[14,16] A temperature of 100 °C is required to form cyclic adducts with 9-bromoanthracene.[16]

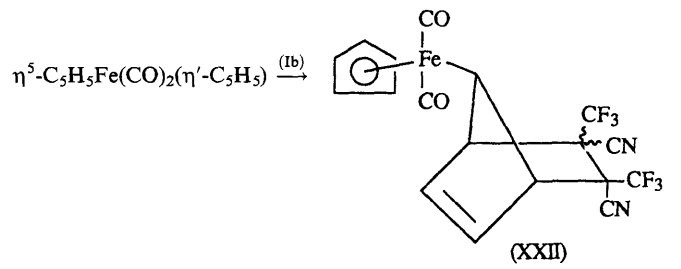


The alkenes (II) and (III) are reactive dienophiles in homo-Diels–Alder reactions.[14] Thus 1,1-dicyano-2,2-bis(trifluoromethyl)-ethylene (II) gives the cyclic adduct (XXI) with norbornadiene even at room temperature. The reaction is complete in approximately three hours, which is significantly less than for the analogous reaction of tetracyanoethylene.[31]

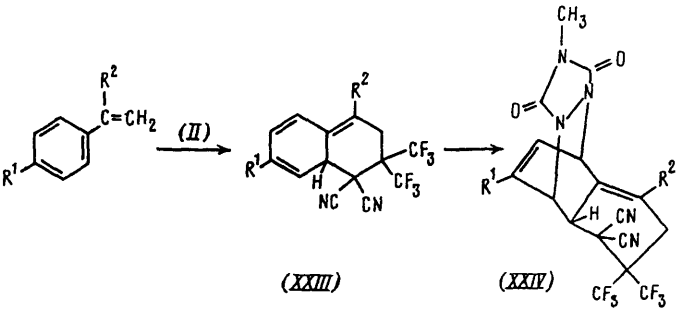


The high reactivity of the alkenes (II) and (III) compared with tetracyanoethylene in the reaction with norbornadiene is explained by their more readily polarisability and the possibility of forming an intermediate or transition state with a larger charge separation.[14]

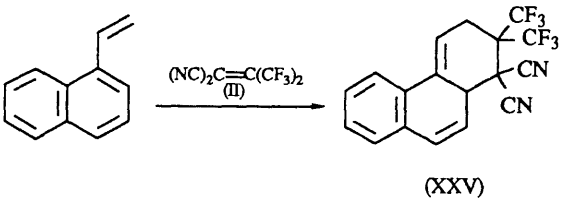
The diene system may be part of an unsaturated hydrocarbon ligand in a transition metal complex. The reaction of η^5-$C_5H_5Fe(CO_2)(\eta'$-$C_5H_5)$ with *trans*-1,2-dicyano-1,2-bis(trifluoromethyl)ethylene (Ib) leads to the 1:1 adduct (XXII) containing a norbornyl ring.[32]



Reactions of [4 + 2] cycloaddition have been reported in which the aromatic benzene nucleus acts as part of a diene system.[33,34] Derivatives of styrene and 1,1-dicyano-2,2-bis(trifluoromethyl)-ethylene (II) are subject to a reversible Diels–Alder reaction. The nonaromatic adduct (XXIII) was isolated and was in its turn the substrate in a [4 + 2] cycloaddition reaction with *N*-methyl-triazolinedione leading to the tricyclic product (XXIV).



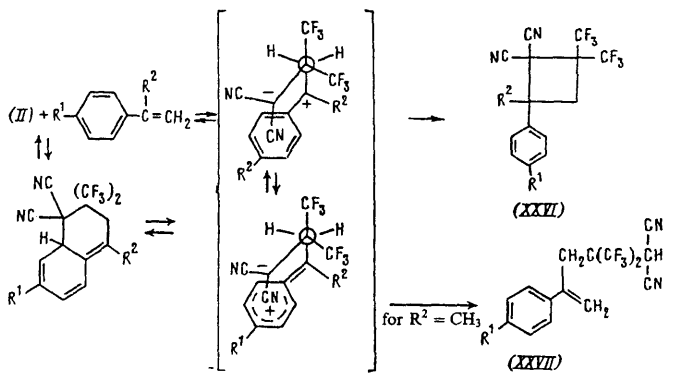
The effects of substituents R^1 and R^2 and the influence of solvent polarity on the reaction rate are in agreement with a synchronous reaction mechanism.[34] It was noted that if part of the initial diene is a naphthalene system then the cycloaddition product (XXV) is stable and the Diels–Alder reaction is irreversible.[34]



(XXV)

This phenomenon is due to the lower loss of resonance energy by the naphthalene system compared with benzene.

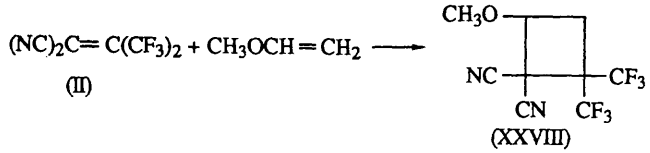
In a detailed study of the conversions occurring in the styrene—1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) system it was shown that at 20 °C a slow irreversible reaction forming the cyclobutane derivatives (XXVI), i.e. a [2 + 2] cycloaddition, competes with the rapid reversible Diels–Alder cycloaddition. Products (XXVII) of the ene reaction were also detected. The overall scheme of these conversions is as follows.[33]



2. [2 + 2] Cycloaddition reactions

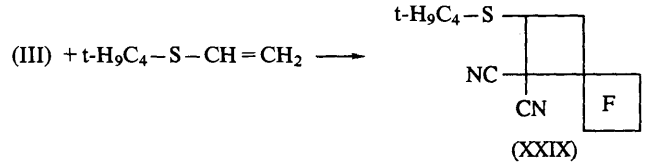
The formation of cyclobutane derivatives together with Diels–Alder reaction products was recorded on reacting the alkene (II) with 1-chloro-1,3-butadiene,[16] 1,1-diarylbutadiene[26] and 1-aryl-1,3-butadiene.[26,27] In the case of 1,1-diarylbutadiene the [2 + 2]

cycloaddition product was the main product.[35] The [2 + 2] cycloaddition reaction with olefins occupies a special place in the chemistry of fluorine-containing dicyanoethylenes as they are often effected under exceptionally mild conditions.[14] Thus 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) reacts practically instantaneously with methyl vinyl ether even at −78 °C forming 1,1-dicyano-2,2-bis-(trifluoromethyl)-4-methoxycyclobutane (XXVIII) in 87% yield.



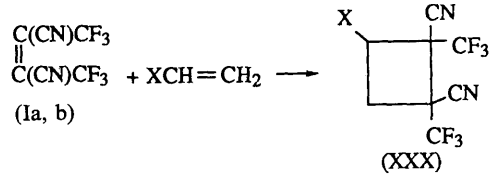
(XXVIII)

The alkene (II) gives a cyclic adduct of type (XXVI) after a few minutes with styrene, 4-methoxystyrene and α-methylstyrene at 0 °C in solvents such as pentane or carbon tetrachloride. No formation of Diels–Alder reaction products is observed at reduced temperatures.[11–14] Under the same conditions t-butyl vinyl sulphide and α-methylstyrene react with dicyanomethylenehexafluorocyclobutane (III) forming the corresponding spiro derivatives of cyclobutane, such as (XXIX).



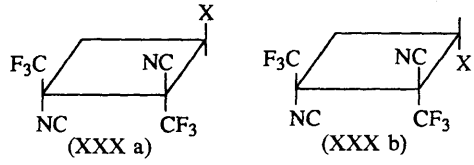
(XXIX)

The stereochemistry of the [2 + 2] cycloadditions of *cis*- and *trans*-1,2-dicyano-1,2-bis(trifluoromethyl)ethylenes (Ia) and (Ib) has been studied.[36] It was found that these alkenes react at room temperature with alkyl vinyl ethers, alkyl vinyl sulphides and 4-alkoxystyrenes forming the cyclobutanes (XXX). The solvent polarity exerts a strong effect on the reaction rate.

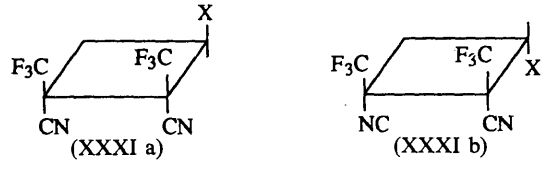


(XXX)

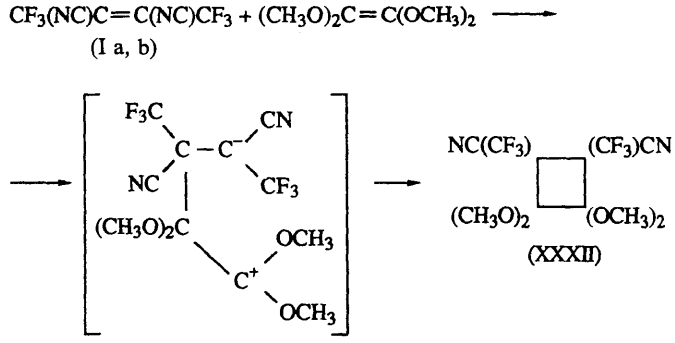
The reaction of (Ib) with the above olefins is stereoselective in the absence of solvent and gives exclusively the cyclobutane diastereomers (XXXa, b).



The corresponding reaction of the *cis* isomer (Ia) leads to the diastereomers (XXXIa, b).

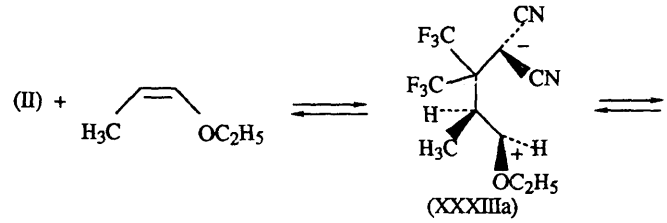


The [2 + 2] cycloaddition of 1,2-dicyano-1,2-bis(trifluoromethyl)-ethylenes (Ia, b) with tetramethoxyethylene has been studied and a zwitterionic mechanism has been proposed for the formation of the adducts (XXXII).[37]

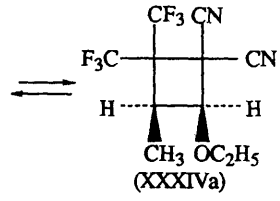


(XXXII)

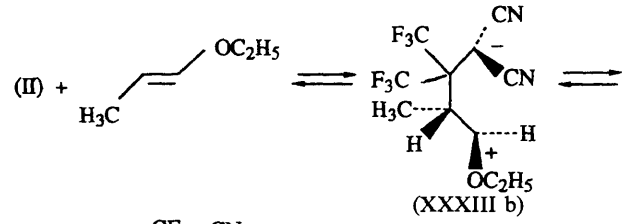
The features and mechanism of the [2 + 2] cycloaddition of 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) and alkyl vinyl ethers has been studied in detail by Huisgen and Bruckner.[38] It was found that the cyclobutane derivatives (XXXIV) are formed through a 1,4-dipolar intermediate which was trapped by reaction with ethanol or acetic acid. No regioisomer (XXXIV) was recorded on NMR investigation of the reaction products. Since the cyano groups stabilise the negative charge better than the trifluoromethyl groups in the 1,4-dipolar intermediate (XXXIII) and the reaction of *cis*- and *trans*-1-ethoxypropene with (II) is not stereospecific, the following [2 + 2] cycloaddition mechanism is proposed.



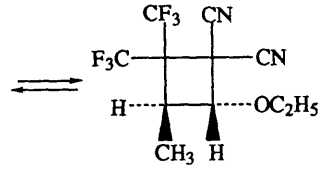
(XXXIIIa)



(XXXIVa)



(XXXIII b)



(XXXIV b)

The reaction of the cyclobutanes (XXIVa, b) with ethanol (2 d, 20 °C) leads to the acetal (XXXV).[38,39]

$$\text{(XXXIV a or b)} \xrightarrow{C_2H_5OH} H(CN)_2C-C(CF_3)_2-CH_2CH(OC_2H_5)_2$$

(XXXV)

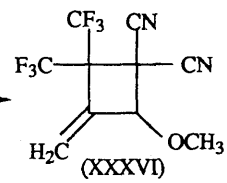
This result is a consequence of the equilibrium (XXXIII) ⇄ (XXXIV). A similar trapping of the 1,4-dipole also occurs on reaction with acetic acid.

A study of the kinetics of the reaction of (II) with ethyl vinyl ether showed the marked effect of solvent polarity on the reaction rate.[35] The rate constants are increased on introducing donor substituents into the α-position of the ethyl vinyl ether while a β-methyl group leads to the opposite effect, probably due to the increased role of steric factors.

Olefins having a cumulative diene system also readily undergo [2 + 2] cycloaddition. For example, 1-methoxy-1,2-propadiene reacts with the alkene (II) leading to the adduct (XXXVI) with an exocyclic double bond.[35]

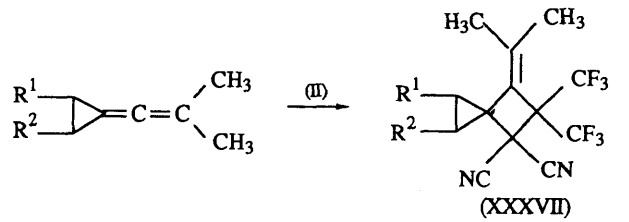
$$H_2C{=}C{=}CHOCH_3 + (NC)_2C{=}C(CF_3)_2 \longrightarrow$$

(II)



(XXXVI)

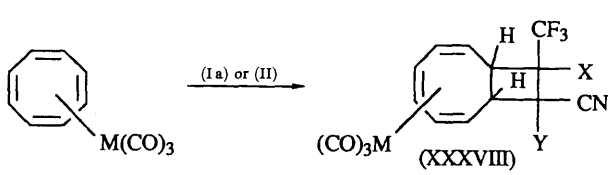
Similar results were obtained for the reaction of 1-(2-methylpropylidene)-2-phenylcyclopropane and 7-(2-methylpropenylidene)-bicyclo[4,1,0]heptane with 1,1-dicyano-2,2-bis(trifluoromethyl)-ethylene (II). In the first case (R^1 = C_6H_5, R^2 = H) an isomeric mixture of the cyclic adducts (XXXVII) is formed.[40]



(XXXVII)

A radical mechanism has been proposed for cycloaddition reactions of cumulene systems with the dicyanoethylene (II).[41] The retention of the cyclopropane ring, indicating the formation of a phenylcyclopropenyl radical which undergoes ring fission with more difficulty than a phenylcyclopropenyl cation, points in favour of this mechanism.

As with the Diels–Alder reaction the [2 + 2] cycloaddition of fluorine-containing dicyanoethylenes may occur with an unsaturated hydrocarbon ligand in a transition metal complex. Thus alkanes (Ib) and (II) react with tricarbonylcyclooctatetraeneruthenium and iron forming adducts of composition 1 : 1 which are assigned the structure (XXXVIII) on the basis of ^1H and ^{19}F NMR spectral data.[41]

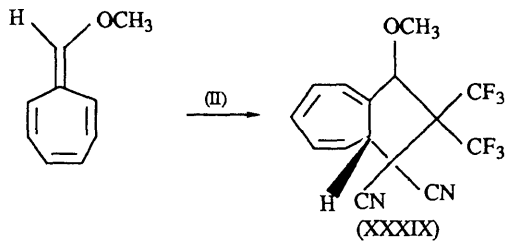


(XXXVIII)

By comparing the reactivity of the alkanes (Ia, b) and (II), (III) with the reactivity of tetracyanoethylene (TCE)[42,43] in reactions occurring by the zwitterionic mechanism, it may be concluded that reactivity decreases in the series (III) > (II) > (TCE) > (Ia, b). Middleton[14] explains the higher reactivity of (II) and (III) compared to TCE and (Ia, b) by their higher polarisability and greater inclination towards the formation of polar intermediates.

3. Other cycloaddition reactions of perfluoroalkyl substituted dicyanoethylenes

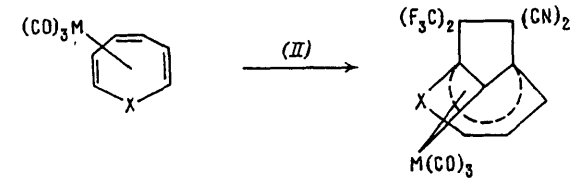
It is known that heptafulvenes with electron-donating substituents may react with fluorine-containing dicyanoethylenes according to an [8 + 2] cycloaddtion. For example, 8-methoxyfulvene and 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) give the cyclic adduct (XXXIX).[44]



(XXXIX)

The reaction is regiospecific and leads to a diastereomeric mixture of hydroazulenes (XXXIX).[44]

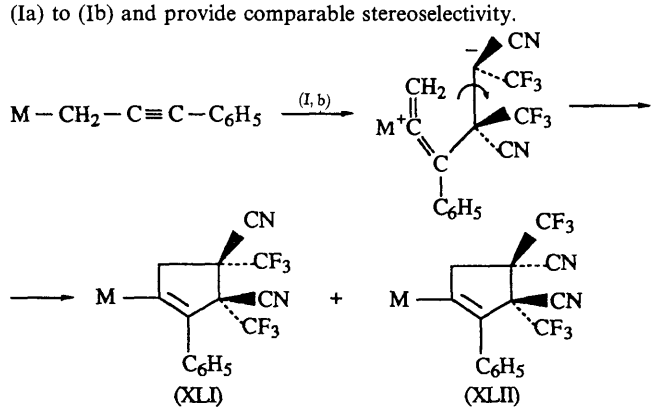
The *exo*-1,3-cyclic adducts (XL) of alkene (II) and tricarbonyl-(η-cycloheptа-2,4,6-trien-1-one) iron and tricarbonyl(η-*N*-methoxy-carbonyl-1H-azepines) iron or ruthenium have been described.[45]



M = Ru, Fe; X = CH_2, NCO_2CH_3 (XL)

A zwitterionic mechanism is proposed for this reaction.

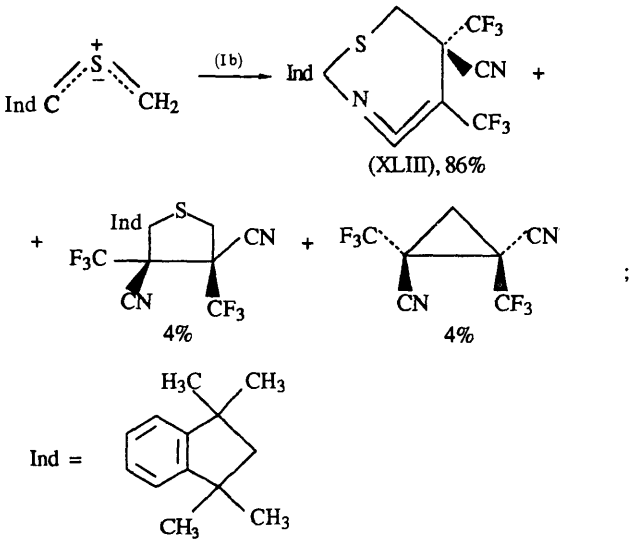
Another example of the cycloaddition of the alkenes (Ia, b) to the unsaturated hydrocarbon ligand of a transition metal complex is the reaction of η^5-$C_6H_5Fe(CO)_2CH_2C{\equiv}CC_6H_5$ with (Ib) in benzene at 20 °C. This leads to compounds (XLI) and (XLII) with 75% regioselectivity.[46] The analogous reactions for the *cis*-isomer (Ia), at least partially if not completely, occur through the isomerisation of (Ia) to (Ib) and provide comparable stereoselectivity.



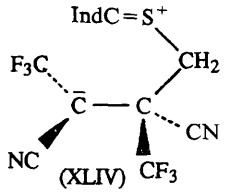
(XLI) (XLII)

M = η^5-$C_5H_5Fe(CO)_2$, $Mn(CO)_5$, $Re(CO)_5$

The [3 + 4] cycloaddition of 1,1,3,3-tetramethylindane-2-thione *S*-methylide and 2,3-bis(trifluoromethyl)fumaronitrile leading to the ketenimine (XLIII) has been studied by Huisgen and collaborators.[47]

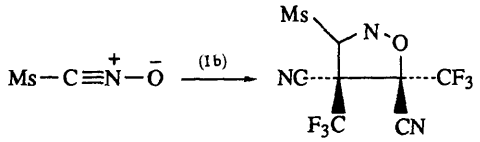


The zwitterion (XLIV) is the probable intermediate.



Similar results are obtained for the cycloadditions of (Ia) and other sulphur methylides.[48]

The mechanism of the 1,3-dipolar cycloaddition of nitrile oxides to the *trans* isomer of alkene (Ib) was studied.[49]

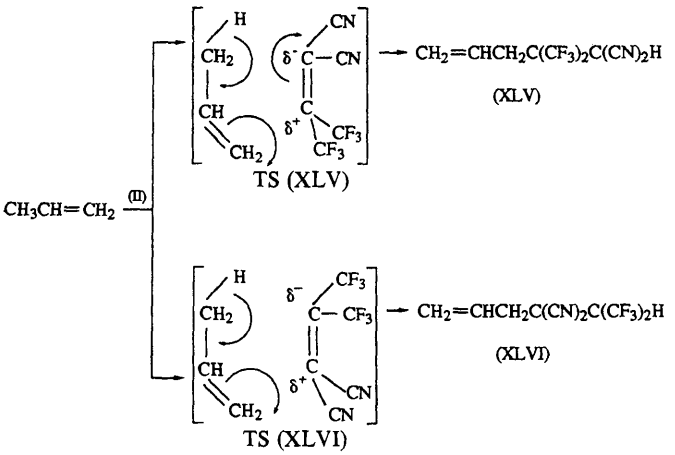


This reaction occurs stereospecifically according to a synchronous cycloaddition mechanism.

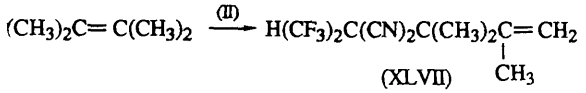
In concluding this section mention must be made of the attempts at computer prediction of the spatial structure of the products of the six-electron cycloaddition of electron-deficient alkenes, such as (Ib), to various olefins.[50]

VI. Reactions of perfluoroalkyl-substituted dicyanoethylenes with olefins involving the allylic hydrogen

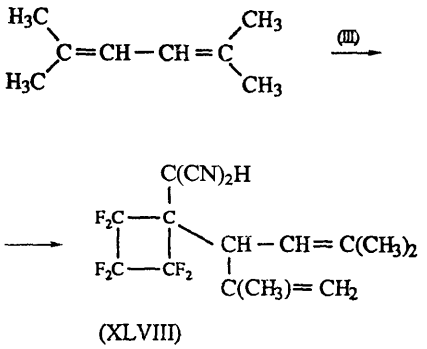
Unactivated olefins which contain an allylic hydrogen atom enter into ene reactions with alkenes (II) and (III). For example, 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) gives a mixture of isomeric adducts (XLVI) and (XLVII) on reaction with propylene at 150 °C.[14]



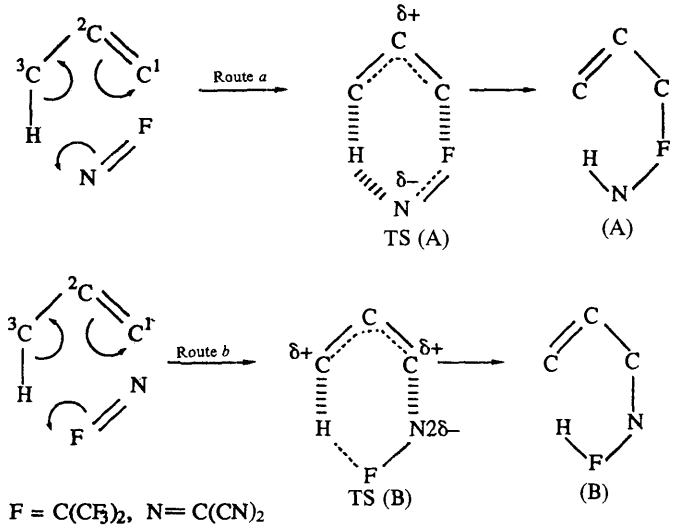
The product (XLV) is formed in good yield which is explained by the high probability of implementing the transition state [TS (XLV)].[14] The formation of the isomer (XLVI) is more favoured. This conclusion is in accordance with the fact that the sterically hindered tetramethylethylene gives a single product (XLVII) at room temperature.[14]



The reaction of alkene (II) with 1,1,4,4-tetramethylbutadiene at 20 °C also leads to the product of the ene reaction (XLVIII).[14]



A detailed study of the reaction of 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) with various olefins has been carried out.[51] The reaction mechanism may be represented as follows using the symbols taken from the original work.



The usual enophiles (maleic anhydride, azodicarboxylic ester, formaldehyde, etc.) are carbophilic, i.e. the new C–C bond is more developed in the transition state than X–H (X = C, N, O ...). The charge distribution for the alkene (II) is determined by the ability of the cyano groups to stabilise the negative charge. Reaction of the F portion of the alkene (II) with C(1) leads to a zwitterion with simultaneous transfer of hydride ion reducing the ionic character of the TS (A). A terminal CH(CN) group appears in the reaction product in this case. On implementing TS (B) the hydride transfer and the formation of the $(CF_3)_2C-H$ bond precede the formation of the C–C bond. The negative charge of the carbanion formed from alkene (II) is better stabilised by the CN groups than by the trifluoromethyl groups in TS (A). In this case the reaction product will contain a terminal $H(CF_3)_2C$ group.

Table 2. Products of the ene reactions of 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene with olefins at 20 °C.[51]

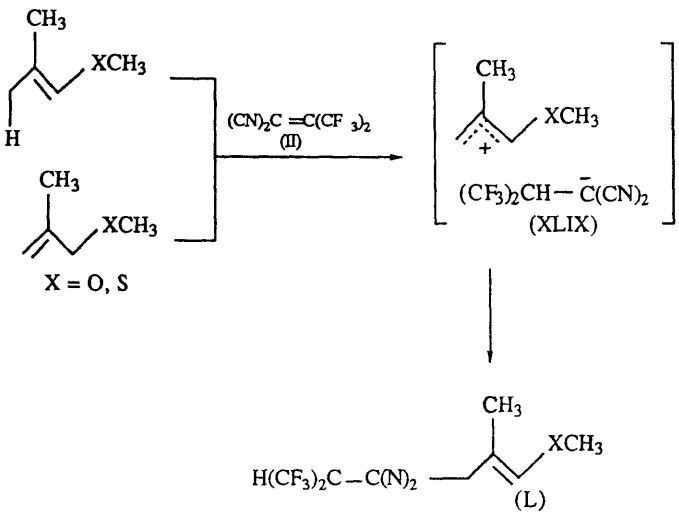
Olefin	Reaction time	Relative amount of products, %	
		(A)	(B)
	12 h	93	7
	18 d	67	33
	141 d	0	100
	18 d	100	0
	40 h	61	39
	29 d	100	0

Both one-stage reactions (*a*) and (*b*) occur with a compulsory shift of the double bond. Recognition of the terminal group of the ene reaction product suggests the implementation of TS (A) or TS (B).[51]

The results of some reactions of alkene (II) with olefins are shown in Table 2.

The introduction of an isopropyl or phenyl group into the C(3) position enables stabilisation of the quasi-allylic cation TS (B). Route *b* is effected in these cases by 33 and 100% respectively. Substituents at C(2) make the quasi-carbocation RS (A) tertiary and consequently aid the formation of the product (A).

The reaction of isobutenyl or methylallyl ethers and thioethers with 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) involving the allylic hydrogen atom has been investigated systematically.[52] In this the ion pair (XLIX) generated in the hydride transfer is the intermediate in the main reaction pathway.



The better stabilisation of the negative charge of (XLIX) by the cyano groups leads to the formation of adducts with terminal $(CF_3)_2CH$ groups. Allyl ethers and thioethers react similarly.

Although the dimethylacetal of dimethylketene is subject only to a [2 + 2] cycloaddition with the alkene (II),[35] the corresponding slow reaction of the dithioacetal gives the product (LI).[52]

$$(CH_3)_2C{=}\,C(SCH_3)_2 + (NC)_2C{=}C(CF_3)_2 \longrightarrow$$

$$\longrightarrow H(CF_3)_2C(CN)_2CH_2C{=}\,C(SCH_3)_2$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad CH_3$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad (LI)$$

It may be concluded from the above that 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) and dicyanomethylenehexafluorocyclobutane (III) are unique enophiles with a marked ability to split off hydride ion from the allyl carbon atom. The alkene (II) is the sole known representative of the ethylene series reacting with unactivated olefins at room temperature without a catalyst.

VII. Reactions of perfluoroalkyl-substituted dicyanoethylenes with nucleophiles

The fluorine-containing dicyanoethylenes readily react with nucleophiles due to their electrophilic nature.

1. Reaction with water and alcohols

1,1-Dicyano-2,2-bis(trifluoromethyl)ethylene (II) readily adds water without a catalyst forming 2,2-dicyano-1,1-bis(trifluoromethyl)ethanol (LII).[14]

$$\underset{\text{(II)}}{(NC)_2C{=}\,C(CF_3)_2} + H_2O \longrightarrow \underset{\text{(LII)}}{H(NC)_2C{-}\,C(CF_3)_2OH}$$

In strongly acidic medium (II) may be hydrolysed to the diamide (LIII).[14]

$$\underset{\text{(II)}}{(NC)_2C{=}\,C(CF_3)_2} \xrightarrow{H_2SO_4/H_2O} \underset{\text{(LIII)}}{(CF_3)_2C{=}\,C(CONH_2)_2}$$

The reaction of adding alcohols to the alkene (II) is reversible and leads to the unstable adduct (LIV) which decomposes to the starting materials even on vacuum distillation. The position of the equilibrium depends on the size of the hydrocarbon group of the alcohol. The equilibrium is shifted to the right in the reaction of (II) with methanol and ethanol. The opposite picture is seen with t-butyl alcohol. Isopropanol and the alkene (II) give approximately equal quantities of the product (LVI) and the starting materials of equilibrium.[14]

$$\text{(II)} + ROH \rightleftharpoons \underset{\text{(LIV)}}{H(CN)_2C{-}\,C(CF_3)_2OR}$$

The reaction of 2-chloro-1,1-dicyano-2-(trifluoromethyl)ethylene (VIa) with alcohols is irreversible and leads, probably according to an addition–elimination mechanism, to 2-alkoxy-1,1-dicyano-2-(trifluoromethyl)ethylenes (LV).[18]

$$\underset{\text{(VIa)}}{(NC)_2C{=}\,C(CF_3)Cl} + ROH \longrightarrow \underset{\text{(LV)}}{(NC)_2C{=}\,C(CF_3)OR}$$

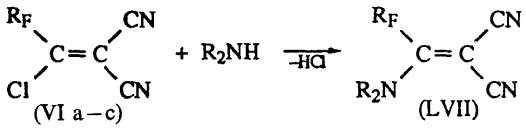
$R = CH_3,\ C_2H_5$

2. Reaction with nitrogen-containing nucleophiles

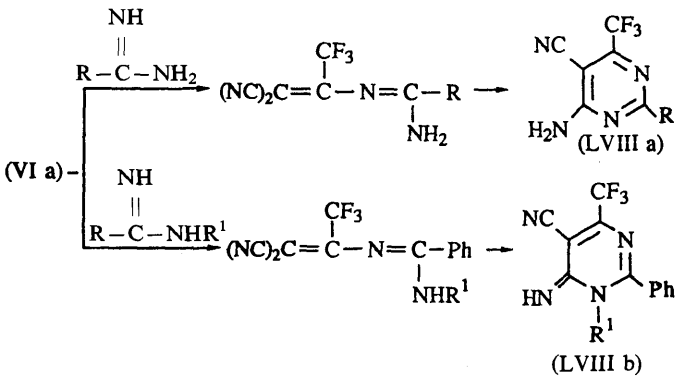
The alkene (II) adds ammonia at the double bond forming an amphoteric amine which was isolated as the tetraethylammonium salt (LVI).[14]

$$\underset{\text{(II)}}{(CF_3)_2C{=}\,C(CN)_2} + NH_3 \xrightarrow[-HCl]{N(C_2H_5)_4Cl} \underset{\text{(LVI)}}{H_2N{-}\overset{CF_3}{\overset{|}{C}}{-}\overset{CN}{\overset{/}{C}}{}^{+}N(C_2H_5)_4 \;\; {}^{CF_3}_{CN}}$$

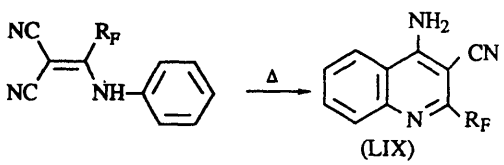
The 1,1-dicyano-2-chloro-2-(perfluoroalkyl)ethylenes (VIa–c) react with primary and secondary aliphatic, primary aromatic amines and amidines with the formation of *N*-vinylation products (LVII).[18,19]



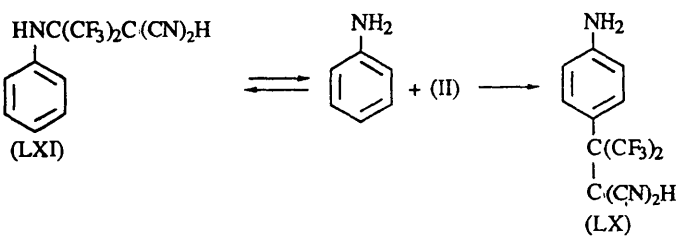
In several cases the resulting *N*-vinyl derivatives undergo further intramolecular cyclisation with the participation of the cyano group. Thus the products of the *N*-vinylation of amidines are cyclised into 5-cyano-4-trifluoromethylpyrimidines (LVIIIa, b).[53]



The *N*-vinyl derivatives of aniline are converted on heating into 4-amino-3-cyano-2-(perfluoroalkyl)quinolines (LIX).[19]

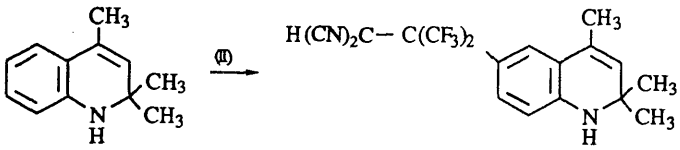


In contrast to dicyanoethylenes containing vinylic halogen atoms 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) reacts with aniline to give the C(4) alkylation product (LX).[11,14,25] It was shown recently that the reaction is complex. The unstable *N*-alkylation product (LXI) is formed first and is in equilibrium with the initial aniline and alkene under the reaction conditions (20 °C, Freon 113). A competing slow irreversible reaction leads to the 4-substituted aniline derivative (LX).[25]



The presence of a substituent in the 2 position to the amino group in *o*-toluidine generates steric hindrance to the formation of an *N*-alkylation product shifting the equilibrium in the *N*-alkylation

product—[arylamine + (II)] system to the right. An increase in the concentrations of the starting materials increases the overall rate of formation of the *C*(4)-alkylation product. The same effect assists rapid *C*(4)-alkylation of the *N*-alkylanilines by the alkene (II). The reaction of alkene (II) with 2,2,4-trimethyl-1,2-dihydroisoquinoline, representing secondary arylamines, also leads to the product of alkylation in the *para* position to the amino group (LXII).[25]

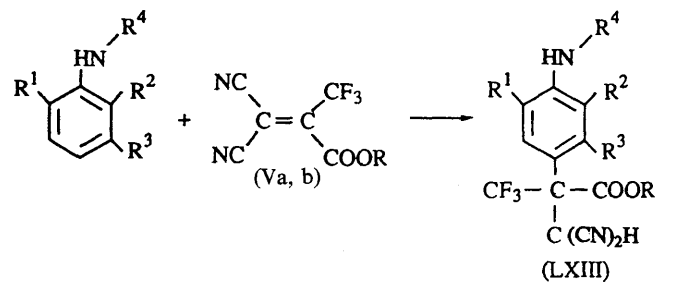


(LXII)

Diphenylamine, in spite of significant steric hindrance to *N*-alkylation, is substituted significantly more slowly which is linked with the reduced nucleophilicity of the benzene nuclei compared with the *N*-alkylanilines. 4-Substituted anilines do not form stable products with the alkene (II).[25]

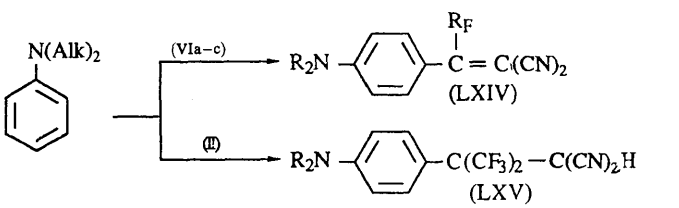
The features of the reaction of anilines with alkene (II) correspond mainly with the results of the tricyanovinylation of aniline with tetracyanoethylene.[54–56]

The reaction of primary and secondary arylamines with the esters of 3,3-dicyano-2-(trifluoromethyl)acrylic acid (Va, b) has also been studied systematically. It was noted that the range of anilines clearly subject to C(4) alkylation by the alkenes (Va, b) was reduced compared to the alkene (II). Positive results were obtained for 2,6-dimethyl- and 2,5-dimethoxyanilines and for diphenylamine. The corresponding derivatives of 4-[2,2-dicyano-1-alkoxycarbonyl-1-(trifluoromethyl)ethyl]aniline (LXIII) were isolated.[17]



(LXIII)

N,N-Dialkylanilines are alkylated at C(4) under mild conditions by the alkenes (VIa–c) and (II) with the formation of the products (LXIV) and (LXV).[16,18,25,27]

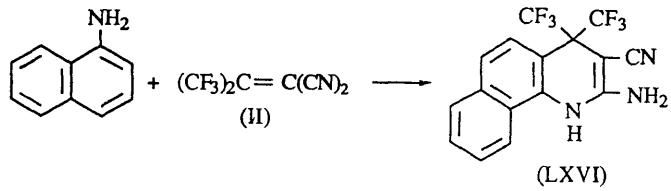


(LXIV)

(LXV)

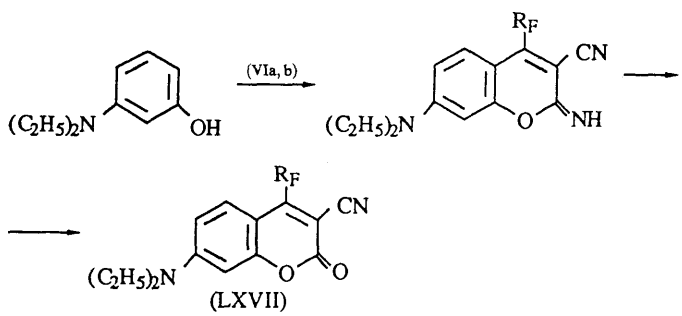
N,N-Dimethylaniline was successfully alkylated at C(4) by esters of 3,3-dicyano-2-(trifluoromethyl)acrylic acid (Va, b) in acetic acid solution.[17]

Cases when the *C*-alkylation of the aromatic nucleus is accompanied by heterocyclisation involving the cyano or some other functional group of the electrophilic alkene are of particular interest. Stable heterocyclic compounds modified by perfluoroalkyl groups are formed. For example, the regiospecific alkylation of 1-aminonaphthalene at C(2) by alkene (II) is accompanied by an intramolecular cyclisation involving a cyano and the amino group leading to the benzoquinoline derivative (LXVII).[25,58]



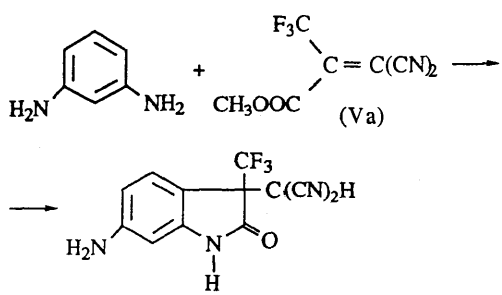
(LXVI)

Cyclisation involving the hydroxyl group of the nucleophile and a cyano group of 2-chloro-1,1-dicyano-2-(trifluoroalkyl)ethylenes (VIa, b) was used in the synthesis of the perfluoroalkyl substituted coumarin derivatives (LXVII).[57]



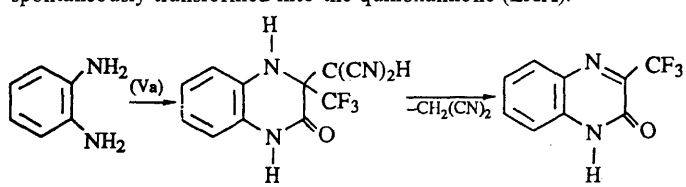
(LXVII)

On reacting the acrylic acid derivative (Va) with *m*-phenylenediamine the *C*-alkylation is accompanied by the formation of a lactam (LXVIII).[17]



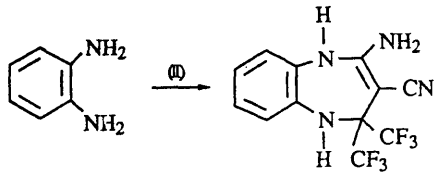
(LXVIII)

Lactamisation reaches *N*-alkylation in the case of *o*-phenylenediamine. The dihydroquinoxaline (LXIX) is formed which is spontaneously transformed into the quinoxalinone (LXX).[17]



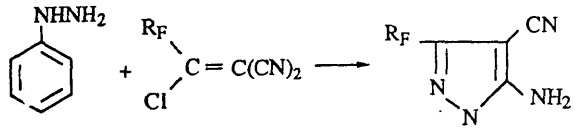
(LXIX) (LXX)

The reacton of *o*-phenylenediamine with 1,1-dicyano-2,2-bis-(trifluoromethyl)ethylene (II) terminates with the formation of the dihydro-1,5-benzodiazepine (LXXI).[17,59]



(LXXI)

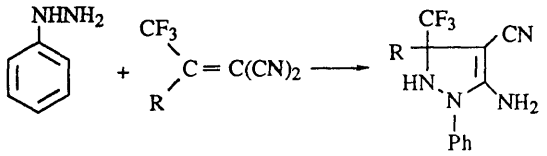
Phenylhydrazine reacts with the dicyanoethylenes (VIa–c) with the formation of the pyrazole derivatives (LXXII).[18,19]



(VIa–c)

(LXXII)

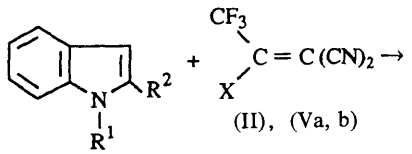
The analogous reaction with 1,1-dicyano-2-(trifluoromethyl)ethylenes (II) and (Va) leads to the pyrazoline derivative (LXXIII).[17,25,60]



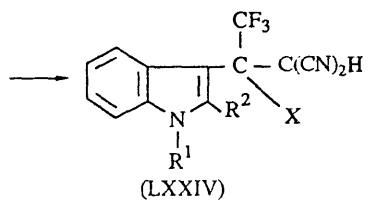
(LXXIII)

R = CF_3 (II); COOMe (Va)

There are only limited data on the *C*-alkylation reactions of nitrogen-containing heteroaromatic compounds with perfluoroalkyl substituted dicyanoethylenes. In addition it is known that indole, 2-methylindole and *N*-methyl-2-phenylindole react under mild conditions with 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) and with esters of 3,3-dicyano-2-(trifluoromethyl)acrylic acid (Va, b) with the formation of products (LXXIV) of substitution of the indole nucleus of C(3).[61]



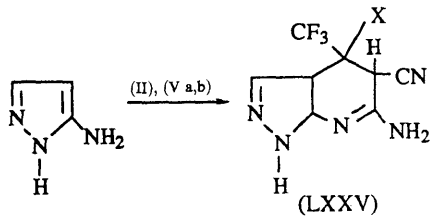
(II), (Va, b)



(LXXIV)

X = CF_3, $COOCH_3$, $COOC_2H_5$

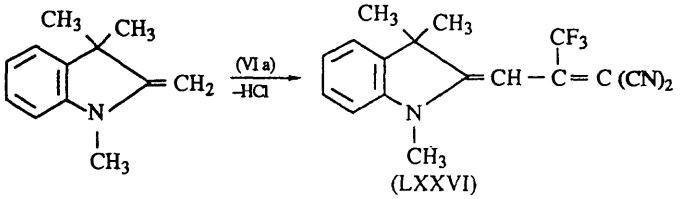
The *C*-alkylation of 3-aminopyrazole is accompanied by heterocyclisation leading to the dihydropyrazolopyridine (LXXV).[17,25]



(LXXV)

X = CF_3, $COOCH_3$, $COOC_2H_5$

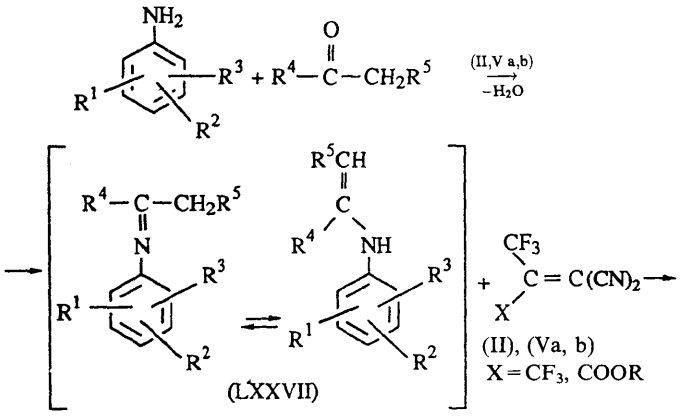
The *C*-alkenylation of 1,3,3-trimethyl-2-methyleneindoline with 2-chloro-1,1-dicyano-2-(trifluoromethyl)ethylene (VIa) is an example of the reaction of perfluoroalkyl substituted dicyanoethylenes with enamines. The strongly coloured compound (LXXVI) is formed.[18]



(LXXVI)

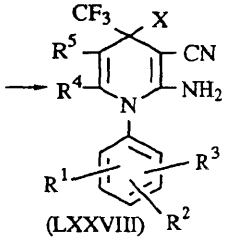
It has been suggested that certain acyclic enamines may react with 1,1-dicyano-2-(trifluoromethyl)ethylenes (II) and (Va, b) with the formation of dihydrobenzene derivatives.[62] The product of β-*C*-alkylation in this case is stabilised by cyclisation involving the nitrile group and the β′-CH fragment of the enamine.

A nonstandard example of the use of compounds existing in a state of imine–enamine equilibrium is the three component reaction of anilines, ketones and 1,1-dicyano-2-(trifluoromethyl)ethylenes (II) and (Va, b) leading to the *N*-phenyl-1,4-dihydropyridine derivative (LXXVII).[62]



(LXXVII)

(II), (Va, b)
X = CF_3, COOR



(LXXVIII)

The key stage of the process is the formation of the Schiff's bases (LXXVII) which are subject to β-*C*-alkylation in their enamine form with subsequent intramolecular cyclisation. A similar heterocyclisation is also effected on reacting alkenes (II) and (Va, b) with anils obtained from aldehydes.[62]

3. Reactions with salts of CH-acids

1,1-Dicyano-2,2-bis(trifluoromethyl)ethylene (II) reacts with sodium cyanide in acetonitrile forming the adduct (LXXIX) which is stable below 300 °C.[14]

$$(NC)_2C=C(CF_3)_2 + NaCN \longrightarrow Na(NC)_2C-C(CF_3)_2CN$$

(II) (LXXIX)

The reaction of alkene (VIa) with the sodium salt of dicyanomethane is known. The tetramethylammonium salt (LXXX) is formed in the presence of tetramethylammonium chloride.[16]

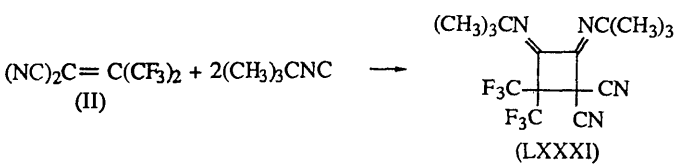
$$(NC)_2C=C(CF_3)CL + (NC)_2CHNa \xrightarrow{N(CH_3)_4Cl} (NC)_2C=C(CF_3)\overline{C}(CN)_2.\overset{+}{N}(CH_3)_4$$

(VIa) (LXXX)

VIII. Other reactions of perfluoroalkyl substituted dicyanoethylenes

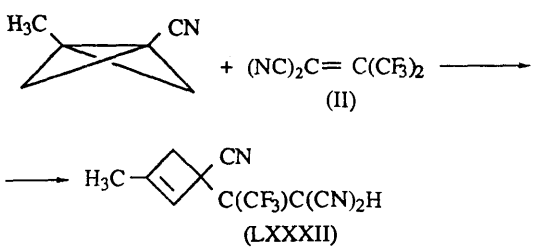
Data are included in this section on chemical conversions of fluorine-containing dicyanoethylenes which have not been systematically covered in the literature or belong to a special area of heteroorganic chemistry but are sufficiently important when creating a more complete picture of the chemical properties of the alkenes under consideration.

The first type includes the reaction of 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene (II) with t-butyl isocyanide at 0 °C. The resulting crystalline adduct of composition 1 : 2 was assigned the structure (LXXXI).[14]



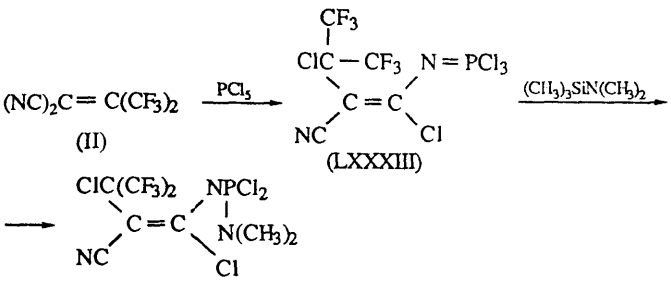
(LXXXI)

The reaction of (II) with bicyclo[1,1,0]butane is an example of an electrophilic addition leading to the cyclobutane derivative (LXXXII).[63]



(LXXXII)

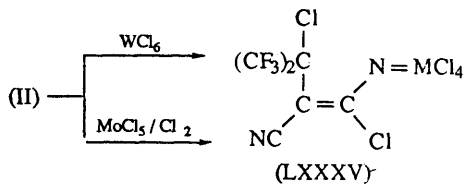
The reaction of the alkene (II) with phosphorus pentachloride leads to the (phosphoranilidenamino)ethylene (LXXXIII), treatment of which with $(CH_3)_3SiN(CH_3)_2$ gives the compound (LXXXIV).[64]



(LXXXIII)

(LXXXIV)

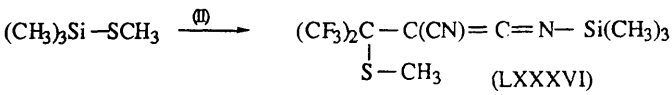
The acyclic nitrenes (LXXXV) may be obtained by the reaction of tungsten hexachloride or molybdenum pentachloride with the alkene (II).[65]



(LXXXV)

M = W, Mo

The olefin (II) reacts under mild conditions by insertion into Si–Si, Si–As, B–S or B–N bonds forming ketenimino derivatives such as compound (LXXXVI).[15,65]



(LXXXVI)

The reactions of alkenes (Ia, b) and (II) with transition metal complexes have been studied fairly widely.[66–70]

IX. Applications of perfluoroalkyl-substituted dicyanoethylenes and compounds obtained from them

1,2-Dicyano-1,2-bis(trifluoromethyl)ethylenes (Ia, b) are patented as stabilising additives for chlorinated hydrocarbons.[71]

The electron-accepting properties of fluorine-containing dicyanoethylenes were used in a study of the photo-dimerisation of 1,4,4a,5,8,8a-hexahydro-1,4,5,8-*endo*, *endo*-dimethanonaphthalene.[72]

Polymers of conjugated trienes, modified with the alkenes (Ia, b) by the Diels–Alder reaction,[28] acquire a high stability towards various actions and also improved electrical insulating properties.

Dicyano-*S*-diaminomethylenesulphilidenes, obtained from 1,1-dicyano-2,2-bis(trifluoromethyl)ethylene oxide and thiourea derivatives, have been proposed for bleaching paper.[12]

The reaction of alkene (II) with aniline gives 4-[2,2-dicyano-1,1-bis(trifluoromethyl)ethyl]aniline (LX) which after diazotisation and coupling with β-naphthol gives an orange dye for wool.[11] Compounds (LXIV) and (LXXIV), which are intensely coloured, may also be used as dyes.[18]

The purpose-directed synthesis of 2,2-dicyanonorbornene derivatives (XIX) from the alkenes (II) and (VIa–d) and study of their biological activity has been carried out by Dupont.[16] It turned out these these compounds are exceptionally toxic (LD50 < 4 mg kg^{-1}) but 2,2-dicyano-3,3-bis(trifluoromethyl)norbornene has an absolutely lethal dose on oral administration to rats of the order of 1.5 mg kg^{-1}, i.e. it is more toxic than sodium cyanide. In addition

the heterocyclic compounds synthesised from trifluoromethyl substituted dicyanoethylenes are obviously interesting from the point of view of searching for new biologically active compounds.

Reactions of polyfluoroketones with unsaturated compounds

A S Golubev, A F Kolomiets, A V Fokin
The A N Nesmeyanov Institute of Elementoorganic Compounds of the Russian Academy of Sciences

ABSTRACT. A review is presented on the reactions of polyfluoroketones with alkenes, alkynes, 1,2- and 1,3-dienes, and certain other unsaturated compounds. The reactivity of polyfluoroketones has been compared with that of diethyl oxomalonate. The characteristic dienophilic, enophilic and 1,2-dipolar properties of polyfluoroketones have been discussed.

I. Introduction

Among unsaturated organofluorine compounds, polyfluoroketones are second only to fluoroolefins in order of importance. The electrophilicity of ketones increases with introduction of fluorine atoms at the α-position, and such activity is at a maximum in polyfluoroketones and derivatives thereof in which one of the fluorine atoms in the α-position is replaced by an electron-accepting group: an alkoxy, carbonyl, nitro, sulphonic acid or fluorosulphonyl group. These are among the most powerful electrophilic agents known, possessing an extraordinary affinity for nucleophiles and towards π-systems with donor properties. Thus, depending on structural features, polyfluoroketones possess a wide range of chemical properties, exhibiting both the classical reactivity of aliphatic ketones.[1–3] and 'anomalous' behaviour specific to this class of functionalised ketone.

The unusual chemistry of polyfluoroketones and their derivatives is due, in part, to their extremely high electrophilicity and, in part, to the ability of perfluoroalkyl residues, especially the trifluoromethyl group, to stabilise adjacent δ-bonds. This explains the facile conversion of polyfluoroketones to stable hemiketals, hemiaminals, aldols, thermodynamically stable enols, α-fluoro-substituted alkoxides, oxetenes and other compounds with a small ring. The high electrophilicity and stabilising effect of polyfluoroalkyl groups is notably manifested in the reactions of polyfluoroketones with alkenes, alkynes, 1,2- and 1,3-dienes, and with a large number of other unsaturated compounds—the subject matter of the present review.

Up to now, there have been no review articles covering general aspects of the reactions of polyfluoroketones with unsaturated compounds; nor have the latter been examined in a critical sense. Previous reviews[4,5] and a monograph[6] in the field of organofluorine chemistry have included this aspect in part, as also has a more recent review.[7] In the authoritative survey of Witt et al.,[8] the authors collected and analysed information on the reactions of hexafluoroacetone with unsaturated elementoorganic and organometallic compounds.

In this article, we have compared the reactivity of highly electrophilic polyfluoroketones towards alkenes, cycloalkenes, alkynes, 1,3-dienes, cumulenes and a number of other unsaturated compounds. We have examined, in particular, the reactions of these unsaturated compounds with perfluorocyclobutanone, nitropentafluoroacetone, hexafluoroacetone (HFA), methyltrifluoropyruvate (MTFP), and with chloropentafluoro- and 1,3-dichlorotetrafluoroacetone. For comparison, information has also been gathered on the dienophilic, enophilic, and 1,2-dipolar properties of diethyl oxomalonate (DEOM)—an activated carbonyl compound with properties very similar to those of polyfluoroketones.

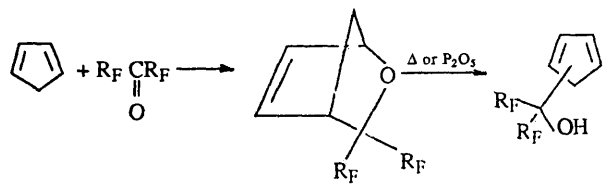
In an analysis of the collected information, an attempt has been made to assess the effect of the polyfluoroketone structure on the ability of these ketones to participate in Diels–Alder reactions, ene reactions, and in [2 + 2]-cycloaddition; the influence of the CF_3 group on these reactions has been examined by comparing the reactivity of hexafluoroacetone, methyltrifluoropyruvate, and diethyloxomalonate.

II. [4 + 2]-Cycloaddition

Among the vast array of available heterodienophiles,[9] including activated carbonyl compounds, polyfluoroketones are particularly noteworthy in that they possess unusually high reactivity in Diels–Alder cycloaddition. Thus, [4 + 2]-cycloadducts are formed between polyfluoroketones and donor-type 1,3-dienes under mild conditions in the absence of a catalyst (Table 1). Furthermore, high reactivity is manifested towards certain 1,3-heterodienes.

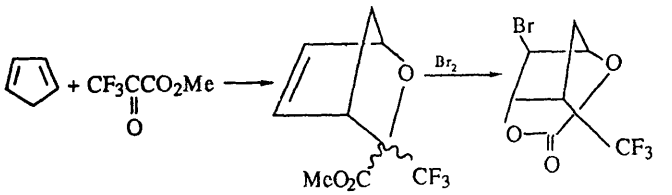
Perfluorocyclobutanone[10] and HFA [12,13] interact with cyclopentadiene even on mixing in the cold. The 2-oxabicyclo[2.2.1]hept-5-ene derivative obtained from perfluorocyclobutanone is relatively stable, and may be isolated pure by distillation under reduced pressure. However, fractionation under the normal conditions results in its conversion to 2-(α-hydroxyperfluorocyclobutyl)cyclopentadiene which readily polymerises. A similar

cycloadduct is formed from HFA, but undergoes retrodiene scission on heating above 20 °C. It is converted into a regioisomeric mixture of α-hydroxyhexafluoroisopropylcyclopentadienes in the presence of P_2O_5.[13]

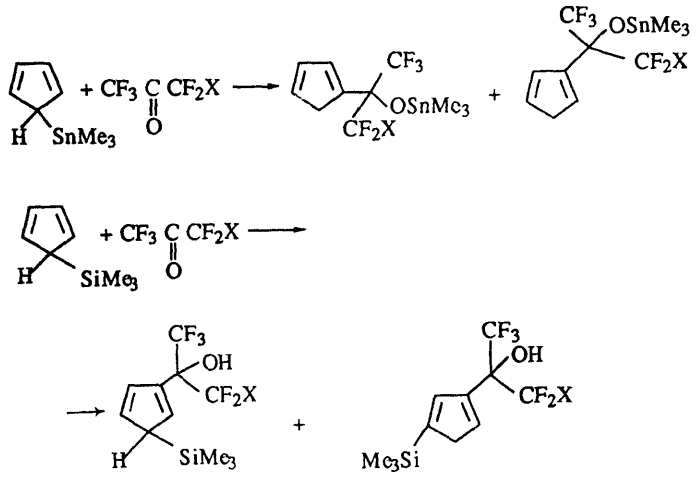


$R_F = CF_3$; R_F, $R_F = -(CF_2)_3-$

Methyl trifluoropyruvate (MTFP) has the same reactivity as HFA towards cyclopentadiene, affording a 2.5:1 mixture of *endo*- and *exo*-2-oxabicyclo[2.2.1]hept-5-enes.[21] The latter cycloadducts revert to the starting materials on heating, and are converted predominantly to a bromolactone on bromination.



No cycloadduct is formed on reaction of HFA or chloropentafluoroacetone with cyclopentadienyltrimethyl-stannane or -silane. Instead, reaction of the cyclopentadienylstannane with these polyfluoroketones at 20 °C leads to insertion of the latter into a C–Sn bond, while reaction with the silyl analogue results in a mixture of 1,2-adducts.[23]



X = F, Cl.

Unlike polyfluoroketones, diethyl oxomalonate does not afford cycloadducts with cyclopentadiene in the temperature range −20 to 135 °C.[24]

Polyfluoroketones interact as readily with 1,3-butadiene and its alkyl and alkoxy derivatives as they do with cyclopentadiene (Table 1). The resulting 5,6-dihydro-2*H*-pyrans are stable and isolable in high yield. No information is available on the conditions required for retrodiene scission, nor on the manner of their decomposition.

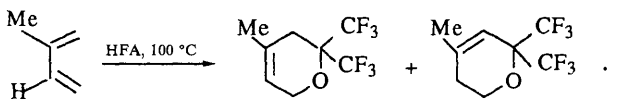
Footnote. A dash means that the reaction time has not been given.

Of the examined polyfluoroketones, perfluorocyclobutanone[10,11] and nitropentafluoroacetone[14,20] are the most reactive, the corresponding cycloadducts with 1,3-butadiene being formed in the cold or at 20 °C. Hexalfuoroacetone is slightly less reactive than nitropentafluoroacetone, interacting with 1,3-dienes at 20 °C.[14,15,20] The assertion of Ishihara et al.[25] that "HFA exhibits low reactivity towards the more familiar 1,3-dienes" is without foundation.

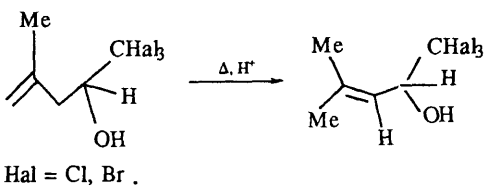
It should also be pointed out that it is not necessary to use harsh conditions for the cycloaddition of HFA or 1,3-dichlorotetrafluoroacetone with 1,3-dienes, as has been reported.[17,19] According to Linn,[12] [4 + 2]-cycloaddition with 1,3-dichlorotetrafluoroacetone at 20 °C is less facile than with HFA. It has recently been reported that MTFP is as reactive as HFA in such cycloaddition.[15]

A comparison of the reactivity of MTFP towards a number of 1,3-dienes has provided some interesting results.[15] Thus, it has been shown that cyclopentadiene, 1,3-butadiene, isoprene, piperylene (as a *cis/trans* mixture) and 2,3-dimethyl-1,3-butadiene interact with MTFP effectively under the same conditions (0–20 °C). It therefore follows that [4 + 2]-cycloaddition of these dienes with MTFP is little affected by structural variation within the dienes, by any variation in the transitional energy from transoid to cisoid form, or by the energy coefficients and degree of localisation of the frontier orbitals. As similar results are obtained with other polyfluoroketones (see Table 1), it is evident that such behaviour is characteristic of this family of dienophile.

The regioselectivity of the cycloaddition of polyfluoroketones with unsymmetrical 1,3-dienes is another characteristic feature. Thus, under all conditions, cycloaddition of the ketone proceeds in such a way that the carbon atom of the carbonyl group attacks the carbon atom of the conjugated system possessing the highest electron density. This is true under both mild and harsh conditions. The assertion that the thermal cycloaddition of polyfluoroketones with isoprene displays low regioselectivity[22] would appear to be unfounded since in the original work of Linn[12] it was shown that HFA affords only the *para*-isomer [sic] (85%) together with an isomer (15%) arising by prototropic shift:



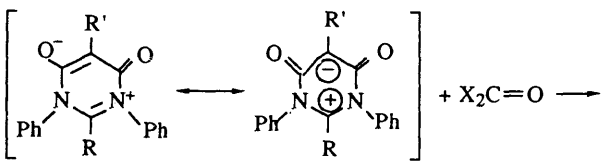
The latter product would be anticipated if traces of acid were present in the medium. Such acid-catalysed prototropic shfits, in fact, are characteristic of structures of the type:[26]

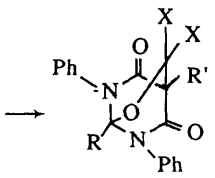


Hal = Cl, Br.

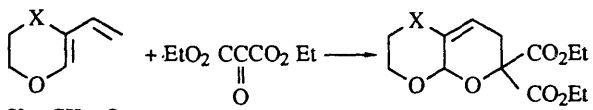
The somewhat anomalous cycloaddition of polyfluoroketones to 1,3-dienes is probably due to the electronic configuration of the carbonyl group and associated charged residues which make a large contribution to the formation of the pericyclic transition state. The high electronegativity of the carbonyl oxygen of the dienophile and the high electron-accepting ability of the perfluoroalkyl group leads to a significant decrease in the level of the LUMO and to its localisation primarily on the carbon atom of the carbonyl group, as has been demonstated with perfluorocyclobutanone.[27]

In this context, it is interesting to note that DEOM is noticeably more reluctant to participate in [4 + 2]-cycloaddition with 1,3-dienes than polyfluoroketones.[9] In fact, cycloaddition of DEOM with 1,3-butadiene and its alkyl derivatives can only be achieved at high temperatures (130–140 °C).[24,28–31] Cycloaddition at a lower temperature (50 °C) is only possible with electron-rich 1,3-dienes, such as 1-alkoxy-3-alkyl-1,3-butadienes,[32] 5-vinyl-3,4-dihydro-2*H*-pyran and 5-vinyl-2,3-dihydro-1,4-dioxin.[33] The notable difference in dienophilic reactivity between HFA and DEOM is apparent from the relative ease of cycloaddition of these compounds with 6-oxo-2,6-dihydro-1-pyrimidinium-4-olates [...3,6-dihydro? (Ed. of Translation)], involving a synchronous [$4\pi_s$ + $2\pi_s$]-mechanism: the former dienophile reacts at 0 °C, whereas cycloaddition with DEOM requires heating at 110 °C.[34] Oxadiazabicyclooctanediones are obtained as the reaction product:



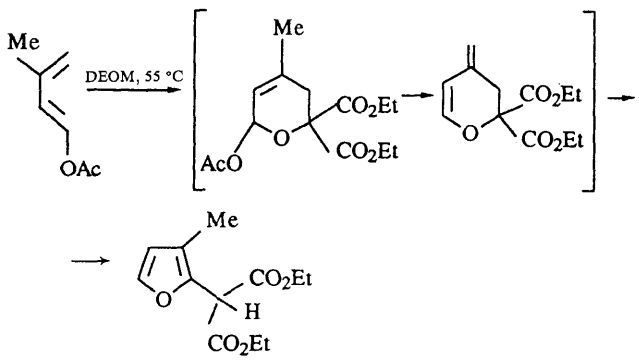


X = CF_3, CO_2Et.



X = CH_2; O.

1-Methoxy-3-methyl-1,3-butadiene forms an intermediate [4 + 2]-cycloadduct with DEOM on heating in THF. This subsequently eliminates acetic acid and rearranges to give a substituted furan.[35]

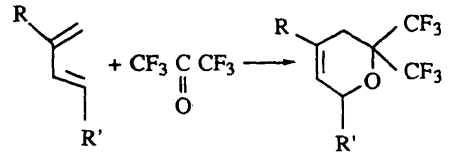


Coupled with the lower activity of DEOM is the somewhat reduced regioselectivity in its [4 + 2]-cycloaddition with unsymmetrical 1,3-dienes.[24] With isoprene, the para-isomer is formed predominantly together with around 10% of the meta-isomer. The regioselectivity of cycloaddition with piperylene is higher, the proportion of ortho- and meta-cycloadducts being 19 : 1.

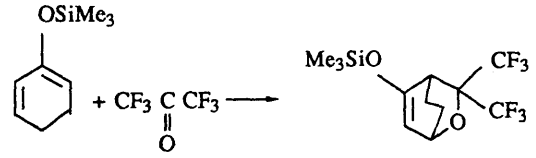
Further differences in the dienophilic activity of polyfluoroketones and DEOM are apparent in their reactions with siloxy-1,3-dienes, which have been extensively studied in the field of natural product synthesis,[36,37] notably in the context of asymemtric diene syntheses based on chiral organoaluminium catalysts.[38,39]

Hexafluoroacetone interacts regiospecifically with a variety of siloxy-1,3-dienes in the absence of catalysts at –40 to –45 °C. The sole regioisomer is that anticipated by considering the polarisation of

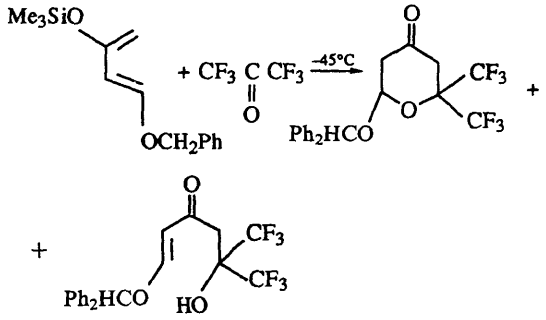
the carbonyl group and the 1,3-conjugated system.[25]



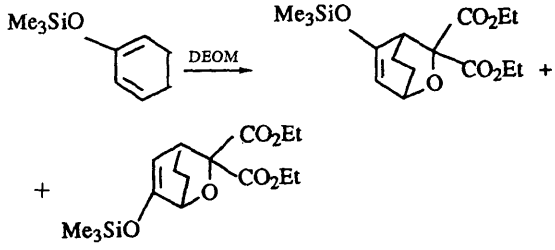
R = H, R' = $OSiMe_3$; R = $OSiMe_3$, R' = H.



However, the reaction of HFA with (*E*)-1-benzyloxy-3-trimethylsiloxy-1,3-butadiene yields both [4 + 2]-cycloadduct and an aldol-type by-product.[40]

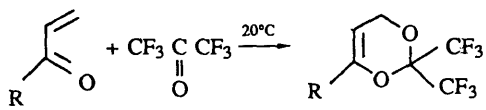


Diethyl oxamalonate (DEOM) normally participates in such reactions at 130–140 °C,[41] although a [4 + 2]-cycloadduct is obtainable on heating this dienophile with the electron-rich 1-methoxy-3-trimethylsiloxy-1,3-butadiene in refluxing THF over several hours.[35] However, the cycloaddition of DEOM with 1,3-dienes displays low regioselectivity. Thus, a 55 : 45 mixture of para- and meta-adducts is formed from 2-trimethylsiloxy-1,3-cyclohexadiene.[41]



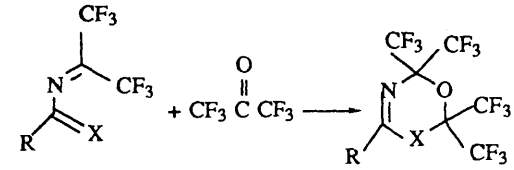
Low regioselectivity was also noted for the reaction of DEOM with 1-methyl-2-trimethylsiloxy-1,3-butadiene.

Dieles–Alder reactions with polyfluoroketones may also be performed with 1,3-heterodienes. Thus, mixing HFA with acrolein or methyl vinyl ketone at low temperature, followed by warming to 20 °C, leads to the corresponding [4 + 2]-adduct in quantitative yield.[42]



R = H, Me

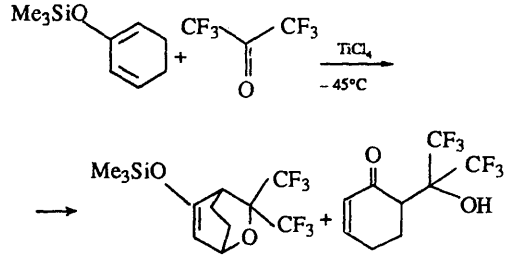
Heating HFA with highly electrophilic acylimine derivatives of HFA affords the corresponding 1,3,5-dioxazine,[43] while thioacylimine and iminoacylimine derivatives give the corresponding 1,3,5-oxathiazine and 1,3,5-oxadiazine derivatives.[44]



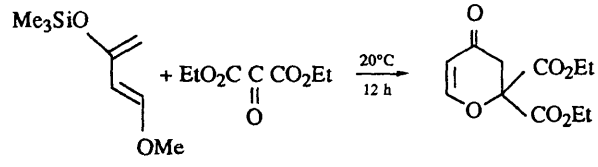
X = O, S, NR^1; R = Ph, 4–ClC_6H_4, Bu^t.

In all such heterodiene syntheses, reaction proceeds by attack of the carbonyl carbon of HFA at the most electron-rich atom of the 1,3-heterodiene component. It should be noted that such Diels–Alder reactions of HFA acylimine derivatives with non-fluorinated carbonyl compounds may be undertaken under milder conditions.[45]

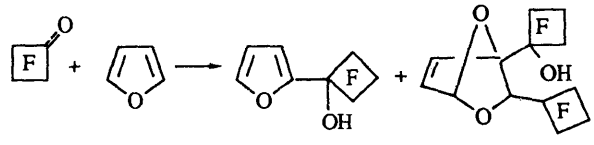
Little information is available on Lewis acid-catalysed cycloaddition of polyfluoroketones with 1,3-dienes. It is reported that the cycloaddition of HFA with 1-trimethylsiloxy-1,3-cyclohexadiene in the presence of $TiCl_4$ is accompanied by the formation of an aldol derivative as by-product.[25]



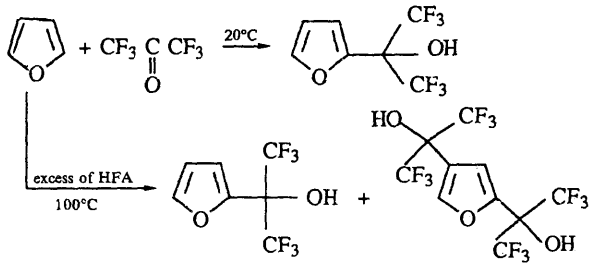
In the $SnCl_4$-catalysed reaction of isoprene with MTFP at –50 °C, an ene adduct is formed together with a [4 + 2]-cycloadduct (see below). The cycloaddition of DEOM with 1-ethoxy-3-alkyl-1,3-butadienes can be successfully carried out at 20 °C in the presence of tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dionato)-europium(III).[46] Zinc chloride (250 mol%) activates the cycloaddition of DEOM with 1-methoxy-3-trimethylsiloxy-1,3-butadiene.[47] This reaction is accompanied by removal of the silyl protective group and elimination of methanol.



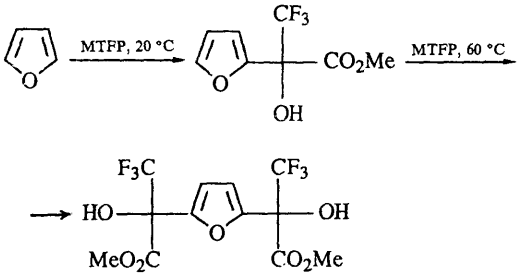
Normally, the interaction of polyfluoroketones with heterocyclic 1,3-dienes leads to 1,2-adducts rather than [4 + 2]-cycloadducts. However, in the reaction of perfluorocyclobutanone with furan, both 1,2- and [4 + 2]-adducts have been isolated.[48]



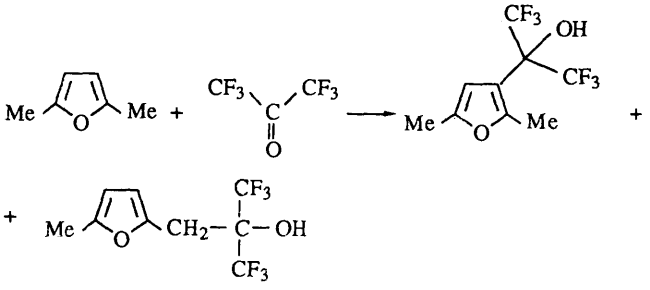
Depending on the temperature and ratio of the reactants, the interaction of HFA with furan leads to either a 2-substituted furan or a mixture of 2-substituted and 2,4-disubstituted furan.[48–50]



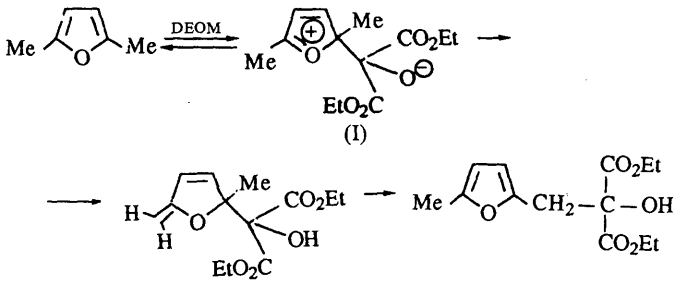
The reaction of furan with MTFP proceeds in a step-wise manner to give the corresponding 2,5-disubstituted furan via mono-substitution.[51,52]



The interaction of 2,5-dimethylfuran with HFA leads to a 3:1 mixture of side chain-substituted and ring-substituted derivatives.[49]



The reaction of DEOM with 2,5-dimethylfuran can only be conducted at elevated pressure.[53] In this instance, side-chain substitution is exclusive. It is thought that a zwitter-ion (I) is formed initially, and subsequently stabilised by a 1,5-sigmatropic shift.[54]

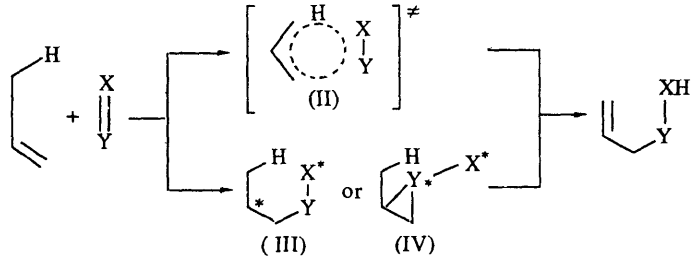


The reactions of *N*-methylpyrrole and thiophene with polyfluoroketones proceed by C-alkylation only.[48,49,51]

III. Ene reactions

An ene reaction is defined as the addition of an electron-rich olefin (the ene component) having a allylic hydrogen to an electron-deficient double bond (the enophile), as a result of which the double bond of the olefin undergoes migration with transfer of the allylic hydrogen atom to the enophile.[55,56]

In his review, Hoffmann alludes to the possibility of there being a broad spectrum of transition states for an ene reaction.[55] One extreme is a symmetry-allowed concerted $[2\pi_s + 2\pi_s + 2\delta_s]$-process, as represented by transition state (II) (see below). However, the symmetry of the transition state is such that the other extreme, namely a step-wise pathway, is also possible. Here, the transition state could be represented by either a zwitter-ionic structure or a biradical having free (III) or restricted (IV) rotation.[56] A study of the several by-products formed during such ene reactions would tend to suggest that a step-wise mechanism is operative.[57,58]

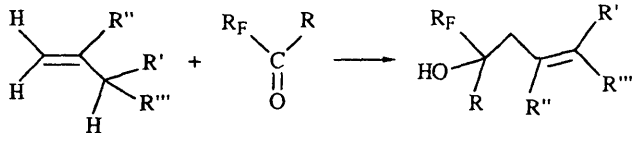


Synthetic applications of ene reactions have been legion in recent years. This is particularly true in the field of asymmetric synthesis in the presence of chiral catalysts.[59]

Polyfluoroketones are among the more interesting enophiles. In view of their high activity in ene reactions, they have sometimes been called "superenophiles",[62,63] as also have trifluoronitrosomethane,[60] DEOM,[62] and thionylimines with electron-accepting substituents.[61]

1. Ene reactions of polyfluoroketones with alkenes

Polyfluoroketones undergo ene reaction with terminal alkenes under mild conditions to give exclusively or predominantly homoallyl alcohols.[10,21,64,65]



R, R_F = — $(CF_2)_3$ —, CF_3, CF_2Cl; $R_F = CF_3$, $R = CF_2Cl$; $R_F = CF_3$, $R = CF_2NO_2$; $R_F = CF_3$, $R = CO_2Me$.

Literature data on these reactions are summarised in Table 2. It should be noted that, contrasting with classical enophiles, polyfluoroketones participate in ene syntheses under mild conditions. Normally, the reaction can be conducted in the temprature range 20–100 °C, and in certain instances below 0 °C. For example, the following reactions can be carried out at 20–25 °C: polyfluorocyclobutanone with propene and 2-phenylpropene;[10,11] nitropentafluoroacetone with 2-methylpropene;[64] HFA with 2-methyl-, 2-methoxy- and 2-phenyl-propene;[64,65] and MTFP with 2-methylpropene and its homologues.[21] 1,3-Dichlorotetrafluoroacetone, HFA and MTFP each undergo ene reaction with active ene components, such as β-pinene and 3,7-dimethylenedicyclo[3.3.1]-nonane.[65,69]

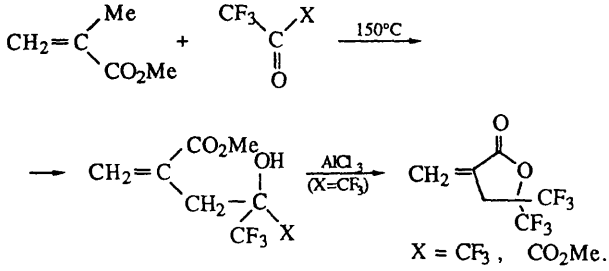
Footnote. A dash means that data are unavailable.

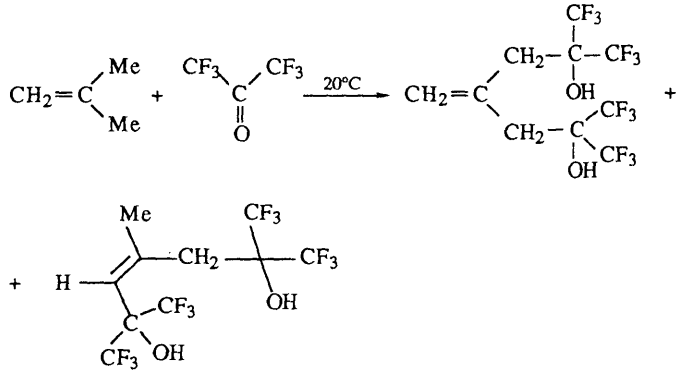
A further feature of polyfluoroketone chemistry is that their enophilic activity towards active ene components is as high as their dienophilic activity towards 1,3-dienes. This distinguishes polyfluoroketones from classical enophiles[55] which participate in ene reactions much less easily than in diene syntheses. It should be noted also that, in the family of highly electrophilic polyfluoroketones, the most active enophile (and dienophile) is perfluorocyclobutanone. This is evident from the reactivity of polyfluoroketones towards propene.[10] Hexafluoroacetone and methyl trifluoropyruvate display similar ene reactivity, while that of chloropentafluoro- and 1,3-dichlorotetrafluoro-acetone is lower and that of nitropentafluoro-acetone is somewhat higher.

It is also significant that polyfluoroketones participate in an unusually wide spectrum of ene reactions. For example, they react not only with classical ene components (differing in their donor properties and polarisation of the C=C bond but also with terminal 2-chloroalkenes, the unsaturation of which is deactivated by conjugation with the chlorine atom.[72] Ene reaction also takes place by interaction of polyfluoroketones with such 3-substituted propenes as 3-aryloxy- and 3-arylthio-propenes,[70] 3-iodopropene,[72] and 3-chloropropene,[65] which are normally unreactive as ene components or only weakly active. Even methyl methacrylate undergoes ene reaction with HFA [65] and MTFP.[72]



The ene adduct obtained with HFA is further converted to a λ-lactone on treatment with $AlCl_3$.[67] Bulky allylic substituents, such as trimethyl- and triphenyl-silyl, in the alkene component do not inhibit ene reaction with HFA or with chloropentafluoro- and 1,3-dichlorotetrafluoro-acetone.[23]

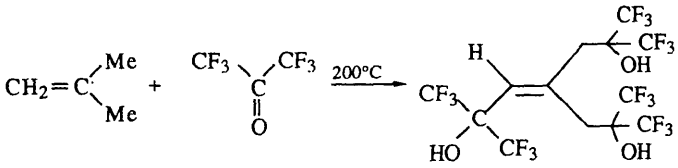
In certain instances the selectivity of the ene reaction between polyfluoroketones and alkenes is lower than normal because the initially formed homoallyl alcohol is itself a highly active ene component and undergoes a subsequent ene reaction to give a 2:1 adduct. The effect of the reaction conditions on such adduct formation has been studied in detail,[68] with particular reference to the reaction of HFA with 2-methylpropene.[66,68,73,74]



Similar products have also been observed on interaction of 2-methylpropene with 1,3-dichlorotetrafluoroacetone.[68,75] and MTFP.[21] In the latter instance, 2:1 adducts are even formed at −20 C.[72] The formation of such adducts also takes place on

reaction of HFA with propene,[68,76,77] 1-butene,2-phenylpropene, 2-methyl-1-pentene, 2-methyl-1-undecene, and 2-methyl-3-phenylpropene,[68] as well as on reaction of 1,3-dichlorotetrafluoroacetone with 2-phenylpropene and 1,5-hexadiene.[66]

A 3:1 adduct has been isolated by reacting 2-methylpropene with a four-fold excess of HFA.[68,78]



The ene reactions of polyfluoroketones with propenes having electron-donating allylic functionality afford tetrahydrofuran derivatives as by-product[64,70–72] the yield of which depends on the temperature and the reaction time. Under certain conditions such tetrahydrofurans are the main product (see Table 3).

Table 3. Reaction conditions and yields of tetrahydrofurans obtained by reaction of polyfluoroketones with terminal alkenes.

Polyfluoroketone	Alkene	*T*, °C	Time*, h	Yield, %	Refs.

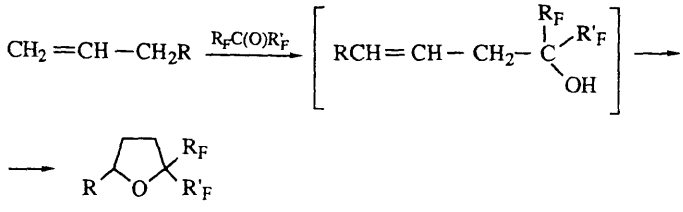
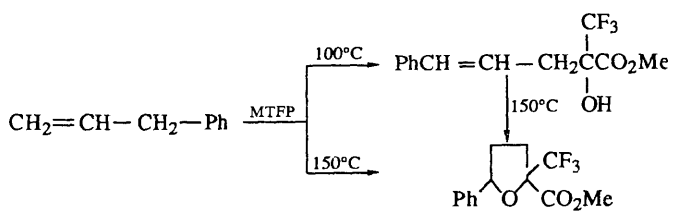
	Allyl phenyl sulphide	150	15	17.8	[70]
$CF_3CCF_2NO_2$ ‖ O	Allyl methyl ether	100	10	30	[64]
CF_3CCO_2Me ‖ O	Allyl methyl ether	110	30	57	[72]
	Allylbenzene	150	14	32.3	[72]
CF_2ClCCF_2Cl ‖ O	4-Allylanisole	45–100	144	91	[71]
	Allyl phenyl ether	45–100	310	67	[71]
	Diallyl ether	45–100	144	97	[71]

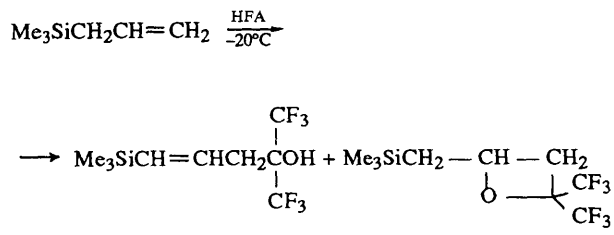
The formation of these products can be explained by cycloisomerisation of the initially formed homoallyl alcohols.



This was confirmed in a study of the reaction of HFA with 4-allylanisole[70] and of MTFP with allylbenzene.[72]

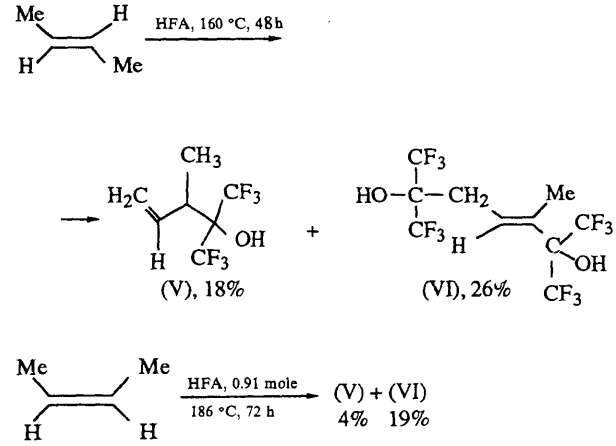


Only one example is known of a thermal reaction between a polyfluoroketone and a terminal alkene wherein by-product formation is kinetically independent of the primary ene reaction. Thus, it has been shown that HFA interacts with 3-(trimethylsilyl)propene to give a mixture of the corresponding homoallyl alcohol and an oxetane.[23]

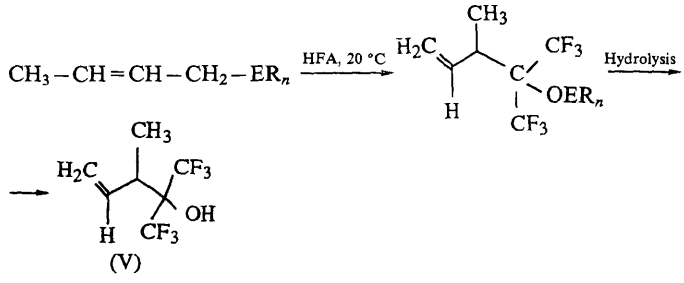


Here, [2 + 2]-cycloaddition coexists with ene reaction as a quite independent pathway.

Contrasting with terminal alkenes, internal alkenes interact with polyfluoroketones only under harsh conditions. For example, the reactions of *trans*- and *cis*-2-butene with HFA require heating at 160 and 180 °C, respectively. The resulting homoallyl alcohols, having a terminal vinyl group, readily participate in a subsequent ene reaction.[68]

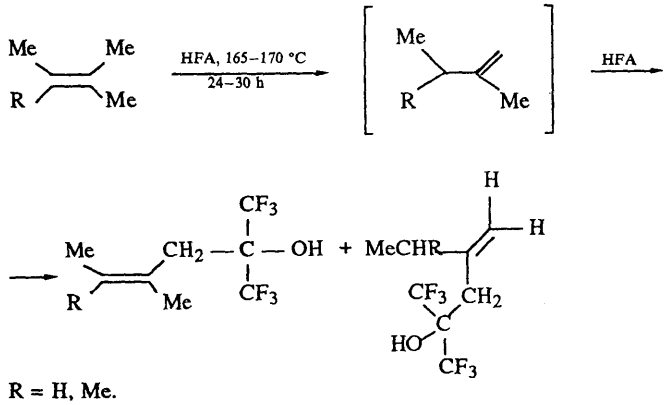


The homoallyl alcohols (V) and chloropolyfluoro analogues have also been prepared by reaction of the corresponding polyfluoroketones with crotyldibutylborane, tricrotylborane,[79] crotyltrimethylstannane or crotyltriphenylstannane.[23] The initial ene reaction proceeds regiospecifically at 20 °C with transfer of the organometallic residue to the oxygen atom of the carbonyl group.



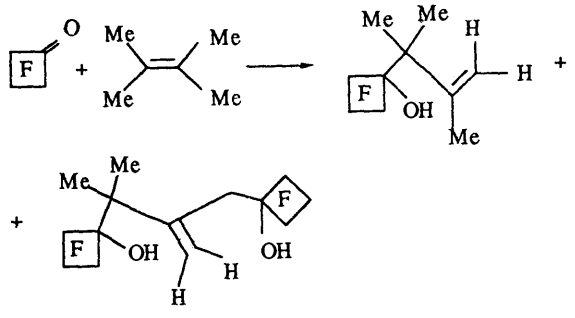
$ER_n = B(n\text{-}Bu)_2$, $B(CH_2{-}CH{=}CH{-}CH_3)_2$, $SnMe_3$, $SnPh_3$.

Treatment of HFA with trimethyl- or tetramethyl-ethene under harsh conditions initially produces a terminal alkene which then reacts with the ketone to give a mixture of two isomeric homoallyl alcohols.[68]

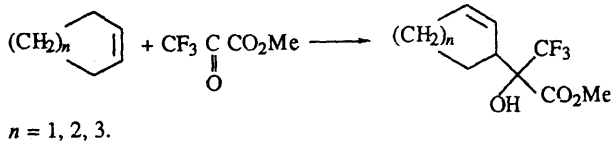


R = H, Me.

Perfluorocyclobutanone, however, reacts at 100 °C with tetramethylethene as a typical internal alkene, i.e. by formation of the corresponding homoallyl alcohol and a 2:1 adduct.[11]



Ene reactions of polyfluoroketones with cycloalkenes require the same forcing conditions as with internal acyclic alkenes. Thus, the interaction of MTFP with cyclohexene affords a preparatively useful yield of ene adduct at 170 °C, while cyclopentene and cycloheptene require heating at 150–160 °C.[21,72]

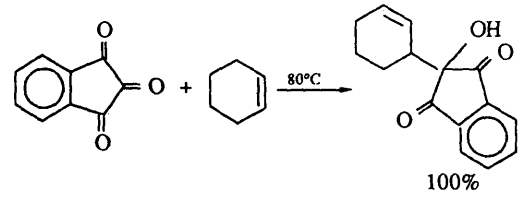


n = 1, 2, 3.

However, only a small yield of ene adduct (up to 5%) is obtained on heating HFA with cyclohexene at 160 °C for 5 h.[65] It is worth noting that ene reactions of the pro-chiral MTFP with cycloalkenes afford a mixture of diastereoisomeric ene adducts. The ratio of diastereoisomers is quite high (up to 85% of one diastereoisomer in the mixture), so that these thermal ene reactions are stereoselective.[72]

The enophilic properties of DEOM are quite different from those of polyfluoroketones. Thus, DEOM reacts with terminal ene components to give the anticipated homoallyl alcohols but under noticeably more forcing conditions.[80–85] More to the point, 3-substituted propenes do not react at all with DEOM even under harsh conditions.[71]

In a comparative study of the reactions of DEOM, HFA and MTFP with 3,7-dimethylenebicyclo[3.3.1]nonane, it was found that DEOM is significantly less reactive than the two polyfluoroketones.[69] However, where ene reactions with internal alkenes and cycloalkenes are subject to steric control, there is little difference in the reactivity of polyfluoroketones[21,65] and DEOM.[30,80,85] From this it follows that ene reactions with polyfluoroketones (HFA and MTFP) and DEOM are equally affected by steric forces, and that the enophilicity of these ketones is less important with bulky ene components. In fact, where the carbonyl group is relatively unhindered, as in 1,2,3-indantrione, ene reaction proceeds under fairly mild conditions, even with cycloalkenes.[62]

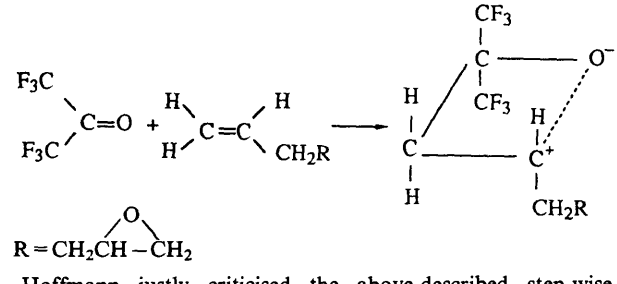


100%

It is evident that differences in the electronic state of the carbonyl group in polyfluoroketones and DEOM are more important. A molecular orbital study of ene reactions indicates that the energy and asymmetry of the LUMO of the enophile has a critical effect on the formation of a pseudoaromatic transition state.[86] It is very significant that, unlike DEOM, polyfluoroketones are characterised by a noticeably lower level for their LUMO which is predominantly localised on the carbon atom of the carbonyl group.[27]

Given the unusual electronic state of polyfluoroketones, one would not anticipate a concerted mechanism for their ene reactions, but rather the formation of a transition state wherein carbon–carbon bond formation has developed to a greater extent than hydrogen migration to the carbonyl group. However, from initial studies, it is evident that such ene reactions do involve a typical concerted pathway with the suprafacial formation of a pseudoaromatic six-membered transition state.[8,64] Gordon arrived at the same conclusion as a result of studying the kinetics of the reaction of HFA with propene in the gas phase.[87] At the same time, it was found that reaction is profoundly affected by steric hindrance, as reflected in the unusually low value for the kinetically derived pseudoexponential factor. It should be noted that thermal ene reactions with DEOM, which have been studied in more detail,[56,83–85,88,89] are also assumed to involve a concerted mechanism, wherein the six-membered transition state takes due account of the non-linear and aymmetric transfer of hydrogen.[56]

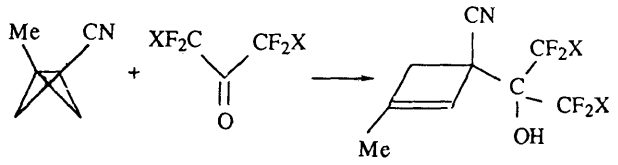
A step-wise mechanism has been proposed in one instance to explain the unexpected reaction of allyl glycidyl ether with HFA.[65] Here, it is thought that a four-centred bipolar ion is formed initially.



Later, Hoffmann justly criticised the above-described step-wise mechanism.[55] Nevertheless, the possibility still exists[56] that thermal ene reactions with polyfluoroketones may deviate from a concerted pathway, given that these enophiles are more reactive than DEOM towards classical ene components and that their behaviour towards 3-substituted propenes is distinctly different. The formation of a

[2 + 2]-cycloadduct from HFA and 3-(trimethylsilyl)propene under mild conditions would also lend weight to a non-concerted mechanism.

Only two examples are known to us where ene products are formed by interaction of polyfluoroketones with a strained δ-bonded system. This involves the reaction of HFA and 1,3-dichlorotetrafluoroacetone with 1-cyano-3-methylbicyclo[1.1.0]butane, as was outlined in Hoffmann's review.[55]



X = F, Cl.

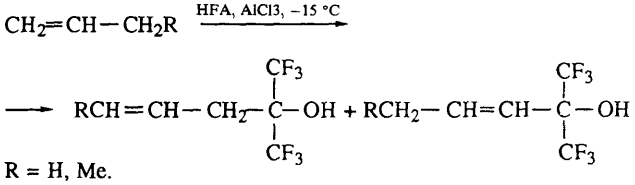
2. Reactions of polyfluoroketones with ene components in the presence of a Lewis acid

Like Diels–Alder cycloaddition, ene reactions are catalysed by Lewis acids.[55]

It has been shown that the lone pair-donating properties of the carbonyl oxygen atom of polyfluoroketones are largely nullified. This is evident from the fact that HFA is virtually unreactive towards electrophilic agents[4] and that the oxygen atom of HFA is not protonated by superacids.[90] It is also evident that no alternative sites in the polyfluoroketone molecule are available for interaction with Lewis acids. Hence only strong Lewis acids coordinate with polyfluoroketones, as is evident in the $AlCl_3$-catalysed reactions of nitropentafluoroacetone, HFA and chloropentafluoroacetone with unsaturated substrates, including ene components.[4,5]

Thus, HFA interacts with cyclohexene in the presence of $AlCl_3$ at −10 °C to give an ene adduct in 56% yield.[91] 1,1,1-Trifluoroacetone reacts similarly with cyclic olefins in the presence of $AlCl_3$ at −78 °C.[92] The $AlCl_3$-catalysed reaction of HFA or chloropentafluoroacetone with propene or 1-butene takes place at −15 °C.[93–95]

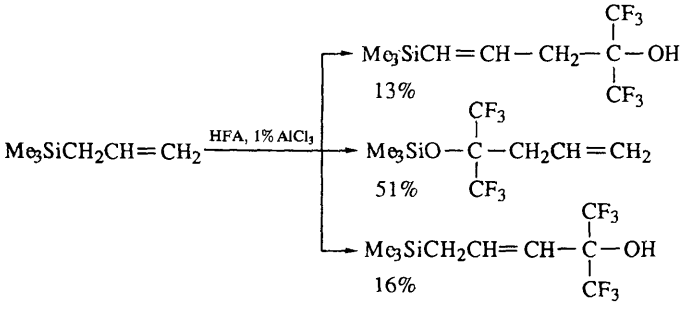
In these reactions, allyl alcohols are formed to a much greater extent than homoallyl alcohols.



R = H, Me.

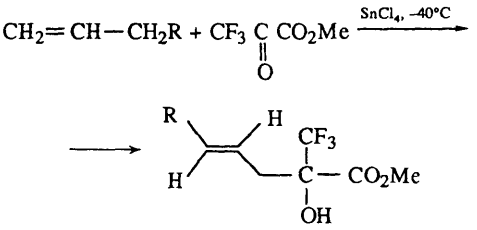
It has also been shown that the resulting allyl and homoallyl alcohols are formed in kinetically independent pathways.

The reaction of HFA with 3-(trimethylsilyl)propene can also be achieved in the presence of $AlCl_3$, but here the ene adduct predominates.[23]



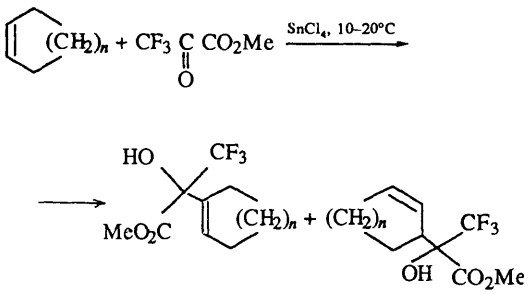
It is thought that the $AlCl_3$-catalysed reactions of polyfluoroketones with terminal alkenes involves the same activation as takes place in Friedel–Crafts reactions.[23,93] Thus, the donor–acceptor complex formed between the ketone and $AlCl_3$ attacks the terminal carbon atom of the unsaturation to give a carbocation, which is stabilised by elimination of a proton from an adjacent carbon atom.

The methoxycarbonyl group in MTFP provides a second site for complexation with the Lewis acid, so that ene reactions with this polyfluoroketone may be performed with $SnCl_4$. In fact, the $SnCl_4$ catalysed ene reactions of MTFP with propene and 1-butene afford exclusively ene adducts even at −40 °C.[21]



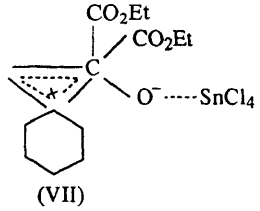
R = H, Me.

The $SnCl_4$-catalysed reactions of MTFP with cyclopentene and cyclohexene take place at 10–20 °C under steric control.[21] Here, the corresponding allyl alcohols are formed predominantly (60–65%), while the yield of ene adducts does not exceed 15%.



n = 1,2.

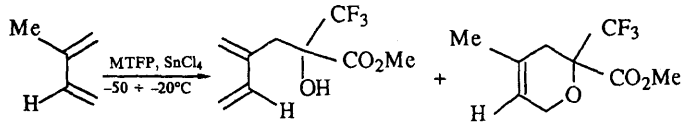
It should be noted that DEOM also reacts readily with terminal and internal alkenes in the presence of $SnCl_4$.[56,83,84] The mechanism of these processes has been studied in detail. A kinetic model has been proposed to explain the observed intramolecular and intermolecular isotope effects. This involves a three-membered intermediate having restricted rotation, exemplified below (VII) for the reaction of DEOM with methylenecyclohexane in the presence of $SnCl_4$.



(VII)

Although $SnCl_4$-catalysed reactions of DEOM and MTFP are apparently similar, one cannot assume that the rules and mechanism applicable to ene reactions with DEOM also hold true for ene reactions with MTFP.

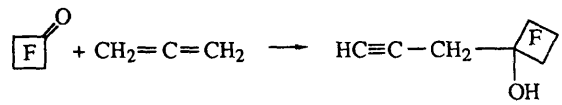
As mentioned above, $SnCl_4$ changes the course of the reaction of MTFP with isoprene in such a way that a 4:1 mixture of ene and Diels–Alder adducts is formed.[15]



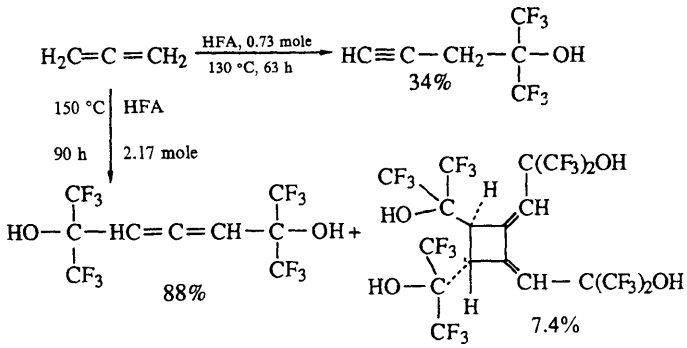
Similar results have been obtained previously for the reactions of chloral and *n*-butyl glyoxylate with isoprene and 2,3-dimethyl-1,3-butadiene.[96]

3. Ene reactions of polyfluoroketones with 1,2-dienes

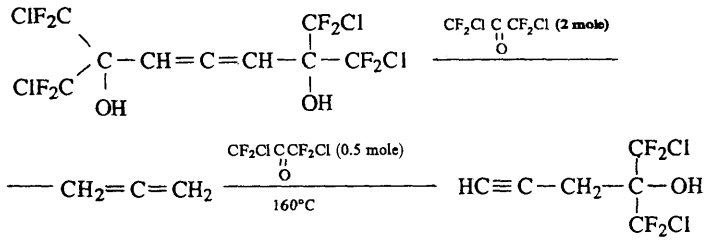
By analogy with the ene reactions considered above,[68] polyfluoroketones might be expected to form ene adducts with 1,2-dienes by a similar step-wise mechanism, taking into account the geometrical constraints of the reacting molecules. However, studies of isotopic effects on the reaction of perfluorocyclobutanone with allene[97,98] have shown clearly that the rate-limiting stage is consistent with a concerted mechanism involving a non-linear and asymmetric transfer of hydrogen. In fact, this reaction leads to an ene adduct (47% yield) even at 20 °C.[10]



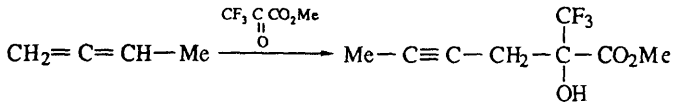
The reactions of allene with other polyfluoroketones can only be achieved on heating. Thus, heating HFA with allene at 130 °C affords an ene adduct (34% yield), which is almost completely transformed at 150 °C to a 2:1 adduct in the presence of an excess of HFA.[68]



Similarly, 1,3-dichlorotetrafluoroacetone interacts with allene at 160 °C to give 1:1 and 2:1 adducts depending on the proportion of the reactants.[99]

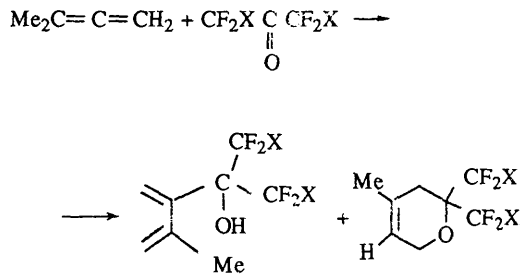


The ene reaction of MTFP with 1,2-butadiene proceeds under milder conditions (80 °C).[72]



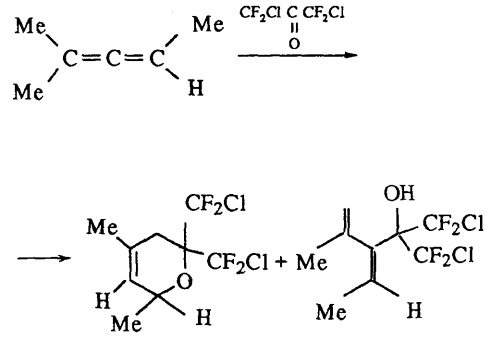
In the presence of polyfluoroketones, 3-methyl-1,2-butadiene and tri- and tetra-methylallene partly or completely isomerise into the corresponding 1,3-diene even at 20 °C. As a consequence, either Diels–Alder adducts or mixtures containing the latter and ene adducts are formed.[17,19]

Thus interaction of HFA or 1,3-dichlorotetrafluoroacetone with 3-methyl-1,2-butadiene at 175 °C affords a mixture of the corresponding hydroxy-1,3-diene and dihydropyran. Reaction is slow at 20 °C, but proceeds rapidly on heating.



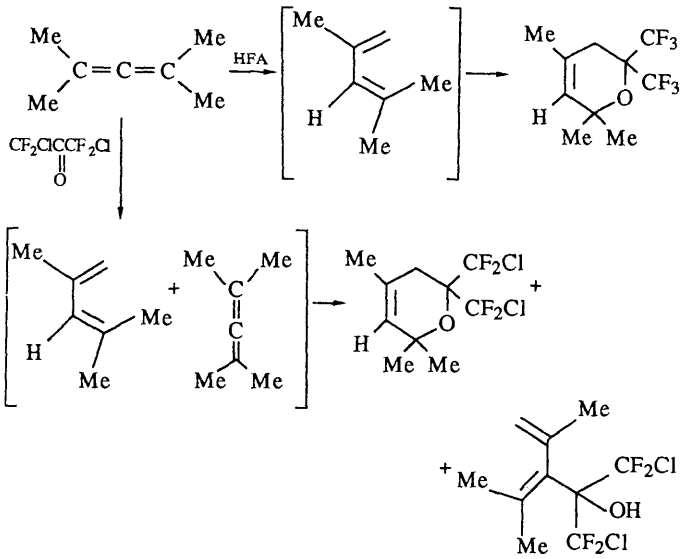
X = F or Cl.

The reason between trimethylallene and 1,3-dichlorotetrafluoroacetone affords the corresponding dihydropyran as the main product (56%) together with a 13% yield of an ene adduct.



Tetramethylallene isomerises completely in the presence of HFA at 20 °C to give 2,4-dimethyl-1,3-pentadiene which, under these conditions, readily undergoes diene synthesis. The isomerisation

proceeds more slowly in the presence of 1,3-dichlorotetrafluoroacetone to give both [4 + 2]-adduct and ene adduct (6%).

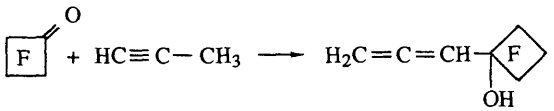


An unsuccessful attempt was made to minimise prototropic rearrangement of polymethyl-substituted allenes to conjugated dienes by carrying out the reaction in the gas phase at 100 °C.[19]

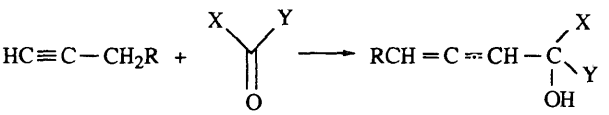
4. Ene reactions of polyfluoroketones with alkynes

Classical enophiles normally do not react with terminal alkynes as readily as they do with alkenes.[55] However, polyfluoroketones are an exception, reacting equally well with both alkynes and alkenes.

Thus, even at 20 °C, perfluorocyclobutanone reacts with propyne to give the corresponding allenealcohol in 43% yield.[10]

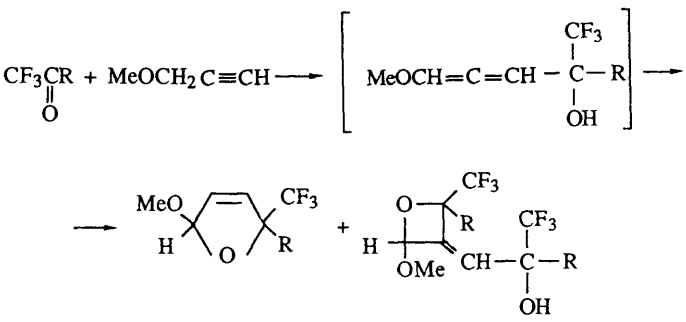


Allenealcohols are obtained similarly from the reaction of HFA with propyne,[99] from the reaction of MTFP with propyne and with 1-hexyne,[72] and from the reaction of 1,3-dichlorotetrafluoroacetone with propyne, 1-pentyne, or 1-undecyne at 50–100 °C. Ene adducts are also formed on interaction of 1,3-dichlorotetrafluoroacetone with propargyl chloride (140 °C),[99] and on interaction of MTFP with propargyl bromide (110 °C).[72]



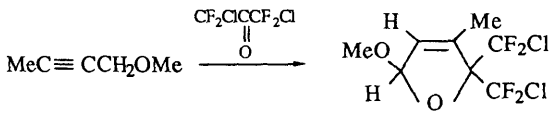
R = H, Et, Pr^n, n-C_9H_{19}, Cl, Br;
X = Y = CF_3, CF_2Cl, X = CF_3, Y = CO_2Me.

A mixture of dihydrofuran and oxetane derivatives was obtained on reaction of HFA, nitropentafluoroacetone or MTFP with methyl propargyl ether.[72,100] It is thought that an initial ene reaction affords the corresponding allenealcohol, which then undergoes cycloisomerisation or participates in [2 + 2]-cycloaddition with a second molecule of the ketone.

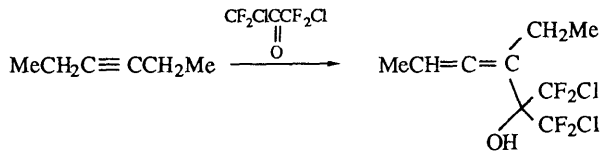


R = CF_3, CF_2NO_2, CO_2Me.

In the patent literature, it is reported that only dihydrofuran derivatives are formed on reaction of 1,3-dichlorotetrafluoroacetone with methyl propargyl ether and on reaction of HFA with ethyl propargyl ether.[101] The interaction of but-2-yn-1-yl methyl ether with 1,3-dichlorotetrafluoroacetone also affords the corresponding dihydrofuran exclusively.[101]



There are also references to ene reactions involving an internal alkyne. Thus, dichlorotetrafluoroacetone reacts with 3-hexyne during 20 h at 170 °C to give the expected allenealcohol.[99]



IV. [2 + 2]-Addition

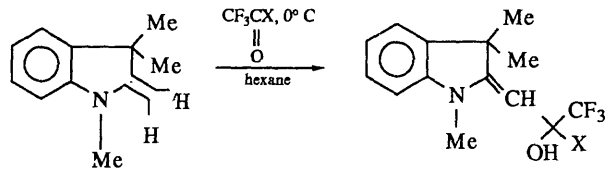
As has been mentioned previously (p. 786), it is the unusual electronic state of the C=O bond in polyfluoroketones which is responsible for their high reactivity with isolated, highly-polarised, electron-rich multiple bonds. As a consequence, several types of conversion are possible, the predominant ones being: [2 + 2]-cycloaddition; [2 + 2]-cycloaddition with subsequent ring opening or [2 + 2]-retroscission; and coupling to give an intermediate 1,4-dipolar zwitter-ion, stabilised by prototropic rearrangement or cycloaddition to the polyfluoroketone molecule. Furthermore, in certain instances, such reaction pathways are also possible with weakly polar and even polarised electron-deficient unsaturated compounds. Thus, the chemistry of [2 + 2]-addition with polyfluoroketones is far more extensive than with other 1,2-dipolarophiles.

All of the above-mentioned reaction types can be readily explained, in qualitative terms, by a step-wise [2 + 2]-addition which is consistent with molecular orbital calculations.[102–105] However, certain [2 + 2]-additions with polyfluoroketones may be interpreted in terms of a pericyclic pathway, the likelihood of which may be ascertained by the perturbation method.[106,107]

1. [2 + 2]-Addition across the C=C bond

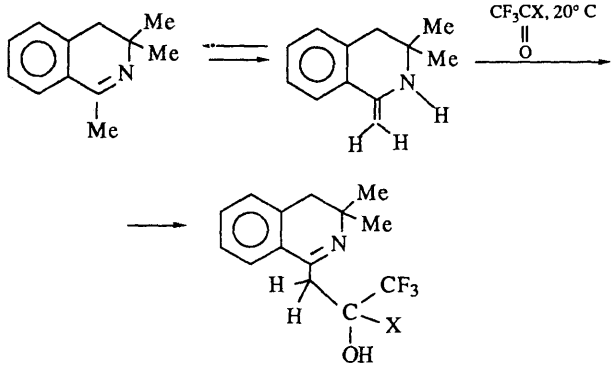
Enamines, ketene acetals, vinyl ethers, and ketenes are all highly reactive towards polyfluoroketones in [2 + 2]-addition. In certain instances, styrene and α,β-unsaturated carbonyl compounds also participate in this reaction.

Enamines interact the most smoothly with classical 1,2-dipolarophiles. Since the atom of nitrogen in the transition state is stabilised by an adjacent cationic centre, such reactions normally proceed via prototropic rearrangement of an intermediate zwitter-ion. This has been established for the reactions of HFA and MTFP with 2-methylene-1,3,3-trimethylindoline at 0 °C.[108]



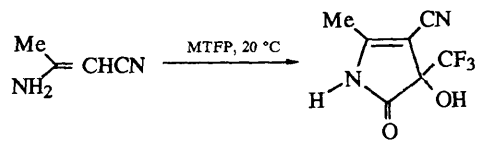
X = CF_3, CO_2Me.

Similarly, HFA and MTFP interact at 20 °C with the enamine form of 3,4-dihydro-1,3,3-trimethylisoquinoline.[109]

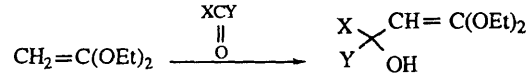


X = CF_3, CO_2Me.

MTFP reacts with 3-aminocrotononitrile in acetonitrile at 20 °C. The ketone initially interacts across the multiple bond, after which intramolecular ring closure takes place to give a lactam in 68% yield.[110]

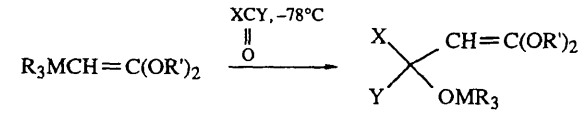


Ketene acetals react energetically with nitropentafluoroacetone, HFA and 1,1,3-trifluoro-1,3,3-trichloroacetone. However, no oxetanes were formed. Instead, reaction takes place at −30 to 20 °C to give the corresponding allylic tertiary alcohols.[111,112]



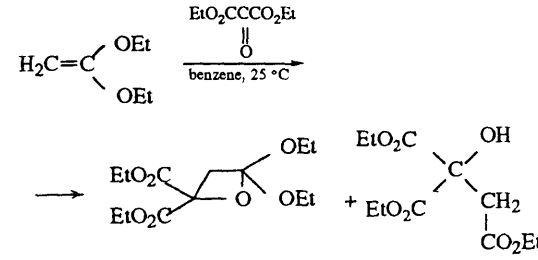
X = Y = CF_3; X = CF_3, Y = CF_2NO_2; X = CF_2Cl, Y = $CFCl_2$.

Acyclic products are also formed on reaction of silyl- and germylketene acetals with HFA, 1,3-dichlorotetrafluoroacetone and 1,1,3-trifluoro-1,3,3-trichloroacetone.[112,113]

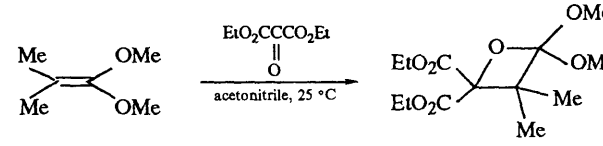


MR_3 = Me_3Si, $MeCl_2Ge$; X = Y = CF_3, CF_2Cl;
X = CF_2Cl, Y = $CFCl_2$; R' = Me, Et.

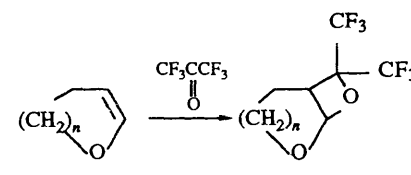
In a spectroscopic study of reactions of polyfluoroketones with 2-trimethylsilylketene acetals at −78 °C, it was shown that the initial product is the corresponding oxetane which is cleaved on raising the temperature. It is worth noting that interaction of DEOM with diethyl keteneacetal in benzene affords a mixture of the corresponding oxetane (58%) and a trace of an acyclic product.[114]



In the highly polar acetonitrile as solvent, this reaction gives a mixture of four products, none of which is the corresponding oxetane. However, the interaction of DEOM with 1,1-dimethoxy-2-methylpropene affords an oxetane exclusively, even in acetonitrile.[114]

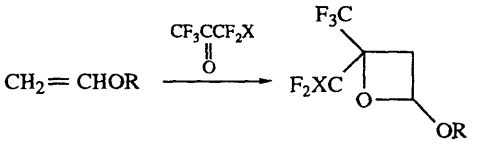


Stable oxetanes have been obtained by reaction of polyfluoroketones with a variety of vinyl ethers.[115–121] The most active of these is 2,3-dihydrofuran which yields a stable [2 + 2]-cycloadduct with HFA at −20 °C in 57% yield. With 3,4-dihydro-2*H*-pyran, however, such cycloaddition requires a higher temperature (50 – 60 °C).[121]



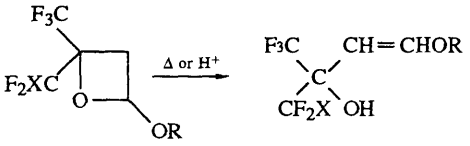
n = 1, 2

Alkyl vinyl ethers react with HFA more slowly at −20 °C. However, a preparative yield of oxetane derivatives is obtainable with HFA and nitropentafluoroacetone at 20 °C in dimethyl sulphate.[115]



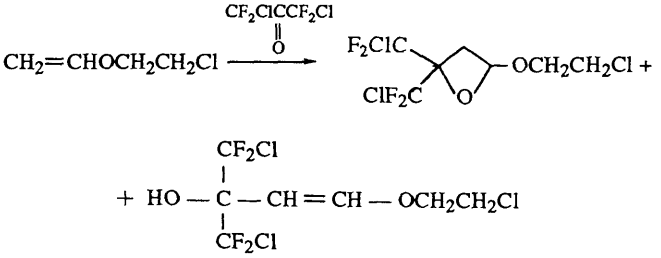
X = F, NO_2; R = Et, Bu^n.

Ring opening of the products takes place slowly at 100 °C, but noticeably faster in the presence of H_2SO_4.

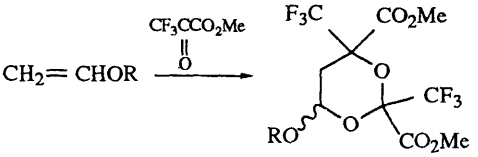


X = F, NO_2; R = Et, Bu^n.

In certain instances, e.g. on reaction of 1,3-dichlorotetrafluoroacetone with 2-chloroethyl vinyl ether, isomerisation of the oxetane takes place during the reaction.[116]

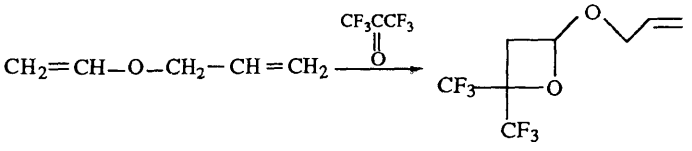


Contrasting with HFA, MTFP reacts with alkyl vinyl ethers in polar media to give products derived by 1,4-dipolar cycloaddition to an initially-formed zwitter-ion.[110] The course of the reaction is not affected by the proportion of the reactants.



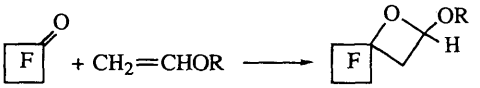
R = Et, Bu^n.

An interesting result was reported on studying the reaction of HFA with allyl vinyl ether.[120] Here, the sole product at 0 °C is an oxetane derivative, formed by exclusive attack of the vinylic unsaturation.



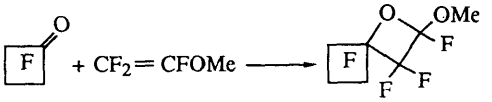
In such instances, polyfluoroketones undergo [2 + 2]-cycloaddition far more smoothly than ene reaction. Evidently, more information is required in order to elucidate the structures of the 2:1 and 3:1 adducts obtained on ene reaction of HFA and nitropentafluoroacetone with methyl allyl ether[64] and on reaction of *N*-methyl-*N*-allylaniline with HFA.[70]

Vinyl esters only participate in [2 + 2]-cycloaddition with perfluorocyclobutanone.[119] Thus, reaction with vinyl acetate and benzoate at 20 °C affords the corresponding oxetane in 54 and 45% yield, respectively.

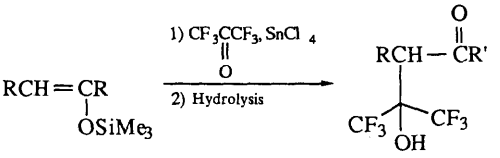


R = COMe, COPh.

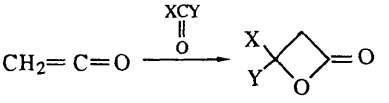
Perfluorocyclobutanone reacts similarly with methyl trifluorovinyl ether.[10]



A study has been made of the catalytic effect of Lewis acids on the reaction of HFA with trimethylsilyl enolethers. Reaction takes place at −45 °C in the presence of $SnCl_4$ or $TiCl_4$. The corresponding ketones were isolated on hydrolysis of the reaction mixture.[25]

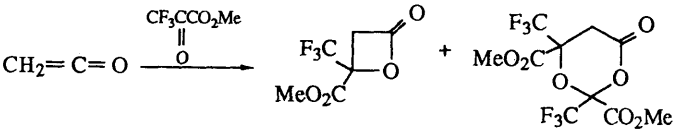


Contrasting with ketene acetals, ketenes form stable [2 + 2]-cycloadducts with polyfluoroketones. Thus 2-oxetanones are obtained in preparative yield by reaction of ketene itself with perfluorocyclobutanone,[119] nitropentafluoroacetone,[122] HFA [123] and with 1,3-dichlorotetrafluoroacetone.[124]

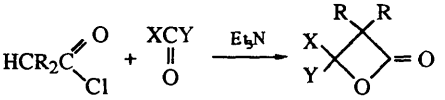


X = Y = −$(CF_2)_3$−, CF_3, CF_2Cl; X = CF_3, Y = CF_2NO_2.

A mixture of 2-oxetanone and 1,3-dioxan-4-one derivatives was obtained on passing ketene into a solution of MTFP in ether.[125]

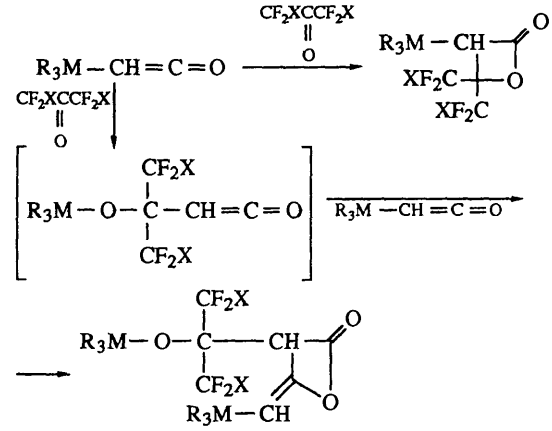


The isolation of 2-oxetanones on reaction of 1,1,3-trifluoro-1,3,3-trichloroacetone and MTFP with acetyl chloride[126] and dichloroacetyl chloride,[110] respectively, confirmed that ketenes are formed *in situ* [in the presence of base].



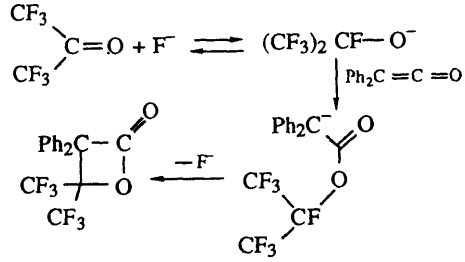
R = H, X = CF_2Cl, Y = $CFCl_2$; R = Cl, X = CF_3, Y = CO_2Me.

Silyl-, germyl- and stannyl-ketenes also interact with HFA and 1,3-dichlorotetrafluoroacetone to give 2-oxetanones.[127] An ionic [2 + 2]-addition takes place simultaneously to give an intermediate ketene which reacts with a second molecule of the starting ketene to give a 4-ene-2-oxetanone as by-product.

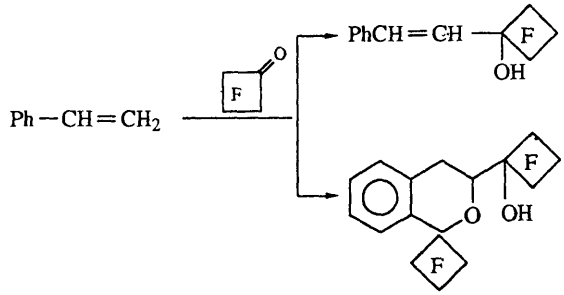


X = F, Cl; R_3M = $SiMe_3$, $GeCl_2Me$, $SnBu^n_3$.

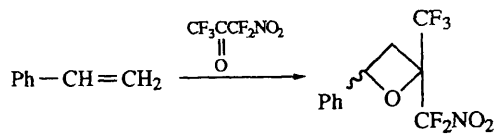
The steric effect of the phenyl groups in diphenylketene prevents reaction with HFA even at 100 °C. However, a 2-oxetanone derivative is obtained in preparative yield under nucleophilic catalysis.[128]



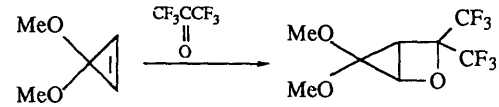
Only the most electrophilic polyfluoroketones react with weakly polarised alkenes. Thus, interaction of perfluorocyclobutanone with styrene at 20 °C yields an ionic [2 + 2]-adduct,[11] while an isochroman is formed in the presence of an excess of the ketone.



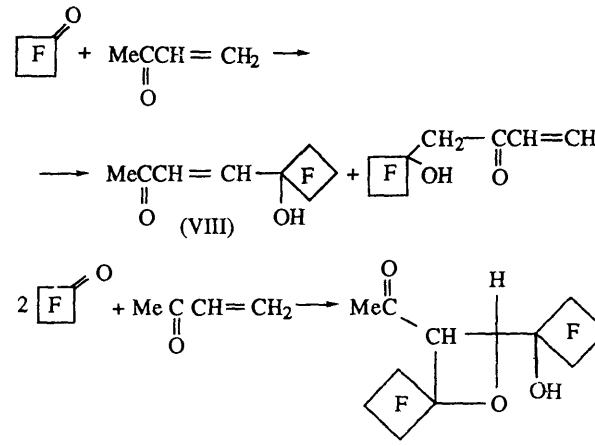
Heating a mixture of nitropentafluoroacetone and styrene at 100 °C for 10 h affords the corresponding oxetane in 37% yield.[129]



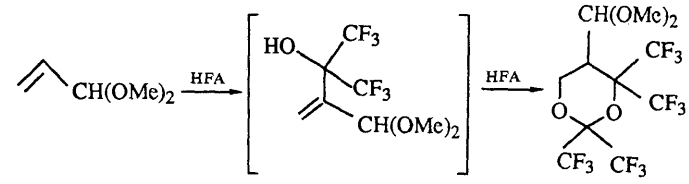
Under similar conditions, HFA initiates polymeristion of the alkene.[65] However, a [2 + 2]-cycloadduct is formed with the strained dimethyl ketal of cyclopropenone at 20 °C.[130]



Electron deficient α,β-unsaturated aldehydes, ketones, esters and nitriles react with polyfluoroketones under forcing conditions in the presence of a catalyst. Thus, treatment of methyl vinyl ketone with perfluorocyclobutanone at 100 °C affords a mixture of compounds, among which a ketol and the anomalous [2 + 2]-adduct (VIII) have been identified. An oxetane is obtained, however, in the presence of an excess of perfluorocyclobutanone. This has been shown to arise by cycloaddition of intermediate (VIII) with a second molecule of the ketone.[11]

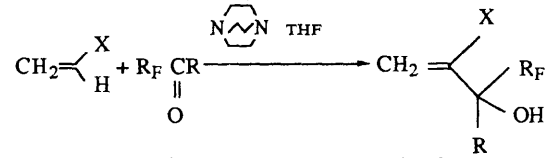


Reaction of acrolein dimethyl acetal with HFA at 150 °C produces a 1,3-dioxane (9%), which is thought to arise by the scheme shown below.[131]



The initial [2 + 2]-addition takes place in accordance with the polarisation of the C=C bond.

The same polarisation factors are at play in the reactions of HFA, MTFP, 1,3-dichlorotetrafluoroacetone and bromopentafluoroacetone with methyl acrylate, acrylonitrile, and acrolein in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO).[132]

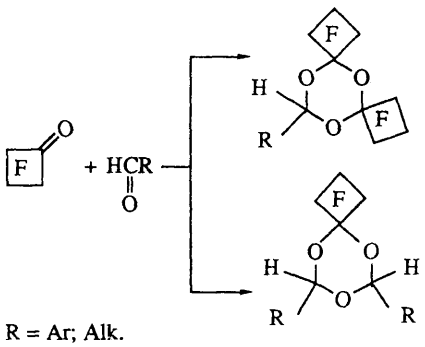


R = R_F = CF_3, CF_2Cl; R_F = CF_3, R = CO_2Me;
R_F = CF_3, R = CF_2Br; X = CO_2Et, CN, CHO, COMe.

Among non-fluorinated carbonyl compounds, only DEOM participates readily in this conversion (known as the Baylis–Hillman reaction).[133] The addition of aliphatic and aromatic aldehydes requires more forcing conditions.[134] The mechanism of the Baylis–Hillman reaction involves addition of DABCO at the β-position of the α,β-unsaturated system, followed by interaction of the carbonyl compound with the generated anionic centre at the adjacent α-site.[135]

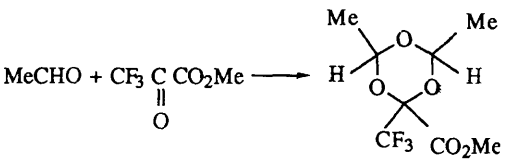
2. [2 + 2]-Addition across hetero-unsaturations, C=Y and X=Y

Polyfluoroketones interact with aliphatic and aromatic carbonyl compounds at room temperature or below. A zwitter-ion is formed initially, this being stabilised by 1,4-dipolar addition either to a second molecule of the polyfluoroketone or to the non-fluorinated component to give the corresponding 1,3,5-trixane. Thus, perfluorocyclobutanone reacts with aromatic aldehydes and certain ketones to give predominantly a 2:1 cycloadduct; a 1:2-cycloadduct, however, is formed with aliphatic aldehydes.[136]



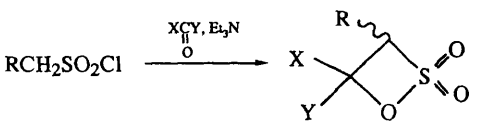
R = Ar; Alk.

Acetaldehyde interacts with MTFP at 20 °C to give a 1:2 cycloadduct exclusively.[110]



In the reactions of polyfluoroketones with aliphatic aldehydes, stable aldols are formed as by-products. The proportion of the latter increases with the length of the aliphatic chain. Enolisable ketones afford predominantly stable ketols with perfluorocyclobutanone,[11] while ketols are formed exclusively with HFA and MTFP.[137–140] The former initiates polymerisation of an acetone/formaldehyde mixture even at −78 °C.[141]

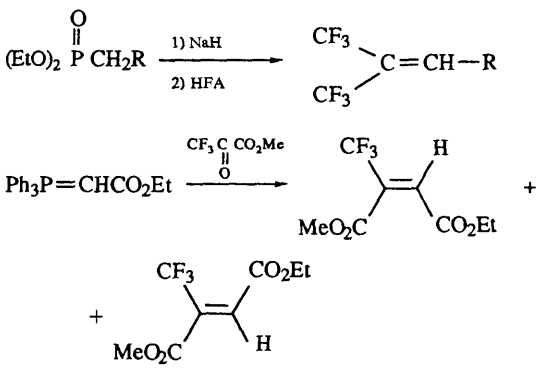
Chloropentafluoroacetone, 1,3-dichlorotetrafluoroacetone and MTFP yield β-sultones on reaction with sulphenes, generated *in situ* by treatment of the corresponding alkanesulphonyl chlorides with Et_3N at 20 °C.[110,142–145]



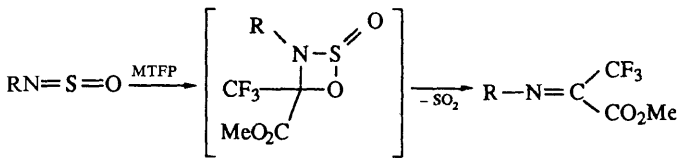
R = H, Cl; X = Y = CF_2Cl; R = H, X = CF_3, Y = CF_2Cl; R = H, X = CF_3, Y = CO_2Me.

A complex mixture of products was obtained with HFA, primarily because this ketone serves as a powerful dehydrogenating agent towards Et_3N.[146,147]

Witt's survey[8] provides extensive data on the reactions of HFA with unsaturated elementoorganic and organometallic compounds. Recently, new information on the use of polyfluoroketones in the Wittig and Horner–Emmons reactions has been made available.[148–150]



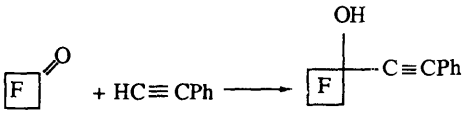
[2 + 2]-Cycloaddition-cycloreversion of polyfluoroketones with isocyanates and thionylimines has already been reviewed in the context of perfluoroketimine chemistry.[43,45] It is worth noting that, contrasting with HFA,[151] MTFP reacts with thionylimines in the absence of catalyst on warming.[152]



R = Ph, COPh, COMe.

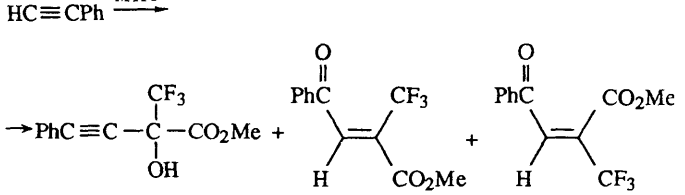
3. Addition across the C≡C bond

Terminal alkynes lacking a propargylic hydrogen atom react with polyfluoroketones to give either Favorskii products (tertiary acetylenealcohols) or [2 + 2]-cycloadducts (oxetenes), electrocyclic ring opening of which leads to α,β-unsaturated carbonyl compounds. For example, phenylacetylene reacts with perfluorocyclobutanone to give exclusively an acetylenealcohol even at 0 °C.[11]



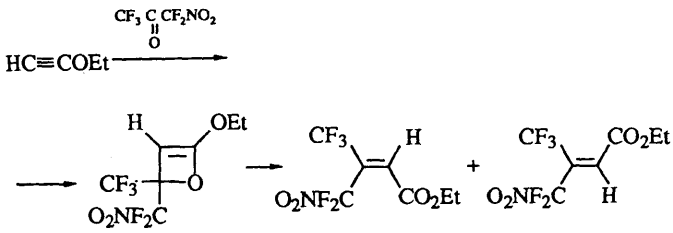
It should be noted that non-fluorinated ketones only participate in the Favorskii reaction in the presence of a strong base.[153]

Phenylacetylene reacts slowly at 20 °C with MTFP, or rapidly above 60 °C, to give a mixture of the corresponding acetylenealcohol and methyl α-trifluoromethyl-β-benzoylacrylate (as a mixture of *Z*- and *E*-isomers).[110]

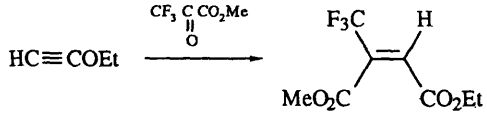


The products of this reaction were isolated pure and shown to be formed in kinetically independent pathways, i.e. no interconversions involving these products were observed, even under forcing conditions.

The reactions of ethoxyacetylene with HFA [154] and nitropentafluoroacetone[111] below room temperature lead to oxetenes, which rearrange at 20 °C to give substituted acrylates. A mixture of *Z*- and *E*-isomers was obtained from nitropentafluoroacetone.

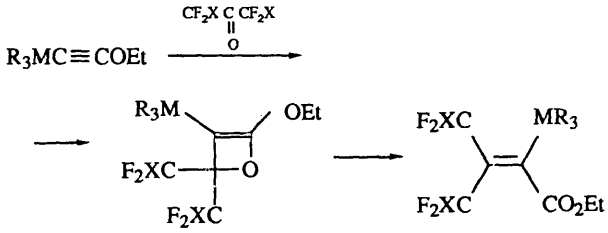


Ethoxyacetylene interacts with MTFP to give a trifluoromethylmaleic acid diester exclusively.[110]



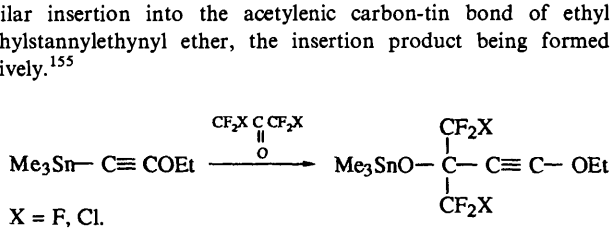
There was no intermediate formation of an extreme derivative under these conditions (20 °C).

Relatively stable oxetenes have been obtained by reaction of polyfluoroketones with trimethylsilyl and trimethylgermyl derivatives of ethoxyacetylene.[155] The resulting trimethylsilyloxete derivatives are converted to the corresponding acrylate at 20 °C over a period of 2 months or at 100 °C during 30 min.



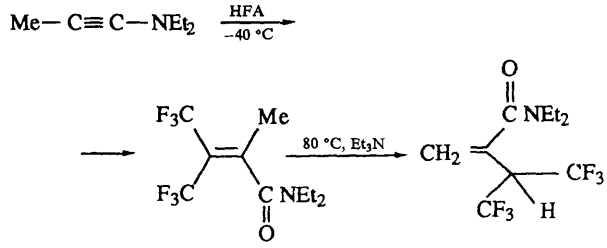
X = F, Cl; MR_3 = $SiMe_3$, $GeMe_3$, $SiEt_3$, $GeEt_3$.

Germyl-substituted acetylenealcohols are obtained as by-products on reaction of polyfluoroketones with ethyl trimethylgermylethynyl ether, i.e. the polyfluoroketones are inserted into the acetylenic carbon-germanium bond. 1,3-Dichlorotetrafluoroacetone undergoes a similar insertion into the acetylenic carbon-tin bond of ethyl trimethylstannylethynyl ether, the insertion product being formed exclusively.[155]



X = F, Cl.

1-Diethylaminoprop-1-yne reacts with HFA even at −40 °C to give an acrylamide derivative by ring opening of an intermediate oxetene. On heating in the presence of Et_3N, the product undergoes prototropic rearrangement to give α-(hexafluoroisopropyl)acrylic acid *N*,*N*-diethylamide.[156]



It was not possible to characterise the intermediate oxetene. Although there is a propargylic hydrogen atom in the starting ynamine, no simultaneous ene reaction was detected, i.e. the [2 + 2]-pathway is exclusive.

Polyfluoroketones (especially HFA) are seen as highly electrophilic ketones, which interact energetically with water, alcohols and amines to give stable hydrates, hemiketals and hemiaminals, respectively. This behaviour is typical of highly electrophilic carbonyl compounds. In fact, they are akin to certain aldehydes (formaldehyde, chloral, fluoral) and ketones with electron-accepting substituents (mesoxalates and certain 1,2-di- and 1,2,3-triketones, etc.).

***

The present review covers one particular aspect of the chemistry of polyfluoroketones—their unusually high affinity towards conjugated and unconjugated donor-type π-systems, with which they undergo uncatalysed [4 + 2]-cycloaddition, ene reaction and [2 + 2]-addition below or at room temperature. Non-fluorinated aliphatic ketones either do not participate in these reactions or do so only under forcing conditions. Even highly electrophilic, non-fluorinated ketones require heating (above 100 °C) or catalytic acitvation.

Recently, it has been shown that reactions of polyfluoroketones with unsaturated compounds are highly selective under certain circumstances. They may proceed regiospecifically with characteristically high stereoselectivity, in certain instances yielding only one stereoisomer. There is much to be gained by further studies in this area, notably with a view to designing effective routes to functionalised unsaturated compounds.

From a comparison of the reactivity of HFA, MTFP and DEOM towards unsaturated compounds, it is apparent that the characteristic properties of polyfluoroketones are a consequence of the lower level of their acceptor LUMO and its significantly higher asymmetry. The structure of the LUMO of polyfluoroketones is itself determined by interactive effects between the carbonyl oxygen atom and the CF_3 group. Thus, replacement of one of the carbalkoxy groups of DEOM by a CF_3 group leads to a qualitatively different electronic state for the C=O bond.

The anomalous electronic state of the C=O group in polyfluoroketones is responsible for the large contribution made by charged structures in the stabilisation of the transition state on reaction with unsaturated compounds. This determines the high affinity of polyfluoroketones towards polarised unsaturated compounds of a donor type. Among the many reactions discussed in this article, a number of charge-induced processes are particularly interesting from a theoretical standpoint; these proceed exothermically or with a low energy barrier, and differ in their regiospecificity and high stereoselectivity.

Fluorine-containing ketimines

S N Osipov, A F Kolomiets, A V Fokin
A N Nesmeyanov Institute of Heteroorganic Compounds, Russian Academy of Sciences

ABSTRACT. **Data appearing in the last ten years have been correlated for the methods of synthesis of fluorine-containing imines, their reactions with N-, O-, S-, P- and C-nucleophiles, with aromatic and heteroaromatic π-donors and in cycloaddition and cyclocondensation processes involving these compounds. The principal theoretical ideas on the reactivity of fluorine-containing ketimines are discussed.**

I. Introduction

The chemistry of fluorine-containing imines may rightfully be considered as one of the most interesting areas of fluorine chemistry. The diversity of the effects of a fluorine atom and of fluoroalkyl groups is shown most completely in these compounds due to the presence of the highly polarisable C=N bond. The mutual effects of fluorine-containing and other substituents on the azomethine bond prove to be extremely prominent. This has caused compounds to appear in the fluoroimine series with contrasting properties, from the very stable chemically inert to the extremely reactive.

Of the great variety of fluorine-containing compounds with a C=N bond the *N*-fluoroimines, imidoyl halides, fluoroazomethines including aldimines and ketimines, ketenimines and acylimines have been studied fairly well. Each type of compound is characterised by special methods of preparation and by a set of specific properties which determine both the features of their chemistry and their area of use. The search for effective components of high-energy fuels and combustion accelerators is linked with *N*-fluoroimines. The fluoroazomethines have attracted attention as potential precursors of heat-transfer agents, greases, other valuable materials and additives. Imidoyl halides, ketenimines and acylimines are most interesting as synthons for fluorine-containing biologically active compounds.

The vast literature on fluorine-containing compounds with a C=N bond is correlated in a series of publications. The principal data on *N*-fluoroimines have been discussed in reviews,[1,2] the chemistry of fluorine-containing ketenimines has been illustrated in a review[3] and in a dissertation,[4] the general state of the chemistry of fluorine-containing imines up to the early eighties is described in review articles.[5–7]

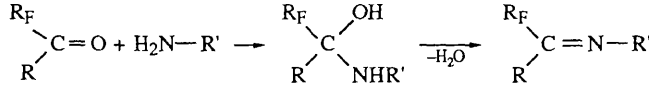
Interest in the various fluorine derivatives of the azomethines has grown during the last ten years. Particular attention has been attracted by the functionally substituted fluorine-containing ketimines, including the acylimines of polyfluoroketones, the imines of various α- and β-ketocarboxylic acids, the imines of unsaturated fluoro-carbonyl compounds and other bi- and trifunctional compounds which are interesting synthons of fluorine-containing biologically active compounds. The present paper is devoted to the correlation of this experimental material and to some of the theoretical investigations carried out in this area.

II. Methods of synthesis

From the multitude of methods developed previously for the synthesis of fluorine-containing ketimines[7] most attention has continued to be paid in the last ten years to the development of methods based on the condensation of fluorocarbonyl compounds with amino compounds. Somewhat less attention has been paid to methods based on cycloaddition–elimination reactions, including the Staudinger reaction. Interesting new approaches to the synthesis of fluorine-containing ketimines have been developed by studying the reaction of fluorine-containing nitriles and ketenimines with HCN, of geminal isocyanatohalo compounds with various nucleophilic reagents and amino compounds with fluoroalkenes and alkynes. Methods specfic for fluorine compounds have also been developed further.

1. Condensation of fluorine-containing ketones with amino compounds

The condensation of fluorine-containing ketones with amino compounds usually leads readily to geminal aminohydroxy compound (hemiaminal or hemiamidal) which is converted into a ketimine either by the elimination of water or (in the case of highly stable hydroxy compounds) by the action of strong dehydrating agents.

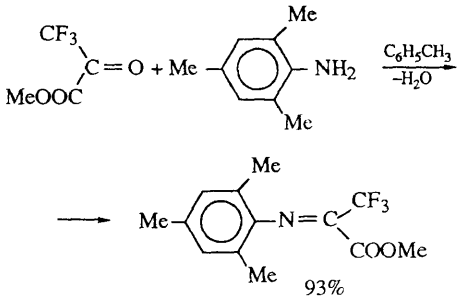


According to recent data[7] the dehydration conditions for a hemiaminal are directly dependent on the electron-accepting properties of the substituents at the ketone carbonyl carbon atom and the basicity of the amino compound. New data summarised in Table 1 define these concepts more precisely.

It turned out that aminals obtained from fluorine-containing α-ketocarboxylic acids (Table 1, No. 1–4) and alkyl(aryl) ketones (Table 1, Nos. 5–8) are readily dehydrated to imines under solvation conditions or by azeotropic distillation of the water formed.[8–18] This is in agreement with previous ideas,[7] since the carbonyl compounds listed contain only one electron-accepting group.

However anils are obtained from methyl trifluoropyruvate under practically the same conditions.[19,20,21] In the reaction of the latter

with mesidine the corresponding anil is formed almost quantitatively (93%).[19]



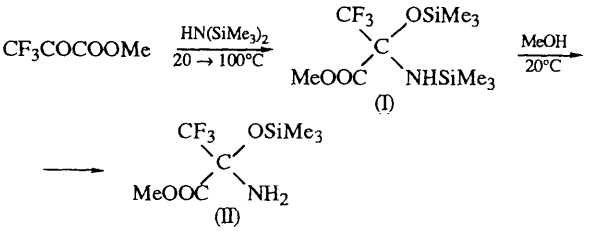
Reaction with aniline under conditions for the azeotropic distillation of water gave 35% yield. The relatively low yield of anil in this case is caused by the occurrence of several side reactions, the nature of which has been discussed.[21] Only the weakly basic nitroanilines did not give anils on reaction with methyl trifluoropyruvate. The hemiaminals formed in this case are not dehydrated even at 200 °C.[21] It must be noted that hexafluoroacetone does not form anils with either aniline[22] or with mesidine[23] under azeotropic distillation conditions. On heating, the hemiaminals are decomposed into the starting materials.

Table 1. Features of the formation of imines from fluorocarbonyl and amino compounds.

No.	R_F	R	R′	Dehydration conditions	Refs.
1	CFHCOOH	COOH	Alk	–	[8]
2	$CFAlk_2$	COOH	Alk	–	[9]
3	CFH_2	COOH	CH(Me)Ph	0–25 °C, EtOH	[10]
4	CFHAr	COOH	Alk	Δ, alcohol	[11]
5	CFH_2	Me	Alk	$K_2CO_3(MgSO_4)$, CCl_4	[12, 13]
6	CF_3	Alk	$(CH_2)OAlk$	Boiling benzene	[14]
7	C_8F_{17}	Me	Alk	Δ, $CHCl_3$	[15, 16]
8	CF_3	Ph	CH(Me)Ph	Δ, toluene *p*-TsOH	[17, 18]
9	CF_3	COOMe	Ar	Boiling benzene	[19, 20, 21]
10	$CF(CF_3)_2$	$C(O)CF(CF_3)_2$	Alk	Δ, $CHCl_3$	[24]
11	CF_3	Ph		$(CF_3CO)_2O$, Py	[25]
12	CF_3	CF_3	C(Ph)=NAr	$POCl_3$, Py	[26]
13	CF_3	COOMe	COOAlk	$(CF_3CO)_2O$, Py	[27]
14	CF_3	COOMe	$C(O)CF_3$	$POCl_3$, quinoline	[28, 29]
15	CF_3	COOMe	SO_2Me, SO_2Ph	$SOCl_2Py$	[28, 30, 31]

The adducts of perfluoro-α-diketones, for example the product of reacting diperfluoro-isobutyroyl with amines (Table 1, No. 10), are readily dehydrated under conditions of azeotropic distillation of water. Carbalkoxy and perfluoroacyl groups, in spite of their high electron-accepting properties, assist the dehydration of an adjacent hemiaminal function. The stabilisation of the intermediate carbocation and of the final azomethine bond by conjugation with the adjacent C=O group is probably decisive in this case.

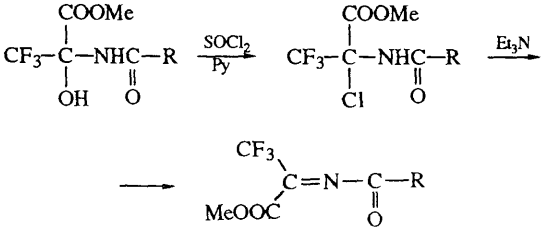
It must be noted that the positive effect of carbalkoxy groups on the dehydration of an adjacent hemiaminal function is not extended to their *N*- and/or *O*-silylated derivatives.[27–31] The silylated hemiaminals (I) and (II), obtained from methyl trifluoropyruvate and hexamethyldisilazane are not converted successfully into the imine of methyl trifluoropyruvate.[32]



The hemiaminal obtained by the desilylation of (II) is also not dehydrated. Under the conditions of its formation this compound undergoes an intramolecular condensation involving the NH_2 and COOMe groups giving oligomers.

Dehydrating agents known previously are used to obtain the new imines of hexafluoroacetone (Table 1, Nos. 11, 12) and the acylimines of methyl trifluoropyruvate (Table 1, Nos. 13, 14).[25,26] More rapid formation and high stability were recorded for the hemiamidal of methyl trifluoropyruvate compared with the hemiamidals of hexafluoroacetone together with more forcing conditions for their dehydration.[28,29]

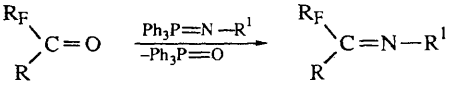
The readily formed highly stable adducts of methyl trifluoropyruvate with sulphonamides are readily dehydrated by boiling $SOCl_2$ in the presence of catalytic amounts of pyridine (Table 1, No. 15). Under these conditions the hemiaminals of methyl trifluoropyruvate are quantitatively converted into the unusually stable geminal amidochloro compounds, which turned out to be smooth precursors of methyl trifluoropyruvate acylimines.[32,33]



R = Me, OEt, CF_3.

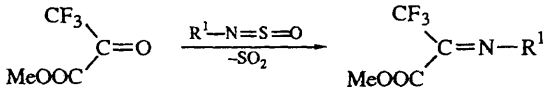
2. Cycloaddition–elimination reactions

Cycloaddition–elimination reactions have been used for obtaining new alkyl-, aryl- and acylimines using the Staudinger reaction.[17,34–38] The data obtained confirm the value of this method which enables any phosphazo compound to react with fluorine-containing aldehydes, ketones and α-ketoacid derivatives.



$R_F = CF_3$; R = H, Me, Ph, COOMe, CF_3; R^1 = Bu, Ph, CH_2Ph, CH(Me)Ph, 4-$MeOC_6H_4$, COOMe.

It is also possible to use thionyl imines for the synthesis of imines and acylimines from esters of fluorine-containing α-ketoacids.[39]

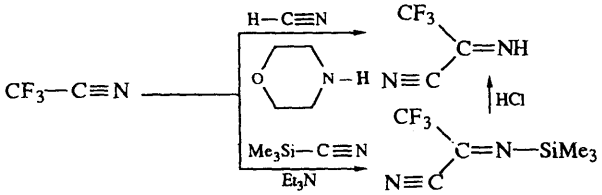


R^1 = Ph, C(O)Ph .

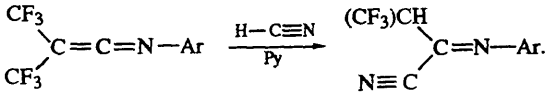
In this case the reaction occurred more readily than for hexafluoroacetone, even in the absence of a catalyst.

3. Addition of HCN to trifluoroacetonitrile

The reaction of HCN with CF_3CN has been carried out under base catalysis conditions,[5] raising the prospect of synthesising α-iminofluorocarboxylic acids. The possibility of using trimethylsilyl cyanide in place of HCN in this reaction is of particular interest,[40] since the *N*-trimethylsilylimines of α-ketoacid nitriles formed are efficienct precursors of a variety of *N*-substituted imines.



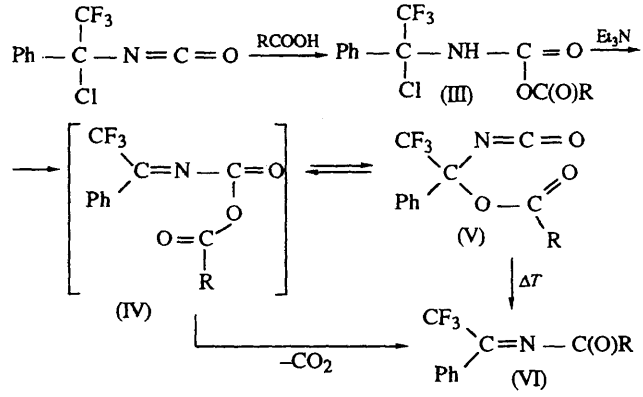
Nitriles of α-iminofluorocarboxylic acids are also formed readily by nucleophilic addition of HCN to fluorine-containing ketenimines.[41]



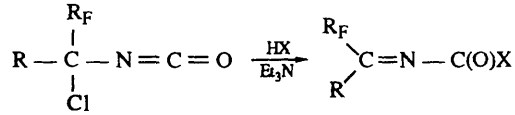
The applicability of this method is limited by the stability of the monomeric fluoroketenimines.

4. Conversion of fluorine-containing geminal chloroisocyanato compounds

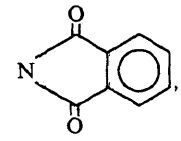
The reaction of $R_FRClCN{=}C{=}O$ with nucleophilic reagents opens broad prospects for the synthesis of various fluoroacylimines. Two types of reaction are used. Carboxylic acids are used as nucleophiles in the first reaction type and form mixed anhydrides with the chloroisocyanato compounds. These undergo rearrangement with decarboxylation on dehydrochlorination.[42] For example, 1-chloro-1-trifluoromethyl-1-phenylmethyl isocyanate reacts vigorously with carboxylic acids giving the corresponding addition products (III), which eliminate HCl above 20 °C. Compounds (III) are converted in the presence of triethylamine into the unstable mixed anhydrides (IV) which are stabilised in one of two ways. One is by decarboxylation and the formation of *N*-acylimines (VI) and the other is by a 3,3-sigmatropic shift of the acyloxy group in the C–N=C triad with the formation of 1-(acyloxy)alkyl isocyanates (V). The latter eliminates CO_2 on thermolysis (above 120 °C) giving the *N*-acylimines (VI).



The second type of reaction of chloroisocyanato compounds includes reaction with O-, N- and S-nucleophiles, such as alcohols,[43,44] imines, diphenylsulphinimine, diphenylamine,[45] potassium *O*-alkyldithiocarbonates,[46] and amides of carboxylic acids[47] in the presence of a dehydrochlorinating agent. The addition of nucleophile at the C=N bond and dehydrochlorination of the geminal chloroamino compound to the acylimines occurs under mild conditions.

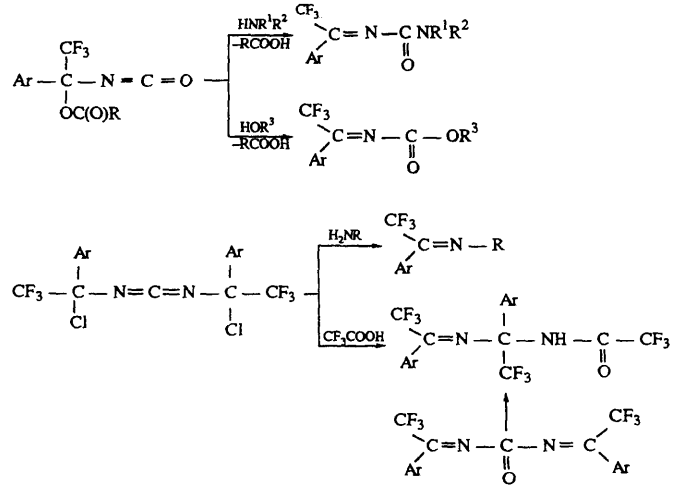


$R_F = CF_3$; R = R_F, Ar; X = OAlk, N=CAlk$_2$, N=SPh$_2$,



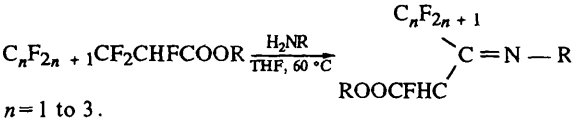
NPh_2, S — C(S)OAlk, N(Ar)C(O)Alk.

1-(Acyloxy)alkyl isocyanates,[48,49] *N,N*-bis(1-chloroalkyl)carbodiimides[42,50,51] and *N,N*-bis(alkylidene)ureas[42] react similarly to the geminal chloroisocyanato compounds. They are readily converted into the corresponding acyl- or alkylimines on reaction with alcohols, acids and amines.



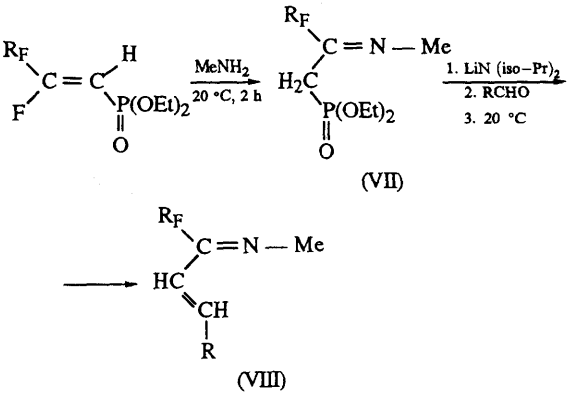
5. Reactions of fluoroalkenes and fluoroalkynes with amines

An original method has been developed for obtaining imines of β-ketofluorocarboxylic acids from esters of α-hydroperfluorocarboxylic acids and primary aliphatic amines. The reaction comprises dehydrofluorination of the initial ester, vinylic replacement of a fluorine atom by an alkylamino group and enamine–imine rearrangement. In spite of being so complex these processes lead to the corresponding imines in 70–82% yield.[52]



$n = 1$ to 3.

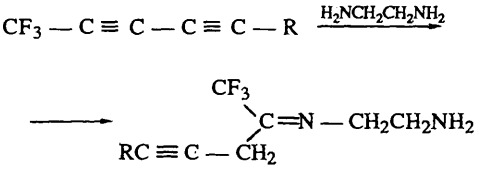
Fluoroalkenylphosphonates are used successfully to obtain fluorine-containing imines with alkenyl substituents at the carbon atom of the C=N bond.[53,54] The vinylic replacement of a fluorine atom by an alkylamino group and subsequent enamine–imine rearrangement lead to the highly reactive CH-acids (VII). Treatment of these with lithium diisopropylamine in ether at −78 °C with subsequent addition of an aldehyde leads to the *trans* isomer of (VIII) in high yield.



(VII)

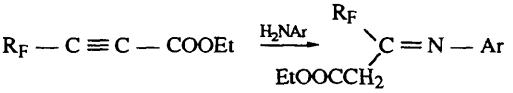
(VIII)

Fluorine-containing imines are obtained by traditional methods by reacting fluorinated diacetylenes with nitrogen-containing binucleophiles.[55]



R = iso-Pr, t-Bu, CMe_2OH.

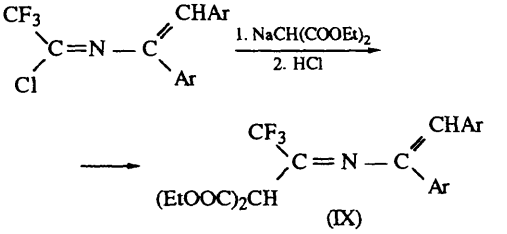
Imines of β-ketocarboxylic acids are obtained by condensing esters of fluoroalkyl substituted acetylenecarboxylic acid with substituted anilines.[56]



$R_F = C_4F_9$, C_6F_{13}, C_8F_{17}; Ar = Ph, 4-ClC_6H_4, 4-$MeOC_6H_4$.

6. Reactions of fluorine-containing imidoyl chlorides with CH-acids

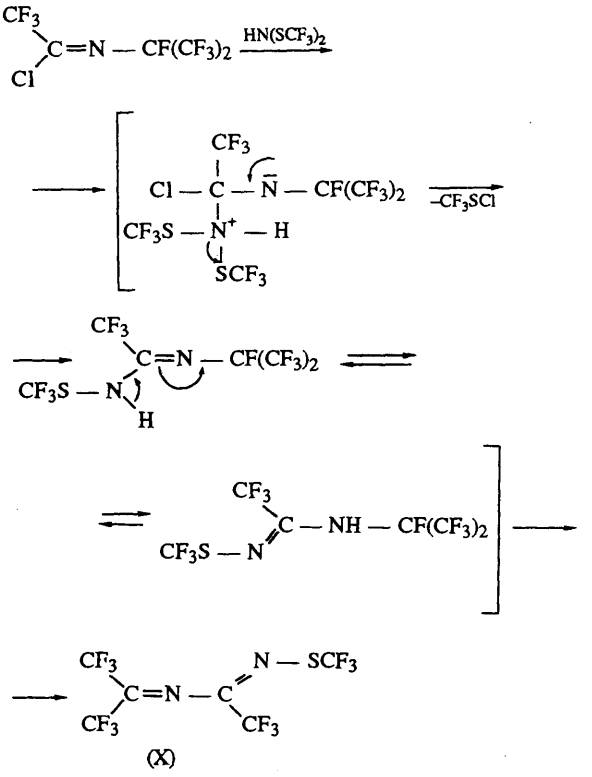
The reaction of imidoyl chlorides with CH-acids is one of the promising routes for synthesising fluorine-containing *N*-alkenylketimines. For example, the ketimines (IX) are obtained in preparative yield by reacting *N*-(1,2-diarylvinyl)trifluoroacetimidoyl chlorides with sodiomalonic ester.[57]



(IX)

Ar = 4-RC_6H_4 (R = H, OMe, Cl)

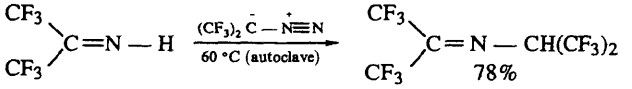
The perfluoroketimine (X) is obtained by the reaction of *N*-perfluoroisopropyltrifluoroacetimidoyl chloride with bis(trifluoromethylthio)amine.[58]



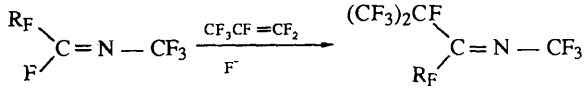
(X)

7. Other reactions

There are few examples of methods of synthesis of ketimines which are specific for fluorine compounds. The preparative value of the reaction of hexafluoroacetone imine with bis(trifluoromethyl)-diazomethane has been shown.[59]

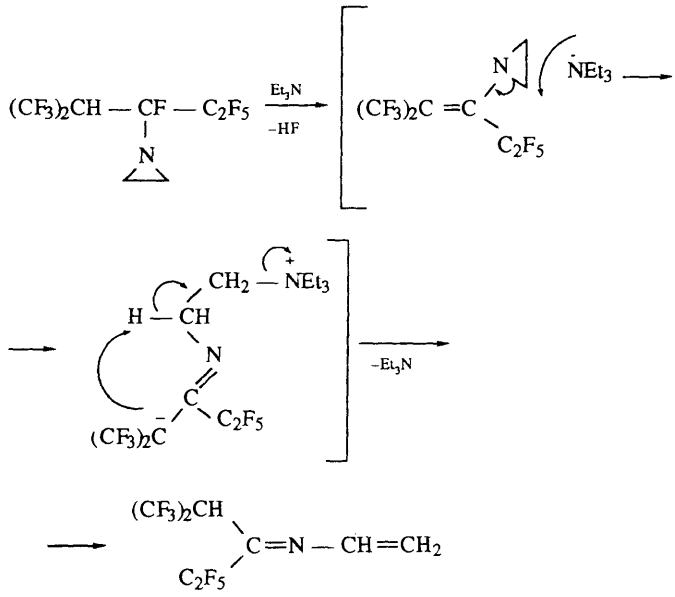


Homologues of perfluoro-2-azapropene form codimerisation products with fluoroolefins in the presence of fluoride ion.[60]

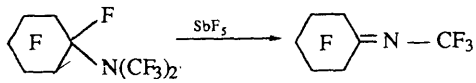


$R_F = CF_3, C_2F_5, C(CF_3)_3$

The addition products of an ethylenimine to an internal fluoroolefin formed under dehydrofluorination conditions undergo an unusual rearrangement with the formation of *N*-vinylpolyfluoroketimines.[61]



Under cationotropic conversion conditions tertiary fluoroamines, such as perfluorodimethylcyclohexylamine, eliminate CF_4 with the formation of a perfluoroketimine.[62]



80%

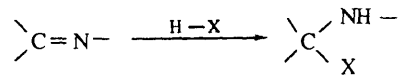
By comparing the data (of the last decade) discussed above on the methods of synthesising fluorine-containing ketimines with the results of previous work,[7] it is easy to see that the investigations in this area have acquired a distinctly applied character. Fundamental attention is now paid to the search for methods of synthesising functionally substituted ketimines. These include the imines of fluorine-containing, α-, β-, and γ-ketocarboxylic acids and their derivatives and various polyunsaturated derivatives, formally belonging to the hetero-1,3-dienes and conjugated heteropolyenes. They are all efficienct precursors of fluorine-containing compounds of various types possessing biological activity.[63,64]

III. Reactivity

At present studies are being vigorously continued on the reactions of fluorine-containing ketimines with nucleophilic reagents and on the cyclocondensation of mono- and bifunctional ketimines with mono- and binucleophiles. A new route has been developed for the polyfluoroalkylamino- and polyfluoroalkylamidoalkylation of aromatic and heteroaromatic π-systems of the donor type by fluorine-containing imines and acylimines. New data have been obtained on various cycloaddition reactions involving ketimines and acylimines.

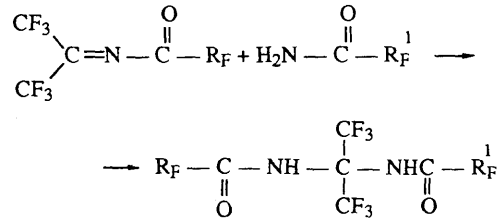
1. Reactions with nucleophilic reagents.

Fluorine-containing ketimines usually react readily with proton-containing nucleophiles giving the corresponding products of addition at the azomethine bond.[7,65–70] Electron-accepting properties and in some cases the structure of the substituent on the nitrogen atom of the C=N bond have a decisive effect on the addition conditions. Sulphonyl- and perfluoroacylimines of polyfluorocarbonyl compounds display the maximum reactivity in these reactions. Reaction of them with O-, N-, S- and P-nucleophiles is effected selectively either on cooling or in dilute solution. It is necessary to carry out the reaction with strong bases under strictly controlled conditions.



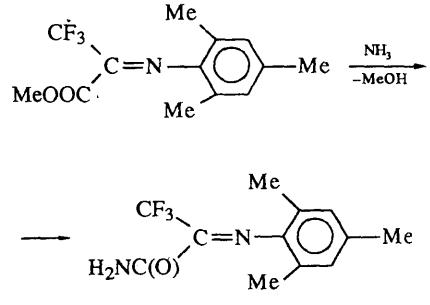
X = OH, OR, OPh, SPh, SR, NH_2, NHR, NR_2, $NHC(O)R$, $NHSO_2R$, PH_2, PHR, $P(O)R^1R$, $P(O)(OR)_2$, P(O)(OR)R.

The nature of the nucleophile used also affects the reaction conditions significantly. Reaction with imines is more difficult with a reduction in nucleophilic basicity. For example, even such highly reactive compounds as the perfluoroacylimines of hexafluoroacetone react with perfluorocarboxylic acid amides only on heating (100–150 °C) in a sealed tube.[71,72]

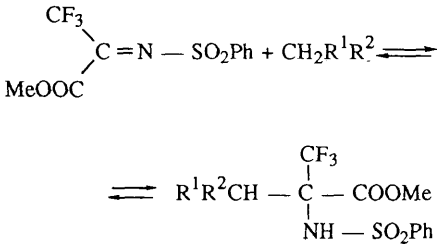


$R_F = CF_3$; $CH(CF_3)_2$; $R_F^1 = CF_3$, $CH(CF_3)_2$, C_4F_9.

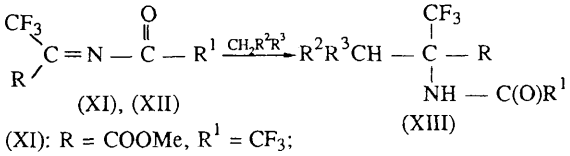
The reaction of nucleophilic reagents with functionally substitued imines occasionally lead to side products. For example, the anils of methyl trifluoropyruvate are converted on treatment with ammonia into anils of trifluoropyruvate amide.[32]



The reactions of sulphonyl- and acylimines of methyl trifluoropyruvate with CH-acids proved to be interesting.[32,70] Products of *C*-alkylation are formed in 25–30% yield on reacting a sulphonylimine with malonic or acetoacetic acid esters or with acetylacetone. The reactions are carried out at room temperature as equilibrium processes.



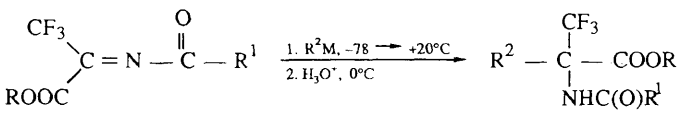
The reaction of the trifluoroacetylimine (XI) with malonic ester is even more difficult and the *C*-amidoalkylation product (XIII) was successfully obtained in 30% yield only on catalysis with toluene-4-sulphonic acid. Furthermore, reaction of the imine (XI) and the benzoylimine of hexafluoroacetone (XII) with CH-acids capable of enolisation, such as acetylacetone, acetoacetic ester and acetophenone, was effected at 20–80 °C leading to the *C*-amidoalkylation product (XIII) in up to 90% yield.[70] It is quite probable that in the latter case the process occurs by a [2 + 4] cycloaddition mechanism with an asymmetrical transition state.



(XI): R = COOMe, $R^1 = CF_3$;

(XII): R = CF_3, R^1 = Ph.

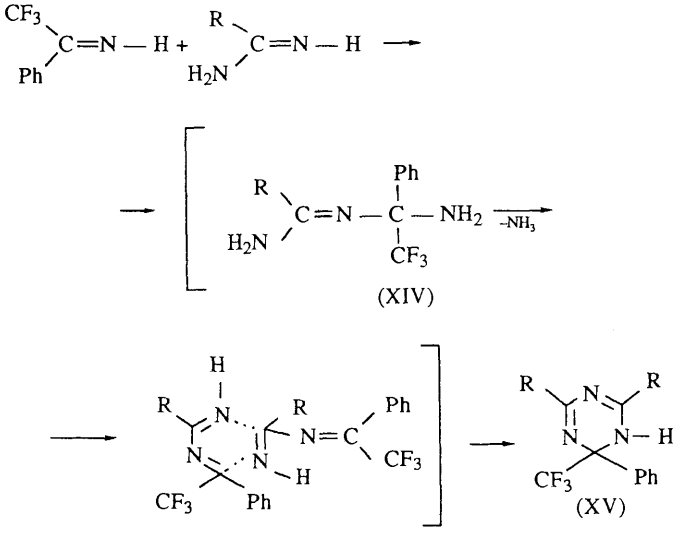
Organometallic compounds of Li, Cd and Mg react extremely vigorously with methyl trifluoropyruvate acylimines. These reactions occur selectively only under strong cooling and lead to derivatives of α-trifluoromethyl-α-amino-acids.[35,73,74]



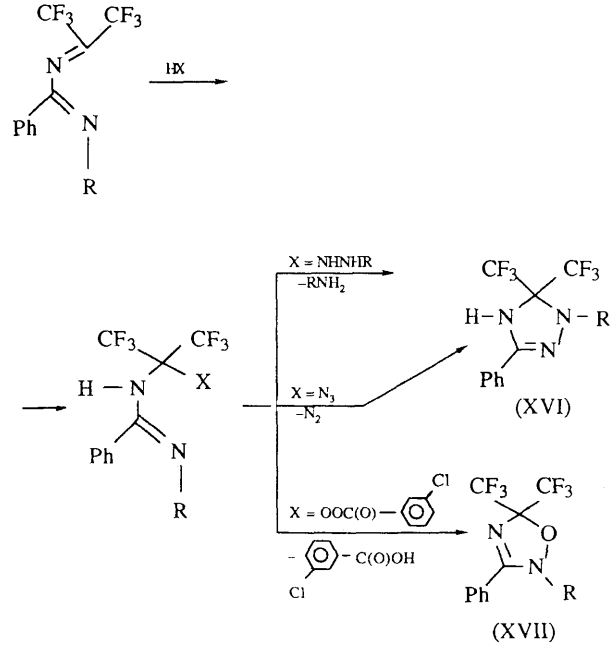
R = Me, Et; R^1 = OAlk, CF_3; R^2 = Me, Pr, Bu, iso-Bu, Ph, $PhCH_2$, $CH_2=CH-(CH_2)_n$ (n = 0 to 4), ; M = Li, CdR^2, MgHal.

The reaction of fluorine-containing ketimines with nucleophilic reagents accompanied by heterocyclisation or cyclocondensation is particularly interesting. Such conversions take place on reaction of functionally unsubstituted ketimines with binucleophiles. For example, reaction of the imine of trifluoroacetophenone with amidines leads to unstable adducts (XIV) which dimerise after elimination of ammonia to the corresponding dihydrotriazines (XV).

An unstable adduct (XIV) is formed with trifluoroacetamidine and is transformed into the triazine only on heating to 200 °C.[75]

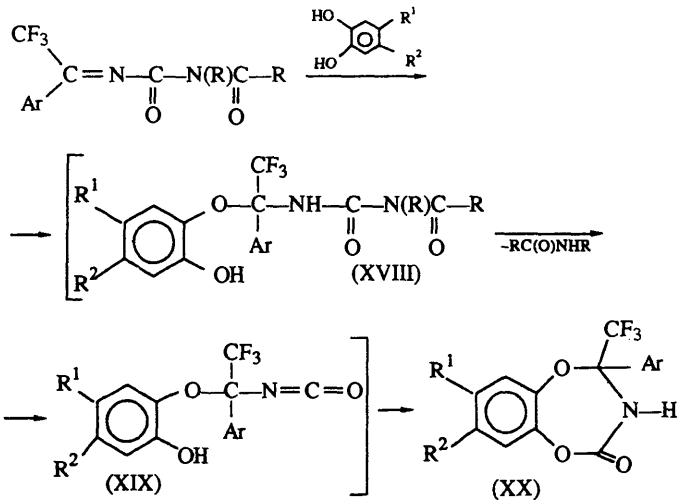


Functionally substituted ketimines also react with mono- and binucleophiles. Burger and collaborators[76–78] showed that the adducts of the iminoacylimines of hexafluoroacetone formed initially with hydrazines,[76] hydrazoic acid[77] and 3-chloroperbenzoic acid[78] cyclise spontaneously into the triazolines (XVI) and the isoxadiazolines (XVII).

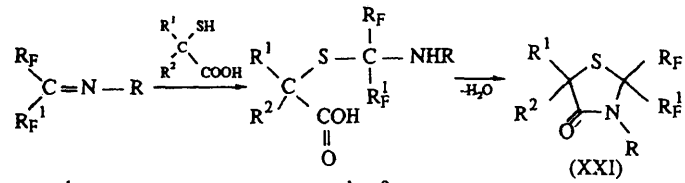


Poorly stable geminal amino-aryloxy compounds (XVIII) are also formed initially on reacting ureidoimines with *o*-dihydroxybenzenes. On boiling in benzene these compounds are converted through the

intermediate isocyanates (XIX) into the 1,3,5-benzodioxazepines (XX).[79]

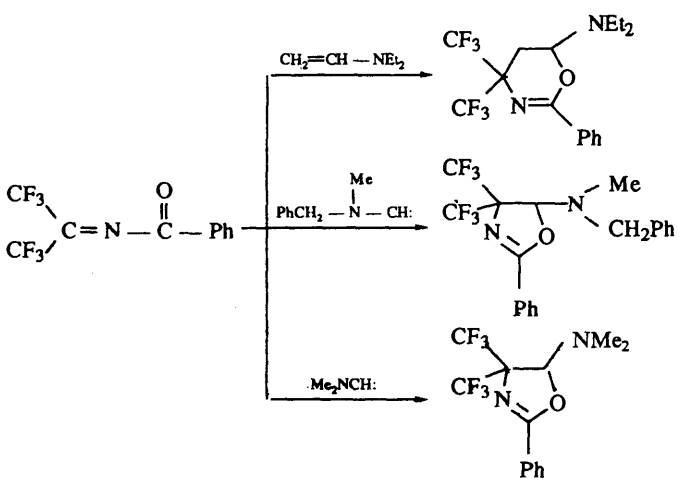


Recently Dupont patented the synthesis of the thiazolidones (XXI) which are plant growth regulators.[80] The method is based on the reaction of various polyfluoroketimines with α-mercaptocarboxylic acids, the first step of which is attack of the S-nucleophile on the C=N bond.

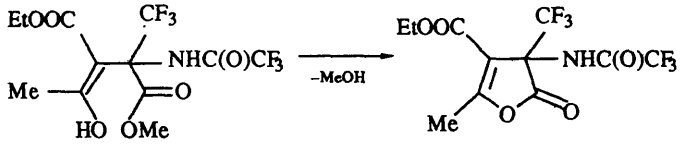


$R_F = R_F^1 = CF_3$, CF_2Cl, C_2F_5, CF_2H; $R^1 = R^2$ = H, Me, CH_2COOH.

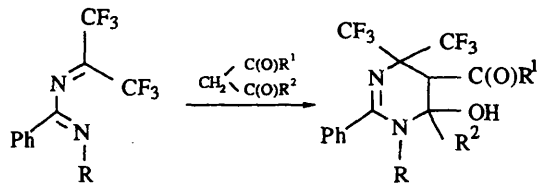
Ring formation also occurs in the reaction of acylimines with tertiary amines. The benzoylimine of hexafluoroacetone, which is an efficient acceptor of hydride ion,[7] converts triethylamine into *N,N*-diethylvinylamine, dimethylbenzylamine into the aminocarbene $PhCH_2(Me)NCH$: and tetramethyldiaminomethane into the aminocarbene Me_2NCH:, which are then stabilised by a second molecule of the benzoylimine as the corresponding [2 + 4] and [1 + 4] cyclic adducts.[81]



Various heterocyclic compounds may be obtained by reacting functionally substituted ketimines with CH-acids. The Michael addition products of acylimines of methyl trifluoropyruvate to enolisable CH-acids cyclise (slowly at 20 °C and rapidly on heating) to butenolides.[70] The mild conditions for the heterocyclisation are due to the stabilisation of the initial compounds in the enolic form.



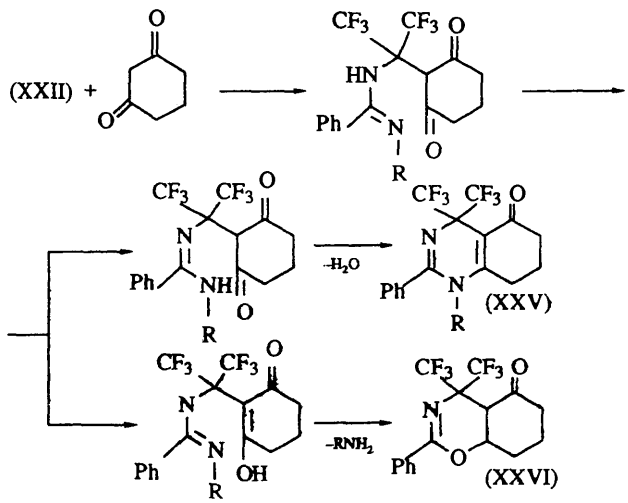
The adducts of CH-acids with acylimines of hexafluoroacetone are not subject to intramolecular heterocyclisation. However, the reaction of the iminoacylimines (XXII) with CH-acids capable of enolisation gives the [2 + 4] cyclic adducts (XXIII) and (XXIV) exclusively.[81]



(XXIII): $R^1 = R^2$ = Me;
(XXIV): R^1 = OEt, $R^2 = CH_2X$.

These differences are explained by the higher nucleophilicity of the terminal nitrogen in the iminoacylimines (XXII) compared to the carbonyl oxygen in the acylimines since the reaction of the acylimines stops at the stage of forming Michael adducts and the initial *C*-amidoalkylation products of (XXII) are transformed further into (XXIII) and (XXIV).

Cyclic 1,3-diketones, the enolic forms of which are not stabilised by an intramolecular hydrogen bond, undergo cyclocondensation with (XXII) giving a mixture of 1,4-dihydropyrimidines (XXX) and 1,3-oxazines (XXVI).[82]

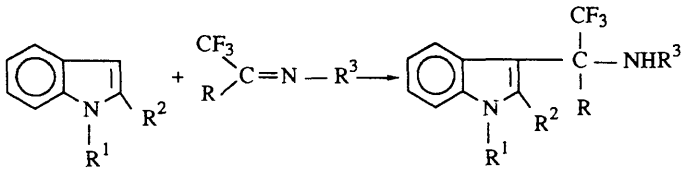


2. Reactions with aromatic and heteroaromatic compounds

A systematic study of the reactions of the imines, sulphonyl- and acylimines of hexafluoroacetone and of methyl trifluoropyruvate with aromatic and heteroaromatic compounds led to the design of a

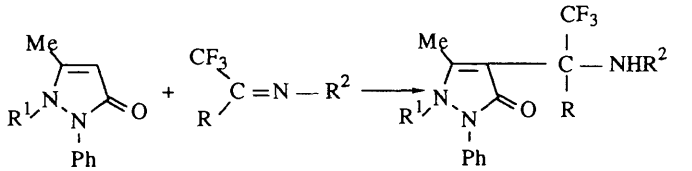
general method for polyfluoroalkyl-α-amino(amido)alkylation of aromatic systems of the donor type. These reactions proved to be closely similar to the known aminomethylation reaction, particularly with several heterocyclic π-donors.

Indole and certain 1- and 2-substituted indoles are almost quantitatively amino(amido)alkylated at position 3. The alkylating properties of $CF_3(R)C=N-R^3$ increase in the following series of R^3: H < $XC_6H_4C(O)$ < RSO_2 < $R_FC(O)$. The optimum reaction temperature in this series is thereby reduced from +120 to −50 °C.[28,83–85]



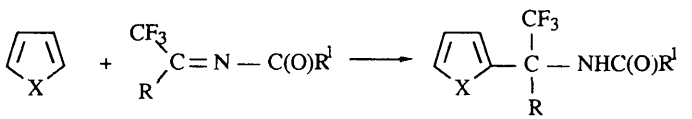
R = CF_3, COOMe; R^1 = H, Me, Ph; R^2 = H, Me, Ph; R^3 = H, 4-$FC_6H_4C(O)$, 2-$FC_6H_4C(O)$, SO_2Me, SO_2Ph, $CF_3C(CO)$, $CF_3(CF_2)_3C(O)$.

Hexafluoroacetone imine, its *N*-acyl derivatives and also the acyl- and sulphonylimines of methyl trifluoropyruvate also display similar properties when reacting with *N*-phenyl-3-methylpyrazol-5-ones.[85,86] Aminoalkylation is effected at the point of maximum π-electron density in the system.



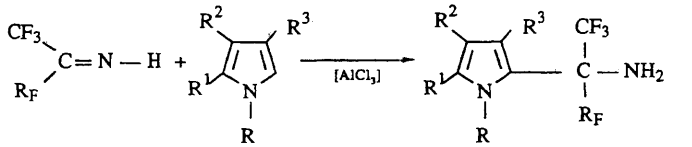
R^1 = H, Me; R = CF_3, COOMe; R^2 = H, SO_2Me, SO_2Ph, $CF_3C(O)$.

Furan, pyrrole and *N*-methylpyrrole are amidoalkylated by *N*-acylimines at −78 °C at position 2.[85,87]

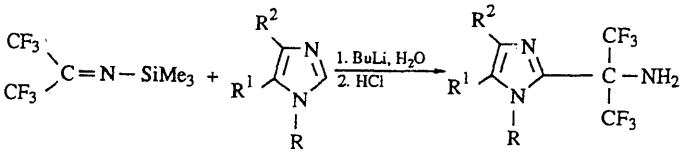


X = O, NH, NMe; R = CF_3 COOMe; R^1 = CF_3, $CH(CF_3)_2$.

According to the patent data the aminoalkylation of substituted pyrroles by imines of polyfluoroketones may be effected in the presence of Lewis acids.[88] The trimethylsilylimines of hexafluoroacetone reacts readily with 2-lithioimidazoles.[89] The *C*(2)-alkylation products formed in both cases possess nonsteroidal antiinflammatory activity.

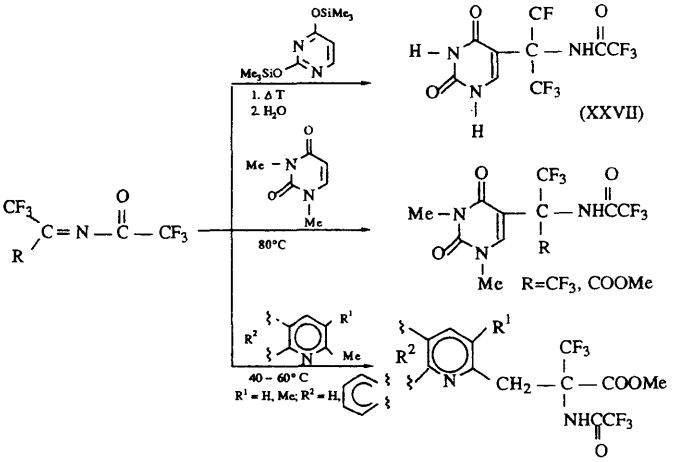


R^1H, Me; $R^2=R^3$=4-FC_6H_4; $R_F=CF_3$, CF_2H CF_2Cl.

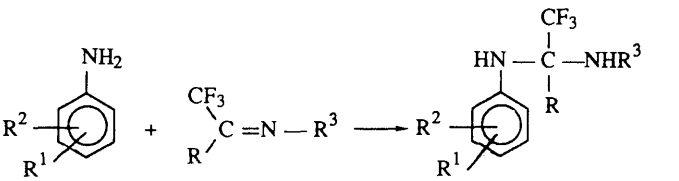


$R^1=R^2$=4-$MeOC_6H_4$; R = CH_2OMe.

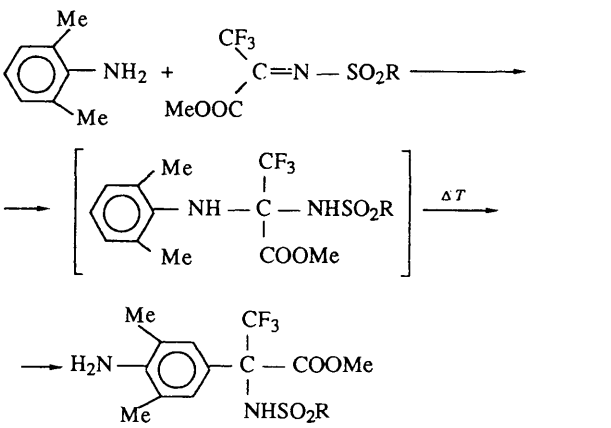
Only the highly electrophilic trifluoroacetylimines of hexafluoroacetone and methyl trifluoropyruvate react successfully with electron-deficient heterocyclic compounds. Thus the trimethylsilyl derivative of uracil forms the *C*(5)-aminoalkylation product (XXVII) on moderate heating.[90] 1,3-Dimethyluracil reacts readily.[91] 2-Methylpyridines and quinolines react at the methyl group with the trifluoroacetylimine of methyl trifluoropyruvate.[32,92]



A systematic study of the reactions of the sulphonyl- and acylimines of hexafluoroacetone and methyltrifluoropyruvate with primary and secondary arylamines[31,32,93–96] led to the conclusion that the *C*-amidoalkylation of these compounds is controlled by the probability of formation and the stability of the *N*-amidoalkylation products. Stable adducts at the nitrogen atom are formed exclusively with primary amines of various structure.

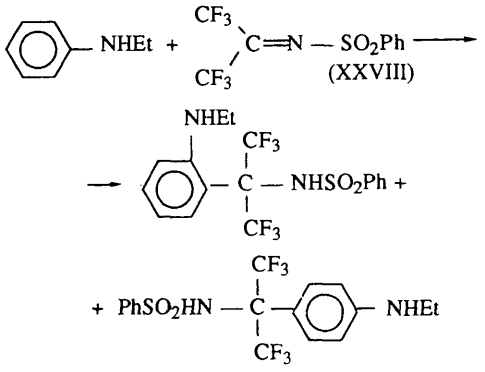


Steric hindrance to the formation of geminal diamino compounds exists in the reaction of the sulphonylimine of methyl trifluoropyruvate with 2,6-dimethylaniline. The initially formed unstable adducts at the nitrogen atom are isomerised quantitatively on boiling for 1–2 h in CCl_4 into products of *C*(4)-amidoalkylation.[32]



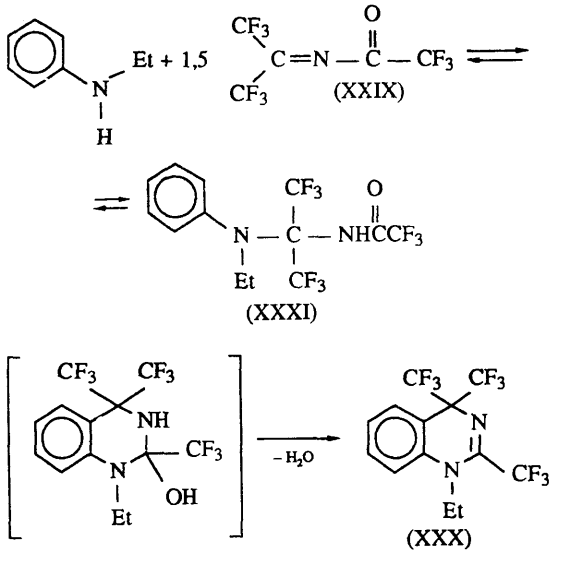
R = Me, Ph.

The probability of *C*-amidoalkylation of secondary arylamines is higher than for primary arylamines. *N*-ethylaniline reacts at 20 °C with the benzenesulphonylimine of hexafluoroacetone (XXVIII) forming products of *C*(2)- and *C*(4)-alkylation in low yield.[95]

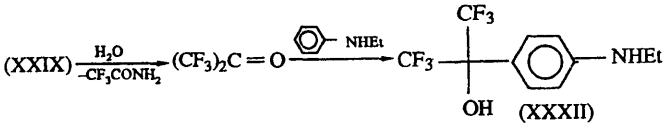


Boiling indoline with the imine (XXVIII) in $CHCl_3$ leads to a complex mixture of products from which the *C*(7)-alkylation product was successfully isolated in low yield (17%). It must be noted that this result is in agreement with the regioselective *C*(7)-alkylation of indoline by hexafluoroacetone described previously.[96]

The reaction of the trifluoroacetylimine of hexafluoroacetone (XXIX) with secondary arylamines is unusual and was studied in detail using *N*-ethylaniline as an example. The reaction unexpectedly leads to the 1,4-dihydroquinazoline (XXX) in 87% yield, i.e. the product of simultaneous *C*(2)-amidoalkylation and cyclocondensation involving the NH and $NHC(O)CF_3$ groups.

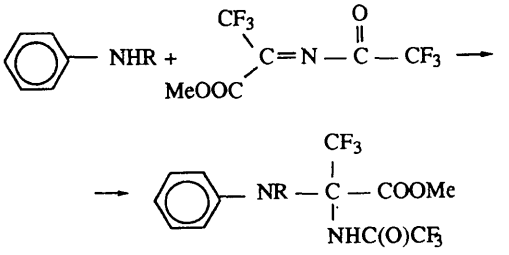


It was shown that the unstable *N*-alkylation product (XXXI) is formed first after mixing the reagents and disappears as compound (XXX) accumulates. The aniline (XXXII) is a side product of the reaction. Its appearance is linked with the decomposition of the acylimine by the water eliminated during cyclocondensation.

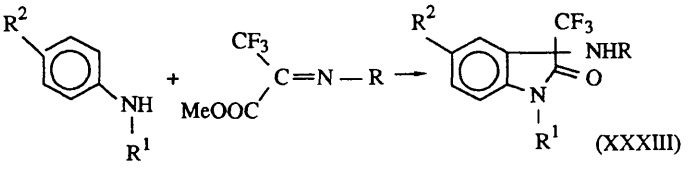


N-Methyl-, *N*-isopropyl- and *N*-phenylanilines and their 4-methoxy and 4-chloro derivatives react like the acetylimine (XXIX).[95] The reaction time was reduced as the volume of the substituent at nitrogen increased in the series of *N*-alkylanilines studied.

The sulphonyl- and acrylimines of methyl trifluoropyruvate give more stable *N*-amidoalkylation products with secondary arylamines. The *C*-amidoalkylation of methyl- and ethylanilines does not take place.

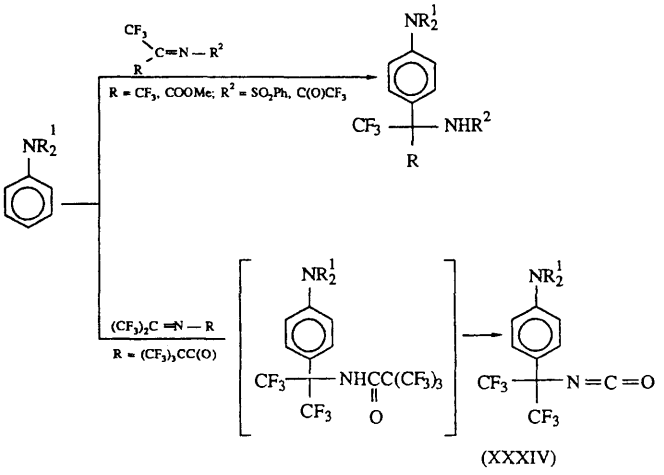


However, the products of simultaneous *C*(2)-amidoalkylation and *N*-acylation, the corresponding indolinones (XXXIII), are obtained in moderate yield with *N*-isopropylaniline, *N*-isopropyl-*p*-toluidine, *N*-isopropyl-*p*-anisidine and diphenylamine.[31]



R_2 = H, Me, OMe; R^1 = iso-Pr, Ph; R = SO_2Me, SO_2Ph, $C(O)CF_3$.

N,*N*-Dimethyl- and *N*,*N*-diethylaniline are *C*(4)-amidoalkylated quantitatively under strong cooling by the sulphonyl- and acylimines of hexafluoroacetone and methyl trifluoropyruvate.[28,31,97] In the case of the *N*-pivaloylimine of hexafluoroacetone the products of *C*(4)-alkylation formed initially eliminates $(CF_3)_3CH$ and is converted into the isocycanate (XXXIV).[97]



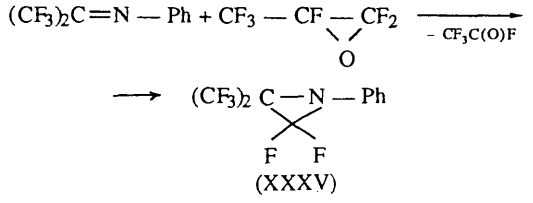
(XXXIV)

3. Cycloaddition reactions

The behaviour of unsaturated compounds in cycloaddition reactions reveals the chemical nature of the fluorine-containing ketimines most completely. It was shown previously[7] that

fluoroketimines with an isolated C=N bond for [1 + 2], [2 + 2], [3 + 2] and [4 + 2] cycloadducts somewhat more readily than their unfluorinated analogues. The sulphonyl-, acryl, thioacyl- and iminoacylimines of hexafluoroacetone are significantly more reactive and react either as activated azomethines or as 1,3-heterodienes in cycloaddition reactions. The new data obtained have extended significantly the concepts of both these reactions and in some cases have enabled electronic models of them to be constructed.

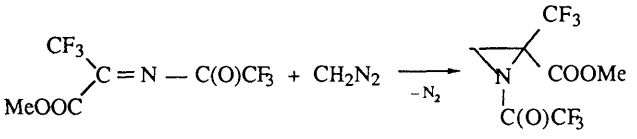
Carbenes, their precursors and the carbenoids usually react unambiguously with fluoroketimines. The reaction of difluorocarbene with fluoroketimines has been demonstrated.[98] The [1 + 2] cyclic adduct, the aziridine (XXXV), was obtained in satisfactory yield by heating a mixture of hexafluoroacetone anil with hexafluoropropylene oxide at 180 °C.



(XXXV)

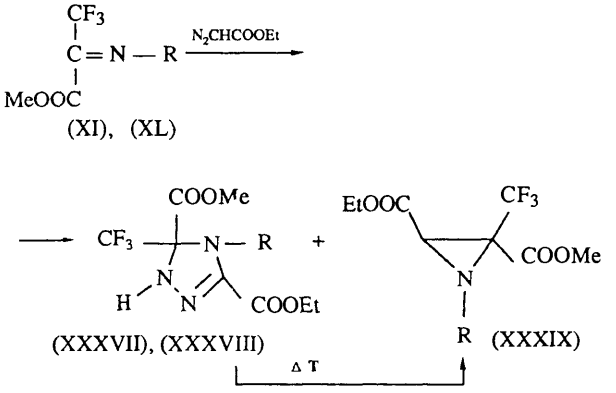
Diazoalkanes are efficient precursors of carbenes in reactions with highly electrophilic fluoroketimines.[7] The behaviour of methyl trifluoropyruvate acylimines in these reactions has been studied.[29,32]

The reaction of trifluoroacetylimine of methyl trifluoropyruvate with diazomethane occurs at −30 °C and is accompanied by elimination of nitrogen and the formation of the aziridine (XXXVI)[29] and not the [1 + 4] cylic adduct as in the analogous reaction with the benzoylimine of hexafluoroacetone.[99]



(XXXVI)

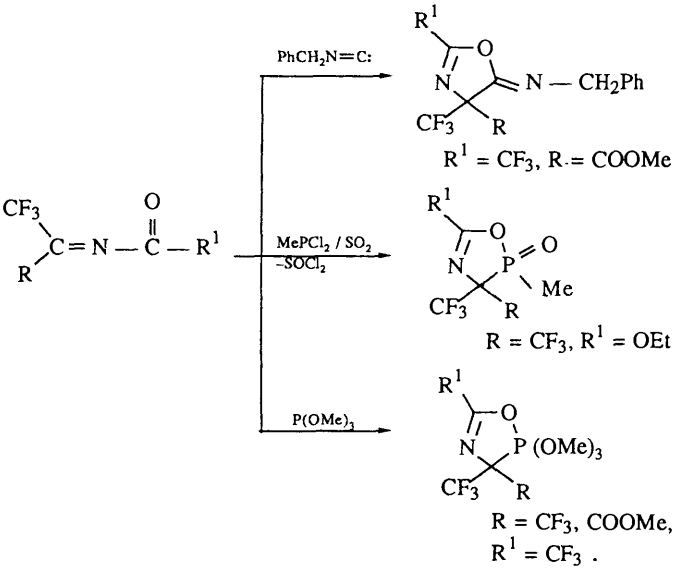
The reaction of the imine (XI) with diazoacetic ester also proceeds in an unusual manner.[29,74] It is effected at 20 °C and leads to a 2:1 mixture of the triazoline (XXXVII) and the aziridine (XXXIX). Thermolysis of (XXXVII) occurs at 180 °C giving the product (XXXIX) in high yield.



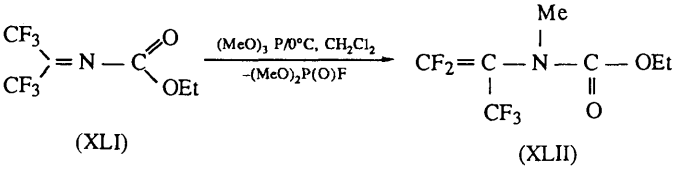
R = C(O)CF$_3$ (XI, XXXVII, XXXIX); SO_2Ph (XL, XXXVIII).

However, diazoacetic ester forms the highly stable [3 + 2] cyclic adduct (XXXVIII) with the sulphonylimine (XL) and no aziridine.[74]

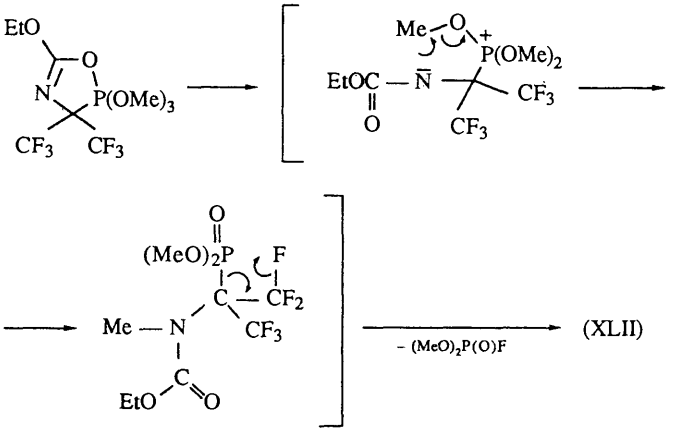
On the other hand, the acylimines of methyl trifluoropyruvate, like the acylimines of hexafluoroacetone,[100] form [1 + 4] cyclic adducts with benzyl isocyanide[32] and with compounds of three-coordinate phosphorus.[74]



An anomalous course for the reaction was established only when reacting the *N*-ethoxycarbonylimine of hexafluoroacetone (XLI) with trimethyl phosphite.[101] The reaction product proved to be the carbamate (XLII) and not the [1 + 4] cyclic adduct.

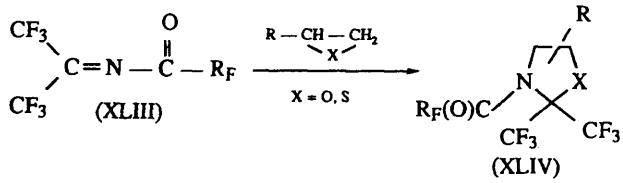


Probably the [1 + 4] cyclic adduct formed initially is readily converted into a zwitterion which is stabilised by intramolecular *N*-methylation with subsequent elimination of dimethyl fluorophosphate.



An important feature of the sulphonylimines of hexafluoroacetone is the extremely mild conditions for their reaction with oxiranes and thiiranes with the formation of [3 + 2] cyclic adducts.[7] The acylimines of hexafluoroacetone react even more vigorously with

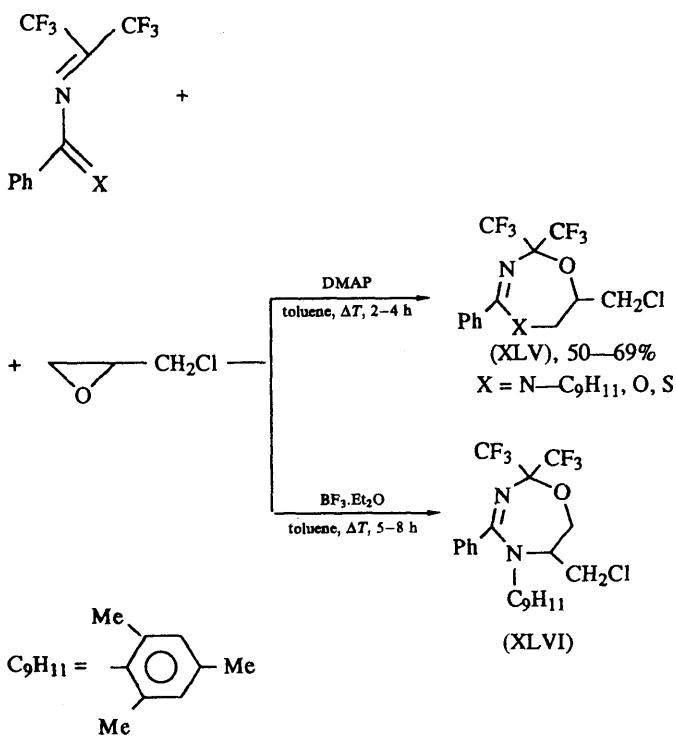
oxiranes and thiiranes.[102] The reaction of the imines (XLIII) with an oxirane occurs even at −70 °C, being accompanied by much oligomerisation, and the corresponding 1,3-oxazolines (XLIV) are successfully isolated in only small yield (15%). Methyloxirane and methylthiirane smoothly add (XLIII) under analogous conditions forming a mixture of regioisomers in 55–75% yield.[102]



(XLIII) (XLIV)

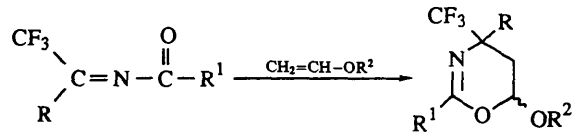
R_F = $CH(CF_3)_2$, CF_3; R = H, Me.

Acyl-, thioacyl- and iminoacylimines of hexafluoroacetone react catalytically with epichlorhydrin[103] giving the [3 + 4] cyclic adducts. On using an equimolar quantity of 4-dimethylaminopyridine (DMAP) as catalyst, the reaction leads to the selective formation of the heterooxazepines (XLV). Conduct of the reaction of the iminoacylimines with a catalytic quantity of boron trifluoride etherate leads to the tetrahydrooxadiazepine (XLVI) in 50% yield. In the absence of catalyst or with an acid catalyst a mixture of compounds is formed.



The properties of acylimines as 1,3-heterodienes have been studied widely.[7] Particular attention has been paid to their reactions with alkenes. Interest in them is due first of all to the fact that the 1,3-oxazine derivatives formed are promising synthetic intermediates.[104–106] Recently acylimines with a prochiral centre in the molecule have been used in these reactions.

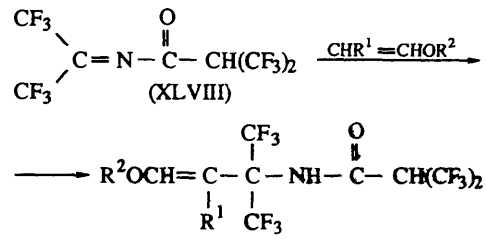
Vinyl acetate and vinyl butyl ether react under mild conditions with the acylimines of methyl trifluoropyruvate and hexafluoroacetone giving the corresponding dihydrooxazines (XLVII). The reaction is effected regioselectively and in certain cases stereoselectively as well.[29,107]



(XLVII)

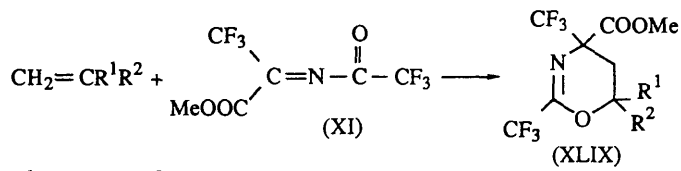
R = COOMe, Ph; R^1 = CF_3; R^2 = Ac, Bu.

The reaction of the *N*-(hexafluoro-α-hydroisobutyroyl)imine of hexafluoroacetone (XLVIII) with alkyl vinyl ethers unexpectedly leads to the product of amidoalkylation of the multiple bond.[108]



This may be explained by the steric effects of the hexafluoroisopropyl group of the imine (XLVIII) which hinders the formation of the symmetrical transition state.

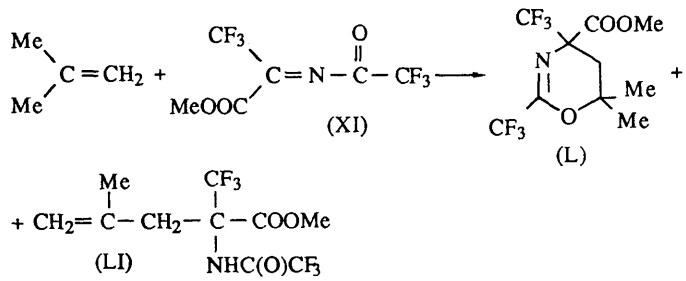
The reaction of the trifluoroacetylimine of methyl trifluoropyruvate (XI) with other terminal olefins such as 2-chloromethylpropene, propylene, methyl allyl ether, allyl iodide, bromide and chloride and methyl methacrylate also occurs regiospecifically giving the corresponding 1,3-dihydrooxazines (XLIX) in preparative yield. The optimum reaction temperature increases from 10 to 70 °C in the series shown.[109]



(XI) (XLIX)

R^1 = H, Me; R^2 = Me, CH_2OMe, CH_2Cl, CH_2Br, CH_2I, COOMe.

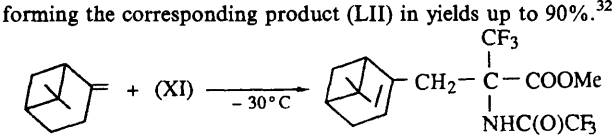
However, the product of the ene reaction (LI) is formed in addition to the 1,3-dihydrooxazine (L) in the reaction of the imine (XI) with 2-methylpropene. The content of (LI) increases from 15 to 25% on increasing the reaction temperature to −78 to 20 °C.[29]



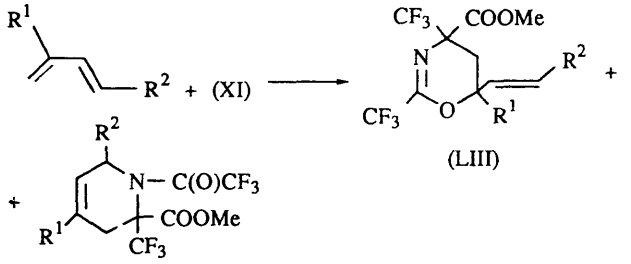
(XI) (L)

(LI)

β-Pinene, being extremely reactive in ene reactions, reacts with (XI) forming the corresponding product (LII) in yields up to 90%.[32]

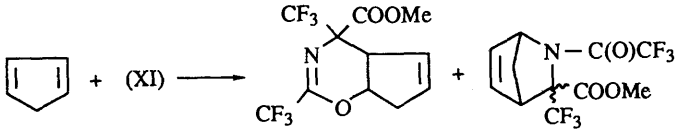


The imine (XI) also displays the properties of a strong 1,3-heterodiene in reactions with 1,3-dienes which is not a characteristic of the perfluoroacylimines of hexafluoroacetone.[110,111] Thus on reacting (XI) with butadiene, isoprene and piperylene the main reaction products proved to be the 1,3-dihydrooxazines (LIII), which are the [2 + 4] cyclic adducts. Products of the Diels–Alder reaction or the [4 + 2] cyclic adducts, which were expected to be the main products, were present only as insignificant contaminants.[109]



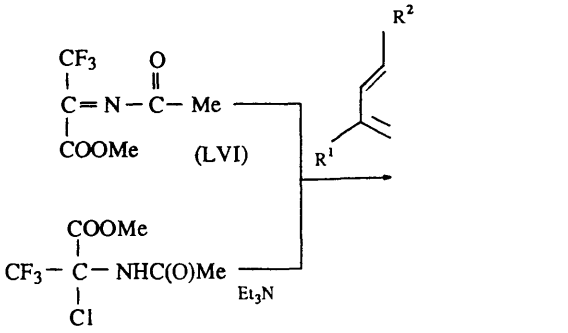
(LIII)

Even such a reactive diene as cyclopentadiene forms with imine (XI) the 1,3-dihydrooxazine (LIV) and the Diels–Alder reaction product (LV) in a ratio of 1 : 3.[109]

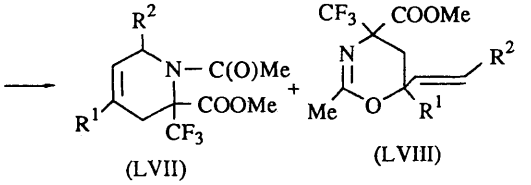


(LIV) (LV)

The character of the reaction of the less electrophilic acetylimine of methyl trifluoropyruvate with 1,3-dienes is reversed. Thus mixtures are formed in the reaction of (LVI) with isoprene and piperylene which contain up to 80% Diels–Alder reaction product (LVII) and no more than 20%, 1,3-dihydrooxazines (LVIII).[32]



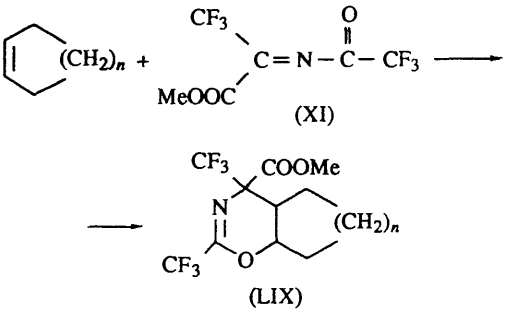
(LVI)



(LVII) (LVIII)

Analogous results were obtained on using the precursor of imine (LVI), the geminal aminochloro compound, and an HCl acceptor (Et_3N) instead of (LVI). The optimum conditions, yield, and product ratio proved to be the same as on using the pure imine.

In contrast to the terminal alkenes, cyclopentene and cyclohexene form [2 + 4] cyclic adducts (LIX) with the imine (XI) only under forcing conditions (150 °C, sealed tube).[29]



(XI)

(LIX)

$n = 1$ or 2.

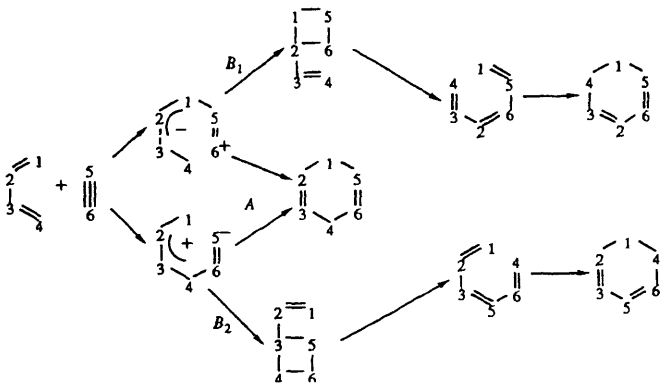
The acyl-, thioacyl- and iminoacylimines of hexafluoroacetone and the acylimines of methyl trifluoropyruvate are inclined to form rings even with such weak heterodienophiles as aldehydes, ketones and nitriles. Products (heterocycles) typical of [2 + 4] cycloaddition reactions are formed in several cases. Examples of these reactions are shown in Table 2.

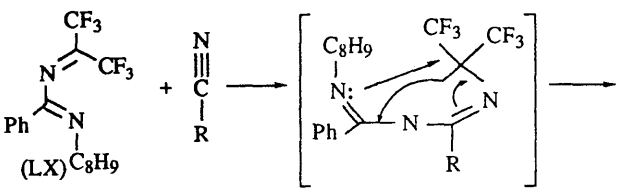
Cases are also known of the formation of compounds of anomalous structure the appearance of which is the result of stepwise conversions. The theoretical aspects of such reactions have

been considered by K Burger and his collaborators.[116] They proceeded from the fact that the reactions of polar 1,3-dienes with polar unsaturated systems usually occur as charge-controlled processes.[119] The stabilisation of the intermediates formed, the 1,X-dipoles (Scheme 1), may be effected by closing either a six- or a four-membered ring. The greater the degree of rotation of the 1,X-dipole the greater its lifetime and the greater the probability of forming a six-membered ring in the reaction. On the other hand, the formation of a four-membered cyclic system is preferred for destabilised 1,X-dipoles and in its turn it may be converted by fission of the 1–2 and 3–4 bonds giving products different from those formed by route *A*.

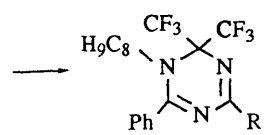
Scheme 1



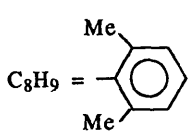
A similar scheme is proposed for the reaction of the 4,4-bis(trifluoromethyl-1,3-diazabuta-1,3-diene (LX) with carboxylic acid nitriles.[116] The reaction of dimethylcyanamide, aceto- and benzonitriles in this system leads to the expected 1,3,5-triazine (Scheme 1, route *A*). However, in the reaction of the diazobutadiene (LX) with electron-deficient nitriles such as 4-chlorophenylazonitrile, trichloro- and trifluoroacetonitrile, the products proved to be the triazines (LXI) with a reorganised diene skeleton which is only possible via route B_1 (Scheme 1).



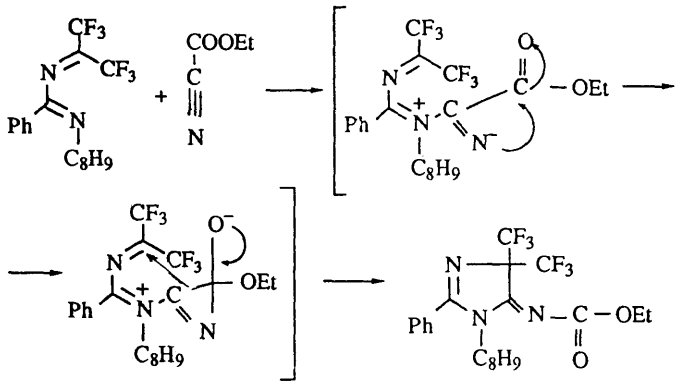
(LX) C_8H_9 =



(LXI)

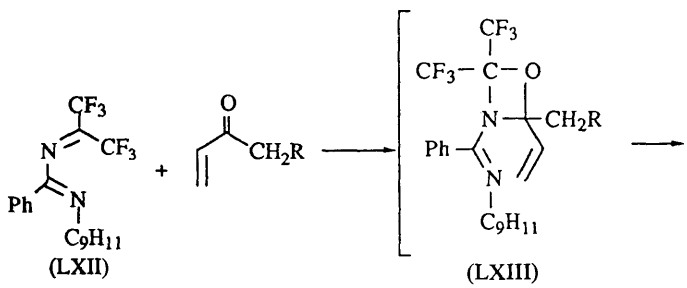


Diazabutadiene (LX) reacts most unusually with ethyl cyanoformate.[120]

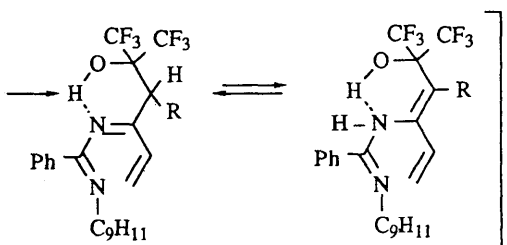


A similar cyclisation was observed previously in the acylation of acetophenone dianion.[121]

The reaction of heterodiene (LXII) with α,β-unsaturated ketones proved to be anomalous in a series of aldehydes and ketones.[122]

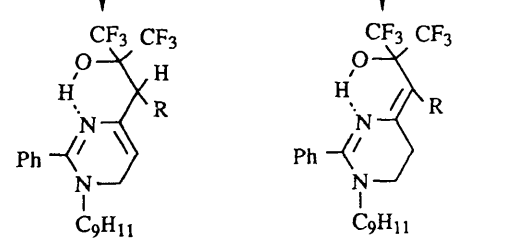


(LXII) (LXIII)



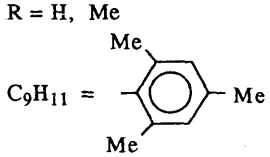
(LXIV) (LXV)

electrocyclisation ene reaction



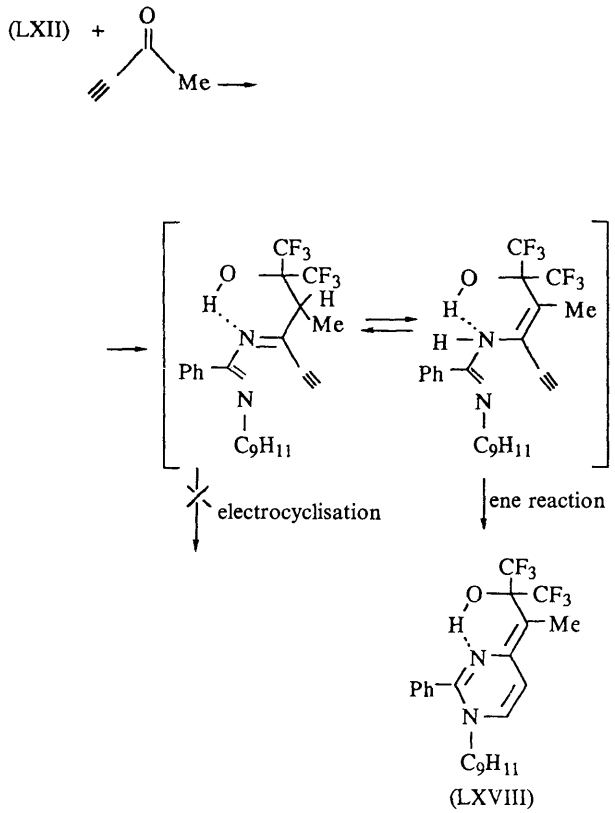
(LXVI) (LXVII)

R = H, Me



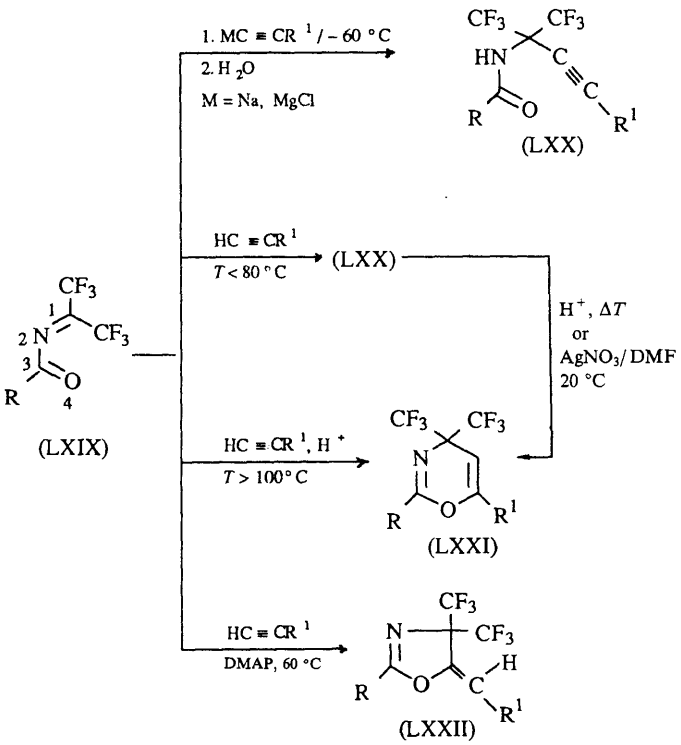
It is considered that the four-membered ring intermediate (LXIII) undergoes decomposition to hexafluoroacetone and a 1,3-diaza-1,3,5-triene which react by an ene mechanism giving the product (LXIV) existing in two tautomeric forms (LXIV) ⇄ (LXV). In their turn compounds (LXIV) and (LXV) cyclise to the final products (LXVI) and (LXVII) electrocyclically and according to an intramolecular ene reaction mechanism respectively.

The heterodiene (LXII) also reacts in a similar manner with acetylacetylene giving only one product (LXVIII) since in this case the electrocyclic reaction is hindered.[122]

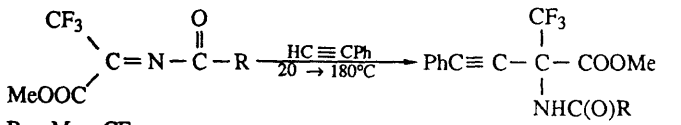


(LXVIII)

Acetylenes react with fluorine-containing 1,3-heterodienes giving the corresponding trifluoromethyl-substituted *N*-propargylamides,[32,123] 4H-1,3-oxazines[118,123] and 2-oxazolines.[123,124] The selectivity of these processes depends on the reaction conditions. Thus the acylimine (LXIX) reacts with electron-rich terminal acetylenes and alkali metal acetylides forming *N*-propargylamides (LXX). Cyclisation of these compounds under the action of acid catalysts or silver nitrate leads quantitatively to the 1,3-oxazines (LXXI). However, the electron-deficient alkynes form five-membered cyclic systems with (LXIX) including in the ring only the terminal carbon atom of the acetylene. The addition of 4-dimethylaminopyridine (DMAP) to the acylimine (LXIX) leads to the reversible blocking of the electrophilic position 1 in (LXIX) which increases the nucleophilicity of position 4. The oxazoline (LXXII) is therefore formed exclusively.

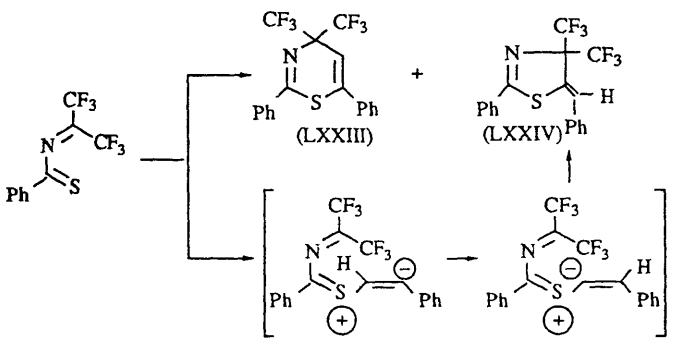


The acylimine (LXIX) forms adduct (LXX) with phenylacetylene by a Michael reaction. On heating the adduct is transformed into the oxazine (LXXI). This was not observed in the case of the acetyl- and trifluoroacetylimines of methyl trifluoropyruvate.[32]



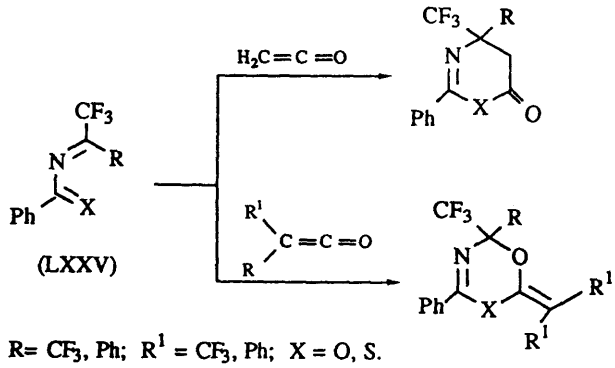
R = Me, CF_3.

On heating in phenylacetylene (80–90 °C) the thio analogue of the acylimine (LXIX) forms a mixture (1 : 1) of the products (LXXIII) and (LXXIV). The product (LXXIII) is formed by a Michael addition but the product (LXXIV) is formed through a cyclisation in which the skeleton of the dienophile is included in the cyclic system only partially. This occurs according to the following postulated mechanism.[124]



An analogous reaction was observed by Giordano[125,126] in the hydrocarbon series when reacting phenylacetylene with the imine generated *in situ* from thiobenzoic acid amide and benzaldehyde by the action of boron trifluoride ethereate.

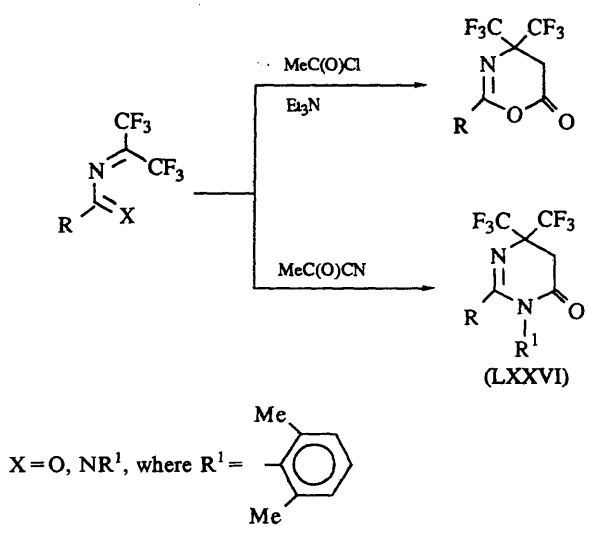
The acylimines of polyfluoroketones react with ketene by a [2 + 4] cycloaddition mechanism forming the corresponding cyclic adducts at the C=C bond.[107,127–129] However, in the reaction of the heterodiene (LXXV) with diphenyl-[127] and bis(trifluoromethyl)-ketenes[129] ring formation occurs at the C=O bond.



R= CF_3, Ph; R^1 = CF_3, Ph; X = O, S.

Desimoni and Tacconi[130] have considered this reaction from the point of view of frontier molecular theory orbitals. They showed by correlation diagrams that the reaction of the benzoylimine of hexafluoroacetone with a ketone occurs as an inverted Diels–Alder reaction, i.e. by a [2 + 4] cycloaddition mechanism. On the other hand the benzoylimine reacts as a π-donor with hexafluorodimethyl-ketene, i.e. a typical [4 + 2] cycloaddition is implemented. This also determines the observed differences in the reaction pathways.

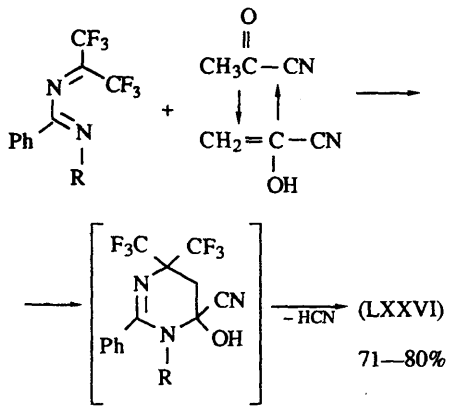
It is also possible to use ketene precursors, such as a mixture of acetyl chloride with triethylamine or nitriles of α-ketocarboxylic acids, in the reaction with acyl- and iminoacylimines.[127]



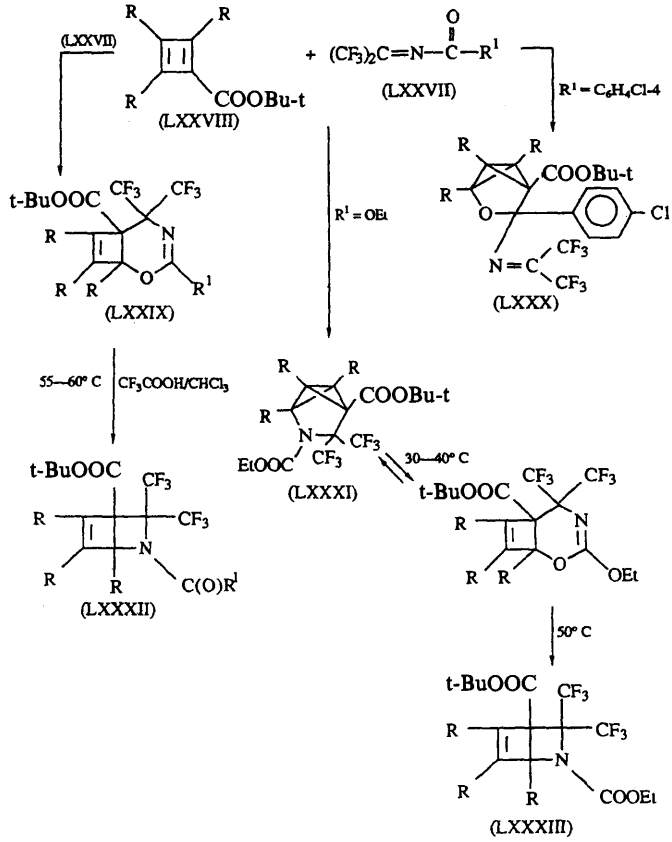
X=O, NR^1, where R^1=

R = Ph, 4-MeC_6H_4, 4-ClC_6H_4 .

Formation of the product (LXXVI) occurs on reaction of the heterodiene with the enolic form of pyruvic acid nitrile. The [2 + 4] cyclic adduct formed initially eliminates HCN spontaneously giving compound (LXXVI) in high yield.



Reaction of the *N*-acylimines (LXXVII) of hexafluoroacetone with cyclobutadiene (LXXVIII) leads to the formation of the oxazabicyclo[4.2.0]octadienes (LXXIX).[131] Exceptions are the reaction of (LXXVIII) with the imine (LXXVII, R^1 = C_6H_4Cl), when the tricyclic isomer (LXXX) is formed, and with the ethoxycarbonylimine of hexafluoroacetone (LXXVII, R^1 = OEt) which leads to the 3-azatricyclo[3.1.0^{2,6}]hexane (LXXXI). Compounds (LXXIX) and (LXXXI) are readily transformed into the bicyclic compounds (LXXXII) and (LXXXIII) respectively.[131]



R = t-Bu; R^1 = iso-Pr, Ph, 4-$MeOC_6H_4$.

(LXXIX) $\xrightarrow[14\ h]{165\ ^\circ C}$ (LXXXII)

The literature data considered in this review suggest that the known methods of synthesising fluorine-containing ketimines may be used for obtaining practically all possible types of these interesting compounds. The broad study of the properties of the various ketimines has increased the preparative accessibility of many biologically active fluorine-containing compounds, particularly fluorine-substituted aminoacids, amines and heterocyclic compounds of various types.

It may be expected that further work on the synthesis and study of the properties of fluorine-containing ketimines will be directed mainly to the development of preparative methods for obtaining various β-fluorine-containing α-aminoacids the biological activity of which is linked with the selective irreversible inhibition of pyridoxal phosphate-dependent enzymes.[132] This will probably trigger research in the least studied areas of the chemistry of these highly reactive synthons, for example, the ene reaction, various heterocyclisation reactions and further conversions of the primary products of cycloaddition reactions.

Chemically modified electrodes as amperometric sensors in electroanalysis

G K Budnikov, J Labuda
Kazan State University
Slovak Technical University

ABSTRACT. The state and prospects in the development of new fields of electroanalytical chemistry, namely amperometric sensors based on chemically modified electrodes, are examined. The methods for the construction of these electrodes, the types of modifying agents, and the mechanisms of their response to substrates are discussed. The analytical possibilities of chemically modified electrodes, including amperometric biosensors based on them, in the solution of problems associated with ecology, medicine, and pharmacology are demonstrated.

I. Introduction

The conviction that success in research and analysis is associated with the degree of purity of the surfaces of electrodes has held sway in electroanalytical chemistry for a long time. Specialists in electroanalysis endeavoured to achieve an ideal insert surface reproducible from measurement to measurement. Such a surface was provided by a mercury drop flowing from a capillary (mercury dropping electrode). The creation of the mercury dropping electrode gave rise to a renaissance in voltammetry and related methods. However, there exist a number of factors which hinder the extension of voltammetry in various practical applications:

the laborious nature of the electroanalytical methods associated with the use of the mercury dropping electrode;

the toxicity of the material of this electrode;

the difficulty of interpreting the results of measurements in cases where the adsorption of the depolariser and intermediate species, the effect of impurities, and the effect of the structure of the electrical double layer, etc. complicate the electrochemical process.

Apart from mercury, other materials and compositions have been used for electrodes.[2] Among them, the so called chemically modified electrodes (CME) have gained the greatest recognition. The study of the American investigators Miller and Van de Mark[3] on the application of an electrode coated with an electrically conducting polymer film was published in 1978. During modification, a chemical compound or polymer film is deposited in a special way on the electrode surface. This alters its capacity for the voltammetric response as a result of the appearance of new electrocatalytic properties. Electrocatalytically active compounds, for example metal, complexes with organic ligands or certain organic compounds capable of functioning as ligands, or enzymes are "bound" to the electrode surface either chemically (covalently), or as a result of adsorption, or by incorporation into the polymer film. The "contamination" of the electrode surface, with which electroanalytical chemists struggled in earlier days, came to be used beneficially and purposefully under control. The quality of the modification is monitored as carefully as the purity of the electrode surface has been estimated previously.

In principle, the concept of the "chemically modified electrode" can be treated in a broad sense. For example, any electrode the molecular structure of the surface of which has been acted upon appropriately (chemically or physically), altering thereby the electrochemical and in particular the amperometric response, can be included among chemically modified electrodes. In a recently published monograph,[4] certain problems of the modification of electrodes by polymer films, their electrocatalytic properties, the mechanisms of charge transfer through these films, and also their use in organic electrochemistry were discussed in detail.

Chemically modified electrodes can be used for various purposes. Thus, stereospecificity in electrosynthesis can be achieved with the aid of such electrodes. This was observed, for example, when cyclodextrins were used as modifying agents.[5] Chemically modified electrodes have been used[6–8] for electroanalytical purposes. Since the voltammetric cell with two electrodes can be regarded as the prototype of the amperometric sensor, the interest in chemically modified electrodes can be explained by the endeavour to construct on the basis of such a cell a kind of sensor with a specific amperometric response to a particular substance—the substrate. Thus the search for a new type of chemically modified electrodes led to a new chemical sensor. The growing stream of information about this field has now led to the accumulation of such a large amount of data that the discussion of all the characteristic features of the operation of chemically modified electrodes by modification methods is impossible in a single review. We shall therefore consider only the principal aspects of studies in the field of chemically modified electrodes and their practical applications as specific amperometric sensors.

II. Amperometric sensors based on chemically modified electrodes

1. Methods for the modification of electrode surfaces

As noted above, the modification of an electrode can be achieved by acting in different ways on its current conducting surface. The chemical compound (the modifying agent) is usually deposited in a special way on the electrode surface, imparting to the electrode new electrocatalytic properties. The following procedures are used for the immobilisation of the catalyst:

irreversible adsorption on the electrode surface;

chemical binding with fixation of the catalyst via different groups with formation of covalent bonds;

incorporation in a polymer film;

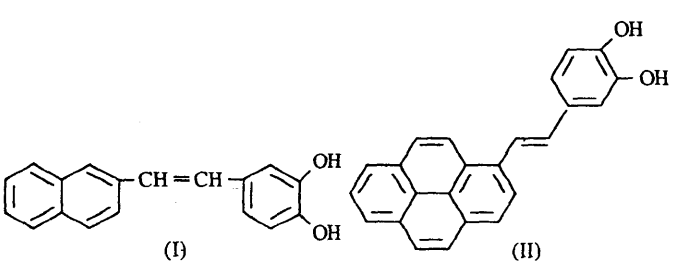
inclusion of various substances, including inorganic materials, in a paste made up of graphite materials.

Modified surfaces containing the so called sensor layer are usually subdivided into three groups depending on the nature of this layer. These can be (1) thin layers of a low-molecular-weight compound, (2) polymer films, and (3) inorganic films. It is not always possible to draw a clear-cut boundary between the groups listed above.[7]

Thus, immobilisation on the electrode surface or in its bulk phase results in the fixation of electrochemically active groups, species, or definite microstructures. The molecules of the modifying agent or its species retain their original nature, i.e. their chemical and physicochemical properties, which they possessed whilst in solution. A number of reviews have been devoted to methods for the immobilisation of modifying agents.[9,11]

The simplest modification procedure is physical or chemical adsorption. Its advantage consists in the fact that it does not require special reagents for the grafting of the catalyst; it is sufficient to activate and purify the electrode surface before depositing the modifying agent. However, its lifetime on the surface is relatively short and it gradually escapes into the solution. Various procedures increasing the retention time of the catalyst on the electrode have been described; they were developed mainly for the immobilisation of various biological materials in the creation of biosensors for a particular substrate.[11] The adsorption of polycyclic aromatic compounds on carbonaceous materials can serve as an example.[10,12] It is based on the principle of the structural similarity of the benzene rings and the hexagons on the carbon surface. Furthermore, adsorption is promoted by the low solubility of these compounds in aqueous solutions.

Adsorption usually results in the immobilisation of several layers of the organic modifying agent, for example, in the case of catalytic oxidation of NADH in the catechol [compounds (I) and (II)]–quinone [the oxidised forms of compounds (I) and (II)] system. The quinones serve as a mediating oxidising agent adsorbed on the graphite electrode. With increase in the number of aromatic rings in the catechols, the degree of their adsorption increases.[10,13]



(I) (II)

The modifying agent was retained on the electrode surface as a result of adsorption forces at a particular potential or its solution was deposited on the electrode surface with the aid of a micropipette with subsequent evaporation of the solvent.[10] This method is satisfactorily reproducible.

In order to increase the surface area of the platinum electrode, the latter is coated with platinum black. This procedure has been extended to retain enzymes as catalysts in biosensors, which will be discussed below.

A more stable immobilisation of the modifying agent can be ensured with the aid of covalent binding.[9,11] Before the chemical binding of the modifying agent, the electrode surface is activated. It is known that the surfaces of carbonaceous materials contain, after a special treatment, quinonoid, carboxy-, and phenolic groups,[2] which are capable of forming covalent bonds, for example, the amide bond, with suitable groups in the modifying agent. Amidation has been used to graft to the surface of a carbon electrode a series of aromatic amines serving as oxidants for ascorbic acid.[14,15] In this case, the carboxy-groups on the electrode surface initially react with thionyl chloride or acetyl chloride with formation of the C–Cl covalent bond which is then converted into an amide bond as a result of treatment with an amine:[6]

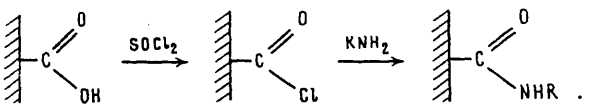


Fig. 1 illustrates schematically the modification of an electrode with the aid of covalent grafting.

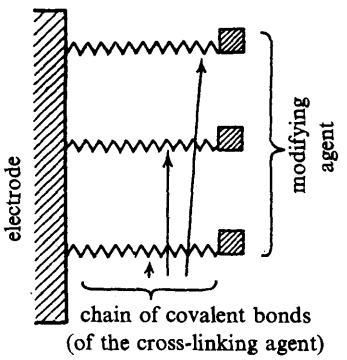

Figure 1. Schematic illustration of an electrode modified by the covalent grafting of a reagent.

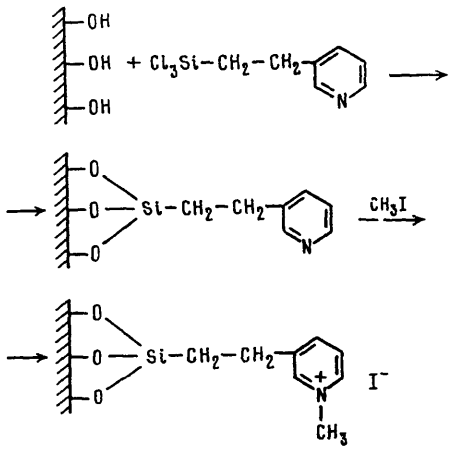
Other examples of covalent binding are silanisation and the formation of ether and C–C bonds.[6,16] In this case treatment of a metallic electrode containing oxides with strong acids leads to the

formation of numerous centres with hydroxy-groups, which then interact with chloro- or alkoxy-silanes:



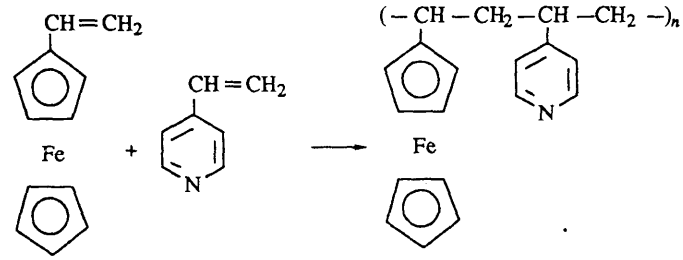
After quaternisation with the aid of methyl iodide, electrode surfaces with new properties are obtained. The coating of the electrode with such a film makes it possible to protect its surface against contamination by, for example, serum proteins, which is particularly important in immunoenzyme analysis.[17] The resulting film acquires ion-exchange properties, by virtue of which it is capable of incorporating in its structure the transferring agent anion $Fe(CN)_6^{4-}$ responsible for the analytical signal. The methods for the activation on the surface of the electrode itself (chemical, thermal, and electrochemical) have been examined in a review.[6]

Procedures for the activation of the surface with subsequent immobilisation of the reagent (catalyst) by covalent binding have been described.[11] Such an activation procedure is used mainly in the construction of biosensors,[11] but it can also be applied to other chemically modified electrodes.

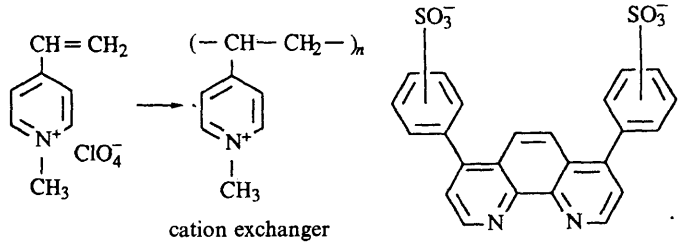
The commonest method for the immobilisation of the reagent is apparently its retention in a polymer film.[3,18–21] For example, an oxidation-reduction modifying agent can be bound to a polymer film on the electrode as a result of the electrostatic interaction of a polyanionic or polycationic electrolyte with a reagent carrying the opposite charge. This procedure is frequently employed to immobilise multicharged ions, for example, $IrCl_6^{2-}$,[22] $Ru(bipy)_3^{2+}$, $Co(bipy)_3^{2+}$, $Ru(NH_3)_6^{3+}$,[23] and $Fe(CN)_6^{4-}$,[24] where bipy represents bipyridyl.

The commonest polyelectrolytes of this kind are perfluorinated Nafion and its analogues.[25,26] In the first studies on chemically modified electrodes, electroactive polymers of the type of polyvinylferrocene were used for the modification. Subsequently, it was noted that polymer films make it possible to achieve reactions and processes such as ion exchange, membrane separation, deposition, coordination, and acid–base and oxidation-reduction equilibria on which analytical chemistry is based. The electroactive fragments of polyvinylferrocene responsible for the reversible electron transfer are the monomer units. In other films, the monomer units perform the function of ligands in reactions with metal ions. For example, the ruthenium(III) complex of EDTA is retained by coordinate bonds in a polyvinylpyridine film.[27]

The polymer film may be polyfunctional, for example, it may contain a complex-forming group in addition to the oxidation-reduction couple. The former binds selectively a particular metal ion, while the redox couple ensures contact with the electrode surface. The copolymer of vinylferrocene (ensures the presence of redox centres) and vinylpyridine (vinylbipyridyl, vinylphenanthroline) can serve as a film of this kind for chemically modified electrodes:[28]



In certain cases, the modifying agent is retained in the polymer film as a result of an ion-exchange interaction: for example, between the anionic form of the modifying agent and the cation-exchange resin:



cation exchanger (film)

anion of the sulpho-derivative of bathophenanthroline

The polymer film may contain several tens of thousands of electroactive centres.[29] The electrical conductivity of the films ensures the transfer of electrons and ions. Polymer films with bound electroactive centres (metal ions or complexes) conduct current as a result of electron exchange between the reduced and oxidised forms of these centres. The thicker the films, the greater their stability and the greater the catalytic effect and the corresponding amperometric signal. However, the coordination of a particular metal ion and the transport of charges may be hindered in films of this kind. The oxidation-reduction centres may be incompletely involved in electrocatalytic steps in thick films even at a low rate of change of the polarising potential.[30]

The electron transfer in chemically modified electrodes is influenced by the structure of the polymer and the disposition of the electroactive fragments in the polymer chain. The formal redox potential of the electroactive fragment depends on its local environment in the polymer structure. The morphology of the polymer film is influenced by the solution and the supporting electrolyte. Films characterised by a high ion-exchange capacity, insoluble in water, and swelling in aqueous solutions have been recognised as promising. Although strongly swelling films are most suitable for chemically modified electrodes because electron transfer in them is fastest, nevertheless they can partly dissolve, particularly if the polymer has a linear structure. In order to prevent this, cross-binding with the aid of bifunctional reagents (for example, glutaraldehyde) is used. The modifying agent molecules are then bound to the polymer, the electrode surface, and to one another (Fig. 2). This method is used in those cases where a long-lived

chemically modified electrode and the stability of its sensor component are required.

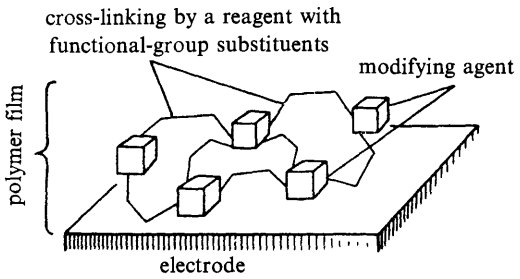


Figure 2. Schematic illustration of an electrode whose surface has been coated by a film with a cross-linked modifying agent.

Polyelectrolyte coatings are formed either by immersing the electrode in a solution (films of the Langmuir–Blodgett type) or by evaporating aliquot parts of the polyelectrolyte solution deposited on the electrode surface. The polyelectrolyte is then retained on the surface by adsorption forces. Electropolymerisation is also used to coat the electrode surfaces with films.

The immobilisation of modifying agents in the paste of a carbon-paste electrode (CPE) merits special attention because of the simplicity and ease of the method of preparation of the electrode and convenience in practical use. The modifying agent together with the carbon powder and the binding hydrophobic filler (oil) are carefully mixed in specified proportions until a homogeneous mixture is obtained and the latter is then placed in the cavity of the carbon paste electrode. The surface of such a modifying electrode is readily renewed mechanically and the amount of the modifying agent can also be readily monitored. The carbon paste electrode can be regarded as an alternative to the mercury dropping electrode (m.c.e.) in view of the ease of the renewal of its surface.

Towards the middle of the 1980s, inorganic materials as modifying agents for chemically modified electrodes attracted the attention of investigators. The layers on the electrode surface, based mainly on zeolites as well as various clays, metal oxides, silicates, etc., exhibit both chemical (in relation to the action of strong acids, oxidants, and other reagents) and thermal stability.[31]

Electrode films made up of zeolites contain three-dimensional rather than two-dimensional structures. The use of the pore dimensions in zeolites for the recognition of particular molecules or ions (the sieve effect), the possibility of discrimination among the latter as regards charge, and also combination of electrocatalysis and heterogeneous catalysis impart extremely attractive properties to such chemically modified electrodes. The cation-exchange capacity of the zeolites, which can be regulated, is also important in such cases. The combination of these factors ensure a fairly high selective response by the chemically modified electrodes. The use of commercial zeolite powders[32–34] has been described: alumino-silicates, aluminophosphates, silicatoaluminophosphates (M = Li, Mg, Be, or a transition metal). The zeolite matrix in the film on the chemically modified electrode plays the role of the "host" for the concentration or retention of a molecule or other species of suitable size ("guest"), which in the case of subsequent reactions and electrodes generate the analytical signal.

A suspension of zeolite powders in solution in a polymer is used to coat the electrode surface. After the deposition of a drop of such a mixture on the electrode, the solvent is evaporated. The retaining film-forming agent is usually polystyrene. The reproducibility of the surface of such a chemically modified electrode does not present special difficulties. Mixtures of zeolites and electrically conducting powders are also promising. The carbon paste composition (the carbon paste electrode) is convenient in this respect. Composite electrodes based on a mixture of a zeolite with a carbon powder and a polymer have also been described. The zeolite and carbon powder particles are then retained with the aid of a copolymer of styrene and a cross-linking reagent (divinylbenzene). The electrode chemically modified with the aid of such a composite mixture has a hard surface which can be readily polished and reproduced. The response time of such a chemically modified electrode is shorter than that of the carbon paste electrode.

It is appropriate to note that the guest–host concept in the mechanism of the response of chemically modified electrodes can be productive not only in the case of zeolites as modifying agents. A wide variety of macrocyclic compounds, forming stable complexes with metal ions, ensure a fairly high selectivity of the determination when present in the sensor component of the chemically modified electrode. This will be discussed below.

2. Electrocatalysis on chemically modified electrodes

It is known that by no means all organic substances are electrochemically active in the accessible range of potentials. Furthermore, the electrode reactions of some of them occur with a high overpotential and the analytical signal under these conditions can acquire a distorted form and can be poorly reproducible. One of the attractive approaches for the elimination of these undesirable phenomena consists in the use of mediators (M) which transport electrons between the electrode and a particular compound (substrate). The mediator species M and M* are components of a reversible oxidation-reduction system capable of subsequently reacting chemically with the substrate S under homogeneous conditions, i.e. in solution:

$$M \pm e \rightleftharpoons M^*, \quad (1)$$

$$M^* + S \rightleftharpoons M + S^* \quad (2)$$

$$S^* \longrightarrow P \text{ (products)}. \quad (3)$$

Thus it is possible to eliminate or greatly diminish the influence of heterogeneous factors (for example, the orientation of the substance at the electrode surface, the effect of the electrode field, the roughness and cleanliness of the surface, etc.) on the rate and degree of completion of the electrochemical reaction of the substrate S. The experimentally observed increase in the mediator current in the presence of the substrate compared with the current in its absence is a source of information about the homogeneous reaction occurring.[10] The substrate can be involved in this way in the electrochemical reaction at the normal potential of the M/M* couple and the overpotential characterising the electrode reaction of the substrate can be reduced. Since M* is regenerated, the homogeneous electron transfer can be included among catalytic processes.

Catalytic processes with subsequent homogeneous oxidation-reduction reaction are described by the familiar mechanism (Fig. 3).[35]

A necessary condition for the occurrence of the homogeneous electron transfer reaction is the stability of M* and the irreversibility of the conversion of the substrate S. Direct electron transfer to S is

characterised by an overpotential determined either by the slowness of the electron transfer stage or by the influence of the subsequent chemical reactions. The mechanism of the homogeneous reaction (2) can be various (Fig. 3). If the reversible M/M* couple functions merely as an electron transferring agent, then one is dealing with oxidation-reduction catalysis[35] or with a homomediator system.[36] On the other hand, if the adduct M*S is forming during the reaction and then decomposes with regeneration of M, then one is dealing with chemical catalysis[35] or a heteromediator system.[36] The pathways in the chemical reactions of the adduct M*S are determined by the experimental conditions (electrode, solvent) and therefore influence the process selectivity.

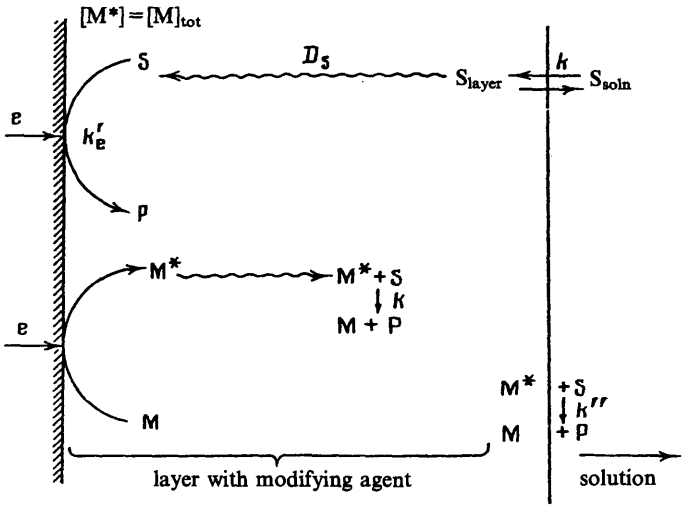

Figure 3. Schematic representation of the electrochemical process on a chemically modified electrode with a polymer coating.

The thermodynamic condition for the occurrence of homogeneous catalysis is that the standard potential of the catalyst couple E^0_{M/M^*} should be more negative (positive) than the potential of the electrode substrate reduction (oxidation) reaction $E^0_{S/P}$, where $E^0_{S/P} - E^{1/2}_S$ is the overpotential. Under these conditions, the regeneration of M depends on the rate of the irreversible reaction (3) (Fig. 3), which shifts the equilibrium in reaction (2) to the right. The irreversible reaction (3) can represent a combination of several stages, which sometimes influence the catalytic current.

Saveant and co-workers[35] considered the difference between the potentials E^0_{M/M^*} and $E^{1/2}_S$ to be the principal factor determining the catalytic effect. This conclusion is based on an experimental fact—the increase in the catalytic current with decrease in ΔE for a number of systems. It is assumed that the rate of the homogeneous transfer is higher the closer the energies of the lowest unoccupied molecular orbitals of the transferring agent and the substrate. The rate of homogeneous electron transfer is appreciable already at $E = 0.2-0.7$ V.

The use of the phenomenon of homogeneous electron transfer in electroanalysis stimulated the search for new ways of immobilising the mediators on a current-conducting surface in order to create amperometric sensors for a specific substrate. The methods for the modification of electrodes examined above ensure a high local concentration of the oxidation-reduction centres for a low overall amount of the catalyst and make it possible to consume the latter economically and to avoid special operations involving the separation of the catalyst from the reaction products.

In the study of the amperometric response of chemically modified electrodes with an immobilised mediator, it is possible to establish the influence of immobilisation on the electrochemical parameters of the mediator, the distribution of redox centres within the coating, and the location where the catalytic reaction occurs, to find the relation between the thickness of the coating, the amount of the reagent, and the catalytic current, and to determine the stability of the chemically modified electrode in time and the reproducibility of the analytical signal, i.e. to estimate a series of metrological and operational characteristics.

The study of a large group of mediators bound covalently to the electrode surface and comparison of their behaviour in solution and under heterogeneous conditions showed that the thermodynamic characteristics of the catalysts are relatively insensitive to immobilisation. Cases where the covalent bond involves an electroactive group in the molecule of the modifying agent may be an exception. In this case the maximum difference between the standard redox potentials ΔE^0 is ~90 mV.[37]

The kinetic requirement for the rapid establishment of the electrochemical equilibrium $M \rightleftarrows M^*$ (stage 1, Fig. 3) is fulfilled best for compounds for which the oxidation-reduction process is associated with the small Gibbs free energy characterising the reorganisation of the structure of the reactant molecule and of its solvation shell as a result of electron transfer.[38] Therefore, one uses such modifying agents as transition metal complexes with organic ligands[39] or organic compounds whose structure contains conjugated π-bonds or metallocenes.

Among the main reasons inducing the difference in ΔE^0 noted above, one may specify the following: (1) the increase in the energy of reorganisation of the solvent and the change in the stereochemistry of the modifying agent, which may accompany the electron transfer involving the immobilised centres (for example, as a consequence of Coulombic repulsion); (2) the influence of immobilisation on the retention of the planar structure of the mediator (for example, in the case of a metal complex); (3) the strong interaction of the mediator with the support (this affects the potential); (4) the interaction between the catalyst molecules in the oxidised and reduced forms.[10] All these factors act more or less appreciably for any immobilisation method.

The mediator performs its function of an electron transferring agent via an outer sphere or an inner sphere mechanism. In the outer sphere interaction between M* and S, an electron simply "jumps" between these species (redox catalysis). In the inner sphere mechanism (chemical catalysis), the mediator plays the role of an electron transferring agent and simultaneously binds the substrate into the intermediate. Thus the reduction of oxygen to hydrogen peroxide on a chemically modified electrode based on the porphyrin-cobalt complex (CoP) incorporated in a Nafion film, proceeds in fact via the chemical catalysis mechanism.[40] The electron exchange takes place within the adduct between the substrate O_2 and the modifying agent, i.e. within the complex $CoPO_2$. In the chemical catalysis, there is a possibility of the transfer of two electrons. For a sufficiently large number of catalytic cycles in the construction of the chemically modified electrode, one may deposit thin films (or even a monolayer). In practice, it is best to use under these conditions an

electrode having a large contact surface area, for example, one made from a porous or fibrous material.[41]

The principal requirements which must be not by mediators are listed below:

the mediator must be stable in relation to atmospheric oxygen (its reduced form should not, for example, be oxidised in air);

the oxidation-reduction potential of the mediator must be low and virtually independent of the pH, i.e. the potential of the M/M* redox couple is not a function of H^+;

the stage in which the mediator interacts with the substrate must be rapid, which is best achieved for an inner sphere mechanism;

the mediator must not be transferred from the surface of the chemically modified electrode to the test solution;

the mediator must be non-toxic.

The disadvantages which are encountered in studies with chemically modified electrodes include a decrease in the activity of the modifying agent on immobilisation or its change as a function of time, possible side reactions which deactivate irreversibly the modifying agent, as well as certain other side processes have been noted. However, these disadvantages of chemically modified electrodes are manifested to a greater extent when they are used for electrosynthesis than in electroanalysis.[41]

The theory of charge transfer in a layer of an immobilised modifying agent as well as the reactions of the substrate occurring on the chemically modified electrode have been described by different workers.[42–53] Depending on the immobilisation procedure, the modifier can be deposited, as noted above, on the surface both in the form of a monolayer and in the form of a film having a definite thickness. Multilayer coatings are as a rule discussed in the literature and the monolayer is regarded as a special case. The processes occurring on the surface of chemically modified electrodes are extremely varied; new transport stages and chemical reactions, any of which may limit the rate of the overall process, are manifested here. Fig. 3 presents a general scheme for the amperometric response on a chemically modified electrode with a polymer catalyst film.[52]

The rate of electron transfer in the direction of the redox centres through the electrode–modifying agent interface is fairly high and is determined by the potential. The M and M* centres participate in the electron transfer within the layer.[54] The charge transfer is partly associated either with the diffusion of counterions having oxidation-reduction properties if polycationic film includes an ion exchanger (see, for example, Anson et al.[55] and Pickup and Murray[56]) or with the movement of electrons along the conducting polymer chain.[57] The overall diffusion coefficient D_c characterises this movement of charges.

It has been suggested that the substrate enters the layer of the modifying agents slowly via diffusion. This process is characterised by a partition coefficient K. In the film itself, the migration of the species S is affected both by the pore size[58] and by the density of the polymer film impregnated with the solvent.[59] The diffusion coefficient of the substrate D_S in the layer of the modifying agent can be lower by 3–4 orders of magnitude than in solution.[60,61] It may happen that not all the immobilised modifying agent species participate in the reaction of the substrate, only some of them being involved, which depends on the kinetic and transport parameters k, k'_e, k'', D_S, and D_e. The reduction of the substrate S directly on the electrode surface (determined by the rate constant k_e) can occur only in the case of thin films[62] and is not typical for the usual layers. The difference in the behaviour of the modifying agent bound directly to the surface and present in the film (i.e. in its reaction layer) is explained by the difference in the solvation of the modifying agent.

The use of polymer coatings differing in the structure and composition of the films opens yet another pathway to the attainment of selectivity in the analytical determinations. For example, ascorbic acid and dopamine, which are oxidised on the carbon glass electrode at virtually identical potentials, can be separated on a chemically modified electrode coated by polyvinylpyridine in which the $IrCl_5^{3-}$ transferring agent has been incorporated.[63] Both the peak potentials on the voltammograms and the rates of the catalytic reaction of these substrates differ appreciably under these conditions.

The establishment of the thickness of the coating on the electrode (for the maximum concentration of the modifying agent in the latter), which affects the catalytic activity, is important. The extent X of the reaction zone, determined by the modifying agent (in the film)/solution boundary, is estimated from the relation

$$X_L = (D_S/k[M]_{tot})^{1/2}. \quad (4)$$

For the electrode surface/modifying agent boundary layer, this distance from the electrode surface is determined from the formula

$$X_0 = (D_e/kK[S]_{soln})^{1/2}. \quad (5)$$

Here $[S]_{soln}$ is the substrate concentration in solution at the boundary near the polymer film and the subscripts L and O indicate the distance from the surface of the electrode proper where the reaction zone begins.

Then types of reaction zones, depending on the site where the modifying agent is located, have been proposed in a detailed study of the mechanisms of the response of chemically modified electrodes[64] (Fig. 4). Eqns. (4) and (5) describe the extreme cases where the reaction zone is located directly in the solution and at the electrode proper. If the rate constant for the reaction

$$M^* + S \xrightarrow{k} M + P$$

in the layer of the modifying agent is zero, the substrate reaches the surface of the electrode proper (Ek'_e type of location). If the electron transfer and the mass transfer of the substrate are reversible, then the reaction proceeds in the layer of the modifying agent and for a low value of k the reaction zone is diffused throughout the thickness of the layer of the modifying agent (Vk type of location). When k is large, the reaction zone narrows down to the size of the layer (RZV type of location).

For reaction zones located on the surface of the modifying agent (types Pk'' and VPk), two cases are distinguished. In the reaction zone with Pk'' type of location, a homogeneous reaction takes place at a high rate (high catalytic effect; $k_2 > 10^4$ litre^2 mol^{-1} s^{-1}). The thickness of the sensor layer is then unimportant. Since the thickness of the film may be decisive for electron transfer, it is best to use thin coatings or even a monolayer of the modifying agent for chemically modified electrodes.

The VPk zone occurs for thick coatings and electrodes. In the ideal case the extent of this zone is described by Eqn. (4). Since the concentration of the electrocatalytic centres in the layer is several times greater than that in the solution, for a sufficient mass transfer of substrate into the layer ($D_S \simeq 10^6$ cm^2 s^{-1}) the quantity k_2 in the layer may be appreciably smaller than in the solution ($k_2 > 10$ litre^2 mol^{-1} s^{-1}). It has been suggested that porous film forming

agents be used fot the immobilisation of the modifying agents on such chemically modified electrodes and that the pore diameter in the layer should be approximately an order of magnitude greater than the diameter of the substrate molecule,[41] the optimum thickness of the layer being ~ 1 μm.[52]

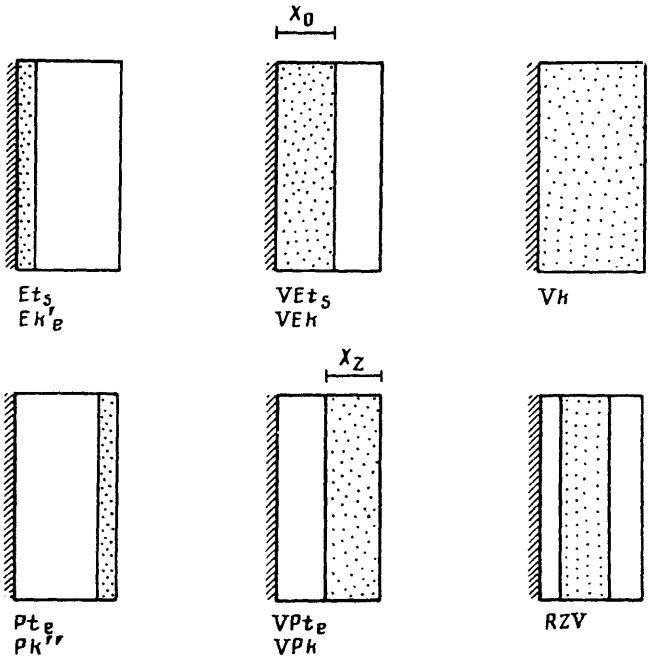

Figure 4. Types of reaction zones in the film of modifying agent on the surface of a chemically modified electrode. Location of the zone: E—electrode; VE—layer at the electrode; V—bulk-phase layer; P—surface of the chemically modified electrode facing the solution; VP—layer at the surface of the chemically modified electrode; RZV—reaction zone in the bulk phase layer. Rate-determining stage: substrate transfer (t_S) and electron transfer (t_e). Rates of reactions: electrochemical reaction (k_e) and catalytic reaction in the layer (k) or on the surface (k'') of the modifying agent (according to Bartlett[64]).

It follows from the data described above that effective catalytic action is observed when the entire bulk of the immobilised catalyst is involved in the process (case Vk), which is difficult to achieve in practice, or when the reaction layer is involved (VPk), its reaction zone being at the maximum distance from the modifying agent/solution interface and extending in the direction towards the surface of the electrode proper. The ratio of the limiting catalytic current at a rotating disc electrode to the limiting current calculated from the Levich equation has been adopted as a measure of the catalytic efficiency of the chemically modified electrodes. For $X < X_{opt}$, the catalytic efficiency of the modifying agent increases with increase in X. For $X > X_{opt}$, a much greater consumption of the modifying agent (which is frequently expensive) is required for a slight increase in efficiency.

Apart from the rotating disc electrode, voltammetry, especially its cyclic version, which makes it possible to determine the rate constant for the reaction of the mediator with the substrate in solution (k_2), is used for the qualitative assessment of the observed kinetic effects. The nature of the catalytic reaction of the substrate can be established in this instance from the cyclic curves.[65] For a low rate of the subsequent chemical reaction (M* + S) and its low constant $k_f = k_2[S]$, the shape of the voltammogram is close to that of the cyclic curve characteristic of a reversible electrode process ($i_p \propto V^{1/2}$; $i_{pa}/i_{pc} = 1$; $\Delta E_p \simeq 0.057/n$ (volts); here V is the rate of change of the polarising potential, i_{pa} and i_{pc} are the currents of the anodic and cathodic peaks, ΔE_p is the difference between the potentials of these peaks, and n is the number of electrons participating in the oxidation-reduction reaction).

For higher values of k_f, the voltammogram contains one step (for example, the cathodic step), the limiting current of which is proportional to $k_f^{1/2}$ and is independent of the rate of change of the polarising potential. In the intermediate situations with average values of k_f, the height of the cathodic peak of the mediator M in the presence of the substrate S is greater, while the height of the anodic peak is lower than in the absence of S. These changes in the peak currents are clearer for low rates of change of the potential ($V = 1-10$ mV s^{-1}).

The diagnostic criteria described in the literature for cyclic voltammetry are used for the qualitative description of the electrochemical behaviour of chemically modified electrodes in the substrate solution.[65] We may recall that useful information can be extracted from the dependence of $i_p/V^{1/2}$ on V. The quantity k_f is found from a series of cyclic voltammograms recorded for different rates of scanning of the potential.[65]

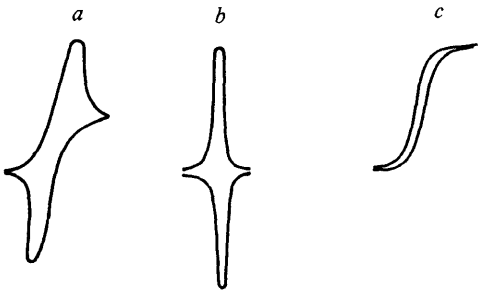

Figure 5. Typical cyclic voltammograms for different types of behaviour of the mediator in the chemically modified electrode: *a*, reversible behaviour of the mediator in solution; *b*, ditto but on the surface of the chemically modified electrode; *c*, catalysis at a high rate (k_f).

As was to be expected, cyclic voltammograms for an immobilised mediator in the absence of the subsequent chemical reactions involving the redox couple contain reversible peaks and we have $i_p \propto V^{1/2}$, $i_{pa}/i_{pc} = 1$, and $\Delta E_p = 0$. Fig. 5 presents for comparison the cyclic voltammograms corresponding to the cases described above.

3. Immobilisation of electron transferring agents in chemically modified electrodes

It follows from subsection 1 that the methods for the retention of modifying agents on the surfaces of electrodes are very varied and one can therefore put forward a large number of procedures for the fixation of the oxidation-reduction centres participating in the catalytic response of the chemically modified electrode. However, in practice, mainly polymer films are used to immobilise electron transferring agents[4,9] because of the simplicity of the operation, its reproducibility, the adequate stability of the chemically modified electrode obtained, and the possibility of varying the film thickness. Here account must be taken only of the fact that the material of the polymer is frequently non-indifferent to the transferring agent, which affects, for example, its formal redox potential.

The electron transferring agent is immobilised in different ways. One of them involves the electrochemical preparation of a conducting polymer with the simultaneous incorporation of the catalyst in the latter. For example, in the electropolymerisation of pyrrole in solution in the presence of hexacyanoferrate(II) ions, quinone, porphyrins, phthalocyanines, and certain other catalysts, films containing these transferring agents are obtained. The polypyrrole films are used more often than other coatings in chemically modified electrodes because polypyrrole is electrically conducting and its thick films do not induce an appreciable passivation of the electrode, are retained both on metal oxide surfaces and on carbonaceous materials, and are chemically stable during the period necessary for analysis.

The use of an *N*-substituted pyrrole as a monomer in electropolymerisation leads to still more stable films. Their polymerisation is accompanied by the immobilisation of bipyridyl and porphyrin metal complexes, ferrocene, anthraquinone, phenothiazine, dyes, and other compounds.[66] However, the polymer films based on *N*-substituted pyrroles exhibit a lower conductivity compared with the unsubstituted analogue, which can be avoided by copolymerising pyrrole and an *N*-substituted pyrrole.[41] Other compositions comprising two polymers are also used.[67,68] The substituted pyrrole as the monomer may contain in its structure groups involved in electron transfer. The substituents in the pyrrole molecule ultimately determine the property of the polymer coating on the chemically modified electrode which influences the mass transfer of the substrate.[69]

The commonest electron transferring agents are the bipyridyl complexes of ruthenium and osmium[57,70] as well as iron and cobalt.[71] They are immobilised in films based on polyvinyls. The porosity of the films, which determines their transport properties, is achieved in different ways, for example, by activating the polymerisation process by means of plasma.[72] The transport of species with electrocatalytic properties from the solution into the polymer film occurs sometimes during a comparatively long period.[73] The cyclic alteration of the potential of the chemically modified electrode over a short time interval in the region of the formal redox potential accelerates this process.[61,74]

As mentioned above, the retention of the species of the modifying and transferring agent can be achieved by means of electrostatic interaction forces. In such cases, an ion exchanger of the type of Nafion is widely used as the retention matrix. Its selectivity in the charge (ion) transfer process is a maximum in relation to hydrophobic species. Another example of the use of electrostatic interactions for the purpose of immobilisation is the fixation of ruthenium hexacyanoferrate(III) complexes on anionic or cationic surfactants immobilised in their turn with polystyrene film.[75] In order to ensure the selectivity of the electrocatalytic response, which is determined by the size and shape of the substrate particles, the modifying and transferring agent is immobilised in various clays or zeolites, which are retained on the electrode surface by polymers, including polymers formed by electropolymerisation.[76] The clay-modified electrode can adsorb certain surfactants, which then extract from the solution transferring agents of the type of hexacyanoferrate(III) ions, ferrocene, etc.[77]

Apart from the immobilisation of transferring agents with the aid of polymer films, their adsorption on the electrode surface is employed. Copper and cobalt complexes with organic ligands and aromatic compounds are immobilised in this way. This method is frequently used to immobilise enzymes or other biological materials in the construction of biosensors.[78] For example, an adsorbed film of microorganisms is capable of retaining combined transferring agents and electrocatalysts comprising hexacyanoferrate(III) ions or ruthenium(III) complexes.[79] The insoluble hexacyanoferrates(II), deposited on the electrode surface, can also function as transferring agents.[80–83] Ruthenium complexes, ferrocene, and benzoquinone are retained on the surface of carbon glass after its electrochemical treatment at an anodic potential.[84]

4. Chemically modified electrodes as biosensors

If a biological material, for example an enzyme or an enzyme-containing preparation, is incorporated in the signal-generating layer of the chemically modified electrode, then such an electrode is called a biosensor or a biochip. Other names are also used.[85] The modifying agent, in the given instance an enzyme, is immobilised by all the procedures which were described above for simpler transferring agents. Much attention has been devoted to the principles of the operation of biosensors and their applications. A series of special reviews have been published, including reviews in Russian journals.[85,86] Here is it appropriate to consider the problems concerning biosensors of the same kind as those arising in the development of chemically modified electrodes. It must be emphasised that studies on chemically modified electrodes, carried out independently and simultaneously with the development of biosensors, made a definite contribution to the expansion of the biosensor field. It was found that many results of studies on chemically modified electrodes have led to advances in the study of biosensors up to the level of their practical application.

In principle, any biosensor can be regarded as one of the versions of the chemically modified electrodes. Since the general principles of the functioning of amperometric sensors based on immobilised enzymes were examined previously,[85] there is no need to return to this problem.

The operation of amperometric biosensors is based either on the direct electron transfer between the active centre of the immobilised enzyme and the surface of the electrode proper or on the involvement of a mediator. In the latter case the biolayer giving rise to a specific response of the substrate is deposited on the modified surface containing an electron transferring agent. In this so called bulk phase technology, the individual components of the biochip constitute, as it were, a physical ensemble. Although such biosensors have now found practical applications, there are difficulties in their preparation on a mass scale. In addition, biochips with comparatively thick membranes have a long response time; complications arise also in their calibration.

The principal requirements which must be met by the mediators in chemically modified electrodes also apply to the biosensors based on them. It must be emphasised that the stage involving the

interaction of the mediator with the active centre of the enzyme must be fairly rapid, i.e. the mediator must behave in essence as if it were a substrate of the enzyme. Ultimately two catalytic cycles occur on such an electrode (Fig. 6).

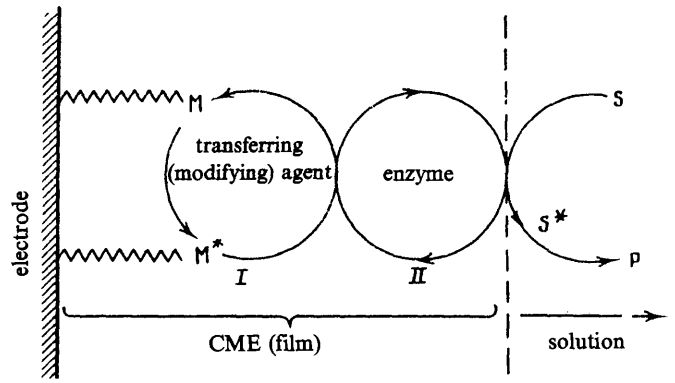

Figure 6. Schematic illustration of the operation of a chemically modified electrode with two catalytic cycles.

Amperometric biosensors are usually based on the so called oxyreductase enaymes in which the electron acceptors are, for example, atmospheric oxygen, nicotinamide-adenine dinucleotide (NAD^+) or nicotinamide-adenine dinucleotide phosphate ($NADP^+$). These components of the chemically modified electrode participate in the recyclisation of the enzyme after its reaction with the substrate. Enzymes employing O_2 as the electron acceptor are usually referred to as oxidases, whereas enzymes operating in combination with NAD^+ or $NADP^+$ are referred to as dehydrogenases or reductases. Among the enzymes in these two groups, oxidases are usually employed for the construction of biosensors.[9,11]

Without going into the details of the practical aspect of the problem of biosensors, the reader being referred to the reviews mentioned above,[9,11] we may note that their selectivity is determined by the specificity of the action of the enzyme and by the nature of the electrochemical reaction proper, in which the components of the enzymic process participate. Oxidases are as a rule highly specific in relation to particular components of the biological specimen. On the other hand, the system transforming the response of the biological reaction involved in the recognition of the substrate molecule into electric current (the system comprising the transferring agent or mediator, also referred to as the transducer) is not always quite as selective as one would wish. Indeed, many metabolites may be oxidised at a platinum microelectrode (transducer) at its operating potential. Thus ascorbic and uric acids, aminoacids, urea, and other components of the biological specimen analysed are oxidised at this electrode at a working potential of +0.6 V.

In order to increase the selectivity of such biosensors, use is made of special films operating on the basis of the principle of filters. For example, in order to suppress the influence of the above components and also of cysteine and proteins, which can be present in biological specimens, for example, in blood serum, use is made of a polymer film based on 1,2-diaminobenzene obtained by electrochemical polymerisation.[87] Such a biosensor with an immobilised glucose oxidase yields satisfactorily reproducible results in the course of 1–1.5 months. Glutaraldehyde may be used to increase the thermal stability of the biolayer.

The advantage of a biosensor with a film permeable only to substrate molecules of a particular size consists also in the fact that such devices have a low noise level in the recording of a useful signal and can be employed in flow injection analysis.

As mentioned above, dehydrogenases can serve as the enzymes in many biosensors.[11] These enzymes operate in combination with NAD^+ or $NADP^+$, the so called coenzymes. During the enzymic process, they are consumed in an amount equivalent to the amount of the substrate. The coenzymes must therefore be regenerated during the operation of dehydrogenase biosensors. This is achieved in a catalytic cycle on an electron transferring agent immobilised on the surface of the transducer proper. Quinone-hydroquinone derivatives are usually employed for this purpose (cycle I, Fig. 6). The coenzyme participates in the second catalytic cycle, which determines jointly with the enzyme the specificity of the response (cycle II, Fig. 6).

A low working potential is applied to such electrodes with an immobilised modifying agent, which imparts to them certain useful properties. Thus an advantage of the biosensors working on the principle of chemically modified electrodes with a double catalytic cycle is the possibility of increasing the selectivity of the response by limiting the number of specimen components, capable of reacting electrochemically when a potential is applied, by increasing the signal/noise ratio. These biosensors have a linear response over a wider range than the biosensors without a modifying agent.

Direct electron transfer between the active centre of the enzyme and the working electrode, i.e. the bioelectrocatalysis proper, is also a method for increasing the metrological and operational characteristics of biosensors. In this case, there is no mediator-transferring agent, in contrast to the previous scheme. A number of reviews and articles have also been devoted to the problem of direct electron transfer.[88–92]

The efficiency of biocatalysis based on an idealised model has been discussed.[88,89] It has been shown that the catalytic activity of enzymes on the surfaces of electrodes can be so great that the amperometric response is determined by the diffusion of the substrate, while the immobilisation of the enzymes ensures a high current density. A limited number of examples of the direct electron transfer from the active centre of the enzyme to the electrode have been described in the literature. Thus the possibility of using cytochrome *c* as the catalyst of the electrochemical reduction of molecular oxygen has been investigated. The rate of formation of hydrogen peroxide increases in the presence of this biocatalyst.[90] Evidence indicating the possibility of the direct electron transfer from the active centre of the enzyme to the electrode has been obtained for the oxygen–laccase–electrode system.[91,92]

Among the amperometric biosensors giving rise to a response in the absence of a mediator, the greatest interest attaches to those where the electrode (the carrier of the immobilised enzymes) is constructed from electrically conducting materials, for example, organic salts of the type tetracyanoquinonedimethane–tetrathiofulvalene (TCQ^-TTF^+).[93] Thus the oxidation of lactate is accelerated catalytically when cytochrome B_2 is immobilised on the complex of TCQ^- with *N*-methylphenazinium. This biocatalytic system has been used as a basis for the functioning of the biosensor for lactate.[94] If instead of cytochrome one uses in this system glucose oxidase immobilised on the same organic salt by means of

irreversible adsorption, then the biosensor makes it possible to determine glucose with an activity which does not change in the course of 100 days.[94] Other enzymes are also adsorbed on this organic conductor. Biosensors for purine, hypoxanthine, and xanthine have been constructed on the basis of such an assembly.[95] Finally one should note that various microorganisms and cells immobilised in a biolayer are used in biosensors, including those with an amperometric response (see, for example, Ivnitskii et al.[86]).

III. Applications of chemically modified electrodes in electroanalytical chemistry

Various practical applications of chemically modified electrodes have been described so far in the literature. Amperometric sensors and the analysers based on them usually give rise to a measured signal which is linear over a wide range as a function of concentration and has a lower detection limit compared with potentiometric sensors. It is noteworthy that each sensor, transducer, or detector, working in accordance with the principles of chemically modified electrodes, is constructed for the solution of a particular specific practical problem and functions under rigorously defined conditions.

After the modification of the electrode surface by one of the methods described above, the resulting chemically modified electrode is introduced into the solution to be analysed. If metal ions are to be determined, then in the course of a certain time (from several minutes to several tens of minutes) the ion is bound (absorbed) on the electrode surface or in its bulk phase as a result of the reaction with the modifying agent. If an immobilised ligand serves as the modifying agent, then the ion is bound as a result of complex formation. The selectivity of the determination is attained not only by selecting the appropriate ligand but also by regulating the pH and the concentration of masking agents.[7] Metal ions may accumulate on the chemically modified electrode due to the electrostatic interaction forces resulting from ion exchange.[7,9,10] Multicharged ions can then be concentrated from highly dilute solutions.

Measurement of the voltammetric response after the electroaccumulation stage gives rise to a peak on the curves whose height (or area bounded by the corresponding contour) is used to determine the concentration of the given ions in the solution. If the electrochemical reaction involving the metal ions to be determined is reversible, then virtually any version of voltammetry or differential-pulse technique can be used to measure the signal. In this case the chemically modified electrode permits single determinations, after which its surface has to be regenerated with repeated modification.[7] On the other hand, if the electrode reaction is irreversible and the metal–ligand bond is ruptured during it but the immobilised ligand is not degraded, then the chemically modified electrode can be used repeatedly.[7]

The lower limit of the determination using chemically modified electrodes depends on the number of binding centres on the electrode surface, the stability of the complexes formed, the parameters of the distribution of ions between the solution and the absorbing phase of the electrode with incorporated modifying agent, and also on the method of recording the voltammetric signal.

Among inorganic ions, those of heavy metals have attracted most attention by investigators, which is associated primarily with the problems of the ecological monitoring of natural and waste waters, air, soils, and agricultural products. The problem of the sensitivity and selectivity of the determination has always been and remains of current interest, particularly now when the importance of analytical monitoring in the community has increased.

Inversion voltammetry combined with chemically modified electrodes has been used recently to increase the sensitivity of the determination. Detection limits for metal ions are then attained at the level of the capacity of physical methods such as atomic absorption voltammetry, which is used most often for such purposes in environmental monitoring. Thus the principles of inversion voltammetry have been used to determine copper(II) on a carbon paste electrode modified with di-8-quinolinyl disulphide.[96] After reduction to quinoline-8-thiol, the latter binds copper(II) ions in a stable complex. The detection limit for copper(II) with the aid of such an electrode reaches 8×10^{-10} M, which is close to the detection limit for copper with the aid of the mercury film electrode.

The carbon paste electrode modified with 2,2′-dithiobipyridyl has been proposed for adsorption accumulation and subsequent voltammetric determination of silver with a detection limit of 8×10^{-9} M. The analysis is hindered by the presence of mercury and copper, but bismuth, antimony, cadmium, cobalt, nickel, and zinc ions present in a 100-fold excess do not interfere.[97]

The carbon glass electrode whose surface has been coated with poly-4-vinylpyridine containing mercury(II) ions makes it possible to determine heavy metal ions (lead, cadmium, and copper).[98] The preliminary accumulation is carried out at a potential of about −1 V for not more than 3 min, after which the differential-pulse voltammogram is recorded.[98]

The graphite electrode modified with diphenylcarbazone has been proposed for the determination of traces of mercury(II) in aqueous solutions.[99] It is made by pressing a mixture of the modifying agent with graphite powder. The mercury(II) ions are concentrated from solutions containing nitric acid. The solution is then changed and the differential-pulse voltammogram is recorded in the new supporting electrolyte. The detection limit is 5×10^{-8} M (for accumulation in the course of 10 min). The determination is interfered with by silver ions, chromate ions, and strong complex-forming ligands.

The principles of inversion voltammetry have also been used to determine small amounts of cobalt with the aid of a carbon paste electrode.[100] The modifying agents were a cation exchanger and phenanthroline. The cobalt(II) detection limit was 8×10^{-10} M. Conditions permitting the analytical determination of this ion in the presence of a number of heavy metal cations have been found.

As an illustration, Table 1 presents data obtained in the determination of certain toxic metal ions, which characterise the analytical possibilities of chemically modified electrodes in voltammetry and its modifications. Although Table 1 does not exhaust all the literature data on the problems involved in the use of chemically modified electrodes in analytical practice, the measured concentrations of metal ions demonstrate convincingly that voltammetry combined with chemically modified electrodes can compete with a method such as atomic-absorption spectrophotometry.

Not only metal ions but also organic compounds are concentrated on the surface of chemically modified electrodes. Ecological as well as medical and pharmacological problems dictate also in this case the choice of the objects for analysis. Substrates with complex structures, proteins, medicinal preparations, vitamins, biologically active compounds, including pesticides, etc. are determined with the aid of voltammetry combined with chemically modified electrodes. Table 2 presents examples illustrating the possibilities of chemically modified electrodes in the electroanalysis of organic substances.

Table 1. Voltammetric determination of inorganic ions in solution with the aid of chemically modified electrodes.

Ion to be determined	Material of electrode	Modifying agent	Method of measurement of signal	Concentration determined, M	Refs.
Cu(II)	Carbon glass	3-Aminopropyltriethoxysilane	Inversion voltammetry, differential-pulse technique	$1\cdot10^{-9}-3\cdot10^{-7}$	[101]
		Poly(pyrrole-*N*-carbodithionate)	Substance concentrated at −0.6 V; cyclic voltammetry	10^{-5}	[102]
As(III)		Ruthenium(II, III) cyanides	Catalysis of oxidation, voltammetry	$5\cdot10^{-6}-2\cdot10^{-3}$	[103]
As(III), Te(II)	Graphite	Mercury complexes	Inversion voltammetry	$3\cdot10^{-9}-5\cdot10^{-10}$	[104]
Sb(III)		Triphenylmethane dyes	–	$3\cdot10^{-8}-4\cdot10^{-9}$	[104]
Ag(I)	Carbon paste	Diethylenetriamine	–	$10^{-11}-10^{-7}$	[106]
Bi(III)		Mercaptans	–	$1\cdot10^{-7}-2\cdot10^{-5}$	[106]
Hg(II)	Graphite	Diphenylsemicarbazone	–	10^{-9}	[99]
UO_2^{2+}	Carbon glass	Tri-n-octylphosphine oxide	Voltammetry	$4\cdot10^{-9}-2\cdot10^{-8}$	[107]
DO_2^{2+}			Inversion voltammetry	10^{-8}	[108]
NO_2^-	Platinum	Poly(4-vinylpyridine) and iodine	Voltammetry	$4\cdot10^{-6}-2\cdot10^{-3}$	[109]
	Carbon glass	$IrCl_6^{3-}$ in a polyvinylpyridine film	Flow-injection analysis	$10^{-4}-10^{-3}$	[110]
		Macrocyclic nickel complex in a Nafion film	Cyclic voltammetry	10^{-4}	[74]
SCN^-	Platinum	Acetylcellulose film with iodide	Flow-injection analysis	$5\cdot10^{-6}-1\cdot10^{-4}$	[111]
	Carbon glass			$2\cdot10^{-7}-4\cdot10^{-6}$	[111]

It does not mention the substrates of enzymes used in biosensors because their determination has already been discussed in detail.[10,11,85]

Table 2 shows that, among the methods for immobilisation of modifying agents on the electrode surface, the incorporation of such agents into a polymer film or into the bulk of the carbon paste electrode is usually employed. Non-traditional solutions are rarely encountered.

Various hydrophobic materials deposited directly on the surface of a solid electrode may be included among unusual modifying agents.[120–122] Thus many medicinal substances reducing blood pressure, of the type of reserpine and rescinnamine, can be determined on lipid-modified electrodes.[121] After the deposition of the lipid film on the carbon glass surface of the electrode, compounds are accumulated in the course of 10 min, whereupon they permeate actively into the hydrophobic layer. The voltammogram is then recorded. The detection limit is 5×10^{-9} M.

Polar electroactive substances (up to a 100-fold excess) do not affect the results of the determination. Electrodes modified by lipid films respond selectively to the presence of hydrophobic organic substances containing the electroactive groups in their structure.[122] Hydrophilic compounds are incapable of permeating into the lipid layer during its accumulation, which prevents their reactions on such a chemically modified electrode. Studies on lipid films prepared on the basis of distearoylphosphatidylcholine and dioleolylphosphatidylcholine showed that the electrode reactions on such chemically modified electrodes are due to the presence of double bonds in the alkenyl chains of the lipids.

Graphite electrodes with stearic acid deposited on their surface have been used to determine dopamine and norepinephrine in rat brain tissues *in vivo*.[120] The carboxy-groups of the modifying agent influence the oxidation potentials of these biogenic amines shifting them towards more positive values. The effectiveness of this chemically modified electrode in the presence of metabolites—electroactive and neurochemical compounds belonging to the group of catecholamines and present in tissue liquids. It has been suggested that there is a relation between the form of the voltammetric signal and the activity of dopamine.

In many instances, chemical modification of the electrodes alters the parameters of the electrochemical reaction and makes the process more reversible, while the form of the analytical signal becomes more convenient. It has been established that the oxidation and reduction of one of the coenzymes in many biological catalysts and in PQQ {sodium salt of 2,7,9-tricarboxy-1*H*-pyrrolo[2,3-*f*]quinoline-4,5-dione—a growth stimulator in a number of microorganisms} on

Table 2. Voltammetric determination of organic compounds in solution using chemically modified electrodes.

Compound determined	Material of electrode	Modifying agent	Method of measurement of signal	Concentration determined, M	Refs.
Ascorbic acid	Carbon glass, carbon paste	Aminophenols	Voltammetry	$10^{-5}-10^{-3}$	[15]
	Graphite	Polypyrrole		10^{-4}	[112]
Catecholamines	Platinum	Iodide ion	Differential-pulse technique	$8\cdot10^{-7}$	[113]
Amines	Carbon paste	Polyvinylpyridine, benzaldehyde-4-carboxylic acid	Square wave voltammetry	$3\cdot10^{-5}-10^{-2}$	[114]
Glutathione		Cobalt-phthalocyanine	HPLC	10^{-10}	[115]
Thiols	Ditto		Ditto	$2.7\cdot10^{-9}$	[115]
Ferredoxin	Gold	Di(4-pyridyl) disulphide	Voltammetry	$4\cdot10^{-4}-9\cdot10^{-5}$	[116]
Oxalic acid	Graphite	Ruthenium and iron complexes in a Nafion film	Voltammetry and chemiluminescence	$5\cdot10^{-2}$	[117]
Hypoxanthine	Carbon paste	Hydroxymethylferrocene + xanthine oxidase in a cellulose triacetate film	Voltammetry	$6\cdot10^{-7}$	[118]
	Graphite	Ferrocene, iron-phthalocyanine	Voltammetry	$1.5\cdot10^{-7}$	[115, 119]
Dopamine, norepinephrine		Stearic acid		$1.5\cdot10^{-7}$	[120]
Reserpine, rescinnamine	Carbon glass	Lipids	Inversion voltammetry	$5\cdot10^{-9}$	[121]
Hydrophobic organic compounds with multiple bonds	Platinum	Phosphatidylcholine	Voltammetry	$5\cdot10^{-9}$	[122]
Alcohols	Graphite	$Fe[(CN)_6]^{3-}$ in a polyvinylpyridine film	Flow-injection analysis	$2\cdot10^{-6}$	[123]
Phenols		Ditto	Cyclic voltammetry, flow system	$0.5\cdot10^{-6}$	[124]
Dopamine, ascorbic acid	Carbon glass	$Fe_4[Fe(CN)_6]_3$	Cyclic voltammetry	10^{-2}	[125]
	Platinum	Ferrocene		$10^{-4}-10^{-3}$	[126]
	Carbon glass	$IrCl_5^{2-}$ in a polyvinylpyridine film		10^{-3}	[127]
Cysteine		$Os(bipy)_3^{3+}$ in a Nafion film	HPLC	$2\cdot10^{-5}-10^{-3}$	[128]

platinum and gold electrodes are irreversible. However, if these electrodes are coated by a polypyrrole film, then cyclic voltammograms show reversible two-electron peaks.[129] If pyrrole is electropolymerised in the presence of PQQ, then the latter is incorporated in the polymer matrix, retaining its oxidation-reduction properties, i.e. it can play the role of a mediator. The latter factor leads to the possibility of preparing biosensors for the determination of sugars.

In the solution of the problems of monitoring (continuous analysis) on the real time scale of the on-line or in-line type, a notable place has been assigned to voltammetry and chemically modified electrodes. In many instances, the aim of the development of chemically modified electrodes was in fact to use them as amperometric transducers in a stream, for example, in flow-injection analysis (FLA) or in high performance liquid chromatography (HPLC). These problems have been partly discussed in other reviews.[11,85] A special review devoted to chemically modified electrodes for the detection of substances in a stream of liquid has been published.[130] In FIA and HPLC, modified electrodes make it possible to ensure high productivity of the determination and ultimately lead to the accumulation of a large amount of information.

Methods for the modification of electrodes designed to impart to them a specific response have begun to be used recently in the miniaturisation of systems for analytical monitoring. This aspect of research and development is regarded as promising because it is possible to obtain ultimately miniature electrodes which permit measurements *in vivo* in tissues or even in individual cells. For example, an ultramicroelectrode based on a carbon fibre modified with tetrakis(4-hydroxy-3-methoxyphenyl)porphyrin in a polymer film has been prepared.[131] It makes it possible to determine nickel in individual biological cells. The film itself, on the surface of the ultramicroelectrode, is formed on electrochemical oxidation of the modifying agent. The number of layers in this film at the tip of the carbon fibre (0.5–1 μm in diameter) reaches 10–90. The calibration plot is linear in the concentration range 5×10^{-5}–5×10^{-3} M. The detection limit is $\sim 10^{-6}$ M nickel(II).

The miniaturisation of chemically modified electrodes makes it possible to construct portable analysers working in an autonomous regime and ensuring the continuous monitoring of biologically active substances in many spheres of human activity.

However, one should note that the chemically modified electrode incorporated in the analyser system is a product of extremely laborious scientific research. Although this problem is in fact of current interest and the need for such sensors is continuously growing, nevertheless more time is required to obtain a device or the corresponding instrument with the required operating properties. Therefore the view that sensors represent the future of analytical chemistry is not without foundation.[85] Advances in related fields of science, particularly in microelectronics, have been attracting increasing attention by researchers in the field of chemically modified electrodes and sensors. The use of the so called planar technology, which is used to create integrated circuits, instead of the traditional three-dimensional technology, in the construction of sensors will probably make it possible to proceed to their mass scale production. The microstructure of the surfaces of electrodes chemically modified with the aid of a multilayer coating has to be monitored already at the molecular level.

The dynamic separation of substances by liquid–liquid extraction

N F Kizim
Novo-Moskovsk Branch, Mendeleev Moscow Institute of Chemical Technology

ABSTRACT. Experimental data on the separation of substances by extraction, based on differences in the rates of their extraction, have been given. The physicochemical principles of dynamic separation have been examined. Approaches to the mathematical modelling of the process have been described, and specific models have been analysed.

The bibliography contains 231 references.

I. Introduction

The method for separating substances based on differences in the rates of their liquid–liquid extraction has been known for a long time. As early as 1947, Barnes[1] showed that copper(II) and mercury(II) can be separated by extracting them with a chloroform solution of dithizone at low pH values. Mercury dithizonate was extracted rapidly, and the equilibrium state was reached in less than 1 min under the conditions of the experiments,[1] whereas the extraction of copper dithizonate took place slowly. Few such examples were known, however, and they were regarded as a possible way of improving the separation of substances in analytical determinations.[2]

In the last two decades, there has been a sharp increase in interest in the study of the kinetics of extraction. This has been due to the need to solve a number of theoretical problems, and also to an extension of the range of practical application of extraction methods. A large number of studies have been carried out, important reviews have been published,[3–9] and a new scientific field has developed, namely the kinetics of the extraction of inorganic substances. The kinetic studies have revealed many systems in which equilibrium is established slowly, and these can be used in practice. However, the separation of substances under non-equilibrium conditions, based on the use of kinetic factors (subsequently, the term "dynamic separation" will be used), has not been widely employed, for the following reasons.

Studies of separation by extraction have involved mainly the search for (synthesis of) effective extracting agents giving the required degree of separation as a result of differences in the thermodynamic parameters of the processes. In the list of factors influencing the separation (the nature of the extracting agent and the diluent, the composition of the aqueous solution, pH), the rate of extraction occupied one of the last places. In fact, there were definite grounds for this. The kinetic studies were at the stage of the development of the experimental procedure and the accumulation of data. For the most part, the kinetics of the extraction of individual substances were studied. Because of differences in the experimental conditions and the indeterminate nature of the hydrodynamic conditions close to the inter-phase boundary, the results of studies of the same extraction system were often inconsistent, and even contradictory. The situation was complicated considerably by the wide range of inter-phase phenomena (chemical reaction, adsorption, the formation of inter-phase films, spontaneous surface convection, electrical phenomena) in the extraction of inorganic substances, the non-uniformity of the inter-phase layer, and the consequent complexity of inter-phase mass exchange. Theoretical studies were based on extensive simplifications, and did not have sufficient predictive power.

At the same time, the determination of the factors leading to differences in rates of extraction and the discovery of criteria for identifying those systems for which the application of kinetic factors would lead to a significantly higher selectivity of separation require the systematic study of the kinetics of the simultaneous extraction of several components. However, the still unresolved fundamental problems of the kinetics of the extraction of individual elements, related mainly to the identification of the rate-determining stage and the location of the reaction, make it impossible for research workers to concentrate their attention on more complex systems. The study of the simultaneous extraction of several components is of considerable interest for a deep understanding of the mechanism of multicomponent liquid–liquid extraction and the general mechanism of the transfer of substances through the interface between two immiscible liquids. Moreover, the practical importance and the possibility of further improvement in the separation of substances is increasing interest in the dynamic separation method. The effective application of this method requires fundamentally new apparatus, but definite results can also be achieved using the equipment traditionally employed.[10–17]

The present review gives the results of experimental and theoretical studies of the dynamic separation of substances by liquid–liquid extraction.

II. Experimental data

1. Systems with dynamic separation

The separation of Cu^{II} from Hg^{II} by extraction with a chloroform solution of dithizone at low pH values, based on the difference in their rates of extraction, has been noted not only by the author cited above[1] but also by other workers.[18] The slow extraction of copper(II) dithizonate has been used in the determination of gold.[19]

Gold is extracted rapidly from 0.5 N H_2SO_4 by a chloroform solution of dithizone, whereas copper is extracted slowly and does not interfere in the determination of gold. The difference in the rates of extraction of zinc, cobalt, and nickel by dithizone solution has been made the basis of a method for their separation. In the extraction under the conditions of the experiments,[20] the extraction equilibrium is established in 15 min for zinc, 20 h for cobalt(II), and 10 d for nickel(II). The optimum conditions for separating the pairs Ni–Zn, Zn–Co, and Ni–Co have been determined.[20] It has been suggested that the high rate of extraction of vanadium(V) by β-isopropyltropolone solution could be used to separate vanadium(V) and iron(III).[21] The influence of kinetic factors on the selectivity of separation in the extraction of chelates has been examined by Freiser.[22]

The rate of extraction of Cu^{II} by Kelex 100, the active component of which is a β-alkenyl-8-quinolinol, is much greater than the rate of extraction of Fe^{III}, so that the selective extraction of Cu^{II} in the presence of Fe^{III} is possible.[23,24] For short phase contact times (less than 2 min) and an equilibrium pH of 0, the extraction of copper is not suppressed by iron. On prolonged mixing (up to 48 h), the ratio of the concentrations of copper(II) and $Fe^{(III)}$ in the organic phase at first increases from 20 to 80 (in 0.5–1 h), and then decreases to 18. Without stirring (after preliminary contact between the phases for 1 min), this ratio remains constant;[25] this is important when the extraction assembly is stopped unexpectedly.

In the range far from equilibrium, the rate of extraction of copper by Kelex 100 is 2.81×10^{-7} mol $cm^{-2} s^{-1}$, and that of iron(III) is 2.24×10^{-8} mol $cm^{-2} s^{-1}$. In the extraction from a nitrate solution (pH 2) by a 0.02 mol dm^{-3} solution of Kelex 100 in chloroform, 85% Cu^{II} is extracted after 2 min, whereas only 7% Fe^{III} is extracted.[26] On prolonged contact between the phases (48 h), Fe^{III} displaces Cu^{II} and the extract is saturated with Fe^{III} to the extent of 92%. The selectivity of the extraction of Cu^{II} is explained by kinetic factors.[26] This is indicated by the fact that for the maximum time of mixing, the degree of extraction of Fe^{III} in the absence of Cu^{II} is 98.9% and above, and the extent of the extraction of Cu^{II} in the absence of iron is 72.7%.

The results of an experimental study of the separation of copper from iron have been published.[27] A solution containing 1.3×10^{-2} mol dm^{-3} Cu^{II}, 1.6×10^{-2} mol dm^{-3} Fe^{III}, and 1 mol dm^{-3} Cl^- was shaken for 4 min with an organic phase consisting of a mixture of 2% Kelex 100 and 8% n-dodecanol in kerosene. The acidity was adjusted so that the final pH of the aqueous solution was 0.9; the separation factor was 30. Thus the system formed by Kelex 100 with the metal chlorides is similar to the corresponding sulphate system[23,25] in that the selectivity of the extraction of copper is also due to kinetic factors. Since $pH_{0.5}$ for Fe^{III} is lower than that for Cu^{II}, it might have been expected that Fe^{III} would be extracted more rapidly, but because of the large difference in the rates of extraction, Cu^{II} is extracted preferentially.[27] Determination of the equilibrium constants and rates of extraction showed that the introduction of the modifier nonylphenol into the organic phase leads to an increase in the distribution coefficient of Cu^{II}, but decreases the rate of extraction. The addition of Fe^{III} ions to the solution leads to an almost ten-fold further decrease in the rate of extraction of Cu^{II}, but has practically no influence on the rate of re-extraction of Cu^{II}. In all cases where Kelex 100 and Kelex 120 (20% Kelex 100 and 80% nonylphenol) are used, the rate of extraction of Cu^{II} remains 10^2 times higher,[28] and this ensures the separation of Cu^{II} and Fe^{III}. In the extraction by a solution of Kelex 100 in chloroform with a phase contact time of 0.5 h, the ratio of the concentrations of Cu^{II} and Fe^{III} in the organic phase was 38, whereas the value after stirring for 276 h was 0.5.[29]

The aminophenol extracting agents 7-(t-butylbenzyl)-8-quinolinol and a mixture of isomeric 7-β-decenyl-8-quinolinols are kinetically selective in the extraction of Cu^{II} from iron-containing solutions.[30] With short phase contact times (6–12 min), the selective extraction of Cu^{II} is possible. When equilibrium is reached, however, Fe^{III} is extracted more effectively than Cu^{II}, so that after prolonged contact between the phases, Fe^{III} begins to displace Cu^{II} from the organic phase.

In the extraction of copper, nickel, zinc, and cobalt(II) from ammoniacal solutions containing 300 g $litre^{-1}$ $(NH_4)_2SO_4$ by a 0.5 kmol m^{-3} solution of Kelex 100 and 10% isodecyl alcohol in Solvesso 150, the extraction and separation are influenced significantly by the phase contact time and temperature.[31] The ease of extraction of Cu^{II} at 323 K is higher than that at room temperature for short phase contact times, but with increase in the time of contact the extraction of Cu^{II} becomes less effective, and less Cu^{II} is extracted with increase in temperature. The extraction of Co^{II} increases regularly with increase in the phase contact time and temperature. The extraction of zinc(II) is higher at room temperature for short phase contact times, and with increase in the contact time, zinc(II) is displaced from the organic phase. Almost no nickel(II) is extracted. The optimum conditions for separating copper(II) and cobalt(II) are achieved for a phase contact time of 30 s at 323 K, or 2 min at room temperature. The separation of copper(II) and zinc(II) is improved by increasing the temperature and the phase contact time. Increase in the concentration of the extracting agent increases the efficiency of separation, but the degree of extraction is decreased. The authors cited[31] point out that the extraction of these elements depends on the nature of the anion and its concentration, the pH of the solution, the concentration of the extracting agent, temperature, and the phase contact time, so that the order of extraction may change: zinc(II) and cobalt(II) or zinc(II) and copper(II) may change positions.

In the extraction from the sulphate solution from the leaching of manganese nodules containing copper, nickel, cobalt(II), iron(III) and manganese(II) at pH 0–9 by a 10–15% Kelex 100 solution, the rate of extraction of copper(II) is greater than that of iron(III). The degree of extraction of iron(III) at pH 0.5–1.5 is greater than that of copper.[32] At pH 2, however, the degree of extraction of iron(III) is 80%, and that of copper(II) is 100%. With increase in the phase contact time and decrease in the ratio of the volumes of the organic and aqueous phases, there is a marked increase in the degree of extraction of copper(II) and an increase in the degree of extraction of iron(III). For a phase contact time of 2 min, the degree of extraction of copper is 93.2%, and the ratio of the concentrations of iron(III) and copper(II) in the organic phase is 0.142.[32] A study of the extraction of cobalt(II) and nickel(II) from sulphate solutions containing 0.25 kmol m^{-3} $(NH_4)_2SO_4$ at pH 4.72 by a 0.03–0.62 kmol m^{-3} solution of Kelex 100 in Shellsol containing added isodecyl alcohol established that at 298 K the rate of extraction of nickel(II) is very low, and equilibrium is not established even after mixing the phases for 120 min.[33] Increase in temperature leads to an increase in the rate of extraction. The addition of dinonylnaphthalenesulphonic acid (DNSA) has an even greater effect on the rate of extraction. For Ni^{2+} in the presence of 0.01 kmol m^{-3} DNSA, equilibrium is established in 1.5 h at 298 K, and in 20 min at 323 K. In all cases the rate of extraction of cobalt(II) is higher than that of nickel(II). At 323 K in the presence of 0.005 kmol m^{-3} DNSA, equilibrium in the extraction of cobalt(II) is achieved in

8 min. The data obtained can be used to improve the separation of Co^{II} and Ni^{II}.

Lix extracting agents are also kinetically selective. In the range far from equilibrium, the rate of the extraction of copper(II) from a nitrate solution with pH 2 by a solution of 0.02 kmol m^{-3} Lix 65N in chloroform is 4.42×10^{-9} mol $cm^{-2} s^{-1}$, and that of iron(III) is 3.01×10^{-11} mol $cm^{-2} s^{-1}$. In the extraction of copper(II) and iron(III), equilibrium is not established even after 6 weeks. The displacement of copper(II) from the organic phase by iron(III) is observed only after 140 h from the start of the experiment: this is much longer than in the extraction of these elements by a 0.02 kmol m^{-3} solution of Kelex 100 in chloroform.[26] When the solutions are mixed for a long time, the degree of extraction of iron(III) in the absence of copper reaches 53.7% and above, and the degree of extraction of copper(II) in the absence of iron(III) is 37.5%, indicating that the selectivity is due to kinetic factors.

In the extraction of copper(II) from a sulphate solution containing 5.13 g dm^{-3} copper(II) and 4.9 g dm^{-3} iron(III) (pH 2) by a 10% solution of Lix 63 in kerosene with the addition of 10% α-bromolauric acid and 3% isodecyl alcohol, a slight decrease in the extraction of copper(II) and a gradual increase in the extraction of iron(III) with increase in the phase contact time from 0 to 60 min is observed.[34] The decrease in the extraction of copper(II) is greater for a mixture containing 10% Lix 63 and 10% di-2-ethylhexyl hydrogen phosphate (D2EHHP) in kerosene with the addition of 3% isodecyl alcohol. The extraction of iron(III) increases sharply in the range 0–20 min, and for phase contact times greater than 45 min the degree of extraction of iron(III) becomes greater than that of copper(II).[34]

In the extraction of copper(II) from acid solutions containing iron(III) by a 20% solution of Lix 64N in the diluent Shell 140 with prolonged stirring (0–48 h), the ratio of the concentrations of copper(II) and iron(III) in the organic phase increases from 28 to 107.[25] Without mixing, this ratio remains constant.

For the extraction from the sulphate solution from the leaching of manganese nodules by a 10–15 vol.% solution of Lix 64N[32] it was established that the rate of extraction of copper(II) is greater than that of iron(III) throughout the pH range studied (0–9). At pH 2, the degree of extraction (E) of copper(II) is 75%, and that of iron(III) is 20%. A study of extraction from a solution modelling the leachings and containing 6 g dm^{-3} copper(II), 6 g dm^{-3} nickel(II), 0.15 g dm^{-3} cobalt(II), and 15 g dm^{-3} iron(III) for a phase contact time of 2 min showed that E_{Cu} is 52.1%, and the ratio of the concentrations of iron(III) and copper(II) in the organic phase is 0.007.[32]

It is also known that there is a difference in the rates of the extraction of non-ferrous metals and iron(III) by solutions of chelating extracting agents such as Hostarex DK-16 and SME-529. The extraction of iron(III) by DK-16 solutions takes place very slowly; the other metals are extracted rapidly, except nickel,[35] for which the rate of extraction by SME-529 is determined by the second stage of complex formation or by the diffusion of the complex being extracted.[36] Equilibrium is established in 30–35 min in the extraction of copper(II), and in 60 min in the extraction of iron.[37] Lix 63 is a kinetically synergetic additive to Lix 65N.[38,39]

A separation based on kinetic factors can be acheived in the extraction of zinc(II) and nickel(II) by solutions of dialkyl and diaryl hydrogen dithiophosphates.[40,41] Thus in the extraction by a 0.475 kmol m^{-3} solution of bis(di-isobutylmethyl) hydrogen dithiophosphate in Solvesso-150 containing 160 g dm^{-3} octanol, equilibrium is established in 1 h for zinc(II), and in 6 h for nickel.[40] In the extraction by 0.475 kmol m^{-3} solutions of di-n-butyl, di-isobutyl, di-n-octyl, di-(2-ethylhexyl), di-n-dodecyl, dicyclohexyl, and diphenyl hydrogen dithiophosphates in Solvesso-150 containing 160 g dm^{-3} octanol, equilibrium is established in 15 min for zinc(II), and in 120 min for nickel(II).[40] A study of the combined extraction of zinc(II) and nickel(II) by a 0.475 kmol m^{-3} solution of D2EHHDTP in the same mixed solvent at a ratio of the aqueous and organic phases of 1:1 established that the distribution of coefficient of Zn^{II} increases at first ($t \leqslant 2$ min), and then decreases, whereas the distribution coefficient of nickel(II) increases, indicating in the opinion of the authors cited,[41] the possibility of dynamic separation. For a phase contact time shorter than 2 min, the distribution coefficient (α) is greater than 6 for zinc(II), and less than 0.15 for nickel(II); when equilibrium is established, $\alpha_{Zn} = 0.68$, and $\alpha_{Ni} = 3.4$.

The difference in the rates of extraction of cobalt(II) and nickel(II) by dialkyl hydrogen dithiophosphates[42,43] can be used to increase the efficiency of their separation. Studies of the extraction of cobalt(II) and nickel(II) by solutions of di-(2-ethylhexyl) hydrogen dithiophsphate (D2EHHDTP) in n-decane showed that under equilibrium conditions the separation is not effective; the separation factor $\beta_{Ni/Co} < 2$. Since the extraction equilibrium is established in 10–45 h for cobalt(II) and in 0.5–2 h for nickel(II), it is possible to select conditions under which their effective separation is possible.[44,45] The extraction by a 0.3–0.5 kmol m^{-3} solution of D2EHHDTP in n-decane from a 1–2 kmol m^{-3} solution of $Co(NO_3)_2$ at a phase ratio of 1:1 with stirring for 0.5–2 h gave $\beta_{Ni/Co} = 150-200$. In these systems, the rate of extraction of Ni^{II} is much slower in acidic solutions, whereas the rate of extraction of Co^{II} remains high. By using kinetic factors under conditions close to equilibrium for Co^{II} and far from equilibrium for Ni^{II}, that is by using short phase contact times, it is possible to obtain high separation factors. In the extraction of Co^{II} and Ni^{II} from sulphate solutions by a 0.5 kmol m^{-3} solutions of D2EHHDTP in the presence of 1 kmol m^{-3} tri-n-butyl phosphate (TEP) for a definite phase contact time and a definite intensity of stirring, the separation factor reaches 20–100.[46] A method for separating Co^{II} and NI^{II} by extracting with a monoalkyl alkylphosphonate has been described.[47] The rate of transfer of Co^{II} into the organic phase is restricted by controlling the pH.

It is possible in principle to achieve higher separation factors ($\sim 10^4$) in systems containing D2EHHDTP.[48,49] The addition of oxygen-containing electron-donor additives (TBP, TOPO, etc.) to the system makes it possible to obtain a high efficiency of separation of cobalt and nickel at the re-extraction stage. With phase contact times restricted to several minutes it is possible to achieve effective separation with preferential re-extraction of cobalt.[50] After re-extraction for 2 min, cobalt is extracted to the extent of 99%, and nickel to the extent of less than 0.2%, corresponding to a separation factor of about 10^5. With long phase contact times, the separation factor decreases. Nickel can be re-extracted by an aqueous 9 kmol m^{-3} solution of HCl. With traces of cobalt at a high nickel concentration, partial separation at the extraction stage is appropriate.

A study of the re-extraction of cobalt(II) and nickel(II) from the extracts obtained in the system formed by D2EHHP and aqueous sulphuric acid solution using a single-stage centrifugal extractor[51] established the existence of a kinetic effect. Thus in the re-extraction from an organic phase containing 5.86 g dm^{-3} Co^{II} and 1.71 g dm^{-3} Ni^{II} (concentration of extracting agent in the original solution 0.58 kmol m^{-3}) with a 0.4 kmol m^{-3} aqueous H_2SO_4 solution at a

ratio of the volumes of the aqueous and organic phases of 1:1, the separation factor (β) decreases with increase in the phase contact time (t_c). At 294 K, β = 1.61 for t_c = 0.33s, β = 1.35 for t_c = 0.86 s, and β = 1.27 for t_c = 7.03 s.[51] A kinetic effect at the re-extraction stage is also possible for the pair copper–nickel,[52] cobalt, and nickel.[53]

The increase in selectivity for short phase contact times has been discussed[54] for the extraction of scandium(III), yttrium(III), and the lanthanides from a solution, after the extraction of uranium, containing up to 5 g dm^{-3} Fe_2O_3 as Fe^{2+} ions, using a solution of D2EHHP in kerosene. The extraction of iron(II), thorium(IV), and titanium(II) depends on t_c, but the extraction of scandium(III) and the lanthanides is almost independent of t_c in the range 2–30 s. For t_c = 2 s, non-intensive stirring (185 r.p.m.) in a turbine mixer gives more selective extraction of scandium(III), yttrium(III), and the lanthanides in the presence of iron(II), compared with their extraction in an ordinary mixer–settler for t_c = 30 s.[54]

A difference in the rates of extraction of iron(III) and uranium(VI) by D2EHHP solutions has been noted.[55] The low rate of extraction of Fe^{III} makes it possible to separate it from the lanthanides and yttrium by extraction with D2EHHP solutions in a centrifugal counter-current extractor. For t_c = 10 s and pH 2, yttrium is extracted from the clarified solution to the extent of more than 95% by a 10–12 vol.% solution of D2EHHP in Shell 140 kerosene. For this value of t_c, almost no Fe^{III} is extracted.[56] Increase in t_c leads to a sharp increase in the extraction of Fe^{III}, which suppresses the extraction of the lanthanides.[57] A concentrate of lanthanide oxides containing 30–60% Y can be obtained[58] by extracting with a 0.1 kmol m^{-3} solution of D2EHHP in kerosene at a ratio of the streams of the aqueous and organic phases of 4:1 with stirring for a short time, by varying the pH and the concentration of the extracting agent.

The significant difference in the rates of the extraction of indium and tin(IV) by alkyl hydrogen phosphates [in the extraction of tin(IV), equilibrium is established only after 60–70 min] led to the conclusion[59] that a considerable quantity of tin can be left in the aqueous phase by controlling the phase contact time. 4-t-Butylphenol-2-azo-1′-benzene-carboxylic acid and its mixture with 4-t-butylphenol-2-azo-1′-methoxybenzene are kinetically selective extracting agents for the extraction of copper(II) from iron-containing solutions. In the extraction of Cu^{II}, equilibrium is established in 10 min. The distribution coefficient of iron is higher than that of copper, so that the separation factor decreases with increase in the phase contact time.[60]

In their extraction by solutions of TBP in n-hydrocarbons, the behaviour of zirconium(IV) differs sharply from that of uranium(VI), for which a weak dependence of the rate of extraction on the TBP concentration was established. At low concentrations of TBP and nitrate ions, the separation of these elements under non-equilibrium conditions is much more effective than extraction under equilibrium conditions.[61]

A separation of the lanthanides has been based on the difference in the rates of extraction of these elements from concentrated solutions of salts of nitric and hydrochloric acids in the presence of an excess of acid by TBP containing a small quantity of di-n-butyl hydrogen phosphate.[62] The rate of extraction increases with increase in the atomic mass or atomic number of the element.

A difference in the rates of extraction of uranium(IV), uranium(VI), neptunium(IV), and plutonium(IV) was established[63] in their extraction by a 30% solution of TBP in hydrogenated tetrapropylene using a centrifugal extractor (phase contact time 0.4–2 s). At a high rate of rotation of the cylinder, complete extraction of uranium nitrates is achieved in 2 s. The rate of extraction of uranium(IV) is lower than that of uranium(VI), and only half the rate of extraction of neptunium(IV) and plutonium(IV).

A study[64] of the extraction of thiocyanate complexes of zinc and nickel from aqueous solution using droplet-dispersed n-butanol established that for short extraction times there is appreciable enrichment of the organic phase in zinc. Thus for t_c = 5 min the ratio of the concentrations of zinc(II) and nickel(II) in the organic phase is 6:1, although in the original aqueous solution the ratio of the concentrations was 1:1.

The differences in the rates of the extraction can be increased by adding complex-forming reagents to the system. Sakka and co-workers[65] studied the extraction of cobalt(II), nickel(II), copper(II), zinc(II), and cadmium(II) from their 2 × 10^{-4} kmol m^{-3} aqueous buffer solutions with an ionic strength of 0.1 kmol m^{-3} (KNO_3) and pH 1–9 by 0.02 kmol m^{-3} solutions of 5-(4-dodecylphenylazo)-8-quinolinol (HL) in chloroform in the presence and absence of complex-forming reagents. In the absence of complex-forming reagents, the extraction of Ni^{II} is slow, and equilibrium is not established even after 10 h. The order of extraction from equilibrium data, Ni→Co→Zn, is reversed when the rates of extraction are compared.

For weak water-soluble complex-forming reagents (polyacrylic acid and citric acid), the extraction curves are displaced slightly to higher pH values. In the stronger reaction when triethylenetetramine (TETA) is added, the value of $pH_{1/2}$ is displaced considerably to higher values, and the slope of the lg α = *f*(pH) relationship, where α is the distribution coefficient, differs considerably from 2, which is observed in the absence of complex formation.[65] In extraction by the "rapid mixing–rapid separation" method or in rate-controlled extraction, as can be seen from the published illustrations,[65] when polyacrylic acid ($\overline{m}$ = 2000) is present, zinc(II) is extracted preferentially, the extraction of cobalt is complex, and the extraction of nickel(II) decreases considerably (pH 4–8). When citric acid is added to the system, similar changes are observed, but the position of cobalt in the order of ease of extraction at pH 7–8.5 is rigorously defined. Its extraction under the conditions indicated (concentration of M^{n+} in the original aqueous solution 2 × 10^{-4} kmol m^{-3}, concentration of HL in the original organic phase 2 × 10^{-3} kmol m^{-3}) does not exceed 25%, whereas the extraction of zinc(II) reaches almost 100%, and that of nickel is close to zero.

The addition of a stronger complex-forming reagent (TETA) leads to a decrease in the rate-controlled extraction of zinc and cobalt, and practically no cobalt is extracted. At pH 8, nickel is extracted preferentially, the extraction of zinc is much lower, and practically no cobalt is extracted. Thus the correct combination of complex-forming reagent, concentration of extracting agent, and pH makes possible the effective separation of zinc, cobalt, and nickel on the basis of kinetic factors.[65]

An analysis of data on the kinetics of the extraction of the trans-plutonium elements (TPE) in systems containing D2EHHP in the presence and absence of complex-forming reagents[66] led to the conclusion that in the absence of a complex-forming reagent the TPE are extracted under diffusion conditions, and the rates of their extraction are approximately equal. The addition of a complex-forming reagent increases the contribution of chemical resistance and produces a difference in the rates of extraction. A Lewis diffusion cell was used to study the kinetics of the extraction of the TPE and various lanthanides by D2EHHP solutions from solutions containing a complex-forming reagent. It was shown for the extraction system

10^{-2} kmol m^{-3} EDTA – 1 kmol m^{-3} ($NaNO_3$, HNO_3) – H_2O – CCl_4 – 1 kmol m^{-3} D2EHHP that extensive purification of the macro-component from micro-impurities is possible. Terbium is extracted more readily than europium, so that the separation of macro-quantities of the former from micro-quantities of the latter is difficult in an equilibrium extraction system. The rate of extraction of europium is much higher than that of terbium, and is independent of the terbium concentration, so that dynamic separation may be effective. Under emulsion conditions, only 15% terbium is transferred to the organic phase in the extraction of 90% europium. The authors cited[66] consider that effective purification of terbium from europium is achieved.

To determine the separation conditions, a study was made of the extraction of a number of TPE (Am, Cm, Cf, Bk), and also La, Ce, Sm, Eu, Gd, Th, Pa, U, Pu, Zr, Nb, Cs, Ru, and Fe using a solution fo 4-(α,α-dioctylethyl)pyrocatechol (Q) in toluene from strongly alkaline solutions in the presence of diethylenetriaminepenta-acetic acid (DETAPA).[67] It was shown that the degree of separation of the elements can be increased by varying the phase mixing time, the alkalinity of the medium, and the concentration of the extracting agent. The degree of extraction of Eu^{III} in the system 10^{-4} kmol m^{-3} Eu^{3+}, 2 kmol m^{-3} NaOH, 5×10^{-3} kmol m^{-3} diethylenetriamine-penta-acetic acid – 0.04 kmol m^{-3} Q in toluene increases from 60% to 100% with increase in t_c from 10 min to 45 – 60 min.[68] The separation of europium from americium can be improved by decreasing t_c. Thus in their extraction from 2 kmol m^{-3} NaOH for a contact time of 10 min, the degree of extraction of europium into the organic phase is 98%, and that of americium only 48%. With increase in the europium concentration, the distribution coefficient decreases, but by varying t_c, the concentration of alkali in the original aqueous solution, and the concentration of the extracting agent it is possibe to find the optimum conditions for their separation.

For 2 kmol m^{-3} NaOH, 10^{-4} kmol m^{-3} DETAPA, 10^{-2} kmol m^{-3} extracting agent, and t_c = 10 min, the degree of extraction of europium into the organic phase is 97%, and that of americium only 10%.[68] Americium(III) is subsequently extracted into the organic phase by a 0.04 kmol m^{-3} solution of Q in toluene with a phase contact time of 45 min.

A decrease was observed[69] in the rate of the extraction of fragment lanthanides from radioactive wastes to which complex-forming reagents (tartrate or citrate ions) had previously been added, in the presence of the ions of various metals (Fe^{3+}, Al^{3+}, Cr^{3+}). The magnitude of the retardation effect is different for different lanthanides. In the presence of Fe^{3+} the extraction of europium(III) and neodymium(III) is suppressed to a greater extent than that of cerium(III), whereas the presence of chromium(III) has a greater influence on the extraction of cerium(III) than on that of europium(III). The undesirable influence of interfering ions is partly eliminated by increasing the concentration of the complex-forming reagent.

The rate of the extraction of the TPE from aqueous solutions containing citric acid by D2EHHP solution is much higher than the rates of extraction of aluminium, iron, and zirconium, and it should be possible to increase the efficiency of separation by carrying out the process under non-equilibrium conditions.[10] The experiments were carried out on a stand of gravitational extractors. The phase contact time was lowered to 1 min, which made it possible to suppress the extraction of impurities. The purification factors achieved were ~10 for the removal of iron and aluminium, and greater than 50 for the removal of zirconium. The losses of the TPE do not exceed 1%. The authors cited[10] pointed out that purification from the elements indicated is not achieved when the process is carried out under equilibrium conditions.

The separation of yttrium and the lanthanides in the D2EHHP – DETAPA system is based on the difference in the rates of extraction; the rate for yttrium is higher than that for the lanthanides.[70]

The degree of extraction of zirconium and niobium from mineral acid solutions containing oxalic acid by solutions of di-n-octyl-methylenediphosphoric acid in petroleum spirit depends on the concentration of the reagents, the acid, and the time of shaking. In their extraction from 0.5 kmol m^{-3} H_2SO_4 solution containing 0.1 kmol m^{-3} $H_2C_2O_4$ and less than 10^{-4} kmol m^{-3} zirconium and niobium, for a concentration of the extracting agent of 2×10^{-3} kmol m^{-3} and a time of shaking of 10 min, the degree of extraction into the organic phase is 95% for zirconium, and 4.9% for niobium.[71]

The separation of zinc and cadmium using dithizone and Complexone III is based on the difference in the rates of their extraction. Thus at pH 8, a ratio of the volumes of the aqueous and chloroform phases of 9:1, and a Complexone concentration of 0.01 kmol m^{-3}, cadmium is practically completely transferred to the aqueous phase in 35 s, whereas significant transfer of zinc is observed only after 90 s.[72] The influence of water-soluble complex-forming reagents on the rate of the extraction of zinc and nickel by a solution of dithizone in chloroform has been studied.[73]

2. Cases where the extraction equilibrium is established slowly

The study of the kinetics of extraction has revealed a whole series of extraction systems, characterised by a sufficiently low rate of attainment of extraction equilibrium, which can be used to develop dynamic separation processes or which must be taken into account in the construction of apparatus for the process.

In the extraction of chromium(III) by a 0.1 kmol m^{-3} solution of 8-quinolinol in isopentyl alcohol at 328 K with a low concentration of sodium acetate (0.3 kmol m^{-3}), equilibrium is not reached even after phase contact for 7 h.[74] The rate is equally slow for the extraction of germanium by 0.01 – 0.1 kmol m^{-3} solutions of 8-quinolinol in chloroform, benzene, nitrobenzene, or isobutyl alcohol from nitrate media with an ionic strength of 0.1 ($LiNO_3$, $NaNO_3$).[75] Nickel is extracted slightly more rapidly.[76] Slow attainment of equilibrium is observed in systems containing dithizone in the extraction of zinc, cobalt, copper,[1,18,19] and bismuth (the equilibrium state at pH 1.0 and a concentration of dithizone in chloroform of 10^{-4} kmol m^{-3} is established in 3 h).[2] The rate of extraction of selenium(IV) by a solution of dithizone in CCl_4 is low. In the extraction from 5 kmol m^{-3} HCl solution by 5×10^{-5} kmol m^{-3} dithizone solution, 98 – 99% selenium is extracted after stirring for 1 – 3 h.[77]

A study of the extraction of indium by 1-(2-pyridylazo)-2-naphthol (PAN) revealed a characteristic feature of the dependence of the degree of extraction on the phase contact time.[78] The form of the kinetic curves depended on the method used to introduce the reagent into the system. When a chloroform solution of PAN was used, the kinetic curves had the usual form, but several hours were required for maximum extraction. When an ethanol solution of the reagent was added to the aqueous phase followed by extraction of the resulting compound with chloroform, indium was extracted almost instantaneously, but with increase in the time of shaking the degree of extraction reached the same values as observed for chloroform solutions of PAN. True equilibrium is established very

slowly. The extraction of indium with the addition of the reagent to the aqueous phase and shaking for 1–3 min[79,80] is carried out under non-equilibrium conditions, although it gives the maximum possible extraction.

Similar relationships were obtained for the extraction of gallium, zinc, iron(III), and manganese(II), but in the extraction of nickel, curves with a maximum were not observed.[78] The extraction of copper by indium and zinc dithizonates, and the extraction of iron(III) by indium, copper, and gallium cupferronates, take place slowly.[76,81] Under conditions in which all the reagent is present in the organic phase as a complex with the macro-element, the rate of extraction of a micro-element is independent of the acidity of the aqueous phase. The rate of exchange extraction decreases with decrease in the concentration of the reagent and with increase in the concentration of the macro-component.[81]

The extraction of iron(III) by a 0.2 kmol m^{-3} solution of thenoyltrifluoroacetone (TTA) in benzene is slow, and equilibrium is established in 12 h.[82] The rate of extraction depends on the composition of the aqueous phase and the acidity.

In the extraction of samarium from nitric acid solutions by a solution of TTA in kerosene with the addition of TBP, carried out in an Erlenmeyer flask with subsequent separation of the phases by centrifuging, the time taken to establish the equilibrium state in all the cases studied[83] is 60 min.

The rate of equilibration in the extraction of gallium, iron(III), zinc, nickel, and manganese depends on the method used to introduce PAN.[78] When a solution of PAN in chloroform is used, equilibrium is established very slowly (in several hours). When PAN is added to the aqueous phase (solution in ethanol) with subsequent extraction of the complexes by the pure solvent, the complexes are transferred instantaneously to the extract, but with increase in the time of shaking the degree of extraction decreases until equilibrium is established. In the extraction of the complexes of zinc, nickel, and manganese(II) by butanol, isopentyl alcohol, and nitromethane, equilibrium is established very rapidly. According to Kuznik's data,[84] in the extraction of dysprosium(III) and ytterbium(III) by PAN, equilibrium is established in 20 min.

A study[85] of the extraction of gallium by bidentate chelating reagents from a solution modelling the liquor of the Bayer process, containing 0.75 g dm^{-3} Ga_2O_3, showed that gallium can be extracted with a distribution coefficient of ~ 1 for a phase contact time of 2 h only by 7-nonyl-8-quinolinol.

There are only a few cases of the slow extraction of metal ions by organic acids. Thus in the extraction of iron(II) from 10^{-3} kmol m^{-3} HCl solution by a 0.5 kmol m^{-3} solution of D2EHHP in kerosene in a nitrogen atmosphere, equilibrium is established in 100 min;[86] in the extraction of titanium from sulphate solutions by D2EHHP the time taken for equilibration is greater than 14 h;[87] equilibrium is also established slowly in the extraction of niobium from fluoride–sulphate media;[88] and in the extraction of tin by a 0.5 kmol m^{-3} solution of D2EHHP in heptane, equilibration requires more than 20 h.[89] Anomalously slow transfer through an impregnated membrane using D2EHHP as the transferring reagent has been detected.[90]

The distribution of europium in the two-phase system Eu^{III}–0.1 kmol m^{-3} $(Na,H)ClO_4$/D2EHHP–toluene is slow, and equilibration takes ~ 4 h.[91] In the extraction of europium from nitric acid solutions by D2EHHP in a diffusion cell with stirring, equilibrium is established in 7 h.[92] In the extraction of yttrium, europium, thulium, lutetium, and americium at an ionic strength of 1 (NaCl, HCl) by a 1 kmol m^{-3} solution of D2EHHP in n-heptane, the time taken for equilibration does not exceed 20 min.[93] The influence of the composition of the aqueous phase on the rate of the extraction of praseodymium(III) by 2-ethylhexyl 2-ethylhexylphosphonate has been noted.[94]

The time taken for equilibration in extraction depends on the method used to bring the phases into contact. Thus in the extraction of uranium from sulphate solutions by D2EHHP the time taken for equilibration is 10 mins in an annular flow reactor, and 1 min in a reactor with mechanical stirring.[95] The kinetic character of the extraction of molybdenum(VI) in the presence of tungstates by D2EHHP solutions has been noted. The extraction of Mo^{VI} from sulphate solutions under emulsion conditions is fairly rapid, and equilibrium is established in 1.5–2 min.[96] The presence of W^{VI} in the acidic solution decreases the rate of extraction of Mo^{VI} by D2EHHP solutions. Equilibration requires phase contact times from 10 min to 6–7 h, depending on the process conditions.[97] The very low rate of equilibration has been attributed[98] to the formation of mixed tungsten–molybdenum polyanions, leading to a sharp decrease in the free concentration of molybdenum(VI).

Cases of slow equilibration in systems with basic extracting agents are known. For example, in the extraction of polymolybdates and the products of their protonation from aqueous solutions with an initial molybdenum concentration of about 0.25 kmol m^{-3} by solutions of trioctylammonium (TOA) chloride in chloroform, the time taken for equilibration increases from 4 h to 24 h with decrease in the pH of the solution from 4 to 1.[99] In the extraction of molybdenum from aqueous solutions containing HNO_3 and $NaNO_3$ by solutions of tri-n-decylamine (TDA) in benzene, the distribution coefficient increases with increase from 5 min to 20 h in the time for which the phases are stirred.[100] The phase contact time influences the distribution coefficient in the extraction of molybdenum(VI) by TBP solutions.[101]

In the extraction of chromium(III) by a 20% solution of Primene JMT in xylene, equilibration requires a phase contact time of 1 h at 80 °C, or 20 d at room temperature.[102] Iron(III) is extracted more rapidly. In the $Fe_2(SO_4)_3$–$(NH_4)_2SO_4$–Primene JMT sulphate–toluene system, equilibrium is established in about 1 h, although some changes take place for 20 h.[103] As a consequence of the higher rate of extraction of iron(III) and the suppression of the extraction of chromium(III), Fe^{III} can be separated from Cr^{III}.[102] A complex dependence of the distribution coefficient (D) on t_c was established for the extraction of Rh^{III} and Pd^{II} by a solution of an alkylthiuronium chloride,[104] of Ir^{IV} by a solution of TBP and diantipyrinylmethane,[105] and of Sb^{III} and Sb^{V} by non-polar solvents.[106] For t_c greater than 1 h, a decrease in D is observed, and the extraction stops after 12 h.[104] Increase in t_c above the value required to establish equilibrium for Sb^{V} leads to an increase in D in the extraction from concentrated H_2SO_4 solution, as a result of the reduction of Sb^{V} to Sb^{III}.[106] The dependence of the extraction of yttrium and strontium by octanoic acid on t_c,[107] and that of the re-extraction of aluminium and iron from aliphatic acids,[108] on the magnitude of t_c have been studied. Hydrolysis and polymerisation of the ions in aqueous solutions have a significant influence on the extraction of Nb, Ta, and Zr. The plot of the degree of extraction against pH shows maxima which disappear with increase in t_c.[109] Systems characterised by a long equilibration time have been noted by a number of authors.[110–118]

III. Physicochemical principles of dynamic separation

In principle, any factor capable of bringing about a difference in the rates of extraction of substances may be responsible for dynamic separation. The factors bringing about dynamic separation can be divided into four groups: differences in mechanisms, differences in conditions, differences in transport and kinetic parameters, and external factors. The following factors lead to dynamic separation.

1. Differences in mechanisms

1.1. Type of reaction
homogeneous/heterogeneous
simple/complex (multistage homogeneous, multistage surface)
1.2. The existence of intermediate steps and stages (in particular surface association, polymerisation, the formation of inter-phase films)
1.3. Colloid-chemical phenomena and processes (micelle formation, solubilisation, etc.)
1.4. The addition of complex-forming reagents, oxidising agents, and surface-active agents to the system

2. Differences in conditions

2.1. Kinetic/diffusion
extraction with a surface reaction
extraction with a bulk reaction
2.2. Intermediate conditions with bulk reaction/diffusion condition
2.3. Intermediate conditions with bulk reaction/kinetic condition

3. Differences in transport and kinetic parameters

3.1. Diffusion mobility
3.2. Rate of chemical reaction
3.3. Adsorption–desorption processes
3.4. The accumulation of intermediate products in the inter-phase region, their aggregation, the formation of a new phase

4. External factors

4.1. The application of external fields
4.2. Change in the process conditions (for example the type of extractor, degree of dispersion, etc.)

The proposed classification of the factors is to some extent arbitrary, but it is sufficiently general. Additional details can be introduced. In particular, in the examination of processes with surface reactions it is possible to note the factors influencing the rate of the surface reaction: adsorption, orientational and steric hindrance, catalysis by the surface, and spatial separation of the charges, leading to the formation of strong electric fields in the region of the phase interface. The ability of charged inter-phase surfaces to accelerate or inhibit extraction has been noted.[5,119] In the examination of differences in mechanisms, when the extraction of one substance can be described by a scheme with a simple reaction, and that of the other by a scheme with a complex reaction, we also have in mind bulk reactions taking place in the aqueous phase and associated with the formation of an extractable form of the substance, for example the displacement of a hydrolytic equilibrium or a monomer–polymer equilibrium, including stable polynuclear compounds. A difference between the relaxation times of these reactions in the extraction of each substance may bring about dynamic separation, but in the proposed classification of factors it will be included in section 3.2. Section 1.4. includes so-called inter-phase transfer catalysts,[120] which are also capable of bringing about differences in the rates of extraction.

Theoretical estimates of the attainable separation effects have been carried out.[121–123] These effects may be considerable when there are differences in the mechanisms and conditions of the processes.

In publications giving the results of experimental studies of the kinetics of the simultaneous extraction of two or more components, insufficient attention is often paid to the description of the method and the apparatus. Unfortunately, this makes it difficult to identify the factors responsible for dynamic separation, and prevents an unambiguous solution of the inverse problem of dynamic separation. At the same time there are publications in which either the authors themselves interpret the factors responsible for dynamic separation or the systems dealt with have been sufficiently well studied from both the thermodynamic and the kinetic viewpoints, and in these cases it is possible to identify the factors responsible for the separation.

The difference between the rates of extraction of U^{VI} and Fe^{III} by D2EHHP[124] is due to a difference in the extraction conditions. At an H_2SO_4 concentration less than 1 M, U^{VI} is extracted under diffusion conditions,[125] and Fe^{III} under kinetic conditions.[126,127] In the opinion of Sato and co-workers,[127] the rate-determining stage includes the reaction of the hydroxo-complex $Fe(H_2O)_3(OH)^{2+}$ with D2EHHP dimers, but in the opinion of Karpacheva and Ilozheva,[126] the rate of extraction of Fe^{III} is limited by the reaction

$$Fe^{3+} + X^-_{(aq)} \rightleftarrows FeX^{2+},$$

which apparently takes place in the aqueous phase. The fairly high activation energy, which according to Sato[128] is 37.8 kJ mol^{-1}, confirms that Fe^{III} is extracted under kinetic conditions.

The separation of Zn^{II} and Co^{II} in their extraction by dithizone, based on kinetic factors,[129] is due to a difference in the mechanisms.[130] It is considered that the limiting stage for the reaction of both Zn^{II} and Co^{II} is the replacement of a water molecule in the inner coordination sphere of the ion by the anion of the extracting agent,[130,131] since its formation is accompanied by the rupture of four coordinate bonds with water molecules. It is suggested that for an aqueous solution with pH 4, the extraction of Zn^{II} is accompanied by a surface reaction,[130,132] and that of Co^{II} by a homogeneous reaction.[130] Other authors,[133,134] however, in a study of the kinetics of the extraction of Zn^{II} and Co^{II} by solutions of dithizone in chloroform with rapid mixing of the aqueous and organic phases, concluded that the rate-determining stage is the formation of the metal chelate in the aqueous phase, and not a surface reaction. The conclusions reached by the authors cited[132] from the results of a study of the kinetics of the extraction of Zn^{II} by the single-drop method do not agree with other conclusions.[134] This difference of opinion makes it impossible to reach an unambiguous conclusion about the mechanism of the dynamic separation of Zn^{II} and Co^{II}. If however it is assumed that in the extraction of both Co^{II} and Zn^{II} the rate-determining reaction takes place in the aqueous phase, it may be assumed that the separation is due to a difference in the rates of the removal of water molecules from the hydration layers of the metal ions. Freiser[135] gives Eigen's

data on the rate constants of the above reaction; the rate constant is 5×10^7 s^{-1} for Zn^{II}, and 5×10^5 s^{-1} for Co^{II}.

Fleming,[26] on the basis of a study of the kinetics of the extraction of iron and copper by Kelex 100 and 8-quinolinol,[24,25,27,136] considers that the selectivity is determined by kinetic factors and is due to the fact that the extraction of copper takes place under diffusion conditions, and that of iron(III) under kinetic conditions. It is known that 8-quinolinol forms much more stable (by factors of $\sim 10^{10}$) complexes with Fe^{3+} than with Cu^{2+}, and that alkyl-substituted 8-quinolinol – Kelex 100 extracts copper(II) more effectively than iron(III).[26] Other authors[23,24,28] reach the same conclusion about the nature of the selectivity. This view is confirmed by the decrease in the rate of the extraction of copper when nonylphenol is added to the organic phase. The decrease in the rate of extraction with increase in the concentration of nonylphenol takes place in parallel with an increase in the inter-phase tension, indicating the formation of hydrogen complexes by Kelex 100 and nonylphenol.[28] The rate of extraction of Cu^{II} remains 10^2 times greater than that of Fe^{III}. At the same time, other authors[137] consider that the rate of the extraction of Cu^{II} from sulphate solutions by Kelex 100 is determined by a surface reaction.

In a study of the difference in the rates of the extraction of Ni^{II}, Co^{II}, and Zn^{II} by HL solutions,[65] it was noted that the rates of extraction change in the same sequence as the rate constants for the replacement of water molecules from the hydration layers of the metal ions, and the difference in the rates of extraction was attributed to a difference in the rates of the chemical reactions, and not to a difference in the rates of "physical" distribution. According to other works,[138] the rate-determining stage is the addition of the second 8-quinolinol molecule. Thus the dynamic separation of Ni, Co, and Zn in their extraction by HL is due to the difference in the reaction rate constants.

The selectivity of the extraction of Cu^{II} compared with Fe^{III} by solutions of hydroxyoximes is attributed to kinetic factors.[26,29,139] If it is assumed, following Danesi and co-workers,[140] that the rate-determining stages in both the extraction of copper(II) and the extraction of Fe^{III} are reactions taking place on the phase interface,

$$Cu(H_2O)_{6-n}Cl_n^{(2-n)+} + Ox^- \rightarrow CuOx^+ + (6-n)H_2O + nCl^-,$$

$$Fe(OH)(H_2O)_{5-n}Cl_n^{(2-n)+} + HOx \rightarrow FeOx^{2+} + (6-n)H_2O + nCl^-,$$

$$Fe(H_2O)_{6-n}Cl_n^{(3-n)+} + HOx \rightarrow FeOx^{2+} + (6-n)H_2O + nCl^- + H^+,$$

it may be assumed that the separation is due to a difference in the rates of these reactions; a possible reason for this difference may be that the copper ions, as a consequence of their small radius, bring about the polarisation of the phenolic oxygen in the hydroxyoxime and facilitate the ionisation of a proton, whereas the Fe^{3+} ions, despite their smaller radius, cannot rapidly form a square-planar complex with hydroxyoximes.[141] A different view of the rate-determining stage in the extraction of copper(II) by Lix 34 has been put forward.[142]

The difference in the rates of extraction of the dithizonates has been used to separate Zn^{II}, Co^{II}, and Ni^{II}.[20] It has been established[130] that the separation of Zn^{II} and Co^{II} is due to a difference in the reaction mechanisms; at pH 4, Zn^{II} is extracted by a heterogeneous mechanism, and cobalt by a homogeneous mechanism. Thus more complete separation, based on the higher rate of extraction of zinc, requires more intensive stirring.[130] The localisation of the reaction is due to the increase in the reactivity of the dithizone ions adsorbed on the phase interface, as a result of the influence of adsorption forces.[130] Other authors[132] also consider that in the extraction of Zn^{II} by dithizone the reaction is localised at the inter-phase surface. In Freiser's opinion,[133,134] the rate-determining stage is the formation of 1:1 chelates in the aqueous phase, but in the case of cobalt(II) at concentrations greater than 8×10^{-5} M the process is limited by the chemical reaction at the phase boundary.[143] The rate constants for the formation of the chelates of zinc, cobalt, and nickel are closely related to the rate constants for the removal of water from the hydration layer of the metal ion.[135] Although the position of the reaction zone has not been finally determined, there is no doubt that the separation is due to kinetic factors, since the thermodynamic approach cannot explain the observed separation effects, even if only because the stability constants of the neutral dithizonate complexes of zinc(II) and cobalt(II) are practically identical.[144] Studies of the kinetics of extraction by halogenated dithizones led to the conclusion[145] that the rate-determining stage is the formation of the metal dithizonate (1:1), which takes place mainly on the surface in the extraction of Ni^{II} and in the bulk of the aqueous phase in the extraction of Zn^{II}.

The rates of the extraction of multivalent ions such as Zr^{IV}, Ru^{IV}, Al^{III}, Ga^{III}, Cr^{III}, and the platinum metals (Pt^{II}, Rh^{III}, Ir^{III}) are often low, so that the separation of these ions from others which are rapidly extracted has been verified under laboratory conditions. The slow extraction of the ions is due to hydrolysis and polymerisation in the aqueous phase and the low rate of formation of the extractable form. The low rate of equilibration in the extraction of molybdates by solutions of tri-n-octylamine in chloroform is due to the existence of polymeric ions, detected by osmometry and chemical analysis.[99] Noting that at low concentrations of TBP and HNO_3 the separation of zirconium and uranium is much more effective under non-equilibrium conditions than under equilibrium conditions, Mailen and co-workers[61] examined the chemistry of the extraction of Zr^{IV}. They assume that of the four complexes present, namely Zr^{4+}, $Zr(OH)^{3+}$, $Zr_3(OH)_4^{8+}$, and hydroxo-polymers, the species extracted are Zr^{4+} and $Zr(OH)^{3+}$, which are present in equilibrium with the other two forms. At $[HNO_3] \geqslant 3$ M, Zr^{4+} ions predominate in the solution, and the rate of extraction is proportional to $[TBP]^2$. At $[HNO_3] \leqslant 1$ M, $Zr(OH)^{3+}$ predominates, and the rate of extraction is proportional to $[NO_3^-]^3$. The behaviour of zirconium differs sharply from that of uranium, which is only weakly dependent on the TBP concentration and which is not influenced by $[NO_3^-]$. The presence in solution of chemical forms of ruthenium with different extraction properties is responsible for the two-stage character of its extraction by TBP — a rapid first stage (~ 0.6 s) and a slow second stage (> 1 h).[146]

The complexity of the ionic equilibria of Sn^{IV} in aqueous solution and the slow transformation of the complexes into the extractable form can be used to separate indium and tin(IV) by extraction using alkyl hydrogen phosphates. By controlling the phase contact time, a large quantity of tin(IV) can be left in the aqueous phase.[59]

The existence of the kinetic factor in the separation of Co^{II} and Ni^{II} in their re-extraction[51] can be attributed to the polymerisation of the Ni^{II} complex in the organic phase.[147] It is known,[148] however, that the view that polymers are formed is not consistent with experimental data on the kinetics of the combined extraction of Co^{II} and Ni^{II} by D2EHHP.

The separation of cobalt(II) and nickel(II) in their extraction by D2EHHDTP is due to a difference in the reaction mechanisms. The extraction of Co^{II} is determined by two factors — the rate of the reaction of Co^{II} with D2EHHDTP and the rate of its oxidation in

the organic phase by atmospheric oxygen. The kinetics of the extraction of Ni^{II} are determined only by the rate of its reaction with the DTP.[48] A study of the extraction of Ni^{II} by solutions of D2EHHDTP in decane showed that nickel is extracted as the diamagnetic complex $Ni[(C_8H_{17}O)_2P(S)S]_2$, which has a low-spin square-planar configuration,[44] whereas in the extraction of cobalt an equilibrium is established in the organic phase between the tetrahedral paramagnetic complex $Co[(C_8H_{17}O)_2P(S)S]_2$ and the diamagnetic low-spin complex $Co[(C_8H_{17}O)_2P(S)S]_3$ with a configuration close to octahedral. The stage of Co^{II} oxidation is relatively slow, and the extraction equilibrium is established in 10–45 h, depending on the conditions, whereas for nickel, equilibrium is established in 0.5–2 h.[44] This provides a basis for separating cobalt and nickel by the preferential extraction of nickel(II).

The addition of donor–acceptor reagents (TBP, TOPO) decreases considerably the rate of oxidation of cobalt. When the phase contact time is restricted, it is possible in principle to separate cobalt and nickel by the preferential extraction of cobalt(II).[46,48] The oxidation of cobalt(II), however, gives kinetically inert complexes,[149] making re-extraction difficult. Various donor–acceptor additives decrease the rate of this process.[50] If the phase contact time is restricted to a few minutes, separation is achieved by the preferential re-extraction of cobalt. The system containing TOPO is preferable to that containing TBP. Re-extraction for 2 min makes it possible to achieve separation factors of $\sim 10^5$.[50]

The separation of zinc and nickel in their extraction by dialkyl hydrogen dithiophosphates (DAHDTP), in particular D2EHHDTP, is due to the difference in the rates of dehydration of zinc and nickel ions.[40,41] Since the rate of extraction is influenced by the nature of the group in the DAHDTP,[150] this may facilitate the choice of separation conditions.

Rates of extraction can be differentiated by adding complex-forming reagents to the system.[65,66,151] The influence of complex-forming reagents is two-fold. On the one hand, complex formation leads to changes in the equilibrium parameters; for example, by adding citrate ion and keeping the solution for 24 h it is possible to suppress the extraction of chromium(III) by D2EHHP almost completely,[152] and in an acetate solution kept for up to 2 d the distribution coefficient of chromium(III) is lowered by a factor of ~ 200.[153] When very weak complex-forming reagents are used, the extraction curves of transition metals are displaced to high pH values, and the $\lg D = f(\mathrm{pH})$ relationship usually studied is linear with a slope differing little from 2, which is characteristic of extraction systems in the absence of complex formation. For a stronger reaction with the complex-forming reagent, the value of $pH_{1/2}$ is displaced considerably to high pH values, and in the case of the strong interaction which takes place, for example, in the Fe^{III}–citrate ion system, the extraction is completely suppressed.[65] Cases are known, however, where the addition of a complex-forming reagent has a levelling action. Increase in the time for which an aqueous solution containing Ni^{II} is kept leads to a three-fold decrease in the distribution coefficient of nickel. The presence of the citrate ion decreases the difference in the distribution coefficients to 1.5. Further increase in the concentration of citrate ions generally counterbalances the effect of keeping the solution beforehand.

On the other hand, the addition of complex-forming reagents influences the rate of extraction.[154] The addition of lactate ion leads to a decrease in the coefficient of mass transfer in the extraction of europium,[155] and produces a marked change in the rate of extraction of copper by SME-529.[156] The extraction of Eu^{III} and Am^{III} by solutions of (α,α-dioctylethyl)-pyrocatechol (Q) in the presence of diethylenetriaminepenta-acetic acid (DETAPA) takes place more slowly, the higher the stability of their complexes in the aqueous phase. Thus in their extraction from 2 kmol m^{-3} NaOH solution by a solution of 0.04 kmol m^{-3} Q in toluene, Eu^{III}, which forms a less stable complex with DETAPA, is extracted into the organic phase to the extent of 98% after 10 min, whereas the degree of extraction of Am^{III} is only 48%.

The transplutonium elements are extracted by D2EHHP under diffusion conditions, and their rates of extraction are identical. In the presence of a complex-forming reagent, the contribution of chemical resistance should be greater, and the rates of extraction will be different.[66] The addition of a complex-forming reagent leads to a change in the extraction conditions for Eu^{III}. With increase in the concentration of the complex-forming reagent, the extraction conditions change from diffusion to kinetic. The authors cited[66] consider that the rate of extraction is determined by the chemical reaction in the aqueous phase or in the inter-phase layer. The results show that to achieve the maximum difference in the rates of extraction of europium(III) and terbium, it is necessary to use the highest possible concentrations of the Complexone. The nature of the functional group of the Complexone has no significant influence, but when the complexes have high stability constants, the concentration of Complexone required to achieve a given effect is lower.[66] In the presence of a Complexone (EDTA), the rate of extraction of europium is much higher than that of terbium, giving effective dynamic separation; under emulsion conditions, only 15% terbium is transferred to the organic phase in the extraction of 90% Eu^{III}.[66]

The dynamic separation of nickel and zinc can be achieved using polyacrylate and citrate as complex-forming reagents.[65] In the extraction of the metal ions from aqueous solutions, the rate of the process is determined by the rate of the removal of water molecules from the hydrated ions. This mechanism does not change significantly in the presence of weak complex-forming reagents, since most of the ions remain hydrated in solution. Greater differences in the rates of the processes may be expected at the re-extraction stage. It appears possible to select catalysts for the decomposition of the complexes.[65] The decrease in the rate of extraction when a complex-forming reagent is added to a system may be due to the appearance of double complexes. For example,[69] in the presence of tartrate ion the addition of chromium(III) for a phase contact time of 3 min lowers the distribution coefficient of Eu^{III} from 1000 to 88 if the concentration of chromium(III) in the solution is 0.001 kmol m^{-3}. A decrease in the rate of the process when a mixture of extracting agents is used has been noted.[157]

IV. Mathematical models

A basis for the mathematical modelling of dynamic separation is provided by the general theory of inter-phase multi-component mass transfer accompanied by inter-phase phenomena. The variety of inter-phase phenomena (adsorption, chemical reaction, inter-phase film formation, spontaneous surface convection, micro-emulsification, association, dissociation, etc.) and the need to take account of the mutual influence of the components being extracted create insuperable mathematical difficulties in this approach, so that a rigorous quantitative calculation of the dynamic separation coefficient is not yet possible.

The simultaneous extraction of several components is complicated by their mutual influence.[158,159] Even in the case of the "physical" distribution of each component, it is necessary in the mathematical modelling of the process to take account of the interaction of the diffusion fluxes in each phase, since it follows from the thermodynamics of irreversible processes that the flux of each component depends on the gradients of the chemical potential of each component of the mixture. The methods described earlier[160–166] can be used. If one of the components is present in the system in microquantities and the other in macro-quantities, the analysis developed earlier[167,168] can be used. The development of this approach is being held up, however, by the absence of published data on diffusion cross coefficients in the organic phase and the extremely limited amount of such data for the aqueous phase. Moreover, allowance for the whole variety of inter-phase phenomena accompanying the extraction of inorganic substances[173–215] practically excludes the possibility of obtaining an analytical solution.

In most cases for specific mechanisms of the process the estimation of the expected value of the dynamic separation factor is carried out using mathematical models based on the assumption that the extraction processes of the separate components are independent, that is that the extraction of one component does not influence the extraction of the other. Naturally, it is assumed that the principle of independence applies at all stages of the extraction process, irrespective of the complexity of the macroscopic process. If it is assumed that the diffusion cross coefficients tend to zero with decrease in the concentrations of the components being extracted, better agreement can be expected between calculation and experiment for dilute solutions containing the extractable components in equal concentrations. With increase in the concentration of the components extracted, the errors in the estimates of the dynamic separation factor will increase not only as a result of the neglect of the mutual influence of the extraction processes but also as a result of the neglect of the non-ideal character of the system and the use of concentrations instead of activities. Nevertheless, this approach is useful for estimating possible values of the dynamic separation factor. When the loading of the organic phase is low, the separation factor can be calculated if the mutual influence of the ions is neglected.[216]

The possibility of a determinate description of the transport stages in non-stirred systems means that an exact analytical solution can be obtained for the flux of the component being extracted by the construction of a mathematical model of the dynamic separation process. For simplicity we shall assume that the phases are semi-infinite, that the diffusion coefficients are independent of the coordinate and of time, that the components being distributed are initially present in only one phase, and that rapid reversible reactions take place at the interface, complicating the processes involved in the distribution of each component. The system of equations with initial and boundary conditions is written in the form[121,122]

$$\frac{\partial C_{ij}}{\partial t} - D_{ij}\frac{\partial^2 C_{ij}}{\partial x^2} = 0, \quad j = \begin{cases} 1, \text{ if } x \in (-\infty, 0) \\ 2, \text{ if } x \in (0, \infty) \end{cases} \qquad (1)$$

for $x = 0$

$$D_{i1}\frac{dC_{i1}}{dx} - D_{i2}\frac{dC_{i2}}{dx} = 0,$$

$$\alpha_i = C_{i1}/C_{i2},$$

$$C_{i1}(x,0) = C_{i1}^0, \qquad C_{i2}(x,0) = 0,$$

where C_{ij}, $C_{ij}(x,0)$ are the current and initial concentrations of the ith component in the jth phase, D the diffusion coefficient, t the time, x the coordinate, and α the local distribution coefficient. The equation† for the flux of the ith component[217]

$$j_i = \frac{C_{i1}^0}{R_i}\left(\frac{D_{i1}}{\pi t}\right)^{1/2},$$

where $R_i = 1 + \alpha_i(D_{i1}/D_{i2})^{1/2}$, determines the quantity of the ith substance (M_i) transferred into phase 2 in a time t through a phase interface F if the integration is carried out in the range from 0 to t,

$$M_{i2} = \frac{2C_{i1}^0 F}{R_i}\left(\frac{D_{i1}t}{\pi}\right)^{1/2}.$$

Adopting for the dynamic separation factor the expression:[121]

$$\beta = \frac{M_{12}}{C_{11}^0} \Big/ \frac{M_{22}}{C_{21}^0},$$

gives

$$\beta = \left(\frac{D_{11}}{D_{21}}\right)^{1/2}\frac{R_2}{R_1}.$$

For a pair of elements with similar properties, the ratio R_2/R_1 can hardly differ greatly from 1, so that high values of β cannot be expected.

The separation of the extractable components may be greater if the extraction of one of the substances is accompanied by a reversible reaction of first order with rate constants k_1 for the forward reaction and k_2 for the back reaction, taking place in the donor phase, while the extraction of the other takes place by a "physical" distribution mechanism. The mathematical formulation of the problem is then altered considerably. The equation for the diffusion of the substance A in the donor phase will be replaced by the equation for diffusion with chemical reaction

$$D_{11}C''_{11xx}(x,t) - \dot{C}_{11t}(x,t) - k_1 C_{11}(x,t) + k_2 C_{21}(x,t) = 0,$$

† It should be noted that the equation for the flux of a substance leads to a situation which cannot be realised physically when $j \to \infty$ as $t \to 0$. This is due on the one hand to the restricted character of the application of the equation of Fick's second law to the description of molecular diffusion when there are large concentration gradients, and on the other hand to the use of the boundary condition $\alpha_i = C_{i1}/C_{i2}$, which reflects an unchanged ratio of the pre-boundary concentrations. As a result, the equation is inapplicable at $t = 0$. If the non-stationary diffusion is described using the hyperbolic equation

$$\frac{\partial C}{\partial t} + \tau\frac{\partial^2 C}{\partial t^2} - D\frac{\partial^2 C}{\partial x^2} = 0,$$

where τ is the relaxation time of the diffusion flux, the divergence of the flux as $t \to 0$ is eliminated. The attainable accuracy of the calculation has been discussed briefly.[5] The unique role of the boundary conditions in the analysis of the kinetics of diffusion-controlled processes has been examined in detail in monographs[169,170] and articles.[171,172]

where C''_{11xx} is the second partial derivative with respect to the coordinate, and C_{11t} the partial derivative with respect to time, and an analogous equation taking account of the diffusion of the reaction product in the donor phase is added. The boundary condition should take account of the fact that there is no accumulation of the reaction product in the inter-phase region.

The time dependence of the dynamic separation factor (β_t) is described by expressions determined by the values of the parameter a_0

$$a_0 = \frac{r_1}{\alpha_1} + \left(1 + \frac{r_1}{\alpha_1}\right) K_c,$$

where D_{11}, D_{21} are the diffusion coefficients of the original substance and the reaction product in the donor phase, α_1 the distribution coefficient of the reaction product at the phase interface, and K_c the equilibrium constant of the chemical reaction:

a, for $a_0 < 1$

$$\beta_t = a_{11} / F_1(t),$$
$$F_1(t) = 1 + a_{12} F_{11}(t) - F_{12}(t),$$
$$F_{11}(t) = \left\{\mathrm{erf}\left[(k_{12} + b_0)t\right]^{1/2} - \mathrm{erf}\left(b_0 t\right)^{1/2}\right\} \exp(b_0 t),$$
$$F_{12}(t) = \left[\sqrt{\pi}\, \mathrm{erfz}(t)\right] / 2a_0 z(t),$$
$$a_{11} = a_2 r_{31} \Big/ \left(1 + \frac{r_2}{\alpha_2}\right), \quad a_{12} = \frac{\sqrt{\pi}}{2} \frac{\left(1 - a_0^2\right)^{1/2}}{a_0},$$
$$a_2 = 1 + \frac{r_1}{\alpha_1} \frac{1 + K_c}{K_c}, \quad b_0 = a_0^2 k_{12} / \left(1 - a_0^2\right),$$
$$k_{12} = k_1 + k_2, \quad K_c = k_1 / k_2, \quad r_1^2 = D_{11} / D_{21},$$
$$r_2^2 = D_{31} / D_{32}, \quad r_{31}^2 = D_{31} / D_{11}, \quad z(t) = \sqrt{k_{12} t},$$

where erf ξ is the probability integral;

b, for $a_0 > 1$

$$\beta_t = a_{11} / F_2(t),$$
$$F_2(t) = 1 + a_{13} F_{21}(t) - F_{12}(t),$$
$$F_{21}(t) = \left[I_1(t) - I_2(t)\right] \exp(-bt) / z(t),$$
$$I_i(t) = \int_0^{\pi_i^2(t)} e^{\lambda^2} d\lambda, \quad \pi_1^2(t) = (b - k_{12})t, \quad \pi_2^2(t) = bt,$$
$$a_{13} = \left(k_{12} / b\right)^{1/2}, \quad b = a_0^2 k_{12} / \left(a_0^2 - 1\right);$$

c, for $a_0 = 1$

$$\beta_t = \frac{K_c r_{31}}{1 + r_2 / \alpha_2} \Big/ \left[1 - F_{12}(t)\right].$$

From the last expression it follows that for short phase contact times, β_t increases with decrease in the time and is given approximately by the expression

$$\beta_t \approx r_{31} F_3(t) \Big/ \left[k_1 \left(1 + \frac{r_2}{\alpha_2}\right) t\right],$$

where

$$F_3(t) = \left[\frac{2}{3} - \frac{1}{5} k_{12} t + \frac{1}{21} (k_{12} t)^2\right]^{-1}.$$

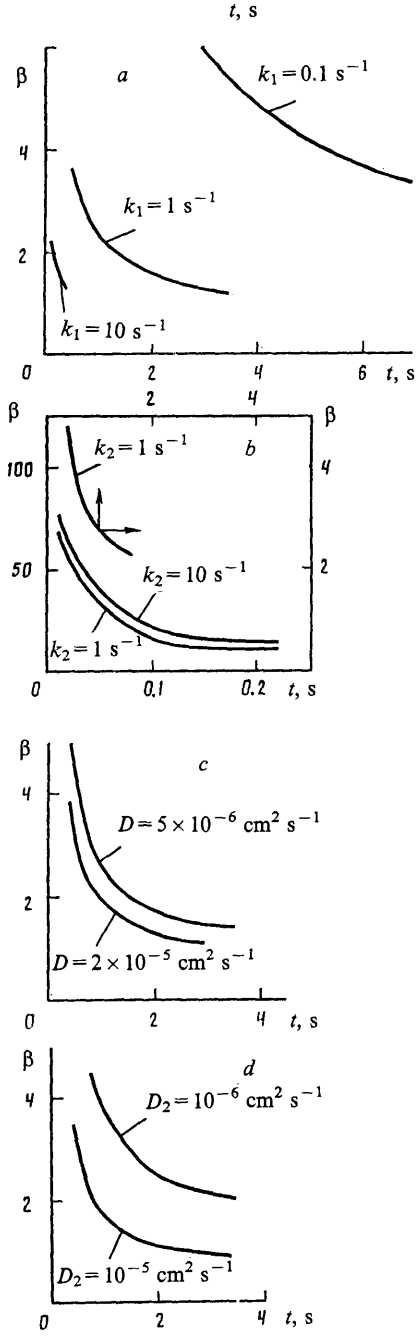

Figure 1. Influence of the rate constants of the forward (*a*) and back (*b*) reactions and the diffusion coefficients of the original substance in the donor phase (*c*) and of the extracted substance in the acceptor phase (*d*) on the time dependence of the dynamic separation factor.

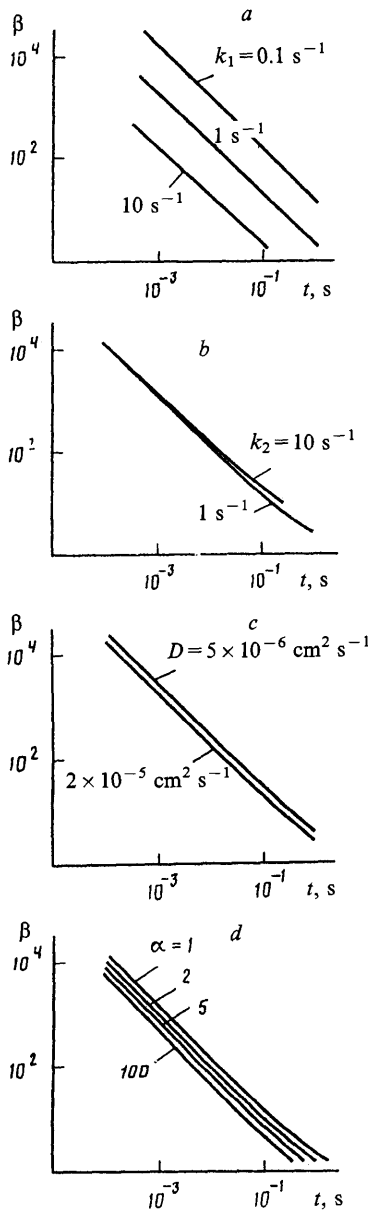

Figure 2. Influence of the rate constants of the forward (*a*) and back (*b*) reactions, the diffusion coefficient of the original substance in the donor phase (*c*), and the distribution coefficient of the reaction product at the phase inter-phase (*d*) on the time dependence of the dynamic separation factor for a short phase contact time; the numbers on the curves give the values of the parameters.

With increase in the time, β_t decreases, and for high values of the time, when $k_{12}t > 25$, the expression for β_t becomes

$$\beta_t = K_c r_{31} \Big/ \left[\left(1 - \frac{\sqrt{\pi}}{2} \frac{1}{z(t)} \right) \left(1 + \frac{r_2}{\alpha_2} \right) \right].$$

It is obvious that as $k_{12}t \to \infty$, β_t tends to a limiting value equal to $K_c r_{31}/(1 + r_2/\alpha_2)$. Restricting the examination to the simplest case ($a_0 = 1$), we note that the range of possible values of β_t is extremely wide. The influence of various parameters on the time dependence of β_t is shown in Figs. 1 and 2. For a slow homogeneous reaction taking place in the donor phase ($k_1 \leqslant 0.1\ s^{-1}$), appreciable dynamic separation factors can be achieved with relatively long phase contact times (~ 10 s).

If the extraction of one of the substances is accompanied in the acceptor phase by a first or pseudo-first order reaction with rate constants of the forward and back reactions k_1 and k_2 respectively, and the extraction of the other takes place under diffusion conditions, the system of equations describing this process has a similar form and an analytical solution is possible.

The expression for β_t depends on the value of the parameter $\bar{a}_0$

$$\bar{a}_0 = K_c/[1 + \alpha_1 r_1 (+ K_c)],$$

where K_c is the chemical equilibrium constant ($K_c = k_1/k_2$):

a, for $\bar{a}_0 < 1$

$$\beta_t = a_1 / F_5(t),$$

$$a_1 = (1 + R_{11}) r_{31} \Big/ \left(1 + \frac{1}{\alpha_2 r_2} \right),$$

$$F_5(t) = 1 + \frac{a_2}{\sqrt{1 - \bar{a}_0^2}} F_{51}(t) - F_{52}(t),$$

$$F_{51}(t) = \exp(-bt) \left[\Phi\sqrt{bt} - \Phi\left(\sqrt{(b - k_{12})t} \right) \right],$$

$$F_{52}(t) = a_3 \operatorname{erf}\left(\sqrt{k_{12}t} \right), \quad a_2 = \bar{a}_0 a_3, \quad a_3 = \frac{\sqrt{\pi}}{2} \frac{\bar{a}_0}{\sqrt{k_{12}t}},$$

$$b = k_{12} / \left(1 - \bar{a}_0^2 \right), \quad k_{12} = k_1 + k_2, \quad r_1^2 = D_{12} / D_{11},$$

$$r_2^2 = D_{32} / D_{31}, \quad r_{31}^2 = D_{31} / D_{11}, \quad R_{11} = \frac{1}{\alpha_1 r_1 (1 + K_c)},$$

$\Phi(\xi)$ is the Kramp function;

b, for $\bar{a}_0 > 1$

$$\beta_t = a_1 / F_6(t),$$

$$F_6(t) = 1 + \frac{a_2}{\sqrt{\bar{a}_0^2 - 1}} F_{61}(t) - F_{52}(t),$$

$$F_{61}(t) = \exp(b_0 t) \left[\operatorname{erf}\left(\sqrt{(k_{12} + b_0)t} \right) - \operatorname{erf}\left(\sqrt{b_0 t} \right) \right];$$

c, for $\bar{a}_0 = 1$

$$\beta_t = a_1 / F_7(t),$$

$$F_7(t) = 1 + \frac{1}{2k_{12}t} \left(1 - e^{-k_{12}t} \right) - F_{52}(t).$$

In particular, it can be seen from the last expression that for low values of t ($k_{12}t \ll 1$)

$$\beta_t \approx a_1 \Big/ \left(\frac{1}{2} + \frac{1}{3} k_{12} t \right).$$

Thus as $t \to 0$, β_t increases and tends to a limiting value $2a_1$. With increase in $k_{12}t$, the value of β_t decreases, and when $k_{12}t \gg 1$ the time dependence of β_t can be approximated by the expression

$$\beta_t \approx a_1 \Big/ \left(1 + \frac{1}{2k_{12}t} - \frac{\sqrt{\pi}}{2}\frac{1}{\sqrt{k_{12}t}}\right).$$

From this it can be seen that with further increase in $k_{12}t$ the second term in brackets can be neglected, so that

$$\beta_t \approx a_1 \Big/ \left(1 - \frac{\sqrt{\pi}}{2}\frac{1}{\sqrt{k_{12}t}}\right).$$

Finally, as $k_{12}t \to \infty$, β_t reaches its lower limiting value a_1.

It can be shown that in cases a and b also, the lower limiting value of β_t, reached as $k_{12}t \to \infty$ and $bt \to \infty$, will also be a_1. Other values of β_t are also possible, however. For example, if $k_c \gg 1$, then $\alpha_1 r_1 < 1$, and the limiting value for β_t is $r_{31}/(1 + 1/\alpha_2 r_2)$, that is $\beta_{t\to\infty}$ is greater, the greater the difference in the diffusion coefficients of the substances in the donor phase and the lower the distribution coefficient of the second substance. By continuing the analysis of the expressions given for β_t, it is possible to establish other particular cases observed for definite ratios of the parameters α_1, r_1, K_c, and t.

The two models of dynamic separation examined above are united by the fact that one of the stages in the extraction of the substance is a homogeneous chemical reaction. This approach, based on the homogenous formation of the complex extracted, is widely used in the description of the kinetics of extraction processes.[5] At the same time, any workers (as indicated, in particular, by discussions of the location of the reaction in the extraction of zinc by dithizone and its derivatives, of various metals by organophosphorus acids, and of copper by extracting agents of the Kelex type) conclude that the chemical reaction involved in the formation of the complex extracted is heterogeneous‡.

In an examination of models of dynamic separation with surface reactions,[122] six models of this type were analysed in considerable detail. A characteristic feature of the mathematical formulation of problems with a surface reaction is that the reaction rate is included in the boundary condition, and not in the equation describing the diffusion from sources and sinks, as has been the case for homogeneous reactions of formation of the complex extracted.

In the mathematical modelling, the accumulation of a substance at the phase interface, leading to the formation of self-generating inter-phase films, can be taken into account formally by the introduction into the boundary condition of an additional term determined by the difference in the fluxes of the substance to the phase interface and from the interface into the depth of the phase. The quantity of substance containing the element being extracted in the acceptor phase can be calculated from the equation

$$m_2(t)/C_2^0 = A_1\sqrt{t} + A_2\left[\exp(\varphi^2 t)\operatorname{erfc}(\varphi\sqrt{t}) - 1\right] - A_3\exp(-k_2 t)\int_0^t \exp(\alpha\tau)\operatorname{erfc}(\varphi\sqrt{\tau})\,d\tau,$$

where A_1, A_2, A_3, α are constants, $\alpha = \varphi^2 + k_2$; $\varphi = k_1\sqrt{D_1}$; k_1 and k_2 are the rate constants for the accumulation of the substance in the inter-phase region and its consumption respectively.

‡ In publications on the kinetics of extraction it is often described as a surface reaction.

Analysis shows that the accumulation of a substance is extremal in character (Fig. 3*a*), in qualitative agreement with experimental data.[212,214] If in the extraction of two elements, one of them can accumulate in the inter-phase region while the extraction of the other takes place by a "physical" distribution mechanism under diffusion conditions, the separation brought about this this difference may be considerable, particularly for short phase contact times (Fig. 3*b*). As expected, the value of β is influenced mainly by the rate constant k_2.

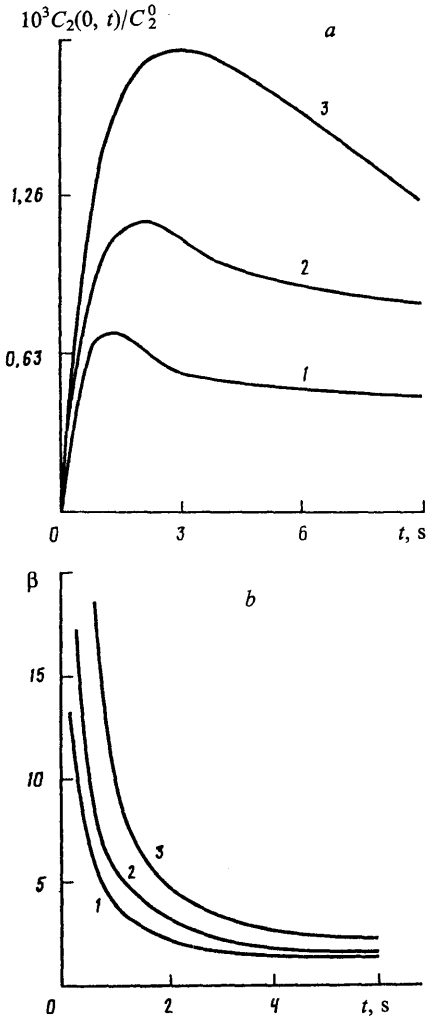

Figure 3. Kinetics of the accumulation of the intermediate product (*a*) and the time dependence of the dynamic separation factor (*b*); calculated for $k_1 = 3.16 \times 10^{-3}$ cm s^{-1}, $D_1 = 10^{-5}$ cm^2 s^{-1}, k_2, s^{-1}: *1*, 2; *2*, 1; *3*, 0.5.

All the above models were based on the distribution of the substance in a system consisting of two semi-finite phases. These models can be used either for comparatively short times, if the phases in contact are finite, or for any values of the time, if the

extent of the phases in the direction of the diffusion flux is considerable.

If the liquid films in contact are sufficiently thin, so that the diffusion front reaches the back boundary in the time of the experiment, it is necessary to include in the mathematical formulation the additional conditions at these boundaries (l_1 and l_2). We can consider, for example, the distribution of two substances (indices 1 and 2) with the assumption that the transfer of the first substance is accompanied by a rapid reversible surface reaction, and that of the second by a fairly slow surface reaction with rate constants k_1 and k_2 for the forward and back reactions respectively. The rate of the surface reaction is taken into account by introducing the additional boundary condition

$$D_{21}C'_{21x}(0,t) - k_1C_{21}(0,t) + k_2C_{22}(0,t) = 0.$$

The conditions for the back boundaries of the phases are written as

$$D_{i1}C'_{i1x}(l_1,t) = 0; \quad -D_{i2}C'_{i2x}(l_2,t) = 0; \quad i = 1;2.$$

It is convenient to express the dynamic separation factor as follows:

$$\bar{\beta}_{12}(t) = \frac{\langle C_{12}(t)\rangle}{\langle C_{11}(t)\rangle} \Big/ \frac{\langle C_{22}(t)\rangle}{\langle C_{21}(t)\rangle},$$

where $< C_{ij}(t) >$ represents the averaged concentrations of the ith component in the jth phase

$$\langle C_{ij}(t)\rangle = \frac{1}{l_j}\int_0^{l_j} C_{ij}(x,t)dx.$$

The expression for the averaged concentrations can be written as the series

$$\langle C_{11}(t)\rangle = \frac{C_{11}^0}{1+K_1l_0} - \sum_{n=1}^{\infty} \frac{C_{11}^0F_4(\mu_n)}{\mu_nF_2(\mu_n)}\exp\left(-\frac{D_{11}}{l_1^2}\mu_n^2t\right),$$

$$\langle C_{12}(t)\rangle = \frac{C_{11}^0}{l_0+K_1^{-1}} + \sum_{n=1}^{\infty}\frac{2C_{11}^0K_1\sin(\mu_n)\sin(\mu_nl_0r)}{\mu_nl_0F_2(\mu_n)}\exp\left[-\frac{D_{12}}{l_2^2}(rl_0\mu_n)^2t\right],$$

$$\langle C_{21}(t)\rangle = \frac{C_{21}^0 + C_{22}^0l_0}{1+K_cl_0} + \sum_{n=1}^{\infty}\frac{a_0\sin(\bar{\mu}_n)\sin(\bar{\mu}_nl_0\bar{r})}{\bar{\mu}_nF_6(\bar{\mu}_n)}\exp\left(-\frac{D_{21}}{l_1^2}\bar{\mu}_n^2t\right),$$

$$\langle C_{22}(t)\rangle = \frac{K_c\left(C_{21}^0 + C_{22}^0l_0\right)}{1+K_cl_0} + \sum_{n=1}^{\infty}\frac{(-a_0)\sin(\bar{\mu}_n)\sin(\bar{\mu}_nl_0\bar{r})}{\bar{\mu}_nl_0F_6(\bar{\mu}_n)}\exp\left[-\frac{D_{22}}{l_2^2}(\bar{\mu}_n\bar{r}l_0)^2t\right],$$

where

$$F_2(\mu_n) = \mu_n\left[(1+K_1l_0)r\cos(\mu_n)\cos(\mu_nl_0r) - \left(K_1 + r^2l_0\right)\sin\mu_n\sin(\mu_nl_0r)\right],$$

$$F_4(\mu_n) = 2K_1\sin\mu_n\cdot\sin(\mu_nl_0r),$$

$$F_6(\bar{\mu}_n) = \frac{1}{2}\bar{\mu}_n\left(\frac{3D_{21}}{l_1} + k_1 + k_2\bar{r}^2l_0\right)\sin\bar{\mu}_n\cdot\sin(\bar{\mu}_n\bar{r}l_0) +$$

$$+\left(\frac{1}{2}\frac{D_{21}}{l_1}\bar{\mu}_n^2 - k_1\right)\cos\bar{\mu}_n\cdot\cos(\bar{\mu}_n\bar{r}l_0) +$$

$$+\bar{r}\left(\frac{1}{2}\frac{D_{21}}{l_1}l_0\bar{\mu}_n^2 - k_2\right)\sin\bar{\mu}_n\cdot\cos(\bar{\mu}_nl_0\bar{r}) -$$

$$-\frac{1}{2}\bar{r}\bar{\mu}_n(k_1l_0 + k_2)\cos\bar{\mu}_n\cdot\cos(\bar{\mu}_nl_0\bar{r}),$$

$$a_0 = k_1C_{21}^0 - k_2C_{22}^0, \quad l_0 = l_2/l_1,$$

$$r^2 = D_{11}/D_{12}, \quad \bar{r}^2 = D_{21}/D_{22}, \quad K_c = k_1/k_2,$$

μ_n are the roots of the equation

$$(K_1/r)\mathrm{tg}\mu rl_0 + \mathrm{tg}\mu = 0,$$

$\bar{\mu}_n$ are the roots of the transcendental equation

$$\sin\bar{\mu}\left(\bar{\mu}\frac{D_{21}}{k_1l_1}\sin\bar{\mu}l_0\bar{r} - \frac{k_2\bar{r}}{k_1}\cos\bar{\mu}l_0\bar{r}\right) - \cos\bar{\mu}\sin(\bar{\mu}\bar{r}l_0) = 0.$$

In some particular cases it is convenient to represent the solution in a different form (for example, using an additional probability integral). Analysis of the given expressions made it possible to distinguish the principal factors influencing $\bar{\beta}_t$. Fig. 4 gives the calculated relationships $\bar{\beta}_t = f(t)$ for the most probable values of the parameters. A noteworthy feature is the complex character of the relationships (curves *6*, *11*) which are realised for definite ratios between the parameters and which are due to the difference in the relaxation times of the diffusion and chemical processes.

A knowledge of the thermodynamic and kinetic parameters of an extraction process (obtained, for example, using the reference literature[218–223] and reviews[3–5]) makes it possible to estimate the possible value of a dynamic separation coefficient without resorting to experiments on the combined extraction of the components.

A formal-kinetic approach was used by Danesi and Chiarizia[224] in an estimation of the dynamic separation factor of Cu^{II} and Fe^{III} in their extraction by a hydroxyoxime. It was based on the kinetic equations describing the extraction of these substances

$$-\frac{d[\mathrm{Cu}]}{dt} = a_ik^*_{1\mathrm{Cu}}\left[\mathrm{Cu}^{2+}\right] - k^*_{-1\mathrm{Cu}}\left[\overline{\mathrm{CuOx}_2}\right],$$

$$-\frac{d[\mathrm{Fe}]}{dt} = a_ik^*_{1\mathrm{Fe}}\left[\mathrm{Fe}^{3+}\right] - k^*_{-1\mathrm{Fe}}\left[\overline{\mathrm{FeOx}_3}\right].$$

The authors cited took as the kinetic parameter of the separation (S_t) the following ratio

$$S_t = \frac{[\overline{\mathrm{Cu}}]_t}{[\overline{\mathrm{Fe}}]_t} \Big/ \frac{[\mathrm{Cu}]_0}{[\mathrm{Fe}]_0},$$

which after integration of the kinetic equations[224] was brought to the form

$$S_t = \left\{1 - \frac{k^*_{-1Cu} + k^*_{1Cu}\exp\left[-\left(k^*_{1Cu} + k^*_{-1Cu}\right)a_i t\right]}{k^*_{1Cu} + k^*_{-1Cu}}\right\} \times$$

$$\times \left\{1 - \frac{k^*_{-1Fe} + k^*_{1Fe}\exp\left[-\left(k^*_{1Fe} + k^*_{-1Fe}\right)a_i t\right]}{k^*_{1Fe} + k^*_{-1Fe}}\right\}^{-1}. \quad (2)$$

For short phase contact times with allowance for the values of the reaction rate constants, the expression for the parameter S_t is simplified considerably:

$$S_0 = \frac{2.83}{0.194 + 9.23\left[H^+\right]},$$

indicating that the separation is influenced by only one factor, namely the acidity of the aqueous phase. For high values of the time, the parameter S_t degenerates into the thermodynamic separation parameter S_∞

$$S_\infty = \frac{\left[\overline{Cu}\right]_\infty}{\left[\overline{Fe}\right]_\infty} \Big/ \frac{[Cu]_0}{[Fe]_0} = \frac{K_{eq(Cu)}K^{-1}_{eq(Fe)}\left[H^+\right]^3 + K_{eq(Cu)}\left[\overline{HOx}\right]_m}{\left[\overline{HOx}\right]_m\left[H^+\right]^2 + K_{eq(Cu)}\left[\overline{HOx}\right]^3_m}.$$

For very low acidities, $S_\infty \simeq 1$, that is separation of Cu^{II} and Fe^{III} does not take place. On the other hand, at a very high acidity, S_∞ becomes large, since the equilibrium for the extraction of Fe^{III} is displaced to the left to a much greater extent than that for Cu^{II}. According to published data,[224] $k_{eq(Cu)} = 0.55$ and $k_{eq(Fe)} = 5.5 \times 10^{-4}$. The authors cited introduce the concept of critical kinetic acidity (CKA), which is defined as the abscissa of the point of intersection of the $S_\infty = f([H^+])$ curve with the $S_0 = f([H^+])$ curve. At acidities lower than the CKA, $S_0 > S_\infty$, and the separation based on kinetic factors is preferable. At acidities greater than CKA, kinetic factors cannot be used, and at an acidity equal to CKA the separation is independent of time. The kinetic separation parameter S_t has been calculated for different values of a_i and t.[224] For acidities lower than CKA, Eqn. (2) can be used to calculate the time necessary to obtain a specified separation; the following quantities must be determined: the chemical composition of the system ($[\overline{HOx}]_m$) and $[H^+]$ and the specific inter-phase surface, which depends on the geometry of the extractor, the intensity of mixing of the phases, the viscosity, density, inter-phase tension, etc. For example, if $[\overline{HOx}]_m = 0.1$ M, $[H^+] = 3 \times 10^{-3}$ M, and $a_i = 5$ cm^{-1}, then after stirring the phases for 2 min, $S_t > 5$ and copper is separated almost completely from iron. After stirring for 5 min, $S_t \simeq 2.5$, and an appreciable quantity of Fe^{III} is transferred into the extract.

If the distribution coefficient of the component extracted and the value of the specific surface (a) of contact between the phases are assumed to be unchanged during the process, the equation for its rate can be written as

$$\frac{dC}{dt} = ka\left(C^* - C\right),$$

where C ad C^* are the current and equilibrium values of the concentration of the component extracted in the acceptor phase, and k the coefficient of mass transfer. Integration of this equation gives

$$\ln(1 - E) = -kat, \quad (3)$$

where $E = C/C^*$ is the degree of completion of the process.

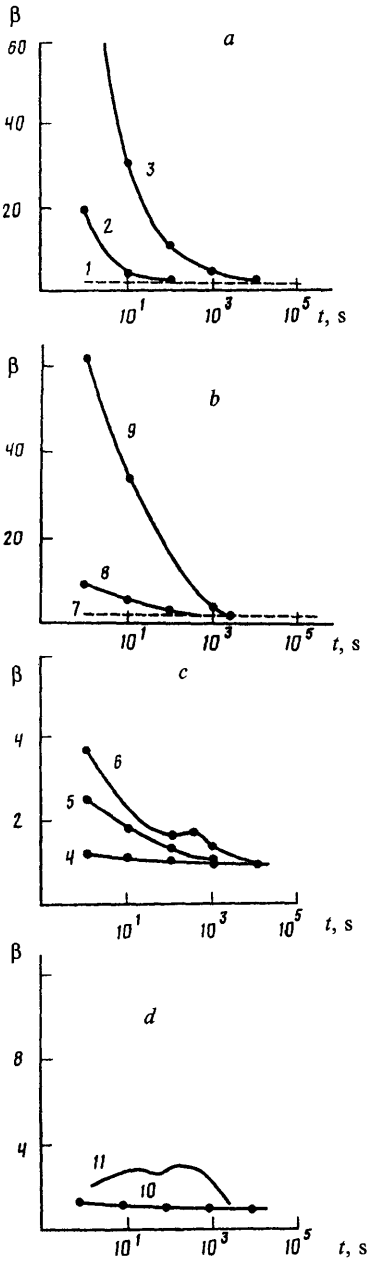

Figure 4. Influence of the equilibrium constant of the surface reaction (a), the rate constants of the forward (b) and back reactions, and the diffusion coefficient (D_{12}) of the substance (d) on the time dependence of the dynamic separation factor; k_1, cm s^{-1}: *1,4–6,7,10,11*, 10^{-3}; *2,8*, 10^{-4}; *3,9*, 10^{-5}; k_2, cm s^{-1}: *7–11*, 10^{-3}; *2,5*, 10^{-4}; *3,6*, 10^{-5}; D_{12}, cm^2 s^{-1}: *1–10*, 10^{-6}; *11*, 10^{-5}.

Relationship (3) is widely used in the treatment of the results of kinetic experiments. If Eqn. (3) is written for each component extracted, it is possible, neglecting the mutual influence of the extraction processes, to obtain expressions for estimating the magnitude of the dynamic separation factor.

If at the initial moment there is a certain amount of substance in the acceptor phase, the equation for the rate of the process becomes[225]

$$1-E=(1-E_0)\exp(-kt),$$

or, expressing E in terms of the extraction coefficient D_e,[226]

$$1-\frac{1+1/D_e^*}{1+1/D_e}=\left(1-\frac{1+1/D_e^*}{1+1/D_0}\right)\exp(-kt).$$

if $E_0 = 0$, the value of D_e attainable at a given stage is determined by the values of D_e^*, t, and k, which the authors cited call the effective rate constant. In general, D_e depends on D_e^0. For a cascade, since the values of D^0 are different for different stages, the values of D will also be variable. From the material balance equation with allowance for the expressions for the extraction coefficients it is possible to obtain relationships between the extraction coefficients in adjacent stages[226]

$$D_{e(i-1)}^{-1}=\frac{1/D_e^*+e^{-kt}}{1+(1/D_e^*)e^{-kt}-(1+1/D_e^*)e^{-kt}A},$$

where

$$A=1-\frac{e^{-kt}(1+1/D_e^*)/(1+1/D_{ei})}{1+(1/D_e^*)e^{-kt}-(1+1/D_e^*)/(1+1/D_{ei})}.$$

The value of D at any of the stages is determined experimentally, after which the values for the other stages of the cascade are calculated.

A mathematical model of the dynamics of counter-current multi-stage extraction in a cascade of mixer–settlers, constructed with allowance for the kinetics of the reactions of the components extracted with the extracting agent, has been published.[227] The introduction of kinetic factors into the model showed that it is possible to increase the selectivity of separation as a result of differences in the kinetics and that there exists an optimum residence time in each stage of the process to give the maximum value of the separation factor. The influence of the constructional parameters of the extraction column on selectivity has been noted.[228]

V. Summary

The present review shows that there exist real possibilities for increasing the efficiency of the extraction separation of substances by making use of kinetic factors. Here it is important to make effective use of differences in the mechanisms of the extraction of the components from a multi-component mixture, or differences in the conditions of the processes, or existing differences in the kinetic or transport parameters of the separate stages of the process. The possibilities for dynamic separation are greatly increased by creating or increasing differences in the parameters of the individual stages under the influence of external factors.

The forms of time dependence of the dynamic separation factor given in the present review show that the efficiency of dynamic separation is greater, the farther the system from the equilibrium state. Thus the realisation of the possibilities of dynamic separation requires a different non-traditional, approach to the construction of equipment for carrying out the process. It is necessary to ensure a short contact time between the phases and effective separation of the phases. The injected flow method which has recently been widely introduced in analytical chemistry would appear to be useful here. It cannot be used to achieve "rapid mixing–separation", however, since only 10–20% of the organic phase is separated from the aqueous phase.[65] The rapid separation of the phases remains a serious problem in the construction of apparatus for carrying out the process. The film systems of Boyadzhiev[229,230] and other methods[231] are of interest in this connection.

The mathematical modelling of the process of dynamic separation is based on a phenomenological and formal-kinetic description, and is greatly simplified. Frequently, no account is taken of the mutual influence of the components in their extraction from a multi-component system; this may be acceptable when modelling the extraction of components from dilute solutions. In the models developed, full account is not taken of the variety of inter-phase phenomena exerting a significant influence on the selectivity of separation. It is important to carry out a detailed analysis of the processes, accompanied by homogeneous and heterogeneous chemical reactions, adsorption–desorption phenomena, the formation of inter-phase films, change in the electrical properties of the phase interface, and spontaneous surface convection. Allowance for inter-phase phenomena or processes complicates the mathematical modelling considerably. The restricted nature of analytical methods can be overcome, however, by using numerical methods, widely employed in the modelling of liquid–liquid extraction processes.

To develop the theoretical ideas it is necessary to establish the relationships between the nature and state of the component extracted and the kinetic parameters of the process, and to select and substantiate criteria for identifying extraction systems for which dynamic separation is preferable to separation based on differences in the thermodynamic parameters of the process.

The solution of these problems associated with dynamic separation will undoubtedly facilitate the practical development of a method which is one of the most promising ways of increasing the selectivity of extraction processes.

Methods for increasing the efficiency of catalysts for the oxidative condensation of methane

O V Krylov
Institute of Chemical Physics, Russian Academy of Sciences

ABSTRACT. Possible ways of increasing the efficiency of catalysts for the oxidative condensation of methane by increasing the pressure, adding other gases to the reaction mixture (methane + oxygen), and carrying out the process under cyclic redox conditions have been examined. In some cases the yield of C_2-hydrocarbons can be increased to 32%.

I. Introduction

The oxidative condensation of methane to give C_2-hydrocarbons, which was discovered in 1981–1984, is one of the most rapidly developing and promising fields of catalysis. About 100 papers on the catalysts, mechanism, and characteristics of this reaction are published every year. A number of reviews have been published.[1–7]

There are now a number of catalytic systems showing activity and selectivity in the oxidative condensation of methane. The chemical relationships governing the selection of catalysts for oxidative condensation have not been fully determined. The most active and selective catalysts are the oxides of the non-transition metals of groups I–IV, that is the oxides of metals with outer *sp*-electrons. High and stable yields of C_2-products have been obtained on PbO deposited on Al_2O_3 or MgO; on a number of lanthanide oxides, in particular Sm_2O_3; on BaO_2; and on Li/MgO. Most transition metal oxides catalyse the extensive oxidation of methane. Among transition metal oxides, for some unknown reason, activity and selectivity are shown by manganese oxides, but only in compounds, and not in pure form.

A number of authors report the existence of various limiting yields of C_2-hydrocarbons.[8,9] According to McCarty,[9] the limiting yield of C_2-hydrocarbons is ~26%. With increase in the conversion of methane, the selectivity decreases. On most catalysts studied, the yield is lower than this value. Other authors[8] give slightly higher limiting yields of about 30%. Even higher yields have been reported: 30.8% on an Li–Mn–Ti–O catalyst,[10] 31.6% on $Ce_{1-x}Sr_xYb_xO_3$,[11] and even 32.3% on Li–Nd–O/MgO,[12] although in each case a careful analysis of the conditions giving these yields is required; they may be artefacts. High yields have also been observed on various chlorine-containing systems (see below).

The highest reaction rate has been obtained on Sm_2O_3 [4]— 828 μmol s^{-1} g^{-1} at 1023 K. The best temperature range for carrying out the reaction is 950–1100 K. Extensive oxidation of methane takes place at lower temperatures. At higher temperatures, in addition to extensive oxidation, extensive catalytic cracking takes place. Many catalysts are unstable under the reaction conditions, both as a result of the loss of the active component and as a result of overheating during this exothermic process.

The heterogeneous–homogeneous mechanism of the oxidative condensation of methane, according to which reaction with the surface gives methyl radicals

$$O_S + CH_4 \xrightarrow{k_1} OH_S + CH_3, \quad (1)$$

and their recombination in the gas phase gives ethane

$$CH_3 + CH_3 + M \xrightarrow{k_2} C_2H_6 + M, \quad (2)$$

is now generally accepted.[1–7]

The selectivity of the gas-phase stages of the reaction is determined by the equilibrium

$$CH_3 + O_2 \underset{}{\overset{K_3}{\rightleftharpoons}} CH_3O_2. \quad (3)$$

At high temperatures, equilibrium (3) is displaced to the left, and the selectivity towards C_2H_6 increases. Below 873–973 K, equilibrium (3) is displaced to the right, and the radical CH_3O_2 leads to extensive oxidation.

An examination of a stepwise mechanism for the oxidative condensation of methane for low degrees of transformation made it possible[13] to put forward the following equation for the limiting selectivity with respect to ethane

$$S_{lim} = \frac{1}{1 + K_3 p_{O_2}(K_3 p_{O_2} k_4/k_2 + k_5/k_2)}, \quad (4)$$

where k_2 is the rate constant of reaction (2), K_3 the equilibrium constant of reaction (3), and k_5 and k_4 the rate constants of the homogeneous gas-phase reactions of the further oxidation of CH_3 and CH_3O_2 radicals. Eqn. (4) does not take account of possible reactions on the catalyst surface, for example extensive catalytic oxidation. For high degrees of transformation, reactions of free radicals in the gas phase, not taken into account, may take place. The oxidative dehydrogenation of ethane gives ethylene, apparently with the intermediate formation of C_2H_5 radicals.

Under stationary conditions, the kinetics of the oxidative condensation of methane are described by an equation of the Mars–Van Krevelen type, characteristic of processes taking place by a redox mecanism

$$r = \frac{k_r p_{CH_4} k_{ox} p_{O_2}}{k_r p_{CH_4} + k_{ox} p_{O_2}}, \quad (5)$$

where k_r and k_{ox} are the rate constants for the reduction of the active centres by methane and their re-oxidation by oxygen respectively.[3]

Possible ways of increasing the efficiency of the oxidative condensation of methane are examined below.

II. Increase in pressure

According to the reaction kinetics described by Eqn. (5), increase in the pressure of oxygen and methane should increase the reaction rate. According to Eqn. (4), increase in the O_2 pressure should decrease the selectivity, but increase in the methane pressure should have no significant influence on it. These equations, however, are applicable only for small degrees of conversion. At high degrees of conversion and high pressures, the ratio between the heterogeneous and homogeneous processes may change sharply in favour of the latter. There may be an increase in the part played by processes giving undesirable products of extensive oxidation.

A decrease in selectivity with increase in the oxygen pressure has in fact been observed by a number of authors.[14–16]

Increase in pressure from 0.1 MPa and 0.8 MPa in the empty reactor increased the degree of conversion of CH_4 from a very low value (< 1%) to 32.7% at 1073 K and a volume rate of 24 min^{-1}.[17] In a study of the influence of pressure on the oxidative condensation of methane on an Li/MgO catalyst, Tyulenin and co-workers[18] filled the empty volume beyond the catalyst with the weakly active MgO, to decrease the reaction in the gas phase. Under these conditions, the degree of conversion of CH_4 increased with increase in pressure, from 28.1% to 34.3%, and the selectivity with respect to C_2-hydrocarbons decreased from 41.1% to 36.0%; the selectivity with respect to C_2H_6 decreased from 20.1% to 10.1%, and the selectivity towards C_2H_4 increased from 20.5% to 26.3%, the ratio $[C_2H_4]/[C_2H_6]$ in the reaction products increased from 1.0 to 2.62, the yield of CO increased slightly, and the yield of CO_2 remained unchanged.

An increase in the selectivity towards C_2H_4 with increase in pressure was noted in other papers.[19,20] The yield of C_2H_4 increases and even exceeds the yield corresponding to the equilibrium $C_2H_6 \rightleftarrows C_2H_4 + H_2$, that is the principal role is played by kinetic factors.

Thus increase in pressure has a positive influence mainly on the second stage of the process—the oxidative dehydrogenation of ethane to ethylene.

Increase in pressure may also have a positive influence on the first stage of the process—the formation of C_2H_6 molecules by the recombination of methyl radicals with the participation of a third molecule M. In highly porous catalysts such as MgO or Li/MgO, reaction (2) hardly takes place within the catalyst granules.[21] This is due to the diffusion of the CH_3 species formed under Knudsen conditions, when these species undergo practically no collisions with one another or with the molecule M, but react with the surface, on which extensive oxidation apparently takes place. As a result, only the outer layers of catalyst take part in the formation of C_2H_6. With increase in pressure, the probability of triple collisions according to reaction (2) increases, and the yield of C_2-hydrocarbons shows a corresponding increase. This also explains the observed[22,23] decrease in activity and selectivity in the oxidative condensation of methane with increase in the specific surface, that is decrease in the specific surface and increase in the pressure in this reaction operate in the same direction.

III. Influence of water vapour

Water vapour is formed both in the oxidative condensation and in the extensive oxidation of methane. In the stages of catalyst reduction and oxidation, water may have a negative influence on the catalysis by blocking the active centres.

Nevertheless, the opposite is also observed—an increase in the degree of conversion of methane with increase in the water vapour pressure with no change in selectivity.[24,25] A redistribution of the products of oxidative condensation towards C_2H_4 has also been observed on Sm_2O_3 + CeO_x, PbO–MgO, and ZrO_2–MgO.[26] Thus water vapour apparently influences the heterogeneous but not the homogeneous stages of the process.

At a high temperature (> 1000 K) in the presence of water vapour, steam conversion of methane takes place on oxide catalysts. The formation of H_2, C_2H_4, and C_2H_6 (the last two in smaller quantities than H_2) has been observed in the reaction of methane and water vapour on a CaO catalyst.[27]

Most interesting results were obtained by Pereira and co-workers.[28] At low temperatures (873 K and below) on a Ca–Ni–K-oxide catalyst for a mixture with $[CH_4]:[O_2]:[H_2O]$ = 3 : 1 : 6.5 at atmospheric pressure, 100% selectivity in hydrocarbon formation was observed, with a degree of conversion of ~10% in one operation. Heating in oxygen increased the activity and selectivity. Activation for 1 h gave a mixture of 38% C_2H_4, 48% C_2H_6, 5.3% C_3H_8, 5.6% C_3H_6, and 2.8% hydrocarbons. If water vapour is replaced by helium, the activity decreases rapidly, that is the catalyst is stable towards water vapour. X-Ray photoelectron spectroscopy showed that $Ni(OH)_2$ is formed on the catalyst surface, and calcium nickelate (charge on nickel > 2+) is formed in the bulk. The formation of carbonates leads to a decrease in the activity of the catalyst.

Another paper by the same authors[29] gives the results of prolonged tests confirming the earlier data. An unusually low activation energy E for the oxidative condensation of methane is reported: 84 kJ mol^{-1}, which is much lower than the activation energy of extensive oxidation (~250 kJ mol^{-1}). On most catalysts studied for the higher-temperature oxidative condensation of methane (without water vapour), the opposite was observed: E for the oxidative condensation was greater than E for extensive oxidation.[3] The most active and selective catalyst for the reaction in the presence of water vapour had the composition $Ca_3NiK_{0.1}O_x$. A much lower activity and selectivity were shown by the catalyst $CaK_{0.1}O_x$, indicating that the presence of the transition metal (nickel) in the catalyst is necessary. The transition metal acts as a promoter.

The mechanism of this low-temperature condensation of methane is not yet clear. The possible steam conversion of methane to give synthesis gas CO + H_2 followed by a Fischer–Tropsch synthesis, that is purely heterogeneous reactions, have been suggested.[29] The distribution of the reaction products—$C_1:C_2:C_3:C_4$-hydrocarbons—to some extent resembles the Schulz–Flory distribution.

The authors cited point out that the synthesis of the hydrocarbons may be influenced by carbon particles. This is confirmed by experiments with $^{13}CH_4$. Water vapour does not play a direct role in the synthesis, but has an indirect influence, probably as a result of the formation of OH groups on the surface. The authors cited also point out that $CaK_{0.1}O_x$ is a very good catalyst for the steam gasification of graphite at relatively low temperatures to give H_2 and CO.[30]

Until the radical products above the catalyst have been determined, possible explanations of the influence of water vapour on the homogeneous stages of the process should not be rejected. High concentrations of hydroxyl radicals were observed in the oxidation of methane on platinum.[31] The action of oxygen led to the hydroxylation of molecularly adsorbed water on Ag(110) and Cu(100) with the intermediate formation of O_2^-.[32] The reaction

$$4(OH)_S + O_2 \longrightarrow 4O_S + 2H_2O, \quad (6)$$

observed[33] in the re-oxidation of reduced methane by an Li/MgO catalyst possibly also involves the intermediate formation of OH or HO_2 radicals.

The characteristics of the low-temperature oxidation of methane noted by other workers are probably also related to the influence of water vapour and OH groups. Water has a strong influence on the acidic properties of a surface. Matsuhashi and co-workers,[34] using a 4.3% Na^+/ZrO_2 catalyst at 873 K, were able to carry out the oxidative condensation of methane with 26.5% conversion and 52.8% selectivity towards C_2-hydrocarbons. On the super-acid SO_4^-/ZrO_2 at 873 K, water vapour led to a marked increase in the transformation of a $CH_4 + O_2$ mixture into oxygen-containing products (to 16.2% for a degree of conversion of 10.8%). It has been shown[35] that an iron phosphate catalyst (Fe/P = 0.6), with or without a carrier, functions even at 850 K (yield of C_2-hydrocarbons up to 8%). The activity of this catalyst was very unstable, however, and its loss and reduction were observed after further heating at 973 K. Although the authors cited[35] do not point out a relationship between the observed effects and the action of water vapour, nevertheless the observed phenomenon is very similar to the analogous effects for an Ni–Ca–K–O-catalyst in the presence of water vapour.[29] The same paper also reported the unexpected deactivation of the catalyst with restoration of the activity after further heating.

IV. Influence of chlorine

In the presence of chlorine-containing compounds both in the catalyst and in the gas phase it is possible to increase considerably the yield of the products of the oxidative condensation of methane. This was first demonstrated by Otsuka and co-workers.[14,36,37] The additives LiCl, NaCl, KCl, CsCl and LiBr were deposited on MnO_x/SiO_2, NiO_y/SiO_2, and other catalysts. With a 2% $NaCl/MnO_x/SiO_2$ catalyst at 1023 K and 90 kPa, the degree of conversion of CH_4 was 46.8%, the selectivity towards C_2-hydrocarbons 66%, and the yield 31.6%, which is 8–10% greater than the yield of C_2 on the same catalyst without NaCl. It has been suggested[14] that LiCl and NaCl act as promoters as a result of the formation of chlorine atoms, which subsequently lead to the formation of additional methyl radicals

$$\begin{aligned} &LiCl + CH_4 + {}^1/_2\,O_2 \longrightarrow LiOH + CH_3Cl, \\ &CH_3Cl \longrightarrow CH_3 + Cl\,, \end{aligned} \quad (7)$$

followed by the gas-phase recombination of methyl radicals (2) and gas-phase reactions involving chlorine atoms

$$\begin{aligned} &Cl + CH_4 \longrightarrow CH_3 + HCl, \\ &Cl + C_2H_6 \longrightarrow C_2H_5 + HCl. \end{aligned} \quad (8)$$

The chlorination of methane is an important industrial process for obtaining chloro-derivatives of methane. At 1000–1200 K it takes place by a chain mechanism to give CH_3Cl, C_2H_5Cl, and ethane. The limiting stage is the removal of an H atom from CH_4 with an activation energy of 16 kJ mol^{-1}. In some experiments with chlorine-containing additives,[38] HCl was not detected in the products of the reaction of methane with chlorine. This suggested that HCl is continuously removed from the system by the reaction

$$HCl + OH = Cl + H_2O \quad (9)$$

with the regeneration of chlorine atoms, which are the active centres of the chain reaction.

The addition of ZSM-5 zeolite to MnO_x + NaCl or NiO_y + LiCl catalysts leads to the formation of aromatics.[38]

Other workers[39–43] observed an increase in the selectivity towards C_2H_6 and more particularly towards C_2H_4 when chlorides are added to oxide catalysts. The formation of chlorine is accelerated in the presence of water in the hydrolysis

$$LiCl + H_2O \longrightarrow LiOH + HCl \quad (10)$$

or the oxidative transformation on CaO + $CaCl_2$ [9]

$$\begin{aligned} &CaCl_2 + {}^1/_2\,O_2 \longrightarrow CaO + Cl_2, \\ &CaCl_2 + H_2O \longrightarrow CaO + HCl, \\ &2HCl + {}^1/_2\,O_2 \longrightarrow Cl_2 + H_2O. \end{aligned} \quad (11)$$

The introduction of water vapour into the reaction mixture on $CaCl_2$ leads to an increase in the yield of C_2-hydrocarbons and CH_3Cl, and also an increase in the ratio $[C_2H_4]/[C_2H_6]$. The high selectivity of ethylene formation is due to the high efficiency of the dehydrogenation of C_2H_6 to C_2H_4 in the presence of chlorine, compared with the dehydrogenation of C_2H_6 under the influence of O_2 alone. A decrease in the rates of the extensive oxidation of CH_4 and C_2-hydrocarbons compared with the pure oxides is also observed, making it possible to achieve a higher selectivity in the formation of ethylene. It has been shown[41] that chlorine initiates gas-phase reactions within a layer of the catalyst $SmCl_3$ or SmOCl. Reactions outside the layer increase the combustion of methane.

The introduction of C_2H_5Cl into the gas phase on $BaCO_3/\alpha$-Al_2O_3 or $BaCO_3/TiO_2$ leads to an almost two-fold increase in the yield of C_2-products. This increase in yield is due chiefly to an increase in the selectivity from 36% to 60%, while the degree of conversion decreases slightly. If C_2H_5Cl (10 p.p.m.) is added continuously to the gas stream, the yield of C_2-hydrocarbons remains constant for a long time. A very high ratio $[C_2H_4]/[C_2H_6]$ = 10.2 was obtained under these conditions on $BaCO_3/TiO_2$.[43]

A kinetic analysis of the heterogeneous–homogeneous scheme for obtaining C_2-hydrocarbons with the participation of Cl_2 showed[40] that C_2-hydrocarbons are formed preferentially at chlorine concentrations below 10^{-10} mol cm^{-3}; at a higher chlorine concentration, CH_3Cl is formed. Estimation of the concentration of CH_3 radicals based on a comparison of the experimental rates of formation of the products and the known rate constants of the elementary reactions gave high values. Increased concentrations of

the radicals possibly exist above the catalyst in a layer having a thickness of the order of the mean free path of the particles.

According to Warren,[43] chlorine has three functions in the oxidative condensation of methane: 1, it increases the conversion of CH_4 by increasing the number of active centres of the catalyst, for example by transforming surface salt centres such as carbonate, aluminate, and titanate into chlorides; 2, it decreases the number of extensive-oxidation centres; and 3, it increases the ratio $[C_2H_4]/[C_2H_6]$ (sometimes to 10). The alkali metal atoms present in the chlorides also inhibit extensive oxidation.

A particularly large number of studies have been carried out with the addition of chlorides to Mn-containing catalysts.[14,36,37,39,44–57]† In some cases a very high yield of C_2-hydrocarbons was obtained. For example, a 13% NaCl–17% MnO_x/SiO_2 catalyst at 1123 K gave a CH_4 conversion of 45.8%, and a selectivity with respect to C_2-hydrocarbons of 74.7%, that is the yield of C_2-hydrocarbons was 32% for a contact time of 0.5 s and a ratio $[CH_4]/[O_2] = 2$.[52] On an $LiCl + B_2O_3 + MnO_2$ (5:7:13) catalyst at 1023 K and a ratio $[CH_4]/[O_2] = 3:1$, the selectivity was 80%, and the yield of C_2 was 33.9%.[53]

The activity of chlorine-containing catalysts decreases during operation as a result of the loss of chlorine. It can be restored by introducing chlorine-containing additives into the gas phase: HCl,[48,51] CH_3Cl,[54] CH_2Cl_2,[40,55,56] CCl_4,[57]† Cl_2.[55] These additives restore the concentration of chlorine in the catalyst.

The phase composition of an Na–Mn–O/SiO_2 catalyst treated with a chlorine-containing reaction mixture has been studied.[58] A multi-phase oxide–halide system containing NaCl, Mn_3O_4, and MnO_2 is formed:

$$\beta\text{-}Na_{0.7}MnO_2 \xrightarrow{CH_4 + O_2 + 1\%\ HCl} NaCl + Mn_2O_3 + Mn_3O_4 + H_2O. \quad (12)$$

The phase transformations of this catalyst have been studied in detail for the oxidative dehydrogenation of ethane to ethylene by *in situ* X-ray diffraction. The initial chloride catalyst contained a phase with variable composition $NaCl.xMnCl_2$. During the $C_2H_6 + O_2$ reaction, a continuous increase in the intensity of the lines due to the NaCl phase was observed, with the appearance of oxide and the liberation of chlorine

$$3[NaCl \cdot 2MnCl_2] + 4O_2 \longrightarrow 3NaCl + 2Mn_3O_4 + 6Cl_2. \quad (13)$$

Comparison of the rates of formation of the NaCl phase (with the loss of chlorine) and ethylene showed a correspondence between these quantities. The rates, expressed in moles per minute, are fairly close to one another. Thus chlorine is generated by the redox oxidation of HCl (Deacon's process):

$$3[NaCl \cdot 2MnCl_2] + 4O_2 \longrightarrow 3NaCl + 2Mn_3O_4 + 6Cl_2 \ (\longrightarrow 12Cl),$$
$$3[4NaCl \cdot MnCl_2] + 2O_2 \longrightarrow NaCl + Mn_3O_4 + 3Cl_2 \ (\longrightarrow 6Cl),$$
$$2Cl^{\cdot} + C_2H_6 \longrightarrow C_2H_4 + 2HCl. \quad (14)$$

Ethylene is also formed in a process parallel to reaction (14), by the reaction of C_2H_6 with surface centres containing Mn^{4+}. A temperature-programmed study showed that the quantity of oxygen liberated from the oxide catalyst is four times the quantity of oxygen desorbed from the corresponding oxide halide catalyst. This weakly bound oxygen is apparently responsible for the extensive oxidation, and decreases the selectivity of the process. The selectivity increases sharply when oxygen is removed. The addition of HCl regenerates the mixed Na–Mn–Cl phase.

In some published studies, however, another opinion is found, namely that the formation of C_2H_4 on chloride catalysts is purely heterogeneous. For example, Conway and Lunsford[59] observed a selectivity in the conversion of CH_4 to ethane of 40.9% on a 65% LiCl/MgO catalyst, and selectivity in the transformation of ethane to ethylene of 70.2% for a degree of conversion of 75–79%, but the activity gradually decreased as a result of the removal of chlorine from the catalyst by its reaction with H_2O. The $LiCl/Dy_2O_3/MgO$ catalyst is even more active and stable.[60] In the opinion of the authors cited,[59,60] the presence of chlorine on the catalyst prevents the adsorption of CO_2 and alters the activity of the O^- centres in such a way that they become capable of activating the weaker C–H bond in ethane, but are still incapable of activating the stronger C–H bond in ethylene (that is for extensive oxidation).

The layer halides $MBi_3O_4X_2$, where M = Li, Na, K, Ag, Pb, Cd, and X = Cl, Br, are relatively stable under the catalysis conditions. Their activity and selectivity are not very high, however, and the yield of C_2 does not exceed 19.4%. Bromides are slightly more active than chlorides.[61,62] The so-called Arpe phases $M_{24}O_{31}Cl_{10}$, where M = Bi, La, Sm, have been studied.[63] These phases are exceptionally stable towards the removal of chlorine, and have a layer structure, but their activity is very low.

The pure chlorides of magnesium, calcium, strontium, barium, and potassium at 1023 K are selective in the formation of C_2H_6, but nonselective in the formation of C_2H_4. The mixed chlorides $LiCl/MnCl_2$ and $NiCl_2/MnCl_2$ are more selective; under the catalysis conditions they are converted into a mixture of chlorides and oxides MnO_x which is more selective.[64]

A $Bi_2O_3.MoO_3.LiCl$ melt at 1023 K gave 18% conversion, 35.8% selectivity with respect to C_2, and 6.4% yield, including only 1.4% C_2H_4. The addition of CH_3Cl to the gas phase increased the selectivity towards C_2H_4 to 100%, related to C_2-products.[65]

The aggressive nature of the halogens may prevent the practical application of reactions involving halogen-containing additives, despite the considerable increase in activity and selectivity.

V. Influence of carbon dioxide

A number of workers point out that CO_2 has a positive influence on the selectivity and a negative influence on the activity of catalysts for the oxidative condensation of methane. CO_2 forms surface carbonates on catalysts with basic properties. These carbonates decrease the number of active centres and hence decrease the activity of catalysts in oxidative condensation, but they decrease the activity in extensive oxidation to an even greater degree, so that the selectivity increases.[66,67]

Equilibrium in the decomposition of the alkaline earth metal carbonates $MCO_3 \rightleftarrows MO + CO_2$ at atmospheric pressure is established at a temperature close to that of the oxidative condensation of methane. Under the catalytic conditions, CaO was covered by a layer of $CaCO_3$,[68] and SrO by a layer of $SrCO_3$.[69] Deactivation of the catalyst with a simultaneous increase in selectivity was observed. Similar effects were observed for the Li/MgO catalyst.[70] An increase in the selectivity under the influence of CO_2 was also observed for catalysts of the oxidative dehydrogenation of ethane.[71]

† See also S Ahmed, J B Moffat *J. Catal.*, 1989, **118**(2) 281, 1190; **121**(2) 408; 1990, **125**(1) 54.

At higher temperatures, CO_2 may take part in oxidative dehydrogenation as an oxidising agent. This was first studied in detail by Aika and Nishiyama.[72] The free energies of the reactions of CO_2 with methane and ethane ΔG (kJ mol^{-1}) at 1073 K are given below:

$$CH_4 + 2CO_2 = C + 2CO_2 + 2H_2O \qquad \Delta G = -27, \qquad (15)$$

$$CH_4 + 3\,CO_2 = 4CO + 2H_2O \qquad \Delta G = -611, \qquad (16)$$

$$CH_4 + CO_2 = 2CO + 2H_2 \qquad \Delta G = -254, \qquad (17)$$

$$C_2H_6 + CO_2 = C_2H_4 + CO + H_2O \qquad \Delta G \sim 0, \qquad (18)$$

$$2CH_4 + CO_2 = C_2H_6 + CO + H_2O \qquad \Delta G = 35. \qquad (19)$$

The ΔG values are negative for the first three processes, and positive for the fifth reaction. All the reactions are endothermic. The equilibrium yield of C_2H_6 at 1073 K even according to reaction (19) should be 13%; this value is fairly high. The equilibrium yield of C_2H_4 by reaction (18) is 57%. By using a $CH_4 + CO_2 + O_2$ mixture it is possible to obtain a higher yield of C_2 and to convert the oxidative condensation of methane into a thermally neutral process, that is to solve the problem of removing heat in the oxidative condensation of methane using oxygen.

Aika and Nishiyama[72,73] studied a number of oxide catalysts of the oxidative condensation of methane. Their properties were compared in two mixtures: 1, $CH_4 + O_2$ (100:1) and 2, $CH_4 + CO_2 + O_2$ (100:100:1). A catalyst with a medium basic strength showed an even higher yield of C_2-hydrocarbons compared with the yield in a $CH_4 + O_2$ mixture. For example, on 50% PbO–MgO the yield of C_2 was 3.28% in the first case, and 4.37% in the second; on $CaO-BaO-CeO_2$ the yields were 2.2% and 3.5% respectively. From these results it was concluded[72] that the oxidative dehydrogenation of hydrocarbons involves oxygen atoms removed from CO_2

$$CO_2 \rightarrow CO + O_{ads}, \qquad (20)$$

$$2CH_4 + O_{ads} \rightarrow C_2H_6 + H_2O, \qquad (21)$$

$$C_2H_6 + O_{ads} \rightarrow C_2H_4 + H_2O. \qquad (22)$$

Experiments with labelled molecules $^{13}CO_2$ and $^{12}CD_4$ [74] showed that ^{13}CO and $^{12}C_2D_6$ appear. This means that all the CO is formed only from CO_2, and not as a result of the further oxidation of hydrocarbons. In the absence of hydrocarbon, CO_2 is completely unreactive on the catalyst. An initial quantity of ethane is necessary to initiate the reaction. The transformation of CO_2 apparently takes place by the reverse reaction to the conversion of water gas

$$CO_2 + H_2 \longrightarrow CO + H_2O \qquad (23)$$

by the action of the hydrogen formed in the gas-phase dehydrogenation of ethane, with intermediate dissociative adsorption (20). Thus in this case the mechanism of the activation of methane and ethane is the same as the mechanism of activation using oxygen alone.

The main processes are the formation of synthesis gas by reaction (17) on pure MgO, reactions (15) and (16) on PbO, and oxidative condensation (18) and (19) on PbO–MgO. The addition of O_2 facilitates reactions (18) and (19), and suppresses reactions (15) and (16). Catalysts with strong basic centres such as Li/MgO and Li/ZnO give less satisfactory results in a $CH_4 + CO_2$ mixture than in a $CH_4 + O_2$ mixture, and are rapidly deactivated.[74]

Reaction (17) takes place mainly at higher tempratures. On $Mn-BaO/Al_2O_3$ and $Mn-CaO/Al_2O_3$ catalysts, for example, this reaction takes palce above 1173 K.[75]

A study of the oxidative dehydrogenation of ethane to ethylene using CO_2 [76–78] showed that the most active and stable systems for the activation of CO_2 and the hydrocarbon are based on manganese oxides. The selectivity of the formation of C_2H_4 was 54% on a 17% MnO_x/SiO_2 catalyst; it increased to 65.4% on 5.5% Cr–17% MnO_x/SiO_2, and when 1.5% K_2O was added the selectivity increased to 76.8% for degrees of conversion of C_2H_6 and CO_2 of 82.6% and 52.3% respectively. The yield of C_2H_4 on the last catalyst was 55.7% at $C_2H_4/CO > 1$.

An *in situ* X-ray diffraction study of the phase composition of the $K-Cr-MnO_x/SiO_2$ catalyst[76,77] showed that the Mn_3O_4 phase observed initially is reduced to MnO under the reaction conditions. The same is observed for the MnO_x/SiO_2 and $Fe-MnO_x/SiO_2$ catalysts.[78] The addition of a second transition metal (iron or chormium) oxide apparently creates an inter-phase boundary which facilitates the redox process. The surface is oxidised both by CO_2 and by O_2. The oxygen capacity in the oxidative dehydrogenation using CO_2 on a $K-Cr-MnO_x/SiO_2$ catalyst was much lower (by a factor of 8) than that when O_2 was used.

The kinetics of the oxidative dehydrogenation of ethane are described by the equation

$$r = \frac{k_1 p_{C_2H_6} k_2 p_{CO_2}}{k_2 p_{CO_2} + k_3 p_{CO}}. \qquad (24)$$

With increase in the ratio $[CO_2]/[C_2H_6]$ the selectivity in the formation of C_2H_4 at first increases, and then reaches a constant value at $[CO_2]/[C_2H_6] > 2.5$. This change in selectivity differs considerably from the change in selectivity under the influence of O_2 in the oxidative dehydrogenation of CH_4 and C_2H_6, which is characterised by a decrease in selectivity with increase in p_{O_2} [see Eqn. (4)]. The increase in the extent of the oxidation of the surface with increase in p_{CO_2} possibly retards the extensive cracking of C_2H_6.

The results show that it is possible in principle to carry out the oxidative dehydrogenation of CH_4 and C_2H_6 using a mixture of the two oxidising agents O_2 and CO_2 by a thermally neutral scheme. The observed[72–74] increase in the yield of C_2H_4 in the oxidative condensation of methane using CO_2 is probably due to the continuous displacement of equilibrium (19) with the removal of ethane by reaction (18). Even higher yields of C_2H_4 than those obtained in the work cited[72–74] can be expected.

VI. Cyclic oxidation and reduction

Oxygen decreases the selectivity of the oxidative condensation of methane [see Eqn. (4)], so that many workers have tried to carry out the reaction in the absence of oxygen in the gas phase. One of the first studies[79] obtained considerable yields of C_2-hydrocarbons by the alternate reduction of the catalyst by methane and its subsequent oxidation by oxygen. Alternate reduction and oxidation also solves to a considerable extent the problem of heat removal. The most active catalyst was MnO_x/SiO_2.

The first Arco has made a detailed study of this cyclic process. The deposited oxides of manganese, indium, gallium, antimony, tin, bismuth, and praseodymium were found to be more active in the cyclic process than in the continuous process. The selectivity reached 10–15%.[80] A subsequent study[80–83] confirmed the high

activity and selectivity of manganese-containing systems and made it possible to improve them by modification. A 15% MnO_x + 5% $Na_4P_2O_7/SiO_2$ catalyst was found to be stable. Successive two-minute pulses of CH_4 and O_2 at 1123 K gave a 17% yield of C_2-hydrocarbons (77% selectivity and 22% conversion); at 1073 K and a low degree of conversion, the selectivity approached 100%.[81] Almost 30000 cycles were carried out on an Li–B–Mn–Mg–O catalyst with almost no loss of activity. Arco constructed a pilot plant based on these experiments.[84] The firm Bechtel developed an improved pilot plant for the cyclic process with reduction of the catalyst in a fluidised bed.[85]

The $Mn-O/Al_2O_3$ catalyst was much less selective than $Mn-O/SiO_2$.[85] Its phase composition changes continuously on oxidation and reduction. In the reaction of MnO_x/SiO_2 with CH_4, the reduction of Mn_3O_4 to MnO was observed, corresponding to the removal of 0.33 g-atom of oxygen per g-atom of manganese.

A study of the reduction of PbO/Al_2O_3 and PbO/MgO catalysts under cyclic conditions showed that in the reduction, up to 23% of the oxygen of PbO is removed, and the metallic lead remaining converts CH_4 mainly into C_2H_6.[86] This result to some extent contradicts X-ray photoelectron spectroscopic data,[87] according to which a Pb phase is not formed on 0.4% PbO/MgO, and also other published data,[33] which show that the reduction of PbO to Pb leads chiefly to the oxidation of CH_4 to CO_2.

4% Na/Pr_6O_{11} was also an active catalyst in the cyclic process.[84] At 1073 K it gave 21% conversion and 76% selectivity. The selective preparation of C_2-hydrocarbons in a cyclic process was carried out on an $Li/NiO/TiO_2$ catalyst; on Li/TiO_2, however, only CO and CO_2 were obtained.[88] The pure oxides Mn_2O_3 and MnO_2 function effectively under cyclic redox conditions, but the addition of even small quantities of oxygen to methane leads to extensive oxidation.[5] Relatively high yields of C_2-hydrocarbons were also obtained under cyclic conditions on an Li/MgO catalyst.[89]

The best catalysts for cyclic redox conditions are systems containing the oxides of transition metals and reducible lanthanide oxides. Their capacity with respect to oxygen is apparently fairly high, while the absence of weakly-bound oxygen on the surface prevents extensive oxidation.

The selectivity of catalysts such as In_2O_3, Bi_2O_3, La_2O_3, and Li/MgO under cyclic conditions is also fairly high, but the capacity with respect to oxygen is much lower.[5,79,81,90]

The oxidative dehydrogenation of CH_4 [75] and C_2H_6 [76,77] using CO_2 has also been studied under cyclic alternating conditions. The selectivity is higher, but the oxygen capacity much lower, than in the case where oxygen is used as oxidant. The rate of the oxidative dehydrogenation on a $K-Cr-MnO_x/SiO_2$ catalyst increases when chromium is introduced. According to the authors cited,[76,77] the inter-phase boundary between MnO_x and CrO_y facilitates the re-oxidation of the catalyst.

One form of separated process involves the use of membranes permeable to oxygen. An advantage of this process may be the possibility of condensation in the absence of oxygen or at a low oxygen pressure.

The formation of ethane on a silver membrane with O_2 on one side of the membrane and CH_4 on the other was observed even at 743 K.[91] 100% selectivity was obtained with a low conversion (0.02%). Increase in temperature to 953 K increased the conversion to 40% for a selectivity of about 40%. C_2H_4 also began to appear in the products at 823 K. The active species is atomic oxygen, which diffuses to the silver surface through the membrane and takes part in the formation of C_2-hydrocarbons. The diffusion is apparently the limiting stage; this is confirmed by the similarity in the rate of formation of the C_2-products and the rate of diffusion of oxygen through silver. The observed activation energy of the formation of C_2-hydrocarbons is 150 kJ mol^{-1}. The authors cited[91] consider the C_2-hydrocarbons may be formed as a result of the reaction of CH_4 with atomic oxygen in the gas phase.

Membranes of PbO or MgO on Al_2O_3,[92] PbO/MgO/dynacerum (ceramic),[93] or Pd/MgO/ceramic[94] have also been studied. In the last case the catalysis took place at a low temperature, 553–683 K; 38% selectivity with 0.45% conversion was observed even at 523 K.

The separated cyclic process can be modified by the sectional introduction of oxygen into the reactor. For example, oxygen has been introduced in portions into four successive reactors.[95] This gave a much higher selectivity of up to 80% at 1103 K and 20% conversion on an La/MgO catalyst when oxygen was introduced in equal quantities into each of the four sections. A selectivity of 62% was obtained for 35.7% conversion.

Finally, an electrochemical version of the process is possible. An electrochemical cell with 80% Y_2O_3/ZrO_2 solid electrolyte, a silver anode, and an Ag/Bi_2O_3 cathode was first used by Otsuka and co-workers.[96] A CH_4 + O_2 mixture was passed over the anode. The selectivity was higher than in the continuous gas-phase process.

Other authors[97–102] carried out the electrochemical process at 1023–1123 K using the same solid electrolyte Y_2O_3/ZrO_2. The electrodes used were the catalysts $La_{0.89}Sr_{0.10}MnO_3$,[97,100] Au, Pd, Ag/Bi_2O_3,[98] Cu, Ag–Pd, La–Li–O,[101] and $LaCoO_3$.[102] The reaction rates were low, however. The electrochemical version is still far from the stage of practical application.

Progress in the field of physiologically active lanosterol compounds

I G Reshetova, R K Tkhaper, A V Kamernitskii
Zelinskii Institute of Organic Chemistry, Russian Academy of Sciences

ABSTRACT. This review correlates the studies (up to 1991) on the isolation, structural determination, biological activity, and synthesis of physiologically active polyoxidised lanosterol derivatives of vegetable (inotodiol, ganoderic acids) and animal (seychellogenin) origin. The cytotoxic, cardiovascular, and other forms of activity of compounds of this type are of considerable interest in relation to their medical use. It is noted that the functionalised side chain (in an open form or containing lactones, lactols, etc.) is generally responsible for the activity exhibited by lanosterol derivatives. Two basic approaches to the derivation of these structures are defined: either by complete reconstruction of the side chain of lanosterol (degradation and rebuilding with oxygen-containing residues) or by progressive functionalisation of the Δ^{24}-side chain of lanosterol. The syntheses of the known anticancer compound "inotodiol", seychellogenins, ganoderic acids, and other compounds are described.

The bibliography includes 105 references.

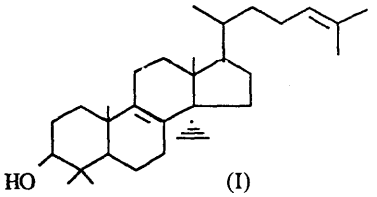
III. Synthetic approaches to lanosterol derivatives with a functionally substituted side chain 865

I. Introduction

Triterpenoids of natural origin with polyfunctional side chains at C(17) and C(20) and with the lanostane skeleton (I) [also known as 4,4,14-trimethylpregn-5α-8(9)-ene or -7,9(11)-diene] have attracted considerable attention[1] from research workers because of their high and varied biological activity.



(I)

Their occurrence in nature, in particular in the plant world and fungi, forms the subject of a number of reviews[2–4] covering the literature up to 1977. It has been established that the main responsibility for their biological activity is borne by the functionalised side chain of lanosterol containing hydroxyl, carbonyl, and other groups, right up to an 18,20-lactone ring, which imparts antifungal and carcinolytic properties to lanostane derivatives. These lactones make up a separate group of triterpenoids—the holothurigenins.[5,6] The regulatory effect on the biosynthesis of cholesterol, when the presence of an O-functional group adjacent to the skeleton [8(9) double bond] is important, constitutes the only exception.[7]

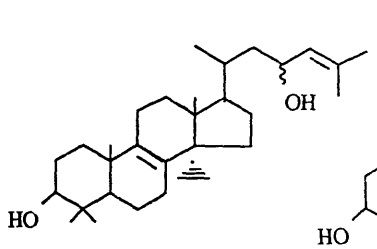
In the present review we have assumed the task of focusing attention on an analysis of the structural features of polyoxidised lanosterol derivatives that have been isolated up to 1991, monitoring the effect of their structure on cytotoxic, antisclerotic, and other types of biological activity, and discussing the most promising synthetic methods. The material has been classified and arranged in an order corresponding to an increase in the degree of oxidation of the side chain of lanosterol. Studies relating to skeletal rearrangements of lanosterol that lead to cucurbitane and fusidic acid have not been covered in this review.[8,9]

II. Natural derivatives of lanosterol

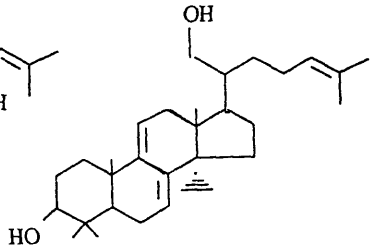
1. Natural derivatives of lanosterol with open side chains containing oxygen functional groups

Of the monohydroxy derivatives of lanosterol, 23ξ-hydroxylanosterol (II) was first isolated in1968 as a metabolite of the fungal mycelium of *Scleroderma aurantium* Pers.[10–12] The absolute configuration at C(23) in natural 23-hydroxylanosterol was determined by correlation of the sign of its molecular rotation with that of known (*R*)(–)- and (*S*)(+)-4-methylpent-3-en-2-ols. The difference between M_D for the natural (23*S*)-23-alcohol and lanosterol is positive while for the synthetic (23*R*)-23-alcohol there is a negative difference.[11] It was subsequently established that this allylic alcohol is unstable and undergoes dehydration during chromatographic separation.[13] The 21-hydroxy derivatives with a

lanosta-7,9(11),24-triene and -8,24-diene skeleton (IIIa, b) were also isolated.[14]

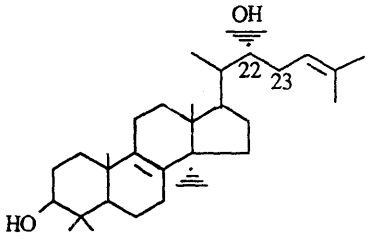


(II)



a: $\Delta^{8(9)}$
b: $\Delta^{7,9(11)}$

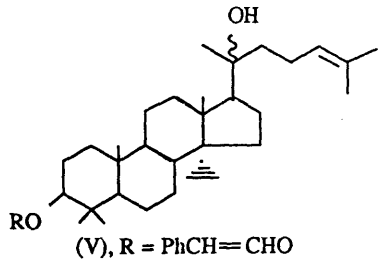
(III)



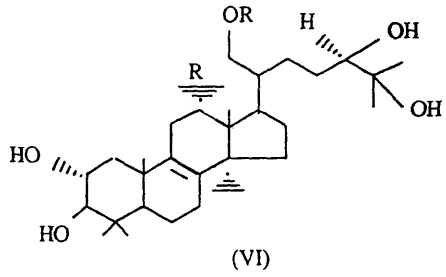
(IV) inotodiol

The 22- and 24-hydroxy derivatives were isolated from the fungus *Inonotus obliquus* and plant *Euphorbius corollatta*,15,16 and the most interesting of these is (22*R*)-hydroxylanosterol (IV)—the so-called inotodiol—a compound which is highly active towards cancer cells grown *in vitro*. It inhibits the growth of sarcoma 180 and carcinoma 755.[17] The 22-hydroxylanosterin derivative with a 4-carboxyl group, which is similar in structure to inotodiol, was isolated from the fungus *Fomes senex*.[18] 25-Hydroxylanosterol was isolated by Japanese researchers.[19] Lanostane with a shortened 22-hydroxy side chain has been isolated from the fungus *Verticillium lecanii*.[20]

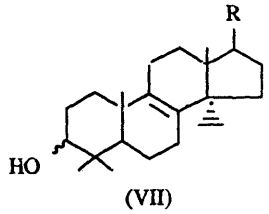
The Indian plant *Euphorbia antiquorum* L has proved to be a very abundant source of 20-hydroxylanosterol (V). Its gum has diuretic, laxative, and toxic properties.[21] It is used in stomatology, in the treatment of nervous disorders, and for treatment of wounds. In the isolation of the active principle, the cinnamic ester of 20-hydroxylanosterol (V), known as anticulol A, was obtained. Its mass spectrum did not exhibit a peak due to the molecular ion but a peak from the dehydrated form with *m/z* 556 occurred. The position of the 20-hydroxy group was confirmed by the ^{13}C NMR spectroscopic data (δ 75.4 ppm). In the PMR spectrum, in addition to the chemical shifts (δ) corresponding to the protons of cinnamic acid, signals from the 21-CH_3 group on C(20)—OH (δ 1.15 ppm) and from C(18)—CH_3 (0.98 ppm) were recorded. The skeletal structure of 8(9)-dihydrolanostane was confirmed by analysis of the ^{13}C and ^1H NMR spectra. Japanese scientists isolated 2α,3β,21,24,25-pentahydroxy derivatives of lanosterol (VI)—the so-called fasciculols, which are novel plant growth inhibitors—from the plant *Naemotoloma fasciculara*.[22] The 22,24-, 22,25-, and 22,23-dihydroxy derivatives of lanosterol (VIIa—d) were isolated from *Pisolithus tinctorius* fungi.[23] These compounds exhibited appreciable cytotoxic activity on hepatoma and tinoma cells *in vitro*. The structure of the side chains, in particular the position of the OH groups has been demonstrated by a combination of known phyiscal methods, including the nuclear Overhauser effect (NOE) and the formation of derivatives.



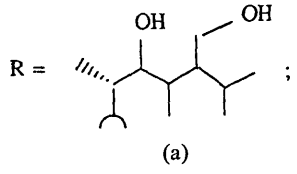
(V), R = PhCH=CHO



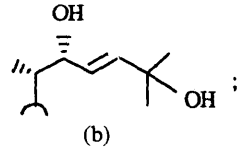
(VI)



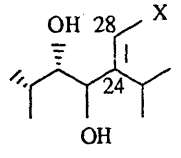
(VII)



(a)



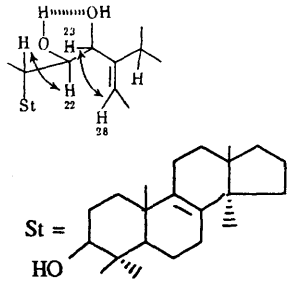
(b)



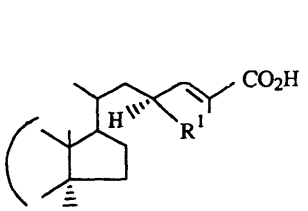
, X = H (c) CH_3 (d)

Thus, the presence of the C—CH=CX group (where X = CH_3) was confirmed from the signals at δ 1.47 ppm (3H, d, *J* 6 Hz) and δ 5.63 ppm (1H, q, *J* 6 Hz) while the secondary OH groups were identified from the multiplets at δ 3.98 ppm (1H, *J* 9 Hz) and δ 3.62 ppm (1H, *J* Hz) due to the protons attached to the carbon atoms bearing these OH groups. Their 22-acetates give chemical shifts at lower field (δ 5.2 and 4.2 ppm). The mass spectra were characterised by fragments corresponding to loss of a single proton from the side chain of the molecule, which indicates that all of the compounds differ only in the degree of substitution of the steroid side chain. The double bond in the side chain was confirmed by oxidation of glycol (VIId) to the 22-aldehyde and 3-methyl-2-methylenebutanal isolated as its dinitrophenylhydrazine derivative. The stereochemistry of the substituents in the side chain of the steroid was demonstrated by means of NOE experiments in the PMR spectra. Thus, a *Z*-configuration was assigned to the 24(28)-olefin because of the interaction of H(28) with H(22) and H(23) rather than with H(25).

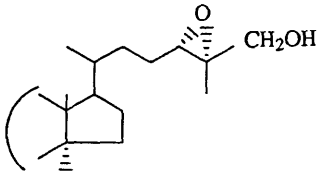
The existence of an intramolecular hydrogen bond was demonstrated.



Extracts from the fungal mycelium of *Ganoderma lucidum* proved extremely interesting in terms of their biological properties.[24] A pharmacological study demonstrated their effect on the cardiovascular system (decrease in blood pressure). Lanostane alcohols and acids—24,25,26-triols and 23-hydroxy-26-acids[25]—were isolated from the mycelium and fruit body of this fungus, and an (*S*)-configuration of the 23-centre was established for the latter by measurement of the Cotton effect (CE) of the 23-monodimethyl-*p*-aminobenzoate.



(VIII), R^1 = $OH, OCOC_6H_4NH_2$,

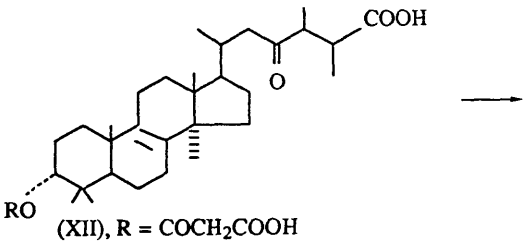


(IX)

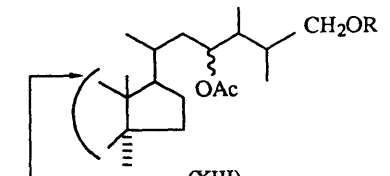
The 24,25-epoxy derivative of the 26-alcohol (IX) was isolated from the same fungus,[26] and the configuration of its oxide ring was established from NOE data and by a method described by Dillon and Nakanishi,[27] which involved the reduction of the α-epoxide with lithium aluminium hydride and determination of the sign of the Cotton effect in the circular dichroism spectrum in the presence of $Pr(dpm)_3$ according to the empirical rule of Nakanishi.[27]

The 21-carboxy derivatives of lanosterol (X), known as trametenolic acids, were isolated by several groups of scientists[28,29] from *Polyporaceae Fomes Hartigii* Allescher fungi; some of these were subsequently called eburicoic acids.[4] The lanosta-7(8),9(11),24-triene-21-acid[30] and lanosta-17(20),24-diene-21-acid substituted at C(6), C(7), and C(11) [31] were also isolated. The 26-acids, so-called polyporenic acids (XI), occur widely in nature.[4] The novel 23-keto-26-acid (XII), known as carboxaquercinic acid, was isolated as its 3-malonate from fungal metabolites of *Daedalea quercina*.[32]

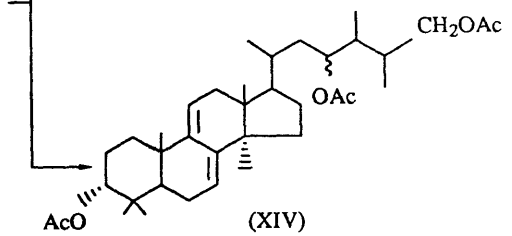
Its structure was demonstrated by a combination of PMR and mass spectrometry data as well as by chemical conversions to the dihydroxy derivatives (XIII) and (XIV).



(XII), R = $COCH_2COOH$

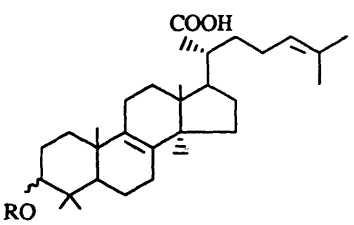


(XIII)

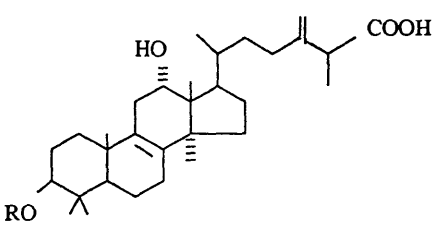


(XIV)

Lanostane 26-acids differing in the configuration of substituents at C(3) have been isolated from Chinese[33] and Mexican[34] plants. A large group of triterpenoids isolated from the fungal mycelium of *Ganoderma lucidum* was made up by 26-acids with a functionalised lanostane skeleton (XV).[35] The useful biological properties of the "ganoderic" acids, in particular their cytotoxicity towards hepatoma cells[36–40] acted as a stimulus for detailed studies on the extracts from fungi used in Chinese, Indian, and Korean popular medicine as anodynes. To date more than 30 studies[35] in which the isolation of ganoderic and ganoderenic acids (labelled with the letters of the alphabet from A to T) is reported to have been published. They have been isolated from a chloroform–ethanol extract by chromatography on silica gel columns. In some cases separation is more effective after conversion of the acid mixtures to their methyl esters. Ganoderic acids differ in the degree of oxidation of the side chain. Thus, the distinctive group fo the 23-keto-26-acid[40,43] and 22-hydroxy-26-acid[40] has been detected. The $\Delta^{20(22)}$-23-keto-26-acid (XV) and 20-hydroxy-23-keto-26-acid (XVI) with the same

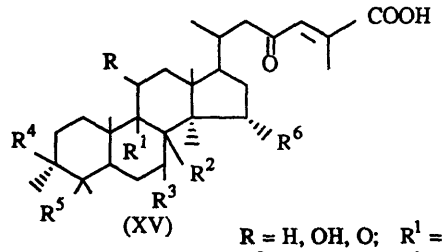


3α– or 3β–(X)



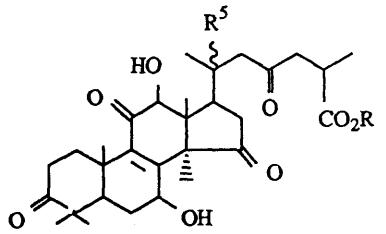
(XI)

functionality in the skeleton, known as ganoderenic acids[44,45] and 21,26-acids,[46] have been isolated from *Ganoderma lucidum* Karst. The amide of the 26-acid (XVII) has also been isolated.[47]

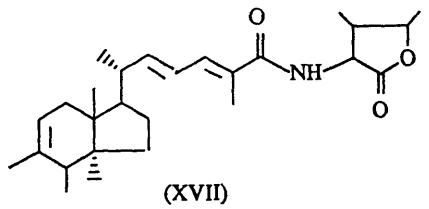


(XV)

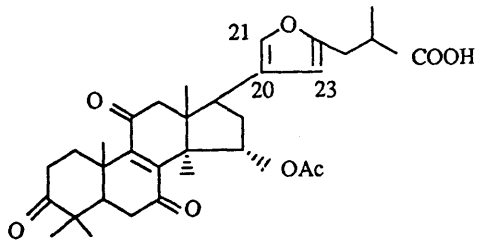
R = H, OH, O; R^1 = H; R^1, R^2 = Δ; R^3 = H, α-OH; R^4, R^5 = O; R^4 = OH; R^5 = H, OH; R^6 = H, OH.



(XVI), R^5 = H, OH; $\Delta^{20(22)}$



(XVII)

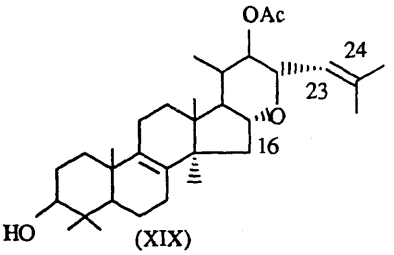


(XVIII)

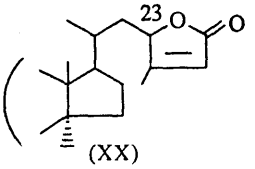
The furanoganoderic acid (XVIII) was isolated by Nishitoba et al.[35] The identification and structural assignment of ganoderic acids was based on an analysis of their ^{13}C and ^1H NMR spectra and the fragmentation in their mass spectra. A structural feature of their skeleton is the presence of the cross-conjugated 7,9(11)-diketo system, in some cases a 7β-hydroxy group and 3-carbonyl, and in certain instances a variable configuration of the 3-hydroxy group. It was noted by Lobo et al.[23] that the variation in the configuration of the substituent at C(3) in ganoderic acids is dependent on the source from which they are isolated — the fruit body of the fungus (3β-hydroxy) or from a culture of mycelium (3α-hydroxy). This finding is interesting in relation to the possible biosynthetic pathways of triterpenoids in *Ganoderma lucidum*. By studying the biosynthesis of ganoderic acids in a culture of mycelium using labelled squalene (1,2-^{13}C)-acetate, Tiasen and Meifen[33] found that ganoderic acid T, for example, is formed from (3*S*)-oxidosqualene via the 3-keto compound by the same route as that which occurs in higher plants with formation of the 3α-hydroxy substituent. All of the ganoderic acids have signals corresponding to the 4,4,14,18,19-CH_3 groups. The presence of double bonds is reflected in the appearance of signals from olefinic protons in the region of 5–6 ppm. Conjugated keto groups are demonstrated by the absorption in the UV spectra. In some cases the presence of a double bond in the molecule of a natural acid can be confirmed by ozonisation and identification of the resulting products. The configuration of the hydroxide at C(3) is determined from the PMR spectroscopic data; 3β-OH appears as two doublets at δ 3.5 ppm with *J* 10.5 Hz while 3α-OH has a lower spin–spin coupling constant. In the PMR spectrum of furanoganoderic acid (XVIII) there was no signal at 2.2 ppm due to a 21-CH_3 group but two signals due to olefinic protons appeared as singlets at δ 6.90 and 5.77 ppm. From these data together with the signals in the ^{13}C NMR spectrum at δ 107.7 and 138.4 ppm (from two methine olefinic carbons) and δ 153.2, 153.6, 150.9, and 124.9 ppm (from four tertiary olefinic carbons), De Bernardi et al.[53] could establish the presence of a 2,4-substituted furan ring in the side chain of this novel ganoderic acid. The structure of furanoganoderic acid — 21,23-epoxy-15α-hydroxy-3,7,11-triketo-5α-lanosta-8,20(21),22-trien-26-oic acid (XVIII) — corresponds to its biogenesis.

2. Natural lanosterol derivatives with lactone, lactol, and furan rings in the side chain

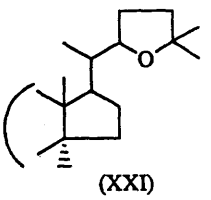
Compounds with a lanostane skeleton and a heterocyclic structure in their side chains have been found amongst natural polyhydroxytriterpenoids.[18,48–51] It has been argued, however, that they may be secondary products formed during isolation as a result of the condensation of hydroxy and keto acids.[32] Echinodol (XIX) [49] and abieslactone (XX) [51] are amongst such compounds. Echinodol was isolated from *Echinodontium tsugicola*[52] fungi and from plants having anticancer activity. The structure of (XIX) was demonstrated by a sequence of reactions, including dehydration, acid hydrolysis, Jones oxidation, and Wolff–Kishner reduction, giving lanosterol, and it was also supported by the PMR spectroscopic data.[52] The structure of abieslactone (XX) was established by X-ray diffraction analysis. It is (23*R*)-3α-methoxy-5α,9β-lanosta-7,24-dien-23,26-olide. Senexenol (XXI) isolated from *Fomes senex* fungi contains a 22,25-tetrahydrofuran residue.[18]



(XIX)



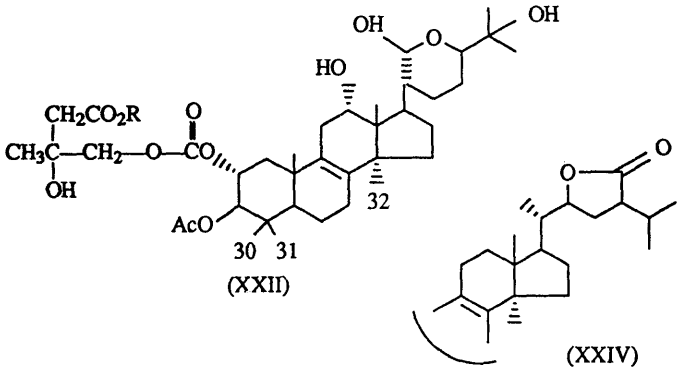
(XX)



(XXI)

3β-Acetyl-2α-(3′-hydroxy-3′-methyl)glutarylcrustulinol (XXII), which is active against leukaemia, was isolated from *Hebeloma species* fungi.[53] The molecular structure of (XXII) was determined

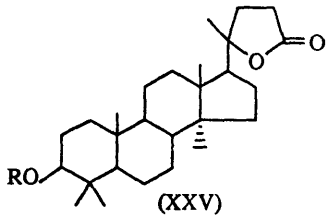
from its ^{13}C NMR data. The three acetyl carbons give signals in the region of δ 170–174 ppm; the methines attached to two oxygen atoms appear at δ 93.2 and 5.48 ppm. The tetrasubstituted 8(9)-double bond gives signals at δ 135.8 and 132.7 ppm. Oxidation of the hemiacetal (XXII) with Fetizon reagent—silver acetate on Celite—gave a δ-lactone (XXIII). The conformation of the tetrahydropyran ring in (XXII) existing in the boat form was established from PMR spectroscopic data. The anomeric OH group and isopropyl group have a pseudoaxial conformation. The γ-lactone (XXIV), which is similar in structure to hemiacetal (XXII), was isolated from the fungus *Pisolithus*,[23] and it also exhibited appreciable cytotoxic activity. Lobo et al.[54] noted that this was the first natural example of a triterpene carboxylic acid derivative. Its structure was demonstrated by elemental analysis and the data of NMR and mass spectrometry. Thus, 4 signals (δ 0.72, 0.97, 0.81, and 0.88 ppm) are attributed to those from the CH_3 groups at C(18), C(19), C(30), and C(31). The groups at C(21), C(26), and C(27) appear as singlets at δ 1.66, 1.02, and 0.94 ppm. The mass spectrum is characterised by a fragment with *m/z* 155 ($C_9H_{15}O_2$), which corresponds to cleavage between the steroid skeleton and side chain. The structure and configuration of (XXIV) was confirmed conclusively by X-ray diffraction analysis.



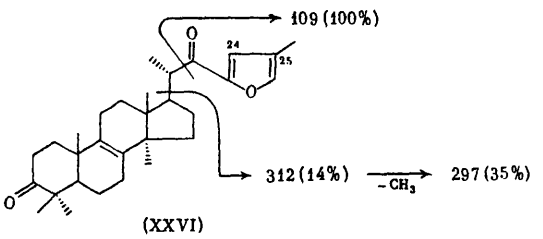
(XXII) (XXIV)

A γ-lactone on C(20) of the side chain of lanostane was isolated[55] from the leaves of the Indian plant *Lansium* qn Bedd and was given the name lansilactone. The structure of (XXV) was established from its ^{13}C and ^{1}H NMR data, and the point of attachment of the lactone ring was determined from the nature of fragmentation in the mass spectra.[55]

The novel furanoid triterpenoid pomacerone (XXVI) [56] was isolated from the fungus *Phellinus pomaceus*.

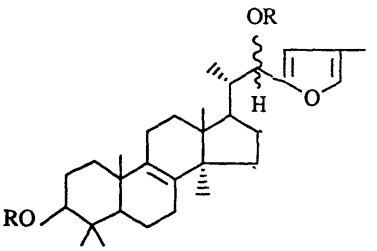


(XXV)

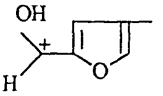


(XXVI)

The presence of a furan residue was confirmed from the absorption in the UV spectrum with λ_{max} at 234, 245, and 292 nm and by the absorptions in the IR spectrum at 1660 and 1600 cm^{-1}. The main fragment in the mass spectrum corresponds to cleavage of the C(20)–C(22) bond (*m/z* 109, 100%). The PMR spectrum of (XXVI) is characterised by signals due to the angular CH_3 groups at δ 0.81, 0.92, 1.05, 1.07, and 1.1 ppm and the one secondary CH_3 group as a doublet at δ 1.17 ppm, which is characteristic of a CH_3 group at C(21). The side chain exhibits the following signals: δ 2.07, 3.22 (1H dq., *J* 6.8, 10.5 Hz), 7.04 (1H, br. s.), and 7.35 (1H, br. s.), corresponding to the protons on C(27), C(20), C(24), and C(26). The signals that appear between δ 2.50 and 0.90 ppm correspond to the two methine protons and eight methylene protons (one of which is at an α-position relative to the carbonyl group at δ 2.45 ppm). With double resonance the symmetric quartet due to H(17) is converted to a triplet by irradiation on the H(20) nuclei at δ 3.22 ppm. This suggests that the coupling constant between H on C(16) and C(17) is of the same order as that between H on C(17) and C(20) and is consistent with the Karplus equation for structure (XXVI). At the same time the *J* values between the protons on C(20) and C(21) (6.8 Hz), C(24) and C(26) (9.9 Hz), C(16) and C(17) (10.0 Hz), C(17) and C(20) (10.5 Hz), and C(26) and C(27) (1.5 Hz) were determined. Thus, on the one hand, interaction between the protons on C(24), C(26), and C(27) is confirmed as is that between the proton on C(20) and the methine proton on H(17) and the protons on H(21), on the other hand. Compound (XXVI) was reduced with lithium aluminium hydride. The resulting 3,22-tetrahydropomacerone (XXVII) displayed signals in its PMR spectrum due to the furan protons at δ 6.10 and 7.15 ppm and at δ 3.20 and 4.72 ppm from the H(3) and H(22) protons that are geminal relative to both OH groups. These signals do not appear when lithium aluminium deuteride is used for reduction. Acetylation of derivative (XXVII) gave 3,22-diacetoxy-23,26-oxidolanosta-8(9),23,25-triene (XXVIII), in whose PMR spectrum the signals due to the H(24) and H(26) furan protons are shifted to δ 6.14 and 7.15 ppm while the signals from H(3) and H(22) occur at δ 4.55 and 5.84 ppm. The mass spectrum of (XXVIII) has a fragment with *m/z* 111 ($C_6H_7O_2$).



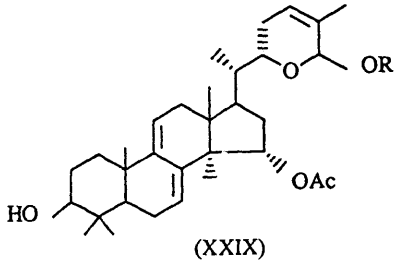
(XXVII), R = H;
(XXVIII), R = Ac



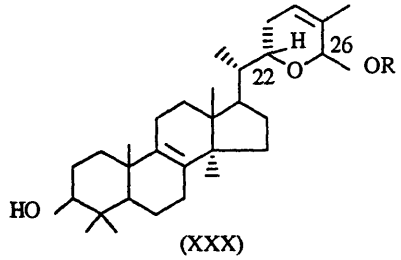
m/z 111

Triterpenoids with a six-membered hemiacetal residue in the side chain—the so-called perenniporiols—were first isolated from the mycelium of the higher fungi *Perennipria ochroleuca*. These compounds with the same structural characteristics as the group of nautral vitanolides[57–60] are of interest because of their high diverse biological activity. Vitanolides with a lanostane skeleton have been isolated in small quantities.[61,62] The structure and configuration of the diaxially interacting (22*S*,26*S*)-sites in (XXIX) have been established by comparision of the ^{13}C NMR spectroscopic data with the results of X-ray diffraction analysis, and the compound has been

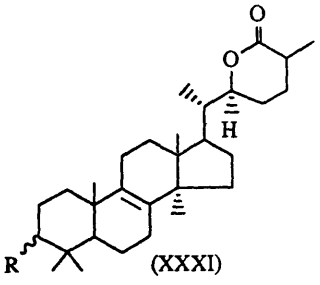
identified as (22*S*,26*S*)-15α-acetoxy-22,26-epoxy-3,26-dihydroxylanosta-7,9(11),24-triene (perenniporiol). The 15-desacetoxy-7,11-dihydroperenniporiol (XXX) was also isolated. The configuration of the lactol rings in both compounds was confirmed by comparison of the PMR spectroscopic data—the *J* values and position of the signals due to H(22) at δ 3.95 ppm (dd. *J* 12 and 2.5 Hz) and δ 5.16 ppm (d. *J* 4.9 Hz).



(XXIX)



(XXX)

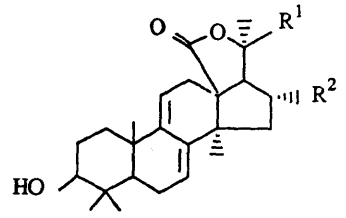


(XXXI)

R = α-H, β-OH (a)
β-H; α-OH (b)

The δ-lactone astrahygrol (XXXI), which has a similar structure, was isolated from the fruit body of the fungus *Astraeus hygrometricus* (Pers) Morgan (*Gasteromycetes*), familiar in Chinese popular medicine as a haemostatic agent.[62] The presence of two secondary and five tertiary CH_3 groups in the PMR spectrum of the molecule of (XXXI) provided support for a lanostane skeleton, and the fragment with *m*/*z* 314, corresponding to loss of the side chain from the molecular ion in the mass spectrum confirmed the presence of a δ-lactone ring in the side chain. The ^{13}C NMR data attested to the presence of a double bond between rings. The structure of the side chain as a δ-lactone was also clearly demonstrated by the respective signals in the PMR spectrum—a single-proton doublet of doublets at δ 4.3 ppm with *J* 11.6 and 3.0 Hz due to the proton on C(22) proton, a single-proton doublet of quartets at δ 2.61 ppm with *J* 10 and 7 Hz due to H(25), and a single-proton doublet at δ 0.99 ppm with *J* 6.3 Hz due to H(21).

Triterpenoids with a 18,20-γ-lactone ring and a double bond at the 8(9)-position or double bonds at the 7(8)- and 9(11)-positions have been isolated from sea cucumbers (holothurians) as glycosides and consequently have been called holothurigenins or seychellogenins. In some cases they contain oxygen substituents at C(16), C(23), and other positions.[7,63–67] These compounds act as powerful growth inhibitors of pathogenic fungi and have significant carcinostatic activity.



(XXXII)

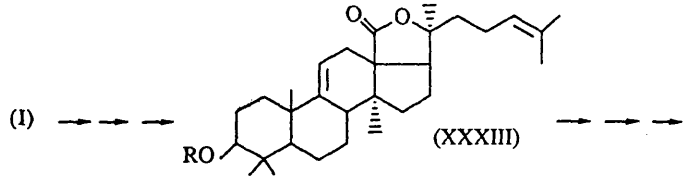
R^1 =  , R^2 = H, 17-desoxy-22,25-oxidoholothurinogenin;

R^1 =  , R^2 = OH, griseogenin;

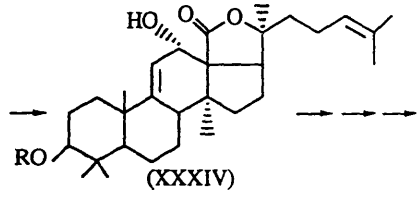
R^1 =  , R^2 = OH 22,25-oxidoholothurinogenin;

R^1 =  , R^2 = H seychellogenin

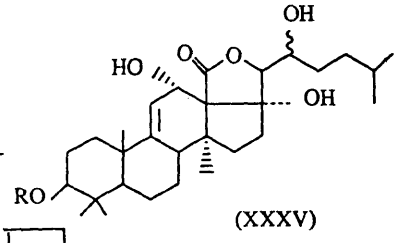
It is assumed that holothurinogenins are formed as a result of bioconversions involving the oxidation of lanosterol according to the scheme shown below. In the majority of cases the 8(9)-double bond of the precursors migrates to the 7(8)-position. Subsequent hydroxylation, acetylation, and saturation of the 24(25)-double bond gives a compound with the general formula (XXXIII). Oxidation of the side chain leads to derivatives (XXXIV)–(XXXVI), etc.



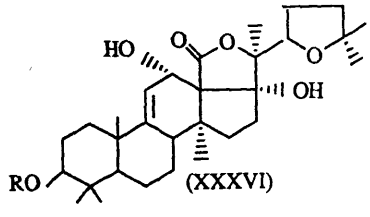
(XXXIII)



(XXXIV)



(XXXV)



(XXXVI)

Thus, it can be seen that natural sources provide a substantial number of compounds that are functionalised both on the lanostane skeleton and in the side chain of the molecule. The existing, generally fragmentary data on their biological activity, in particular on the medicinal properties of the plants and fungi containing these compounds that are frequently used in popular medicine, especially in countries of the East, suggest the possibility of finding interesting and promising drugs amongst them and their analogues. However, the "active principles" are present in extremely small quantities and sometimes undergo unwanted conversions during isolation. Therefore, the synthesis of these complex structures and their biological study have been and remain an important task.

III. Synthetic approaches to lanostane derivatives with a functionally substituted side chain

One of the possible courses in the modification of lanosterol aimed at yielding biologically active derivatives is the introduction of oxygen-containing substituents into the side chain. There are a number of examples in the literature on this type of approach.

The introduction of oxygen substituents into the lanosterol molecule has been carried out without disruption of the C(18)-side chain using the existing 24(25)-double bond of 3β-hydroxylanosta-8,24-diene (I). An alternative route is degradation of the side chain to C_2-C_4 and its reconstruction.

1. Partial conversions of the side chain of lanosterol

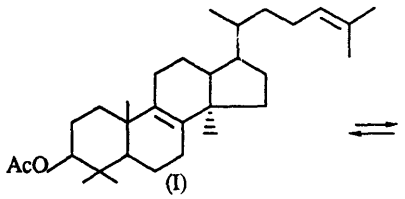
Oxidised sterols are potential inhibitors of the demethylation of lanosterol to cholesterol. It has been proposed that lanosterol derivatives with an oxidised side chain may be converted to metabolites that have the ability to inhibit the biosynthesis of cholesterol.[5,68] In order to study this problem, mono- and poly-oxidised derivatives of lanostane—22ξ-hydroxy-, 24-hydroxy-, 25-hydroxy-, and 26-hydroxy-lanosterols were synthesised and the following series of decreasing activity was drawn up: 26-hydroxy- > 25-hydroxy- > (24*R*)- and (24*S*)-hydroxy-24,25-dihydrolanosterol > (22*R*)- and (22*S*)-hydroxylanosterol.[5,68]

The synthesis of 25-alcohols is the simplest to carry out.[69] Several methods, such as direct hydration of the Δ^{24}-bond and the use of an intermediate 24,25-epoxide, have been developed.

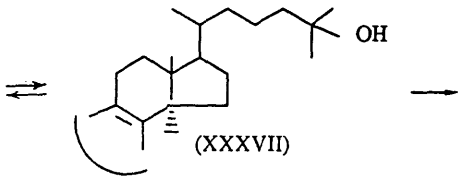
Hydration of the Δ^{24}-bond leading to 25-hydroxydihydrolanosterol was used by Rodewald and Jagodzinski[70–74] as a method for the synthesis of 25-alcohols and for selective protection of this bond for the isolation of analytically pure lanosterol from a mixture also containing dihydrolanoserol and dihydroagnosterol in a commercial product.

In fact, all methods for the isolation of pure lanosterol that were developed in the 1960s involve the selective addition of bromine to the side chain, crystallisation of the mxiture of bromides, and reduction of the resulting 24ξ,25-dibromo derivative with zinc in acetic acid to the 24-ene. These yield the required starting material in low yield. A method for selective hydration using a hydroxymercuration—demercuration reaction has been proposed. For this purpose a mixture was treated with mercuric acetate in a water–THF mixture[70] and the resulting organomercury compound was reduced with sodium borohydride. Separation on a silica gel column gave the analytically pure 25-alcohol (XXXVII) in quantitative yield. The Δ^{24}-bond may be regenerated as required by refluxing in a mixture of acetic anhydride and acetic acid. Thus, the total yield of pure 8,24-diene is more than 70% based on the commercial product. The same 25-alcohol (XXXVII) was obtained by low-temperature epoxidation of the Δ^{24}-bond, reduction with lithium aluminium hydride, and acetylation of the 3β-hydroxy group.

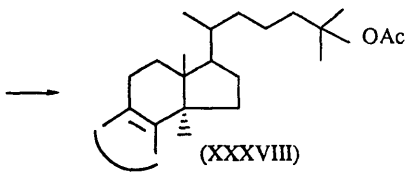
25-Hydroxylanosterol is itself of interest as a possible precursor of vitamin D analogue. The use of 25-hydroxylation as a means of protecting the double bond was investigated in the oxidation of the 8(9)-double bond of lanosterol to give seco derivatives.[71] It was shown that the alcohol is stable during oxidation with chromium trioxide and during alkali treatment. However, under acidic conditions dehydration in the side chain occurs. In order to prevent the occurrence of side reactions, the 25-hydroxy group in (XXXVIII) is acetylated with isoprenyl acetate. The 25-acetate is stable towards elimination in an acid medium.



(I)



(XXXVII)

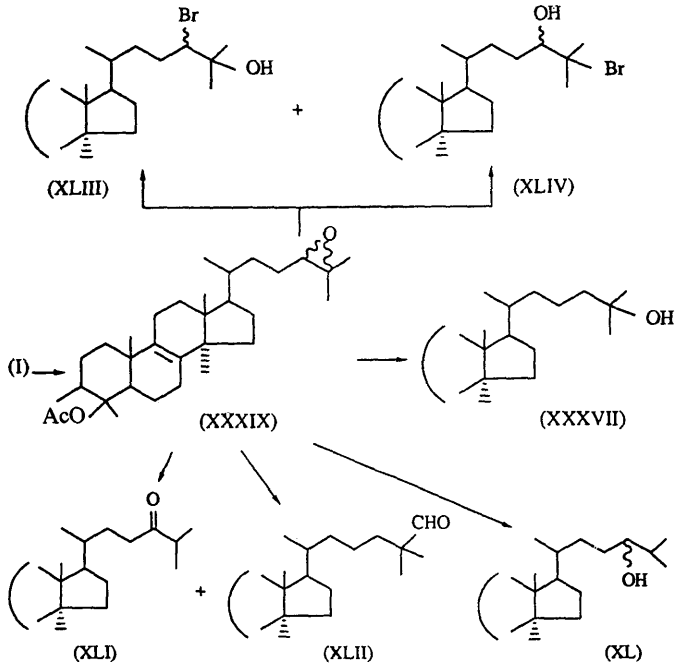


(XXXVIII)

The 25-alcohol is also formed on opening of the 24,25-epoxide (XXXIX) with HBr followed by removal of bromine. The absolute configuration of 24ξ,25-epoxylanostanes was established by converting them to the corresponding 24ξ-alcohols (XL) through reduction with diborane oxide and sodium borohydride, without affecting the C(24)–O bond. The configuration of the 24-alcohols was established by the method of Horeau.[75,76]

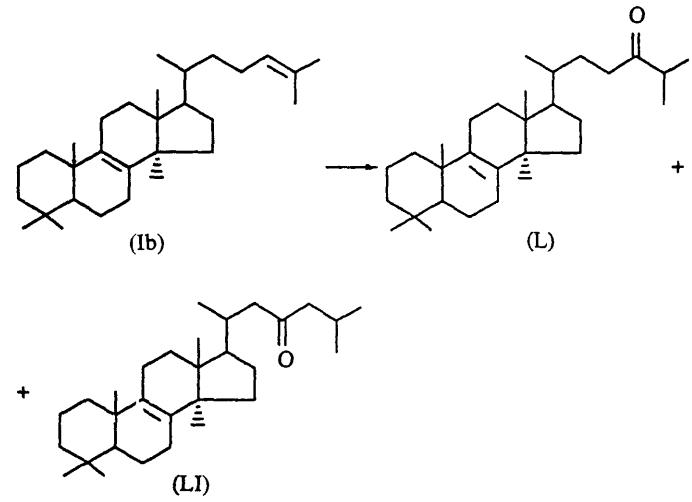
24-Hydroxy derivatives may also be obtained by isomerisation of the 24,25-epoxide on treatment with boron trifluoride etherate followed by reduction of the corresponding ketone (XLI).[77] However, in this reaction isomerisation of the oxide (XXXIX) to the

24-aldehyde (XLII) occurs together with formation of the 24-ketone (XLI).[77,78]

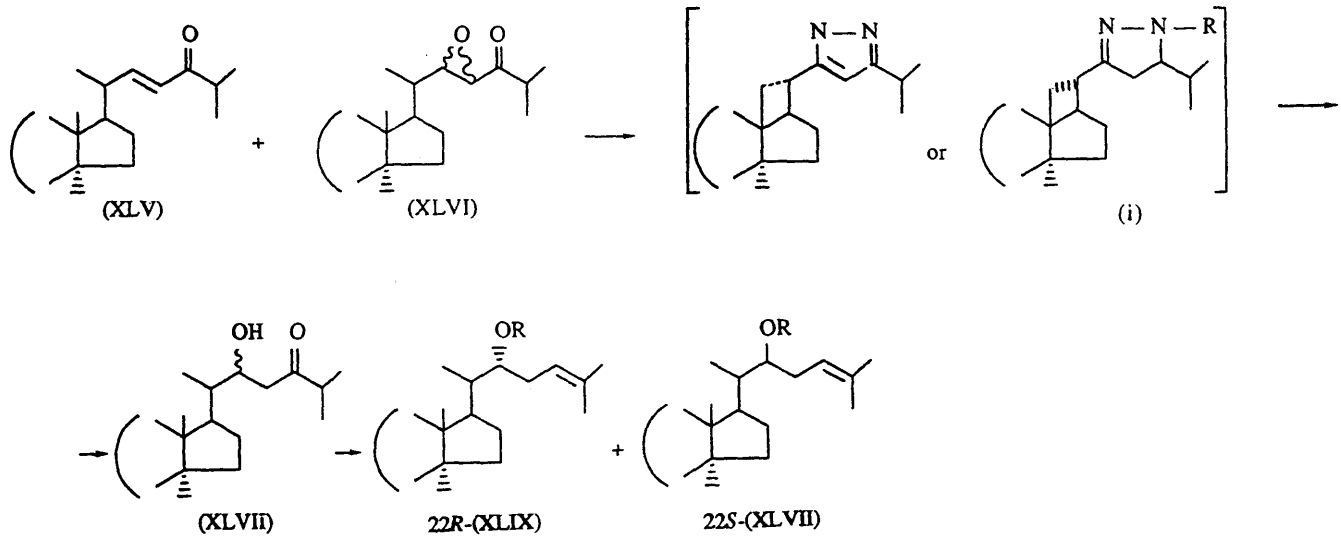


On dehydrogenation of the 24-ketone (XLI) using selenium dioxide,[77] the α,β-unsaturated 24-ketone (XLV) was obtained, albeit in low yield. It was epoxidised with hydrogen peroxide in an alkaline medium. The resulting predominant isomer of the 22,23-epoxyketone (XLVI), gave an intermediate of the type (i) when a Wolff–Kishner reduction was attempted, and this was then converted by decomposition of the diimide with alkali to give a mixture of C(22)-isomers of 22-hydroxy-24-ketosteroids (XLVII). Subsequent acetylation, reduction of the 24-keto group with sodium borohydride, dehydration on treatment with $POCl_3$, and hydrolysis gave (22*S*)- and (22*R*)-hydroxylanosterols (XLVIII) and (XLIX) in the ratio 2:1.[79]

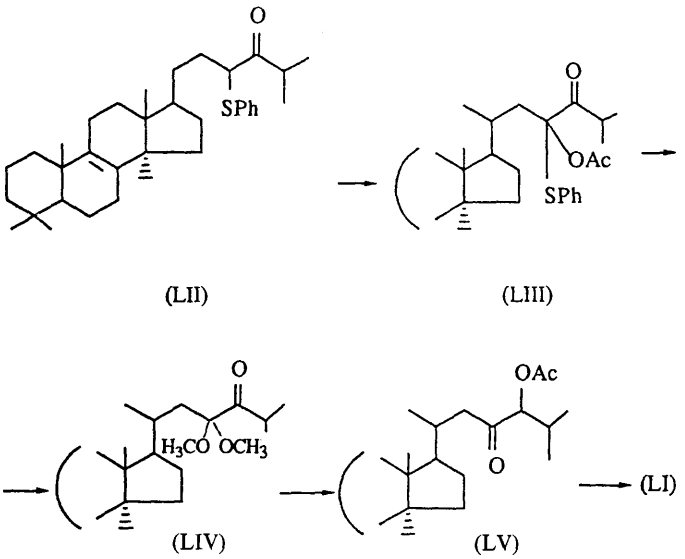
The 24-ketone of 3-desoxylanostane (L) was synthesised by Yamashita et al.[80] by hydroboration of the Δ^{24}-bond followed by oxidation of the resulting 24-alcohol. The authors found that, depending on the reaction conditions (hydroboration directly with diborane or with sodium borohydride in the presence of boron trifluoride etherate), very small quantities of the 23-derivative (LI) were formed together with the expected product. The mechanism of formation of 23-ketodihydro-3-desoxylanosterol (LI) is not clear; it was assumed to be a rearrangement product and it was detected using high-resolution liquid chromatography.



The presence of additional methyl groups at C(4) and C(14) in the lanostane skeleton compared to steroids results in a considerable steric effect on the reactivity of the α-carbon atoms relative to the 24-ketone in the side chain. The difficulty in enolisation at the C(23) position and its preferred route on C(25) has been attributed to this.[81] Numerous attempts to functionalise the 23-position of 24-keto-3-desoxylanostane proved unsuccessful. Regioselective sulphenylation at C(23) was achieved[82] in the case of the 24-ketolanostane (L) only under kinetically controlled conditions by the addition of (L), lithium isopropylamide, hexametapol, and THF



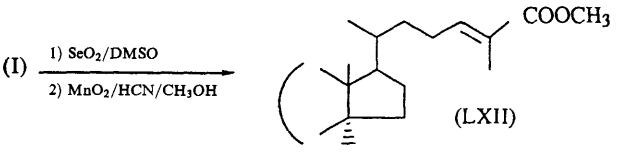
at −78 °C to a solution of diphenyl disulphide. The key sulphur-containing compound (LII) after treatment with lead tetraacetate was converted to a mixture of diastereomers at C(23) (LIII). Subsequent treatment with methanol and iodine gave the 23-dimethylacetal (LIV), and reduction of the 24-carbonyl group, removal of the acetal protecting group, and acetylation yielded the 24-acetoxy-23-ketone (LV). Hydrogenolysis of the 24-acetate using calcium in liquid ammonia gave the 23-ketolanostane (LI).



The successive introduction of hydroxy groups into the C(8)-side chain of lanosterol to obtain 26-hydroxy and 24,25,26-trihydroxy derivatives has been reported by Sato et al.[77,83] The 26-alcohol (LVI) was obtained by the allylic oxidation of lanosterol with selenium dioxide. Epoxidation of its acetoxy derivative (LVII) with peroxyacetic acid in the presence of concentrated sulphuric acid[84] gave the 24ξ,26-diacetoxy-25ξ-hydroxy derivative (LVIII), and hydrolysis of its acetoxy groups led to the formation of 24ξ,25ξ,26-trihydroxylanosterol (LIX). 24ξ,25-dihydroxylanosterol (LX) was obtained by reduction fo the 25-hydroxy-24-ketone (LXI) with sodium borohydride. The latter ketone was detected[77] amongst the products of the oxidation of lanosterol with the oxide system $KMnO_4-NaIO_4$. These polyoxidised lanosterol derivatives exhibited considerable anticholesterolemic activity.

The vicinal 24,25-diol (LX) is a convenient starting compound for the preparation of the 24-aldehyde, which is used to extend the side chain by the Wittig reaction.[85]

By applying more severe conditions in the allylic oxidation of lanosterol it is possible to obtain 26-acids of the polyporenic type (LXII).[4]



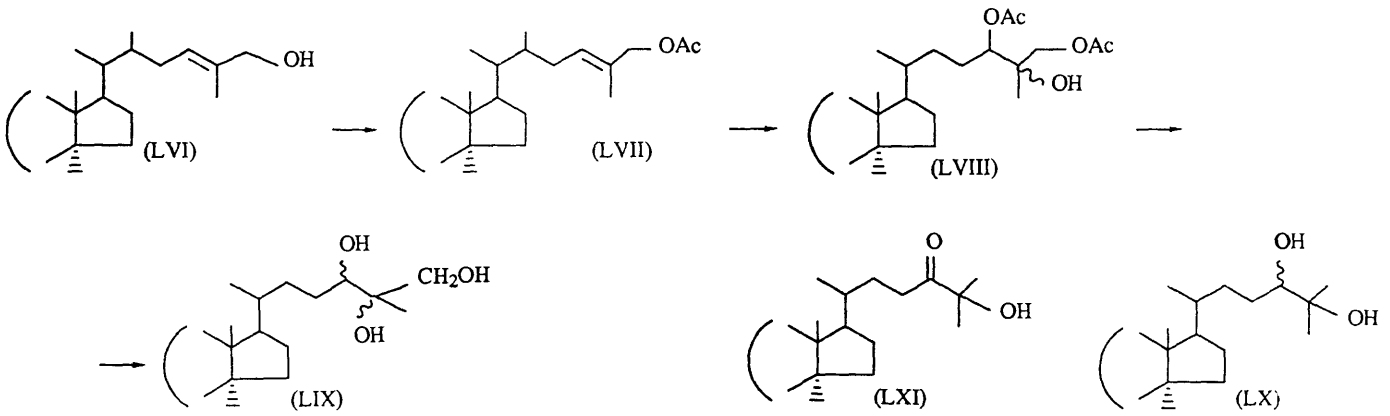
2. Chemical methods for degradation of the side chain of lanosterol

All the methods described in the literature for degradation of the side chain of lanosterol are essentially based on preparation of key 17(20)-, 20(22)-, and 22(23)-olefins. Their successive epoxidation, hydroxylation or direct ozonisation can give the required or intermediate epoxides, aldehydes or ketones (with a shortened side chain).

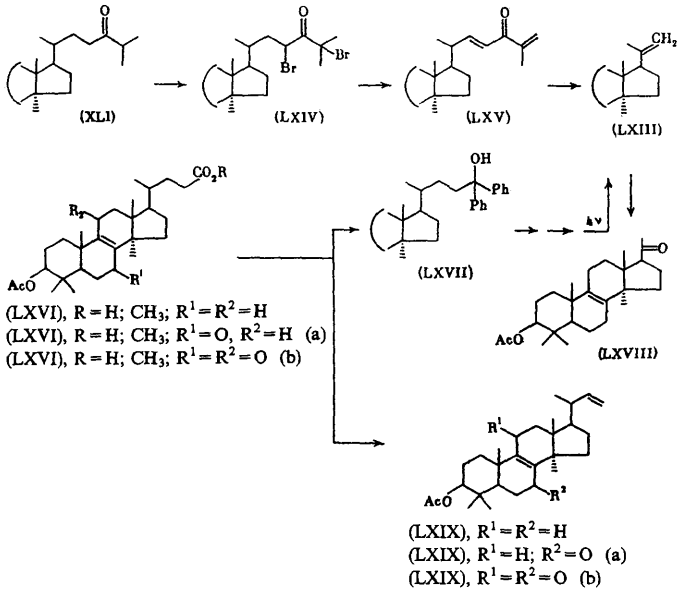
It should be noted straight away that degradation of the side chain of 3β-hydroxylanosta-8,24-diene is not always simple since by-products that are highly oxidised in the skeleton are often formed.

Several schemes for degradation of the side chain of lanosterol using chemical methods have been developed. These are all generally multistage processes and differ in the number of stages and chosen sequence of reactions, and the yields are low.

Thus, three main methods for the preparation of the 20(22)-olefin (LXIII) have been reported. The first (with the greatest number of stages and the least effective)[78] involves the bromination of the above-mentioned 24-ketolanosterol (XLI) to the dibromide (LXIV), its dehydrobromination, and subsequent irradiation. Another scheme[87] involves cleavage of the Δ^{24}-bond in lanosterol to the 24-acid (LXVI). Conversion of (LXVI) with phenylmagnesium bromide to the tertiary alcohol (LXVII), its subsequent isomerisation, and irradiation of the keto derivative afford (LXIII). The third,[88] most effective method of preparing the 20(22)-olefin (LXIII) involves the treatment of the 24-acid (LXVI) with carbonyldiimidazole followed by irradiation at λ_{max} 220 nm.[89]



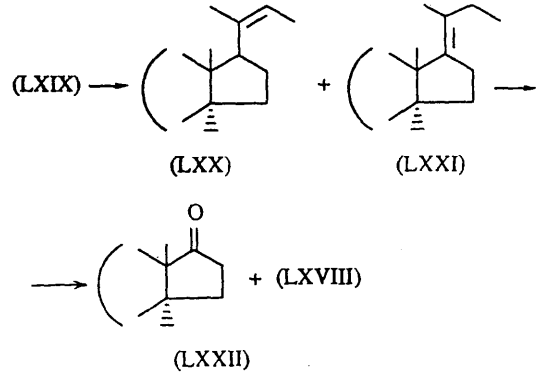
Hydroxylation of olefin (LXIII) accompanied by oxidation with periodic acid, gives the pregnenolone analogue (LXVIII) with a lanostane skeleton.[87]



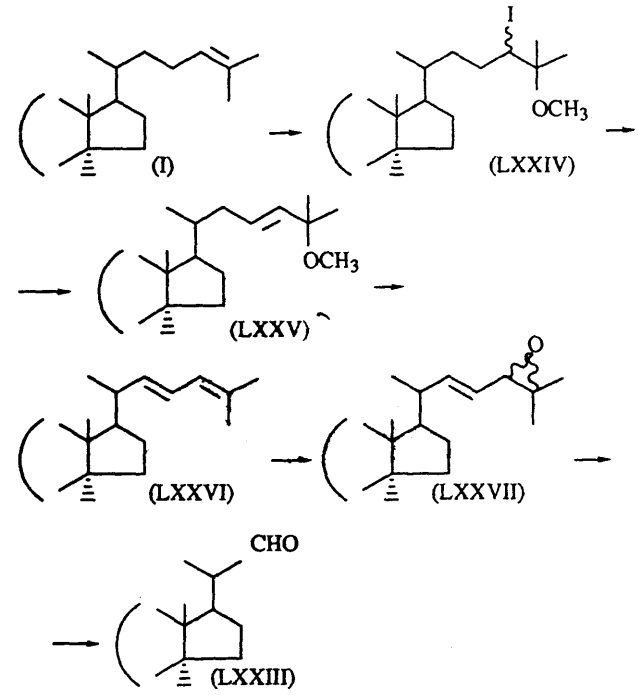
Key lanostane olefins with the double bond at a position other than 20(22) have been obtained by decarboxylation of the 24-acids. It was shown by Reshetova et al.[90] that the Δ^8-7-keto acid (LXVIa) and Δ^8-7,11-diketo acid (LXVIb) were formed in addition to the Δ^8-acid (LXVI) on oxidation of lanosterol by the method of Lumé–von Rudolf. Decarboxylation of these keto acids gave 24,25,26,27-tetranor-Δ^8-7-keto- and 24,25,26,27-tetranor-Δ^8-7,11-diketo-lanosta-8,22(23)-dienes (LXIX)–(LXIXb), which act as intermediates in the stereospecific introduction of oxygen functions into the lanosterol molecule.[91]

In two studies[77,92] the initially formed terminal 22(23)-olefin (LXIX) was isomerised on treatment with lithium in ethylenediamine to the 20(22)-olefin (LXX) and 17(20)-olefin (LXXI).

In most studies all of the olefins described were primarily used for preparing 17- or 20-ketolanostanes or aldehydes. However, ozonisation generally has low selectivity and gives mixtures of highly oxidised analogues of 17-ketones, 17-acids, etc.[77,92]



A more effective method than that of Sato and Sonoda[77] was degradation of the side chain of lanosterol to obtain the 22-aldehyde (LXXIII) by means of the electrophilic addition of methoxyiodide to the Δ^{24}-bond.[93] The subsequent elimination of hydriodic acid from (LXXIV) using potassium t-butoxide accompanied by the elimination of methanol on treatment with acetyl chloride and sodium iodide in a mixture of acetonitrile and methylene dichloride resulted in the formation of the 22,24-diene (LXXVI).[94] In a study of the ozonisation of this diene it was shown that both the C(22)- and C(24)-aldehydes are formed, with the latter in slight excess. Further ozonisation of the 24-aldehyde does not give the required 22-aldehyde. Consequently, the regioselective epoxidation of diene (LXXVI) was carried out with a complex of *m*-chloroperoxybenzoic acid and KF, which gave the 24,25ξ-monoepoxide (LXXVII). Ozonisation of the epoxyene (LXXVII) gave the 22-aldehyde (LXXIII) in high yield (~60%).



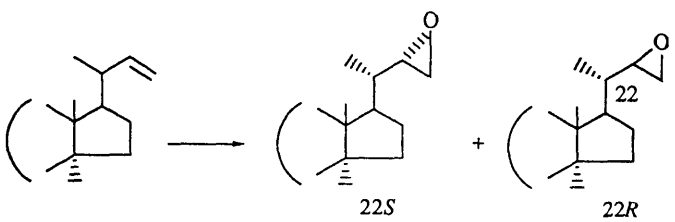
The lanostane derivatives with C_2- and C_3-side chains that are synthesised in this manner have been used in many studies in nucleophilic addition reactions to create novel polyfunctional lanosterol analogues.

3. Formation of oxygen-containing side chains in lanosterol

Many methods have been developed for the stereospecific building of polyfunctional side chains in steroid compounds.[95] However, as demonstrated in compounds simulating the *C/D* rings of lanostane,[96] these cannot be directly transferred and adapted to triterpenoids and 14α-methylsteroids, especially in those cases where the reactions occur in the vicinity of ring *D*, where the α-region is equally or more hindered than the β-region of the molecule. That is probably the reason for the comparatively small number of studies on building up the side chains. There are virtually no studies on the construction of side chains on 17-ketolanostanes

Methods for building the side chains of triterpenoids have been developed with terminal olefins[97] of the type (LXIX) and (LXIII), formed by decarboxylation of 24-acids (as described above), 20-ketones,[98] 22-aldehydes,[9,97] and 24-aldehydes[85,99] as starting materials.

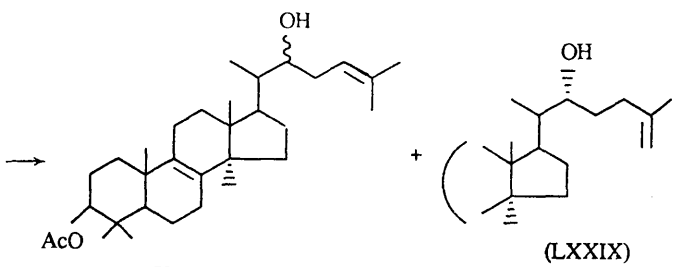
The strategy of Poyser et al.[97] for using 22,23-olefins involved their conversion to the corresponding epoxides and including the latter in a Grignard reaction with a suitable alkyl halide. However, it was demonstrated right at the beginning in studies on this route[97] that epoxidation with peroxyacids under normal conditions usually has an effect on the intraring 8(9)-double bond, with the result that a whole range of reaction by-products is formed. Therefore, the preparation of 22,23-epoxides (LXXVIII) was carried out via bromohydrins followed by dehydrobromination. This procedure, however, gave a mixture of isomeric (22*S*)- and (22*R*)-epoxides.



(LXIX) 22*S* (LXXVIII) 22*R*

Hence a Grignard reaction with isobutenylmagnesium bromide gave a mixture of (22*S*)- and (22*R*)-22-hydroxylanosterols (XLVIII) and (XLIX) that was difficult to separate. Furthermore, the terminal olefin (LXXIX) — a product of isomerisation of the double bond during reaction — was formed. An attempt to oxidise the mixture of 22-alcohols to the ketone followed by reduction with lithium aluminium hydride did not have favourable results.[97]

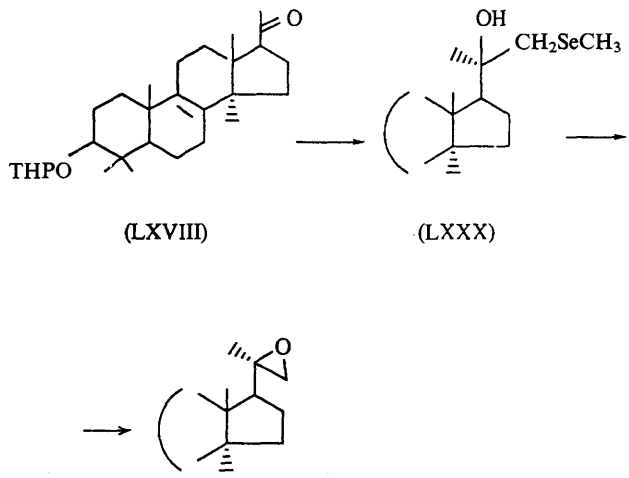
(LXXVIII) →



(XLVIII) + (XLIX) (LXXIX)

Epoxides are known to react with organomagnesium reagents in different ways. Depending on the nature of the reagents and the reaction conditions they give alcohols formed by nucleophilic ring opening (with no change in configuration, as described above) or rearranged alcohols formed by attack of the reagent on an aldehyde intermediate.

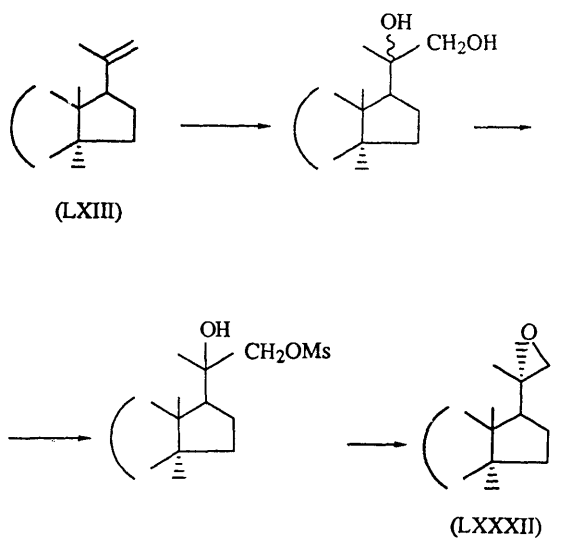
Thus, 22-hydroxy-substituted lanosterols may be obtained from 22-aldehydes that are formed, as we have described above, from a 20(22) olefin or during rearrangement of 20(22)-oxides. At the same time the conditions for stereospecific formation of a chiral centre at C(20) can be selected. The problem of stereoselective synthesis of lanostane 20(22)(*R*)- and (*S*)-epoxides was solved by Schauder and Krief[98] through the use of the reaction of 3-tetrahydropyranyloxy-20-ketolanostane (LXVIII) with methylselenomethyllithium. The resulting 20-alcohol (LXXX) on treatment with base gave the (20*R*)-epoxide (LXXXI) in 60% yield.



(LXVIII) (LXXX)

(LXXXI)

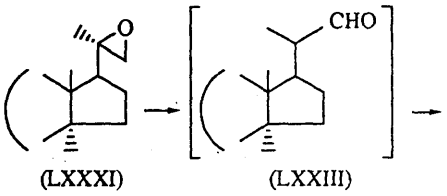
At the same time the (20*S*)-epoxide (LXXXII) was obtained from the 20(22)-olefin (LXIII) by hydroxylation of the latter with osmium tetroxide, mesylation of the 22-hydroxy group, and elimination of methanesulphonic acid on treatment with alkali:



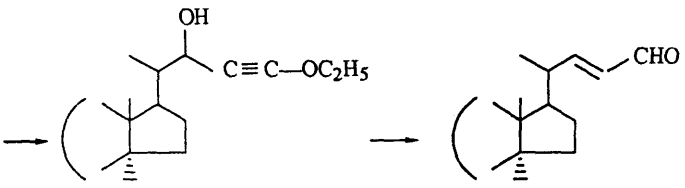
(LXIII) (LXXXII)

Schauder and Krief[98] made a detailed study of the synthesis of 22-alcohols that was stereoselective with respect to C(20) by varying the conditions of a Grignard reaction with ethoxyethynylmagnesium bromide. Moreover, this reagent was used instead of isobutenylmagnesium bromide so as to avoid the formation of regioisomeric by-products (with respect to the position of the double bond in the side chain). It was found that the solvent plays a decisive role in a controlled reaction of the magnesium salt with epoxides.

By conducting the reaction in ether at 20 °C, high yields of the acetylenic alcohol (LXXXIII) (via the 22-aldehyde) were achieved.



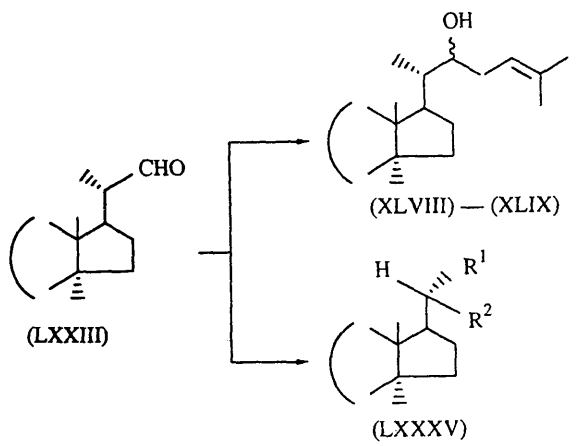
(LXXXI) (LXXIII)



(LXXXIII) (LXXXIV)

Reduction of the ynol ether (LXXXIII) with lithium aluminium hydride and subsequent acid hydrolysis of the resulting γ-hydroxy-enol ether gave the (*E*)-α,β-unsaturated aldehyde (LXXXIV), consisting mainly of the (20*R*)-isomer (98%), which is a precursor in the synthesis[98] of (20*R*)-lanosterol (after hydrogenation of the aldehyde and its Wittig reaction with isopropylidenetriphenylphosphorane). Schauder and Krief[98] obtained (20*S*)-lanosterol with the same sequence of reactions. This scheme appears to have realised its full potential in the synthesis of functional derivatives of (20*R*)- and (20*S*)-lanostane.

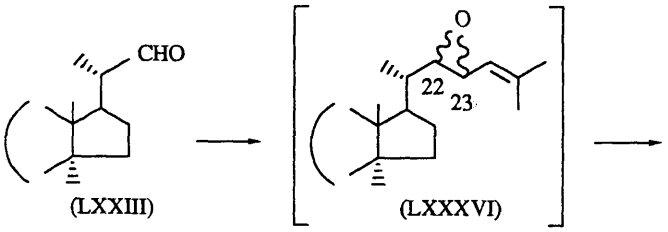
In order to build up the side chain, the 22-aldehyde may be obtained by ozonisation of the olefin or by hydroboration[99] followed by mild oxidation. The use of (LXXIII) in a Wittig reaction[99] or reaction with the Grignard reagent from 4-chloro-2-methylbut-2-ene provided the authors with novel functional lanostane side chains.



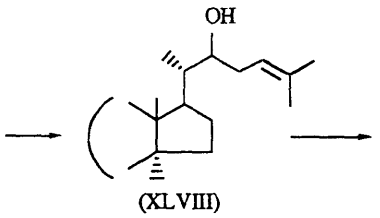
(LXXIII) (XLVIII) — (XLIX) (LXXXV)

$R^1 = CH_3$, $R^2 = C_6H_{11}$, CH_2OH, $CH=CH_2$, $(CH_2)_2CHO$, etc.

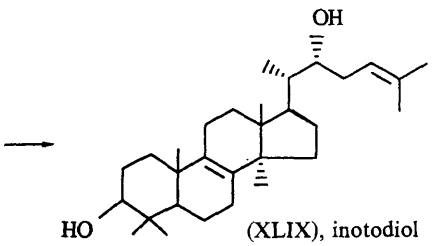
However, a detailed study[93] of the reaction conditions with the 22-aldehyde for formation of a 22-hydroxy-$\Delta^{24(25)}$ residue showed that neither a Grignard reagent nor a sulphur ylide can be used successfully. As was mentioned above, the dimethylallyl residue undergoes rearrangement. If an α-anion of a sulphone is condensed with aldehyde (LXXIII), a sulphinate residue is not eliminated in the latter. Amann et al.[93] solved this problem by using an arsenic ylide obtained from (3-methylbut-2-enyl)triphenylarsonium tetrafluoroborate[100] and n-butyllithium. Condensation of this ylide with the 22-aldehyde (LXXIII) gave the 22,23-epoxy-24(25)-ene intermediate (LXXXVI), and it was reduced with lithium triethylborohydride stereoselectively to give (22*S*)-22-hydroxylanosta-8,24-diene (XLVIII). In order to invert the 22*S* configuration to 22*R*, which is characteristic of the biologically active inotodiol, Amann et al. used the method of Corey—mesylation in pyridine followed by treatment with KO_2 and 18-crown-6 in a mixture of DMF and DMSO. Thus, the overall yield of inotodiol by this synthetic route was about 30%.



(LXXIII) (LXXXVI)



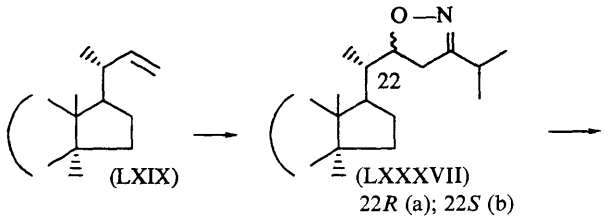
(XLVIII)

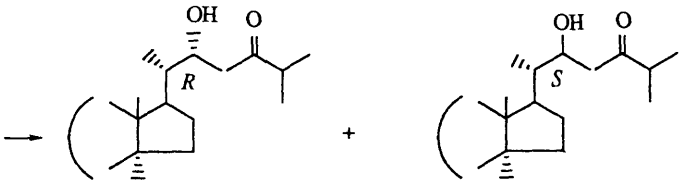


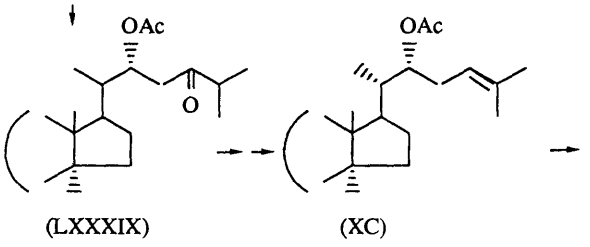
(XLIX), inotodiol

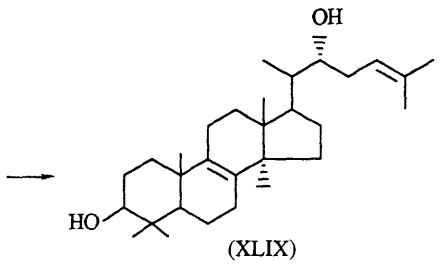
Key intermediates in the stereospecific introduction of oxygen functional groups into the C(22)-position of lanosterol were the 22(23)-terminal olefins (LXIXa, b), obtained by decarboxylation of lanostane 24-acids, by involving them in a 1,3-dipolar cycloaddition reaction.[101,102] Cleavage of the isopropylisoxazolinolanostanes (LXXXVIIa, b) in an atmosphere of hydrogen in the presence of boric acid after resolution of the 22-epimers followed by acetylation provided a route to (22*R*)-3β,22-diacetoxylanost-8-en-24-one (LXXXIX). This isomer was successfully used in a highly effective novel stereoselective synthesis of inotodiol (XLIX),[101–103] which differs from that described above by virtue of its simple operation, greater accessibility of reactants, and lower number of stages. The

yield of required product was about 26% and could be increased if the Corey isomerisation of the (22*S*)-isomer was used.[93]



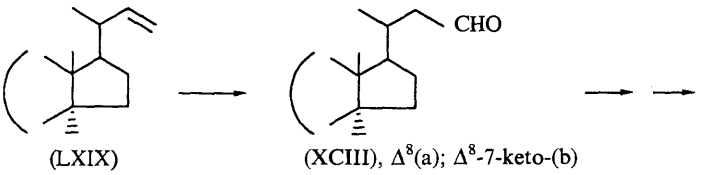


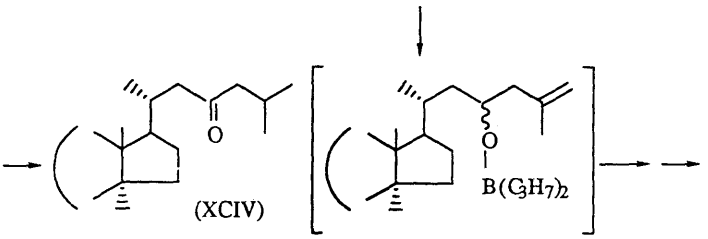


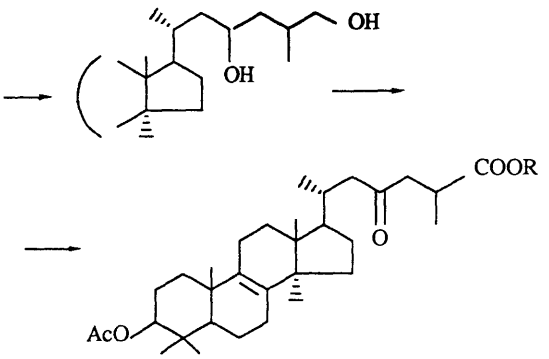


Use of the same diacetate (LXXXIX) in a Reformatsky reaction with ethyl bromoacetate followed by dehydration gave the δ-lactone of (22*R*)-3β-acetoxy-22-hydroxylanosta-8,24(31)-dien-32-oic acid (XCII), which was the first lanostane analogue of the sex hormone of *Achlya* marine fungi[101]

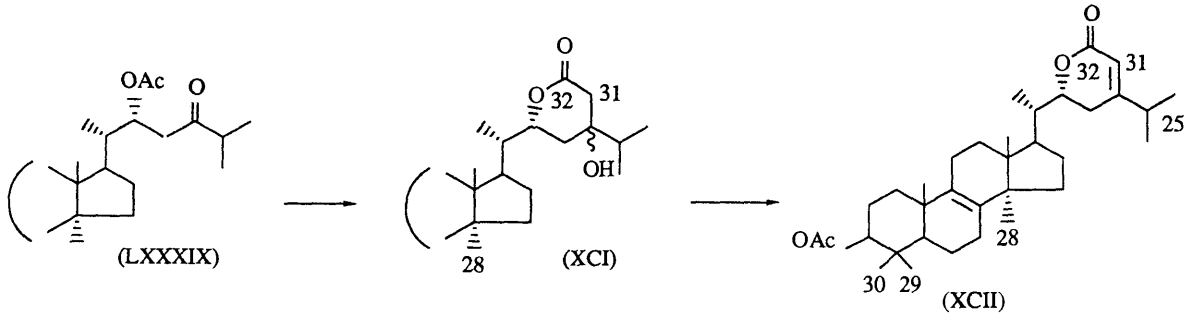
Conversion of 22(23)-olefins to 23-aldehydes (XCIIIa, b) by hydroboration[91] followed by oxidation made the 23-aldehyde (XCIIIa) a convenient starting material for the synthesis of 23-keto-lanostanes (potential cardiotonics) (XCIV).[102] The first two-stage synthesis of 3β-acetoxylanost-8-en-23-keto-24-oic acid (XCV)—a ganoderic acid analogue—was achieved by reaction of allylborane with the 23-aldehyde (XCIIIa) together with the subsequent hydroboration and oxidation in a single stage.[91]





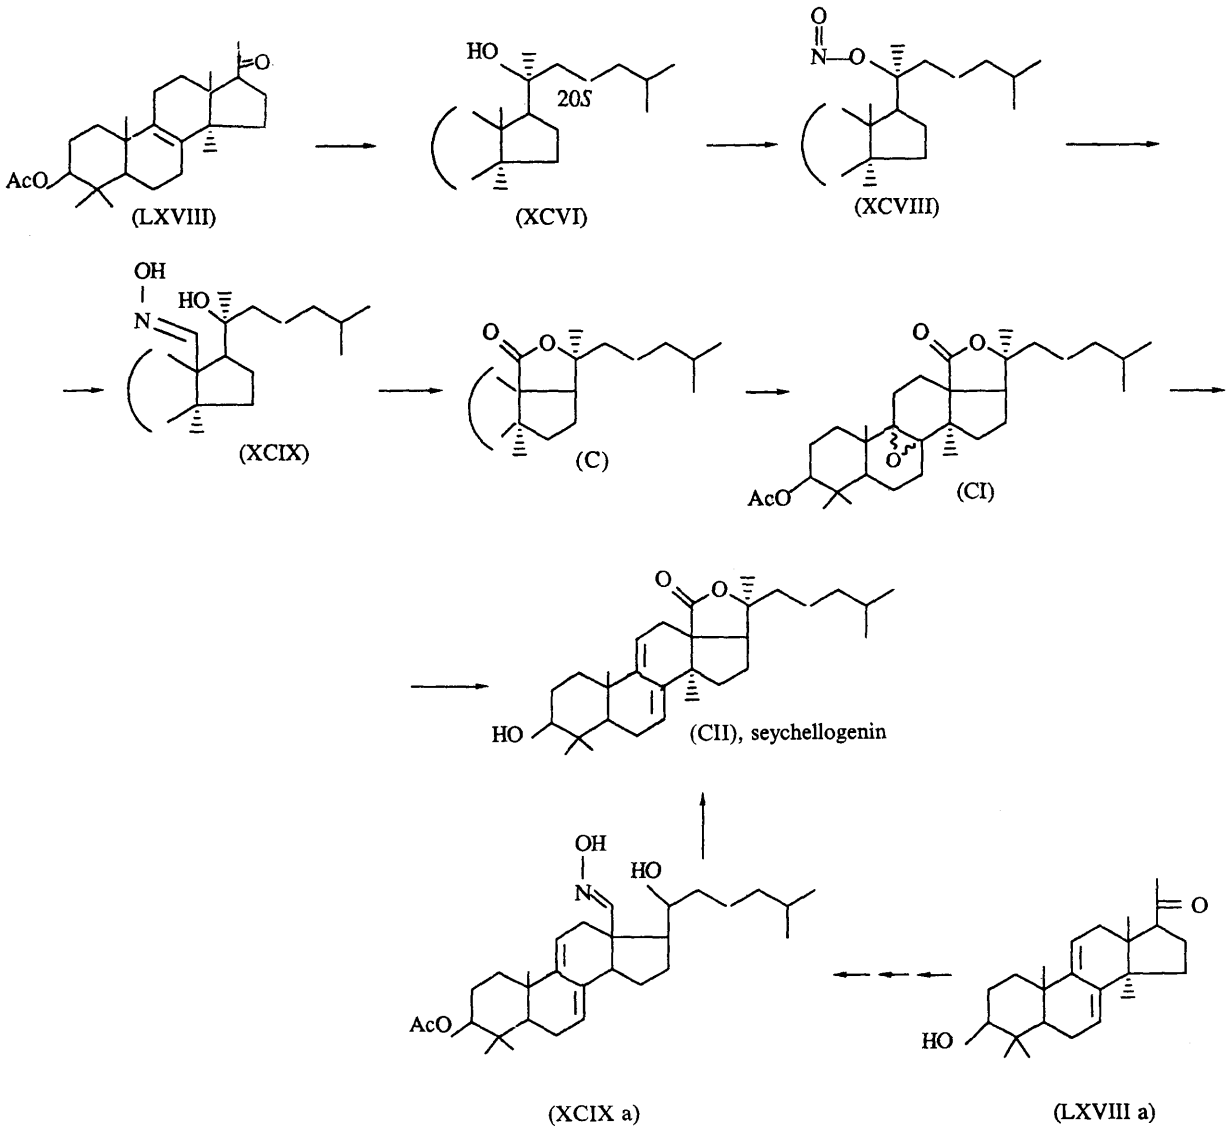


Seychellogenins have various useful biological properties. In view of their limited availability from natural sources, considerable attention has been given to their synthesis. After methods had been developed for dehydrating the side chain of lanosterol and converting it to the 20-ketone (LXVIII),[78] attempts to functionalise the 18-methyl group were initiated. The original scheme for the

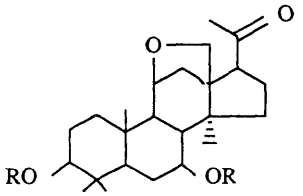


synthesis of seychellogenin[104] involved conversion of the 20-ketone (LXVIII) by a Grignard reaction with isohexylmagnesium bromide to give (20*S*)-dihydrolanost-8-ene, which was converted on treatment with nitrosyl chloride to the nitroso derivative (XCVIII). Photoisomerisation of the latter to the oxime (XCIX) occurred with a yield of 8%, and this governed the low overall yield of (CII) (2%), which included oxidation to the γ-lactone (C), epoxidation of the interring double bond, and acid hydrolysis of the 8,9-epoxide (CI) to the 7(8),9(11)-diene system of (CII). A variant of this scheme used the 20-ketone of 3-hydroxylanosta-7,9-diene (LXVIIIa) as a starting compound.

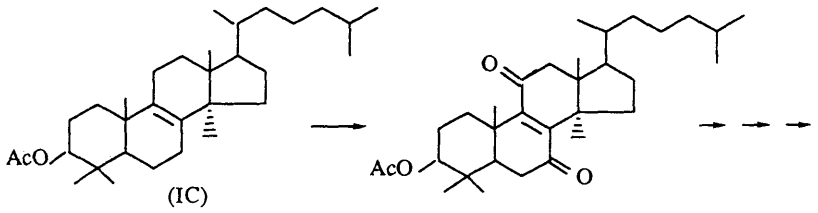
The aim of the second, fundamentally different approach[6,105] was to improve the yield of the required seychellogenin (CII). At the first stage of the synthesis, commercial lanosterol containing a certain amount of 24,25-dihydrolanosterol was hydrated, and pure dihydrolanosterol (IC) was thus obtained. After oxidation of the allylic methylene groups in the rings at C(7) and C(11) with chromium trioxide, the central double bond was reduced using zinc in acetic acid. Further reduction with lithium aluminium hydride followed by selective acetylation gave the 3,7-diacetoxy-11-hydroxylanostane (CIII), which was converted by photoreaction with lead tetraacetate in the presence of iodine to the cyclic ether (CIV). Cleavage of the latter with boron trifluoride etherate in anhydrous acetic acid, hydrolysis with KOH, and hydrogenation of the 9(11)-double bond gave the compound (CVI) with the required *trans* linkage of the *B*/*C* rings. An important subsequent feature was selective acetylation, so that the hydroxyl group at C(18) would remain free. After this problem was solved and (CVII) was obtained, a photoreaction was carried out under the conditions described above to give the cyclic ether (CVIII), oxidation of which with ruthenium tetroxide, hydrolysis, and further selective acetylation gave compound (CX). After dehydration and oxidative introduction of the diene system using mercuric acetate, the acetate of seychellogenin (CII) was obtained in satisfactory yield. The authors of the above synthesis of seychellogenin believe that the 20-ketone having the structure (CXII) would be an excellent precursor in the



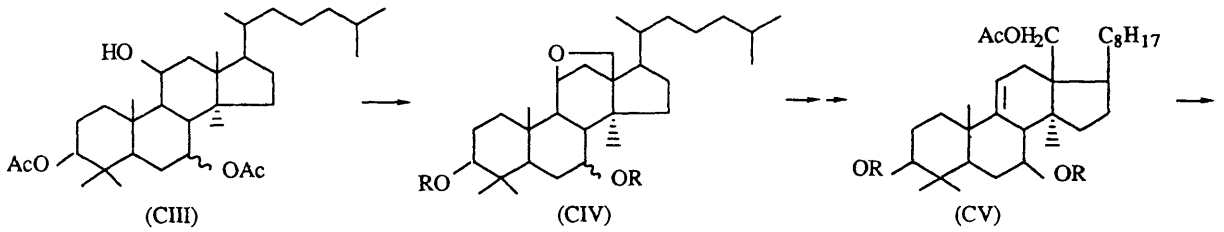
synthesis of other holothurigenins. It is simple to obtain by a combination of the two synthetic methods[104,105] with degradation of the side chain of lanosterol.



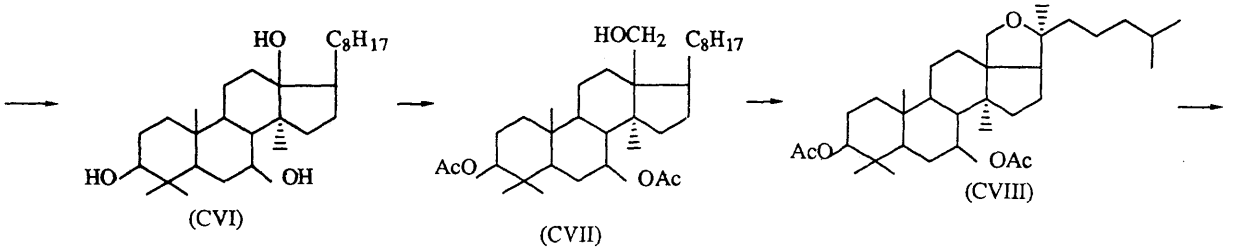
(CXII), R = Ac



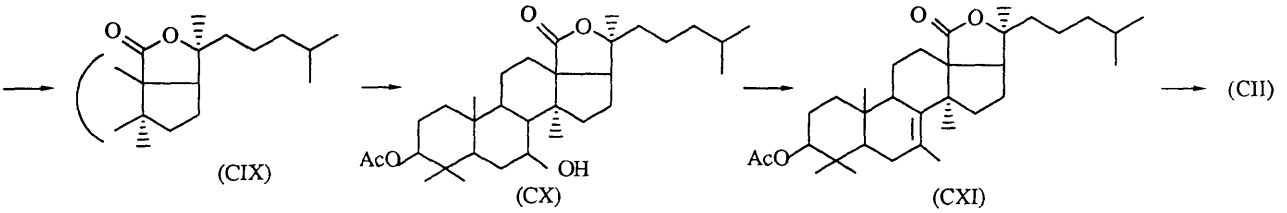
(IC)



(CIII) (CIV) (CV)



(CVI) (CVII) (CVIII)



(CIX) (CX) (CXI)

The molecule of (CXII) can be converted to the 17α-hydroxy derivative as well as to a compound with a natural 9(11)-double bond after cleavage of the cyclic ether. Although most of the intermediates in these syntheses were converted to hemisuccinates in order to impart greater solubility to these molecules in water, not one of the derivatives exhibited the same degree of activity (toxicity) as the natrual glycosides.[7] Habermehl and Kirsch[5] proposed in future to modify the molecule of natural seychellogenin in this manner in order to study the structure–function relationship.

Thus, it may be concluded from an analysis of the literature that nature has an abundance of various polyfunctional lanosterol derivatives that possess therapeutic properties that are useful for human medicine. Lanosterol itself is an inexpensive, available product that is isolated from the wool "suint" together with cholesterol. This makes it an attractive source in the preparation of synthetic triterpenoids and steroids having hydrophobic alkyl groups in the molecule which play an important part in the interaction with receptors. Therefore considerable opportunities are being opened up in the chemistry of lanosterol for research both into novel reactions and in the application of established methods in steroid chemistry for deriving biologically active polyfunctional structures.

Structural features and spectroscopic and energy characteristics of alkali metal molybdates and tungstates

V V Fomichev, M E Poloznikova, O I Kondratov
Institute of Fine Chemical Technology, Moscow

ABSTRACT. The results of X-ray structural, i.r. and Raman spectroscopic, and thermodynamic studies of alkali metal molybdates and tungstates $A_2M_nO_{3n+1}$ (A = Li, Na, K, Rb, Cs; M = Mo, W) are reviewed and analysed. The dependence of the vibrational spectra, activation energies, and crystal lattice energies on features of the structures of these compounds is discussed.

The bibliography comprises 51 references.

I. Introduction

In recent decades there has been increased interest in the study of molybdates and tungstates of various compositions. The range of compounds whose structures have been determined using precision techniques has expanded considerably. It has been found that molybdates and tungstates can form a large number of fundamentally different structures, the number of structure types running to dozens. Molybdenum and tungsten have the ability to form various oxygen coordination polyhedra which have a tendency to condensation at appropriate cation ratios.

The general crystal-chemical principles of molybdates and tungstates are set out in two monographs[1,2] but there is not a great deal of discussion of the alkali metal compounds.

There are many publications devoted to studies of molybdates and tungstates by vibrational spectroscopic methods (i.r. and spontaneous Raman).[3–5] However no serious attempts have so far been made to collect together the available data and to review them together with X-ray structural data.

The present work aims to fill this gap. We have interpreted the vibrational spectra of the alkali metal molybdates and tungstates on the basis of an analysis of their crystal structures and proposed explanations for the variation in the spectroscopic and thermodynamic characteristics along this series of compounds. However information on the thermodynamics of molybdates and tungstates is disconnected and very meagre. Some values (atomisation energies and crystal lattice energies) have been calculated by the authors using known experimental data. Such information, and to such an extent, is not present in any of the available publications.

The compounds under discussion have structures with discrete tetrahedral or octahedral oxygen coordination polyhedra and also various types of linking of these to form chain or block structures. However alkali metal cations introduce very small perturbations into the energetics of molybdenum-oxygen or tungsten-oxygen ensembles compared to the cations of other elements. There is no mixing of the vibrations of the cationic sublattices with the vibrations of the molybdenum-oxygen or tungsten-oxygen systems. Lithium compounds form an exception. The frequencies of lithium cation vibrations appear in the deformation region of the oxygen polyhedra but they can be fairly safely distinguished in experiments using specimens in which the lithium is isotopically substituted ($^6Li-^7Li$).

Thus structural features of the molybdenum-oxygen and tungsten-oxygen systems and the type of interatomic interactions in them are controlling factors affecting the energy characteristics (vibration frequencies, thermodnamic values) of the molybdates and tungstates under discussion. The correlations obtained for them can be used successfully to interpret the results of studies of molybdates and tungstates of elements which form stronger cation–oxygen bonds with appreciable covalent contributions.

II. Crystal chemistry of the alkali metal molybdates and tungstates

Alkali metal molybdates and tungstates can be divided into four structural series depending on the types of molybdenum-oxygen and tungsten-oxygen polyhedra and the way in which they are joined together:[1]

structures with isolated tetrahedral MO_4 anions;

structures with chain-type anions composed of MO_4 tetrahedra (or MO_5 pyramids) and MO_6 octahedra;

polygon-network structures based on MO_6 octahedra sharing corners;

block structures formed by MO_6 octahedra sharing edges.

The first series comprises compounds with the general formula A_2MO_4 (A = Li, Na, K, Rb, Cs; M = Mo, W) in which the $MO_3:A_2O$ ratio is equal to one. They have structures formed by isolated MO_4 tetrahedra. The type of coordination polyhedron of the alkali metal depends on its ionic radius and varies along the series from lithium to caesium as the coordination number (CN) of the cation A increases from 4 to 10 (Table 1).

For example, in the structures of Li_2MoO_4 and Li_2WO_4 [6,7] the lithium has close tetrahedral coordination (hexagonal phenacite Be_2SiO_4 structure type[7]). On moving to Na_2MoO_4 and Na_2WO_4 [8,9] a spinel structure with octahedral coordination of the sodium cations by oxygen is found. As the size of the alkali metal cation increases further its CN rises to 8 in K_2MoO_4 and K_2WO_4, and also in

Rb_2MoO_4 and Rb_2WO_4 [10,11] while caesium, the largest cation in this series, has two types of coordination polyhedra, with CN's of 6 and 10, in Cs_2MoO_4 and Cs_2WO_4.[12]

Table 1. Changes in structural features in the alkali metal molybdates and tungstate series.

*For the set of compounds with chain structures formed from tetrahedra and octahedra all the r_{M-O}(oct) values are listed in the order: r_{M-O}(terminal), r_{M-O}(bridging, *trans*), r_{M-O}(bridging, *cis*).

Since molybdenum and tungsten in higher oxidation states have fairly similar ionic radii[5] molybdates and tungstates with the same alkali metal cation are expected to be isomorphous. However, this assumption is valid only for the low-temperature modifications of A_2MO_4. As the $MO_3:A_2O$ ratio is increased diferences appear in the structure of isopolymolybdates and isopolytungstates. Nevertheless in both instances systems of condensed MO_n (n = 4, 5, 6) polyhedra are formed.

The structure of $Li_2W_2O_7$, which forms triclinic crystals,[6] is composed of LiO_4 tetrahedra and distorted WO_6 octahedra linked by shared edges to form $(W_2O_7)^{2-}$ anions, which in turn form infinite chains. Moving to the larger sodium cation in $Na_2Mo_2O_7$ [7] and $Na_2W_2O_7$ [8] leads to changes in the coordination of both the alkali metal and the molybdenum or tungsten. Here the $(M_2O_7)^{2-}$ anions, which form infinite chains, are composed of MO_4 tetrahedra and MO_6 octahedra with shared corners. This combination of different coordination polyhedra is typical of the stereochemistry of molybdenum and, to a significant extent, tungsten. The sodium has octahedra coordination in $Na_2Mo_2O_7$ but occupies two sets of positions, in oxygen octahedra and pentagonal pyramids, in the structure $Na_2W_2O_7$.

A further increase in the size of the alkali metal cation is accompanied by an increase in the CN to 9. The structure of $K_2Mo_2O_7$,[9] like that of $Na_2Mo_2O_7$, is composed of chains of molybdenum-oxygen tetrahedra and octahedra but their mutual arrangement is different. A pair of octahedra has a shared edge and is linked by means of two tetrahedra, via shared corners, to the next pair. Each tetrahedron and octahedron has two free vertices.

Increasing the $MO_3:A_2O$ ratio to three leads, in the structure of $K_2Mo_3O_{10}$,[10,11] to the production of a new type of chain which is formed from square-pyramidal MoO_5 polyhedra and MoO_6 octahedra. The chain unit comprises an octahedron and two pyramids but each octahedron is linked via corners to four pyramids.

Thus there is a general tendency to a change in the chain structure on going from $Na_2Mo_2O_7$ to $K_2Mo_2O_7$ and $K_2Mo_3O_{10}$. In $Na_2Mo_2O_7$ the octahedra share corners and are also linked in pairs by tetrahedra. In $K_2Mo_2O_7$ two neighbouring octahedra share edges and each pair is joined to the next pair via the corners of two tetrahedra; the relative number of tetrahedrally coordinated molybdenum atoms is greater than in $Na_2Mo_2O_7$. In the structure of $K_2Mo_3O_{10}$ all the octahedra are linked by pairs of tetrahedra with a change in the latter to distorted tetragonal pyramids due to the formation of a fifth, longer Mo–O bond with the tetrahedra drawn appreciably closer together.

A comparison of the MoO_6 octahedra in these structures reveals a number of trends in the Mo–O bond lengths:

(i) there is a tendency to form two long, two short, and two medium-length bonds between the central atom and oxygen;

(ii) in the *trans* position to a short bond there is a long bond and this is usually longer (weaker), the shorter (stronger) is the short bond;

(iii) the mean Mo–O distances are fairly similar (~1.94 Å) in compounds with different compositions.

These rules are also valid for the WO_6 octahedra in the structure of $Na_2W_2O_7$.[8]

In all cases a decrease in the Mo_{tetr}–O bond lengths is accompanied by lengthening of the associated O–Mo bonds, the tetrahedron becoming quasi-free (the bonds in the octahedron nearest to it are weakened while the bonds in the tetrahedron itself are strengthened).

Although the molybdenum-oxygen distances differ considerably the lengths of the O...O edges of the octahedra lie within a fairly narrow range, 2.75 ± 0.1 Å. The preference of the oxygen atoms to be spaced at equilibrium distances from each other influences the magnitude and form of the angular distortions. The electron density is increased at one, two, or three *cis*-located Mo–O bonds but decreased at the others. This phenomenon can be likened to a *trans* effect.

The polymolybdates $K_2Mo_3O_{10}$, $Rb_2Mo_3O_{10}$, and $Cs_2Mo_3O_{10}$ are isostructural.[11] The structure of $K_2W_3O_{10}$ [12] differs considerably from that of the molybdates of similar composition. Among the compounds under discussion it provides the simplest example of a polygon-network structure with planar nets made up of ensembles of WO_6 octahedra linked to form infinite chains and channels running through the whole structure. The potassium cations occupy positions in the channels with coordination numbers of 9 and 13.

When the $MO_3:A_2O$ ratio is increased to 4 or more the molybdenum or tungsten atoms change to exclusively octahedral coordination. Thus on going from simple molybdates to di-, tri-, and tetra-molybdates the coordination of molybdenum by oxygen changes from tetrahedral with octahedral, square pyramidal with octahedral, and finally pure octahedral.

An oxygen atom deficiency in the tetramolybdates necessitates appreciable joining together with the edges and/or corners of the octahedra. For example, $Li_2Mo_4O_{13}$ has a three-dimensional block structure.[13] The structure of $Na_2W_4O_{13}$ [14] is composed of groups of four WO_6 octahedra sharing edges and linked to form an infinite chain, also via shared edges, whereas the tunnel structure of $K_2W_4O_{13}$ [15,16] contains WO_6 octahedra linked by shared contents to form six-membered rings. The reason for this is that the larger potassium ion requires a larger number of neighbours and the rigid unit chain of octahedra present in $Na_2W_4O_{13}$ cannot be distorted to such an extent.

The triclinic potassium and rubidium tetramolybdates are isomorphous.[17] Caesium tetramolybdate probably has a similar structure.[17] In the structure of $K_2Mo_4O_{13}$ groups of four MoO_6 octahedra with almost coplanar central atoms have shared edges and are joined to similar groupings, by shared edges, to form infinite chains. The latter do not have shared oxygen atoms but are held together by potassium ions in eight-coordinate positions.

With this mutual arrangement of the MoO_6 octahedra the molybdenum atoms are drawn closer together, leading to their mutual repulsion from the centres of the octahedra. This in turn causes differences between the molybdenum–oxygen interatomic distances which is typical of many structures of compounds containing molybdenum in a high oxidation state.

The three types of chain structure known at present for di-, tri-, and tetra-molybdates remain stable in the presence of alkali metal cations of a certain size. The lower limit of the cation size is determined by the arrangement of the chains but the upper limit depends on the way in which the polyhedra are joined together to form a chain and also their potentiality for ensuring coordination of large cations. For example, the helical chain structure of the trimolybdate may remain stable in the presence of potassium, rubidium, or caesium due to it ability to rotate and to extend somewhat whereas the dimolybdate chain structure is not in a position to be extended and is therefore not found with cations larger than sodium.

The tetramolybdate chain structure is the most compact of those discussed and even with its greater rigidity it proved possible to retain it for potassium and rubidium cations. The structure of caesium tetramolybdate is however different from those of $K_2Mo_4O_{13}$ and $Rb_2Mo_4O_{13}$.[17]

The occurrence of polymolybdates with the largest $MoO_3:A_2O$ ratio for rubidium and caesium is evidently due to the ability of these large cations to be combined effectively with the largest number of molybdenum-oxygen fragments.

III. Vibrational spectra

The study of the vibrational spectra of alkali metal molybdates and tungstates has received great attention. However most of the research has been concerned with the compounds in the A_2MO_4 (A = Li, Na, K, Rb, Cs; M = Mo, W) series which have comparatively simple structures. Their i.r. spectra in the region down to 70 cm^{-1} [3,4] and Raman spectra of polycrystalline specimens[28–31] have been obtained.

A group-theoretical analysis of the distribution of the vibrations of MO_4^{2-} anions, which form the basis of the crystal structure of these compounds, among the irreducible representations of the point group T_d gives

$$\Gamma_{vib} = A_1(\text{Raman}) + E(\text{Raman}) + 2T_2(\text{IR, Raman}).$$

Hence the Raman spectrum of "free" tetrahedral MO_4^{2-} anions will contain one line due to the totally symmetric stretch $\nu_1(A_1)$, one line due to the triply degenerate vibration $\nu_3(T_2)$, and two lines due to the deformations $\nu_2(E)$ and $\nu_4(T_2)$. Only the two triply degenerate vibrations $\nu_3(T_2)$ and $\nu_4(T_2)$ will be i.r.-active.

The values of the vibrational wavenumbers of "free" MoO_4^{2-} and WO_4^{2-} ions have been obtained from measurements of the spectra of aqueous solutions[29] in polarised light and of ions isolated in an inert-gas matrix,[31–34] in conjunction with a theoretical analysis of the wavenumbers and modes of the normal vibrations.[35]

Table 2. Wavenumbers (cm^{-1}) of the vibrations of the free tetrahedral ions.[35]

Ion	$\nu_1(A_1)$	$\nu_2(E)$	$\nu_3(T_2)$	$\nu_4(T_2)$
MoO_4^{2-}	896	381	833	318
WO_4^{2-}	931	373	833	320

The effect of the alkali metal cations on the vibrations of MoO_4^{2-} and WO_4^{2-}, as functions of their concentration, was considered. The presence of lithium and sodium cations in the solution increases the vibrational wavenumbers of the anions, the effect being more marked in the case of lithium. The introduction of potassium, rubidium, and caesium cations into the system leads to a reduction in the vibrational wavenumbers due to enhancement of the effective polarisability of the water molecules surrounding the anions. The perturbation recorded was more appreciable for the tungstate ion. Extrapolation of the experimental data to infinite dilution gives values of the symmetric vibration ν_1 of 931 cm^{-1} for WO_4^{2-} and 896 cm^{-1} for MoO_4^{2-}.

The data given in Table 2 provide a basis for analysing the vibrations of crystalline specimens. Such vibrations are described not only by the wavenumbers of the internal vibrations of the oxo-anions but also by the wavenumbers of the external vibrations — the librations of the anions and the translational vibrations of the anions and cations.

The changes in the wavenumbers in the vibrational spectra of Na_2MoO_4 and Na_2WO_4 on moving from liquid to crystalline specimens have been analysed.[36] The Raman lines at 928 and 892 cm^{-1} were assigned (by analogy with the spectra of the solutions) to the symmetric stretches $\nu_1(A_1)$. Lines at 813 and 808 cm^{-1} were assigned to $\nu_3(T_2)$. The fact that, if the anion symmetry is T_d, only the T_2 mode can appear in the i.r. spectra of crystalline Na_2MoO_4 and Na_2WO_4 enables the two remaining wavenumbers to be safely assigned to the deformations $\nu_2(E)$ and $\nu_4(T_2)$.

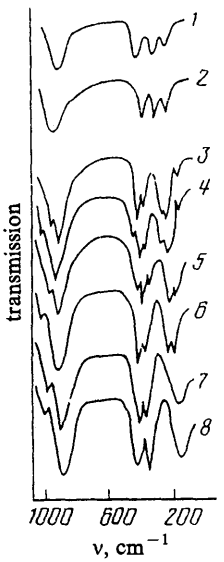

Figure 1. Ir spectra of alkali metal monomolybdates and monotungstates:[25] *1*, Na_2MoO_4; *2*, Na_2WO_4; *3*, K_2MoO_4; *4*, K_2WO_4; *5*, Rb_2MoO_4; *6*, Rb_2WO_4; *7*, Cs_2MoO_4; *8*, Cs_2WO_4.

It was found that $\nu_2(E) > \nu_4(T_2)$ for both the free ions and the anions in a crystal field, so that there is inversion of these wavenumbers in the spectra of Na_2MoO_4 and Na_2WO_4 compared to those in the spectra of the tetrahedral anions ClO_4^-, SO_4^{2-}, PO_4^{3-}, and CrO_4^{2-}, for which $\nu_4(T_2) > \nu_2(E)$. Similarly $\nu_1(A_1) > \nu_3(T_2)$ which is also in the reverse order compared to the wavenumbers for the other tetrahedral ions. The Raman lines at 116 and 93 cm^{-1} in the spectra of crystalline Na_2MoO_4 and Na_2WO_4 relate to external lattice vibrations. Similar results were obtained from a study of the i.r. and Raman spectra[4] of anhydrous mono-molybdates and -tungstates of the whole series of alkali metals, with the exception of lithium in the region down to 70 cm^{-1} (Table 3, Figs. 1 and 2). The spectra were interpreted using the results of a group-theoretical analysis of the vibrations of Na_2MoO_4 crystals which have a spinel structure composd of MoO_4 tetrahedra and NaO_6 octahedra.[8] The bands in the spectra of the other alkali metal compounds were assigned by analogy with Na_2MoO_4. All the vibrations are active in both the Raman and i.r. spectra. This, and also the considerable difference between the wavenumbers observed in these spectra, is due to interaction between the vibrations of crystallographically equivalent tetrahedral anions and their distortion in the crystal field.

For all the compounds under discussion the vibrations of the tetrahedral oxo-anions were found to occur in the regions shown in Table 2.

In the molybdates and tungstates the vibrations of the alkali metal cations with octahedral coordination occur below 230 cm^{-1}. The two i.r. bands at 230 and 170 cm^{-1} and the Raman line at 120 cm^{-1} in the spectrum of Na_2MoO_4 are assigned to T_{1u} and T_{2g} type vibrations. The wavenumbers of the vibrations of the cations decrease in the order Na > K > Rb > Cs and show little change on going from molybdates to tungstates. The proposed assignment is fully consistent with the results of a calculation of the vibrational wavenumbers and modes of K_2WO_4 and K_2MoO_4.[37]

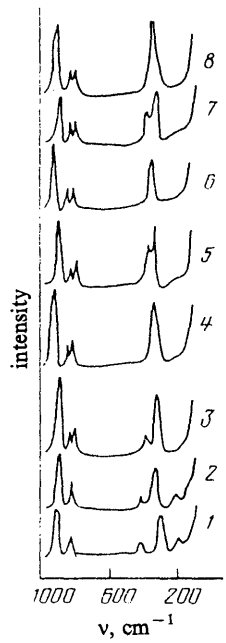

Figure 2. Raman spectra of alkali metal monomolybdates and monotungstates:[25] *1*, Na_2WO_4; *2*, Na_2MoO_4; *3*, K_2MoO_4; *4*, K_2WO_4; *5*, Rb_2MoO_4; *6*, Rb_2WO_4; *7*, Cs_2MoO_4; *8*, Cs_2WO_4.

Analysis of the vibrations modes and the displacements of the atoms shows that the Raman line at 926 cm^{-1} and the i.r. band at 925 cm^{-1} in the spectra of K_2WO_4 are due to vibrations of the WO_4 tetrahedron with the predominant change in the shortest W—O bond (1.76 Å); the Raman line at 829 cm^{-1} and the i.r. band at 830 cm^{-1} are due to the longest bond (1.81 Å). The wavenumbers in the 357—298 cm^{-1} region are assigned to deformations of the tetrahedron. The bands at 164, 145, 132, and 100 cm^{-1} in the spectrum of K_2WO_4 can be assigned to the predominant vibrations of the potassium cations involving the oxygen neighbours and the tungsten atoms.

Lithium molybdates and tunsgate Li_2MO_4, whose crystal structures contain almost undistorted MO_4^{2-} tetrahedra, have simple i.r. spectra the interpretation of which causes no difficulties.[38]

The analysis of the vibrational spectra of alkali metal polymolybdates and polytungstates is an incomparably more serious problem due to the complex structure of the anions which are composed to condensed molybdenum or tungsten coordination polyhedra. This makes it impossible to interpret the vibrational spectra using the "free" ion approximation.

Nevertheless such attempts were made in some of the earlier papers. From studies of the i.r. spectra of $Na_2Mo_2O_7$, $Na_2W_2O_7$, and $Na_2W_4O_{13}$ the existence of $(O_3M-O-MO_3)^{2-}$ ions was proposed[39,40] by analogy with ions like $P_2O_7^{4-}$, $S_2O_7^{2-}$, $Cr_2O_7^{2-}$. It was found that in the vibrational spectra of molybdates and tungstates, and also vanadates, and in contrast to the spectra of phosphates, sulphates, and chromates, the wavenumbers of the M–O symmetric stretches are always higher than those of the antisymmetric vibrations. Tarte[40] showed that the wavenumbers of the M–O stretches increase as the number of oxygen atoms coordinated to the molybdenum or tungsten decreases. Further, the higher the degree of condensation of the molybdenum–oxygen or tungsten–oxygen groups, the higher are the wavenumbers of the stretches of the polyhedra.[40]

The vibrational spectra of alkali metal polymolybdates and polytungstates have been analysed.[5] The i.r. spectra of the compounds $A_2M_nO_{3n+1}$ (A = Na, K, Rb, Cs; M = Mo, W) in the 4000–200 cm^{-1} region were studied (Table 4). An interpretation of the observed spectra was proposed on the assumption that in the structures of these compounds distorted MO_6 octahedra and MO_4 tetrahedra are linked by shared corners. It was shown by spectroscopy that there is a similarity between the structures of potassium, rubidium, and caesium tetramolybdates on one hand, and rubidium and caesium tritungstates on the other.

The vibrational wavenumbers of polymolybdates isotopically substituted with lithium ($^6Li-^7Li$) and molybdenum ($^{92}Mo-^{100}Mo$),[37,41,42] supplemented with our own previously unpublished data for tungstates, are given in Table 5.

In analysing the spectra of complex systems containing octahedral, as well as tetrahedral, groupings it must be borne in mind that for an isolated, regular MO_6 octahedron with O_h symmetry six normal vibrations are possible:

$$\Gamma_{vib} = A_{1g}(\text{Raman}) + E_g(\text{Raman}) + 2T_{1u}(\text{IR}) + T_{2g}(\text{Raman}) + T_{2u}(\text{n.a.}),$$

of which only ν_3 and ν_4 with symmetry T_{1u} will be i.r.-active. On the basis of these ideas, and using known structural data for $Na_2Mo_2O_7$, $Na_2W_2O_7$, and $K_2Mo_3O_{10}$,[15,16,18] Caillet and Saumagnt[39]

*Our data.

[Ref. 4? (Ed. of Translation)] assigned the highest wavenumbers to the $\nu_3(T_{1u})$ vibrations of the MO_6 octahedra. Confirmation of the correctness of this assignment was evident in the splitting of the corresponding band in the i.r. spectra of many polymolybdates and polytungstates into three components due to removal of the degeneracy. The next highest wavenumber was assigned to $\nu_1(A_1)$ of the MO_4 tetrahedron. The $\nu_3(T_2)$ vibration of the same tetrahedron appears in the i.r. spectra as a strong triplet with its centre at $\sim$890 cm^{-1}. The i.r. bands in the 350–200 cm^{-1} region were assigned to deformations of the tetrahedron $[\nu_2(E)]$ and $[\nu_3(T_{1u})]$. The absence of simple criteria led to difficulties in interpreting the spectra in the 560–350 cm^{-1} region where bands due to the vibrations $\nu_4(T_{1u})$ or $\nu_5(T_{2g})$ of the octahedron and $\nu_4(T_2)$ of the tetrahedron are expected.

The proposed assignment is rather provisional and open to serious doubts in a number of aspects. For example, the wavenumbers of the stretches of the tetrahedral MO_4 groups will, because of the smaller interatomic distances and higher bond energies, be higher than those of the stretches of the MO_6 octahedra.

The structures of the other polymolybdates and polytungstates were established later and therefore a hypothetical assignment of their vibrational wavenumbers was made from a comparison with the spectra of the whole series of compounds, and also of $Na_2Mo_2O_7$ and $Na_2W_2O_7$ as described previously. In the 400–200 cm^{-1} region there are a number of i.r. bands with increased wavenumbers which were difficult to describe by considering only structural fragments formed from tetrahedra and octahedra. No analysis of the vibrations of the cationic sublattice was made in Ref. 35.

The i.r. spectra of $Na_2Mo_2O_7$ and $Na_2W_2O_7$, studied by Dupuis and Veltange,[39] were also found to be very similar. Antisymmetric stretches of the M–O–M bridges were assigned to the bands in the 600 cm^{-1} region for $Mo_2O_7^{2-}$ (a very strong band) and the 625–575 cm^{-1} region for $W_2O_7^{2-}$ (a doublet of strong bands). It is likely[39] that the symmetric vibrations of the bridges occur at 465 cm^{-1} for $Mo_2O_7^{2-}$ and 455 cm^{-1} for $W_2O_7^{2-}$. The antisymmetric stretch of MO_3 groups appears as a doublet in the 825–780 cm^{-1} region for $Na_2Mo_2O_7$ and the 825–775 cm^{-1} region for $Na_2W_2O_7$. Deformations were recorded at 360, 333, and 315 cm^{-1} for $Mo_2O_7^{2-}$ and 418 and 360 cm^{-1} for $W_2O_7^{2-}$. Thus it was shown that the i.r. spectra of sodium dimolybdate and ditungstate can be interpreted and satisfactorily in terms of the vibrations of a model $M_2O_7^{2-}$ anion with symmetry C_{2v} and containing two symmetrical MO_3 groups linked by an M–O–M bridge, as in pyrophosphates, pyrosulphates, and dichromates. The wavenumbers of the stretches of the M–O–M bridges decrease as the atomic weight of M increases.

The Raman spectra of polycrystalline $K_2W_3O_{10}$ and $K_2W_4O_{13}$, and also polytungstates with a higher tungsten content, have been published and discussed.[43] In the opinion of the authors the vibrations of terminal W–O bonds appear in the Raman spectra of these compounds as a pair of lines at 962 and 902 cm^{-1}.

The external vibrations of the alkali metal tungstates and molybdates have not been studied in detail. However precision studies of the i.r. and Raman spectra of a number of lanthanide molybdates, where the greatest attention was paid to the external vibrations,[44] confirm the assignment, proposed from an analysis of the spectra of compounds with the scheelite structure,[45] of the wavenumbers 140–110 cm^{-1} to translational, and 260–200 cm^{-1} to librational, vibrations of the molybdate ions. It seems that these values are general, remaining valid for the alkali metal molybdates (and with small adjustments tungstates also) provided, of course, that the structure of the compound contains tetrahedral anions.

The appearance in print of Refs. 15, 18, and 19 with a description of the structures of a large number of molybdates stimulated studies of their vibrational spectra.

A number of recent papers[37,41,42] have been concerned with a detailed study of the vibrational spectra of potassium and sodium molybdates including a factor-group analysis of the vibrations of the crystals and a theoretical calculation of the normal vibrational modes and wavenumbers using the valence-force field approximation, with the aim of demonstrating the relationship between the type of spectrum and the structure. The compounds K_2MoO_4, $K_2Mo_2O_7$,[37] $K_2Mo_3O_{10}$,[41] and $Na_2Mo_2O_7$ [42] were chosen as models for the calculation because of the diversity of their crystal structures [including structures with isolated tetrahedral anions (K_2MoO_4), chain structures with tetrahedra and octahedra ($Na_2Mo_2O_7$, $K_2Mo_2O_7$), and chain structures with trigonal bipyramids and octahedra ($K_2Mo_3O_{10}$)] and hence the presence of

different types of Mo—O—Mo bridging bonds, to the vibrations of which particular attention was paid. The range of Mo—O bond lengths in the compounds studied was 1.64—2.27 Å, so enabling the effect of the interaction at "long" Mo—O bonds on the vibrational spectrum to be investigated.

In Refs. 37, 41, and 42 experimental data are given on the i.r. and Raman spectra in the 4000—50 cm^{-1} region (Figs. 3 and 4) of specimens isotopically substituted with molybdenum ($^{92}Mo-^{100}Mo$) and an assignment of the vibrations of the different sublattices in the crystal is made. These data were supplemented by the results of studies of some alkali metal tungstates by the authors of the present review.

The lengthening of the Mo—O bonds in $K_2Mo_2O_7$ crystals to 2.27 Å leads to a reduction of the wavenumbers of the vibrations involving these bonds to 600—480 cm^{-1}.[37] In this region the coordinates of the change in the O—Mo—O angles also make a substantial contribution to the vibrational modes. An analysis of the normal vibrations of $K_2Mo_3O_{10}$ [41] shows that the vibrations in the system with the highest wavenumbers (970—900 cm^{-1}) are accounted for by the coordinates of the change in length of the very short terminal Mo—O bonds and the vibrations of the Mo—O—Mo bridging bonds occur over a broad spectral range (860—480 cm^{-1}). A single vibration is not found for the closed grouping  , which is present in the crystal structure of this compound; this is evidently due to the considerable different between the bond angles at the bridging oxygen atoms.

The vibrations of the tetrahedral MoO_4^{2-} grouping in $Na_2Mo_2O_7$ [45] occur over a broader spectral range (910—770 cm^{-1}) than is the case for the isolated tetrahedra in the A_2MoO_4 structures or for the free MoO_4^{2-} ion.[4] The coordinates of the bonds in the octahedral grouping make the predominant contribution to the vibrations in the 940—460 cm^{-1} region which is considerably broader than the wavenumber range for stretches of isolated MoO_6 octahedra.[5] The reasons for these discrepancies are both the presence in the structure of long Mo—O bonds (up to 2.26 Å) and the formation of Mo—O—Mo bridging bonds between a tetrahedron and an octahedron and between two octahedra. The broadening of the range for deformation of the molybdenum-oxygen polyhedra to 420—240 cm^{-1} is also due to condensation of the coordination polyhedra.

The analysis of the vibrations for the series of alkali metal molybdates enabled the assignment of the wavenmbers in their i.r. and Raman spectra to be improved and also the effect of the bridging bonds on the crystal lattice dynamics to be found. A comparison of the geometrical and spectroscopic characteristics of the bridging groups (Table 6) shows that an increase in the Mo—O interatomic distances is accompanied by a decrease in the wavenumbers of the vibrations of these groups and that an increase in the bond angles at the oxygen atoms leads to an increase in the wavenumbers of their antisymmetric vibrations and a decrease in those of the symmetric vibrations. The latter occupy the wavenumber region between the stretches and deformations of the coordination polyhedra and this complicates the interpretation of the spectra. The values of the force constants of the Mo—O bonds which we obtained in these calculated show a correlation with the interatomic distances.

We obtained similar results for $Li_2W_2O_7$ and $Na_2W_4O_{13}$. In these compounds we are faced with a more complex structure for the set of condensed polyhedra. In addition to W—O—W bridging bonds formed by pairs of tungsten coordination octahedra, the structures of these compounds contain oxygen nodes shared between three tungsten octahedra.

*$\Delta\nu = \nu_{antisym} - \nu_{sym}$ was determined from the mean wavenumbers of the vibrations of the bridging oxygen atoms.

**The data given are for the terminal M—O bonds in the MO_4 tetrahedra.

***Oxygen atom in the field of three tungsten atoms (node). For $Li_2W_2O_7$ the vibrations of the bridging and nodal oxygen atoms are strongly mixed.

[*The units used for the force constant are not clear (Ed. of Translation)].

For lithium ditungstate the wavenumbers of the antisymmetric vibrations of the bridging and nodal oxygen atoms are mixed and lie in the fairly broad range 1015—852 cm^{-1}. In sodium tetratungstate

these vibrations are separated in mode and wavenumber. The wavenumber range 920–882 cm^{-1} is asigned to the vibrations of the nodal oxygen atoms and the range 790–774 cm^{-1} to vibrations of the bridging bonds. As in the molybdates, the symmetric vibrations of these structural fragments occur in the region of the spectrum adjacent to the high-wavenumber limit of the deformations of the tungsten-oxygen polyhedra.

The lithium isotope effect is well developed in the i.r. spectra of $Li_2W_2O_7$, $\Delta\nu$ reaching 16 cm^{-1}. The relatively high wavenumbers of the vibrations of the cations in the lithium sublattice (up to 500 cm^1) are consistent with tetrahedral coordination by oxygen and short lithium–oxygen interatomic distances.

In all the polymolybdates and polytungstates the antisymmetric vibrations of the M–O–M bridging atoms usually have higher wavenumbers than the vibrations of the terminal oxygen atoms, given that the interatomic distances are comparable.

IV. Stability of the crystals

Various thermodynamic quantities are used for comparing the stabilities of crystalline compounds: the enthalpies of formation of crystalline compounds from the elements under standard conditions $\Delta H^\circ_{f298.15}$ or $\Delta H^\circ_{ok\,298.15}$ [of representing formation of crystal (Ed. of Translation)], the melting point T_f, the crystal lattice energy U, or the energy of atomisation E_a. Urusov[46] showed that the most definitive characteristic of binding energy in a crystal is the energy of atomisation E_a which is released as a result of the formation of the crystal from an infinitely rarefied gas of individual atoms. However, the crystal lattice energy, which is used fairly frequently, is the energy released on formation of the crystal from individual gaseous ions at infinite distances from each other. For all compounds the energy of atomisation E_a is measured from the absolute zero level of the energy of interaction of a rarefied gas composed of atoms and it can therefore be used quite rigorously for comparison with various properties in a series of compounds of the same type. The greater the absolute value of the energy of the atomisation, the more stable is the structure.

The experimental determination of the lattice energy at 0 K[47] is based on use of the equation:

$$U_0 = \Delta H^0_{298} - \sum_M \Delta H^0_{298}(M) - \sum_X \Delta H^0_{298}(X) - \sum_M I + \sum_X F - \int_0^{298} C_p(MX)dT + \sum_{M,X} \int_0^{298} C_p(M,X)dT$$

where ΔH°_{298} is the enthalpy of formation of a crystalline compound from the elements under standard conditions

$$\sum_M \Delta H^0_{298}(M), \quad \text{and} \quad \sum_X \Delta H^0_{298}(X) —$$

are the sums of the enthalpies of formation of gaseous atoms of the metal (M) and metalloid (X) respectively from the elements under standard conditions, $\sum_M I$ — is the sum of the ionisation enegies of all the cations, $\sum_X F$ — the sum of the electron affinities of all the anions, and C_p the heat capacity at constant pressure.

The last two integrals allow for the enthalpy change on going from the standard temperature to 0 K; the first represents the enthalpy change of the crystal and the second that of a gas of individual ions.

The experimental value of the energy of atomisation is determined using the following cycle:

$$E^0_a = \Delta H^0_{298} - \sum_M \Delta H^0_{298}(M) - \sum_X \Delta H^0_{298}(X) — \int_0^{298} C_p(M,X)dT + \sum_{M,X} \int_0^{298} C_p(M,X)dT.$$

Hence

$$U_0 - E_a = \sum_M I + \sum_X F.$$

We have calculated the crystal lattice energies and the energies of atomisation for the compounds A_2MoO_4 (A = Li, Na, K, Rb, Cs) (Table 7). Use was made of the enthalpies of formation of the crystalline compounds from the elements under standard conditions,[48] and enthalpies of formation of the gaseous atoms from the elements and the ionisation energies of the alkali metals[49] and the ionisation energy of molybdenum;[47] the affinity of oxygen for two electrons was taken to be −142 kcal.[50] An original method for calculating $-\Delta H^\circ_{298}$ using the thermal and energy characteristics of the compounds has been proposed.[51] The values of $-\Delta H^\circ_{298}$ so obtained are somewhat different from the experimental reference data[48] but the discrepancies are no more than 5%.

The calculated crystal lattice energies of A_2MoO_4 decrease as the atomic number of the alkali metal increases, indicating a decrease in the stabilities of the respective structures. The values of the energies of atomisation very similarly. This rule breaks down only for Cs_2MoO_4 (which has E_a = 793.6 kcal mol^{-1} whereas for Rb_2MoO_4 E_a = 790.9 kcal mol^{-1}). Thus Li_2MoO_4 has the most stable, and Rb_2MoO_4 the least stable, of these structures. The energy of atomisation of Li_2MoO_4 exceeds the corresponding values for the other members of the series by ~40 kcal mol^{-1}.

The particular stability of Li_2MoO_4 is evidently due to its structural peculiarities: the lithium has a tetrahedral environment of close packed oxygen atoms,[7] i.e. its CN is 4 whereas the CN of the other alkali metals is 6 in the structure of the Na_2MoO_4, 8 for potassium and rubidium, and 6 and 10 for caesium. These conclusions agree with results obtained by studying the perturbing effect of the alkali metal cation on the vibrations of the MoO_4^{2-} anion,[4] the effect being greatest for Li^+.

It is commonly assumed that there is a correlation between the variation in T_f and E_a.[47] However in the alkali metal molybdate series the variation in T_f, $\Delta H^\circ_{f298.15}$, and $\Delta G^\circ_{298.15}$ is not uniform. Rb_2MoO_4 has the highest T_f (1228 K) and Na_2MoO_4 the lowest (960 K) (see Table 7).

It was found[47] that $U - E_a$ is greater, the greater the deviation of the character of the A–O bond from the ionic type. However in the present A_2MoO_4 series the difference $U - E_a$ decreases as the ionisation energy of the alkali metal decreases. Thus on going from caesium to lithium the estimation of the stability of the molybdates using the ionic model introduces an ever increasing error in accordance with a greater deviation of the A–O bond from the ionic type as the ionisation energy of A increases.

For the alkali metal tungstates, owing to the paucity of reference data the energy of atomisation and crystal lattice energy can be calculated only for the first three members of the series: Li_2WO_4, Na_2WO_4, and K_2WO_4 (see Table 7). In the series A_2WO_4 (A = Li, Na, K) E_a and U very in the same way and, as with the molybdates, the lithium compound has the highest stability: the increase in the energy of atomisation from the potassium to the sodium compound

* Our determination.

is only 1 kcal mol^{-1} but lithium tungstates has a value which is much higher (by 38.1 kcal mol^{-1}). As with the molybdates, the appreciable stabilisation of Li_2WO_4 compared to the other members of the series can be attributed to tetrahedral close packing of the oxygen atoms around the lithium cations.[6] In the light of this the slightly higher value of the energy of atomisation of Cs_2Mo[4] compared to Rb_2MoO_4 is understandable as being due to the placing of some of the caesium cations in positions with a smaller CN.

Turning to Na_2WO_4 and K_2WO_4 the CN's of the alkali metals increases to 6 and 8 respectively and less compact structures are formed. As with the alkali metal molybates, a comparison of the melting points of the tungstates does not lead to the correct conclusion regarding the relative stability of the compounds. K_2WO_4 which is the least stable compounds in the series $Li_2WO_4-Na_2WO_4-K_2WO_4$ has the highest T_f (1196 K). It is clear from Table 7 that the difference $U - E_a$ varies in the same way for A_2WO_4 as for A_2MoO_4. Hence the use of the crystal lattice energy to estimate the stability is the least reliable in the case of the lithium compounds.

Furthermore the standard enthalpies and Gibbs free energies of formation of the compounds do not match the variation of the energy of atomisation and the melting points in the A_2MO_4 (A = Li, Na, K, Rb, Cs; M = Mo, W) series.

To compare the stabilities of the crystals in the series $A_2MO_4-A_2M_2O_7-A_2M_3O_{10}-A_2M_4O_{13}$ is quite difficult because the calculation scheme presupposes the summation of the contributions of individual atoms and for comparison the values of the energy of atomisation quoted are required. One of the possible methods is to compare the E_a values obtained with the sum of the E_a values for the respective constitutent oxides. In the potassium molybdate series the differences obtained increase on moving from potassium molybdate to the dimolybdate, the trimolybdate, and then the tetramolybdate (Fig. 5). However the greatest increase in E_a is for $K_2Mo_2O_7$. This is likely to be the most stable of these compounds. The condensation of the coordination polyhedra in the structure of $K_2Mo_2O_7$ results in there being very short M–O bonds which have relatively high dynamic coefficients for bridging bonds.

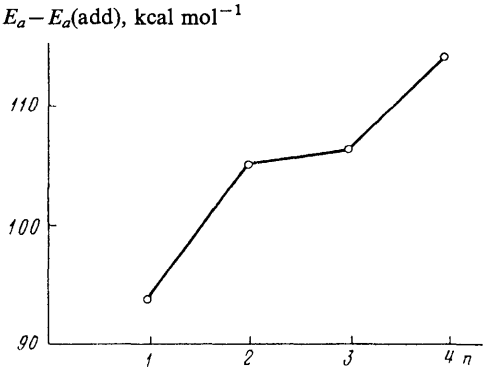

Figure 5. Variation of the activation energy ΔE_a for the potassium molybdates $K_2Mo_nO_{3n+1}$ (n = 1–4) with their composition.

The data for alkali metal molybdates and tungstates presented here and their analysis show that vibrational spectroscopy is a sensitive method enabling very small changes in the structures of the compounds to be recorded. However, because the vibrations of complex condensed systems are not characteristic, it is not always possible to interpret the results obtained unambiguously. Systematic changes in the crystal structure with the size of the alkali metal cation and the cation content in the system show correlations with the thermodynamic properties. Nevertheless the latter, being integrated quantities, are not responsive to the detailed features of the structure of the substance.

Cooperative models of dissolution of metal crystals

G V Khaldeev, V V Kamelin
A M Gorki State University, Perm

ABSTRACT. The results of new approaches to the problem of dissolution of metal crystals in electrolytes are summarised and analysed. The analysis is based on consideration of a metal/electrolyte interface as a system of two coupled, structurally organised, condensed phases in which cooperative excitation processes take place. Excitation (suppression) of dissolution is discussed in terms of local initiation (inhibition) of surface linearly extended defects of the crystal structure. The ideas proposed are supported by experimental results.

The bibliography contains 63 references.

I. Introduction

The study of the mechanism of dissolution of metals is a task with many practical applications (protection from corrosion, cementation, electrochemical technologies, etc.). In the last few years new models of dissolution of metals have been proposed[1–3] and in these models the dominant role is assigned to surface defects. The kinetics of dissolution of a metal depends on its crystallographic characteristics governed by the type of face. Different dissolution mechanisms are proposed for flat atomically smooth singular F faces and for rough S and K faces that have surface defects.

According to the Ising and/or cluster representations, the adsorption centres on the surface of a metal form structure elements which are short in one dimension ($\leqslant 10a$, where a is the lattice parameter). The structure motif in adsorbed films of inhibiting surfactants depends on predominance, on the surface of a dissolving crystal, of faces with a specific orientation (hkl). There is a considerable interest in the dissolution of rough S faces with linearly extended surface defects such as steps (ledges). In accordance with the terrace-step-kink (TSK) or terrace-ledge-kink (TLK) model, the terraces are closely packed, whereas extended defects (steps or ledges) carry highly active centres known as kinks, which represent projections of the step edge (Fig. 1).

The possibility of appearance of kinks on steps as a result of thermal fluctuations was first demonstrated by J Frenkel (1945). Heating of modified metal surfaces in vacuum gives rise to monatomic steps with a surface roughness (r). Formation of kinks increases greatly r. An estimate of the roughness of a step due to the formation of kinks (r_K) is important in estimates of corrosion and, if allowance is made only for the first coordination sphere (nearest neighbours), it depends nonlinearly on the metal–metal binding energy (E_{M-M}):

$$r_K=[\sinh(E_{M-M}/2k_BT)]^{-1}$$

where k_B is the Boltzmann constant and T is the absolute temperature.

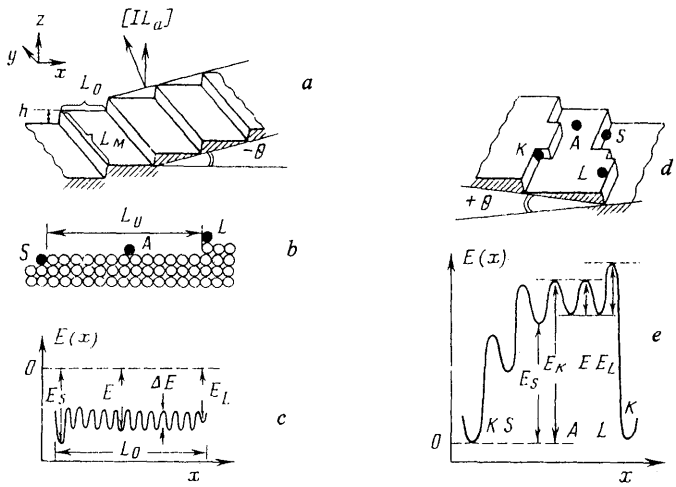

Figure 1. Energy diagram of adsorption of particles on S (a–c) and K (d, e) faces of a crystal. The diagrams show the binding energies of an adparticle on a terrace A (E), at the ledge of a step L (E_L), on the face of a step S (E_S), and in a kink K (E_K); the rest of the notation is explained in the text.

When a metal is in contact with an electrolyte, nonlinear wave processes occur on the surface of the metal crystal and they generate roughness of a dissolution step. Even if the description of dissolution is limited to a planar (two-dimensional) model, computer modelling of the displacement of dissolution steps $<IL_a>$ (L_a is a lattice step and I is the number of steps) on a cubic face of a Kossel crystal[4] shows—if allowance only for the interaction with the nearest neighbours is taken into account—that the process of dissolution does not reduce to the events of ionisation on a metal at specific active centres. The dissolution and growth of crystals is

modelled on the basis of ideas put forward by Gilmer.[5] It had become obvious that when the roughness is strong (i.e. when the Jackson–Temkin factor $E_{M-M}/2k_BT$ is small), the opposite to dissolution, i.e. crystallisation, involves cooperative attachment of chains of atoms and not consecutive growth of a new phase at an active centre.

From the thermodynamic point of view the appearance of roughness during the process of dissolution is the result of the 'fight of a crystal to ensure survival'. This should lower and then stabilise the rate of corrosion. However, when a metal/electrolyte system is acted upon by an external perturbation (for example, when an anodic potential is applied, a crystal is deformed in a solution, activating ions are introduced into an electrolyte, or when a metal is hydrogenated), linearly extended defects (waves) moving on the surface and characterised by a higher chemical activity may produce the opposite effect, i.e. they may prevent deceleration of the corrosion process with time.

It follows from the diagram demonstrating changes in the free energy of an adsorbed atom in the TLK model (Fig. 1) that an adsorbed surfactant particle experiencing a periodic field of the potential E on a terrace (position A) reaches states with higher coordination (K, S, L). The ease and strength of adsorption at a kink (position K) in the case of a low concentration of a surfactant in a solution ($C_{surf} = 10^{-4}-10^{-3}$ M) makes it possible to account for numerous observations of effective nonmonolayer ($\theta_{surf} < 1$ monolayer) inhibiting adsorption.

Stepped surfaces (Fig. 1*a*) are described by the Miller indices of the terraces and steps; for example, in the case of the b.c.c. and f.c.c. crystals we have $[n(110)-(011)]$, $[n(110)-(001)]$, $[n(111)-(001)]$, etc. Some ('magic') vicinal stepped surfaces are stable because of reconstruction of the steps. The width (L_0) of a stabilised step is close to an integral multiple of a superstructure period.[6] In the course of dissolution of a polycrystalline solid its surface is bounded by stabilised grain faces with specific values of (hkl), which are the planes of b.c.c. crystals with the $[n(110)-(001)]$ steps. Less closely packed $[n(110)-(0\bar{1}\bar{1})]$ or $[n(110)-(011)]$ vicinal faces are more stable and carry less strongly bound adatoms. The rate of dissolution of a metal then decreases with time.

However, in spite of the physical attractiveness of the TLK model (ionisation of a metal is regarded as a system of consecutive transitions of metal ions M from the lattice into a solution: $M_L^{n+} \rightarrow M_S^{n+}$), it fails to describe satisfactorily the process of dissolution at high and/or very low corrosion rates. The first problem is the disagreement between the characteristic times of adsorption of the solution particles forming a surface intermediate layer and the characteristic times of elementary events of the ionisation of a metal. The second problem is related to high densities ($i_a \geqslant 10^4$ A/m^2) of anodic currents in the electrochemical process at defects on the K faces; such high local rates cannot be retained for a long ($>10 \times 10^3$ s) time. If the dissolution rate depends only on the local concentration of the electrolyte, then in the absence of diffusion limitations we can expect only spherical corrosion pits. The third problem is the delocalisation of atoms in the first layers of the crystals, which are in contact with a liquid phase, at sufficiently high anodic overvoltages ($\eta_a > 0.2$ V). A special structurally disordered state appears in such layers.

It is therefore necessary to consider alternative mechanisms of dissolution of a metal which allow for the cooperative ionisation events when the first surface layers of the atoms of the metal crystal go over to an excited state. Such resonant excitation creates a quasi-liquid (quasi-crystalline) state in a surface layer of a metal crystal and it is characterised by a short-range order typical of a two-dimensional ($2-D$) adsorption layer in an electrolyte. Concentration and deformation waves appear on the surface of a dissolving crystal as a result of collective excitations in the contact layers of the metal/electrolyte system. Resonant tunnelling of light chalcophilic particles near extended surface defects no longer occurs because of enhancement of the localisation of adsorbed solution particles. Therefore, the action of a corrosion inhibitor (when C_{surf} = const) is manifested more effectively on a stepped surface than on one which is atomically smooth.

This review summarises the results of theoretical investigations of dissolution of transition metals in electrolytes, which is treated by a new approach to the surface layers. A phase transition occurs in such contact layers by excitation of linear one-dimensional ($1-D$) surface defects.

II. Kinematic theories of dissolution

The first theoretical concepts allowing for cooperative effects during dissolution of crystals, known as kinematic theories, were proposed by Lighthill and Whitham[7] and by Frank,[8] and then extended by Hirth, Rouse, and Pound.[9] An analogue of such work in electrochemistry is the unusual approach of Hertz,[10] who considered collective effects of motion of electrolytes without recourse to the concepts of a 'charge' or 'electrochemical potential' and used only the equations for a nonlinear oscillator.

A microscopic approach to dissolution on singular and diffuse (nonsingular) faces of metal crystals shows that a morphological manifestation of a sequence of elementary events involved in the transfer of atoms from a crystal to a liquid phase involves formation of dissolution steps of different height h. The process of dissolution begins as a local form at a subsurface structure defect of a passive metal and rapidly changes to generation of dissolution steps (Fig. 2). Tunnelling electron microscopy has shown that local forms (0.4–0.6 mm) are observed on a passive surface of a crystal of stainless steel even as a result of brief (< 100 s) contact with a 3% aqueous solution of NaCl. The velocity of dissolution steps (V_S) increases on reduction of the density of these steps $\beta_0 = L_0^{-1}$ (which is the number of steps per unit length). In the case of a diffuse surface the height h and the flux of dissolution steps $J_S = f(\beta_0)$ depend strongly on the surface indices (hkl), on the degree of supersaturation of the solution $\Delta\gamma^*$, on the applied electrode potential E, and on the kinetics of diffusion processes at the phase boundary. An important experimental observation is that local dissolution nuclei, usually formed at a subsurface structure defect, grow quite independently and that dissolution steps propagate along the surface without 'noticing' one another.

Even the early kinematic theories of dissolution of ionic crystals deal with systems of $1-D$ (steps) and $2-D$ (terraces) regions with a low step concentration β_0, when the boundary effects can be ignored. Enhancement of dissolution of ionic crystals at steps is attributed to breakdown of the electrical neutrality at a phase boundary and to the long-range effects of steps in the process of their decoration with impurities from the solution. The steps on nonsingular faces of metal crystals have a considerable influence on surface reconstruction in the course of adsorption of the solution particles. A theoretical description of the reconstruction process is based on the theory of phase transitions. This process always occurs on the surface of a metal considered as the main defect of a solid.[11] Adsorption of the solution particles changes the kinetics and

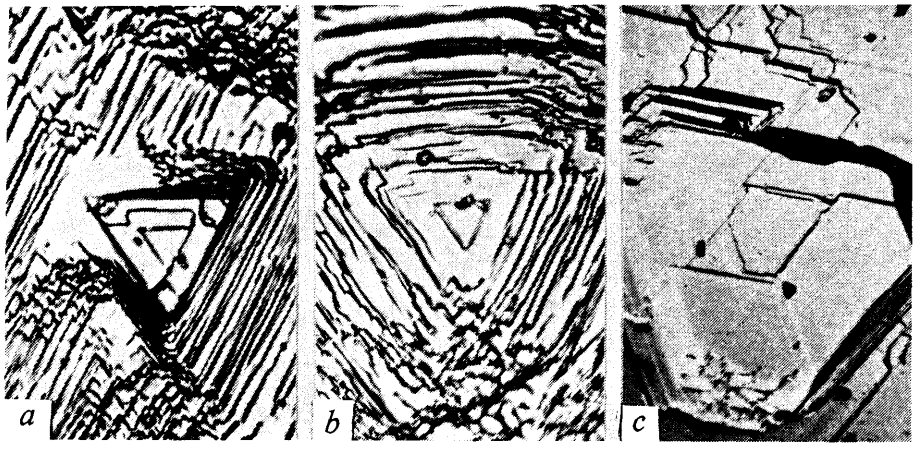

Figure 2. Evolution of dissolution steps beginning from a single subsurface defect in a system formed by (111)Ni and 1 M HNO_3 solution, obtained using an anodic current of density i_a = 50 A/m^2; 298 K; magnification 960. Time t (s): *a*, 20; *b*, 40; *c*, 60.

sometimes even the phase diagram because of reconstruction. The rate of dissolution i of a crystal in an electrolyte is largely determined by supersaturation with metal ions $\Delta\gamma^*_{M^{n+}}$ and with a surfactant $\Delta\gamma^*_{surf}$ at the phase boundary, and by the diffusion of M^{n+} in the bulk of the solution.

III. Dissolution in the form of a monatomic step

An ideally atomically smooth singular low-index F face should form a monatomic step during dissolution and the step should move from the extreme positions on a crystal. Experiments[12] have shown that such monatomic steps appear when the electrode potential is 'cycled' and a surface is prepared carefully under near-equilibrium conditions from a high-purity single crystal.

The shape of monatomic steps, which represent Frenkel–Kontorova surface dislocations, can be described at a given moment t by a wave function

$$\varphi(x, t) = \pi - 4\arctan\{\exp[-(x_i - V_i t)/kD_V]\} \quad (1)$$

where kD_V is the half-width (size) of the Frenkel–Kontorova dislocations; D_V is the diffusion coefficient (viscous); V_i is the velocity of an i-th atom of size a moving from one cell to another; $x_i = ika$ is the diplacement. The mathematical solution given by Eqn. (1) represents a domain wall with a kink; it is obtained by solving the nonlinear differential equation of the sine–Gordon type

$$\varphi_{tt} - \varphi_{xx} + \sin\varphi = 0, \quad (2)$$

where $\varphi = \Phi(X)$ and $X = x_i - V_i t$. The master equation for $\Phi(X)$ is

$$\tfrac{1}{2}\left(V_i^2 - 1\right)\Phi_x^2 + 2\sin^2 \tfrac{1}{2}\Phi = A,$$

where A is a constant of integration related to the wave amplitude.

It follows from an investigation of Eqn. (2) that the appearance of a dissolution step and its subsequent behaviour (including the stability of a step wave against external perturbations by an electrolyte) depends on the initial velocity and the initial amplitude of the wave.[13] Dissolution steps stable in the presence of such perturbations form in at least two cases. The first is represented by $A < 0$ and $V_i^2 - 1 < 0$, when helical waves obeying the following relationships are observed

$$\Phi_x = \pm\left[\frac{2}{1 - V_i^2}\left(|A| + 2\sin^2 \tfrac{1}{2}\Phi\right)\right]^{1/2}, \quad (3a)$$

where Φ_x may increase or decrease. In the second case we have $A > 2$ and $V_i^2 - 1 > 0$, when helical waves obeying the following relationship appear:

$$\Phi_x = \pm\left[\frac{2}{V_i^2 - 1}\left(|A| + 2\sin^2 \tfrac{1}{2}\Phi\right)\right]^{1/2}. \quad (3b)$$

The source of the Frenkel–Kontorova dislocations may be the edges of a crystal, where the characteristics of the displacement processes reach their critical values, or the numerous subsurface defects. When the solution particles are adsorbed, the local positions of a strong disturbance of the translational invariance of a crystal stimulate the motion of a step wave.

In the case of a monatomic dissolution step (a Frenkel–Kontorova dislocation) on a metal crystal the velocity of its propagation in a surface layer is governed primarily by the density ρ of the metal and by the surface tension of stress γ_S:

$$V_S = \left(2\pi\gamma_S/\rho b\right)^{1/2} \sin\left(\frac{\pi a}{b}\right) \Big/ \left(\frac{\pi a}{b}\right). \quad (4)$$

If the distance between the atoms is $b \gg a$ (where a is the lattice parameter), then bearing in mind that $\sin x \approx x - x^3/3!$, we find that Eqn. (4) can be reduced to

$$V_S = (2\pi\gamma_3/\rho b)^{1/2}\left(1 - \frac{\pi^2 a^2}{6b^2}\right). \quad (5)$$

Eqn. (5) is used to describe dissolution of f.c.c. and h.c.p. crystals in view of the anisotropic dependence of the corrosion rate on (hkl).

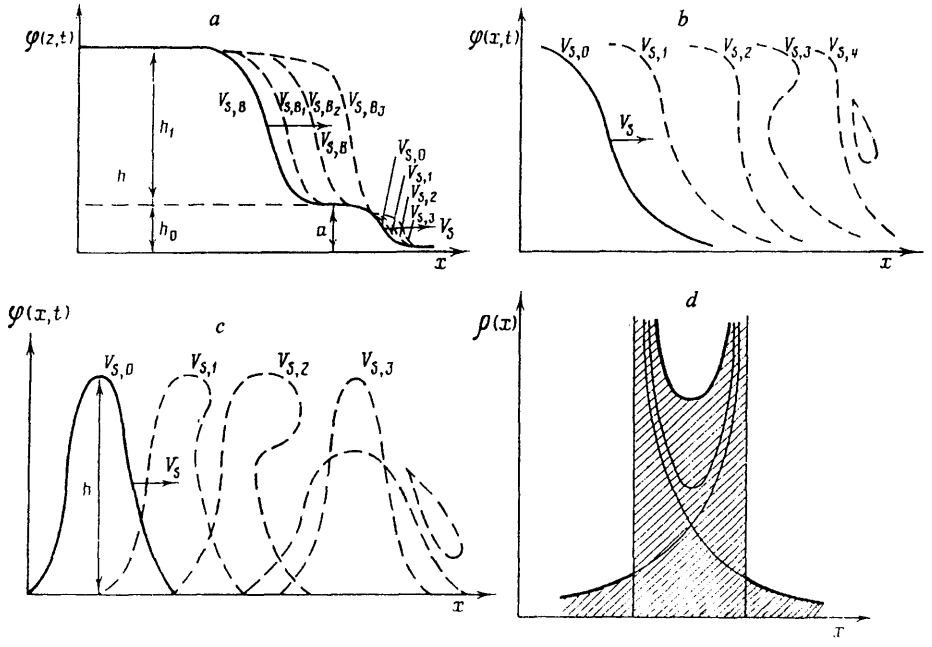

Figure 3. Changes in the surface profile of a dissolving crystal in the case of a shock wave (*a*), a kink (*b*), and a solitary wave (*c*), and characteristic features of the density of a crystal in the course of evolution of a kink (*d*).

Such an integral characteristic as the density $\rho = f(S_{hkl})$, where S_{hkl} is the reticular density of a crystal face, may be modified anisotropically on adsorption of the solution particles (reconstruction of the surface layer). The distance between the first and second (Δa_{12}) layers along the normal to the surface is less than the corresponding distance in the bulk. The changes in Δa_{12} appear under the action of unidirectional mechanical surface tension forces and the stimulus for the reconstruction is provided by the energy gained by the electron states as a result of a small deformation of the surface structure. The appearance of a monoatomic step is usually analysed in terms of the surface stresses γ_S, directional strains $\vec{\varepsilon}$, displacements x_i, and the elastic energy $E_{L,a}$ of a step of atomic length. The energy of appearance of a Frenkel–Kontorova dislocation E_{FK} originates mainly from perturbations of the electron and phonon subsystems, and it has two components: an elastic energy E_{La}, associated with directional strains $\vec{\varepsilon}$ in the course of phase modification of the surface layer, and a linear energy E_K, localised at distances $< k$ (Burgers vector) and estimated in terms of the free energy of an outer face of the step.

A strong reduction in γ_S as a result of adsorption of nucleophilic surfactants (such as halogen ions, OH^-, H^-, etc.) on a hydrophilic surface of a *d*-metal reduces V_S and slows down correspondingly the dissolution rate. An adsorbed surfactant quenches vibrations (reduces the vibration amplitude Φ) in the surface layer of atoms and in the final analysis destroys the resultant surface Frenkel–Kontorova dislocation.

These ideas are based on a Kossel–Stranski model of a defect-free crystal on the surface of which a particle may be in various energy states (Fig. 1*d*). A description of a model of monatomic parts of the first surface layer can be given in two variants: as a shock wave (kink) and as a solitary wave ('rolled-up carpet'). In the former case (*i*) a nonlinear diffusion equation of the Burgers type is considered:

$$\varphi_t + \varphi\varphi_x = D_V\varphi_{xx}, \qquad (6)$$

where D_V is the viscosity of a concentration wave $C(z, t) = C(t)\exp(ikz)$, in which the dependence of the particle concentration C on time t along the coordinate z, directed into a solution, obeys the second Fick law $dC/dt = D_V(\partial^2 C/\partial z^2)$ in the electrode layer (Fig. 3*a*). The amplitude of a concentration wave in a solution is h_1 and the velocity of its motion $V_{S,B}$ is higher than the velocity of a kink V_S in the first surface layers of a crystal of thickness a ($V_{S,B} \gg V_s$, $h_1 \gg a$). The profile of a kink (Fig. 3*b*) corresponding to Eqn. (1) changes in the course of dissolution. In the case of the curves representing the dependence of $\varphi(x, t)$ on x there are regions with a negative slope $[d\varphi(x, t)/dx < 0$, represented by the curve $V_{S,3}]$. From this moment we can expect resonant excitation of a surface layer of a metal and a phase transition $M_L^{n+} \rightarrow M_S^{n+}$, corresponding to the position $V_{S,4}$. The amplitude does not change in the course of the subsequent nondissipative development of the process.

In the phase space on a rolled-up surface, when the projection ($0z$, $0x$) is nonmonotonic — $dx/dt > 0$ above the $dx/dt < 0$ below — the path of a particle in the course of the $M_L^{n+} \rightarrow M_S^{n+}$ transition is such that the motion is slow on the upper and lower planes, but it is catastrophic at the fold.

We shall now analyse the process. It is known[14] that a mathematical description of a quantum-mechanical potential differs from the expression for the potential energy by a multiplicative constant. Any system tends to assume a position which minimises its energy and, if there are several minima, these minima can be identified with different phase states. The minima of the relevant

potential reflect the phase states. The catastrophe theory[15] shows that if a function depends on parameters, then there are such zones or such states that—depending on the set of parameters—a smallest deviation results in a transition from one phase state to another.

We shall consider a potential of the type

$$E(x) = E_0 - a_0 \frac{e^2}{\Omega^{1/3}} x + b\frac{e^2}{\Omega^{2/3}} x + c\frac{e^2}{\Omega} x^3 + d\frac{e^2}{\Omega^{4/3}} x^4,$$

where Ω is the atomic volume; $a_0 = 6 - 12/\sqrt{2} + 8/\sqrt{3} - \ldots$ is the Madelung parameter which depends on the geometry of the metal crystal lattice; b, c, and d are constants that determine the properties of the metal.

We shall find the surface of the minimal potential

$$a_0 \frac{e^2}{\Omega^{1/3}} + 2b\frac{e^2}{\Omega^{2/3}} x + 3c\frac{e^2}{\Omega} x^2 + 4d\frac{e}{\Omega^{4/3}} x^3 = 0$$

and reduce it to the form

$$x^3 + rx^2 + sx + t = 0,$$

where

$$r = \frac{3c}{4d}\Omega^{1/3}, \quad s = \frac{2b}{4d}\Omega^{2/3}, \quad t = \frac{a_0}{4d}\Omega.$$

The boundary of a catastrophic phase transition lies on a surface described by the equation

$$\left(\frac{P_L^3}{3}\right)^3 + \left(\frac{Q_L}{2}\right)^2 = 0, \tag{7}$$

where

$$P_L = \frac{3s - r^2}{3}, \quad Q_L = \frac{3r^3}{27} - \frac{rs}{3} + t.$$

The resultant fold-type singularity is a V-shaped curve with a kink in the space of the parameters. Inside the region bounded by this curve the system is stable. At the boundary of the region the above function has three roots, two of which are identical. Consequently, in the case of the inner part of the region there are three real but different roots. A slight 'tremor' may displace a point from the boundary into the region in question, giving rise to a multisheet surface of a metal and a phase transition at the metal/electrolyte boundary between the condensed media. An analysis of Eqn. (7) shows that the occurrence of a catastrophe does not depend on E_0, e, or Ω: it is related only to the constants a_0, b, c, and d.

What is the process that gives rise to a concentration wave? In a general model of dissolution this is very important, since a nondissipative process of propagation of a dissolution step in a surface layer of a crystal may become a resonant effect on interaction with a concentration wave that appears in the adjoining electrolyte. The functional relationship between $V_{S,B}$ and V_S is manifested by a monotonic increase in V_S on increase in $V_{S,B}$. If $h_0 \gg a$ (where a is the lattice parameter) and the front of a concentration wave overtakes the front of a kink in the metal investigated, a solitary wave (soliton) appears (Fig. 3*c*) and its evolution in a nondissipative scenario involves either conservation of its amplitude or a reduction in the amplitude accompanied by a simultaneous broadening of the face of the wave. In time such a solitary wave may degenerate into a 'rolled-up carpet',

Dissolution differs from crystallisation of a metal because the motion of the M^{n+} ions is in the former case to a condensed medium with an undersaturation of M^{n+}, whereas in the latter case the motion of M^{n+} occurs from a supersaturated state. In the course of dissolution the M^{n+} particles may not 'notice' one another. However, the ionisation occurs at inequivalent positions on the crystal surface and, therefore, after a time t the fast particles (from defects) will overtake the slowly moving ones.[15] The velocity field V_S becomes triple-valued: three fluxes of particles may cross the same point in space (Fig. 3*b*) and their velocities at each point are different. If initially the density of the medium at a point x_0 is $\rho_0(x_0)$, it changes with time giving rise to a density singularity: at a distance x from the point on the fold the density is of the order of $(I\Omega)^{-1/2}$ (Fig. 3*d*). After a sufficiently long time t at the points with an infinitely high density of the medium we can expect formation of particle clusters, i.e. the $M_L^{n+} \rightarrow M_S^{n+}$ transition takes place. This conclusion applies also to a multidimensional space. Therefore, a concentration wave is excited in a surface layer of the electrolyte adjoining a metal because of inequivalence of the active points on the surface of the metal. Such a wave is coupled resonantly to a surface layer of the metal and excites there a kink (Fig. 3*b*) or a solitary wave (Fig. 3*c*).

The concentration wave penetrates the electrolyte when the matching of the solid (crystal) to the electrolyte supersaturated with M^{n+} is coherent. A combination of the equations for the dissolution rate (representing the density of the flux of the M^{n+} particles) $i = i_0 \sin V_j t$ (i_0 is the exchange current density) with the second Fick law leads to an equation describing a concentration wave with an amplitude that decays with depth (along the coodinate z) in the solution[16]

$$C(z,t) = C_0 + \Phi \exp\left(-\sqrt{\frac{V_j}{2D_i}} z\right) \sin\left(V_j t - \sqrt{\frac{V_j}{2D_V}} z - \frac{\pi}{4}\right), \tag{8}$$

where Φ is the amplitude, which is proportional to i_0, and V_j is the velocity of the wave (its angular frequency).

It follows from Eqn. (8) that

$$\frac{\partial C(z,t)}{\partial z} = -\Phi\sqrt{\frac{V_j}{D_V}} \exp\left(-\sqrt{\frac{V_j}{2D_V}} z\right) \sin\left(V_j t - \sqrt{\frac{V_j}{2D_V}} z\right). \tag{9}$$

The amplitude Φ of the concentration wave in the electrolyte and the depth of its penetration z_0 into the electrolyte fall proportionally to $V_j^{1/2}$.

When a kink or a solitary wave propagates in a metal, the value of the viscosity coefficient D_V depends on the action of periodic forces in a regular lattice, when

$$D_V \simeq \nu_L^{-1} \simeq 1\ \mathrm{P}^{-1},$$

where ν_L is the viscosity of a crystal (sound attenuation coefficient), or in the absence of a periodic short-range of a crystal when

$$D_V \simeq D_F/K_C a^2 \simeq 10^{-8}\ \mathrm{P}^{-1},$$

D_F is the diffusion coefficient of phasons and K_C is the elastic (Young's) modulus of a crystal.[17] If D_F is small, the solution of Eqn. (6) differs from Eqn. (1) and corresponds to a shock wave (kink) of the type

$$\varphi(x, t) = kD_V[1 - \tanh^{1/2}(kz - D_V k^2 t)], \tag{10}$$

which obviously appears when filamentary single crystals of metals with perfect singular surfaces are dissolved (Fig. 3*b*). In the limit

$z \to \infty$, we have $(x,\ t) \to 0$, whereas for $z \to -\infty$, we have $(x,\ t) \to 2kD_V$. The approach of a shock wave to the edge of a crystal results in an abrupt fall in the concentration and excitation of a new concentration wave

$$C(t) = C(t_0)\exp[-\alpha(k)t],\ \alpha(k) = D_V k^2, \quad \text{(I)}$$

which moves in the opposite direction. Near the edge the properties of a crystal are unusual: the Gaussian curvature ($R_G = r_1 r_2$, where r_1 is the largest and r_2 is the smallest curvature) has a finite discontinuity of universal amplitude; the fall of the transverse curvature is described by an universal exponent.

In the second case (*ii*) an allowance is made for the fact that crystals very rarely have singular faces and that diffuse (nonsingular) faces have a ready-made step right from the beginning. The subsequent development in the kinematic theories of dissolution of diffuse K faces is due to Lighthill and Whitham[7,13] who based their ideas on the models of dissolution of the surfaces of a crystal which have terraces, steps and kinks on the steps (TLK model). The steady-state velocity of linear steps in accordance with the 'rolled-up carpet' mechanism, representing consecutive detachment of a semi-infinite chain of atoms in the upper layer from atoms in the lower layer, can be described by the following nonlinear relationship containing parameters which can be determined experimentally:

$$V_S = 2K\bar{x}_S \tanh(L_0/2\bar{x}_S)\, D_V\Omega(C_0 - C_0')/(h\delta), \quad (11)$$

where $\bar{x}_S$ is the mean free path in the diffusion of the M^{n+} ions on a step; $\delta = 4.5(D_V/\nu_c)^{1/3}(\nu_c\bar{x}_S/V_L)^{1/2}$ is the thickness of the Nernst diffusion layer (in aqueous solutions this thickness is $\delta \approx 10^{-5}$ monolayer); ν_c is the kinematic viscosity of the solution; V_L is the velocity at which the solution moves away from the steps; $K = f(\tan\theta) \equiv f(P)$ is a kinetic coefficient; C_0 is the equilibrium concentration of the M^{n+} ions in the solutions; C_0' is the concentration of the M^{n+} ions in the metal near the phase boundary. The passage of a dissolution step along the surface of a crystal at a velocity V_S is determined by the relationships between the constants in Eqn. (11). The kinetic coefficient, depending functionally on a slope θ of a given face relative to a singular face (Fig. 1), is governed by the process of incorporation of atoms at the steps[18]

$$K(P) \simeq a\nu_D(a/\bar{L}_K)\exp(-E_{M-M}/k_BT),$$

where $\bar{L}_K$ is the average distance between the kinks on the steps and $\nu_D \approx 10^{13}\ s^{-1}$ is the Debye frequency of vibrations of the surface atoms.

The velocity of translational motion of a step reaches its limiting value $V_{S,\infty}$ when the hyperbolic tangent with the argument $\bar{x}_S \approx L_0/6$ or $L_0/2\bar{x}_S \approx 3$ in the relationship (11) becomes equal to 1:

$$V_{S,\infty} \simeq D_V\Omega(C_0' - C_0)L_0/3\delta h. \quad (12)$$

An analysis of Eqn. (12) shows that if $C_0 \to C_0'$ or, more accurately when the activities of the M_S^{n+} ions in the solution in the surface of the investigated crystal and of the M_L^{n+} ions in the metal are equal, the velocity of a dissolution step falls to zero. The size of the active surface which appears as a result of the passage of dissolution steps is determined by their density $\beta_0 \equiv L^{-1}$ and their height h:

$$L_0 h \equiv h/\beta_0 \simeq (hk_BT/19\Omega E_M)\ln(C_0' - C_0). \quad (13)$$

The relationship (13) includes the free surface enegy E_M, which rises and thus reduces the active surface of a metal. The difference between the concentrations $C_0' - C_0$ determines the supersaturation $\Delta\gamma^*$ at the phase boundary. In other words, we have

$$V_S \sim \Delta\mu = \mu_K - \mu_L = k_BT\ln(C_0' - C_0) \simeq -k_BT\Delta\gamma^*,$$

i.e. the velocity of a dissolution step is proportional to the difference between the chemical potentials of the M^{n+} ions in the solution and of the metal lattice.

The growth (dissolution) rate of a crystal normal to a singular F face in electrolytes can be estimated from a relationship similar to Eqn. (11):

$$V_{S,\perp} = K\Omega C_0(\Delta\gamma * - \Delta\gamma_{cr}^*), \quad (14)$$

where $\Delta\gamma_{cr}^*$ is a critical supersaturation governed by the mechanism of growth (dissolution) of a step, which may be two-dimensional nucleation or a dislocation mechanism. The critical supersaturation $\Delta\gamma_{cr}^*$ is different near the surfaces of large and small crystals and it depends strongly on the index (*hkl*) of the surface.

The undersaturation near the surface of a small crystal results in its faster dissolution; in the case of a polycrystalline aggregate the smaller crystallites (grains) with the orientations of the faces characterised by smaller values of E_M disappear first.

Slowing down of the tangential motion of the dissolution steps may be the result not only of lowering of E_M, but also of crystallographic features of vicinal faces. It had been mentioned earlier[6] that specific 'magic' vicinal surfaces are stabilised by reconstruction. An investigation of the surface structure and of the energetics of the (100)Au and (111)Au vicinal faces by the model of multiparticle forces and molecular dynamics has shown that in the case of surfaces of the $(K11)$Au(100) type, where $K = 3-45$, the 'magic' orientations correspond to the (111) and (511) faces. These surfaces are characterised by local surface energy minima ($E_M = 1.06 \times 10^4$ and 1.04×10^4 meV/nm^2, respectively) of the dependences of the surface energy on $P \equiv \tan\theta$ [where the tilt angle is $\theta = 0-0.5$ rad, defined by $\theta = \tan^{-1}(h/L_0) = \tan^{-1}(h\Delta\mu/19\Omega E_M)$]. Stabilisation of other vicinal faces occurs as a result of formation of a set of these 'magic' orientations for surfaces tilted slightly from (100)Au. In the case of the surfaces $(H + 1,\ M - 1,\ H)$ close to (111)Au, the 'magic' vicinal faces are different: they correspond to minimisation of the energy for $H = 11, 22, \ldots$, when the step with L_0 is a multiple of the superstructure period.[19] Therefore, faceting of the surface by the motion of monatomic steps and formation of 'magic' orientations may reduce the rate of dissolution of the metal to zero. This unexpected result of recent experimental investigations has not yet been considered properly from the practical point of view.

It also follows from Eqn. (11) that an increase in the height h of the steps should slow down the velocity of their motion. A kinetic and morphological analysis of a metal/electrolyte contact between condensed phases, based on the experimental results, demonstrates the opposite: the value of V_S increases on increase in h. This conflict is implicit in the very 'rolled-up carpet' model, which has been applied successfully to monatomic spallation when $h \approx a$. If $h \gg a$, a solitary wave 'collapses' (see curve $V_{S,2}$ in Fig. 3*c*) and the velocity of this wave falls strongly.

Determination of the rate of growth of crystal faces in accordance with the $2-D$ nucleation mechanism,[20] shows that difficulties associated with the relationship between V_S and h can be overcome. The rate of normal growth of a crystal face due to the motion of a growth step is

$$V_{S,\perp} = hi_n S\Big/\left[1 + \left(S\Big/\beta b_n^{1/3}\right)(i_n/V_S)^{2/3}\right], \quad (15)$$

where $i_n = f(\Delta\gamma^*_{cr})$ is the nucleation rate; S is the area of the growing face; $\beta \approx 1$; b_n is the shape factor (in the case of dome-shaped nuclei, we have $b_n = \pi$). Eqn. (15) had been checked by computer modelling using the Monte Carlo methods and by experimental studies of electrochemical nucleation.

In Eqn. (11) the quantity $\bar{x}_S$ for one dimensional diffusion-like random motion is

$$\bar{x}_S \equiv \left\langle U_x^2 \right\rangle^{1/2} = \left(2D_V t\right)^{1/2},$$

whereas in the case of two-dimensional and three-dimensional motion, we have, respectively,

$$\bar{x}_S = 2(D_V t)^{1/2} \text{ and } \bar{x}_S = (6D_V t)^{1/2}.$$

In a surface nonisotropic layer of a crystal the rate V_S must be regarded as dependent on the action of directional forces $\vec{\varepsilon}$ (for example, a gradient of particle concentrations in the regions between the phases). We then have

$$\vec{\varepsilon} = -\frac{\partial}{\partial x} k_B T \ln \frac{C'_0}{C_0} = -\frac{k_B T}{C'_0} \frac{\partial C'_0}{\partial x}. \quad (16)$$

Eqn. (16) follows from generalisation of the Fermi–Dirac distribution to the case of a transition between two phases of any charged particle. In the case of directional (drift) velocity of motion of a dissolution step, we can write down[21]

$$V_S = (D_V / k_B T)\vec{\varepsilon}, \quad (17)$$

where ε is proportional to the displacement Δa and to the step height h, and is governed by directional tangential displacements of atoms in a surface layer $< U_x^2 >$:

$$\vec{\varepsilon} = \Delta a \left\langle U_x^2 \right\rangle h. \quad (18)$$

It follows from Eqns. (17) and (18) that the step velocity V_S is proportional to the step height h at low stresses in the surface layer which set the dissociation steps in motion:

$$V_S = D_V \left(\Delta a \left\langle U_x^2 \right\rangle h\right) / k_B T. \quad (19)$$

The differences in the kinetic situation in respect of the step height h appear not only because of the differences between the drift and diffusion of steps, but also largely as a result of nonuniform adsorption blocking of steps with smaller or larger height h by a surfactant.

IV. Multilayer dissolution steps

At high dissolution rates (anodic process) it is usual to find high steps ($h \geqslant 0.1$ μm) on the S faces; the value of h depends on (hkl) indices of the surface: the greater the deviation from singularity, the higher the step. High-index nonsingular faces of transition metals dissolved in electrolytes form the highest dissolution steps the heights of which are considerably higher than those of monatomic layers and they are quite readily distinguishable when examined in an electron microscope (with a resolution of 0.2–0.3 nm).

The height of a step h, multiplied by its length L_M, provides an estimate of an active surface which, combined with the density of steps β_0 given by Eqn. (13), can be used to obtain a preliminary value of the rate of dissolution of individual crystallites in a surface layer of a metal. For example, Fig. 4*a* illustrates dissolution in a galvanostatic anodic process ($i_a = 5 \times 10^2$ A/m^2, 295 K, $t = 120$ s) of a nickel single crystal with a nonsingular stepped surface close to (111)Ni when immersed in a 5% ethanol solution of HNO_3. The degree of deviation of the close-packed singular (111)Ni surface, deduced from $\gamma' = h\beta_0$, is $\gamma' = 0.4$, and we then have $\theta = \tan^{-1}(\gamma') = 15°$. Differences between the rates of dissolution of the individual crystallites of annealed polycrystalline samples of high-purity metals can also be seen quite clearly (Figs. 4*b* and 4*c*). The experimental data reported in Refs. 22 and 23 demonstrate that in the case of b.c.c. structures a higher rate of dissolution is exhibited by the {111} faces which are those with the 'loosest' packing.

It should be pointed out that already in the early kinematic theories[24] it has been assumed that a stepped surface of a metal has a discrete nature and the velocity of the steps depends on β_0. A change in the separation between the steps L_0 results in a discontinuity of the density of the steps; such an effect is observed readily in the case of polycrystalline samples near crystallite boundaries (Fig. 4*d*). Branching of the steps and a discontinuity of their density gives rise to shock waves [see Eqns. (1) and (10) and Fig. 3]. According to the kinematic theory of dissolution the velocity of a single monolayer microscopic step is higher than the velocity of a multilayer shock wave (Ref. 24), which depends directly on the diffuseness of a face

$$V_S = \left(V_0 - V_1\right) / \left(\gamma'_0 - \gamma'_1\right), \quad (20)$$

where the rate of sinking of the metal is $V = (dz / dt) = \beta_0 h V_S$ and the diffuseness if $\gamma' = h\beta_0$, and the subscripts in the above equation correspond to the times t_0 and t_1 ($t_1 > t_0$). Hence it follows that for a fixed density of steps $\beta_0 = \text{const}$ an increase in the height of a step h tends to increase the velocity of a multilayer step V_S. This conclusion is in agreement with an analysis made above [see Eqn. (19)]

Microscopic steps are crystallographic planes[18] with the orientation P which can be determined from

$$P \equiv \left(dz/dx\right) = h\gamma' + hJ_S\left(dx/dt\right), \quad (21)$$

where x is the direction of motion of the steps, z is the direction perpendicular to such motion, and $J_S = V_S h^{-1}$ is the flux of steps at a given point. It follows from Eqn. (21) that in the case (*i*) when the density of steps β_0 is fixed, the orientation of the surface remains the same during dissolution ($P = \text{const}$), whereas in the case (*ii*) for a specific crystallographic orientation, when $P = \text{const}$, the dissolution occurs where

$$(dx / dt) = dJ_S / d\gamma'. \quad (22)$$

In the case (*ii*) the condition of conservation of the steps should be observed. In the absence of external perturbations, Eqn. (22) for a metal/solution system transforms to

$$\frac{dV}{d\beta_0} \frac{\partial \beta_0}{\partial x} + \frac{\partial \beta_0}{\partial t} = 0$$

or

$$\frac{\partial \beta_0}{\partial t} + V_c \frac{\partial \beta_0}{\partial x} = 0,$$

where $V_s(\beta_0) = dV/d\beta_0$. If $\beta_0 = \text{const}$, we have

$$\Delta\beta_0 = \frac{\partial \beta_0}{\Delta x} \Delta x + \frac{\partial \beta_0}{\partial t} \Delta t = 0$$

or

$$\frac{\Delta x}{\Delta t} = -\left(\frac{\partial \beta_0}{\partial t}\right) \Big/ \left(\frac{\partial \beta_0}{\partial x}\right) = V_S.$$

The regions of constant tilt characterised by P = const (kinematic waves) have the same dissolution rates, which agrees with Eqn. (20).

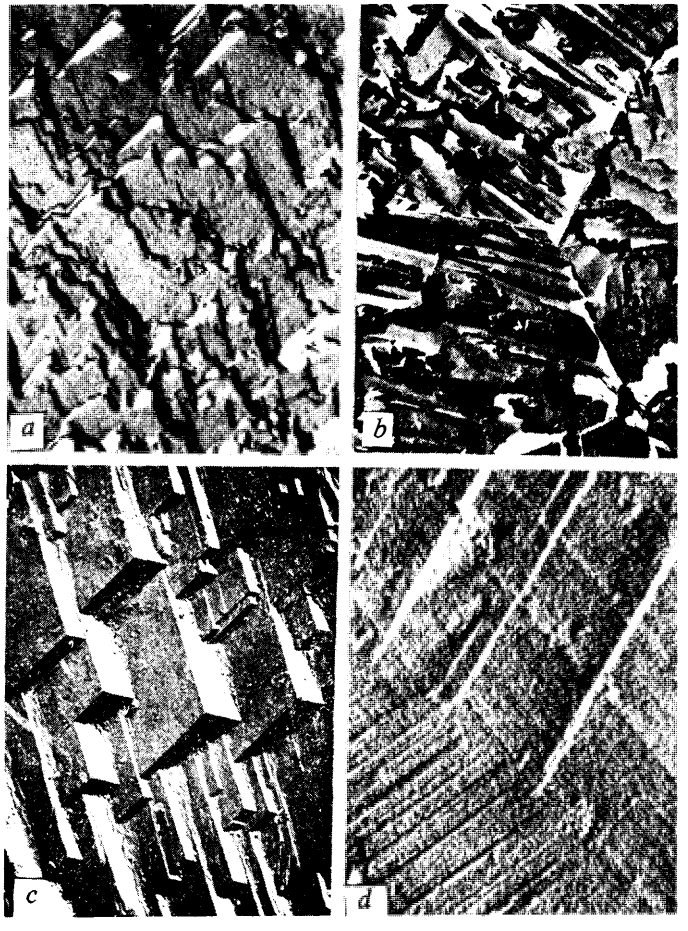

Figure 4. Dissolution steps on a [7(111)–(001)]Ni face (*a*), and on surfaces of high-purity (99.99%) polycrystalline samples of Ni (*b*) and Fe (*c*); magnification 12 000. Photomicrograph *d* shows a discontinuity of the density of dissolution steps on the surface of an Fe bicrystal.

If steps can travel not only along the x direction but also along the y axis on a face of a crystal (xy plane), an equilibrium shape of a crystal is described by[25]

$$z(x, y) = (\partial z / \partial x)x + (\partial z / \partial y)y - E_M(P), \quad (23)$$

where

$$x = (\partial E_M / \partial P)_x, \; y = (\partial E_M / \partial P)_y,$$
$$P = (\partial z / \partial x, \partial z / \partial y) = (P_x, P_y).$$

The term $E_M(P)$ is the free surface energy determined for a (hkl) face within the framework of the TSK model

$$E_M(P) = \gamma_S(\theta_L)|P| + \sigma_S(\theta)|P|^3 + \theta_L|P|^4,$$

where θ_L is the angle between the y axis in the direction of motion of the steps and σ_S is the specific surface energy.

In an analysis of the dissolution mechanism of metal crystals it is necessary not only to deal with the kinetic and morphological differences between the theory and experiment, but also to allow for the fact that the cooperative motion in the surface layer of a crystal (which differs considerably in the physical sense from the bulk) is practically dissipation-free. In a theory of solitons[26] a series of solutions of nonlinear diffusion equations has been proposed to describe a kink or a solitary wave (Figs. 3*b* and 3*c*). In practice it is possible to observe monatomic dissolution steps (Frenkel–Kontorova dislocations), by tunnelling electron microscopy, in an electrolyte and steps of significant height in the range 10^2 nm $\leqslant h \leqslant 10^4$ nm can be studied by optical spectroscopy and by the replica method (Figs. 2 and 4). It should be pointed out that a concentration wave which reaches the edge of a dissolution step may excite the passage of a kink in a plane perpendicular to the initial one. This process can account for the retention of an abrupt face on dissolution steps even after prolonged corrosion (Fig. 4).

We shall now go over from considering dissolution steps in the form of Frenkel–Kontorova dislocations [monatomic steps, see Eqn. (1)] to the dependences that describe the excitation of several surface layers of atoms. If the lattice step of a cubic Kossel–Stranski crystal (see Figs. 1*a* and 1*b*) is denoted by L_a, the potential describing the interaction of an immobile lower layer with the i-th atom in the upper layer is

$$U(x, t) = A[1 - \cos(2\pi x_i / L_a)], \quad (24)$$

where $x_i = ika$ is the displacement of the i-th atom and A is the amplitude.

The mean-square displacements of atoms in surface layers are anisotropic in respect of the dependence on the directions $<hkl>$ in a crystal and depending on its lattice (b.c.c., f.c.c., etc.). Subject to Eqn. (24), we obtain the following equation of motion:

$$m\ddot{x}_i = -2\pi A L_a^{-1} \sin(2\pi x_i / L_a) + \beta(x_{i+1} - 2x_i + x_{i-1}), \quad (25)$$

where making the substitutions $\Phi_K = 2\pi x_i / L_K$, $A = L_a^2 \overline{A}$, and $\beta = \overline{\beta} L_a^{-2}$ (β is the force constant) and going to the limit $L_a \to 0$ can yield one of the forms of the sine–Gordon equation

$$m\Phi_{tt} = \overline{L}_a \Phi_{xx} - (2\pi)^2 \overline{A} \sin \Phi, \quad (26)$$

where m is the mass of a soliton representing a dissolution step.

The solution of the soliton Eqn. (26) is a kink similar to a Frenkel–Kontorova dislocation

$$\varphi(x, t) = 4 \operatorname{arctg}\left[\exp 2\pi x \left(\overline{A}\overline{\beta}\right)^{1/2}\right], \quad (27)$$

which is formed at the expense of an energy

$$E_S = 4\pi^{-1}\left(\overline{A}\overline{L}_a\right)^{1/2}, \quad (28)$$

corresponds to 5–10 eV/atom and localised in a very small volume of a crystal (with a radius not exceeding 5a).

In general, the energy of a soliton is proportional to its mass (in accordance with the relationship similar to that used in the special

theory of relativity)

$$E_S = mV_0^2\left(1 - V_S^2/V_0^2\right)^{-1/2}, \quad (29)$$

where V_0 is the velocity of small-amplitude elastic waves (which is the velocity of sound in a metal). It follows from Eqn. (29) that if $E_S \leqslant 1$ eV, the velocity of a dissolution soliton, like that of a dislocation in a crystal, cannot exceed the velocity of sound in a given metal ($V_0 \leqslant 10^3 - 10^4$ m/s). In fact, numerous microscopic observations of the development of the morphology of the surfaces of metal crystals undergoing dissolution demonstrate that the velocities of dissolution steps are relatively low ($< 10^4$ m/s).

V. Soliton dissolution models

It follows from Eqn. (28) that a dissolution step forms a kink if the directional motion of atoms takes place in a surface layer of a crystal. Such motion is local and, as demonstrated by the above analysis, is in the nature of beats. The question is what are the mean-square displacements $(\overline{AL}_a)^{1/2}$ necessary for the appearance of a kink and what are the reasons for the displacements? The reasons can be adsorption of chalcophilic surfactant particles on the surface of a crystal or a charge (electron) density wave. The amplitude of waves moving tangentially relative to the surface (surface Rayleigh waves) decays exponentially with distance from the surface. These elastic waves in the bulk of a crystal represent superposition of waves with longitudinal and transverse components; in the case of surface waves it is not possible to separate the components.[27]

In the approximation of an ideal lattice the thermal vibrations of atoms in deeper layers can be estimated as follows. The distribution of the amplitudes of the vibrations is described by the Gaussian[28]

$$P_L(U) = \left(2\pi\langle U^2\rangle\right)^{-3/2} \exp\left[-U^2/2\langle U^2\rangle\right], \quad (30)$$

where $< U^2 >$ are small amplitudes of the distributions. In the $1-D$ case, we have

$$P_L(U) = \exp\left[-U_x^2/2\langle U_x^2\rangle\right]\left(2\pi\langle U_x^2\rangle\right)^{1/2}. \quad (31)$$

For cubic crystals, we obtain

$$\langle U_x^2\rangle = \langle U_y^2\rangle = \langle U_z^2\rangle = 1/3\langle U^2\rangle.$$

In the $2D$ case the square of the thermal amplitude of the vibrations is $< U_S^2 > = < U_x^2 > + < U_y^2 >$. The Debye temperature is $\theta_D = h_P \nu_D / k_B$ and, therefore,

$$\langle U^2\rangle = \frac{3h_P^2 T}{m_a k_B \theta_D^2}\left[\Phi\left(\frac{\theta_D}{T}\right) + \frac{\theta_D}{4T}\right], \quad (32)$$

where

$$\Phi(\xi) = \frac{1}{x}\int_0^x \frac{y\,dy}{e^y - 1}$$

is the Debye function, m_a is the mass of an atom, and h_P is the Planck constant. The Debye function can be represented graphically by a straight line when the coordinates are $\Phi(\theta_D/T)$ and θ_D/T; then, in the case of low amplitudes in the distributions, we have

$$\langle U^2\rangle = 439.2\left[\left(\frac{\Phi(\xi)}{x} + \frac{1}{4}\right)\Big/ m_a\theta_D\right], \quad (33)$$

where $\xi = \theta_D/T$. The Debye temperatures and the mean-square deviations are listed in Table 1 for a number of d metals and it follows from this table that the maximum values of θ_D and the minimum values of $< U_x^2 >$ are exhibited by the d metals with a half-filled d shell (Cr, Mo, W). These are the metals that form the most stable oxide structures and have a higher resistance to chemical action. The thermodynamic stability of the transition metals is related to the ease of the $s \rightarrow d$ electron transition; it rises steeply along the $3d < 4d < 5d$ series of metals (and this is accompanied by a rapid fall of θ_D at high values of $< U_x^2 >^{1/2}$).

Table 1. Parameters of d metals at 293 K.

Metal	Type of lattice	a, nm	θ_D, K	$\langle U_x^2\rangle^{1/2}$, nm
V	b.c.c.	0.3024	360	0.0082
Cr	b.c.c.	0.2884	485	0.0061

The displacements of atoms in the surface layers of the metals have their own cooperative characteristics. Anisotropic mean-square displacements are inversely proportional to the frequency ($\nu_D = k_B T/h_P \approx 10^{13}$ s^{-1}) of vibrations of single atoms near their equilibrium positions:[29]

$$\langle \overline{AL}\rangle^{1/2} \equiv \langle U_{\vec{r}}^2\rangle = (h_p/2m_a)\int_0^{\lambda_m} \lambda^{-1/2}\rho_{\vec{r}}(\lambda)\coth(h_p\lambda^{1/2}/2k_BT)\,d\lambda, \quad (34)$$

where λ_m is the maximum value of the square of the frequency; $\rho_{\vec{r}}(\lambda)$ is the spectral density due to the vector $\vec{r}$. Displacements (quasi-stable pulsations) each reach several nanometers. Cooperative displacements of atoms due to the passage of a soliton in the form of a kink facilitate mass transfer of metal ions to a solvated state in the solution $M_L^{n+} \rightleftarrows M_S^{n+}$. The resultant local supersaturation in the electrode layer induces a delay before the appearance of the next soliton. Improvement in convection conditions [lower values of δ and ν_c, see Eqn. (11)] increases the frequency of appearance of a dissolution soliton.

A different soliton solution can be in the form of a solitary wave. We shall base it on the Boussinescq equation[30] for the $1-D$ case. We shall assume that there are N particles with a unit mass m_a and fixed final points; $x_{r,i}^{\rightarrow}$ is the displacement from an equilibrium

position of the i-th particle in the direction $\vec{r}$; then, the equation of motion can be written in the form

$$\ddot{x}_{\vec{r},i} = f\left(x_{\vec{r},i+1} - x_{\vec{r},i}\right) - f\left(x_{\vec{r},1} - x_{\vec{r},i-1}\right), \quad (35)$$

where

$$f(x_{\vec{r}}) = \gamma x_{\vec{r}} + \alpha < x^2_{\vec{r}} >,$$

i.e. the nonlinearity is quadratic and α and γ are the constants which can be determined experimentally. We shall introduce $L_a = \sqrt{2a}$ (lattice step) and define the variable representing the displacement $x = ika$ (here, $k = \sqrt{2}$) as the distance along the lattice; we shall also define the slope $P = dz/dx$ as $x_{\vec{r}} = L_a P$. Then, $\varphi = \partial P/\partial x$ is described by the Boussinescq equation

$$\varphi_{xx} - \varphi_{tt} + 6\left(\varphi^2\right)_{xx} + \varphi_{xxxx} = 0. \quad (36)$$

We shall identify the cases in which a soliton solution is obtained. The existence of such a solution was pointed out by Hiroma.[31] We shall seek the solution in the form $\varphi(\zeta) = \varphi(x - V_i t)$. Substituting in Eqn. (36) and integrating twice from respect to ζ, we obtain

$$\varphi_{\zeta\zeta} = A_\zeta + B - \left(1 - V_i^2\right)\varphi - 6\varphi^2, \quad (37)$$

where A and B are integration constants. We shall assume that $A \equiv 0$. We shall show that in this case there is a soliton described by

$$d^2\varphi / d\zeta^2 = B - \left(1 - V_i^2\right)\varphi - 6\varphi^2. \quad (38)$$

We shall substitute $d\varphi/d\zeta = z$ in Eqn. (38), which gives

$$d^2\varphi / d\zeta^2 = (dz / d\zeta)(d\zeta / d\varphi) = (dz / d\varphi)z,$$

$$zdz = [B - (1 - V_i^2)\varphi - 6\varphi^2]d\varphi$$

or

$$z^2/2 = B\varphi - \frac{1}{2}\left[\left(1 - V_i^2\right)\varphi^2\right] - 2\varphi^3 + D,$$

where D is an integration constant. We shall introduce

$$B\varphi - \frac{1}{2}\left[\left(1 - V_i^2\right)2\varphi^2\right] - 2\varphi^3 + D = f(\varphi), \quad (39)$$

and then we shall integrate Eqn. (39) as the equation of conservation of motion of particles in a field with the potential $f(\varphi)$ bearing in mind that φ and $\zeta = x - V_i t$ are the spatial and temporal coordinates. A solitary wave on the surface of a crystal appears if the roots of the cubic polynomial obey the condition $\gamma = \beta \neq \alpha$, where $\gamma \leqslant \beta \leqslant \alpha$.

Since $\lim_{\zeta=\pm\infty} \varphi(\zeta) = \varphi_{\pm\infty} = \gamma$, it follows that by introducing $\alpha - \gamma = \Phi_z$ and integrating (Φ_z is the amplitude of a displacement normal to the surface of a dissolving crystal), we obtain the following solution in the form of a solitary wave:

$$\varphi(\zeta) = \varphi_\infty + \Phi_z \operatorname{sech}^2 \sqrt{\frac{\Phi_z}{2}}\left[x - \left(\Phi_\infty + \frac{\Phi_z}{3} t\right)\right]. \quad (40)$$

An analysis of Eqn. (40) demonstrates that, in contrast to a kink [see Eqns. (1), (10), and (27)], a solitary wave describes less satisfactorily the process of dissolution (Fig. 3). It is found that the solitary-wave mechanism of dissolution begins to predominate when the density of a metal ρ is low, the directional interparticle interaction forces $\vec{\varepsilon}$ are weak, and the values of Δa are large. Shorter characteristic times of adsorption of the particles in the solution are required in the case of a solitary wave. Suppression of the motion of a kink is usually due to adsorption of the solution particles and the formation of stable films on steps.[29–32]

Therefore, we have to distinguish the motion of small (monatomic steps, representing Frenkel–Kontorova surface dislocations) and large (high dissolution steps) solitons on the surface of a crystal. Depending on the anodic value of a voltage η_a [and, consequently, on the supersaturation near the surface $\Delta\gamma^* = f(\eta_a)$], there can be quite considerable differences in the morphology of the dissolving surface. The experimental observations of Heusler et al.[36] of the distribution of steps with different kink concentrations ($\beta_{0,k}$) on a close-packed (110)Fe and 'loose' (112)Fe faces, dissolved in 1 M $NaClO_4$ and 1 M $HClO_4$ solutions, had demonstrated that $\beta_{0,k}$ depended linearly on $\eta_a = \partial \ln \beta_{0,k}/\partial \eta_a = F/RT$ (F is the Faraday constant) and increased on enhancement of the potential E of the iron electrode. The average distances between the steps $\overline{L}_0$ (when η_a = const) decreased (but the density β_0 increased) on increase in pH; $d\tan\overline{L}/d\mathrm{pH} = -0.6$.

The velocity of large parallel dissolution (growth) steps is described by a relationship similar to Eqn. (11) if use is made of the theory of Burton, Cabrera, and Frank.[8,24] If the velocity of these steps V_S is proportional to the flux

$$V_S = L_0 J_S / S_{hkl}, \quad (41)$$

the flux becomes

$$J_S = \frac{2}{L_0}\Gamma_\infty D_V \left(\frac{\Delta\gamma^*}{\gamma_\infty}\right)\frac{\sqrt{2}}{\overline{x}_S}\tanh\left(\frac{L_0}{\sqrt{2}\overline{x}_S}\right), \quad (42)$$

where Γ_∞ is the maximum coverage of the surface by particles M_L^{n+} and

$$\tanh\left(\frac{L_0}{\sqrt{2}\overline{x}_S}\right) = [1 - \exp(-2L_0/\sqrt{2}\overline{x}_S)]/[1 + \exp(-2L_0/\sqrt{2}\overline{x}_S)].$$

If $\overline{x}_S = a$ (where a is the lattice parameter), the quantity $\sqrt{2}\overline{x}_S$ corresponds to a lattice step

$$(L_a = \sqrt{2}a = \sqrt{2}\overline{x}_S)$$

and the whole surface area of a crystal becomes active.

If (case i) the distance between the steps is considerably less than the mean free path of ions M^{n+} on a step, $L \ll \overline{x}_S$, then

$$\tanh(L_0/\sqrt{2}\overline{x}_S) \to L_0/\sqrt{2}\overline{x}_S$$

and the flux depends linearly on the supersaturation

$$J_S = \tau_{\mathrm{surf}} \nu_D \Delta\gamma^*,$$

where τ_{surf} is the lifetime of surfactant particles M_L^{n+} in a surface layer given by $\tau^{-1}(M_L^{n+}) \approx \nu_D \exp(-\Delta H_{\mathrm{des}}/k_B T)$ and ΔH_{des} is the heat of desorption of the M_L^{n+} particles in the course of the process $M_L^{n+} \to M_S^{n+}$.

If (case ii) $x_S \ll L_0$, then

$$\tanh(L_0/\sqrt{2}x_S) \to 1$$

and the flux is governed by the surface morphology:

$$J_S = [L_0/\sqrt{2}\overline{x}_S]^{-1} \tau_{\mathrm{surf}} \nu_D \Delta\gamma^*.$$

The M^{n+} ions in the metal lattice (M_L^{n+}) are not equivalent to the ions M_S^{n+} in the low-entropy electrode layer of the electrolyte. In the electrolyte they are solvated, whereas in the metal lattice they are

screened by the electron gas. The high supersaturation $\Delta\gamma^*$ in terms of the M^{n+} ions in the electrolyte layer in the quasi-liquid excited state of the surface layer of the metal allows us to construct a model of dissolution in the form of matched shock waves (bora wind) in the electrolyte of height h_1 and a kink h_0 in the metal (Fig. 3*a*). The velocity of such a fast large dissolution soliton, which appears under anodic potentials, is governed by its height h (the larger the value of h, the higher the soliton velocity):

$$V_{S,B} = [Gh(h_0 + h) / 2h_0]^{1/2}. \quad (43)$$

Here, G is the shear modulus and the heights are related by $h = h_1 + h_0$. If $h_0 \neq 0$ and $h_1 \gg h_0 \approx a$, $h \approx h_1$, then Eqn. (43) becomes

$$V_{S,B} = (Gh^2 / 2a)^{1/2}. \quad (44)$$

The rate of dissolution of a metal predicted by this model depends differently on the heights of the layers in the electrolyte and in the metal.

The models of cooperative dissolution events allow us to explain many new experimental observations that cannot be accounted for by the Burton–Cabrera–Frank (BCF) theory. The soliton mechanism of dissolution allows us to understand the primary event in corrosion of perfect ideally smooth (on the atomic scale) surfaces of single crystals. According to the BCF theory, dissolution of a defect-free ideal face of a metal is impossible, because there is no defect to stimulate the first elementary dissolution event. However, in spite of our better understanding of real crystals, which always have defects, the BCF theory is still valuable,[24] especially as the physical interpretation of the dissolution and growth processes assumed in this theory is very simple and attractive.

What are the reasons (stimuli) responsible for the appearance of a dissolution soliton? They include, above all, local fluctuations of the surface concentration (or density) when the solution particles are adsorbed and the surface coverage by a surfactant is less than one monolayer ($\theta_{surf} < 0.2$ monolayer) and also a metastable state of the surface layer characterised by an increase in the entropy factor and the appearance of fluctuations of strains in this layer. In the case of singular low-index faces a dissolution soliton may appear also because of the alternating, along the z axis, difference between the lattice parameter in the first atomic layers of a surface layer of a metal, which is damped nature $\Delta a_2 = \pm a \exp(-kz)$, where k is the damping (attention) coefficient. The lattice parameter a, occurring also in Eqn. (44) for the velocity of a large dissolution soliton, implies also the physical meaning of the dimensions (or mass) of an atom $\Omega \propto f(a\ m_a)$. At low binding energies E_{M-M}, when the dissolution of M involves solitary waves (Fig. 3*c*), the change in the parameter Δa_z is of fluctuating nature on transition from the state $V_{S,2}$ to the state $V_{S,3}$.

Discontinuous fluctuations of the density in the case of solitary waves (when a phase transition takes place) correspond to dissolution[37]

$$\varphi(x,t) = (10\Gamma\varphi'' / \varphi^{v})^{1/2}\tau^{-1}, \quad (45)$$

where $\tau = x/h_0$ is the time, $\Gamma = h\varphi'''(\vec{\varepsilon})/\varphi''(\vec{\varepsilon})$ is the Grüneisen constant, $h_0 = a(1 + \Delta a)$, and $\varphi(\vec{\varepsilon}) \equiv \varphi[a(1 + \Delta a)]$.

Therefore, the greater the value of Δa, the higher the strains $\vec{\varepsilon}$ in the surface layer and the most probable is the spallation of a $2-D$ plate of thickness $h_0 \approx a$ from the bulk of the metal crystal when this plate has the parameters of the interior of the crystal.

The points of emergence of dislocations on a highly heterogeneous surface of an imperfect crystal give rise to a 'loose' adsorption-active position, the preferential filling of which by the solution particles may induce the appearance of a dissolution soliton (spherical kink). As the process of the dissolution of a metal develops, a linear subsurface effect creates concentric waves and soliton kinks. The motion of the resultant kink during the dissolution of a crystal is then no longer related to the subsurface defect, but it is governed by the indices $<hkl>$ of the surface (by direction of motion of the dissolution steps).

A dissolution step (which in the simplest case is a Frenkel–Kontorova dislocation) can start to move under the influence of a very small ($\Delta a \approx 0.001$ nm) tangential displacement of each atom along the x, y, and/or normal (along z to the surface). When the degree of hydrogenation of a metal is low (the process of hydrogenation is practically always accompanied by the dissolution of a metal), the displacements as a result of modification of the surface by hydrogen may be particularly large ($\Delta a \approx 0.010$ nm). For example, when the surface coverage with hydrogen is $\theta_H = 0.3$ monolayers, the displacement of W atoms in the first surface layer on the (100)W face reaches $\Delta a_{12} \approx 0.003$ nm, whereas for the (011)Ni face it is $\Delta a_{12} = 0.011$ nm (Ref. 38). Surface atoms go over to a metastable state after the passage of a dissolution soliton and this facilitates rapid solvation of the resultant intermediate products, since it gives rise to a slowly moving fluctuation characterised by a lower density of the investigated metal and a higher concentration of the solution particles involved in the solvation process. However, the capillary forces by themselves are insufficient to initiate the first dissolution event and we have to allow for the electronic structure of the metal being dissolved and of the particles being adsorbed (this represents a state of non-Coulomb 'glue' in a double electrical layer located on the metal side).

The soliton mechanisms are fully acceptable (they agree with experiments) for the description of motion of linear defects in surface layers of crystals containing hydrogen[1,3] as well as condensed adsorbed layers of H_3O^+ where a proton can move.[39] In the case of epitaxial matching the double electrical layer between the condensed metal (M) and electrolyte phases when the continuity is preserved across the phase boundary, the cooperative model (Fig. 3*a*) describes practically all the corrosion processes. The soliton dissolution mechanism is capable of accounting for the differences between the rates of corrosion of semiconductor alloys of the III-V type, and of crystalline and amorphous structures with the same chemical composition. A close-packed amorphous structure (representing a disordered alloy of the d elements with one another or with nonmetals), where only the short-range order is preserved, is characterised by a low corrosion rate because of an irregular motion of a soliton along the surface. The dependences of the velocity of propagation of steps (dissolution solitons), with positive or negative deviations from the closest packing, on the index (hkl) of a face and on the direction of growth $<hkl>$ of a crystal was estimated theoretically in Ref. 40 and observed experimentally for hydrogenated low-index faces of nickel single crystals in sulphate solutions.[41]

In the stepped surface model the probability that a particle being adsorbed reaches a step moving 'upwards' is not equal to the probability for a step moving 'downwards' (Ref. 40). This unusual situation can be understood if we turn back to Fig. 1*c*. An adatom diffusing along the x axis along a close-packed terrace to its edges becomes more strongly bound in a 'niche' which is at a position S, than at the 'edge of a dip' L ($E_S > E_L$, $\Delta E = E_S - E_L$). In the

former case an atom is reflected by a potential barrier of a monatomic step (external projection), whereas in the latter it 'drops' into the potential well (E_L). Diffusion of an adatom along the y axis (parallel to a step) depends weakly on the step density β_0^{-1}.

The dependence of dissolution of 'loose' faces of an Ni crystal in 0.5 M H_2SO_4 solution on the direction of removal of layers of crystallographically identical faces[32] can be explained by differences in the adsorption activity of dissolution steps moving along different directions. There is some analogy between this model and positive and negative kinks on dislocations. In the BCF theory these kinetic differences are explained as follows. In the $2-D$ case the slope of the surface after the passage of dissolution steps is

$$P \equiv (dz / dx) = h\beta_0,$$

and the sinking of the surface of a dissolving crystal (velocity of displacement along the z axis of a plane normal to the surface of a crystal) is given by

$$-(dz/dt) = \frac{P}{\rho}\left(\frac{m_a}{2\pi k_B T}\right)^{1/2} = hJ_s.$$

Allowing for the functional relationship between the flux J_S and the density of steps β_0 plotted using the coordinates β_0 and J_S, we can describe two types of step motion: inhibited and uninhibited. In the latter case at low densities β_0 there is a proportionality between β_0 and J_S. For all β_0 the $\beta_0 = f(J_S)$ curve has a negativity curvature ($\partial^2 J_S/\partial\beta_2^0 < 0$) and the velocity of a single dissolution step is higher than the velocity of a kinetic wave: $V_S > V$. If $V_S = V$, there is a proportional relationship, but this time it is between β_0^2 and J_S and the curvature of the kinetic wave exhibits reversal of the sign ($\partial^2 J_S/\partial\beta_2^0 < 0$). It should be pointed out that the efficiency of the action of a surfactant depends on the direction of motion of waves: it is possible to suppress the wave process by a small amount of a surfactant that blocks the wave nucleation centres.

Initiation of the formation of dissolution steps and their propagation on the surface of a crystal occurs when a metal is subjected to tensile elastic loads that alter the values of γ_S. In this case the range of protectic (inhibiting) concentrations of a surfactant moves toward higher values.[42,43] There is special interest in the propagation of a soliton in surface layers of metals covered by oxides, which can be insulating or semiconducting. High-intensity fields in the oxides ($>1 \times 10^5$ V/cm) give rise to electrostriction phenomena and generation of solitons at the metal–oxide surface, where the electrostrictive strains are concentrated.

VI. Inhibition of motion of dissolution steps

The problem of drag or acceleration of steps during dissolution or growth of a crystal by inhibiting (stimulating) impurities is very important in the practical sense and its solution has attracted the interest of many electrochemists and physicists working on crystals. The mathematical solutions proposed for the growth of a crystal with a stepped surface are based on the following mechanism. Impurities are captured by a step moving during the growth of a crystal ($2-D$ process) and their motion disturbs the Boltzmann distribution. The concentrations of impurities in a surface layer formed by the passage of such a step are not the equilibrium values. The process of relaxation results in a redistribution of the impurities in the surface layer during the passage of the second step. Therefore, in the kinetic estimates an important characteristic is the density of steps β_0, the frequency W at which they occur, the height h, the frequency f of jumps of impurity atoms into the surface layer from the bulk of the metal, and the frequency f_L of jumps of impurities between bulk layers.

In the case of monatomic spallation (Frenkel–Kontorova dislocations) the solutions of these problems can be obtained using the theory of dislocations: blocking of the motion is due to the formation of chain-like segregations (clouds) along the line of a defect.[21] In the case of a linear $1-D$ system, a chain of atoms in which a defect inhibiting the chain vibrations is incorporated at distances characterised by a period L_D (the defect may be an adparticle of an inhibiting surfactant with a mass exceeding the mass of a crystal atom, $m_d > m_a$) and the solution of the equation of motion of the type given by Eqn. (35) reduces to the differential Korteweg–de Vries equation, which has the following soliton solutions[44]

$$\frac{\partial W_D}{\partial \tau} + \Phi_D W_D \frac{\partial W_D}{\partial \zeta} + V_{S,D}\frac{\partial^3 v_D}{\partial \zeta^3} = 0, \qquad (46)$$

where

$$\Phi_D = (\alpha_D/2\eta_D)\theta^3,\ V_{S,D} = \left(\delta_D\theta^4/2\eta_D\right)\frac{\partial v_D}{\partial \zeta} = W_D.$$

The constants Φ_D and $V_{S,D}$ determine the amplitude and velocity of a soliton with a defect. The parameter

$$\theta = (\eta / \eta_D)^{1/2} = (m_a K_D \beta_D^2 / m_D K \beta^2)^{1/2}$$

contains the constants β and K (velocity constant), as well as m_a (mass of an atom of M): the index D denotes that a particular property describes a defect;

$$\alpha = -3\beta\eta^{1/2},\ \delta = \eta / 12,\ \tau = \varepsilon^3\eta t,\ \xi = \varepsilon(x - t),$$

$$x = \eta^{1/2} n = m_a(2k\beta^2)^{1/2},\ \varepsilon = (m_a - m_D) / m_a$$

is the order parameter. Near a surfactant particle adsorbed and incorporated in the metal lattice we can expect the appearance of additional spherical solitons similar to kinks of subsurface dislocations. The length of an arc for spherical solitons is πr_0 (r_0 is the radius of a critical nucleus). The process of motion of a dissolution step across the resultant obstacles (spherical solitons) is retarded in the $2-D$ case when the condition $L_D \geqslant 2r_0$ is obeyed.

The velocity of a wave described by a Korteweg–de Vries equation of the type (46) is determined by the amplitude Φ_D and the higher the amplitude of the wave, the faster its motion. This is in good agreement with the experimental observations of the process of dissolution of nonsingular faces of crystals with a relatively low ($<99.6\%$) degree of purity. Irregular incorporation (departure from the period L_D) of many inhibiting particles with a large mass m_D destroys a dissolution soliton. Multidimensional ($2-D$ and $3-D$) variants of the Korteweg–de Vries equations demonstrate[26] the possibility of appearance of specially active localised states due to their interaction with solitons.

The lowering of the amplitude and reduction in the velocity of a dissolution step is due to its coarsening and broadening (Figs. 3*b* and 3*c*). Multilayer steps also become coarser as a result of adsorption of the solution particles. The criterion of this dynamic process is[45]

$$E_S^2 / (h\rho\Delta\mu\, k_B T) \simeq r_0 / L_0 \leqslant 1,$$

where $\Delta\mu = \mu_S - \mu_L$; $L_0 = \beta_0 D_{surf}$ is the correlation length; E_S

is the free energy of a step; as pointed out above, in the case of $2-D$ nucleation, we have $V_S \propto K\Delta\mu$ and the critical radius is $r_0 = E_S/h\rho\Delta\mu$.

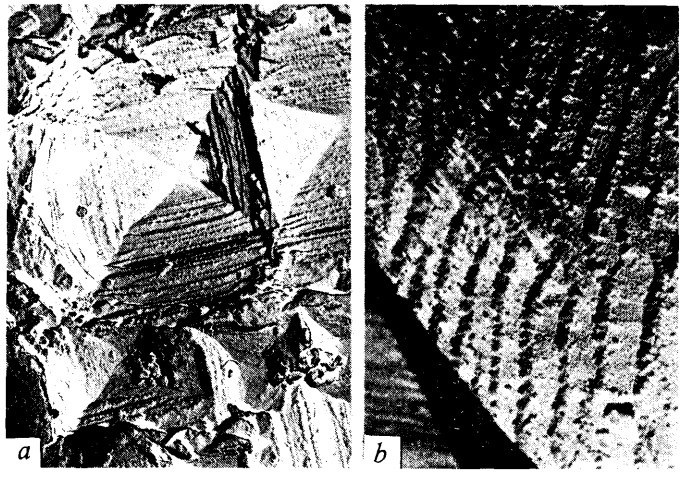

Figure 5. Blocking of the motion of dissolution steps by clusters of adparticles from a solution on [5(111)−(001)]Ni (*a*) and [9(110)−(001)]Cu (*b*) faces; magnification 9000.

The surface energy of a vicinal stepped F face (Fig. 1*a*) consists of two terms:[18]

$$E_V = E_0\cos\theta + (E_S/h)\sin\theta,$$

where E_0 is the surface energy of a terrace (close-packed singular face). When the angle is $\theta = 0, \pm\pi/2, \pi$, the values of E_V have sharp minima. Spreading of a multilayer step occurs when the surface energy E_S is much less than the surface energy of a terrace ($E_S/\gamma_S h \ll 1$), as shown in Fig. 5, but the opposite behaviour is observed and a clear step is conserved if $E_S/\gamma_S h \approx 1$ (see Fig. 4).

Numerous experimental data confirm that the velocity of large solitons depends on the distance between them L_0 (in general, it depends also on β_0: the higher the value of β_0, the lower the velocity V_S). A dependence of the wave velocity on amplitude h follows even from a $1-D$ analysis, which leads to the simple dependence

$$V_S = \left(\frac{hg}{2\pi} + \frac{2\pi\gamma_S}{h\rho}\right)^{1/2},$$

(g is the gravitational contant), from which it follows that lowering of h reduces rapidly the role of the first term and increases the importance of the capillary forces (second term). In the case when $h \approx b$ (the latter representing the distance between the atoms) the Thomson equation reduces to Eqn. (4).

A dissolution step of dislocation dimensions ($h \approx b \approx a$) may be decelerated by the adsorpton of point defects or the emission of vacancies in the course of its motion. The drift (directional) velocity of a step travelling a distance l along x under equilibrium conditions in the system formed by a dissolution step and a point defect can be estimated from [46]

$$V_S = \frac{4\pi D_V}{h}\left[\exp\left(\frac{\Delta a\langle U_S^2\rangle l\beta_0^{-1}}{k_B T}\right) - 1\right] \quad (47)$$

(where D_V is the diffusion coefficient of a point defect). For low values of Δa the velocity of the steps is

$$V_S \propto \frac{4\pi D_V \Delta a\langle U_S^2\rangle l\beta_0^{-1}}{hk_B T}, \quad (48)$$

and for large values, it is

$$V_S \propto \frac{4\pi D_V}{h}\exp\left(\frac{\Delta a\langle U_S^2\rangle l\beta_0^{-1}}{k_B T}\right). \quad (49)$$

The term $\langle U_S^2 > 1\beta_1^{-1}$ represents the area 'swept through' during the motion of a dissolution step. When Δa influences not only the adsorption of surfactant on a step, but also the actual mechanism of the distribution of a surfactant in a double electrical layer located in the electrolyte near the crystal surface, hyperbolic functions appear in the relationships for the velocity

$$V_S \propto \sinh\frac{\Delta a\langle U_S^2\rangle l h}{k_B T}. \quad (50)$$

In electrochemical terms the strength of the dissolution current i_a is given by an expression similar in form to Eqns. (11), (41), and (42), which is natural because the initial assumptions are based on the kinetic representations of the BCF theory. The steps may travel in the form of concentric circles, Archimedes spirals, or linearly extended formations. Without allowance for the kinks on the steps the above description is still quite accurate and has been confirmed by experiments. In the $2-D$ case the slope of concentric steps is described by[47]

$$(dy/dx) = (x + ky)/(kx - y). \quad (51)$$

Integration of Eqn. (51) yields a dependence of the type

$$r = r_0\exp(K\varphi), \quad (52)$$

where $\varphi = \arctan(y/x)$ and $r_0 = (x^2 + y^2)^{1/2}$. If $K = 0$, concentric points propagate from the origin of the coordinates. If $K > 0$, an Archimedes spiral is observed. Eqns. (51) and (52) describe a stable pattern. When dealing with the multidimensional case of the dynamics of changes in a concentric (spherical) kink, considered by I A Bogolyubski and B G Makhan'kov in 1976 (see Ref. 26), it is necessary to base the analysis on the Klein−Gordon equation

$$(\partial^2\varphi/\partial x^2) + (\partial^2\varphi/\partial y^2) - \varphi_{tt} = F(\varphi), \quad (53)$$

which in the one-dimensional case reduces to the sine−Gordon Eqn. (2) if $F(\varphi) = \sin\varphi$. In a situation when $F(\varphi) = \varphi^{IV}$. The initial conditions for a spherical kink expanding from the origin can be written in the form of a steady-state solution of Eqn. (53), which is $\varphi(r, 0) = \tanh(r - r_t)/\sqrt{2}$ and the running radius is $r_t \gg 1$. Numerical calculations on a computer[26] showed that such a kink first collapses (at $t > 0$) and then expands giving rise to what is known as a pulson. In experiments such a situation is encountered when an edge dislocation emerges on the surface of a crystal. The propagation conditions become easier when a screw dislocation emerges on the surface and then a pulson gives rise to a nonvanishing dissolution step.

The structure of equations of the (42) type describing dissolution dynamics becomes more complex in the electrochemical case. Then if a step propagates in the form of an Archimedes spiral,[16] the velocity (current density i) of dissolution is controlled by an electrochemical term multiplied by a hyperbolic function that describes the transport of charges in a double electrical layer at the phase boundary

$$i = i_0\{\exp(\alpha nF\eta_a/RT) - \exp[-(1-\alpha)^n F\eta_c/RT]\}\frac{L_0}{2\pi r_0}\tanh\left(\frac{2\pi r_0}{L_0}\right), \quad (54)$$

where $a \approx 0.5$ is the coefficient of transport by the anodic and cathodic reactions, η_c is the cathodic overvoltage, R is the gas constant, and n is the valence of the electrode reaction,

$$L_0 = (nFD_{M^{n+}}\bar{c}/i_0)^{1/2}\exp(-\alpha nF\eta_a/2RT),$$

$$\tanh\left(\frac{2\pi r_0}{L_0}\right) = [1-\exp(-4\pi r_0/L_0)]/[1+\exp(-4\pi r_0/L_0)].$$

Bockris and Dem'yanovich[48] used, as in the preceding case [Eqn. (54)], the ideas of Whitham[13] to derive a similar relationship for linearly extended steps

$$i = i_0\{\exp(\alpha nF\eta_a/RT) - \exp[-(1-\alpha)nF\eta_c/RT]\}\times$$
$$\times\left(\frac{4\beta_0 D_{M_K^{n+}}}{P}\right)\tanh\left(\frac{P}{4\beta_0 D_{M_K^{n+}}}\right)^{1/2}, \quad (55)$$

where

$$P \equiv L_0^{-1} = i_0\Big/\left(nFC_{S,M_{S,K}^{n+}}\exp\left[-(1-\alpha)nF\eta_K/RT\right]\right), C_{S,M_{S,K}^{n+}}$$

$C_{S,M_{S,K}^{n+}}$ is the equilibrium concentration of M^{n+} on a step, and $D_{M_K^{n+}}$ is the surface diffusion of M^{n+}. The steps disappear when the correlation length is large, so that

$$P \le \beta_0 D_{M_K^{n+}}, \left(4\beta_0 D_{M_K^{n+}}/P\right)^{1/2}\tanh\left(P/D_{M_K^{n+}}4\beta_0\right)^{1/2} = 1$$

and Eqn. (55) reduces to the usual equation of electrochemical kinetics.[16] In the other case when $P \gg \beta_0 D_{M_K^{n+}}$, Eqn. (55) becomes

$$i = i_0\{\exp(\alpha nF\eta_a/RT) - \exp[-(1-\alpha)nF\eta_c/RT]\}\frac{4\beta D_{M_K^{n+}}}{P}. \quad (56)$$

At low anodic overvoltages ($\eta_a < 0.1$ V) and when the radius of curvature of an Archimedes spiral satisfies the condition $r > L_0$, a segment of the spiral travels at a velocity

$$V_S = V_\infty(1 - r_t/r_0).$$

Linearly extended steps are not related to a point source of expansion. The substitution $P^{-1} = \beta_0 \equiv 2L_0$ allows us to obtain from Eqn. (55) a very simple expression for the velocity of such steps:

$$V_S = i_0(L_0C_0nF)^{-1} = i_0(0.5\beta_0C_0nF)^{-1}, \quad (57)$$

from which it follows that if i_0, an increase in the equilibrium concentration C_0 of M_S^{n+} in the solution and of the density of steps β_0 lowers V_S. This conclusion applies also in the case of propagation of steps during growth of a crystal. If the flux deduced from Eqn. (41) is

$$J_S = S_{hkl}V_S/L_0 \quad (58)$$

and the law describing growth obeys the Arrhenius dependence

$$J_S = KC_{surf}\nu_D\exp(-E_S/RT) \quad (59)$$

(C_{surf} is the concentration of a surfactant in the solution, E_S is the metal–surfactant binding energy on a step—see Fig. 1*e*), then the combination of Eqns. (58) and (59) yields

$$V_S = KS_{hkl}^{-1}L_0C_{surf}\nu_D\exp(-E_S/RT). \quad (60)$$

It is clear from Eqn. (6) that the velocity of steps (solitons) of dissolution may be influenced decisively by impurities in the form of inhibiting surfactants in the solution. The concentration of impurities on terraces $C_{A,surf}$ in front of a step and on a step $C_{S,surf}$ are different. The values of $C_{A,surf}$ and $C_{S,surf}$ are related functionally to the parameters of motion of steps by the expression $C_{A,surf} = C_{S,surf}[1 - \exp(-K\beta_0)]$. During the motion of a step the surfactant impurities are pushed away when the surface drops and go into solution (which is opposite to the burying of impurities in a growing crystal).

Inhibiting impurities may 'poison' the motion of steps when crystals with a low degree of purity are dissolved (see Fig. 5) and the blocking particles (the elements C, S, P) are supplied to the surface from the bulk of a crystal which is dissolving: the particles of carbon, sulphur, or phosphorus which cluster on the steps of the surface of a metal lower the dissolution rate. At low concentrations of such particles on the surface ($\theta_{C,S,P} < 0.2$ monolayers) we have the opposite effect of acceleration of the anodic process. For example, in the case of Ni–2.9% P alloys the density of the anodic current i_a increases in acid media, whereas in the case of Ni–12.3% P there is a reduction in i_a (Ref. 49). Examples of this kind are particularly numerous in the case of carbon steels when inert carbon from dissolving cementite Fe_3C decelerates the motion of the dissolution steps. However, the rate of dissolution of low-carbon steels may be higher than that of high-purity zone-melted iron (99.99%) because of the high level of elastic stresses in the matrix. The stresses are induced in α-iron by cementite precipitates.[50]

The velocity of a dissolution step (soliton) depends on the surface tension (stress) in a crystal γ_S. The velocity constant K in Eqn. (60) can be expressed in the form $K = (2\pi\gamma_S)^{1/2}$. A strong reduction in γ_S as a result of adsorption of a surfactant (for example, adsorption of nucleophilic particles such as Hal^-, OH^-, and H^-) on a hydrophilic surface of a *d* metal reduces strongly V_S. If the adsorption of a surfactant is described by the Langmuir isotherm

$$\theta_{surf} = \frac{\Gamma_i}{\Gamma_\infty} = \frac{C_{surf}}{\Lambda + C_{surf}}, \quad \Lambda = \frac{\Gamma_\infty\nu_D\exp(-\Delta H_{ads}/k_BT)}{(kT/2\pi m_D)^{1/2}},$$

the lowering of γ_S on adsorption of a surfactant (heat of adsorption ΔH_{ads}) from solutions with a concentration C_0 can be expressed using

$$d\gamma_S/dC_0 = (\Gamma_i k_B T)/C_{surf}$$

and the Shishkovskii equation, so that the final result is

$$\Delta\gamma = k_\beta T\Gamma_\infty\ln(1 - \Gamma_i/\Gamma_\infty) < 0.$$

The most effective surfactant (reducing γ_S) impurity is adsorbed hydrogen.

When a Langmuir adsorption equilibrium is established and also when γ_S begins to depend linearly on C_{surf}, the reduction in the surface tension $\Delta\gamma$ begins to influence decisively the propagation of a dissolution step, so that its velocity becomes

$$V_S = \theta_{surf}\Pi[E_{surf} - \Delta E_{surf}\exp(-Kt)], \quad (61)$$

where $\Pi = 1 - \exp(-\Delta\mu/k_BT)$ is the undersaturation of a solution in respect of the M_L^{n+} particles, $\Delta E_{surf} = E_{surf} - E_M$, E_M and E_{surf}

are the surface energies of clean and inhibited surfaces, respectively. The physical meaning of the dimensional velocity constant K follows from the above relationship. An adsorbed surfactant quenches oscillations and destroys a soliton and reduces (possibly to zero) the velocity of its propagation on a surface.

How can one block the motion of a dissolution step and thus increase the resistance of a crystal to the chemical action of an electrolyte? The first sufficiently rigorous thermodynamic solution of the problem of disappearance of a step on a singular F face was obtained by Onsager (1946). He used the Ising representations ($2-D$ model) of complete blocking by surfactant particles of one of two adjacent terraces separated by a step on which no surfactant adsorption takes place. In the interpretation of Dunning,[51] the thermodynamic solution is as follows. Let us assume that the potential energy per unit surface area is $E_{surf}/2a_0^2$ (a_0 is the Madelung parameter). A surfactant adsorbed on one of the terraces (θ_{surf} = 1 monolayer) is transferred to an unoccupied terrace and this is accompanied by simultaneous formation of surface vacancies on a deblocked terrace. The transition occurs as a result of diffusion on the surface of an ideal terrace and undoubtedly this is a correlated process which does not necessarily follow the shortest path. The total path or the displacement $<U^2(t)> = f\lambda^2 t$ is governed by the mean length of an elementary (from one adsorption centre to another) jump λ and by the frequency of such jumps f.

The formation of a vacancy increases the surface energy by $4E_{surf}/2a_0^2$, which is the energy of four dangling bonds. The surface energy density is then

$$E_M = E_{surf}/2a_0^2 + \theta_{surf} 4E_{surf}/2a_0^2 \quad (62)$$

and it is the same for adjacent terraces when the degrees of coverage of the steps by vacancies and surfactants become equal ($\theta_{surf} = \theta_V$). Such a situation occurs at T = 0 K. At higher temperatures it follows from the BCF theory that

$$E_S(T) = (E_{surf}/2a_0^2)\left\{2 - \frac{1}{2}\left[1 + (2/\pi)(1-k_1^2)^{1/2} K(k_1)\coth\eta\right]\right\}. \quad (63)$$

where

$$\eta = E_{surf}/2k_BT, k_1 = 2\sinh\eta/\cosh^2\eta$$

and

$$K(k_1) = \int_0^{\pi/2} \left(1 - k_1^2 \sin^2 \nu_i\right)^{-1/2} d\nu_i$$

is an elliptic integral.

The nonlinear relationship (63) includes the main energy parameters of blocking of a step, such as the binding energy of the nearest neighbours, the distance between the interacting particles, and the vibration frequencies of adparticles. The relationship (63) is used widely in computer modelling of modification of crystal surfaces due to external perturbations.

However, this model ignores the change in the energy of vibrations of adparticles. The dependence of $E_S(T)$ on the value of the Jackson–Temkin factor $\eta_1 \exp(-E_{surf}/2k_BT)$ is described by the Avrami–Kolmogorov equation $E(T) = (1 - \eta_1)^n$; a tangent to the curve representing the dependence at a point corresponding to a transition temperature T_c obeys the condition $\sinh H_c = 1$ and, consequently, $T_c \approx 0.57E_{surf}/k_V$. At the transition temperature the surface coverages become equal, $\theta_{surf} = \theta_V = 0.5$ monolayers, and the step separating the terraces disappears.

It was established quite early that the adsorption activity of steps and kinks is considerably higher than the activity of terraces (Fig. 3). An atom on a step (S) or in a kink (K) has at its disposal a large number of d holes the filling of which requires a lower energy: $E_K > E_S > E_L > E_s$ (E_A). The energies of chemisorption of chalcophilic particles (oxygen and hydrogen) on stepped surfaces of transition b.c.c. metals are calculated out by Jardin et al.[52] Differences between the energy characteristics of steps and terraces on surfaces of d.c.c. crystals were quite large: −3.78 and −5.90 eV for oxygen atoms, and −2.30 and −3.78 eV for adsorbed H atoms. In contrast to a metal/gas contact, when there is no need to allow for the short-range order in condensed thin layers adsorbed in different ways on terraces and steps, in the case of metal/electrolyte systems this order is of decisive importance. Purely topological treatments of dimensional effects on adsorption of solvated inhibiting surfactant particles have proved insufficient.

In models of this kind[53] the influence of impurities in a solution on the motion of dissolution steps is considered in two separate variants: blocking of 'loosely' packed steps, which occurs mainly due to adsorption at kinks, and also as a result of formation of discontinuous irregular adparticle islands on close-packed steps (Cabrera fence—see Fig. 5). According to Bliznakov,[54] blocking by a substance being dissolved on a nonideal surface of a crystal by surfactant fluxes may be achieved independently. Consequently, the overall rate of dissolution is a sum of the partial rates of dissolution of a metal $V = \sum_{ij} V_{ij}$. We then have

$$V_i = \Gamma_i(1-\theta_{surf})\exp(-E_a/k_BT), \quad (64a)$$

$$V_j = \Gamma_i\theta_{surf}\exp[-(E_a + \Delta H_{ads})/k_BT. \quad (64b)$$

The surface concentration Γ_i of adparticles is a function of the lifetime of surfactant particles on the surface of a metal $\tau_{surf}^{-1} = \nu_D \exp(-\Delta H_{des}/k_BT)$ and of the heat of desorption of surfactants from the surface ΔH_{des}. Combining Eqns. (64a) and (64b), and introducing the notation

$$E_a = 0.5E_{surf},\ V_{0,l} = \Gamma_i \exp(-E_{surf}/2k_BT),$$

$$E_S(T) = 1 - \exp(-E_{surf}/2k_BT),$$

where $V_{o,l}$ is the rate of dissolution of a crystal in a pure solution, we obtain the simple dependences:

$$V_S = V_{0,l}[1 - \theta_{surf} E_M(T)]. \quad (65)$$

If θ_{surf} = 1 monolayer and E_a = const, it follows from Eqn. (65) that

$$E_M(T) = (V_{0,l} - V_\infty) / V_{0,l}, \quad (66)$$

or if the rate of adsorption of a surfactant exceeds significantly the limiting rate $V_{surf} \gg V_\infty$, we find that

$$V_S = V_{surf}(1 - \theta_{surf}). \quad (67)$$

The blocking of the surface by screening can be allowed for by means of Eqn. (67), but we have to know the density of states β_0 and at least qualitatively the evolution of this density:

$$\beta_0 = f(t).$$

Even the early models have allowed for the energy aspects of adsorption-active linearly extended surface defects in dealing with the adsorption isotherms, so that the pre-exponential terms in Eqns. (64a) and (64b) are modified. In the case of sympathetic changes in the concentrations of a surfactant in the solution C_{surf} and on the surface of a metal Γ_i under conditions of a weak supersaturation

$\Delta\gamma^*$, the velocity of dissolution steps V_S decreases linearly on increase in $\Delta\gamma^*$ [see Eqn. (61)]. Experimental estimates of V_S for transition metals are in agreement with the Langmuir isotherm and are described by dependences of the type[55]

$$V_S = 2\theta_{surf}\Delta\gamma * \left(\frac{2(1-\theta_{surf})}{1+\Delta\gamma * \theta_{surf}}\right)^{1/2}\left[1-\left(\Delta\gamma * \theta_{surf}\frac{1-\theta_{surf}}{1+\Delta\gamma * \theta_{surf}}\right)^2\right]^{-1/2}. \quad (68)$$

At low supersaturations $\Delta\gamma^* = \Delta\mu/k_BT$ the evolution of a step in accordance with the screw dislocation mechanism is faster than at other defects [for example, at (111) stacking faults on f.c.c. crystals[56]]. According to Ref. 56, this is due to the relationships between the nucleation times t_n and the time t_S taken by a step to rotate around a point of emergence of a dislocation dipole on the surface. In the case of low values $\Delta\gamma^*$ we have $t_n > t_S$, whereas at high supersaturations we find that $t_n < t_S$.

An approach based on formal kinetics has been developed subsequently to allow for the formation of discrete $2-D$ and $3-D$ surfactant lattices on substrates with local dangling bonds. In the $1-D$ Ising case the process of blocking of step motion by adsorption of the solution particles is considered on the basis of square $\{IL_a\}$ lattice of a $2-D$ crystal (Fig. 1*a*). This is a very simplified model of the surface of a crystal with growth steps. Atoms in deeper layers $I \geqslant L_a$ lie on the steps and the density of dangling bonds for them is higher.

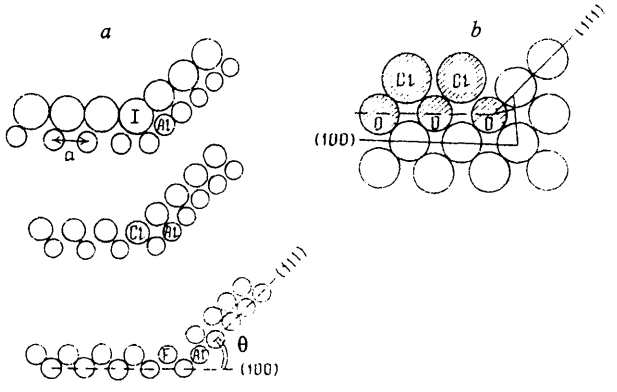

Figure 6. Schematic representations of the adsorption of Hal^- ions on clean (*a*) and oxygen-coated (*b*) stepped [*n*(001)−(111)]Al surfaces.[57]

In a practical analysis of inhibition of dissolution of a metal it is possible to use quite productively the principle of dimensional correspondence, particularly in studies of dissolution of individual faces of metal single crystals in aqueous solutions of the acids HF, HCl, HBr, and HI. For example Politizky and Fischer carried out a pioneering work[57] on the dissolution of stepped Al faces ({001} terraces + {111} close-packed steps) and found that the F^- ions were readily adsorbed in highly coordinated *s* states both on steps and terraces, whereas Cl^- and Br^- ions reached the *s* positions only on cubic {001} faces. Large I^- ions were unable to maintain the *s* states on {001} faces or on {111} octahedral faces (Fig. 6).

In modern interpretations,[58] subject to allowance for the relationship between the electrochemical characteristics of dissolution of Al in halide solutions and the changes in $\{hkl\}$ on a surface, it is usual to consider partial or total transfer of charge in the course of adsorption (Table 2) and formation of an intermediate particle in a two-stage electrochemical process:

$$Al + 2Hal^- \rightleftarrows AlHal_{2,ads} + 2c, \quad (69a)$$

$$AlHal_{2,ads} \rightleftarrows AlHal_2^+ + c, \quad (69b)$$

followed by a fast chemical stage

$$AlHal_2^+ + Hal^- \rightarrow AlHal_3.$$

The transported charge (represented by the Esin−Markov coefficient K_{EM}) depends on the topology of the particles adsorbed on the surface of a metal, starting from the reticular density S_{hkl} of the surface. A reduction in S_{hkl} and an increase in the dimensional mismatch $\Delta r_{hkl} = r_{hkl,Al} - r_{Hal}$ on transition from the (111)Al to the (011)Al surface makes possible a strong adsorption of the F^- ions at a multicentre *s* position. The values of the Gibs potential ΔG and of the normal potentials E_0 depend strongly on the nature of the Hal^- ion, and it is found that the F^- ions are characterised by anomalously high values of these quantities.

Table 2. Correlation between electrochemical parameters of dissolution in halide acids and crystallographic characteristics of aluminium.

Parameter		F^-	Cl^-	Br^-	I^-
Ionic radius, nm		0.136	0.181	0.195	0.216
Atomic radius, nm		0.072	0.099	0.114	0.133
$\Delta r_{hkl} = r_{hkl,Al} - r_{Hal}$, nm	(111)Al	−0.012	−0.039	−0.054	−0.073
	(001)Al	+0.071	+0.044	+0.029	+0.010
	(011)Al	+0.016	+0.089	+0.074	+0.055
ΔG_{AlHal_3}, eV		−12.76	−6.61	−5.24	−3.26
$E_{0,Al/Hal}$, V		4.25	2.20	1.74	1.08
$E_{0,Hal^-/Hal}$, V		2.85	1.36	1.07	0.54
$E_{0,Al/Hal^-}$, V		−1.40	−0.84	−0.67	−0.54

Halogen ions adsorbed in multicentre states on {001} and {011} of f.c.c. crystals 'feel' quite comfortable. The 'loosely' packed steps on the Al surface are blocked effectively by the I^- ions[59] and the change in the capacitance of a single-crystal Au electrode is then well correlated with the terrace length L_M and with β_0. There is experimental evidence that the electrochemical activity of steps is higher also in the case of other crystals of noble metals (Pt, Pd) with a stepped surface. 'Poisoning' of steps (and this applies even more strongly to kinks) results in an effective deceleration of the motion of steps in a corrosion process by the high concentrations of the

halogen ions, in accordance with the series $F^- > Cl^- > Br^- > I^-$ ($C_{Hal} > 10^{-1}$ monolayers). In the case of solutions containing Hal^- on an oxygen-coated stepped surface of Al the oxygen adatoms are gradually displaced by halogen atoms, as postulated by Fischer.[60]

Naturally, the blocking of steps on the surfaces of transition *d* metals and their passivation are performed effectively by oxygen atoms. This process occurs in several stages depending on the coverage θ_0. Direct experiments on well-investigated stepped faces are needed to obtain reliable electrochemical data: they should be carried out by the methods of low-energy electron diffraction (LEED) and an analysis of the electron energy loss spectra (EELS) when hydrogen and oxygen are adsorbed simultaneously.[11,61] Oxygen adsorbed on (001)Ni forms structures with a periodicity $p(2 \times 2)$ when the coverage is $\theta_0 = 0.25$ monolayers; at higher coverages of $\theta_0 = 0.5$ monolayers they transform into $c(2 \times 2)$ structures; in the case of the close-packed (111)Ni face we can expect $p(2 \times 2)$ structures for $\theta_0 = 0.25$ monolayers and $(\sqrt{3} \times \sqrt{3})R30°$ for $\theta_0 = 0.33$ monolayers. Low coverages of (110)Ni with oxygen ($\theta_0 < 0.1$ monolayers) do not modify this phase, which has the loosest structure; high values of θ_0 cause filling of long bridge positions and give rise to $a(2 \times 1)$ structures. The results of investigation by the EELS method of a system of this kind indicate that hydrogen is adsorbed in the molecular form only by kinks (Table 3). If oxygen fills kinks and steps, then hydrogen atoms can be adsorbed only on (001)Ni terraces. When $c(2 \times 2)$ structures appear on terraces at high values of θ_0, the nonsingular stepped (510)Ni surface is transformed into (410)Ni or (610)Ni.

Table 3. Density of adsorbed hydrogen layers on (510)Ni surfaces, determined by the EELS method.

State of adsorbent	Position	Energy loss, meV	
		hydrogen	deuterium
Atom	vacancies on terraces	58	43 60
Atom	short bridge, step	103 142	78 102
Atom	long bridge, step	95 154	71 115
Molecule	kink	28 83 147 398	21 69 116 286

It has been found subsequently[62] that deceleration of the motion of steps is largely due to easier formation of stacking faults on steps which penetrate terraces. Formation of such specially active adsorption positions enhances adsorption and gives rise to kinks on dissolution steps (Fig. 6). Chains of precipitates of inhibiting surfactants form along a step saturated with stacking faults, the motion of such a step slows down, and the result is a reduction in the rate of dissolution of a metal.

VII. Conclusions

We shall conclude our analysis of the cooperative models of dissolution of crystals by stressing the following features. The development of the cooperative models will depend in future on determination of the characteristic features of dissipation-free motion of a dissolution step along a basal plane of a crystal in contact with an electrolyte. These features are related to the conversion of a step from the normal to the superfluid state.[63] The problem has been solved for quantum crystals and the approach is fully applicable to a hydrogen sublattice in surface layers of *d* metals.

The models based on soliton solutions of the equations of motion of ensembles of particles, including elements of the catastrophe theory, provide a picture which is clearest from the physical point of view. Important aspects of the approaches described above are an allowance for change in the fine structure of double electrical layers of a metal and an adjoining electrolyte, for modification of the first layers in a crystal, for changes in the electron and photon subsystems of such a crystal, and for local processes of the solution particles. The cooperative models of dissolution are the most general and are capable of describing dissolution even of defect-free singular faces. This would have been impossible in the case of molecular-kinetic models

The influence of relativistic effects and the crystal field on the properties of actinyl ions

G V Ionova, G A Gerasimova
Institute of Physical Chemistry, Russian Academy of Sciences

ABSTRACT. The electronic structure and properties of the most covalent compounds of the actinides, namely the actinyl ions AnO_2^{2+} (An = U, Np, Pu, Am, Cm, Bk, and Cf), have been analysed on the basis of X_α-SW calculations. The regularity of the change in the redox, crystal-chemical, spectral, magnetic, and other properties in a series of compounds containing the actinyl ions has been studied. The strictly regular, regular, or irregular (stepwise) nature of the dependence of different properties on the atomic number of the element is determined by the extent of the participation of the 5*f*- and 6*d*-electrons in chemical bond formation, that is by the crystal field effect and the influence of relativistic spin–orbit coupling.

I. Introduction

In the last two decades, the regularity of the change in various physicochemical properties in the lanthanide and actinide series with change in the atomic number of the element has been studied, and a large number of models have been developed to explain them.[1] Some of these have survived, while others have been found untenable. The reason for this variety of models is the difficulty of obtaining an adequate description of the compounds of the *f*-elements using purely ionic or purely covalent models.[2] Thus the ionic model describes the properties of the compounds of the trivalent lanthanides effectively, and those of the trivalent actinides less effectively, but provides a poor description of the tetravalent actinides, and cannot be used at all to describe the electronic structure of compounds of An in high oxidation states (An^V, An^{VI}, and An^{VII}).

For compounds with a high bond polarity, there is a definite periodicity in the change in their physicochemical properties (P) with change in the atomic number of the element.[3] This is a general feature, and extends to the ionic compounds of both the *f*- and *d*-series and the super-heavy transactinide elements. The properties P of the lanthanides (Ln), actinides (An), or transition *d*-elements (M) with f^q- or d^q-electron configurations change periodically in accordance with the periodic change in the quantum numbers L of the normal terms. Thus in each series there are characteristic double–double effects $d^0-d^5-d^{10}$, $f^0-f^7-f^{14}$, $g^0-g^9-g^{18}$, $h^0-h^{11}-h^{22}$, and in each half of the series pairs of triads $d^0-d^1-d^2$, $d^3-d^4-d^5$, tetrads $f^0-f^1-f^2-f^3$, $f^4-f^5-f^6-f^7$, pentads $g^0-g^1-g^2-g^3-g^4-g^5$, and hexads $h^0-h^1-h^2-h^3-h^4-h^5-h^6$.[3] This periodicity is obviously revealed in the properties of the free atoms. The greater the difference between the atom in a molecule and the free atom, the greater the deviation from periodicity.

The present review deals with the most covalent systems formed by the actinides, namely the so-called actinyl cations AnO_2^{z+} (z = 1, 2), beginning with the uranyl ion UO_2^{2+}, whose stability is comparable to that of the vanadyl ion VO^{2+}. The actinyl ions are present as structural units in many compounds of the pentavalent and hexavalent actinides.

The regularity of the change in the crystal-chemical, redox, thermodynamic, spectral, magnetic, and other properties in the series of actinyl ions is determined by the extent of the participation of the 5*f*- and 6*d*-electrons in chemical bond formation, that is by the deviation from the purely ionic model. The study of these regularities represents a fundamental problem in the physical chemistry of the actinides, namely the problem of the "localisation–delocalisation of the 5*f*–6*d*-electrons", which to some extent can be solved by quantum-chemical calculations of the molecular orbitals (MO) of the ions AnO_2^{2+} or AnO_2^{+}, where An = U, Np, Pu, Am, Cm, Bk, and Cf.

A fundamental feature of the change in energy is the increase in the localisation of the 5*f*-electrons with increase in the atomic number of the actinide Z_{An}, which leads to a decrease in the overlap between the 5*f*-AO of the actinide and the 2*s*, 2*p*-AO of the ligands. Increase in the localisation of the 5*f*-electrons leads to an increase in the energy of excitation of the 5*f*-electrons into electron configurations involving 6*d*- and 7*s*-AO. As a result of these effects, increase in Z_{An} leads to a decrease in the stability of the actinyl and actinoyl ions in an isovalent series. This regularity is observed not only for the cations AnO_2^{2+} and AnO_2^{+} but also for other oxygen-containing molecules and ions, in particular the octahedral oxoanions AnO_6^{z-}.[2]

In the present review we try to analyse various aspects of the problem of the localisation–delocalisation of electrons in the most covalent actinide compounds, namely the actinyl ions, on the basis of the relativistic version of the X_α scattered-wave method, to obtain answers to the following questions:

—which fragments of the energy levels can be most definitely distinguished in AnO_2^{2+} and AnO_2^{+} cations, and to what extent are the electrons localised in these fragments;

—to what extent can these fragments be regarded as components for the series of actinyl and actinoyl ions;

—what changes take place in these fragments under the influence of the equatorial ligands X in AnO_2X_y;

—is it possible to distinguish a predominant electron configuration of an actinide in an ion and to go from it to a structural formula with a definite number of the multiple bonds—single, double, or triple?

The answers to these questions will make it possible to solve the fundamental problem in the chemistry of the actinides: in which cases and for what reasons can we expect a strictly regular, regular, or stepwise change in the properties of the actinyl ions along the series?

II. Experimental studies

1. An—O bond parameters obtained from structural studies and vibrational spectroscopy

A vast amount of experimental material has now been accumulated on compounds containing the actinyl and actinoyl ions of uranium, neptunium, plutonium, and americium.[4–31] The material for the uranyl ion has been reviewed.[32] For the problems formulated above, we shall analyse only the regularity of the change in the physicochemical properties of these ions with increase in Z_{An} observed in experimental studies.

For various reasons, the experimental studies which can be carried out for compounds of the elements from uranium to americium with corresponding compositions make up only a small part of the chemistry of actinyl compounds. Most of the studies relate to the uranyl ion. The properties established experimentally for this ion and its compounds are often extended to the neptunyl ion, and are sometimes extrapolated to the other ions, assuming a linear relationship between P and Z_{An}. As shown below, however, for most properties this relationship is irregular.

We shall end the description of various experimental properties of the actinyl ion series with the formulation of the regularity characterising these properties and with its theoretical interpretation if this follows from the classical MO scheme or with the formulation of the theoretical problem of this interpretation if the change in properties with increase in Z_{An} does not correspond to the semi-empirical classical MO scheme and requires up-to-date calculations.

Because of the exceptional stability of the uranyl ion and the ready availability of uranium, X-ray diffraction studies have been carried out for several hundred compounds of this ion, together with a number of studies for other actinyl ions.[33–40]

All the compounds contain a linear symmetrical or slightly distorted actinyl group. The related compounds of uranium, neptunium, plutonium, and americium are isostructural.[41–46] A common feature of all the compounds is the existence of short An—O distances (R_{An-O}) in contrast to the distances to the other ligands in the equatorial plane (R_{An-X}).

Figures 1 and 2 give the dependence of R_{An-O} on Z_{An} for various compounds. These relationships may be regular [as for $RbAnO_2(NO_3)_3$], strictly regular [as for $NaAnO_2Ac_3$ and $AnO_2(ClO_4)_2$], or irregular (as for $K_3AnO_2F_3$ and $Cs_2AnO_2Cl_4$). $R_{An-O}-Z_{An}$ relationships similar to those in Fig. 1*a* have been called arch-like (Ω-type), and relationships similar to those in Figs. 1*b*, 1*c*, 2*a*, and 2*b* have been called zigzag (*N*-type).[47] It is not always easy to distinguish these two types from the values of the internuclear distances. Thus in Figs. 1*b*, 1*c*, and 2*a* the continuous lines denote relationships of the Ω-type. For these series of compounds, the two types of relationship lie within the experimental error. From an examination of the series of relationships in Figs. 1 and 2 it can be reliably concluded that the internuclear distances R_{An-O} increase with increase in Z_{An} in related compounds of the elements for uranium to americium, and that these relationships are not linear, unlike the dependence of the ionic radii $R_{An^{6+}}$ on Z_{An}.

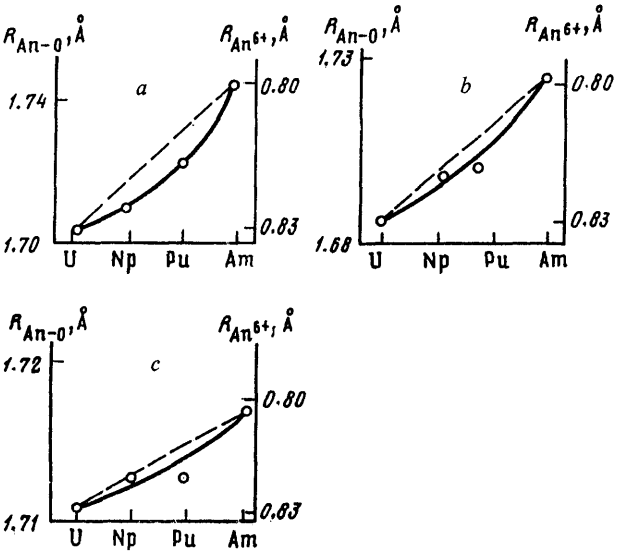

Figure 1. Dependence of the ionic radii of the sextuply-charged ions An^{6+} (broken line) and the internuclear distances R_{An-O} (continuous line) on Z_{An}:[48] *a*, *b*, strictly regular relationships for $NaAnO_2Ac_3$ [32] and $AnO_2(ClO_4)_2$;[35] *c*, regular relationship for $RbAnO_2(NO_3)_3$.[32]

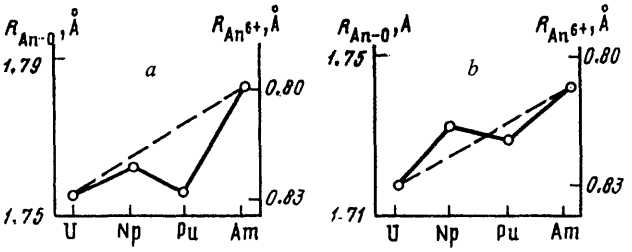

Figure 2. Dependence of the ionic radii of the sextuply-charged ions An^{6+} on Z_{An} (broken line) and the irregular dependence of R_{An-O} on Z_{An} for the compounds $K_3AnO_2F_3$ (*a*) [15] and $CsAnO_2Cl_4$ (*b*).[32]

Both types of relationship (Ω- and *N*-types) can be observed in other properties of the actinyl ions, and a qualitative explanation is not simple. Thus the ionic radii of the sextuply-charged actinide ions are 0.83, 0.82, 0.81, and 0.80 Å for uranium, neptunium, plutonium, and americium respectively.[48] If it is assumed that the ionic radius of the O^{2-} ion is 1.36 Å, the values of R_{An-O} in the actinyl ions of uranium, neptunium, plutonium, and americium should be 2.19, 2.18, 2.17, and 2.16 Å respectively. The experimental values of R_{An-O}, however, not only are 0.5 Å shorter but also change in the opposite order with increase in Z_{An}.

Thus an important problem in structural theory is to establish a direct relationship between the electronic structure of the actinyl ions and the non-additive, regular, or irregular increase in the internuclear distances R_{An-O}. The question of whether the *N*-type of relationship observed for the internuclear distances R_{An-O} is determined by the electronic structure of the free actinyl ions or by the influence of the equatorial ligands still remains open.

The changes in R_{An-O} are to some extent reflected in the values of the force constants of these bonds K_{An-O} in hexavalent actinyl compounds. The change in K_{An-O} for related compounds of uranium, neptunium, and americium shows a number of characteristic features.

1. The force constants of the An–O bonds decrease on going from the uranyl to the americyl ion. Our estimates of K_{An-O} for the curyl ion indicate a further decrease in the strength of the actinide–oxygen chemical bond. These results correspond to increasing localisation of the 5*f* electrons with increase in Z_{An} and increase in the number of antibonding electrons.

2. The change in K_{An-O} with change in Z_{An} is non-additive, and two types of deviation from additivity are observed: positive for $NaAnO_2Ac_3$ (70.8, 69.7, 67.5, 63.4 μdyn nm^{-1}) and $AnO_2(ClO_4)_2$ (77.5, 78.1, 77.1, 73.5 μdyn nm^{-1}) and negative for $Cs_2AnO_2Cl_4$ (68.0, 65.1, 63.6, 62.7 μdyn nm^{-1}).

3. Finally, it is possible to distinguish two types of $K_{An-O}-Z_{An}$ relationships, namely Ω- and *N*-types. Naturally, the separation of the curves into Ω- and *N*-types involves certain assumptions, as in the case of the internuclear distances.

For the perchlorate complexes, the force constant increases on going from the uranyl to the neptunyl ion. This is possibly due to errors in the measurement of the wavenumber of the antisymmetric stretches ν_{as} for U^{6+} or Np^{6+}. Morss[49] gives the same value ν_{as} = 935 cm^{-1} for the two ions, taken from an early paper.[50]

For the fluoride complexes of plutonium and neptunium, $K_{Pu-O} > K_{Np-O}$. A decrease in ν_{as} and K_{An-O} with increase in Z_{An} appears more logical if it is assumed that the influence of the equatorial ligands on the electronic structure of the cations is the same for all cations.

There are fewer published X-ray diffraction studies for compounds containing pentavalent actinoyl ions than for their hexavalent analogues.[51–56]

Studies of compounds containing AnO_2^{2+} and AnO_2^{+} ions reveal many common features in the stereochemistry of these complexes, namely in the values of the coordination numbers (CN) and the types of coordination polyhedra. Naturally, all the interatomic distances R_{An-O} in the actinoyl compounds are greater than those in the corresponding actinyl analogues. On the average, the difference in the bond lengths R_{An-O}, where An = Np and U, is 0.012 ± 0.006 nm.

A complete set of values of K_{An-O} and R_{An-O} for all the actinoyl ions is not available. The use of some published data[49,50] for $NpO_2(ClO_4)_2$ and $AmO_2(ClO_4)_2$ gave the following values of K_{An-O} for the AnO_2ClO_4 series (in μdyn nm^{-1}): 53.1, 56.5, 58.6, and 57.7 for An = U, Np, Pu, and Am respectively, and the use of other data[35] gave the values 50.1, 52.5, 52.9, and 50.7 μdyn nm^{-1} respectively. The $K_{An-O}-Z_{An}$ relationships observed are of the same Ω-type observed for the actinyl compounds with the same perchlorate anions.

Thus each of the above characteristics of the change in K_{An-O} with increase in Z_{An} represents a problem for quantum-chemical interpretation.

2. Optical spectra

The interpretation of the electronic–vibrational spectra[57–62] and the optical spectra by the method of molecular orbitals (MMO)[63–69] has led to important conclusions about the nature of the chemical bond in the actinyl series. In compounds containing "yl" groups, two types of electron transition have been detected in the visible range: uranyl-like charge-transfer transitions E_{CT} and *f*–*f* transitions. The first correspond to the excitation of an electron from a higher bonding MO of predominantly 5*f*-character. For the actinyl anions AnO_2^{2+}, the values of E_{CT} for An = U, Np, Pu, and Am are respectively 20679 ± 472, 13358 ± 338, 15396, and 10086 cm^{-1} [70–73] (Fig. 3).

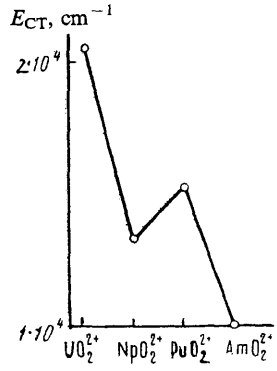

Figure 3. Dependence of the energy of the uranyl-like charge-transfer transition (E_{CT}) in actinyl ions on the atomic number of the acitnide.

Table 1. Energies of the *f*–*f* electron transitions for AnO_2^{2+} (cm^{-1}).[69]

Transition	NpO_2^{2+}	PuO_2^{2+}	AmO_2^{2+}
$\varphi_{5u}-\delta_{3u}$	-	-	-
$\varphi_{5u}-\varphi_{7u}$	6750	-	-
$\varphi_{5u}-\delta_{5u}$	8180	12024	13630
$\varphi_{5u}-3\pi_{1u}$	18180	19193	19300
$\varphi_{5u}-3\pi_{3u}$	21100	24040	-
$\delta_{3u}-\delta_{5u}, \varphi_{7u}$	-	10186	11710
$\delta_{3u}-3\pi_{1u}$	-	16060	16190
$\delta_{3u}-3\pi_{3u}$	-	21320	21420

For NpO_2^{2+}, a series of absorption bands has been detected with energies 13918, 16072, 16092, 7967, and 1951 cm^{-1} [70] or 13239, 15402, 15678, 16795, 19371 cm^{-1}.[71] For PuO_2^{2+} the values of E_{CT} are 15280, 15498, and 15658 cm^{-1}.[72]

In the sequence of E_{CT} values for the actinyl ions, a red shift is observed. The same shift should obviously be observed in the values of E_{CT} for the actinoyl ions.

The energies of the $f-f$ transitions are given in Table 1.[69] The energies of transitions of the same kind tend to increase with increase in Z_{An}.

There are few published experimental data on the values of the energies of the $f-f$ transitions for compounds containing actinoyl ions. For example, for the absorption wavenumbers of $Cs_3NpO_2Cl_4$ the ranges 6035–11111, 16437–22309, and 12810–15973 cm^{-1} have been given.[71]

The transitions of greatest interest for analysing the chemical bonding in actinyl compounds are the uranyl-like transitions, whose energies change irregularly along the series UO_2^{2+}, NpO_2^{2+}, PuO_2^{2+}, AmO_2^{2+}, giving an N-type relationship.

3. Redox potentials

The formal potentials E^0 in perchlorate solutions have been determined experimentally for the AnO_2^{2+}/AnO_2^{+} couples; the values obtained are 0.089 ± 0.002, 1.160 ± 0.005, 0.940 ± 0.004, and 1.624 ± 0.009 for An = U, Np, Pu, and Am respectively.[74] Fig. 4 shows that the dependence of E^0 on Z_{An} is irregular (N-type). Comparison of Figs. 3 and 4 shows an analogy in the changes in E_{CT} and E^0 with change in Z_{An}, leading to a linear relationship between E_{CT} and E^0 (Fig. 5).

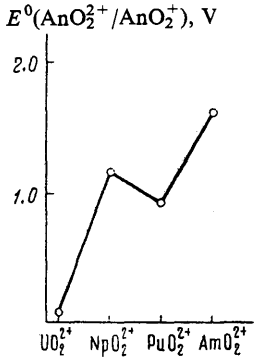

Figure 4. Dependence of the redox potentials (E^0) of AnO_2^{2+}/AnO_2^{+} couples on Z_{An}.

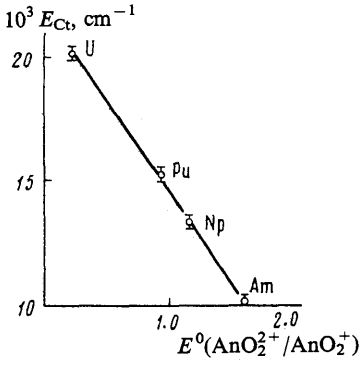

Figure 5. Linear relationship between the calculated energy of the uranyl-like transitions (E_{CT}) of the actinyl ions[123] and the measured redox potentials.[74]

The irregular change in the redox potentials may be due either to the specific features of the electronic structure of the actinyl ions themselves or to the influence of the equatorial ligands; this is again a problem for theoretical study. In any case, it is impossible to avoid semi-empirical MO schemes for an explanation of the irregular changes in the redox properties. From general qualitative considerations it is obvious that the redox potentials increase towards the end of the first half of the series, in particular from the uranyl to the americyl ion. The extremal change in E^0 for the PuO_2^{2+}/PuO_2^{+} couple, however, does not fit into the usual qualitative interpretation.[75–77]

4. Thermodynamic properties

The free energies and enthalpies of the actinyl and actinoyl ions have been discussed.[33,34,49] Fig. 6 shows the dependence of the standard enthalpies of formation of the actinyl (a) and actinoyl (b) ions on the atomic number of the actinide. In both cases the relationship is strictly regular. We noted above that the redox potentials $E^0(AnO_2^{2+}/AnO_2^{+})$ of the chemical reactions

$$(AnO_2^{2+})_{aq} + e \rightarrow (AnO_2^{+})_{aq}\,, \qquad (1)$$

for the same sequence of actinyl ions change irregularly. The change in free energy for reaction (1) can be written as

$$\Delta G_0^0 = FE^0(AnO_2^{2+}/AnO_2^{+}), \qquad (2)$$

where F is the Faraday constant, or

$$\Delta G_0^0 = \Delta G_0^0(AnO_2^{2+})_{aq} - \Delta G_0^0(AnO_2^{+})_{aq}\,. \qquad (3)$$

Comparison of Eqns. (2) and (3) shows that with a regular change in both terms in Eqn. (3), their difference can be represented by an irregular relationship.

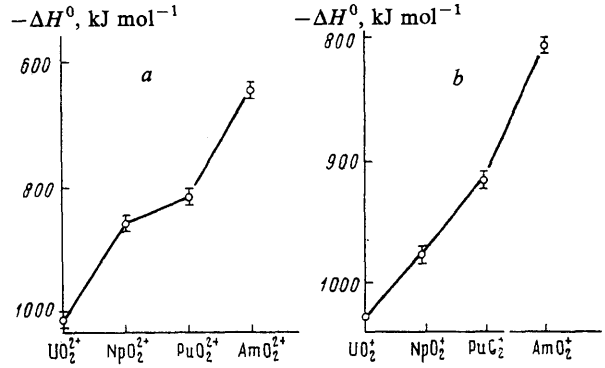

Figure 6. Change in the standard enthalpy of formation of actinyl (a) and actinoyl (b) ions.[30]

Fig. 6b shows that the dependence of $\Delta H^0(AnO_2^{+})$ on Z_{An} is almost linear, whereas the dependence of $E^0(AnO_2^{2+}/AnO_2^{+})$ and $\Delta H^0(AnO_2^{2+})$ on Z_{An} is of the N-type. This important feature,

characteristic of actinyl ions, will be examined below in relation to the electronic structures of these ions.

Finally, the molar polarisability R_M [47] and the refractive index n_d [78] show an identical tendency to undergo an irregular change of the *N*-type with change in Z_{an}. It can be shown that the enthalpy of formation of the actinyl ions and the molar polarisability and refractive index depend on the same parameters related to the electronic structure of the actinyl ions. One of the most important problems in the theory of the structure of the actinyl ions is to find these parameters and identify the fine difference in the electronic structures of the ions which gives an irregular relationship of the *N*-type when revealed in some properties, and a regular relationship when it is not revealed.

5. Extraction of the actinyl ions

There are now extensive published data on the extraction of lanthanides and actinides by various extracting agents.[79–85] Two approaches to the theoretical interpretation of the results may be noted.

A correlation has been noted[80–83] between the change in lg *D*, where *D* is the extraction coefficient for different extracting agents, and the orbital quantum numbers *L* for the normal terms of the *f*-ions. At the same time, a *J*-model has been used,[79] that is it has been shown that in the extraction of tervalent lanthanides by tributyl phosphate (TBP), the change in lg *D* follows the values of the quantum numbers *J* of the normal terms of the free ions, as in the case of the magnetic properties of the lanthanides.

The change in the free energy of extraction

$$\Delta G_e^0 = -RT \lg D ,$$

decreases both with increase in the quantum number *L* and with increase in the quantum number *J*. In the ionic approximation for the series of actinyl ions $U^{6+}(^1S_0)$, $Np^{6+}(^2F_{5/2})$, $Pu^{6+}(^3H_4)$, and $Am^{6+}(^4I_{9/2})$ being considered, the change in the free energy of extraction ΔG_e^0 should decrease regularly from the uranyl ion to the americyl ion if it is assumed that $\Delta G \simeq -L$ or $\Delta G \simeq -J$. In the extraction of the actinyl ions by solutions containing TBP and mineral acids (HNO_3, $HClO_4$, or HCl), the value of ΔG_e^0 when nitric and perchloric acids are added to TBP increases on going from the uranyl to the plutonyl ion, but when hydrochloric acid is added, the value decreases on going from the uranyl to the neptunyl ion and increases on going from the neptunyl to the plutonyl ion.[84] The main conclusion from these experimental data is that the thermodynamic parameters of the extraction of the actinyl ions reflect changes taking place in the electronic structures of these ions on complex formation in the aqueous phase.

6. Complex formation by actinyl ions

Comparison of the values of lg *K* (*K* represents the formation constants of the complexes AnO_2SO_4, $AnO_2(SO_4)_2^{2-}$, $AnO_2(CO_3)_2^{2-}$, $AnO_2(CO_3)_3^{4-}$, AnO_2H^+, $(AnO_2)_2(OH)_2^{2+}$, and $(AnO_2)_3(OH)_5^+$ (in aqueous solution at 25 °C[85–89]) shows two types of lg $K-Z_{An}$ relationships (curves *1*–*7* in Fig. 7).

The first type of relationship is characterised by extremal values of lg *K* for the neptunyl ion (curves *2*–*5* in Fig. 7), and the second corresponds to a regular increase (curve *1* in Fig. 7) or decrease (curves *6* and *7* in Fig. 7) in the values of lg *K*. The change in lg *D* for the actinyl ions, where *D* is the extraction coefficient, shows a regular decrease with increase in Z_{An} for 0.6 M HNO_3 + TBP solution (curve *8* in Fig. 7), and an extremal value for the neptunyl ion in the case of 2 M HCl + TBP solution (curve *9* in Fig. 7).

Thus the change in the thermodynamic parameters in extraction reflects their change on complex formation, that is complex formation is the most important stage determining the thermodynamics of the extraction process. It follows from published data[84] that the entropy term is responsible for the change in ΔG^0 on formation of the di- and tricarbonate complexes of the actinyl ions, and that the enthalpy term is responsible in the case of the mono- and disulphate complexes. In all cases examined except $AnO_2(CO_3)_3^{4-}$, the enthalpy and entropy terms show opposite trends in the change with increase in Z_{An}.

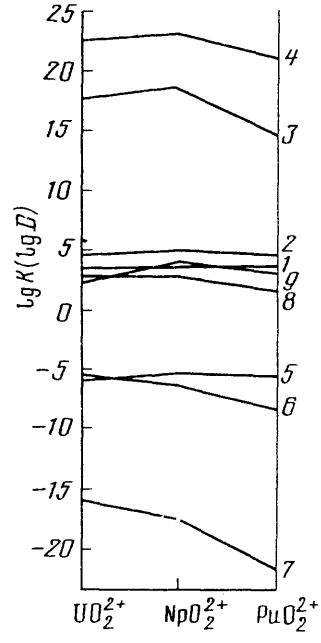

Figure 7. Change in lg *K* (*K* is the equilibrium constant of the reaction $AnO_2^{2+} + X \rightarrow AnO_2X$ in aqueous solution at 25 °C) and ln *D* (curves *8* and *9*) for actinyl ions extracted in 0.6 M aqueous solution by HNO_3 + TBP (*8*) and HCl + TBP (*9*) 25 °C:[84] *1*, AnO_2SO_4;[86] *2*, $AnO_2(SO_4)_2^{2-}$;[86] *3*, $AnO_2.(CO_3)_2^{2-}$;[87] *4*, $AnO_2(CO_3)_3^{4-}$;[88] *5*, AnO_2H^+;[87] *6*, $AnO_2(OH)_2^{2+}$;[89] *7*, $(AnO_2)_3(OH)_5^+$.[89]

The dependence of these thermodynamic parameters on Z_{an} for the extraction of AnO_2^{2+} from HNO_3 + TBP and HCl + TBP solutions shows[84] that in the extraction by nitric acid the trends in the changes in the free energy and the entropy term are the same, whereas in the extraction by hydrochloric acid the trends in the changes in the free energy and the enthalpy term are the same. The experimental data show that in almost all cases examined, the neptunyl ion shows an extremal (or irregular) change in the thermodynamic functions on complex formation or extraction.

In the extraction of the actinyl ions by HNO_3 or $HClO_4$ solution[84] and on formation of the complexes $AnO_2(CO_3)_2^{2-}$ and $AnO_2(CO_3)_3^{4-}$, the free energy and the entropy term change in the same sense with increase in Z_{An}. In the extraction by HCl solution

and on formation of the sulphate complexes AnO_2SO_4 and $AnO_2(SO_4)_2^{2-}$, the free energy and the entropy term change in the opposite sense.[90–95]

III. Electronic structure of the actinyl ions

1. Theoretical studies of actinyl and actinoyl ions

The first model of the molecular orbitals of the uranyl ion, proposed by Eisenstein and Pryce[96] in 1955, was designed to explain the magnetic properties of uranyl compounds. Subsequent studies[65,66,97] were aimed at interpreting the optical spectra of the uranyl ion, and the discussion was based entirely on the MO method. The very first applications of the MO method to the description of the structure of the uranyl ion gave important results. The MO of the uranyl ion were classified on the basis of general symmetry properties; calculations of the overlap integrals made it possible to obtain a measure of the interaction of the atomic orbitals of uranium and oxygen and to determine the principal features of the sequence of the bonding MO of the uranyl ion. The first attempts were made to interpret the magnetic properties and absorption spectra of uranyl compounds.[98–101]

The first quantitative calculations of the molecular orbitals of the uranyl ion were carried out using the theory of the SCF-X_α-method, which makes it possible to obtain a good description of many-electron systems, in particular the complexes of *f*-elements.[102] Calculations carried out up to the present have been restricted mainly to the study of the electronic structure of the uranyl ion by different methods,[103–113] some of which cannot give a clear quantitative picture of the electron density distribution and the structure of the energy levels.[114,115] There is no doubt that it is important to take account of relativistic effects in systems containing heavy atoms.[116–118] There are no published studies, however, of the electronic structure of plutonium and the transplutonium elements, which would make it possible to follow the changes in electronic structure in the actinyl ion series. Until recently there were no published data on the quantum-chemical study of the actinoyl ions, that is there were no published systematic studies of the electronic structure of the series of ions AnO_2^{2+} and AnO_2^{+}. This problem has been examined and reviewed[119–123] using a relativistic version of the X_α-SW method.

2. Calculation procedure

The completely relativistic X_α-SW method is based on the solution of the Dirac equation by the multiple-scattering method.[124]

All the studies have been carried out in the quasi-relativistic (QR) approximation of the SCF-X_α method.[125–133] The essential feature of the QR approximation is the change, for the radial wavefunctions, from the four-component Dirac spinors to two-component spinors with simultaneous exclusion of spin–orbit coupling and neglect of contributions from small components in the construction of the self-consistent central potential and the total electron density. After obtaining self-consistent QR orbitals, spin–orbit coupling was taken into account using perturbation theory and a basis set of QR orbitals, determined with allowance for such relativistic effects as the dependence of mass on velocity and Darwin interaction. The differential equation for the radial function G_{nl} of a large component has the form:

$$[H_{NR} + H_m + BH_D]\, G_{nl} = E_{nl} G_{nl}\,.$$

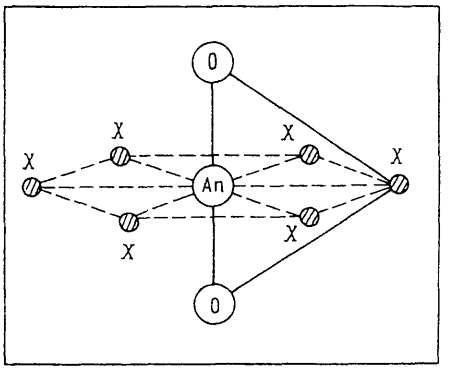

Figure 8. Model of the cluster of an actinyl ion with six ligands X in the equatorial plane of the O–An–O group.

Here, H_{NR} is the standard non-relativistic operator, used to describe the central field (with an exchange $X_\alpha l$-potential), H_m the standard operator for the dependence of the mass of the electron on velocity, and H_D the Darwin operator.[134] The operator B has the form

$$B = \{1 + (\alpha^2/4)[E_{nl} - V(r)]\}^{-1},$$

where $\alpha = 1/137$, and $V(r)$ is the one-electron potential of the central field. The effects of spin–orbit coupling on the molecular orbitals are calculated using perturbation theory in a basis set of self-consistent quasi-relativistic orbitals: $H'_{so} = BH_{so}$, where H_{so} is the standard operator of spin–orbit coupling from Pauli theory.[135–148] As basis orbitals it is possible to use either individual orbitals with a given characteristic value (RX_α-*SO* calculation) or groups of orbitals with similar characteristic values (RX_α-*SO'* calculation, higher orders of perturbation theory).[148–156]

3. Results of the calculations

Model calculations have been carried out[116–120] for the ions AnO_2^{2+} and AnO_2^{+} (An = U, Np, Pu, Am) with interatomic distances R_{An-O} decreasing in accordance with the actinide contraction: 1.73, 1.72, 1.71, 1.70 Å in AnO_2^{2+} and 1.76, 1.75, 1.74, 1.73 Å in AnO_2^{+} for U, Np, Pu, Am respectively. In the works cited, however, no account was taken of the fact that the equatorial ligands X in compounds AnO_2X_y (Fig. 8) have a significant influence on the interatomic distances R_{An-O}, leading, firstly, to their increase with increase in the atomic number of the actinide element, and not to their decrease, as predicted by the effect of actinide contraction and, secondly, to an irregular dependence of R_{An-O} on Z_{An}. We carried out analogous calculations for the actinyl ions in the series of isostructural compounds $NaAnO_2Ac_3$ (a), $Cs_2AnO_2Cl_4$ (b), $RbAnO_2(NO_3)_3$ (c), and $AnO_2(ClO_4)_2$ (d) with different types of dependence of R_{An-O} on Z_{An}. The values of R_{An-O} for all series of compounds with An = U, Np, Pu, and Am respectively (in Å) are given below:

Series	U	Np	Pu	Am
(a)	1.704	1.709	1.721	1.743
(b)	1.1718	1.733	1.731	1.747
(c)	1.683	1.692	1.692	1.712
(d)	1.673	1.670	1.675	1.695

Fig. 9 gives the energy level diagrams for the sequence of doubly-charged AnO_2^{2+} cations, obtained in RX_α-SO′ approximations. The sequence of energy levels remains practically unchanged to the end of the series for different forms of dependence of R_{An-O} on Z_{An}.

The lowest-lying MO ($1\sigma_g - 2\sigma_u$) are formed by the strong covalent mixing of the 6*p*-AO of the actinide and the 2*s*-AO of oxygen, and are inner valence molecular orbitals (IVMO). Above them there is a group of levels formed mainly by the 6*d*- and 5*f*-AO

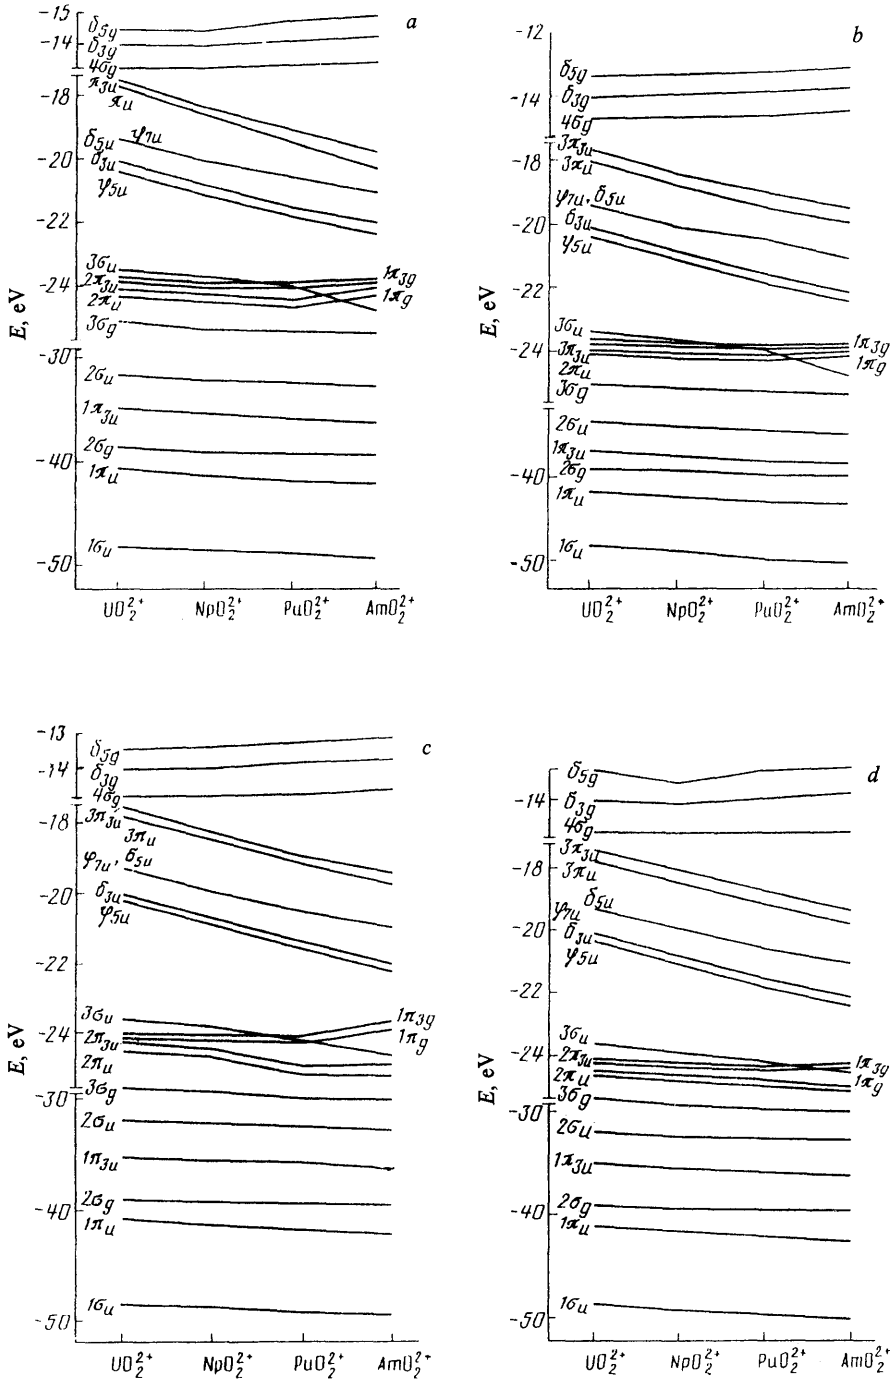

Figure 9. Energies of the MO in actinyl ions calculated by the RX_α-SO′ method: *a*, $NaAnO_2Ac_3$; *b*, $Cs_2AnO_2Cl_4$; *c*, $RbAnO_2 \cdot (NO_3)_3$; *d*, $AnO_2(ClO_4)_2$.

of the actinide and the 2*p*-AO of oxygen, the so-called outer valence MO (OVMO). Even higher, separated by an energy gap (ΔE), are the non-bonding and antibonding levels of 5*f*-character. In the RX_α-SO′ approximation the orbitals φ_{7u} and δ_{5u} are accidentally degenerate. This leads to a qualitative similarity in the electronic structures of the actinyl ions, making it possible to distribute their energy levels of similar composition in groups. In this sense it is possible in the actinyl ions to distinguish the following fragments corresponding to the maximum bonding between various AO: 6*s*(An) + 2*s*(O); 6*p*(An) + 2*s*, 2*p*(O); 5*f*, 6*d*(An) + 2*p*(O); 5*f*(An); and 6*d*(An).

The highest bonding MO (HBMO) for UO_2^{2+} and NpO_2^{2+} is the $3\sigma_u$-MO, but from PuO_2^{2+} and beyond, the π_g-orbital becomes the HBMO. Fig. 9 shows that on going to the heavier actinides, the energies of the non-bonding and anti-bonding MO (of 5*f*-character) gradually decrease, whereas those of the highest bonding MO remain almost unchanged. The greater lowering of the levels of 5*f*-character takes place as a consequence of the gradual increase in the number of electrons localised in them, and also as a consequence of the fact that the energies of the 5*f*-AO decrease with increase in the atomic number of the actinide. The energies of the bonding MO, where the main contribution is made by the AO of oxygen, remain practically unchanged. The magnitude of ΔE decreases along the series from 3.2 eV for UO_2^{2+} to 1.5 eV for AmO_2^{2+}.

Analysis of the electronic structure of the actinyl ions clearly shows the existence of common characteristic groups of levels both in the system of bonding levels and in the system of antibonding levels, corresponding to the interactions 2*s*−6*p*, 2*s*, 2*p*−6*p*, 2*p*−6*d*,5*f* between the valence 2*s*,2*p*-AO of the ligands and the 6*p*, 6*d*, and 5*f*-AO of the actinide atoms from uranium to californium.[122]

Separation of the energy levels into fragments is observed for all the oxygen-containing compounds of the actinides. Comparison of the analogous groups of levels in the isovalent anions and cations, for example in UO_6^{6-} and UO_2^{2+}, NpO_6^{6-} and NpO_2^{2+}, etc., shows, however, that the electrons are more localised in the anions than in the cations. This means that in the anions, in the fragments mainly responsible for their properties, the 2*p*−6*d*,5*f*-electrons are localised to a greater extent in the 2*p*-AO of the oxygen atoms in the bonding levels, and in the 5*f*-AO in the antibonding levels. In the anions, the electronic structure of the fragments is closer to that of the free atoms, that is the bonding levels (2*p*−6*d*,5*f*) approach 2*p*(O), and the antibonding levels (6*d*,5*f*−2*p*) approach 6*d* + 5*f*(An). It can be stated definitely that the series of actinyl ions is described by a set of transferable fragments in such a way that with each of them it is possible to associate a certain energy increment. The cations differ mainly in the electron distributions in the fragments.

In the inner valence MO the most probable distribution of electron density corresponds to its displacement into the 6*s*- and 6*p*-AO of the actinide. In the outer valence MO, the electron density distribution corresponds to covalent bonding.

Finally, in the series of non-bonding and antibonding levels the displacement of electron density corresponds to the direction An←2*p*(O), that is for an anion taken separately the completely "classical" electron density distribution is obtained, and it is preserved in all the actinyl ions. On going from one cation to another, a qualitative modification of the fragments takes place, involving the greater localisation of the 5*f*-electrons with increase in Z_{An} in AnO_2^{2+}, less extensive participation of the 6*d*- and 7*s*-electrons in chemical bond formation, gradual localisation of the core 6*s*- and 6*p*-electrons, and a lowering of the corresponding energy levels.

All this decreases the strength of the An−O bond in the actinyl ions with increase in Z_{An}, and gives a general picture of their qualitative change. This qualitative picture is insufficient, however, for the interpretation of the chemical properties.

Thus the gradual localisation of electrons in the fragments of the actinyl ions with increase in the atomic number of the actinide should have corresponded to a gradual and regular change in their properties.[157–164] The properties of the actinyl ions (from uranyl to americyl), however, generally change in irregular fashion.[1] This means that it is necessary to take account of the difference in the structures of the fragments;[165–170] the transferability of the fragments gives only the zeroth approximation to the qualitative picture.

4. Interpretation of the experimental properties of the actinyl and actinoyl ions, based on the results of SCF-X_α-SW calculations

We shall begin the discussion of the experimental properties with the most important chemical property—the redox potential of the AnO_2^{2+}/AnO_2^{+} couple. The available experimental data give a relationship of the *N*-type for the redox potentials in the series from the uranyl to the americyl ion. To explain this dependence of E^0 on Z_{An}, we can first examine the ionic model, that is the ionisation of the free ions in the gas phase or in solution

$$An^{z+}(f^q) \rightarrow An^{z+1}(f^{q-1}) + e. \quad (4)$$

The oxidation potential of this reaction under equilibrium conditions is written as:

$$E^0 = \frac{0.05916}{n} \ln K_p, \quad (5)$$

where K_p is the chemical ionisation equilibrium constant. The free energy of this reaction ΔG^0 and K_p are related by the familiar expression

$$\Delta G^0 = -RT \ln K_p. \quad (6)$$

At the same time, for standard conditions:

$$\Delta G^0 = \Delta H^0 - T\Delta S^0. \quad (7)$$

Thus each of the quantities ΔG^0, E^0, and $\ln K_p$ can be calculated in terms of the others if they are related to reaction in the same phase, that is solution or gas. Thus, for the chemical equilibrium constant in the gas phase we readily obtain

$$K_p(T) = \frac{g(f^q)}{2g(f^{q-1})} \left(\frac{2\pi}{m}\right)^{3/2} \frac{h^2}{T^{5/2}} \exp(\Delta E/kT), \quad (8)$$

where $g(f^q)$ and $g(f^{q-1})$ are the statistical weights of the normal states of the ions $An^{z+}(f^q)$ and $An^{z+1}(f^{q-1})$, *m* the mass of the ion, *T* the temperature, and ΔE the energy difference between the normal terms of the ions with the f^q- and f^{q-1}-electron configurations.

It can readily be shown that at *T* = constant for all the ions, completely neglecting covalent effects, the change in K_p along the series depends on the ratio $g(f^q)/g(f^{q-1})$, and the change in the free energy of the redox reaction (4) being considered, in accordance with Eqn. (6), depends on the logarithm of this ratio, $\ln[g(f^q)/g(f^{q-1})]$.

The multiplicity of the degeneracy of $g(f^q)$ and $g(f^{q-1})$ depends on the electronic structure of the ions, which also determines the applicability of the *L*- and *J*-models. The dependence of ln K_p on Z_{An} for both models is shown in Fig. 10*b*. The relationship is the typical strictly regular Ω-relationship, that is the ionic model leads to the regular relationship!

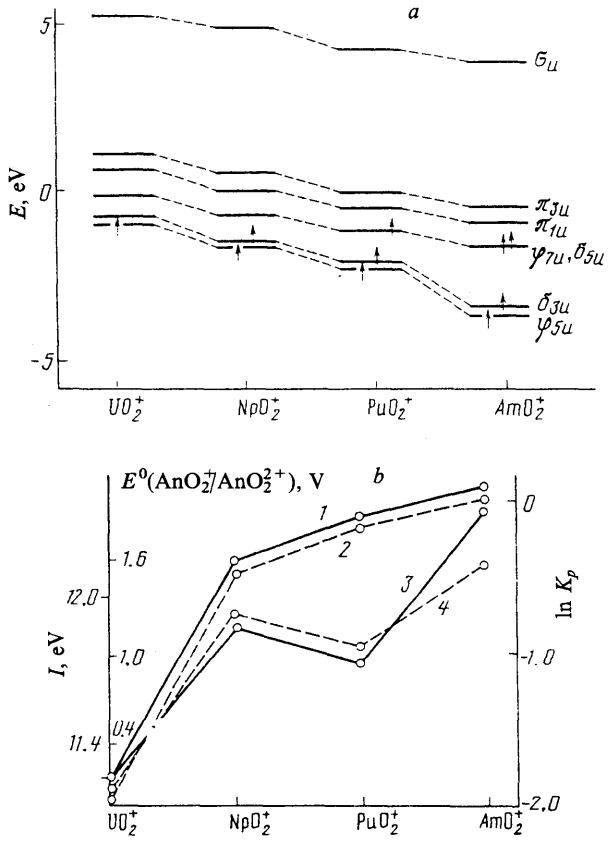

Figure 10. MO diagram for the actinyl ions (*a*) and the dependence of ln K_p [in the *J*-model (curve *1*) and the *L*-model (curve *2*)], the ionisation potentials *I* (curve *3*), and the oxidation potentials E^0 (curve *4*) of the actinyl ions on Z_{An} (*b*).

We can now examine the influence of the crystal field together with spin–orbit coupling. As shown above, the valence 5*f*-AO in the symmetry point group $D_{\infty h}$ are split into δ_u-, φ_u-, π_u-, and σ_u-MO. As a result of spin–orbit coupling, the δ_u- and φ_u-MO are split into δ_{5u}-, φ_{7u}-, δ_{3u}-MO, and π_u into π_{3u} and π_{1u}. Fig. 10*a* shows the filling of these MO with electrons for the actinoyl ions AnO_2^+: $UO_2^+ - \varphi_{5u}^1$; $NpO_2^+ - \varphi_{5u}^1$; $PuO_2^+ - \varphi_{5u}^1\delta_{3u}^1(\varphi_{7u}\delta_{5u})^1$; $AmO_2^+ - \varphi_{5u}^1\delta_{3u}^1(\varphi_{7u}\delta_{5u})^2$. The energy distance between the φ_{5u}- and δ_{3u}-MO is determined mainly by the spin–orbit effect for the free ions, since they are almost pure 5*f*-levels, and the splitting of the π_u-levels is due to the effects of the crystal field and the spin–orbit coupling (CF + SOC) resulting from the considerable mixing with the 2*p*-AO of the oxygen atoms. As a result, the energy distance Δ_1 between the φ_{5u}- and δ_{3u}-MO in AnO_2^+ is about 1500 cm^{-1}, while the distance Δ_2 between the δ_{3u}- and $\varphi_{7u}\delta_{5u}$-MO is greater, and amounts to about 6000 cm^{-1}. In accordance with the scheme adopted for the filling of the MO by electrons and the values of Δ_1 and Δ_2, the change in the ionisation potentials of the actinoyl ions is irregular (Fig. 10*b*); the so-called *N*-relationship is observed. This analysis reveals the reasons for the appearance of a stepwise relationship of the *N*-type. Since the main energy contribution to the oxidation potential $E^0(AnO_2^+/AnO_2^{2+})$ for the chemical reaction $AnO_2^+ \rightarrow AnO_2^{2+} + e$ is associated with the removal of the electron from the AnO_2^+ ion, the corresponding ionisation potentials and the oxidation potential change in the same sense (Fig. 10*b*).

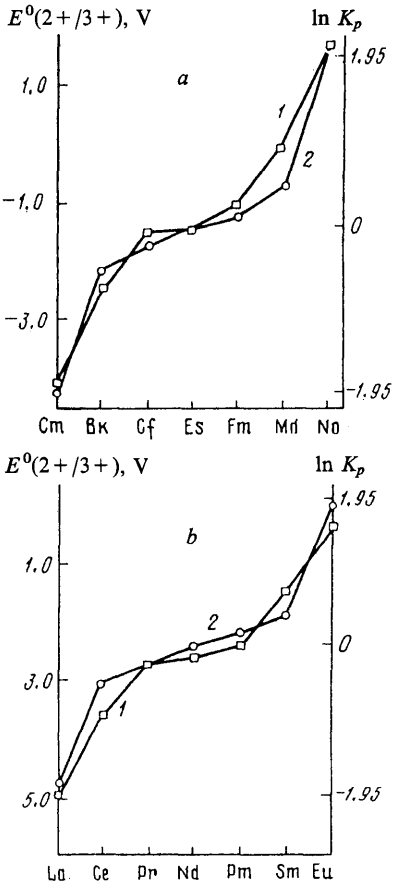

Figure 11. Regular dependence of the potentials $E^0(2+/3+)$ on Z_{An} (*a*) and Z_{Ln} (*b*) (curves *1*), resulting from weak crystal fields and relativistic effects; two Ω-type relationships can be distinguished in each half of the series; the theoretical dependence of ln K_p on *Z* is also given (curves *2*).

Thus when account is taken of strong crystal fields and spin–orbit effects, the Ω-type regular relationship ($K_p - Z_{An}$) in the *L*- or *J*-models becomes an irregular relationship of the *N*-type ($I - Z_{An}$, $E^0 - Z_{An}$).

In other words, it can be stated that the **irregular nature of the dependence of E^0 on the atomic number of the actinide is due largely to strong crystal field and spin–orbit effects.** The opposite is also true: **for weak crystal field and spin–orbit effects, the dependence of E^0 on Z_{An} is regular, of the Ω-type,** like the dependence of K_p on Z_{An}. This is the case for compounds with the electron configurations f^1, f^2, f^3, and f^4 (Fig. 11).

Thus the principal effects responsible for the anomalous properties of the heavy elements are relativistic contraction, spin–orbit splitting, and self-consistent interaction of the orbitals. Relativistic contraction in the case of the *s*-electrons, which have a low density next to the nucleus, leads to a decrease in the radii and an increase in the ionisation potentials of the corresponding ions.

Relativistic effects influence the *p*-AO in the same direction as the *s*-AO, but to a much smaller extent. Finally, relativistic effects influence the *d*- and *f*-electrons in the opposite direction, that is the radii increase and the ionisation potentials decrease. In other words, for an electron configuration $f^q ds^2$ the relativistic effects make the 7*s*-AO more compact and strongly bound, and the 6*d*- and 5*f*-AO more diffuse and weakly bound. In the atom, the relativistic effects for the 5*f*-, 6*d*-, and 7*s*-AO partly compensate one another.

The compounds of actinides in lower oxidation states (3+ and 4+) are practically ionic. This means that in these states the $6d7s^2$-electrons of the actinide are transferred to the ligands, and the 5*f*-electrons are non-bonding. The relativistic effects and crystal field effects increase with increase in the oxidation state.

These postulates can be verified from the values of the redox potentials. In the chemistry of the *f*-elements it is possible to consider two limiting cases: the actinyl and actinoyl ions (strong crystal fields and spin–orbit effects) and the lanthanides and actinides in lower oxidation states 2+ and 3+ (weak crystal fields and spin–orbit effects). Thus in accordance with this approach the oxidation potentials $E^0(2+/3+)$ for the lanthanides and actinides (Figs. 11*a* and 11*b*), with increase in the atomic number of the actinide or lanthanide, change regularly in accordance with the theoretical dependence of ln K_p on Z_{An}. Each half of the series in Fig. 11 shows two relationships of the Ω-type on both the experimental and the theoretical curves. The potentials $E^0(2+/3+)$ for La, Ce, Pr, and Cm were estimated by us, and those for Pm, Bk, Cf, Es, Fm, Md, No [171] and Nd, Sm, Eu [172] were taken from published data. These relationships confirm that the anomalous behaviour of the redox potentials $E^0(AnO_2^{2+}/AnO_2^+)$ corresponding to high oxidation states is due to strong relativistic effects and strong crystal fields.

These conclusions can be verified from the values of the redox potentials $E^0(3+/4+)$ for the actinides. These potentials have been published.[173] Fig. 12*a* gives the relationships for the measured redox potentials and ln K_p, calculated using the model. Fig. 12 shows that the trends in the changes in E^0 and ln K_p from thorium to curium are identical.

For the actinides with oxidation states of 5+ and 4+, the regular dependence of the redox potentials on Z_{An} breaks down. This is related to the formation in acidic solutions of $PaOOH^{2+}$ and AnO_2^+ (An = U, Np, Pu, Am) from Am^{4+}.[173] The dependence of $E^0(4+/5+)$ on Z_{An} is shown in Fig. 12*b*. In accordance with relativistic X_α-SW calculations for the AnO_2^+ ions, the last occupied MO in the ions UO_2^+, NpO_2^+, PuO_2^+, and AmO_2^+ are the orbitals δ_{3u}^1, $(\varphi_{7u}\delta_{5u})^1$, $(\varphi_{7u}\delta_{5u})^2$, and π_{1u}^1 respectively. The energies of these MO can be regarded as providing a measure of the electron affinity (A) of the actinoyl ions. The dependence of A on Z_{An} for these ions is shown in Fig. 12*b*.

The energies of the last occupidd MO in the actinoyl ions and the corresponding redox potentials $E^0(4+/5+)$ increase regularly with increase in Z_{An} for An = U, Np, and Pu, and then decrease for americium. The partly occupied low-lying levels in the actinoyl ions form three groups: $\varphi_{5u}\delta_{3u}$, $\varphi_{7u}\delta_{5u}$, $3\pi_{1u}3\pi_{3u}$. The last level σ_u lies fairly high. Of the three groups of levels, the first two are practically 5*f*-levels, but in the third group of levels there is extensive mixing of 5*f*- and 2*p*-AO.

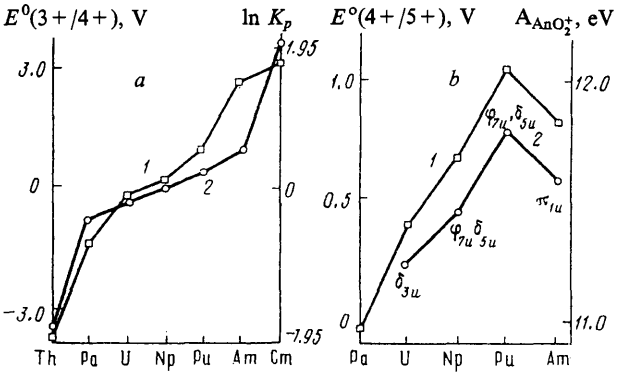

Figure 12. Regular dependence of the redox potentials $E^0(3+/4+)$ for the actinides from Th to Cm, showing agreement with the theoretically expected dependence of ln K on Z (*a*), and the deviation from regularity of the theoretical potentials $E^0(4+/5+)$, corresponding to the change in the electron affinity A (*b*).

The reduction of the actinoyl ions of uranium, neptunium, and plutonium involves the first two groups of levels, and that of americium involves the third group. The replacement of the purely actinide levels taking part in the reduction by levels of mixed character is responsible for the irregular change in the redox potentials (Fig. 12*b*). The correlation between $E^0(4+/5+)$ and A underlines the correctness of the chosen model for explaining the dependence of the redox potentials on Z_{An} within the X_α-SW method.

The same approach can be used to explain the irregular change in $E^0(AnO_2^{2+}/AnO_2^+)$ with change in Z_{An}. In the oxidation of AnO_2^+, the last occupied MO loses an electron; in UO_2^+ and NpO_2^+ it belongs to the first group, and in PuO_2^+ and AmO_2^+ it belongs to the second group. The change in the levels responsible in a given case for the oxidation again breaks down the regularity of the dependence of E^0 on Z_{an}, but now for plutonium.

Thus the satisfactory qualitative interpretation of the redox properties provides support for the key model assumption that the increasing effects of spin–orbit coupling and the crystal field with increase in the oxidation state are responsible for the chemical anomalies in the redox potentials of the actinides.

We can now consider the changes in the electronic absorption spectra of the actinyl ions. X_α-methods give good agreement with experiment in the range of X-ray photoelectron excitation. It is also possible to obtain satisfactory agreement for the visible range of the spectrum, however. Table 2 gives the energies of the electronic

charge-transfer transitions which we obtained for UO_2^{2+}. Comparison of our data with published data[57,58] shows that for the uranyl ion the calculations give effectively the energy distance between the last occupied and the first unoccupied MO.

Table 2. Energies of the electronic charge-transfer transitions for UO_2^{2+} (cm^{-1}).

							26247	27758

*Here and subsequently (in Tables 3–5) the data are given from a series of calculations for the compounds $NaAnO_2Ac_3$ (*a*), $Cs_2AnO_2Cl_4$ (*b*), $RbAnO_2(NO_3)_3$ (*c*), $AnO_2(ClO_4)_2$ (*d*).

Naturally, it is impossible to interpret a large number of lines using a one-electron model. In each case, therefore, the energy of the electron transitions which we obtained corresponds to the weighted-mean energy of several many-electron excited states.

Table 3 gives our calculated energies of the "uranyl-like" transitions for the first four actinyl ions in the actinide series, for compounds with the different types of dependence of R_{An-O} on Z_{An} given earlier. In our calculations, the last occupied orbital is the $3\sigma_u$-MO for UO_2^{2+} and NpO_2^{2+}, and the π_g-MO for PuO_2^{2+} and AmO_2^{2+}, and the "uranyl-like" transitions take place from these MO into unoccupied orbitals of 5*f*-character. The energies of these transitions decrease with increase in the atomic number of the actinide as a result of the lowering of the energy levels of 5*f*-character.

Experimental studies of the neptunyl ion have established that the excited state is described by the electron configuration $3\sigma_u^1\delta_u^1\varphi_u^1$, which leads to the appearance in the spectrum of bands with energies 13918, 16072, 16092, 17967, and 19510 cm^{-1} [70] or 13239, 15239, 15678, 16795, and 19371 cm^{-1}.[71] Similar results were obtained in other studies.[61,62] The charge-transfer bands (E_{CT}) in the actinyl ions correspond to electron transfer for the $3\sigma_u$-MO to the φ_{5u}- and δ_{3u}-MO in the uranyl and neptunyl ions, and from the π_g- to the $\varphi_{7u}\delta_{3u}$, $\varphi_{7u}\delta_{3u}$-MO in the plutonyl and americyl ions respectively. Although the absolute values of E_{CT} differ from the experimental values, the *N*-type of the relationship is clearly revealed. It can be stated that the irregular character of the dependence of E_{CT} on Z_{An} is due to the strong crystal field combined with the spin–orbit effect. Both of these effects are revealed in such properties, different at first sight, as the energies of the uranyl-like transitions and the oxidation potentials, and are responsible for the linear relationship between the potentials $E^0(AnO_2^+/AnO_2^{2+})$ and E_{CT} for these ions. Thus these two properties apparently depend on the same MO.

	49841	47268	44196	39599*	(d)

Note. Transitions for the π_g-orbital are marked with an asterisk.

In fact, the oxidation potentials $E^0(AnO_2^+/AnO_2^{2+})$ are determined by the ionisation potential of the actinoyl ion $I(AnO_2^+)$ or the electron affinity $A(AnO_2^{2+})$. The values of E_{CT} depend mainly on the electron affinity of the AnO_2^{2+} ions. It is not the whole set of MO, but only individual MO, that make the main contribution to the vlalues of E^0 and E_{CT} and are responsible for the identical (*N*-type) dependence of these properties on Z_{An}.

The classical object for the study of the energy of *f*–*f* transitions is the neptunyl ion, which contains one electron in the φ_{5u}-level. Table 4 compares our calculated energies of the *f*–*f* electron transitions for the neptunyl ion with experimental data,[59,71,73] and Table 5 gives the energies of the *f*–*f* transitions in the actinyl ions. These data indicate that the centres of gravity of bands corresponding to transitions of the same kind are displaced along the actinyl ion series towards an increase in their energies. As noted above, the spectra of the *f*–*f* transitions reflect two trends in the

change in the energies of the MO: the decrease in the splitting of the 5*f*-AO by the crystal field of the ligands along the series, and the increase in their splitting as a result of spin–orbit coupling. Thus in the uranyl ion the splitting of the 5*f*-AO by the crystal field is twice their splitting by spin–orbit coupling, whereas towards the end of the series the two effects are of almost equal magnitude.

Table 4. Energies of the *f*–*f* electron transitions in NpO_2^{2+} compounds (cm^{-1}).

The splitting by the crystal field and spin–orbit coupling is much smaller in the actinoyl ions than in the actinyl ions.[119]

Overall, in the actinyl and actinoyl ions, increase in the atomic number of the actinide displaces transitions of the same kind into the ultra-violet range of the spectrum.

To interpret the redox properties and electronic absorption spectra of the actinyl and actinoyl ions we used individual MO, responsible for the ionisation potentials, their electron affinity, energy transitions, etc. Other properties, for example the thermodynamic properties, depend not on the energy of the last occupied MO but on the energies of the whole set of MO for the compound or ion that is on their sum.

We can write an expression for the standard enthalpy of formation of AnO_2^{2+} using the ionic approximation

$$\Delta H^0(AnO_2^{2+}) = \Delta H^0(An^{6+}, \text{gas}) + A(R_{An^{6+}} + R_{O^{2-}})^{-1} + B, \quad (9)$$

where

$$\Delta H^0(An^{6+}, \text{gas} = \Delta H^0(An, \text{gas}) + \sum_{z=1}^{6} I_z + 15RT. \quad (10)$$

Here, A and B are constants, and $R_{An^{6+}}$ and $R_{O^{2-}}$ the ionic radii of An^{6+} and O^{2-}. The error in the calculation of $\Delta H^0(AnO_2^{2+})$ is due to the neglect of the interaction of the 5*f*-, 6*d*-, and 7*s*-AO with the 2*p*-AO of the oxygen atoms. This is a crude and approximate calculation scheme, so that we shall restrict ourselves to qualitative estimates of the thermodynamic quantities.

The trend in the change in the enthalpies of formation of the actinyl ions is determined by the second term in Eqn. (10), that is by the sum of the ionisation potentials of the actinide atom, and not by the last ionisation potential, as in the case of the redox potentials. The sum of the first two ionisation potentials remains almost unchanged for U, Np, Pu, and Am, and has the values 17.58, 17.58, 17.50, and 17.633 eV respectively. Thus the trend in the change in $\sum_{z=1}^{6} I_z$ is determined by the sum $\sum_{z=3}^{6} I_z$, and that for $\sum_{z=1}^{5} I_z$ is determined

Table 5. Energies of the *f*–*f* electron transitions for AnO_2^{2+} (cm^{-1}).

by the sum $\sum_{z=3}^{5} I_z$. From Eqn. (8) we can write the sum of the ionisation potentials $\sum_{z=3}^{5} I_z$ in the form:

$$\sum_{z=3}^{5} I_z = \sum_{z=3}^{5} \ln \frac{2L_z\left(f^{q-1}\right)+1}{2L_z\left(f^{q}\right)+1}, \qquad (11)$$

where the values of $L(f^{q-1})$ and $L(f^q)$ correspond to the reaction

$$\mathrm{An}(f^q) \rightarrow \mathrm{An}(f^{q-1}) + \mathrm{e},$$

and are determined from the values of the normal terms of the actinide ions

	U	Np	Pu	Am
An^{2+}	*I*	*H*	*F*	*S*
An^{3+}	*I*	*I*	*H*	*F*
An^{4+}	*H*	*I*	*I*	*H*
An^{5+}	*F*	*H*	*I*	*I* .

(12)

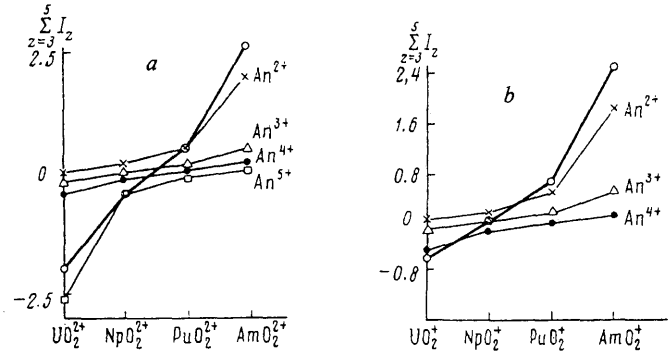

Figure 13. Qualitative trend in the change in the dependence of the sum of the ionisation potentials of the actinide atoms An^{5+} [Eqn. (11)] $\sum_{z=3}^{5} I_z$ on Z_{An}, determining the change in the enthalpy of formation of the actinyl (*a*) and actinoyl (*b*) ions (thick line); the thin lines show the trend in the change in the successive ionisation potentials of An^{2+}, An^{3+}, etc.

The trends in the changes in the separate ionisation potentials of An^{2+}, An^{3+}, etc., and also their sums, determined from Eqn. (11) with allowance for the values of the normal terms, with change in the atomic number of the actinide are shown in Fig. 13. The complete analogy between the experimental relationship for the enthalpies of formation (Fig. 6) and the theoretical relationship (Fig. 13) shows that the trend in the change in the enthalpies of formation is determined by the sum of the first six ionisation potentials for the actinyl ions, and by the sum of five ionisation potentials for the actinoyl ions. In the sum of the ionisation potentials, the spin–orbit contribution is small compared with the electron–electron interaction energy, so that it does not determine the trend in the change in properties, in contrast to the redox potentials, where relativistic corrections make a significant contribution to the values.

It is of interest to consider the relationship obtained for the redox properties by examining them using the purely ionic model, that is using not the ionisation potentials of the actinoyl ions $I(AnO_2^+)$ but the ionisation potentials of the free ions, namely $U^{5+}(^2F,f^1)$, $Np^{5+}(^3H,f^2)$, $Pu^{5+}(^4I,f^3)$, and $Am^{5+}(^5I,f^4)$. The dependence of the redox potentials calculated in the ionic approximation on Z_{An} will be regular, and of the Ω-type and not the *N*-type, as observed experimentally.

Fig. 14 shows the dependence of the effective charges on the actinide ions (An = U, Np, Pu, and Am) on Z_{An}. The relationship is of the Ω-type. For the actinyl ions the larger the distance R_{An-O}, the smaller the effective charge on the actinide atom, that is for an infinitely large distance R_{An-O} the charge on An tends to +2, corresponding to the presence of the free actinide ion An^{2+} and oxygen atoms.

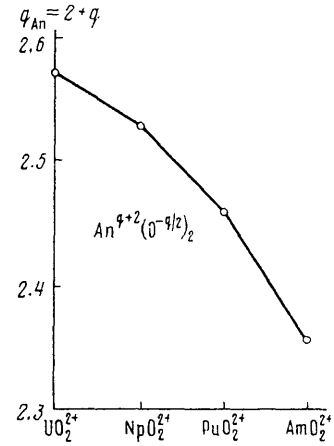

Figure 14. Dependence of the effective charges in the actinyl ions on the atomic number of the actinide.

From the electron density distribution in the actinyl ions it follows that the effective electron configuration of the actinide atoms in the bonding levels is $5f^{2.6-3.2}6d^1$. This electron configuration corresponds approximately to a double bond in the uranyl ion. The 6*s*- and 6*p*-AO will increase the U–O bond order slightly.[40]

It may be concluded that the Ω-type dependence of q_{An} on Z_{An} for the actinyl ions from UO_2^{2+} to AmO_2^{2+} will lead to an Ω-type dependence of R_{An-O} on Z_{An} (see Fig. 1). At the same time, there is a linear relationship between q_{An} and R_{An-O}. This conclusion applies either to the free ions AnO_2^{2+} or to compounds AnO_2X_y in which the ligands X do not have a significant influence on the electronic structure of the actinyl ions.

If, as is usually done in chemistry, the reactivity of ions is characterised by the ionisation potentials and electron affinity, and the electronegativity is defined as $F = I + A$, it is found that the values of I, A, and F change irregularly according to a relationship of the N-type (Fig. 15), that is a relationship of the type already encountered for various properties of the actinyl and actinoyl ions, such as the internuclear distances, bond force constants, molecular polarisabilities, refractive index, etc. Since the irregular relationships for I, A, and F are due to relativistic effects and the crystal field, it may be concluded that the properties of the N-type of the actinyl complexes determined by these parameters will also be due to these effects. The N-type of relationship is determined by the electronic structure of the actinyl ions, and the ligands X increase or decrease the strength of this type of relationship, by donating or accepting electron density. Here, there are two possibilities.

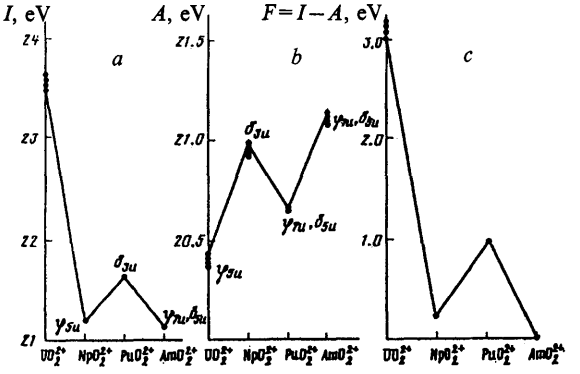

Figure 15. Irregular N-shaped change in the ionisation potentials (a), electron affinity (b), and electronegativity (c) of the actinyl ions on Z_{An}; the MO responsible for the change in these quantities in each ion are shown.

1. The ligands X in the equatorial plane decrease the strength of the An−O bond, which becomes more ionic, and the effects of the crystal field decrease. The L-model begins to "operate". The dependence of the properties on the atomic number of the actinide is of the Ω-type.

2. The ligands X increase the strength of the An−O bond, the effects of the crystal field increase, and the dependence of the properties on Z_{An} remains of the N-type, as for the free AnO_2^{2+} ions.

If it is assumed that complex formation by AnO_2^{2+} ions with ligands X involves the reaction of unoccupied and partly occupied levels of the 5f-type, and also occupied σ- and π-levels mainly of oxygen atoms, it is possible to explain why the enthalpy of formation of the complexes AnO_2X_y will have an extremal value on going from the neptunyl to the plutonyl compounds. This also applies to the enthalpy of extraction. The strong crystal field, combined with the spin−orbit effect, also determines these important chemical characteristics, giving a dependence of the N-type. If the An−O bonds are sufficiently weakened by the ligands X, these properties change according to a relationship of the Ω-type.

The effects of spin−orbit coupling and the crystal field divide the actinyl ions of the first half of the series into two tetrads sharing the americyl ion: UO_2^{2+}, NpO_2^{2+}, PuO_2^{2+}, AmO_2^{2+} and AmO_2^{2+}, CmO_2^{2+}, BkO_2^{2+}, CfO_2^{2+}. In the approximation of free sextuply-charged actinide ions, this division corresponds to the normal terms $^1S_0$, $^2F_{5/2}$, $^3H_4$, $^4I_{9/2}$ for the first tetrad, and $^4I_{9/2}$, $^3H_4$, $^2F_{5/2}$, $^1S_0$ for the second tetrad.

Similarly, the actinoyl ions form two tetrads, from PaO_2^+ to PuO_2^+ and from PuO_2^+ to BkO_2^+.

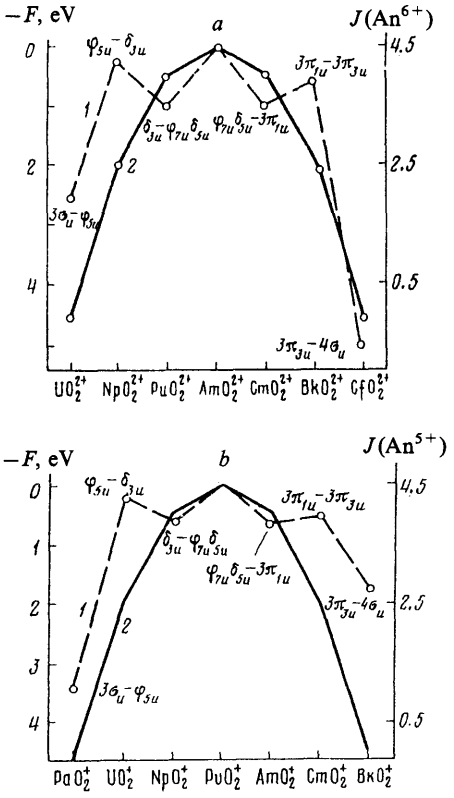

Figure 16. Dependence of the electronegativity $F = -I + A$ for the actinyl (a) and actinoyl (b) ions (curve 1) and the quantum numbers J (curve 2) for the normal terms of the sextuply-charged (a) and quintuply-charged (b) ions on Z_{An}; the MO determining the quantities I and A are shown on the dependence of F on Z for each ion.

Figure 16 shows the dependence of the electronegativities of the ions AnO_2^{2+} (Fig. 16a) and AnO_2^+ (Fig. 16b) on Z_{An}. The dependence of the quantum numbers J for the free sextuply-charged An^{6+} and quintuply-charged An^{5+} ions on the atomic number of the actinide is given for comparison. The "saw-tooth" dependence of F on Z_{an} for the actinyl and actinoyl ions has the general character of bell-shaped curves and is similar to the dependence of the quantum numbers J on Z_{An} for the quintuply- and sextuply-charged ions. This means that there should be a qualitative

correlation between various properties of the actinyl and actinoyl ions and the quantum numbers J for the free ions An^{6+} and An^{5+}. These are tetrads in the J-model, but not in the L-model. It follows from Fig. 16 that the values of F in both tetrads change with increase in Z_{An} according to an N-relationship. Curves of this type are observed when the properties of the actinyl and actinoyl ions depend on definite MO, and not on the entire set of MO as a whole. Thus the electronegativity of the uranyl ion is determined by the energy corresponding to the charge-transfer band $F_{UO_2^{2+}} = E_{3\sigma_u} - E_{\varphi_{5u}}$; the electronegativity of the neptunyl ion is smaller, since it depends on the energy of spin–orbit splitting $F_{NpO_2^{2+}} = E_{\varphi_{5u}} - E_{\delta_{3u}} \simeq \zeta$; for the plutonyl ion, the value is $E_{PuO_2^{2+}} = E_{\delta_{3u}} - E_{\varphi_{7u},\delta_{3u}} \simeq 2.5\zeta$; finally, for AmO_2^{2+}, $F \simeq 0$, since the degenerate φ_{7u},δ_{5u}-MO contains one electron. The irregular $F_{AnO_2^{2+}}$ relationship is responsible for the appearance of relationships of the N-type in each of the tetrads from the uranyl to the americyl ion and from the americyl to the curyl ion.

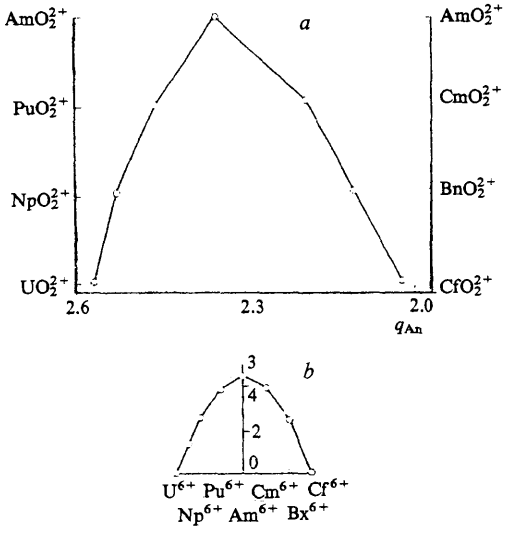

Figure 17. Dependence of the effective charges on the actinide atoms in the actinyl ions (*a*) and the corresponding dependence of the quantum numbers J of the total angular momenta for the sextuply-charged ions An^{6+} in the ground electronic state (*b*) on Z_{An}.

In the so-called summative properties which depend on all the MO, such as the electron density distribution, a relationship of the Ω-type is observed. This type of relationship is shown in Fig. 17*a* for the effective charges on the actinide atoms in the actinyl ions. The two tetrads for the change in q_{An} are completely analogous to the two tetrads for the values of the quantum numbers J of the normal terms of the sextuply-charged actinide ions in Fig. 17*b*.

IV. Summary

Before summarising the interpretation of the physicochemical properties of the actinyl and actinoyl ions based on X_α-SW calculations, we ask the question: is the chemistry of compounds of this class enriched by new chemical ideas as a result of these calculations, or do they provide a basis only for the quantitative interpretation of the properties? We have never been under the illusion that calculations for a particular molecule, no matter how well they are carried out, that is using the entire arsenal of computer techniques, will open the gates of the unknown. We have emphasised this idea many times (see for example our earlier review[174]). The calculation for a series of molecules or ions of the same type, as in the present case, has made it possible to determine the reasons for the irregular change in a number of properties along the series, and this cannot be done by restricting the calculation to one ion, for example the uranyl ion, as has been the practice until now. The calculations should not be restricted to the simple Hückel method, since it has been found that the irregularity is a manifestation of relativistic effects combined with the crystal field effect. X_α-SW calculations have made it possible to understand why some properties change regularly while others change irregularly.

The division of MO into fragments is not a new idea in chemistry. In the case of the actinide compounds, however, there is a characteristic specific reason for this division, related to the division of the AO of the actinide atoms into three groups, according to the energy values: $6s + 6p$, $5f$, and $6d + 7s$. This gives a characteristic fragmented system of energy levels; in the fragments, individual MO of the same type have similar AO compositions.

Finally, there is considerable debate in the literature on the existence of the tetrad and double–double effects and their interpretation and limits of applicability.[47,80–84] In fact, at first sight it appears strange that such "down to earth" properties of the compounds of the lanthanides and actinides as the extraction constants or complex-formation constants of the f-ions correlate with the quantum numbers L and J of the normal terms, not to mention that there is no difference between them, that is the logarithms of the extraction coefficients of the lanthanides for a given extracting agent in some sources correlate with the quantum numbers J and in others with L.[84,85] By using the methods of statistical physics combined with calculations for the entire series of observed and hypothetical ions AnO_2^{2+} and AnO_2^{+}, we have been able for the first time to go beyond simple "property–quantum number" correlations and have been able to show why and when these correlations are significant, and also that these correlations determine the trend in the change in properties, but no more. Without a series of calculations it was impossible to suggest (and nobody has done it!) that the effective charges on the actinide ions in actinyl compounds obey the tetrad relationship. Moreover, it can be stated that in isovalent compounds of the actinide series, for example in $AnHal_6$, where An = U, Np, ..., Bk, the relationships observed will be of the same type as for the actinyl ions (strictly regular, regular, and irregular relationships). These questions will be examined in later papers, but here we point out that the relationship is general and provide an explanation. Thus the problem of determining the electronic structure of the actinyl and actinoyl ions, formulated in the Introduction, can be regarded as solved. In the carrying out of systematic series of calculations for systems of the same type we see the optimum use of the methods of computational quantum chemistry for analysing experimentally observed relationships and predicting new ones.

Solid state reactions as a method of introducing transition metal cations into high-silica zeolites

A V Kucherov, A A Slinkin
Zelinskii Institute of Orgnanic Chemistry, Russian Academy of Sciences

ABSTRACT. Solid state reactions can be used to introduce one or more multivalent transition metal cations into high-silica zeolites. Most such cations cannot be introduced into these matrices by other methods. The influence of various factors on the processes of stabilisation of the cationic species in the zeolite channels is analysed. Pentasil-based systems with distinct, isolated centres form unique subjects for studying the relationship between the catalytic properties of the transition metal cation and the local structure of the centre. Highly active and stable catalysts for the complete oxidation of alkanes and for the decomposition of nitrogen oxides can be obtained by solid-state modification of the pentasils.

I. Introduction

The introduction of different ions into zeolites is one of the methods of modifying their adsorption and catalytic properties and there is therefore great interest in this topic. For wide-pore zeolites, e.g. those of the faujasite type, exchange from the liquid phase (usually from aqueous solution) is a universal method for introducing any ion into the cationic sites. The results obtained by using ion exchange for such zeolites have been reviewed.[1,2]

However, ionic exchange from the liquid phase has very limited potentialities for zeolites of the pentasil type because the channels are too small for diffusion of multiply charged ions in their solvation shells. For this type of zeolite only singly charged, and some doubly charged, ions can be introduced by exchange methods but most transition metal ions, which are precisely those of greatest interest from the point of view of oxidation-reduction catalytic properties, cannot be introduced into the channels by this means. Modified high-silica (HS) zeolites particularly have unique potentialities for the catalytic processes to be analysed at the atomic-molecular level because it is possible to produce in them a distinct set of isolated centres whose topography and structure are determined by the type of zeolite lattice and whose spatial environment is determined by the structure of the channels.

HS-zeolites have a framework that is thermally highly stable and this enables us to use topochemical methods of introducing cations by means of solid state reactions with various transition metal compounds. The present review is devoted to an analysis of this particular line of research, which only started to be developed in the last decade.

Our aim was to summarise the data on the introduction of transition metal ions into HS-zeolites by means of solid state reactions and to discuss the nature of the oxidation-reduction centres formed and the catalytic processes involving them. The subject matter is to a large extent a review of our own work because we have a great interest in the topic under discussion and have carried out systematic research in this field since 1984.

II. Procedure for carrying out exchange in the solid state and methods for studying the products

The typical procedure for exchange in the solid state is very simple, involving heating a mechanical mixture of the zeolite with a transition metal oxide (or salt) in a stream of inert gas, under vacuum, or in air. Soluble compounds can be deposited on the outer surface of the zeolite more uniformly by the "dry" impregnation method and this makes the subsequent solid state reaction more rapid.

The temperature at which the solid-state exchange reaction reaches an appreciable rate depends on the type of cation and anion. Under sufficiently drastic conditions the degree of exchange reaches the maximum possible for a given zeolite and the excess of the transition metal compound remains in the mixture as a separate phase.

A number of methods can be used to study solid-state exchange reactions with the NH_4- or H-forms of zeolites: i.r. spectroscopy, RFES [probably X-ray photoelectron spectroscopy (Ed. of Translation)], thermogravimetric analysis, and analysis of the gaseous products liberated (HCl in the case of metal chlorides, H_2O for oxides). However EPR is extremely sensitive and informative for transition metal cations. For cations such as Cu^{2+}, Mn^{2+}, Cr^{3+}, Fe^{3+}, V^{4+}, Cr^{5+}, and Mo^{5+} EPR data not only enable the process of dispersion of the ions in the zeolite matrix to be recorded but also provide a safe estimate of the coordination environment of isolated cations and the changes in it on reaction with various molecules.

In the early 1970's some interesting results were obtained which showed that solid state reactions between a zeolite and alkali metal salts can be accompanied by ion exchange. For example, Rabo and co-workers[3–5] observed replacement of the residual protons by Na^+ cations when mixtures of the zeolites NaY, CaY, BeY, and LaY with NaCl are heated (at 575–675 K). HCl was evolved during the reaction and the catalytic activity of the zeolites in reactions catalysed by acidic groups decreased sharply. After CaY and LaY had been heated with NaCl their i.r. spectra showed a reduction in the intensities of the bands due to acidic OH groups. A solid state reaction with NaCl has been used to remove the residual acidic groups in a Y zeolite.[3–5]

In the preparation of specimens for EPR studies, evolution of HCl and stabilisation of ions in the cationic centres of zeolites of types A, X, and Y occurred as a result of solid state reactions of the H-forms of these zeolites with zinc, cobalt, nickel, and chromium chlorides.[6]

This line of research, related to the modification of the acid-base properties of zeolites by alkali metal and alkaline-earth metal salts, has recently been extended to HS-zeolites (mordenite, H-ZSM-5). Detailed studies in this area have been made by a group under the direction of Professor Karge (see Ref. 7 for a summary of their results). In the present review we shall not be concerned with the modification of the acid-base properties of zeolites by alkali metals but shall concentrate on systems with transition metal cations.

Table 1. Specimens studied by Kucherov and Slinkin.[11]

Zeolite	Si_2O_2/Al_2O_3	Exchange of Na^+ by H^+, %	Zeolite	Si_2O_2/Al_2O_3	Exchange of Na^+ by H^+, %
NaM	10	0	pentasil-140	140	95
HNaM	10	50	pentasil-280	280	95
HM	10	95	amorphous alumino-silicate ($S = 360\ m^2\ g^{-1}$)	14	—
HNa-ZSM-5*	69	40			
H-ZSM-5	69	95			

*Obtained by baking out the organic cations from a specimen with 40% deficiency of Na^+.

III. Introduction of transition metal ions into the cationic sites in HS-zeolites by means of solid state reactions

The first papers in which the migration of transition metal ions through zeolite crystals was discussed were Ref. 6 and also Refs. 8–10, in which reduction–reoxidation processes in the ion-exchange zeolites of CuY, CuM, and AgY were investigated. With CuY specimens reduced in hydrogen two types of Cu^0 crystals are formed:[8] inside large cavities in the zeolite and on the outer surface. Reoxidation of small Cu^0 crystals takes place easily and is accompanied by the reappearance of Cu^{2+} in the cationic sites of the zeolite. When CuM specimens are reduced no Cu^{2+} ions are left in the mordenite channels but Cu^0 particles ~200 Å in diameter are formed on the outer surface.[9] However, reoxidation of the specimens does not lead to the formation of CuO crystals on the outer surface but to migration of Cu^{2+} ions which are then trapped in the mordenite channels. Thus in the H-forms of the zeolite there can be diffusion from the outer surface to the cationic sites in an oxidising atmosphere. Similar effects were observed by Beyer, et al.[10] who found that the reoxidation of AgY can be regarded as a solid state reaction between the H-form of the zeolite and an Ag/Ag_2O phase situated on the outer surface of the crystals.

The papers quoted above naturally provided an impetus to detailed studies of solid state reactions in HS-zeolite–transition metal oxide (or salt) mechanical mixtures. Research was carried out first on copper-containing systems because Cu^{2+} ions (unlike most transition metal ions) can be introduced into HS-zeolite by ion exchange. The detailed studies of ion-exchange specimens carried out recently form an excellent basis for a comparative analysis.

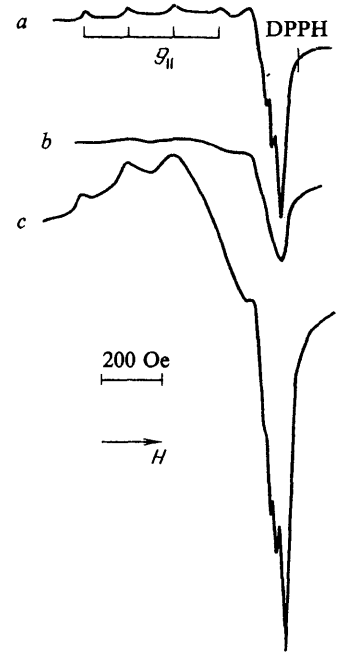

Figure 1. EPR spectra (at 20 °C) of an [HM + BCC] mixture heated in air:[11] *a*, 550 °C, 1 h, specimen evacuated at 20 °C; *b*, air admitted; *c*, 700 °C, 1 h + 800 °C, 1 h, specimen evacuated t 20 °C. [DPPH = diphenylpicrylhydrazine.]

1. Topochemical reactions of copper compounds with mordenite and pentasils

The introduction of Cu^{2+} cations using solid state reactions at 400–800 °C between copper compounds [CuO, basic copper carbonate (BCC), copper metal, $CuCl_2$, CuF_2, $Cu_3(PO_4)_2$, Cu_2S] and various mordenite and pentasil specimens has been investigated thoroughly[11,12] (Table 1).

The EPR spectra of Cu^{2+} ions in an [HM + BCC] mixture heated at various temperatures are shown in Fig. 1. Access of air at 20 °C leads to reversible broadening of the hyperfine-structure (HFS) lines in the spectra and the disappearance of the splitting in the perpendicular component (Fig. 1*b*). On oxidative heating of the [HM + Cu^0] mixture a complex pattern of EPR signals is observed. The only difference is that after heating for an hour at 550 °C the EPR signal is ~5 times weaker than the spectrum in Fig. 1*a* (the HFS agrees completely). However, raising the temperature to 700 °C leads to a considerable increase in the intensity of the signal and after heating at 800 °C for an hour the signal for the [HM + Cu^0] mixture (Fig. 1*c*) agrees with that for the [HM + BCC] mixture in both shape and intensity.

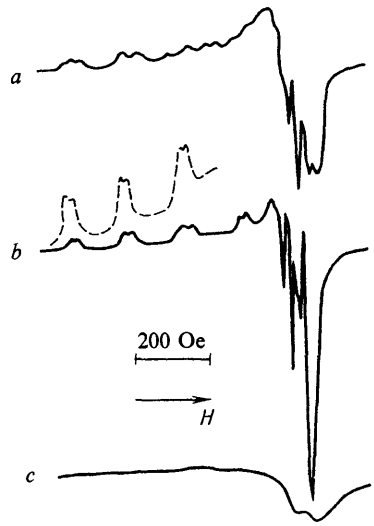

Figure 2. EPR spectra (at 20 °C) of an [H-ZSM-5 + Cu^0] mixture heated in air:[11] *a*, 550 °C, 1 h, specimen evacuated at 20 °C; *b*, 800 °C, 1 h, specimen evacuated at 20 °C; *c*, air admitted.

There are qualitatively no differences between the processes accompanying the oxidative heating of the mixtures of zeolites with BCC, CuO, and Cu^0. In all three cases the reaction of course involves copper(II) oxide which, at the temperatures used, is formed rapidly from both BCC and Cu^0. However, the degree of dispersion of the CuO has a marked effect on the rate of the reactions. In the most heterogeneous system, where Cu^0 powder with a particle size measured in tens of microns is used, the rate of formation of isolated ions, which give the EPR signal, is substantially lower. However it is of fundamental importance that, when the various mixtures are heated under sufficiently drastic conditions, the intensity of the EPR signal from the dispersed Cu^{2+} ions reaches the maximum possible for the given zeolite specimen.

EPR signals from Cu^{2+} do not appear when an [NaM + BCC] mixture is heated at 550–800 °C in air, i.e. there is no exchange of Na^+ by Cu^{2+}; protonic centres are necessary for the stabilisation of Cu^{2+} ions.

The EPR signals produced when an [H-ZSM-5 + Cu^0] mixture is heated in air are shown in Fig. 2. The HFS of the EPR signal (Fig. 2*b*) shows no change and the intensity does not increase when the heating time at 800 °C is increased to 4 h. Admitting O_2 to the specimen at 20 °C causes pronounced reversible broadening of the Cu^{2+} lines in the EPR spectrum (Fig. 2*c*).

The EPR signals obtained when HNa-ZSM-5 is heated with CuO have different parameters (Table 2) and the maximum intensity of the EPR signal from Cu^{2+} is appreciably smaller in this case than for H-ZSM-5. Clearly the Na^+ cations present in the zeolite block those centres that are capable of binding Cu^{2+} cations in H-ZSM-5.

Table 2. Parameters of the EPR spectra due to Cu^{2+}.[11]

Specimen	Heated at (°C)	$g_{\parallel}$	$g_{\perp}$	$A_{\parallel}$, Oe	$A_{\perp}$, Oe
HM+CuO	550	2.325	2.055	144	19
HNa-ZSM-5+CuO	550 and 800	2.37	2.075	135	—
H-ZSM-5+CuO	550	2.33	2,07	142	17,5
		2.27	2,045	175	29
H-ZSM-5+CuO	800	2.31	2.06	153	
		2.29	2.05	156	23
H-ZSM-5+CuF_2 or $Cu_3(PO_4)_2$	500 and 700	2.31		153	
		2.29		156	
		2.37		120	
		2.38		120	

The reaction of CuO with pentasil specimens with various modules gives EPR spectra with almost the same shape but a different maximum intensity. The intensity of the Cu^{2+} EPR signal is linearly dependent on the aluminium content of the zeolite, providing clear confirmation that the Cu^{2+} is located at the sites of the cationic vacancies formed by the Al^{3+} in the framework.

Heating a mixture of H-ZSM-5 with anhydrous $CuCl_2$ under vacuum at 400 °C for 30 min gives the Cu^{2+} EPR spectrum shown in Fig. 3*a*. Heating the mixture at 550 °C for an hour causes a considerable increase in the signal intensity and heating in air at 800 °C for an hour gives the signal shown in Fig. 3*b*. Heating mixtures of H-ZSM-5 with CuF_2 and $Cu_3(PO_4)_2$ under vacuum at 550–800 °C also gives EPR signals from isolated Cu^{2+} ions. Admitting air leads to reversible broadening of the EPR lines. X-Ray analysis shows that there is no disruption of the zeolite framework when H-ZSM-5 is heated with CuF_2 at 800 °C for 2 h. The parameters of the EPR spectra of Cu^{2+} ions in specimens studied by us previously[11,12] are given in Table 2.

Analysis of the results obtained greatly facilitates detailed comparisons with the data for copper-containing zeolites prepared from the same specimens by ion exchange and studied thoroughly previously,[13,14] and also with data for CuH-ZSM-5.[15,16] When markedly heterogeneous mechanical mixtures of the H-forms of mordenite and pentasil with CuO are heated there is evidently considerable dispersion and migration of some of the Cu^{2+} ions into the zeolite channels. The ions in mordenite and pentasil are located at the same cationic sites as are found in the corresponding

specimens obtained by ion exchange. Thus the EPR signal produced when HM is heated with BCC under fairly mild conditions (Fig. 1*a*) is almost the same as the spectrum of an ion-exchange specimen of CuHM with a small degree of exchange [1 Cu^{2+} ion for each 3 unit cells (u.c.)], where almost all the copper introduced occurs as isolated ions with square pyramidal coordination. The broadening of the components of the Cu^{2+} ion EPR spectrum due to dipole-dipole interaction with O_2 molecules present in the first coordination sphere indicates 100% dispersion of the Cu^{2+} cations in the zeolite channels. When the thermal treatment of HM with CuO is made more severe the EPR spectrum increases in intensity and its shape changes, indicating an interaction between the Cu^{2+} ions. The spectrum shown in Fig. 1*c* is characteristic of weak association of interacting Cu^{2+} ions and is identical in shape and intensity to the spectrum of an exchange specimen of CuHM containing two Cu^{2+} ions to one unit cell. Thus the pattern of changes in the EPR signals accompanying the solid state reaction of HM with CuO is identical to that observed on increasing the concentration of exchanged Cu^{2+} cations in HM. Hence as the migration of Cu^{2+} ions in HM increases they occur first as isolated cations and then as they increase in number in the channels weak associates are formed and a maximum possible concentration is reached (notwithstanding the large excess of CuO on the outer surface).

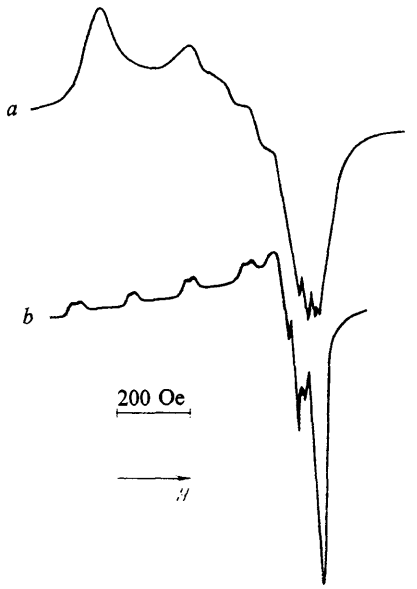

Figure 3. EPR spectra (at 20 °C) of a mixture of H-ZSM-5 with $CuCl_2$ heated under vacuum:[12] *a*, 400 °C, 30 min; *b*, 800 °C, 1 h.

In order to compare the amounts of Cu^{2+} introduced into mordenite by different methods, the oxidative heating of a mixture of BCC with an ion-exchange specimen of CuHM with the maximum degree of exchange was investigated.[12] No increase in the intensity of the Cu^{2+} EPR signal was obtained by heating at 700–800 °C. Hence for mordenite the maximum number of Cu^{2+} cations is not significantly dependent on the method of introduction but is determined by the number of accessible sites in which they can be located. This number is only half of the total cation capacity.

For pentasil-type zeolites the Cu^{2+} introduced by exchange in aqueous solution can be ~20% of the amount of aluminium in the framework and after heating at 500 °C all the copper occurs as two types of isolated, coordinately unsaturated cations with square pyramidal ($g_{||}$ = 2.31, $A_{||}$ = 155 Oe) and square planar ($g_{||}$ = 2.27, $A_{||}$ = 175 Oe) coordination. On increasing the ignition temperature to 800 °C two types of location are retained (square pyramids with a degree of distortion towards square planar). The EPR spectra obtained by heating mechanical mixtures (Fig. 2, *a* and *b*) agree completely with the spectra of the Cu^{2+} cations in the exchange specimen CuH-ZSM-5 which has been heated at 550 °C and 800 °C respectively. The effect of O_2 on the HFS of the EPR spectra is equally pronounced for both the exchange specimen and the heated mechanical mixtures.

Thus for pentasil also, the diffusion of Cu^{2+} ions from the outer surface leads to their being trapped in the cationic sites that are characteristic of the exchange specimens. In spite of the large excess of CuO on the outer surface of the pentasil the number of Cu^{2+} ions dispersed singly reaches a constant value and formation of associates does not take place. The maximum degree of occupation of the cationic vacancies in H-ZSM-5 by Cu^{2+} ions diffusing from the surface has been estimated as 30–40% of the total capacity.[12] When a mixture of the ion-exchange specimen CuH-ZSM-5 (20% exchange) with BCC is heated oxidatively at 700–800 °C the intensity of the EPR signal from isolated Cu^{2+} ions increases by a factor of ~1.5; this also indicates an increase in the degree of exchange to 30%. Thus, for pentasil solid state reactions lead to a somewhat greater degree of exchange than does ion exchange in aqueous solution.

It should be emphasised that the ion-exchange specimens and the specimens prepared by heating mechanical mixtures with CuO are identical as regards adsorption of various substances from the gaseous phase. All the changes in the coordination of the isolated Cu^{2+} ions are absolutely identical for the two types of specimen. This applies both to adsorption of strong ligands (NH_3, pyridine C_3H_6 [17,18]) and to the effects produced by the physical adsorption of hexane and xenon.[19,20]

2. Changes in the ligand environment of Cu^{2+} on adsorption of various molecules in H-ZSM-5

The number of states in which the Cu^{2+} cations occur in the zeolite ZSM-5 depends on the thermal treatment conditions and the Cu^{2+} cation concentration in the zeolite. Anderson and Kevan[15] introduced Cu^{2+} cations by ion exchange into the zeolite NaH-ZSM-5 which is obtained by decomposition of NaTPA-ZSM-5 under vacuum at 600 °C. After the exchange the zeolite contained approximately one Cu^{2+} cation per 10^3 tetrahedra. Dehydration of this zeolite at 400 °C gave an EPR signal from Cu^{2+} ions present in only one state ($g_{||}$ = 2.310, $g_{\perp}$ = 2.052, $A_{||}$ = 172 × 10^{-4} cm^{-1}). The concentration of Cu^{2+} cations in this zeolite was 1 cation per 10 u.c. According to Sendoda and Ono[16] there are ~6 Cu^{2+} cations in 10 u.c. of the zeolite and the EPR spectrum of a specimen which has been dehydrated under vacuum at 400 °C contains three signals corresponding to three Cu^{2+} cation states ($g_{||}^1$ = 2.31, $A_{||}^1$ = 164 × 10^{-4} cm^{-1}; $g_{||}^2$ = 2.30, $A_{||}^2$ = 163 × 10^{-4} cm^{-1}; $g_{||}^3$ = 2.27, $A_{||}^3$ = 176 × 10^{-4} cm^{-1}). When dehydration under vacuum is carried out at 550 °C one of the states of the Cu^{2+} ions disappears and the two remaining states have almost the same EPR parameters

($g_{\|}^1$ = 2.31, $A_{\|}^1$ = 170 × 10^{-4} cm^{-1}; $g_{\|}^2$ = 2.30, $A_{\|}^2$ = 175 × 10^{-4} cm^{-1}). In other studies[11–14,19,20] the amount of Cu^{2+} in H-ZSM-5 reached ~1 cation to 1 u.c., with the zeolite containing two types of Cu^{2+} cation (see Table 2), and the specimens obtained by exchange and by a solid state reaction were identical.

There is an important aspect of the behaviour of Cu^{2+} ions in the zeolite H-ZSM-5 during vacuum conditioning. The intensity of the EPR signal decreases significantly after conditioning of the specimen under vacuum at various temperatures for 3 h.[16] However this effect is not observed if the specimen undergoes oxidative thermal treatment immediately before evacuation.[11–14] It is not impossible that the reduction in intensity is due to the presence of small quantities of adsorbed organic impurities in the specimen. Judging from their results, Sendoda and Ono[16] made no observation of oxidative treatment of the specimen before the vacuum conditioning.

Adsorption of NH_3 at 20 °C does not lead to a significant change in $A_{\|}$ [17,18] and, in contrast to other reports,[15,16] splitting due to interaction with the nuclear spin of the atoms in the coordinated NH_3 molecules was not observed in the $g_{\perp}$ region. This may be due to steric hindrance in the reaction of the NH_3 molecules with the Cu^{2+} cations trapped in the ZSM-5;[16] the steric hindrance probably increases as the concentration of Cu^{2+} cations in the zeolite increases.[15] The two types of Cu^{2+} cation react differently with NH_3.[16,17] The reaction of the Cu^{2+} in the zeolite ZSM-5 with pyridine is more hindered than that with NH_3.[16] In accordance with this the parameter of the EPR spectrum of the Cu^{2+} cations change even less[17,18] and no HFS component due to interaction with the nuclear spin of the nitrogen atom is observed in the $g_{\perp}$ region.

There is a vigorous reaction between $(CH_3)_2O$ molecules and the Cu^{2+} cations in ZSM-5.[17,18] Both types of Cu^{2+} cations are evidently involved in this reaction with formation of two types of complex which probably contain different numbers of $(CH_3)_2O$ molecules in the coordination sphere.[15] Several adsorption complexes with different numbers of molecules are also produced in the reaction of CH_3OH with Cu^{2+} in the zeolite ZSM-5. It is found that the type of change in $g_{\|}$ and $A_{\|}$ in the reaction of Cu^{2+} cations with $(CH_3)_2O$ and CH_3OH molecules ($g_{\|}$ increases and $A_{\|}$ decreases compared to the values for the Cu^{2+} cations in the initial specimen) is similar to the changes in these parameters on hydration of the Cu^{2+} cation;[15] this confirms that the complex-formation reaction takes place with escape of the complexes into a straight channel or to the point of intersection of the channels.

Substantial additions to the information on the stereochemistry of paramagnetic Cu^{2+} complexes in H-ZSM-5 were obtained by using pulsed spin-echo spectroscopy as well as EPR.[15,16]

Anderson and Kevan[15] consider that in the initial hydrated specimen the Cu^{2+} is octahedrally coordinated by 6 water molecules and this complex is located at the intersection of the channels. Evacuation at 20 °C is found to be sufficient for the removal of three molecules of water while activation at 400 °C leads to complete removal of H_2O and formation of Cu^{2+} species with restricted accessibility from the large channel in the zeolite, i.e. situated in a five-membered ring. Adsorption of polar molecules (H_2O, NH_3, pyridine, alcohols) causes rapid migration of Cu^{2+} to positions in the large channels and the formation of Cu^{2+} complexes coordinated to two CH_3OH molecules, three C_2H_5OH or pyridine molecules, or four ammonia molecules. The reaction of Cu^{2+} with the non-polar molecules ethylene and benzene is considerably worse.

The absence of modulation by ^{27}Al in spin-echo spectra shows that the Cu^{2+} cations are not located preferentially on the negatively charged AlO_2^- units in the lattice (the Cu–Al distance is not less than 6 Å). The Cu^{2+} concentration in the zeolite may play an important role in the formation of Cu^{2+} ions coordinated in different ways.[15] For example, for a specimen containing 7 times more copper two types of species were detected after evacuation at 20 °C.[16] It was also found that on adsorption of pyridine a Cu^{2+} complex with two, not three, molecules is formed.

The coordination and location of the Cu^{2+} are affected not only by a low copper concentration in the zeolite but also by the presence of sodium.[11–14] Na^+ ions in the zeolite occupy most of the sites securely, blocking them from coordination with Cu^{2+}. This can only be avoided by using the initial H- or NH_4-forms of ZSM-5.

This was confirmed by Sendoda and Ono[16] who compared the ability of Cu^{2+} in H-ZSM-5, Na-ZSM-5, K-ZSM-5, and Ca-ZSM-5 to form complexes with methanol and ethanol. This ability was found to depend on the presence of the second cation and it is suggested that complexes with 4 molecules of the alcohol are formed in H-ZSM-5 but with only 3 molecules of the alcohol in the other specimens. Furthermore the EPR spectroscopic parameters quoted for Cu^{2+} in pure H-ZSM-5 are similar to our values[11–14] ($g_{\|}$ = 2.27, $A_{\|}$ = 180 Oe; $g_{\perp}$ = 2.05) and are markedly different from those for Cu^{2+} in a zeolite containing Na^+ (see Table 2).

3. Physical adsorption of n-hexane and xenon

In studies of the interaction of isolated Cu^{2+} cations with various molecules in the channels in ZSM-5 it was found that not only unsaturated and polar molecules affect the coordination of the Cu^{2+} but the adsorption of n-hexane is also accompanied by measureable changes in the EPR spectra. We have made a detailed analysis of the effects produced by the physical adsorption of alkanes (n-hexane) and inert gases (Ar, Xe) in the channels in CuH-ZSM-5.[19,20] The EPR signal from the initial CuH-ZSM-5 which has been heated at 800 °C is a superposition of two spectra from isolated Cu^{2+} ions: $g_{\|}^1$ = 2.30, $A_{\|}^1$ = 159 Oe, and $g_{\|}^2$ = 2.31, $A_{\|}^2$ = 156 Oe. The perpendicular components were not completely resolved but the analysis gave the values $g_{\perp}^1$ = 2.05, $A_{\perp}^1$ = 23.5 Oe, and $g_{\perp}^2$ = 2.06, $A_{\perp}^2$ = 22.5 Oe. These values show that the specimen contains two distinct types of isolated Cu^{2+} cations located in square pyramids with appreciable distortion towards square planar.

Adsorption of argon (~150 mm Hg) on to the CuH-ZSM-5 specimen at 20 °C did not produce measureable changes in the Cu^{2+} EPR spectrum. However, sorption of xenon (200 mm Hg) was accompanied by an appreciable and reversible effect on one of the two sets of EPR lines.

Sorption of n-hexane (at 20 °C and saturated vapour pressure) was also accompanied by changes in the HFS of one of the Cu^{2+} EPR signals. A slow increase in temperature to 200 °C with continuous evacuation (to 10^{-6} mm Hg) was accompanied by slow changes in the Cu^{2+} EPR spectrum and after evacuating at 200 °C for 30 min the EPR spectrum reverted almost completely to the original spectrum.

Thus appreciable changes in the EPR parameters on adsorption were found for only one of the two types of Cu^{2+} cation ($\Delta g_{\|}$ = 0.03–0.04, $\Delta g_{\perp}$ = 0.01, $\Delta A_{\|}$ = 9–12 Oe, $\Delta A_{\perp}$ ~ 3 Oe). Hence the Cu^{2+} cations located in two distinct sites which differ very little in their type of coordination show a significant difference in their ability to interact with adsorbed molecules of xenon or hexane. For one type of ion the changes in the coordination are negligibly small but for the other type sorption causes an appreciable reduction in the distortion of the square pyramidal coordination of the Cu^{2+}.

Changes in the symmetry of the Cu^{2+} ion due to formation of a coordinate or covalent bond are common for most compounds (unsaturated and polar molecules). However it is difficult to imagine the formation of bonds between Cu^{2+} ions and a non-polar saturated molecule (hexane) and even more so with an inert gas atom (xenon). It is known that the sorption of hexane in H-ZSM-5 at 20 °C can be described as filling of the channels with the liquid hydrocarbon. The sorption does not take place at specific centres but the whole volume of the channels is filled with the condensed phase. In our opinion[19,20] the results obtained indicate some geometrical displacement of the Cu^{2+} ions to one of the types of cationic site due to a dispersion interaction with the adsorbate molecules (or atoms) occupying the channels in the zeolite.

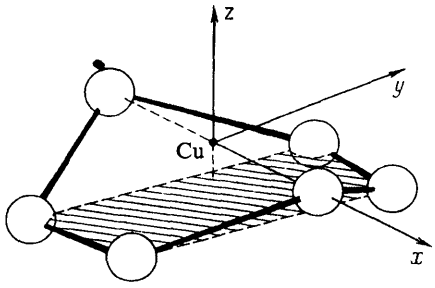

Figure 4. $[Cu^{2+}(O_b^{q-})_6]^{Q}$ **cluster model for an isolated** Cu^{2+} **ion in a structural unit in H-ZSM-5,[17] as determined by X-ray diffraction.[21]**

4. Quantum-chemical analysis of the interaction of molecules with isolated Cu^{2+} cations in H-ZSM-5

There is only one instance where the position of a transition metal cation (Ni^{2+}) in the zeolite H-ZSM-5 has been determined by X-ray diffraction.[21] The ions were found to be located in two sites: (1) in a straight channel close to the wall, and (2) inside a $T_{14}O_{20}$ unit composed of five-membered rings. The cation in the straight channel is bonded to only 3 oxygen atoms in the network but it must have oxygen ligands outside the network. The second site is less accessible and the cation in this site has 6 network ligands. The geometry of this site is shown in Fig. 4. Aspects of the location of the copper cation have been analysed using quantum-chemical calculations.[17,18] The components of the g tensor g_{qq} calculated by the standard method using the Stown approximation agree well with the components of the experimental spectrum. The almost equal components g_{11} and g_{22} are close to the value $g_{\perp} = 2.05$ and the theoretical value g_{33} agrees satisfactorily with the experimental $g_{||}$. However, the most interesting result is that small displacements of the Cu^{2+} ion in the chelate site under discussion can cause marked changes in the parameters of the g factor. Even a negligibly small displacement of the ion ($\Delta z = 0.01$ Å) will lead to appreciable changes in the components g_{qq} (especially g_{33}). There is also a marked dependence of the calculated parameters of the EPR spectrum on changes in the donor-acceptor properties of the ligand environment of the Cu^{2+} when $\Delta z = 0$.

Quantum-chemical calculations of the components of the g tensor[17,18] were also used to assess the interaction of Cu^{2+} in this centre (see Fig. 4) with ammonia. The EPR parameters of complexes with 1 or 2 NH_3 molecules situated on the z axis above and below the Cu^{2+} ion with typical $Cu^{2+}-NH_3$ distances can easily be calculated. However, the differences between the calculated and observed parameters are very large. For complexes with one NH_3 molecule above the cluster $g_{11} = 2.003$, $g_{22} = 2.383$, and $g_{33} = 2.493$, and for those with two NH_3 molecules $g_{11} = 2.003$, $g_{22} = 2.057$, and $g_{33} = 2.090$. Hence either the interaction with ammonia takes place with removal of the Cu^{2+} from such a site or the NH_3 molecule is located sufficiently far away from the cluster under consideration.

Thus it is possible for some of the Cu^{2+} ions in H-ZSM-5 to be located in positions where the EPR parameters are very sensitive to both small geometrical displacements of the ion and small changes in the donor-acceptor properties of the ligand environment. The results of the quantum-chemical calculation confirm that it is possible for the weak effects of physical adsorption of xenon or hexane to cause measurable changes in the Cu^{2+} EPR parameters, as mentioned above.

5. Aspects of the reaction of H-ZSM-5 with various copper compounds

Results published by us[11,12] show that protonic centres in HS-zeolites can be regarded as powerful energy traps for migrating ions. From this point of view the topochemical reaction under discussion can be described as the reaction of CuO with an acid (the protonic centres) and formation of a sort of "salt" of a weak base and a strong acid. The reaction of CuO with H-ZSM-5 at 550–800 °C under vacuum (10^{-6} mm Hg) takes place exactly the same as in air, i.e. the absence of O_2 from the gaseous phase has no effect on the migration and location of Cu^{2+} ions in H-ZSM-5.

It was noted above that H-ZSM-5 can react in the solid state with various compounds. High-temperature reactions of H-ZSM-5 under vacuum with $Cu_3(PO_4)_2$, $CuCl_2$, and CuF_2, like the reaction with CuO, give EPR signals from isolated Cu^{2+} ions (see Figs. 3 and 4). However, the marked differences in the HFS of the EPR spectra in these cases clearly demonstrate the effect of the anion which will act as a ligand, for the isolated Cu^{2+} cations trapped in the zeolite, which is outside the framework (see Table 2).

The appreciable migration of Cu^{2+} at 400 °C in a mixture of $CuCl_2$ with H-ZSM-5 is due to the low stability of the $CuCl_2$ lattice (m.p. 596 °C). Differences occur in the types of coordination of Cu^{2+}, due to the presence of different anionic fragments. For example, in the heated systems (H-ZSM-5 + CuF_2) and [H-ZSM-5 + $Cu_3(PO_4)_2$] at least 4 types of coordination can be distinguished. Two of these are entirely the same as the types found for (CuO + H-ZSM-5) but the other two correspond to a crystal field with octahedral symmetry. It therefore appears that a significant proportion of the isolated Cu^{2+} cations in the zeolite channels interact with the strong ligands F^- and PO_4^{3-} which are outside the framework.

Studies of the reaction of H-ZSM-5 with a copper(I) compound such as Cu_2S [12] show that isolated Cu^+ ions can also migrate to cationic sites in the zeolite after the mixture has been heated under vacuum and their subsequent oxidation produces isolated Cu^{2+} ions.

Thus, using copper-containing high-silica zeolites as an example,[11,12] it has been shown that, due to the thermal stability of the framework of the HS-zeolite and the characteristics of the protonic centres present in them, it is possible to introduce cations by solid state reactions. Not only physicochemical studies but also catalytic data, which will be discussed in a later section, confirm that the specimens obtained are identical to ion-exchange specimens.

In addition to the research on copper-containing HS-zeolites a whole series of papers has been published in which the potentialities of solid state reactions are analysed using a number of other transition metals as examples.

6. Reactions of mordenite and pentasils with chromium compounds

Solid state reactions of mordenite and pentasils (see Table 1) with chromium oxides at 500–820 °C have been studied thoroughly.[22–26]

Heating mechanical mixtures of the H-forms of zeolites with CrO_3 and Cr_2O_3 gives EPR signals of isolated Cr^{5+} ions. When different mixtures are heated under sufficiently drastic conditions the intensities of these signals reach a limit which is determined by the concentration of acidic centres in the zeolite. Heating mixtures containing NaM to 820 °C does not give EPR signals representing isolated ions.

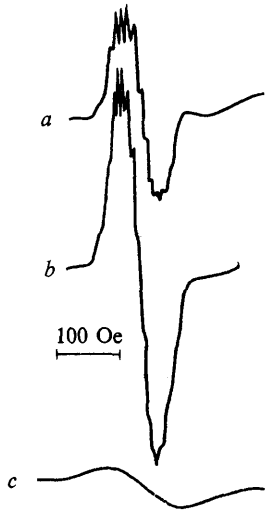

Figure 5. EPR spectra (at 20 °C) of Cr^{5+} ions introduced into H-ZSM-5 by a reaction with CrO_3:[23] *a*, specimen heated in air at 550 °C for 1 h and evacuated at 20 °C for 5 min; *b*, specimen heated at 800 °C for 1 h and evacuated at 20 °C for 5 min; *c*, air admitted to specimen (*b*).

The EPR spectra produced by heating a mechanical mixture of H-ZSM-5 with CrO_3 in air and under vacuum are shown in Fig. 5. Cooling the specimen to –196 °C under vacuum increases the intensity of the signal (Fig. 5*b*) without changing its form (ΔH = 50 Oe, g_0 = 1.98). Admitting air at 20 °C causes a marked, but reversible, broadening of the signal (Fig. 5*c*).

For the initial mixture of H-ZSM-5 with 1.2 mass% Cr_2O_3 the EPR spectrum at 80 °C is a broad symmetrical line (ΔH = 460 Oe) characteristic of bulk antiferromagnetic α-Cr_2O_3. Heating this mixture in air leads to a considerable reduction in the intensity of this signal from the Cr_2O_3 phase and the appearance of a sharp line observed at 20 °C which is identical to the spectrum shown in Fig. 5*b*.

Thus copper is not exceptional and similar processes involving the migration and redistribution of ions in the solid state can occur for other transition metals.

Results published by us[22–25] indicate unequivocally that Cr^{5+} ions are trapped in the H-forms of mordenite and pentasils. In the pentasils the ions occur as isolated, coordinately unsaturated cations which are accessible to molecules from the gas phase. When air is admitted a dipole-dipole interaction with O_2 molecules leads to a marked, reversible broadening of the HFS lines in the spectrum (Fig. 5*c*).

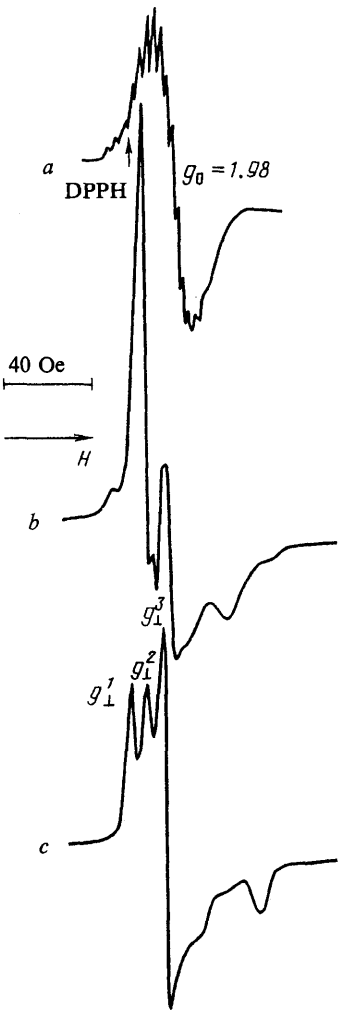

Figure 6. EPR spectra (at 20 °C) of Cr^{5+} ions introduced into H-pentasil-280:[24] *a*, specimen evacuated at 20 °C for 5 min; *b*, after admitting NH_3; *c*, after admitting pyridine; [$g_\perp^1$ = 2.00; $g_\perp^2$ = 1.99; $g_\perp^3$ = 1.98; $g_\parallel^1$ = 1.95; g^2 = 1.93; $g_\parallel^3$ = 1.91].

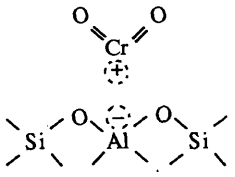
An important aspect of the Cr/HS-zeolite system needs emphasising: the chromium ions in the cationic sites are stabilised in the chromium(V) state when the reaction is carried out in an oxidising medium using both chromium(VI) (CrO_3) and

chromium(III) (Cr_2O_3) compounds. Thus stabilisation of the chromium cations in the matrices of HS-zeolites makes the valence state Cr^V stable.

It is difficult to imagine that, in the HS-zeolites, highly charged pentavalent ions are trapped as cations with no ligands outside the framework and we have therefore suggested[23,24] that the ions stabilised in the cationic sites of the pentasil are not isolated Cr^{5+} ions but isolated CrO_2^+ species balancing the single charge on the framework. The maximum concentration of the CrO_2^+ species depends on the concentration of acidic centres in the specimen.[23,24]

The extra hyperfine structure (EHFS) in the Cr^V EPR spectra (see Fig. 5) provides direct evidence for interaction of the ionic species with an Al^{3+} ion in the framework, creating a cationic vacancy.[23,24] EHFS was also observed for Cr/H-Y.[27,28] In reactions of specimens with NH_3 and pyridine the EHFS disappears and two or three anisotropic signals from Cr^V are superimposed (Fig. 6), i.e. the interaction with these strong ligands leads to a considerable change in the coordination sphere of the cations.[23,24]

The splitting by an aluminium atom situated nearby in itself again confirms the cationic location of Cr^V in the zeolite. However our interpretation of the spectrum with HFS[23,24] was not definitive because, from a formal point of view, an EPR signal with ~15 components obtained in the *X*-band may not be interpreted in terms of splitting by one ^{27}Al nucleus but by two or three aluminium atoms side by side. Although such close alignment of the aluminium atoms in the framework of the ZSM-5 zeolite is improbable, this interpretation of the spectrum (see Fig. 5) is still possible. The problem has been solved by Hemidy, et al.:[29,30] the EPR spectrum of the same Cr^V/ZSM-5 specimen is recorded in the *Q*-band (λ = 8 mm) for comparison (Fig. 7*a*). Using recording in the *Q*-band the anisotropic nature of the spectrum becomes considerably more marked. The groups of lines can be divided into parallel and perpendicular components (6 lines) with slightly different splittings. It is clear from this spectrum that in this system there is an interaction of an isolated Cr^{5+} cation with one Al^{3+} ion in the framework, creating a cationic vacancy. The small magnitudes of the splittings (6–7.5 Oe) indicate that the Al^{3+} is situated in the second coordination sphere of the Cr^{5+} cation and the following mutual arrangement, which allows an interaction between the unpaired electron and the ^{27}Al nuclear spin, is proposed:



The dependence of the distribution of chromium cations in different valence states in a ZSM-5 type zeolite (Si/Al = 20) on the chromium concentration and the conditions of the oxidation-reduction treatment has been studied in detail using chromium concentrations from 0.8 to 3.5 mass%.[25,26] It was shown that at different stages of the thermal treatment of impregnated Cr–TsVM specimens containing 0.8 and 1.8 mass% Cr the Cr^{5+} cations can have different coordination environments. After impregnation and drying in air at 140 °C the major part of the chromium in the specimens occurs as chromates. However even heating at this temperature is sufficient for some of the Cr^{5+} cations to be stabilised within the zeolite channels as hydrated octahedral complexes. When the thermal treatment in air is more drastic the concentration of isolated, coordinately unsaturated Cr^{5+} cations in the zeolite channels increases and aluminium atoms are found in their coordination sphere. The concentration of this type of cation is determined by the concentration of chromium introduced at the impregnation stage.

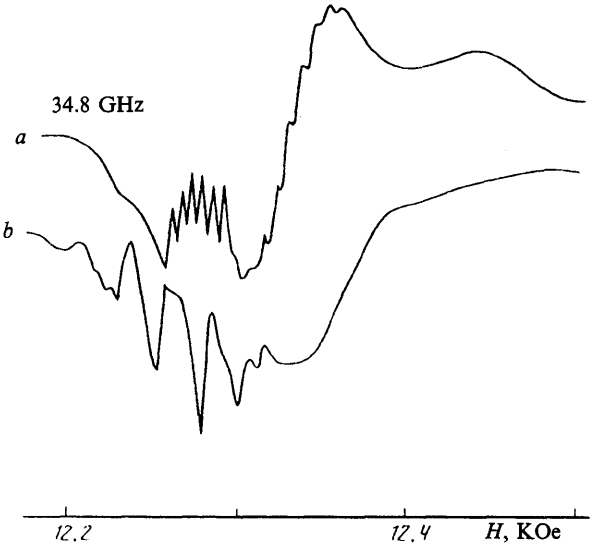


Figure 7. EPR spectra recorded in the *Q* band at 20 °C due to Cr^{5+} cations[28] in: *a*, H-ZSM-5; *b*, H-[Ga]ZSM-5.

A further increase in the concentration of chromium in the chromium–zeolite system leads to new features in its distribution. For example, for specimens containing 2.5 and 3.5 mass.% Cr no EPR spectra due to Cr^{5+} cations were observed either after drying (at 140 °C) or after heating in air at 500 °C for 10 min. This indicates that fairly large crystals of a chromium-containing phase are formed on the outer surface of the zeolite and diffusion of chromium cations from this phase and their stabilisation in the zeolite channels as Cr^{5+} take place slowly. However, heating for an hour is sufficient for this concentration to become high. On passing through the Néel point (314 K), in addition to the signal due to Cr^{5+} cations, an intense broad EPR signal due to formation of large antiferromagnetic crystals of α-Cr_2O_3 on the outer surface of the zeolite is produced. For the specimen containing 3.5 mass% Cr the proportion of Cr^{5+} cations formed is only 20% of the total number of chromium cations in the specimen because a considerable amount of the chromium is stabilised as Cr^{3+} cations in the α-Cr_2O_3 crystals. In other words, these results[25,26] show that the Cr^{5+} cations in an H-ZSM-5 type zeolite may be trapped in several types of centre with different symmetries and with some of the ligands in the first coordination sphere not belonging to the zeolite framework. The results also indicate that, in spite of the considerable variation in the total chromium content and the treatment conditions, it is not possible to introduce more than $(9-10) \times 10^{19}$ Cr^{5+} cations per 1 g of zeolite, i.e. ~0.8 mass% Cr and corresponding to a Cr/Al ratio of ~0.2.

Using a 2.5% Cr–TsVM specimen an investigation was also made of the consistency of the distribution of the different forms of chromium on repetition of the oxidation-reduction treatment at 500 °C.[25,26] It was found that the distribution of the components obtained on preparation of the specimen is very stable and repeating the oxidation-reduction treatment 20 times does not lead to any irreversible changes in the distribution of Cr^{5+} and Cr^{3+} cations in the channels and on the outer surface of the zeolite. An analysis of the EPR spectra due to Cr^{3+} confirms that heating the specimens in hydrogen at 500 °C has no effect on that part of the chromium occurring in the Cr–TsVM in the form of α-Cr_2O_3 crystals. However the Cr^{5+} cations are reduced very easily and quantitatively, most probably to form Cr^{2+} ions.

The results in Refs. 23–26, where the chromium is introduced into H-[Al]ZSM-5, can be compared with more recent research[31] where aspects of the stabilisation of chromium in H-[Cr]ZSM-5, a chromium-silicate with the pentasil structure which contains no aluminium, are discussed. In this matrix, which has the same lattice geometry, some of the Cr^{3+} ions enter the zeolite framework in the synthesis. After the specimens have been heated in air the major part of the chromium introduced is aggregated into an inert Cr_2O_3 phase on the surface of the zeolite but a small proportion of the chromium ions are firmly stabilised by the zeolite as isolated Cr^{5+} ions with a low coordination. However, these ions, which remain grafted to the framework of the H-[Cr]ZSM-5, have properties which differ markedly from those of the CrO_2^+ cationic species that are the counter-ions of the framework aluminium in H-[Al]ZSM-5.

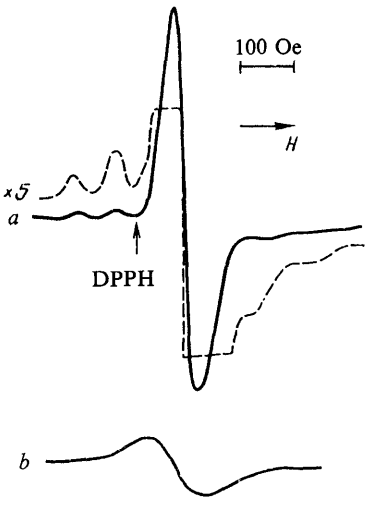

Figure 8. EPR spectra of Mo^{5+} ions introduced into H-ZSM-5 by a reaction with $MoCl_5$ at 450 °C under vacuum:[23] *a*, under vacuum; *b*, in air.

7. Introduction of Mo^{5+} cations into HS-zeolites

Studies have been made of the solid state reactions of mordenite and pentasils with molybdenum compounds.[24,25] The processes of migration of ions into HS-zeolites (see Table 1) when mechanical mixtures with MoO_3 and $MoCl_5$ are heated in air or under vacuum at 150–820 °C have been discussed. Heating mechanical mixtures of the H-forms of zeolites with $MoCl_5$ gives EPR signals from isolated Mo^{5+} ions (Fig. 8). As in the case of Cu^{2+} and Cr^{5+}, when the heating is under sufficiently drastic conditions the intensities of these signals reach a limit which is determined by the concentration of the acidic centres. No isolated molybdenum ions are produced in reactions with NaM up to 820 °C.

Heating mechanical mixtures of the zeolites with MoO_3 or ammonium paramolybdate in air or under vacuum does not give an EPR signal due to Mo^V nor does subsequent reduction in hydrogen give appreciable quantities of Mo^{5+}.[24,25] The reason given for the failure to introduce molybdenum cations by this means is that MoO_3 forms large polymeric fragments even in the vapour phase and does not give cationic species,[24,25] i.e. Mo^{6+} ions do not penetrate into the zeolite channels at all on heating in air.

The reaction of various zeolite specimens with $MoCl_5$ under vacuum is different. Fragments of this volatile compound (b.p. 268 °C) migrate extremely easily both on HS-zeolites and on an amorphous aluminosilicate. The EPR spectrum observed at 20 °C (Fig. 8*a* and *b*) is characteristic of isolated Mo^{5+} ions and the weak HFS lines (6 components with a splitting of ~80 Oe) are due to splitting at the ^{95}Mo and ^{97}Mo nuclei which have a nuclear spin of 5/2 (~24%). The cations are considerably more strongly bound to the zeolites than to the amorphous aluminosilicate. This is shown by experiments in which the specimens are heated at temperatures considerably above the volatilisation temperature of $MoCl_5$. On the amorphous carrier the concentration of cations starts to decrease noticeably at 450 °C and they are removed from the surface quantitatively by heating at 550 °C for 30 min. On zeolites the same thermal treatment does not remove more than one-third of the Mo^{5+} cations. Thus the cationic sites in HS-zeolites are powerful energy traps for Mo^{5+} ions (or rather $MoCl_4^+$ specimes which diffuse easily into the zeolite channels in the reaction with $MoCl_5$).

8. Aspects of the introduction of vanadyl cations into HS-zeolites

Reactions of HS-zeolites with V_2O_5 and the properties of the systems obtained have been studied.[24,25,32–34] Topochemical migration into the cationic sites in the zeolites was shown to be characteristic also of vanadium ions. The reaction of H-ZSM-5 with V_2O_5 at 550–800 °C gives a typical EPR signal from isolated V^{4+} cations ($g_{\|} = 1.93$, $g_{\perp} = 2.00$, $A_{\|} = 198$ Oe, $A_{\perp} = 85$ Oe).[32] Admitting O_2 to the specimen at 20 °C leads to a marked, but reversible, broadening of the lines in the spectrum. As with the other transition metals studied, the maximum concentration of isolated vanadyl ions depends on the concentration of acidic centres in the zeolite.

An important and unusual aspect of the stabilisation of vanadyl cations is their extraordinary stability in both reducing and oxidising media: almost the same EPR signal from V^{4+} ions in H-ZSM-5 is obtained when the specimens are heated at 800 °C in H_2 and in O_2.[24,25]

As the vanadyl ion, with the configuration $3d^1$, is electronically analogous to the Cr^V ion, we may expect EHFS in the EPR spectra for the vanadyl cations in V-H-ZSM-5, as for systems containing chromium.[23,25] EHFS was in fact found in the spectra by a careful EPR study of this system in the temperature range from –196 to 300 °C.[33] The HFS lines in the spectrum of isolated V^{IV} ions (Fig. 9*a*) undergo additional splitting due to EHFS coupling (Fig. 9*b* and *c*). The resolution of the EHFS components ($\Delta H \approx 7$ Oe) is considerably dependent on the temperature at which the spectrum is

recorded. At −196 °C EHFS is almost absent and at 20 °C the poor resolution makes it impossible to determine the number of components. As the temperature is increased the EHFS lines become narrower and signals with a fairly well resolved EHFS can be obtained at 200−300 °C (see Fig. 9*b* and *c*).

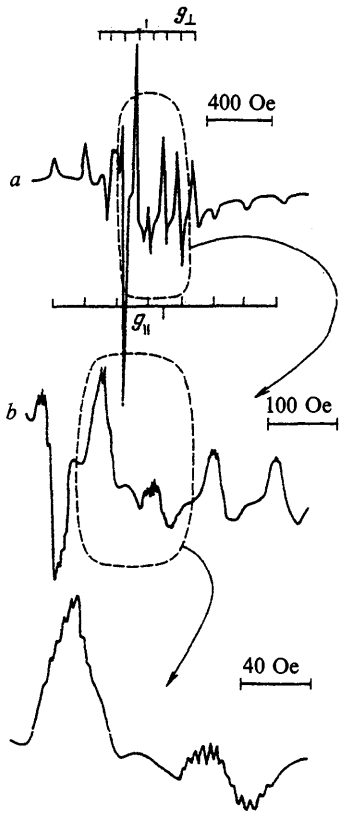

Figure 9. EPR spectra of isolated vanadyl cations ($^{51}V^{IV}$, $3d_1$, I = 7/2) introduced into H-ZSM-5:[33] *a*, complete spectrum recorded at 20 °C; *b* and *c*, parts of spectrum (*a*) recorded at 200 °C.

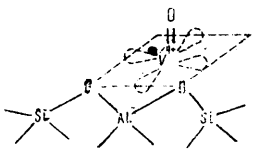
The detection of EHFS at a ^{27}Al nucleus in the V^{IV} EPR spectra (see Fig. 9) provides unambiguous evidence for an electronic interaction between the vanadyl cation and an Al^{3+} ion in the framework of the zeolite. The mutual disposition of the two ions will pave the way for an interaction between their outer electron shells and this will place limitations on the spatial arrangement of the vanadyl ions in the H-ZSM-5 channel. By taking into consideration the small magnitude of the EHFS splitting, which indicates that the Al^{3+} ion is in the second coordination sphere of the V^{IV}, and also that the unpaired electron is in the d_{xy} orbital of the V^{IV}, the following arrangement of the ions has been proposed:[33]



Solid state reactions of the H- and Ca-forms of ZSM-5 with V_2O_5 have also been shown to give paramagnetic vanadium species that are amenable to reactions with H_2O and O_2.[34] The number of V^{4+} ions formed is less for the Ca-form than for pure H-ZSM-5, the Ca-form having a smaller concentration of protonic acidic centres. The use of spin-echo spectroscopy as well as EPR[34] enabled the mutual arrangement of the vanadium and aluminium ions to be deduced from echo data at 4 K. The distance from the V^{4+} to the nucleus of the framework aluminium was found to be not more than 5 Å. The effect of the conditions under which the zeolite is heated with V_2O_5 was also investigated[34] and the possible reduction of V^{4+} with hydrogen was proposed. This conclusion was based on very small changes in the parameters of the EPR spectrum from paramagnetic vanadium and also changes in the colour of the specimens from yellow to grey. However these arguments are not very convincing in view of the fact that mixtures containing 4 mass% V_2O_5 were used in this work. This is a large excess compared to the amount required to fill all the cationic vacancies in the zeolite channels, i.e. some of the V_2O_5 will remain on the outer surface of the zeolite in the form of a phase, the changes in which will account for the observed effects.

In order to investigate thoroughly the distributiom of V^{IV} cations in the structure of the zeolite H-ZSM-5 and to analyse the properties of the vanadyl cations introduced by the solid state reaction, the changes in the parameters of the EPR spectra due to V^{4+} occurring on adsorption of various molecules (NH_3, pyridine, 2,4,6-trimethylpyridine *p*-xylene, nitrobenzene) were studied.[32] The adsorption of these molecules (with the exception of 2,4,6-trimethylpyridine) leads to splitting of the initial EPR spectrum into two, indicating that there are two types of VO^{2+} cation in the zeolite structure. Since adsorption of the sterically hindered 2,4,6-trimethylpyridine molecules has no effect on the parameters of the spectrum it is clear that the two types of cation are located inside the zeolite structure and not on the outer surface. It was shown previously that the zeolite CuH-ZSM-5 contains two types of Cu^{2+} cation, one of which is probably located in a channel and the other in a five-membered ring adjacent to a channel, with square pyramidal coordination. We have suggested[32] that a similar situation may apply to the trapping of VO^{2+} in H-ZSM-5. When a weak ligand such as *p*-xylene is adsorbed there is almost no change in the parameters of the EPR spectrum due to V^{4+} but there is some narrowing of the components and disappearance of the EHFS due to interaction of VO^{2+} with the framework Al^{3+}. By analogy with the effects of weak ligands on Cu^{2+} cations in H-ZSM-5 [20,21] there may be a small displacement of the VO^{2+} cations in the chelate site due to the effect of occupation of the channels in H-ZSM-5 by the *p*-xylene molecules.[32] The *p*-xylene molecules react not only with the cationic centres but also with the oxidation-reduction centres, giving an intense EPR signal from cation-radicals in the region of g = 2.004. Thus the introduction of VO^{2+} cations into the zeolite does not suppress the one-electron transfer centres in the zeolite.

The adsorption of pyridine, NH_3, and nitrobenzene is accompanied by considerable changes in the EPR spectral parameters due to the entry of these strong ligands into the coordination sphere of the VO^{2+}. An analysis of the spectra suggests that, on adsorption of pyridine and NH_3, delocalisation of the unpaired electron from the d_{xy} orbital to the ligand orbitals takes place, leading to increased covalency of the bonds. On the other hand, on adsorption of nitrobenzene the electron delocalisation is reduced and the V=O bonds become more polar.

As was mentioned above, the valence state of a VO^{2+} cation trapped in the zeolite H-ZSM-5 is extremely stable under high-temperature oxidation-reduction conditions: there is no oxidation of this cation to V^{5+} even on heating in a stream of air at 800 °C. This feature has been discussed using ideas put forward in a paper by us[32] where it was shown that the value of $B = \Delta g_{\|}/\Delta g_{\perp}$ characterises the strength of the V=O bond. For example, for V^{4+} cations deposited on Al_2O_3 and SiO_2 B has the values 2.1 and 2.4 respectively but after further reduction it decreases to 1.1 for the V^{4+}/Al_2O_3 system, i.e. the V=O bond becomes weaker, but it increases to 3.1 for the V^{4+}/SiO_2 system, i.e. the V=O bond becomes stronger. However in these instances the B values are small, i.e. on these carriers the V=O bond is not very strong and the V^{4+} cations will undergo oxidation-reduction changes. For VO^{2+} cations stabilised on H-ZSM-5 the B values calculated[32] vary from 8 to 15 and hence in these instances the V=O bond is considerably stronger than for deposition of vanadium cations on Al_2O_3 and SiO_2. However the physical reasons for this are not clear. The question as to which features of the structure of H-ZSM-5 and the location of the VO^{2+} cations guarantee such a high vanadyl bond strength remains undecided.

The solid state reaction of V_2O_5 with the zeolite NaY in air at 420–480 °C has been studied using a combination of methods (X-ray analysis, EPR, ^{29}Si and ^{129}Xe NMR, electron microscopy).[36] When the vanadium concentration is appreciable [R = V/(Al + Si) = 0.2] the lattice of the Y zeolite breaks down and the structure collapses. However, when R = 0.005 or 0.05 the zeolite structure is retained although the V_2O_5 phase disappears during the reaction. Some of the entrances to the zeolite cavities are blocked by a compound which contains V^{4+} ions. It is suggested that the reation of V_2O_5 with Na^+ may lead to formation of a vanadium bronze of the $NaV_5^{V}V^{IV}O_{15}$ type but there is no direct confirmation of this. However it is significant that in this case also,[36] where the zeolite NaY was used, there is an intense solid state reaction between the zeolite and V_2O_5 at fairly low temperatures.

9. Introduction of manganese cations into ZSM-5 zeolites

A number of methods (EPR, RFES†, adsorption of Ar, thermal desorption of NH_3, catalytic testing) have been used to study thoroughly the possible introduction of Mn^{2+} ions into H-ZSM-5 and Na-ZSM-5, both by ion exchange and by solid state reactions with MnO, $MnCl_2$, and $MnSO_4$.[37–39] It was shown that during a solid state reaction with H-ZSM-5 at 430–650 °C the manganese salts or MnO disappear from the surface of the zeolite and manganese ions are uniformly distributed throughout the zeolite crystals. The introduction of the ions is accompanied by a reduction in the number of strong Brønsted acid centres. There is no reaction with the Na-form of the zeolite. Hence, as with the other ions discussed above, stabilisation of the manganese is due to the presence of free protonic centres. However, note that the replacement of the strong acidic centres in H-ZSM-5 reaches a limit of only ~50%.[37,38] Using $MnCl_2$ an exchange reaction takes place to an appreciable extent even on heating at 300 °C for 1 h.[38] Under identical conditions the degree of exchange decreases in the order: $MnCl_2 > Mn_3O_4 > MnSO_4$.[39] Some of the manganese cations are stabilised in the zeolite as manganese(II), which is very stable and undergoes no changes on oxidation-reduction treatment in a stream of oxygen or hydrogen. The properties of the isolated Mn^{2+} cations do not depend on the method of introduction into the zeolite (ion exchange or solid state reactions). However the specimens may also contain manganese in other oxidation states which will complicate the analysis of their properties.

There is another feature of the Mn^{2+}–H-ZSM-5 system: only hydrated specimens give a typical EPR signal in the X-region with HFS due to isolated Mn^{2+} ions (6 components, g = 2.00); in the absence of H_2O molecules the signal is markedly broader.[37–39] This phenomenon has been analysed in detail for Mn^{2+} ions in Y zeolites.[40,41]

10. Reactions of H-ZSM-5 with iron compounds

Reactions between iron compounds and H-ZSM-5 have been studied thoroughly by the EPR method.[42,43] The location, coordination and properties of Fe^{3+} in this zeolite were investigated and comparisons made with a Y type zeolite, and also with a ferrisilicate analogue of the ZSM-5 zeolite (H-[Fe]ZSM-5) containing Fe^{3+} in the framework tetrahedra.

The initial mixtures of H-ZSM-5 with iron oxides give EPR spectra having only a very broad line with $g \simeq 2.0$. No new EPR signals due to Fe^{3+} are obtained by heating the mixtures to 800 °C under vacuum or in air. Heating specimens prepared by exchange with $(NH_4)_4Fe(CN)_6$ does not give any lines due to Fe^{3+}. However, the situation is different when $FeCl_3$ is used.[42,43]

The EPR spectrum of the initial mechanical mixture of H-ZSM-5 with $FeCl_3$ (specimen 1)[43] is shown in Fig. 10*a*. Heating this specimen under vacuum at 300 °C for 2 h (specimen 2) leads to the formation of the signal shown in Fig. 10*b*. Cooling specimen 2 to −196 °C produces an anomalous increase in the intensity of the EPR line with $g = 4.27$ [by a factor of more than 100: $I = (2-3) \times 10^{19}$ spins g^{-1}]. There are no changes in this signal when specimen 2 is heated under vacuum at 300−400 °C for a longer time.

The subsequent heating of specimen 2 in air at 300 °C for 30 min (specimen 3) leads to a decrease in the intensity of the line with $g = 4.27$ and a considerably more complicated EPR spectrum (Fig. 10*d*). When the sample is heated at 550 °C (specimen 4) the intensities of the two low-field lines ($g = 5.65$ and 6.25) continue to increase, the intensity of the line with $g = 4.27$ decreases considerably, and the lines with g factors equal to 9.1, 4.95, 3.7, and 3.4 disappear (Fig. 10*e*). No further changes in the spectrum result from increasing the time of oxidation of specimen 4 at 550 °C to 4 h or raising the temperature of oxidation (to 750 °C, 30 min). Measuring the EPR spectra of specimen 4 at −196 °C increases the intensities of all the lines in the spectrum (Fig. 10*d*) by a factor of only 2.5−3, i.e. there are no anomalous changes in intensity on cooling as were observed for the line with $g = 4.27$ for specimen 2 (see Fig. 10*b* and *c*). Admitting dry oxygen to specimen 4 at 20 °C causes a significant reversible broadening of the low-field lines in the spectrum (Fig. 10*f*). Adsorption of NH_3 or pyridine on specimen 4 at 20 °C leads to complete disappearance of the lines with g equal to 5.65 and 6.25 (Fig. 11*a* and *b*) and after adsorption the intensity of the line with $g = 4.27$ starts to show an anomalous dependence on temperature (Fig. 11*b* and *c*). On the adsorption of H_2O on specimen 4 the intensities of the lines with g equal to 5.65 and 6.25 decrease by a factor of approximately 3 and there is a similar increase in the intensity of the low-temperature line with $g = 4.27$.

Thus these results[42,43] show that solid state reactions do not give isolated Fe^{3+} ions in all cases. Nevertheless this method can be used to introduce Fe^{3+} into H-ZSM-5 but the part played by the anionic fragment is a controlling factor.

The data on the reaction of iron oxides with H-ZSM-5 are inconsistent: we found[42,43] that reactions with FeO and Fe_3O_4 do not proceed at an appreciable rate up to 800 °C but in other work[37] a reaction with Fe_2O_3 led to the introduction into the zeolite of Fe^{3+} ions giving an EPR signal with $g = 4.27$ and readily amenable to reduction. These peculiarities may be due to the different stabilities of the lattices of the iron oxides. When $FeCl_3$, whose lattice is considerably less stable (m.p. 309 °C), is used[42,43] the migration and redistribution of Fe^{3+} is observed at 250−300 °C. The appearance of the EPR signal with $g = 4.27$ (Fig. 10*b* and *c*) unambiguously indicates the occurrence of isolated Fe^{3+} ions in a strong crystal field of low symmetry. In the case of iron[42,43] the ion stabilised is not likely to be Fe^{3+} but the singly charged species $FeCl_2^+$ and FeO^+ which balance the single charge on the framework. The changes in the EPR spectrum on oxidative heating of specimen 2 (Fig. 10*b*−*e*) are precisely due to a gradual change from $FeCl_2^+$ type cationic species to FeO^+. The disappearance of the anomalous signal with $g = 4.27$ and the appearance in its place of lines with g equal to 6.25 and 5.65 can be interpreted in terms of a further reduction in the symmetry of the Fe^{3+} crystal field.

The reversible broadening of the lines in the EPR spectrum occurring when oxygen is admitted (see Fig. 10*f*), which is due to a dipole-dipole interaction with the O_2 molecules, indicates that the Fe^{3+} ions giving the EPR signals with $g = 6.25$ and 5.65 are accessible to molecules in the gas phase. The changes in the spectra due to Fe^{3+} occurring when strong ligands such as NH_3 and pyridine are adsorbed on specimen 4 (see Fig. 11) confirm the suggestions made above. The interaction of coordinately unsaturated Fe^{3+} ions with these ligands will lead to an increase in the crystal-field symmetry of the Fe^{3+} and a shift of the EPR lines towards lower g values, as has been observed.[42,43]

A comparison of the optical spectra shows[43] that the lines in the u.v. region (250 and 320 nm) are due to the presence in the specimen of Fe^{3+} ions with low coordination. Adsorption of NH_3 raises the coordination of the Fe^{3+} and leads to disappearance of these bands.

Reduction of specimen 4 by the adsorbed NH_3 does not take place up to 300 °C.[42,43] More drastic thermal treatment (550 °C, 30 min) is accompanied by the complete disappearance of Fe^{3+} and the appearance of iron metal species which give a ferromagnetic resonance (FR) spectrum. The broad FR line is characteristic of fairly large Fe^0 particles which may be located on the outer surface of the zeolite crystals.

Reoxidation of the reduced iron-containing H-ZSM-5 is accompanied by the complete disappearance of the FR line due to Fe^0, but it does not lead to full restoration of the EPR spectrum due to isolated Fe^{3+} ions.[43] The concentration of such ions is 3−5 times lower than the original even after reoxidation at 750 °C for an hour. There are two possible reasons for this irreversible decrease in their concentration due to the reduction-oxidation treatment: (1) the number of centres in which the Fe^{3+} ions are located is reduced, and (2) there is no reduction in the number of centres in the channels but migration of the oxide species occurring on the outer surface of the zeolite crystals takes place with great difficulty (as with mechanical mixtures of H-ZSM-5 with iron oxides). An experiment involving the reintroduction of $FeCl_3$ into this specimen[43] shows that the second suggestion is correct. The migration of mobile $FeCl_2^+$ species leads to refilling of all the vacant cationic sites in the zeolite and the concentration of isolated Fe^{3+} ions reaches the original value.

The changes in the EPR spectra due to the Fe^{3+} in H-ZSM-5 occurring on reaction with weak ligands such as H_2O and *p*-xylene[42,43] indicate that there is considerable coordination unsaturation of the Fe^{3+} in the specimens. Furthermore effects due to the weak interaction of coordinately unsaturated Fe^{3+} cations with xenon and n-hexane physically adsorbed in the channels in H-ZSM-5 have been observed.[20] The sorption of xenon or hexane at 20 °C causes appreciable broadening of the lines with $g^2 = 5.8$ and $g^3 = 6.3$ in the EPR spectrum due to Fe^{3+} ions.[20] In addition, the sorption of n-hexane results in an anomalous variation of intensity with temperature for the lines with $g^1 = 4.3$; the original evacuated specimen does not show this anomaly. This effect may indicate some reduction in the disortion of the environment for some of the Fe^{3+} cations, caused by displacement of the cation due to a dispersion interaction with the hexane molecules occupying the

channel. The broadening of the low-field lines at 20 °C[20] may also indicate some changes in the conditions of the spin-lattice interaction due to changes in the symmetry of the environment. Such an effect is significant only for Fe^3 ions located in a very strong crystal field with low symmetry.

The set of properties of the Fe^{3+} cations in H-ZSM-5 described above enable them to be distinguished quite clearly from the isolated Fe^{3+} ions introduced isomorphously into the H-ZSM-5 framework on synthesis. Although the isolated tetrahedral Fe^{3+} ions in the zeolite lattice give very similar low-field EPR spectra, they are quite insensitive to interactions with various molecules (even including strong ligands) and differ in being very difficult to reduce.

11. Introduction of Ni^{2+} ions into H-ZSM-5

Solid state reactions of H-ZSM-5 with NiO, $NiCl_2$, $NiSO_4$, and $Ni(CH_3COO)_2$ have been investigated.[38,39] When $NiCl_2$ is used heating in a stream of dry oxygen at 500 °C for 6 h leads to complete replacement of the strongly acidic OH groups in the zeolite (on the basis that an Ni^{2+} cation replaces 2 acidic protons). Subsequent reduction of the specimen with hydrogen at 450 °C or exchange with NH_4NO_3 leads to the complete reduction of the initial concentration of the acidic centres. When nickel sulphate is used the reaction with H-ZSM-5 is less effective and there is no reaction at all with nickel acetate and NiO. Thus for nickel ions also, the anionic fragments have an important role in the solid state reactions.

12. Reactions of H-ZSM-5 with zinc and gallium oxides

The modifying effect of ZnO and Ga_2O_3 on the catalytic properties of H-ZSM-5 has been mentioned in many studies but in the present review we shall concentrate on a group of papers[44–47] in which attempts have been made to observe the physicochemcial changes in [ZnO + H-ZSM-5] and [Ga_2O_3 + H-ZSM-5] mixtures during heating by employing a number of methods (RFES, TPR, thermal desorption of NH_3, i.r. spectroscopy). Thermal treatment leads to migration of Zn^{2+} ions from the outer surface into the zeolite channels and to a decrease in the concentration of Brønsted acid centres.[44] The Zn^{2+} ions in H-ZSM-5 are more easily reduced than is the ZnO phase.[44] Migration into the pores of H-ZSM-5 has also been observed for gallium oxide,[45,47] the gas phase having a decisive role. Using oxidative heating the Ga_2O_3 phase is located on the outer surface of the zeolite crystals and the features of the introduction affect only its degree of dispersion.[47] However treatment in a hydrogen or hydrocarbon atmosphere results in the Ga-phase entering the zeolite channels, the gallium introduced having an oxidation state appreciably less than three.[45,46] Migration of Ga_2O species and their stabilisation in the vicinity of Brønsted acid centres in the zeolite channels has been proposed.[47]

13. Aspects of the introduction of transition metal cations into H-ZSM-5 (and of their properties) resulting from isomorphous replacement of framework Al^{3+} ions by Ga^{3+} or Fe^{3+}

It is known that the properties of the acidic centres in high-silica zeolites can be changed by isomorphous replacement of the framework Si^{4+} ions by other triply charged ions instead of Al^{3+}. Conclusive evidence for the possible synthesis of gallosilicates and ferrosilicates with the ZSM-5 structure has been published and the lower strength of the acidic centres in such structures (H-[Al]ZSM-5 > H-[Ga]ZSM-5 > H-[Fe]ZSM-5) and the changes in the catalytic properties in acid-base reactions resulting from this have been demonstrated. The stabilisation of cations in the same zeolite matrix, but at weaker acidic centres, is naturally of considerable interest. In addition changing from Al^{3+} ions (nuclear spin $I = 5/2$) to Ga^{3+} ($I = 3/2$) will lead to changes in the EHFS of the spectra of Cr^V and V^{IV} due to interaction of the unpaired electron on the cationic species with the nucleus of the framework ion creating the cationic vacancy.

Solid state reactions of H-[Ga]ZSM-5 with CuO, $FeCl_3$, CrO_3, V_2O_5, and $VO(NO_3)_2$ at 300–800 °C have been studied and the results obtained compared with data for the zeolite H-ZSM-5.[27,28] The migration of Cu^{2+} ions in H-[Ga]ZSM-5 is identical to that observed for H-ZSM-5. The results obtained[27,28] indicate conclusively that the concentration and coordination of isolated Cu^{2+} cations in H-ZSM-5 and H-[Ga]ZSM-5 are very similar. Specimens heated at 550 °C contain two distinct types of Cu^{2+} coordination: square planar and square pyradmidal. These two types are retained in specimens heated at 800 °C (the square pyramids showing considerable distortion towards square planar). A comparison of H-ZSM-5 and H-[Ga]ZSM-5 shows only very small differences in the degree of distortion of the environment.

The changes in the EPR spectra due to the interaction of Cu^{2+} with various adsorbates show that the Cu^{2+} cations in H-ZSM-5 and H-[Ga]ZSM-5 are equally accessible to molecules from the gas phase. For example, adsorption of O_2 causes broadening of the lines in the spectrum due to dipole-dipole interactions, and adsorption of ammonia changes the parameters of the spectrum, indicating some reduction in symmetry. In the case of the physical non-localised adsorption of xenon some geometrical displacement of the Cu^{2+} cations due to dispersion forces is observed, as in CuH-ZSM-5.

Thus the replacement of Al^{3+} ions by Ga^{3+} in a zeolite framework with the ZSM-5 structure causes no appreciable changes in the concentration, coordination, and reactivity of the Cu^{2+} ions introduced into the cationic sites in the zeolite by solid state reactions.[27,28]

The same conclusion was reached for iron:[27,28] the processes of solid state introduction of Fe^{3+} into the cationic sites in H-[Ga]ZSM-5 and H-ZSM-5 are identical. The properties of the cations introduced into the two zeolites are almost the same. For the Fe^{3+} ions in H-[Ga]ZSM-5 location in crystal fields with low symmetry is also found. Adsorption of NH_3 increases the symmetry of the Fe^{III} environment (the lines with $g = 5.7$ and 6.3 disappear) and changes the spin-lattice relaxation conditions (the anomalous temperature dependence for the line with $g = 4.3$ appears).

The processes of introducing chromium into H-ZSM-5 and its gallosilicate analogue are similar and interesting features are observed in the EHFS of the EPR spectra due to Cr^{5+}.[27,28] Heating H-[Ga]ZSM-5 with CrO_3 at 420 °C for an hour gives an anisotropic EPR signal from isolated Cr^{5+} ions (two quartets with the parameters $g_\perp = 1.99$, $A_\perp = 28$ Oe, $g_{||} = 1.94$, and $A_{||} = 26.5$ Oe). Heating at 700 °C gives a signal with $g_0 = 1.97$ and $A \sim 24$ Oe. Chemisorption of NH_3 causes an immediate change in the EPR signal with disappearance of the EHFS and the appearance of anisotropic lines; this indicates a considerable change in the coordination of the Cr^{5+} due to attachment of an additional strong ligand. This EPR spectrum is identical to the signal observed in the reaction of Cr^V/H-ZSM-5 with NH_3 (see Fig. 6).

Thus the Cr^{5+} cations have the same coordination in the presence of NH_3 in the channels of H-ZSM-5 and its gallosilicate analogue (two distinct Cr^V positions with different distortions of the coordination symmetry). One of the two types of Cr^{5+} ion is more easily reduced when the specimens with adsorbed NH_3 are heated. The changes in the EHFS of the Cr^V EPR spectra resulting from the change from Al^{3+} to Ga^{3+} in the ZSM-5 framework are shown in

Fig. 7. The signals in the Q-band are more markedly anisotropic (see Fig. 7), making their interpretation easier. The following conclusion is drawn by reference to theory: the EHFS is due to interaction of a CrO_2^+ cation with one framework Al^{3+} ion ($I = 5/2$) and changing to Ga^{3+} (which has $I = 3/2$) reduces the number of EHFS components from 6 to 4. However there is a marked increase in the splitting constant (from 6 to 24 Oe), i.e. the unpaired electron of the CrO_2^+ has a much stronger interaction with a Ga^{3+} nucleus than with an Al^{3+} nucleus. This change cannot be attributed to a difference in the nuclear magnetic moments: whereas for ^{27}Al $\mu_I/\mu_K = +3.64$, for ^{69}Ga $\mu_I/\mu_K = +2.00$ and for ^{71}Ga $\mu_I/\mu_K = +2.55$. The change in the magnitude of the splitting most likely indicates a small change in the geometry of the cation site since the ionic radius of Ga^{3+} (0.62 Å) is appreciably larger than that of Al^{3+} (0.50 Å).

Comparison of the zeolites H-ZSM-5 and H-[Ga]ZSM-5 containing Cr^V or Fe^{III} shows a marked difference in their thermal stabilities: the Ga^{3+} ion is less strongly bound in the lattice than the Al^{3+} ion. In H-ZSM-5 there is no noticeable disruption of the cationic sites at 750–800 °C. In H-[Ga]ZSM-5 this temperature is sufficient for fairly rapid irreversible disappearance of the sites of the isolated Cr^{5+} or Fe^{3+} cations although X-ray diffraction data indicate that the crystallinity of the zeolite is preserved.[27,28] The disappearance of the sites in which cations are trapped is evidently due to Ga^{3+} escaping from the framework. The isolated cations migrate to the outer surface and are aggregated to form oxides. For Fe^{3+} this is confirmed by EPR data.

In addition to the acidic centres in H-[Ga]ZSM-5 being thermally less stable traps for cationic species than the centres in H-ZSM-5, in the gallosilicate the strength of these centres is insufficient for stabilisation of isolated vanadyl cations. In contrast to H-ZSM-5, the reaction of H-[Ga]ZSM-5 with V_2O_5 at 400–800 °C gives hardly any isolated V^{4+} ions.[27,28] Nor are such ions produced by heating H-[Ga]ZSm-5 under vacuum with compounds such as $VO(NO_3)_2$.

In the ferrisilicates H-[Fe]ZSM-5, which have even weaker and thermally less stable acidic centres, it is not possible to stabilise even such transition metal cations as Cu^{2+} and Cr^{5+}. A comparison of the properties of H-ZSM-5 and H-[Fe]ZSm-5 using a highly sensitive EPR method[38,39] showed that isolated Cu^{2+} ions are not stabilised in a ferrisilicate matrix with the ZSM-5 structure.

14. The concurrent introduction of highly charged ions into H-ZSM-5

EPR has been used to investigate the possible introduction of the ions $[Cu^{2+} + CrO_2^+]$, and also $[Cu^{2+} + VO^{2+}]$, into H-ZSM-5 in the solid state and to study the effect of the thermal treatment conditions on these processes.[48,49] In a number of instances it is possible to replace one highly charged ion by another, and also to introduce two different cations simultaneously. It is significant that the different ions are found to have the same location sites and the processes of their location are competitive and depend on the conditions under which the solid state reaction is carried out.

For example, the reaction of H-ZSM-5 with $CuCrO_4$ at 550–800 °C gives a superposition of two EPR spectra due to Cu^{2+} and Cr^{5+} ions. The well resolved HFS of the spectra indicates that the Cu^{2+} and Cr^{5+} ions are isolated and their coordination is the same as when they are introduced individually. It is suggested[48,49] that the copper and chromium ions are distributed statistically in the cationic sites in H-ZSM-5. Estimation of the intensities of the EPR signals indicates that the concentrations of these isolated ions in the specimen are comparable ($Cu^{II}/Cr^V \simeq 2-3$). It is interesting to compare this specimen with the double mixture [(H-ZSM + 1% CrO_3) + 5% CuO] in which the reactions with the oxides were carried out consecutively.[48,49]

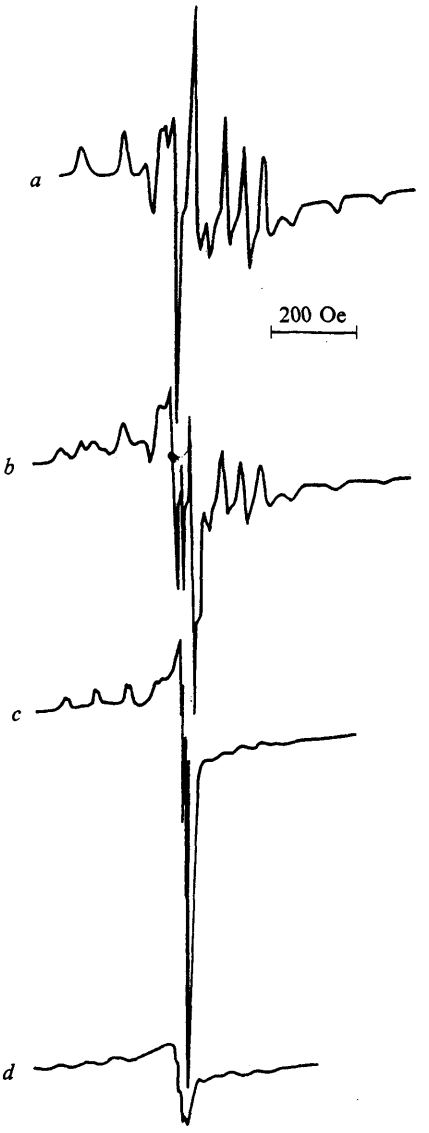

Figure 12. EPR spectra of a [(H-ZSM-5 + V_2O_5) + CuO] mixture under vacuum:[49] *a*, (H-ZSM-5 + CuO) mixture heated in air at 800 °C for 1 h; *b*, the triple mixture heated in air at 500 °C for 1 h; *c*, the same mixture heated in air at 800 °C for 1 h; *d*, after reduction of the specimen in H_2 at 400 °C for 2 h.

Heating H-ZSM-5 with CrO_3 at 800 °C for an hour leads to replacement of the accessible cationic sites in the zeolite by isolated Cr^{5+} ions, giving an intense EPR signal (see Fig. 5*b*). In the subsequent reaction with CuO there are two simultaneous processes:

the intensity of the signal due to Cr^{5+} decreases and that of the signal due to Cu^{2+} increases. It is clear from the changes in the spectra that there is replacement of one ion by the other in the cationic sites, giving a Cu^{II}/Cr^{V} ratio of $\sim 20-30$. It is likely that the equilibrium obtained on heating to a high temperature is dynamic and is dependent on the ratio of the concentrations of the two ions on the outer surface, which in the present case is equal to 5. Reduction of the specimens containing Cu^{2+} and Cr^{5+} ions with hydrogen leads to a rapid disappearance of their EPR signals.

The studies of the reaction of H-ZSM-5 with V_2O_5 and CuO in different media[48,49] are of great interest because Cu^{2+} is easily reduced in hydrogen at 400 °C but VO^{2+} is stable in both oxidising and reducing media up to 800 °C. The maximum concentration of isolated V^{4+} ions in the cationic sites is obtained by heating H-ZSM-5 with V_2O_5 at 800 °C, as is shown by the EPR signal in Fig. 12*a*. A subsequent reaction with CuO in air leads to a gradual decrease in the intensity of the EPR signal due to V^{4+} and the simultaneous appearance of a signal due to Cu^{2+} which increases in intensity (Fig. 12*b* and *c*). The intensity ratio of the signals shows that more than 90% of the V^{IV} in the cationic sites in H-ZSM-5 is replaced by Cu^{II}. Since both oxides were introduced in excess and are present in similar concentrations on the outer surface it is concluded[48,49] that VO^{2+} is appreciably less strongly bound in the cationic sites in H-ZSM-5 than Cu^{2+}. Presumably, during the reaction with CuO the V^{4+} ions are removed to the outer surface of the crystallites and undergo aggregation, with possible conversion to V^{5+}.

An experiment involving the subsequent reduction of the specimen in hydrogen at 400 °C enabled the location of the ions to be determined more accurately. This temperature is high enough for fairly rapid reduction of Cu^{2+} to Cu^0 yielding the metal on the outer surface but it is too low to ensure diffusion of the V^{4+} ions which takes place at an appreciable rate above 500 °C. If V^{5+} ions were in the immediate vicinity of the cationic sites within the zeolite, we would expect the removal of Cu^{2+} from their sites in the reducing atmosphere to be accompanied by conversion of V^{5+} to V^{4+} and the appearance of the corresponding EPR signal (Fig. 12*a*). However no signal due to vanadyl ions is observed; there is merely a considerable reduction in the intensity of the signal due to Cu^{2+} (Fig. 12*d*). It is only when the temperature is increased to 800 °C, and rapid diffusion of V^{4+} ions occurs again, that they again migrate from the outer surface to the cationic sites and their concentration reaches the same maximum limit as in the initial (H-ZSM-5 + V_2O_5)/800 °C specimen. Repeating the oxidising treatment, in which the formation and migration of Cu^{2+} ions occur, again leads to replacement of almost all the isolated VO^{2+} ions by Cu^{2+}.

The replacement of one transition metal cation by another in H-ZSM-5 was also observed very clearly in the reaction of Fe^{3+}-H-ZSM-5 with CuO.[42,43] After a specimen of FeH-ZSM-5, which contains isolated Fe^{3+} cations, was heated with CuO at 550–750 °C the intensities of the signals due to Fe^{3+} with different coordinations (g = 6.25, 5.65, and 4.27) decreased almost by a factor of 1000 and signals due to Cu^{2+} appeared in their place, i.e. more than 99% of the isolated Fe^{3+} cations were replaced by Cu^{2+}. It is emphasised[42,43] that both the concentration and the coordination of the isolated Cu^{2+} ions are the same as in a CuH-ZSM-5 specimen, i.e the Cu^{2+} ions which replace the Fe^3 are introduced into the same cationic sites as are found in H-ZSM-5.

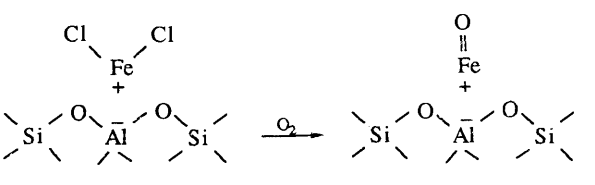
The results obtained demonstrate the complex nature of the processes of migration and redistribution of transition metal ions in HS-zeolites occurring when they are heated to high temperatures. This complexity is due to the differences in the strength of binding of the ions in the cationic site.

IV. The role of the gas phase and the anionic part of the salt in solid state exchange in HS-zeolites

The overwhelming majority of solid state reactions between HS-zeolites and transition metal compounds have been carried out in air in the presence of water vapour and the possible hydrating effect of H_2O molecules cannot be discounted. However the cation migration processes also take place effectively when compounds that are insoluble in water, such as CuO, Cr_2O_3, and V_2O_5, are used. In many instances (V_2O_5, CuO, $CuCl_2$, $FeCl_3$, $MoCl_5$) the reactions take place under high vacuum ($\sim 10^{-5}$ torr), i.e. in the absence of H_2O. Hence the presence of water is not a necessary condition for solid-state ion exchange in HS-zeolites. A similar conclusion was reached regarding solid state processes involving the introduction of alkali metal cations.[7]

A comparison of solid state exchange under vacuum and in air indicates that in the majority of cases (CuO and copper salts, V_2O_5, CrO_3) oxygen has almost no effect on the migration of ions in the zeolite. However in the case of Cr_2O_3 the reaction will not take place under vacuum up to 820 °C but can be carried out in air.[23,24] This peculiarity is probably related to the very high stability of the lattice of the initial oxide (m.p. 2340 °C). It is likely that more labile fragments capable of migrating into the zeolite at 550–800 °C are only formed on the surface of the Cr_2O_3 in the presence of oxygen.

It is clear that the temperature of the reaction can be reduced and the potentialities of the solid-state exchange method extended by using compounds (salts) of a given element which have considerably different labilities. However it must be stressed that the anionic part of the salt, which facilitates the migration, also acts as a ligand for the highly charged cation in the zeolite which is outside the framework, i.e. it changes the symmetry of the crystal field of the cationic centre. In some instances (Cl^-) the ligand can be replaced by heating in air:



but in many cases (PO_4^{3-}, SO_4^{2-}, F^-) the ligand is bonded to the centre very strongly and cannot be removed even by heating the specimens in air at 800 °C.

Clearly, when using transition metal compounds in which the anionic ligand can be replaced by oxygen, the reaction must be carried out under vacuum or in an inert gas. An example of this is the reaction of H-ZSM-5 with $FeCl_3$.[42,43] The reaction with this low-melting salt under vacuum leads, even at 250–300 °C, to stabilisation in the zeolite of isolated $FeCl_2^+$ cationic species. If the specimen is subsequently heated in air the symmetry of the Fe^{3+} environment is reduced, evidently due to conversion to an FeO^+ species.

The effect of a reducing medium (H_2, hydrocarbons) on the state of the cations in HS-zeolites (including those introduced by a solid state reaction) has been studied in many papers. For ions which can be reduced to the metal fairly easily (Cu, Ni, Fe) replacement of the cations within the channels by H^+, migration of the metal atoms, and formation of fairly large metal particles on the outer surface of the zeolite are usually observed. For such metals there is clearly no point in carrying out the solid state exchange in a reducing medium. Reactions with other transition metals in a hydrogen or hydrocarbon atmosphere have hardly been studied but exceptions to this are research involving V^{4+} ions[24,25,32] and gallium ions.[45–47] The solid-state migration of gallium from Ga_2O_3 into the zeolite H-ZSM-5[45–47] takes place only in a reducing medium and the stabilised cations have a charge less than 3+. Vanadyl cations are stable in a reducing medium and they will migrate into the cationic sites in the H-ZSM-5 in a hydrogen atmosphere. For the binary system (Cu + V)/H-ZSM-5, in an oxidising medium the Cu^{2+} ions are bonded to the cationic vacancies much more strongly than the VO^{2+} ions but in hydrogen the Cu^{2+} ions are reduced, Cu^0 drifts to the outer surface, and VO^{2+} cations are stabilised in the sites that have been freed.[48,49]

Thus the possibilities for solid state exchange in HS-zeolites can be extended by varying the transition metal salt and the atmosphere in which the reaction is carried out. However the results obtained indicate a possible substantial redistribution of the modifying components when the atmosphere is altered, e.g. under the conditions of a catalytic reaction.

V. Transition metal cations in an H-ZSM-5 matrix as isolated catalytic centres

In this section a full analysis of all the catalytic data for transition metal/HS-zeolite systems has not been undertaken. Primarily, examples of the oxidation-reduction catalytic properties of HS-zeolites modified by solid state reactions are given and some results obtained for ion-exchange specimens are quoted for comparison.

An important feature of HS-zeolites with the ZSM-5 structure is the stabilisation of isolated cationic species in coordinately unsaturated ligand environments (in fields with low symmetry) and in consequence the high reactivity of such cations with various classes of substances. For example, the H-ZSM-5 matrix provides stabilisation for Cu^{2+} with square planar coordination,[11,12] Fe^{3+} ions in crystal fields with very low symmetries,[42,43] and chromium and vanadium ions in the normally unstable oxidation states Cr^V and V^{IV}.[23–25] Such ions interact not only with the molecules of strong ligands (NH_3, pyridine, H_2O) but also with physically adsorbed molecules of n-hexane and *p*-xylene, and even xenon atoms, which occupy the channels in the zeolite.[20,21,32] In other types of zeolite the cationic centres do not have such a high coordination unsaturation. Furthermore, an important characteristic of the ZSM-5 matrix is that the cationic centres are well separated from each other, i.e. isolated active centres are formed (but only 2–3 distinct types). The coordination of the cations can be altered to a considerable extent by introducing additional anionic ligands.

Thus the cationic centres stabilised by a ZSM-5 matrix provide a unique method for investigating the relationship between the catalytic and physical properties of isolated transition metal ions. In other words, these structures can be regarded as "inorganic analogues of enzymes", in which the isolated active centre is situated in the topologically defined internal space of the zeolite channel. For most transition metals these are oxidation-reduction centres because the ions can easily change their oxidation state. Of course, for ZSM-5 type zeolites, in which the [Si]/[Al] ratio is not less than 16–20, the concentration of isolated centres in 1 g cannot be very large (not more than 1–1.5 mass% of the transition metal compound can be dispersed into the channels and stabilised in the cationic sites created by the framework Al^{3+} ions). However, the abnormally high specific reactivity of the centres suggests that the system is not only of importance theoretically but also has possible practical applications.

Among the oxidation-reduction reactions on modified pentasils the decomposition of NO_x and the burning of hydrocarbons have recently attracted attention.

1. The decomposition of NO and its reduction by hydrocarbons on Cu-H-ZSM-5

The catalytic decomposition of NO on various types of cation-containing zeolites has been studied in a number of papers.[50–58] Cu-containing zeolites display considerable activity and the specific activity of Cu-H-ZSM-5 is unusually high.[50,51] The dependence of the specific activity on the copper content is an S-shaped function. This may indicate the presence of two types of Cu^{2+} ion with considerably different specific activities.[53] The activity of the H-form of ZSM-5 in the stoichiometric decomposition of NO is low.

The situation regarding the reduction of NO by hydrocarbons is more complex: this reaction also takes place on the H-forms of zeolites.[56] However the introduction of copper into H-ZSM-5 has a significant positive effect in lowering the conversion temperature to ~250 °C.[55,57]

The reaction mechanisms and the structure of the active complex were not investigated in detail in the papers quoted above but it was assumed that Cu^+ ions are involved in the catalytic decomposition process. However the effect of SO_x on the decomposition of NO on Cu-H-ZSM-5 has been studied.[58,59] Use of the EXAFS and XANES methods showed that the Cu^{2+} cations in H-ZSM-5 have more ionic character than in CuO.[59] Treatment with SO_x, which causes deactivation of the catalyst, is accompanied by changes in the local structure of the Cu^{2+} and formation of $CuSO_4$-type species.

All the above results were obtained using ion-exchange specimens of Cu-H-ZSM-5 but our recent results indicate that a system with the same catalytic properties, which are of interest for environmental protection, can also be obtained using solid state reactions. This is not surprising because detailed studies of Cu^{2+}/H-ZSM-5 show that there are no differences between the properties of the cations introduced by these two methods.[11–18]

2. Complete oxidation of alkanes

We have studied the burning of low concentrations of CH_4 at 500 °C on H-ZSM-5 containing a number of transition metal ions.[60–64]

In the oxidation of CH_4 and C_2H_6 by oxygen up to 550 °C pure H-ZSM-5 has a negligibly small catalytic activity but the stabilisation of cations in this inert matrix leads to the appearance of activity. This system is very suitable for comparing the specific activities of different ions and also of the same ions with different coordinations.

Coated chromium-containing systems (chromosilicates, chromo-aluminosilicates) are known to be active catalysts for complete oxidation. A study of aspects of the oxidising properties of the well characterised Cr/H-ZSM-5 system is therefore clearly of interest.

Results on the oxidation of CH_4 at 500 °C [60–62] are shown in Fig. 13. The specific activity of the chromium in the zeolite system is very high, much higher than that of chromium on amorphous substrates. Note that if, instead of relating the activity to the whole of the chromium, it is related to the number of isolated Cr^{5+} cations (broken line in Fig. 13) the specific activity is almost constant over a wide range of total chromium concentration in the zeolite (0.5–3.5%). It is therefore likely that the excess chromium which is present on the outer surface in the form of α-Cr_2O_3 crystals, makes no contribution to the activity, which is determined by the number of isolated cations (which are able to change their oxidation state easily). The extremely high activity of these isolated ions is due to their stabilisation in a coordinately unsaturated enviroment, as is found in the H-ZSM-5 zeolite.

The same reaction has been studied on Cu/H-ZSM-5 specimens with a copper content between 0.25 and 2.8 mass% which were obtained by solid state reactions.[60–64] The dependence of the activity of specimens heated at 550 °C on the copper concentration is shown in Fig. 14. The activity increases for 5–10 min and then reaches a stationary value which shows no decrease during treatment at 500 °C for 10 h. Heating in air at 550 °C for 15 h also gives no reduction in catalytic activity, but heating Cu-H-ZSM-5 at 800 °C for 2 h reduces the activity by a factor of 1000.

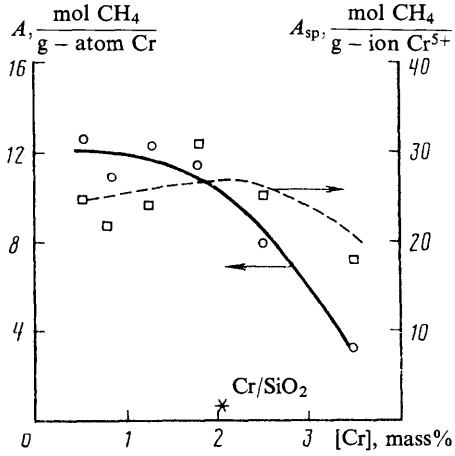


Figure 13. Specific activity of Cr/H-ZSM-5 in the complete oxidation of alkanes.[60]

The relationship shown in Fig. 14 indicates non-uniformity of the active centres. An analysis of catalytic data[63,64] and aspects of the copper distribution which have been thoroughly studied indicate that the high catalytic activity is due mainly to the formation of very coordinately unsaturated (square planar) isolated Cu^{II} ions. In the specimen containing 0.25% copper, which has a low activity, the number of such ions is very small and most of the ions have square pyramidal coordination. Increasing the total copper concentration to 1.0% leads to a significant increase in the concentration of square-planar Cu^{II} ions and there is a good correlation between this and the increase in activity. When the concentration of isolated Cu^{II} ions reaches a maximum (1.5–2.0% Cu) the activity of the catalyst also reaches a limit (see Fig. 14), which remains unchanged when the copper concentration is increased to 2.8 mass%. Therefore an excess of CuO on the outer surface of the zeolite crystals makes no contribution to the catalytic activity of Cu-H-ZSM-5 in the complete oxidation of CH_4.

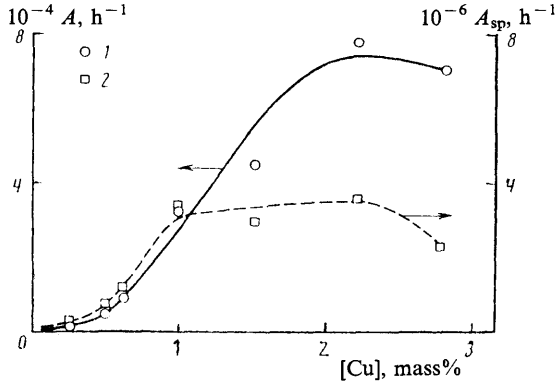

Figure 14. Activity of Cu/H-ZSM-5 specimens in the complete oxidation of CH_4 at 500 °C:[61] *1*, total activity; *2*, activity per 1 g copper.

The deactivation of the catalysts after heating at 800 °C [63,64] may also indicate the role of the coordinately unsaturated, isolated active centre: the number of accessible isolated Cu^{2+} cations is not appreciably reduced by heating at 800 °C but the ligand environment of the Cu^{II} changes considerably. Heating at 800 °C leads to the complete disappearance of the very unsaturated square-planar coordination of Cu^{II} and instead the specimens contain two distinct types of cation with distorted square-pyramidal coordination. Cu^{2+} ions in an HM zeolite or on the surface of SiO_2 (where there is no square-planar copper) have a specific activity that is lower by a factor of 100 than that of Cu^{2+} in H-ZSM-5 which has been heated at 500–550 °C. Such sharp differences in activity also demonstrate clearly the effect of the coordination of the isolated Cu^{2+} ion on its catalytic properties.[63,64]

Systems with a number of other cations (V, Fe, Ni, Co, Mn) have been investigated for comparison with Cu/H-ZSM-5 and Cr/H-ZSM-5.[60-62] The V/H-ZSM-5 system, in which the isolated V^{4+} cations are coordinately unsaturated but incapable of changing their oxidation state, shows a complete absence of catalytic activity in the oxidation of methane. In Fe/H-ZSM-5 specmens micro-crystals of iron oxide on the outer surface of the zeolite make an appreciable contribution to catalysis but the overall activity is not large. However systems containing nickel, cobalt, and manganese ions show significant catalytic activity in the oxidation of methane.

The influence of the local topography of the isolated active centres on the oxidation of C_2H_6 on Cu/H-ZSM-5 has been analysed.[65] The studies were performed on the same catalysts, prepared by solid state reactions, as were used in the work discussed above[63,64] but different conditions were used (low degrees of conversion, temperatures of 270–500 °C). It was shown that the

specific activity of an isolated Cu^{2+} ion in the complete oxidation of C_2H_6 can be varied by a factor of 1000 depending on the coordination of the cation. Cu^{2+} ions with low coordination (square planar) display the highest activity and using a zeolite containing such centres the reaction will proceed at an appreciable rate at 270–300 °C.[65]

VI. Conclusion

HS-zeolites modified by various cations can be used to analyse catalytic processes at the atomic-molecular level because it is possible to produce in them distinct sets of isolated active centres with different topologies. However the standard ion-exchange method cannot be used for the introduction into these matrices of the majority of transition metal ions which are of most interest from a catalytic point of view. The potentialities of this field can be extended by using topochemical methods of introducing cations by means of solid state reactions. The following conclusions can be drawn from a generalisation of the results currently available.

Solid state reactions can be used as a new, environmentally clean method for modifying HS-zeolites with one or more multivalent transition metal cations (Cu^{2+}, Fe^{3+}, V^{4+}, Cr^{5+}, Mo^{5+}, Ni^{2+}, Co^{2+}, Ga^{3+}, Mn^{2+}, Zn^{2+}), the majority of which cannot be introduced into these matrices by other methods.

The ions can be introduced by a solid state reaction because of the presence of free acidic centres in the HS-zeolites. These centres can be regarded as energy traps for migrating cationic species. The potentialities of the method can be extended considerably by using transition metal compounds with different anionic fragments and carrying out the reactions in different gaseous media.

Solid state reactions can be used to replace one highly charged cation by another and also to introduce different cations into the HS-zeolite simultaneously. The different cations occupy the same sites and the processes of their location are competitive and dependent on the conditions used for the solid state reaction.

A distinctive feature of the pentasil matrices is that the isolated cations are stabilised in environments with high coordination unsaturation (low-symmetry crystal fields). A result of this is the very high reactivity of the cations towards various adsorbates.

Pentasil-based systems with distinct isolated centres form unique subjects for physicohemical studies and a proper analysis of the relationship between the local structure and the properties of the isolated transition metal cation. The isolated cationic centres formed in pentasils display an abnormally high and stable catalytic activity in the complete oxidation of alkanes and the decomposition of nitrogen oxides. Therefore, in spite of the low density of active centres produced in the solid state reactions, transition metal cation/pentasil catalysts may be of interest for both theoretical studies and environmental protection.

Thermodynamics of formation reactions and hydrometallurgical application of metal–ammonia complexes in aqueous solutions

V E Mironov, G L Pashkov, T V Stupko
Institute of Chemistry and Chemico-Metallurgical Processes, Siberian Branch, Russian Academy of Sciences

ABSTRACT. Critically selected activity coefficients of individual ions stepwise stability constants, and enthalpy and entropy changes during formation of metal–ammonia complexes in aqueous salt solutions are summarised and analysed. Special attention is paid to the specifics of ammonia complexation in solutions with high ammonia concentrations ($\geqslant 1$ mol dm^{-3}), which are of interest in hydrometallurgy. Certain problems and prospects for use of metal–ammonia complexation in hydrometallurgy are discussed. The bibliography includes 154 references.

I. Introduction

The theoretical principles of ammonia hydrometallurgy have been formulated by investigating aqueous equilibria:

$$M(H_2O)_N^{z+} + nNH_3 \rightleftharpoons M(NH_3)_n(H_2O)_{N-n}^{z+} + nH_2O, \quad (1)$$

where $n = 1, 2, \ldots N$, and N is the limiting coordination number of M^{z+}. These investigations were performed and summarised in the doctoral dissertation of J Bjerrum, the second printing of which appeared in Russian.[1]

The studies of Caron[2,3] enabled industry to utilise the most common method of ammonia hydrometallurgy. The Nicaro plant in Cuba was the first to implement this technology (Ref. 4, p. 129).

However metal–ammonia complexation in aqueous salt solutions has not yet been sufficiently studied.[5] Thus, the unique capabilities of ammonia hydrometallurgy such as the selectivity, mildly aggressive solutions, reagent recycling and ecological benignity[4,6,7] are not fully appreciated.

The lack of thermodynamic data for the formation of Fe^{II}– and Mn^{II}–NH_3 complexes represented a large gap in studying equilibria of type (1).[8–12] Ammonia complexation in sulphate and carbonate solutions,[5] in which most processes of ammonia hydrometallurgy are carried out has not been studied. The position of equilibrium (1) at temperatures greater than 45 °C is almost completely unknown. Reliable stability constants and other thermodynamic functions of Pd^{II}, Tl^{I}, Pb^{II}, Cr^{II}, Li and alkaline-earth complexes with NH_3 are not available.[8–12] The possibility of ammonia–ammonium complexation was not considered in examining equilibria of type (1).[13,14]

Thermodynamic parameters for the reaction of individual cations and anions with NH_3 in aqueous salt solutions have been calculated[15] only assuming that the activity coefficients of ammonium and chloride are constant. However, this assumption is incorrect in concentrated aqueous ammonia.[13]

Protonation constants of NH_3 in aqueous ammonium carbonate and sulphate solutions have not yet been determined.[8–12,14] These are the most important salts in ammonia hydrometallurgy.

The present review is written with the intent of reducing the aforementioned and a number of other wide gaps in the chemistry of aqueous salt solutions of NH_3. The review is based on studies by us and our co-workers that were published in 1986–1991.

The applied part of the review involves current problems of ammonia hydrometallurgy and prospects for broader utilisation of this chemical technology in the future development of hydrometallurgy.

II. Aqueous salt solutions of NH_3

The dissolution of NH_3 in water is a two-step process described by the following equilibria

$$NH_3(gas) \rightleftarrows NH_3(l)$$

$$NH_3(l)H_2O(l) \rightleftarrows NH_4^+(l) + OH^-(l). \quad (2)$$

The quantitative characteristics of these reactions are Henry's constant (K_H, usually in mol kg^{-1} atm^{-1}) and the base dissociation constant (K_B^0) of NH_3. These constants are defined by the expressions

$$K_H = m_{NH_3}\gamma_{NH_3} / P_{NH_3}, \quad (3)$$

$$K_B^0 = m_{NH_4^+}\gamma_{NH_4^+} m_{OH^-}\gamma_{OH^-} / (m_{NH_3}\gamma_{NH_3} a_{H_2O}), \quad (4)$$

in which m_i are the molalities of the i-th components, P_{NH_3} is the partial pressure of NH_3, γ_i are the molal activity coefficients and a_{H_2O} is the activity of water (usually on a mole fraction scale).

Recently the Pitzer equation[16,17] was recommended for a quantitative description of the solubility data of NH_3 in water and multicomponent aqueous salt solutions. This equation enables the activity coefficients and osmotic coefficients of NH_3 and salts in its aqueous solutions to be rather accurately calculated.

It has been demonstrated[18,19] that Henry's constant as defined by Eqn. (3) varies with temperature according to the expression

$$\ln K_H = a + bT^{-1} + cT, \quad (5)$$

where a, b and c are constants equal to -8.09694, 3917.507 and -0.00314[18] or -8.097, 3917.5 and -0.00314,[19] respectively, at $T = 273-313$ K.

The influence of temperature in the range 273–313 K on K_B^0 as defined by Eqn. (4) gives the equation[18]

$$\ln K_B^0 = 16.9732 + 4411.025 / T - 0.0440T. \quad (6)$$

The molal activity coefficients of NH_3 in solutions with insignificant concentration of ions is expressed as[18]

$$\gamma_{NH_3} = \exp(2m_{NH_3}\lambda_{NH_3,NH_3} + 3m^2_{NH_3}\mu_{NH_3,NH_3,NH_3}), \quad (7)$$

where λ_{NH_3,NH_3} and μ_{NH_3,NH_3,NH_3} are the coefficients of paired and tripled interaction of NH_3. The tripled interaction coefficients in the temperature range 273–313 K contribute little to γ_{NH_3} as defined by Eqn. (7) up to aqueous ammonia concentrations of 20–25 mol kg^{-1} H_2O. The paired interaction coefficients of NH_3 (Table 1) vary with temperature according to the equation

$$\lambda_{NH_3,NH_3} = 0.033161 - 21.12816 / T + 4665.1461 / T^2.$$

The molal activity coefficients of individual ions for $M_{\nu+}X_{\nu-}$ in aqueous salt solutions of NH_3 have been calculated[18,20] using the expressions

$$\nu \ln \gamma_{\pm} = A + 2m_{NH_3}\left(\nu_+\lambda_{NH_3,M^{\nu-}} + \nu_-\lambda_{NH_3,X^{\nu+}}\right) + 3m^2_{NH_3}\left(\nu_+\mu_{NH_3,NH_3,M^{\nu-}} + \nu_-\mu_{NH_3,NH_3,X^{\nu+}}\right) + bm_{NH_3}m_{M_{\nu+}X_{\nu-}}\left(\nu^2_+\mu_{NH_3,M^{\nu-},M^{\nu+}} + 2\nu_+\nu_-\mu_{NH_3,M^{\nu-},X^{\nu+}} + \nu^2_-\mu_{NH_3,X^{\nu+},X^{\nu-}}\right), \quad (8)$$

where A are $M^{\nu+}-X^{\nu-}$ interionic interaction terms defined by the Pitzer equation.[16,17] Experimental data for the average ionic molal activity coefficients ($\gamma_{\pm}$) of salts in aqueous ammonia provided a basis for calculations using Eqn. (8). These primarily yielded coefficients of paired and tripled interactions of ions with NH_3. These coefficients were used to calculate γ_+ and γ_-. The molal activity coefficients of the ions, like the calculation of the coefficients of paired and tripled interactions (Table 1), were calculated[18,20] using the unconventional thermodynamic assumption that in aqueous ammonia

$$\gamma_{NH_4^+} = \gamma_{Cl^-} = 1 \text{ (Refs. 15, 18)}. \quad (9)$$

or

$$\gamma_{Cs^+} = \gamma_{I^-} = 1 \text{ (Ref.20)} \quad (10)$$

Table 1. Critically selected parameters for reaction of NH_3 with ions in aqueous salt (in mol kg^{-1} H_2O) solutions at 25 °C.[18,20]

Ion (i)	$\lambda_{NH_3,i}$		Ion (i)	$\lambda_{NH_3,i}$	
	calc.*1	calc.*2		calc.*1	calc.*2

Cl^-	0.0	0.048	CH_3COO^-	0.036	0.090
Br^-	−0.022	0.030	OH^-	0.103	0.15
I^-	−0.051	0	NH_3	0.01472	−0.035

*1Calculated assuming $\gamma_{NH_4^+} = \gamma_{Cl^-} \approx 1$.[15] Coefficients of tripled interaction, i.e. $\mu_{NH_3,NH_3,i}$, are shown in parentheses.
*2Calculated assuming $\gamma_{Cs^+} = \gamma_{I^-} = 1$.[20]
*3The contribution of $\mu_{NH_3,NH_3,i}$ is noticeable at $c_{NH_3} > 8-15$ m; however, the accurate value of $\mu_{NH_3,NH_3,i}$ was not calculated.

Table 2. Logarithms of molar activity coefficients (y) of ammonium cations and chloride anions in aqueous ammonia mixtures of ammonium perchlorate and chloride (1.0 mol dm^{-3}) at 25.0 °C.[13,21]

c_{NH_3}, mol dm^{-3}	lg y of the ions	
	NH_4^+	Cl^-
2.0	−0.10	0.10
4.0	−0.22	0.23
6.0	−0.33	0.36
8.0	−0.46	0.40
10.0	−0.56	0.52

Note. It was assumed that $\lg y_{KClO_4} = \lg y_{K^+} = \lg y_{ClO_4^-}$ (Ref.13).

Table 1 summarises such calculations that are based on Eqn. (8) as paired interaction coefficients of ions with NH_3. The numerical data of Table 1 indicate that the unconventional thermodynamic assumptions (9) and (10) produce different paired interaction

coefficients of NH_3 with the ions. However, if the two assumptions mentioned above are used, these coefficients differ by practically identical amounts of 0.05–0.06.

However, assumption (9) is not valid for concentrated aqueous ammonia[13] since ammonium and ammonia form the $NH_4NH_3^+$ compelex with a stability constant of 8.0 ± 0.5 (taking into account the water activity in mol dm^{-3}) in aqueous solutions with ionic strength 1.0 at 25.0 °C.[21] Chloride in these same solutions salts out NH_3, as indicated by the data in Table 2. Therefore, adding NH_4Cl to aqueous ammonia has no affect on the activity of dissolved NH_3 as was proposed on the basis of assumption (9).

The molar activity coefficients (y) have been calculated for a large number of individual ions[13,22] for aqueous ammonia with an ionic strength of 1.0 held constant with NH_4ClO_4 at 25.0 °C. The calculations were performed using the unconventional thermodynamic assumption that

$$y_{KClO_4} = y_{K^+} = y_{ClO_4^-} = 1. \quad (11)$$

Assumption (11) for solutions with $[NH_3]$ less than 12.0 mol dm^{-3} has been confirmed to be valid by various methods.[23–27] It was found[22] that, depending on the molar $(NH_3]$ (c_{NH_3}), these activity coefficients vary with high correlation coefficients (ρ) according to the equation

$$\lg y_i = Ac_{NH_3} + B, \quad (12)$$

where A and B are constants with the values given in Table 3. It is noteworthy that B for all ions (Table 3) is statistically equal to zero within error limits. Thus, log $y_i \to 0$ as $c_{NH_3} \to 0$ according to Eqn. (12).

Table 3. The constants A and B in Eqn. (12).[13,22]

Ions	$A \pm 3\sigma$	$B \pm 3\sigma$	ρ
Cl^-	0.065 ± 0.008	- 0.03 ± 0.05	0.999
Br^-	0.057 ± 0.008	- 0.05 ± 0.05	0.992
NO_3^-	0.047 ± 0.008	- 0.03 ± 0.05	0.986
BrO_4^-	0.091 ± 0.006	- 0.05 ± 0.04	0.998
IO_4^-	0.153 ± 0.003	- 0.02 ± 0.02	0.999
SO_4^{2-}	0.28 ± 0.05	- 0.2 ± 0.3	0.994
$C_2O_4^-$	0.24 ± 0.07	- 0.05 ± 0.4	0.982
CO_3^{2-}	0.24 ± 0.05	- 0.2 ± 0.3	0.992
Tl^+	- 0.100 ± 0.007	0.06 ± 0.04	0.998

The equilibrium below has been studied in a series of careful pH titrations[14,28–30]

$$H^+(solv) + NH_3(solv) \underset{}{\overset{K}{\rightleftharpoons}} NH_4^+(solv), \quad (13)$$

in aqueous solutions with ionic strengths (I) held constant by various monotypic salts (MA_z) and their mixtures (MA_z + BX) at 25.0 °C. It was found in these studies that the equilibrium constants (K) for Eqn. (13) in MA_z salt solutions obey the following linear relationships with a correlation coefficient greater than 0.999:

$$\lg K = \lg K^\circ + bI, \quad (14)$$

where K° are the constants standardised using solutions with zero ionic strength and b are constants (Table 4). It should be especially emphasised that data standardised to ammonium sulphate and carbonate solutions also obey Eqn. (14). These are the most common salts of ammonia hydrometallurgy for which the equilibrium constants of Eqn. (13) have not yet been determined.[14] The validity of Eqn. (14) has also been confirmed with correlation coefficients of 0.99 by other investigators.[31,32] However, these studies did not involve all salts (Table 4) and covered a narrower range of ionic strengths. The results of these studies[31,32] were recently the subject of a thorough mathematical analysis.[14]

Table 4. Equilibrium constants (13) of Eqn. (14) at 25.0 °C.[14]

Background salt	$\lg K^\circ$	b	Range of I	Number of experimental K
$LiNO_3$	9.228 ± 0.006	0.168 ± 0.005	0.1 ± 6.0	14
$NaNO_3$	9.229 ± 0.004	0.192 ± 0.001	0.1 ± 6.0	14
KNO_3	9.199 ± 0.004	0.192 ± 0.002	0.1 ± 3.5	9
$LiClO_4$	9.245 ± 0.003	0.210 ± 0.001	0.1 ± 4.0	10
$NaClO_4$	9.221 ± 0.004	0.250 ± 0.001	0.1 ± 5.5	13
NH_4ClO_4	9.226 ± 0.004	0.141 ± 0.004	0.1 ± 1.5	5
NH_4NO_3	9.230 ± 0.002	0.141 ± 0.001	0.1 ± 6.0	14
$(NH_4)_2SO_4$	9.38 ± 0.01	0.138 ± 0.003	0.3 ± 6.0	5
$(NH_4)_2CO_3$	9.31 ± 0.01	0.131 ± 0.001	0.3 ± 6.0	5

The equilibrium constants of Eqn. (13) in $MA_z \to BX$ salt mixtures with constant ionic strengths lie on the line described by the following equation with a correlation coefficient greater than 0.99

$$\lg K_{(MA_z \to BX)} = \lg K_{(MA_z)} + \lambda_{BX} c_{BX}. \quad (15)$$

where $K_{(MA_z \to BX)}$ and $K_{(MA_z)}$ are constants in the mixed and monotypic salt solutions, c_{BX} are the molar concentrations of BX salts and λ_{BX} are constants (Table 5).[14,30] It is interesting that the constants λ_{BX} can be calculated from the constants b (Tables 4 and 5) in Eqn. (14). Thus, λ_{BX} can be divided into ionic components, the addivity of which can be used to predict $K_{(MA_z \to BX)}$ in mixed solutions of still unstudied salts.

An analysis of the ionic components of λ_{BX} indicates (Table 5) that the cationic components are less than the anionic ones for the salts included in Tables 4 and 5. This is due to the fact that the reagents of equilibrium (13) are cations, the particular behaviour of which depends more on the nature of the anions than on that of the cations.

Table 5. Equilibrium constants (13) of Eqn. (15) at 25.0 °C.[14]

Background salt	Ionic strengths	No. of K	λ_{BX}	
			from Eqn. (15)	from b values
$LiNO_3 \rightarrow NaClO_4$	2.0; 5.0	16	0.083 ± 0.007	0.083 ± 0.005
$Li(NO_3 \rightarrow ClO_4)$	2.0; 4.0	14	0.030 ± 0.005	0.043 ± 0.006
$Na(NO_3 \rightarrow ClO_4)$	2.0; 3.0; 5.0	23	0.052 ± 0.005	0.057 ± 0.005
$(Li \rightarrow Na)NO_3$	2.0; 4.0; 6.0	27	0.028 ± 0.003	0.026 ± 0.004
$(Li \rightarrow NH_4)NO_3$	2.0; 4.0; 6.0	27	−0.024 ± 0.003	−0.023 ± 0.004
$(Li \rightarrow Na)ClO_4$	2.0; 4.0	14	0.033 ± 0.006	0.040 ± 0.007

The additivity of the ionic components of λ_{BX} is not unexpected. The influence of a large number of alkali and alkaline-earth salts on the vapour pressure of NH_3 has been represented and analysed[33] as activity parameters of the individual ions. These parameters were used to predict the analogous functions of unstudied ions. Empirical laws were used for the prediction for example

$$\Delta P = a + bz / r^2, \tag{17}$$

where ΔP are the relative NH_3 vapour-pressure changes caused by ions of charge z and radius r and a and b are constants, or

$$\Delta P = 0.20\Delta G_{A^-} - 49.5, \tag{18}$$

where ΔG_{A^-} is the free energy of hydration of the anions (in J mol^{-1}).

It is interesting that the prediction was made using Eqn. (18)[33] and later experimentally confirmed[13] that cations of the type $Co(en)CO_3^+$ (en = ethylenediamine) salt out NH_3 whereas large anions such as picrate, HgI_3^-, etc. bind NH_3 in aqueous salt solutions.

The ionic components are used to calculate Sechenov constants, which characterise the behaviour of NH_3 in aqueous solutions of alkali metal salts.[34] It is true that the calculated constants did not always agree with those found experimentally. However, the following equation

$$K_s = 0.053z / r_{A^{z-}} - 0.22,$$

where $r_{A^{z-}}$ is the crystallographic radius of A^{z-} (in nm), rather well gives the NH_3 salting-out constants (K_s) by the anions.[13]

Judging from the previous studies,[30,35,36] NH_3 is protonated according to Eqn. (13) owing to a negative enthalpy component of the Gibbs free energy with a small entropy decrease (Table 6). The enthalpy and entropy components become more negative as the ionic strength of the studied solutions increases. Changing from Li to Na salts slightly decreases the entropic barrier. This barrier for both Li and Na sats increases in the order $ClO_4^- < NO_3^- < Cl^-$. However, these effects are small considering that the determination errors of the examined entropy changes ($\pm\sigma$) are ±1 J mol^{-1} K^{-1}.

Footnote: No Eqn. (16) in Russian text.

*Values of y obtained from extraction of NH_3 into $CHCl_3$ are given in parentheses.

Many properties of aqueous salt solutions of NH_3 are determined by their activity coefficients. The coefficients markedly increase in solution with $[NH_3] > 1$ mol dm^{-3}.[1,13,14,37,38] The molar NH_3 activity coefficients (up to 18 mol dm^{-3}) at 25.0 °C in aqueous NH_4NO_3 (2.0 mol dm^{-3}) that were recently measured[37] by an electrochemical method using a glass electrode and by extraction into $CHCl_3$ are presented in Table 7. This salt solution is most frequently used to study metal–ammonia complexation equilibria. These activity coefficients have been used in many of our studies[14,37,39–51] to investigate the processes expressed by Eqn. (1) in aqueous solutions with a high $[NH_3]$.

Careful measurements of the NH_3 vapour pressure (P_{NH_3}) over an aqueous $NaClO_4$ solution (1.0 mol dm^{-3}) containing less than 12 *M* NH_3 at 25.0 °C led to the equation[38]

$$P_{NH_3} = 1.58 + 12.4c_{NH_3} - 1.66c_{NH_3}^2 + \\ + 0.937c_{NH_3}^3 - 0.119c_{NH_3}^4 + 0.00529c_{NH_3}^5.$$

Up to $[NH_3]$ = 2 mol dm^{-3}, this function was practically linear and gave a Henry's constant of 12.4. Taking this into account, the NH_3 activity in all studied solutions is correctly described by

$$a_{NH_3} = P_{NH_3} / 12.4.$$

The vapour pressure of NH_3 over the whole concentration range (0–100%) of its aqueous solutions has been measured over a wide temperature range (32–345 °C).[52] The activity coefficients of NH_3 that were standardised to its pure state (i.e. liquid NH_3) were determined under these conditions.

The dependences of the standard solvation enthalpies of NH_3 on the charge density of the cations and anions in aqueous calcium, alkali metal, tetramethyl- and tetraethylammonium chloride solutions and in sodium halide, nitrate and sulphate solutions have been analysed.[53] These functions are nonlinear for the anions and cations owing to the considerable differences in the hydration mechanism of the various ions and in the size of the noncoulombic contributions (covalent, hydrophobic and hydrogen bonds) to the interaction energy of the ions and molecules in the examined solutions.

III. Formation of metal–ammonia complexes in highly concentrated aqueous ammonia

The formation of metal–ammonia complexes in aqueous solutions according to Eqn. (1) involves the metal ions, NH_3 molecules, $M(NH_3)_n(H_2O)_{N-n}^{z+}$ and water molecules. Modern experimental methods for studying equilibria of type (1) in order to determine *n* and the overall stability constants (β_n) of the complexes formed are based on measurements of various properties of $M(H_2O)_N^{z+}$, NH_3 and $M(NH_3)_n(H_2O)_{N-n}^{z+}$ (the metal ion, ligand and complex methods, respectively).[54] Potentiometry with electrodes reversible toward $M(H_2O)_N^{z+}$, polarography and the solubility of salts containing M^{z+} are the most common varieties of the metal-ion methods. Extraction (NH_3),NH_3 vapour-pressure determination over solutions and pH titrations are varieties of ligand methods. Electronic spectroscopy, NMR, thermochemistry and extraction of $M(NH_3)_n^{z+}$ are examples of complex methods.

Ligand methods have provided the most information[8–11] on the composition and stability constants of $M(NH_3)_n^{z+}$. Among these methods, pH titrations have most frequently been used. The equilibrium $[NH_3]$ in aqueous solutions with low total metal concentrations ($c_{M^{z+}}$) and various $[NH_3]$ (c_{NH_3}) are usually measured against a background of practically constant high ($\geqslant$0.1 mol dm^{-3}) concentrations of ammonium salts. These measurements were used to calculate the formation functions ($\bar{n}$).[1] Calculations of the latter yielded the equation

$$\bar{n} = (c_{NH_3} - [NH_3]) / c_{M^{z+}}. \qquad (19)$$

However, Eqn. (19) is incorrect[55] for aqueous salt solutions with $[NH_3]$ > 1.0 mol dm^{-3}. Even Bjerrum demonstrated[1] that $\bar{n}$ calculated for $M(NH_3)_n^{z+}$ using Eqn. (19) are reduced in solutions with high $[NH_3]$. This reduction of $\bar{n}$ is mainly due to the salting-out action of NH_3 on the reagents of equilibrium (1), to the use of experimental NH_3 activities (a_{NH_3}) and not its equilibrium concentrations and to a number of less important factors.[13] The effect of all aforementioned factors can formally be ascribed to the variability of the activity coefficients for the reagents of equilibrium (1) in solutions with $[NH_3]$ > 1.0 mol dm^{-3}. Therefore, equilibrium constants of Eqn. (1) even for aqueous solutions with high and constant concentrations of ammonium salts but with $[NH_3]$ > 1.0 mol dm^{-3} should be represented only in terms of activity, i.e. by the expression

$$\beta_n = \frac{\left[M(NH_3)_n(H_2O)_{N-n}^{z+}\right] y_{M(NH_3)_n(H_2O)_{N-n}^{z+}} a_{H_2O}^n}{\left[M(H_2O)_N^{z+}\right] y_{M(H_2O)_N^{z+}} [NH_3]^n y_{NH_3}^n}, \qquad (20)$$

where y are the molar activity coefficients and a_{H_2O} is the water activity (usually expressed in mole fractions).

The complex concentrations from Eqn. (20) are defined by the equation

$$\left[M(NH_3)_n(H_2O)_{N-n}^{z+}\right] = \beta_n \left[M(H_2O)_N^{z+}\right] [NH_3]^n y_{NH_3}^n a_{H_2O}^{-n}, \qquad (21)$$

if it is assumed that the ratio of $M(H_2O)_N^{z+}$ and $M(NH_3)_n.(H_2O)_{N-n}^{z+}$ activity coefficients is equal to unity and does not change with increasing $[NH_3]$. To a first approximation this assumption is valid since the charges of these ions are identical and their sizes are very similar.[56]

The following equation is obtained by combining Eqns. (19) and (21) and making simple transformations

$$\sum_n (\bar{n} - n)\beta_n [NH_3]^n y_{NH_3}^n a_{H_2O}^{-n} = 0, \qquad (22)$$

and can be used to find $\bar{n}$ and β_n. However, $\bar{n}$ should be corrected for the variable activity of the molecular–salt solution after their determination in solutions with $[NH_3]$ > 1.0 mol dm^{-3} [55] in order accurately to calculate *n* and β_n using Eqn. (22). Bjerrum attempted to determine the size of this effect in terms of corrections ($\Delta\bar{n}$) to the $\bar{n}$ functions. However, the scatter of $\Delta\bar{n}$ in solutions with $[NH_3]$ = 7–10 mol dm^{-3}, according to his data (Ref. 1, p. 149), reached 300%. The reasons for such a scatter were recently discussed.[13,14,37] The neglect of the formation of Ba–NH_3 complexes,[13] the existence of $Ag(NH_3)_3^+$ [47] and the nature of the anion in determining $\Delta\bar{n}$ [20] produced such a scatter.

The quantities $\Delta\bar{n}$ for 1–10 mol dm^{-3} (Refs. 13, 57, 58) and even 1–20 mol dm^{-3} (Refs. 14, 37, 43) for NH_3 solutions of ammonium perchlorate, chloride or nitrate with constant ionic strengths of 1.0 and 2.0 have recently been determined in a series of studies. The most accurate $\Delta\bar{n}$ were determined for Zn^{II}–NH_3 complexes.[37] The Zn^{II} cation is completely converted to the tetrahedral coordinatively saturated $Zn(NH_3)_4^{2+}$ complex even in 0.5 M aqueous ammonia.[1] Increasing $[NH_3]$ further up to 20 mol dm^{-3} causes $\bar{n}$ to decrease from 4.0 to 1.2–1.5.[14,43] Use of the expression

$$\Delta\bar{n} = 4 - \bar{n} \qquad (23)$$

for $Zn(NH_3)_n^{2+}$ in solutions with $[NH_3]$ = 1–20 mol dm^{-3} yielded $\Delta\bar{n}$ over the widest range of $[NH_3]$ (Table 8). Analogous $\Delta\bar{n}$ were obtained during a study of the formation in concentrated aqueous ammonia salt solutions of NH_3 complexes of Ag^I and Cu^{II} [taking

into account formation of $Ag(NH_3)_3^+$ and $Cu(NH_3)_5^{2+}$].[37,43] It is noteworthy that the $\Delta\bar{n}$ found by us (Table 8) are very close to those obtained by Bjerrum using the behaviour of $Cu^{II}-NH_3$ complexes.

Table 8. Average corrections ($\Delta\bar{n}$) to the Bjerrum function for $M(NH_3)_n^{z+}$ in aqueous NH_4NO_3 (2.0 mol dm^{-3}) with high [NH_3] at 25.0 °C.[43]

$-pNH_3^*$	$\Delta\bar{n}$	$-pNH_3^*$	$\Delta\bar{n}$	$-pNH_3^*$	$\Delta\bar{n}$
0	0.05	0.75	0.77	1.50	1.70
0.25	0.22	1.00	1.06	1.75	2.12
0.50	0.50	1.25	1.38	2.00	2.50

Note. Data for the ammonia complexes of Zn^{II}, Cu^{II}, and Ag^I were averaged.
*$pNH_3 = -\log([NH_3]\gamma_{NH_3}/\alpha_{H_2O})$, where a_{H_2O} is in mole fraction and [NH_3] is in mol dm^{-3}.

The averaged $\Delta\bar{n}$ (Table 8) were used to calculate the corrected ($\bar{n}_{corr}$) values of the Bjerrum function.[13,37,47,59] The latter were calculated using

$$\bar{n}_{corr} = \bar{n} + \Delta\bar{n}. \quad (24)$$

The Bjerrum functions corrected by $\Delta\bar{n}$ were substituted into Eqn. (22) during a study of the formation of $Li-NH_3$ complexes (Table 9)[47,51] and Mg−, Ca− and $Cd-NH_3$ complexes (Table 10)[14,37] in addition to those of Tl^I (Refs. 13, 54) and alkaline earths (Table 11)[59] in solutions with $c_{NH_3} \leqslant 18$ mol dm^{-3}. These studies were carried out using a pH-titration ligand method[14,37,47,54] or NH_3 extraction into $CHCl_3$.[13,47,51,59] Some of these complexes were also studied by a thermochemical method,[47,51,60] i.e. by one of the complex methods. The composition and stability constants were calculated using

$$\Delta\bar{H} = \sum_{n=0}^{N} \Delta H_n \alpha_n, \quad (25)$$

where $\Delta\bar{H}$ are the enthalpy changes from Eqn. (1), ΔH_n are the enthalpy changes on formation of $M(NH_3)_n^{z+}$ and α_n are the mole fractions of the complexes, i.e.

$$\alpha_n = \beta_n [M^{z+}] a_{NH_3}^n a_{H_2O}^{-n} / c_{M^{z+}}.$$

*From Eqn. (26).

The ligand method with a correction for $\Delta\bar{n}$ and the complex method (thermochemistry) without corrections for the solvent effect gave identical stability constants for the NH_3 complexes of Li (Table 9), Cd (Table 10) and Tl^I (Table 10).[54] This fact and results from a number of other investigations[13] indicate that the solvent effect for $M(NH_3)_n^{z+}$, like for complexes of anions,[54,61] are decreased on going from a metal method to a ligand method and a complex method.

It should be emphasised that the correct stepwise stability constants for a number of weak ammonia complexes that are formed in highly concentrated NH_3 solutions are summarised for the first time in Tables 9−11. It is interesting that all stepwise stability constants of Ca−, Sr− and $Ba-NH_3$ complexes (Table 11)

decrease with increasing ionic strength (I) using NH_4ClO_4 according to

$$\lg K_n = \lg K_n^0 + AI, \quad (26)$$

where K_n^0 are the constants at $I = 0$ and A is a constant equal to 0.16.[37,59]

The stability constants of $Ca(NH_3)_n^{2+}$ with $n = 1-4$ that are calculated using Eqn. (26) agree with those found for 2.0 M ammonium nitrate (Table 10) and perchlorate (Table 11). Even before the stability of NH_3 complexes of alkaline earths was studied,[37,59] it had been demonstrated[13] that Eqn. (26) is valid for $Mg-NH_3$ complexes in 0–2.0 M aqueous NH_4NO_3.

*3Values of I in mol kg^{-1} H_2O in $(NH_4)_2SO_4$ solutions.

It is important that Eqn. (26) is consistent with decreased stability of the alkaline-earth–ammonia complexes as the ionic strength increases whereas this phenomenon is not observed for NH_3 complexes of other metals[1,28,62–64] with the exception of Tl^{I},[22] Pb^{II} (Ref. 65) and Ag^{I},[1] for which Eqn. (26) is applicable with negative A (Table 12).

The influence of $[NH_3]$ on the equilibrium constant for the hydrolysis (K_h) of hexaamminecobalt(III) has been studied.[66–68] It follows the equation

$$Co(NH_3)_6^{3+} + H_2O \rightleftharpoons Co(NH_3)_5OH^{2+} + NH_4^+. \quad (27)$$

The ammonia molecule does not explicitly appear in Eqn. (27). However, it has been established[66–68] that K_h in 1.0 M NH_4NO_3 decreases with increasing $[NH_3]$ ($c_{NH_3} = 2-14$ mol dm^{-3}) at 25.0 °C according to

$$-\lg K_h = 1.32 + 0.070\,(c_{NH_3} - 2.0), \quad (28)$$

which is valid with a correlation coefficient of 0.996. This equation indicates that NH_3 has little influence on equilibrium (27) at $c_{NH_3} \leqslant 2.0$ mol dm^{-3}. However, it decreases the hydrolysis of hexaamminecobalt(III) at $c_{NH_3} > 2.0$ mol dm^{-3}. This fact is important for ammonia hydrometallurgy[4,6] where hexaamminecobalt(III) is salted out by NH_3 from aqueous solutions in order to separate Ni and Cu.

Equation (28) was quantitatively explained[66] by analysing the effect of $[NH_3]$ on the molar activity coefficients of $Co(NH_3)_6^{3+}$, $Co(NH_3)_5OH^{2+}$ and NH_4^+. The dependence of $\log(y_{Co(NH_3)_5OH^{2+}} \cdot y_{NH_4^+}/y_{Co(NH_3)_6^{3+}})$ on C_{NH_3} within error limits agrees with the change of K_h from Eqn. (28).

Changing the concentration of background NH_4NO_3 from 0.25 to 6.0 mol dm^{-3} decreases $\log K_h$ from –1.18 to –2.54 (Table 13).[67] Changing NH_4NO_3 to the sulphate has no noticeable effect on $\log K_h$. Changing the temperature has a substantial effect on equilibrium (27) (Table 13).

Table 13. Effect of ionic strength, nature of background salt and temperature on equilibrium (27).[67]

Background salt	Ionic strength	T, °C	$-\lg K_n$	Background salt	Ionic strength	T, °C	$-\lg K_n$
NH_4NO_3	0.25	25.0	1.18	$(NH_4)_2SO_4$	1.0	25.0	1.33
	0.50	25.0	1.25		2.0	25.0	1.65
	1.0	25.0	1.35		3.0	25.0	1.89
	2.0	25.0	1.69		4.0	25.0	2.50
	3.0	25.0	1.91		1.0	15.0	1.70

IV. Thermodynamic functions of metal—ammonia complexation

Much handbook data is available for the composition and stability constants of metal—ammonia complexes in aqueous solutions.[8–12] A significant part of this information in addition to data for the enthalpy and entropy changes on formation of $M(NH_3)_n(H_2O)^{z+}_{N-n}$ is contained in tables of critically selected, i.e. recommended values.[10,11] However, many mistakes were found through a comparison of these tables. For example, the critical values for an unknown reason include the incorrect stability constant of the Tl^{I} monoammine complex (Ref. 10, p. 41), which varies with increasing $[NH_3]$ in 2.0 mol dm^{-3} aqueous NH_4NO_3 (Ref. 1, p. 183). Approximate stability constants of Li,[51] Mg and Ca[37] ammonia complexes are found in these same tables.[10] The enthalpy and entropy changes for formation of $Mg(NH_3)_n^{2+}$ that are included in the critical tables are also inaccurate.[10]

Unfortunately, it is difficult to select reliable information for the thermodynamics of complexation in solutions even by analysing in detail recent original results[69] since the experimental and mathematical details are not given in many publications.

The most correct, in our opinion, recent stepwise thermodynamic functions for formation of ammonia complexes of various metals are collected in Table 14. Several of these values appear in the critical tables[10] and have additionally been verified or first determined in our new studies.[14,28,43–51,70]

Requirements set for recommended, preliminary, dubious and incorrect complex stability constants in addition to enthalpy and entropy changes during their formation are clearly formulated in the literature.[71] However, these requirements are not fulfilled and are sometimes meaningless for some systems. For example, accurate enthalpy changes during complexation cannot be determined by two different methods, as previously recommended.[71] The correct values of these functions can only be calculated from thermochemical data. This condition is also partially valid for determining the entropy changes during complexation. It is sometimes meaningless to use two methods to determine the stepwise stability constants if the errors in one of the methods are much less than those of all others. The reasons listed above and several others produced the already noted glaring mistakes in selecting the recommended thermodynamic functions of ammonia complexes.[10] In our opinion, the number of such mistakes was held to the minimal possible in Table 14. Almost all (except Pd^{2+} and Au^{3+}) cations that stepwise form labile and comparatively stable ($\log K_1 \geqslant 1.0$) ammonia complexes are included in Table 14. All these complexes are formed through Eqn. (1) owing to the negative enthalpy component of the Gibbs free energy with (in the first coordination step) or without an entropy barrier.

The stepwise enthalpy changes of $M(NH_3)_n^{z+}$ (Table 14) do not depend on n. The enthalpies for adding a fifth NH_3 to Cu^{II}, a third and fourth to Hg^{II}, and a third to Ag^{I} and Cu^{I} are exceptions. The quantity ΔH_n for $M(NH_3)_n^{z+}$ is considered to be constant for the characteristic coordination number, which is four for Cu^{II} and two for Hg^{II}, Cu^{I} and Ag^{I}.

The entropy changes of almost all stepwise changes (within experimental uncertainty) for dications (Table 14) (except Zn) are well described by

$$\Delta S_n = \Delta S_1 + a(n-1), \qquad (29)$$

where a is a constant in the range 7—11 and ΔS_n is in J mol^{-1} K^{-1}. The constant a increases in the order $Mn^{2+} < Fe^{2+} < Co \approx Ni < Cu \approx Cd$, being 7, 9, 10 and 11, respectively. The entropy barrier

increases (Table 14) as n in $M(NH_3)_n^{2+}$ increases. The quantity $\log K_n$ decreases smoothly as n increases for all complexes listed in Table 14 (except the Zn compounds). This decrease for most systems is close to the statistical one[1] taking into account that $N = 6$.

The cation Zn^{II} exhibits an anomalous ability to complex NH_3. The stepwise stability constants for it within error limits are identical for $n = 1-4$ (Table 14). For this reason, it is practically impossible accurately to determine all of its stepwise thermodynamic functions.

Evidence has appeared[60] that addition of the fifth NH_3 to Cd^{II}, in contrast with the first four molecules, occurs with a much more negative entropy change. However, this assertion has not been verified.

Recently, the formation of ammonia complexes of Cu,[46,62] Ni^{I},[72] Co^{II}(Ref. 73) and Zn and Cd[48,74] in aqueous solutions at temperatures from 5 to 100–125 °C has been studied. Semiquantitative data[75,76] have been obtained for the stability of the ammonia complexes of Ag^{I} up to 160 °C and for Ni up to 180 °C. These polythermal investigations of NH_3 complexation were standardised to 2.0 mol dm^{-3},[46,62,75,76] 2.0 mol kg^{-1} H_2O (Ref. 48) or 5.0 mol kg^{-1} (Refs. 72, 73) aqueous NH_4NO_3. Ammonia complexes of Zn, Cd and Cu^{II} (Ref. 74) were only studied in 0.33, 0.66, 1.0 and 1.33 mol kg^{-1} H_2O solutions of $(NH_4)_2SO_4$, i.e. at constant ionic strengths of 1.0, 2.0, 3.0 and 4.0 at temperatures of 5–125 °C.

In the temperature range 5–125 °C, it was found that the dependence of $\log K_n$ on T^{-1} is nonlinear for the ammonia complexes of Cu^{II},[62] Ni^{II},[72] Co^{II} (Ref. 73) and Zn and Cd.[48] Therefore, the enthalpy changes during NH_3 complexation are variable in this temperature range. The enthalpy and entropy changes for formation of ammonia complexes of Co^{II} and Ni^{II} in aqueous salt solutions at 100 °C are given in Table 15. The experimental errors of the thermodynamic functions (Table 15) are large since these quantities were obtained from the temperature dependence of the stability constants.[77] However, a comparison of the numerical data (Tables 14 and 15) unambiguously indicates that a temperature increase causes the enthalpy component of the Gibbs energy for the NH_3 complexes of Co^{II} and Ni^{II} to become more negative. The entropy becomes more negative with increasing temperature than the enthalpy. Hence, a temperature increase decreases the stepwise stability constants of $M(NH_3)_n^{z+}$ and causes n to decrease. The conclusions about the effect of heat on the formation of ammonia complexes of Cu^{II},[46,62] Ni^{II} (Ref. 72) and Co^{II} (Ref. 73) were validated using ammonia complexes of Zn and Cd in ammonium nitrate[48] and sulphate[74] solutions as examples.

An equation of the type

$$\lg K_n = \lg K_n^0 + Al + B(T - 298), \qquad (30)$$

where K_n and K_n^0 are stepwise stability constants of $M(NH_3)_n^{z+}$ in solutions with ionic strengths I and at $I = 0$, T is the temperature and A and B are constants used in many studies (Table 12) to characterise the effect of the ammonium salt concentrations and the solution temperature on equilibrium (1). The value of A was usually constant up to $I \leqslant 6$. The constant B did not vary in the range 20–50 °C. The constants A and B for complexes of various metals are summarised in Table 12. An analysis of these constants indicates that changing from ammonium nitrate to perchlorate or sulphate or from a molar to a molal concentration scale has little effect on their values. In all systems for which data appear in Table 12, temperature increases substantially increase B.

Table 15. Enthalpy (ΔH_n, kJ mol^{-1}) and entropy (ΔS_n, J mol^{-1} K^{-1}) changes for stepwise formation of $M(NH_3)_n^{2+}$ in 5.0 mol kg^{-1} H_2O NH_4NO_3 solutions at 100 °C.[72,73]

V. Outer-sphere metal–ammonia complexes

Larsson[78–80] first studied the formation of outer-sphere ammonia complexes in aqueous solutions using Co^{III} complexes as examples

$$[Co(NH_3)_6](H_2O)_Q^{3+} + qNH_3 \rightleftharpoons [Co(NH_3)_6](NH_3)_q(H_2O)_{Q-q} + qH_2O, \qquad (31)$$

where $q = 1, 2...Q$ and Q is the limiting coordination number of the second sphere of Co^{III}. The increase of solubility of hexaamminecobalt(III) in 1.0 M aqueous NH_4ClO_4 containing 0–3.5 M NH_3 was used to demonstrate the formation of outer-sphere ammonia complexes with $q = 1$ and 2. The overall stability constants of these complexes at 20 °C are 0.24 ± 0.05 ($q = 1$) and 0.05 ($q = 2$). Only K_1, equal to 0.3 ± 0.2 for an aqueous solution with $I = 0.1$, was determined using electronic spectroscopy.[79]

Equilibria of the type (31) have often been studied using hexaammine, anionopentaammine, *tris*-ethylenediamine, and 2,2′-bipyridyl complexes of Co^{III} and Cr^{III} as examples.[80–85] However, all these investigations were carried out in dilute (usually $\leqslant 1.0$ M) NH_3 solutions. Hydrolysis of the anionopentaammine complexes was not considered. The small outer-sphere interactions enabled formation constants to be calculated only for the monoammine complexes. These often had large uncertainties that have already been discussed in detail.[13]

Wide-ranging studies[13,58,86–91] of the formation of outer-sphere ammonia complexes of Co^{III}, Cr^{III} and Pt^{IV} in solutions with $[NH_3]$ reaching 10–12 mol dm^{-3} have recently been completed. The solubility of the complexes, pH titration, electronic spectroscopy and NMR were used in the investigations. A part of the new data for the logarithms of the stepwise stability constants of the outer-sphere ammonia complexes are summarised in Table 16.

The numerical data (Table 16) indicate that the experimental data obtained by the various experimental methods (solubility, pH titration, electronic spectroscopy and NMR) that differ in principle give practically identical stepwise stability constants for the outer-sphere ammonia complexes of Co^{III}, Cr^{III} and Pt^{IV}. Unfortunately, complexes of this type with other metals have not yet been quantitatively studied. In our opinion, the lack of data on the outer-sphere coordination of NH_3 by Rh^{III}, Ir^{III}, Ir^{IV}, Ru^{II}, Ru^{III} and Os^{III} in aqueous solutions of various inner-sphere complexes of these cations represents a particular gap.

It can be seen from the stepwise stability constants (Table 16) that changing from hexaammine to *tris*-ethylenediamine Co^{III} and Cr^{III} complexes slightly decreases the stability of the outer-sphere ammonia complexes. An analogous effect is observed on replacing Co^{III} by Cr^{III}. These differences in the stepwise stability constants

Table 16. Logarithms of stepwise stability constants (K_q) of outer-sphere NH_3 complexes in aqueous solutions with constant ionic strength (I) at 25.0 °C.[91]

*1 For Co^{III} and Cr^{III} complexes taking into account $[H_2O]$ in equilibria (31), log K_q are given on a molar scale; for Pt complexes, in mole fractions.

*2 S, solubility; pH, pH titration; SP, spectrophotometry; $NMR^{59}Co$, ^{59}Co chemical shift in NMR spectra.

*3 Ignoring the dependence of the ^{59}Co chemical shift in $Co(en)_3(H_2O)_Q^{3+}$ on $[NH_3]$.

are probably due to a change of the size of the coordination spheres, i.e. the inner spheres. Increasing the crystallographic radii of the inner spheres apparently decreases the stability of the outer-sphere ammonia complexes.

It should be especially emphasised that neither hexaammine- nor *tris*(ethylenediamine)Pt^{IV} in aqueous solutions is capable of forming outer-sphere ammonia complexes. Adding NH_3 to aqueous solutions of these compounds leads firstly to deprotonisation of one of the inner-sphere NH_3 or the ethylenediamine.[86,87] Only the triply charged $Pt(NH_3)_5NH_2^{3+}$ and $Pt(en)_2(enH)^{3+}$ that result from the deprotonisation from mono- and probably diammine outer-sphere complexes. Tri- and tetraammine outer-sphere complexes of Pt^{IV} in aqueous solutions have not been detected, in contrast with Co^{III}.

The cation $Pt(NH_3)_5NH_2^{3+}$ binds NH_3 more strongly than $Pt(en)_2(enH)^{3+}$.[91] It should be emphasised that log K_q for outer-sphere $Pt^{IV}-NH_3$ complexes are greater than those of outer-sphere complexes of Co^{III} and Cr^{III}. It should also be emphasised that log K_q (Table 16) for the last ones were calculated taking into account the molar concentration of H_2O and not the mole fractions as for the other complexes examined in the present review and in the bulk of the handbooks.[8–12]

Therefore, the stability data for outer-sphere ammonia complexes given in Table 16 decrease as a function of the nature of the metal in the order $Pt^{IV} > Co^{III} > Cr^{III}$. It is possible that the asymmetry of the inner sphere is responsible for the higher strength of the outer-sphere ammonia complexes of $Pt(NH_3)_5NH_2^{3+}$ and $Pt(en)_2(enH)^{3+}$. However, we think that this assertion needs more thorough verification.

Existing data for the enthalpy and entropy changes during formation of outer-sphere ammonia complexes and for the influence of ionic strength on log K_q are extremely contradictory. Judging from the new data,[13,87] Eqn. (26), in which A is 0.54 (I = 0.1–1.0) and −0.10 (I = 0.5–6.0), is valid for monoammine complexes of hexaamminecobalt(III) and $Pt(en)_2(enH)^{3+}$. Such ionic strengths are maintained by ammonium perchlorate and nitrate.

VI. Problems and prospects of ammonia hydrometallurgy

The thermodynamics of formation and dissociation of metal–ammonia complexes in aqueous solutions determines the specifics of most industrial processes of ammonia hydrometallurgy, i.e. the leaching, purification, separation and isolation of metals.

Few cations can form labile and comparatively stable (log $K_1 \geqslant 1.0$) ammonia complexes in aqueous solutions.[92] These include such cations as Zn^{II}, Cu^{I}, Cu^{II}, Ni^{II}, Co^{II}, Fe^{II}, Mn^{II}, Cd^{II}, Ag^{I}, Pd^{II} and Hg^{II} (see Table 14). The elements forming these cations occupy a triangle in the expanded periodic table. The corners are occupied by Mn, Cu and Hg. The elements inside this triangle are leached into aqueous salt solutions of ammonia.

Ammonia hydrometallurgy is presently used to produce a large part of the Ni and Co. This is considered to be the most feasible method of treating oxidised Ni ores.[93,94] Such ores contain ~85% of the world reserves of Ni.[95] Ammonia hydrometallurgy has been used to prepare Cu,[96–99] Mn,[100] Zn[101] and Ag.[102,103]

One of the most important advantages of ammonia hydrometallurgy is the high selectivity of extracting Cu, Ni, Co, Zn and Cd over Fe and gangue. Iron extracts into ammonia–ammonium solutions only after reductive leaching as $Fe(NH_3)_n^{2+}$.[14] Under oxidative conditions, which are usually present for ammonia leaching, this cation decomposes into insoluble $Fe_2O_3 \cdot xH_2O$.

However, the ease and completeness of separating precious metals from iron by ammonia leaching entails low (50–70%) Co extraction. This is observed during processing of both sulphide[104] and oxidised[105] ores and secondary raw materials. It was found[106] that Co during ammonia leaching is first dissolved and then sorbed on Fe^{III} hydroxide.

The ammonia complexes of Ni^{II} and Co^{II} exhibit the same capability to be sorbed on Fe^{III} hydroxide. However, the losses of Co due to this are much greater than those of Ni. The principal reason for these differences involves the oxidation of sorbed Co^{II} to Co^{III} and conversion to $Co(NH_3)_5OH^{2+}$ and $Co(NH_3)_6^{3+}$. These are sorbed much more strongly than ammonia complexes of Co^{II}.

Studies of Co sorption[107–111] led to development of a feasible method for releasing Co sorbed by Fe^{III} hydroxide.[112] This method significantly increases Co leaching in ammonia–carbonate solutions, i.e. solves one of the most important problems of ammonia hydrometallurgy.

Contradictory data have been obtained for the optimal ratio of $[NH_3]$ and $[CO_2]$ and the process temperatures for autoclave winning of ores and secondary materials containing Cu, Co and Ni.[93,112–116] Changing the type of starting material probably has the largest effect on optimising these factors. However, careful investigations and computer analysis of the data[112] enabled this problem of ammonia hydrometallurgy to be solved for arsenide–arsenate ores of Cu, Co and Ni by increasing the dissolution of these metals.

Distillation of NH_3 and Co^2,[3,112,117,118] precipitation of the sulphides,[3,93,96] extraction,[7,119–122] sorption[123–126] and electrolysis[3,93,127] have been used to separate and isolate metals from ammonia solutions. For the last 20 years, the capabilities of ammonia hydrometallurgy have sharply increased owing to the incorporation of extraction methods involving new types of specific extractants for Cu, Ni, Co[121] and Ag[128] in addition to the combination of extraction with electrolysis.[120] The latter can produce high-quality Cu, Co and Ni powders if the ammonia complexes are used.[129]

In our country, the ammonia–carbonate scheme was successfully used to process high-magnesium oxidised ores of the Buruktalsk deposit.[95] This same scheme was used to process arsenide–arsenate polymetallic ores at the Tuvakobalt plant,[115,130] where a collective carbonate concentrate containing Cu, Co and Ni was produced. The Tuvakobalt plant is the only installation in our country at which ammonia hydrometallurgy is used on an industrial scale. The poor knowledge of the formation and decomposition processes of $M(NH_3)_n^{z+}$ have prevented all the capabilities of ammonia hydrometallurgy from being used. Our studies and those of our co-workers[13,14,51,62,64,72,73,112,131–138] that have been carried out in the last few years have certainly contributed to a deeper understanding of the chemistry of ammonia hydrometallurgy and have led to operating procedures at the Tuvakobalt plant that are new in principle.

It has been demonstrated[14] that As^V can be separated from Co in ammonia–carbonate solutions using the Fe found in the ore. Thus, the leaching can at first be carried out in a reducing and then in an oxidising solvent. The complex $Fe(NH_3)_n^{2+}$ forms in the reducing solvent. This converts to Fe^{III} in the oxidising solvent. The Fe^{III} then completely precipitates the arsenate. This original and simple method for highly purifying Co from As has not yet been implemented. Furthermore, a method for preparing analytically-pure grade hexaamminecobalt(III) oxalate from the distilled liquid of the Tuvakobalt plant has been found.[13] Synthesis methods of various Co salts and As compounds[112,135,136] have been developed on the basis of process solutions of this plant. The ability to prepare reactive salts of Co, Ni and Cu from the ammonia complexes by avoiding isolation of the free metals has been demonstrated. This represents the great promise of ammonia hydrometallurgy.

The combination of ammonia–carbonate distillation with sulphide precipitation of metals opened the way to produce selective Cu, Ni and Co concentrates instead of their mixture at the Tuvakobalt plant.[112] Thus, Co is practically completely separated from As, i.e. one of the important problems of hydrometallurgy was serendipitously solved.

VII. Conclusion

Stability constants and other thermodynamic functions of the ammonia complexes of many metals in aqueous solutions are experimentally difficult or impossible to determine owing to the relatively weak affinity of the cations for ligands containing nitrogen and to their comparatively high propensity to hydrolyse.[92] However, these cations form complexes suitable for studies in aqueous solutions with a number of other ligands containing nitrogen (N–L) and oxygen (O–L). Glycolate, glycinate, hydroxyacetate, iminodiacetate, maleate, asparaginate, [(2-hydroxyethyl)imino]diacetate, [(2-aminoethyl)imino]diacetate, dihydroxyethylenediacetate and ethylenediamine-*N*,*N*′-diacetate are some of the O–L and N–L ligands for which stability constants have been determined.[8–12] Formation constants of many unstudied monoammine complexes (Table 17) were calculated[92] on the basis of linear dependences of the differences of the logarithms of the first stability constants of complexes with N–L and O–L ligands on the logarithms of the stability constants of the monoammine complexes (assuming the same structure for the compared complexes). The quantities $\log K_1$ for certain of these complexes have recently been experimentally determined.[59,63–65] The calculated and experimentally determined $\log K_1$ (Table 17) are in good agreement. The predicted stability constants of the monoammine complexes are interesting for ammonia hydrometallurgy, for modelling the acid–base behaviour of metals in aqueous solutions,[139] and for a deeper understanding of the chelate[140] and macrocyclic[141] effects.

An analysis of a large body of critically selected stepwise stability constants of the ammonia complexes of Mg, Mn^{II}, Fe^{II}, Co^{II}, Ni^{II} and Cu^{II} in aqueous solutions with ionic strengths 0–6.0 (using ammonium nitrate or sulphate) in the range 5–55 °C and in a number of systems up to 125 °C yielded the empircal equation[14]

$$\lg K_n^0 = (0.751 - 0.0611n)E_2 + 0.597n - 10.468 + aI - b(T - 298), \quad (32)$$

in which $n = 1-6$ (for Cu^{2+} $n = 1-4$) and E_2 are the second ionisation potentials of the analysed metals. This equation enables the stepwise stability constants to be calculated under any of the aforementioned conditions using the constants a and b from Table 12. Reliable information on the mole fraction of $M(NH_3)_n^{z+}$ can be obtained from stability constants calculated using Eqn. (32) under conditions encountered in processes of ammonia hydrometallurgy.[4,6,93]

It is thought (Ref. 121, p. 7) that ammonia processing of ores (at least those containing Cu, Co and Ni) will soon become one of

Table 17. Predicted ($\log K_1^{II}$)[92] and experimental ($\log K_1^0$) stability constants of $M(NH_3)^{z+}$ in aqueous solutions at 25 °C.

M^{z+}	$\lg K_1^n$	$\lg K_1^0$	M^{z+}	$\lg K_1^n$
Ba^{2+}	−0.15	−0.11±0.03 (Ref.59)	Ga^{3+}	4.1
Cr^{2+}	1.51*	–	In^{3+}	4.0
Mn^{2+}	0.8	0.84±0.01 (Ref.63)	La^{3+}	0.2
Fe^{2+}	1.4	1.40±0.02 (Ref.64)	Lu^{3+}	0.7
Fe^{3+}	3.8	–	Sc^{3+}	0.7
Pb^{2+}	1.6	1.66±0.03 (Ref.65)	Y^{3+}	0.4
Bi^{3+}	5.0	–	UO_2^{2+}	2.0

* $\log K_1^{II}$ are calculated using Eqn. (32).[14]

the most important methods of hydrometallurgy. In our opinion, such thinking is hardly justified. However, the appearance of many studies[143–151] with novel approaches attests to the promise of ammonia hydrometallurgy for solving problems connected with processing of secondary raw materials and oxidised ores. Unfortunately, the unique capabilities of ammonia hydrometallurgy are not fully utilised although 60% of Ni is obtained using ammonia solutions in hydrometallurgy.[143]

Construction of "M^{z+} activity–pH" graphs, where M^{z+} is Co, Ni, Cu,[152] Mn[153] and Fe,[154] enabled the mechanism of many processes of ammonia hydrometallurgy in aqueous salt solutions to be unravelled and a number of improvements to be made in them. The separation of metals through the production of two phases in solutions of ammonium sulphate and carbonate after their saturation with NH_3, i.e. in effect "extraction without an extractant",[150] the leaching of metals by NH_3 in sulphite–carbonate solutions,[149] the widespread use of Caron processes[144] in combination with extraction[121,148] and the application of autoclaves[143] may become very fruitful directions for future development of ammonia hydrometallurgy.

Conductometry of electrolyte solutions

L P Safonova, A M Kolker
Institute of Chemistry of Nonaqueous Solutions, Russian Academy of Sciences, Ivanovo

ABSTRACT. A review is given of the theories of the electrical conductance of electrolyte solutions of different ionic strengths and concentations, and of the models of ion association. An analysis is made of the methods for mathematical processing of experimental conductometric data. An account is provided of various theories describing the dependence of the limiting value of the ionic electrical conductance on the properties of the solute and solvent

Introduction

Conductometry, i.e. measurement of the electrical conductivity, is used widely in fundamental investigations of electrolyte solutions and in tackling many applied problems. It is one of the simplest and yet most accurate methods for the investigation and analysis of substances. It makes it possible to carry out studies over a wide range of temperatures, pressures, and electrolyte solutions (from strongly dilute to melts), and this can be done using practically any solvent. The fact that the electrical conductance of electrolyte solutions can be measured with a high degree of precision at low concentrations makes it possible to apply quite rigorous theories and model representations which can give information on the state of particles in a solution, their effective size, mobility, and association. Combination of the conductometric method with determination of the transport (transference) numbers makes it possible to find the transport characteristics of individual ions without making any assumptions.

Many monographs and reviews have been published on the conductometric method.[1–9] However, the majority of them concentrate on the theory and practice of the determination of the resistance of electrolyte solutions and less prominence is given to theoretical interpretations of the results obtained. The present review therefore stresses a theoretical description of the dependence of the electrical conductance of an electrolyte solution on the concentration, temperature, pressure, and properties of the solvent, and also the problems encountered in mathematical processing of the experimental results, particularly selection of a suitable algorithm needed to find the parameters of interest.

II. Dependence of the electrical conductance on concentration

The existing theory of electrolyte solutions is incapable of describing, from a unified point of view, the concentration dependence of the electrical conductance of an electrolyte solution throughout the full range of compositions. There are different approaches to the interpretation of the electrical conductance of strong and weak electrolytes.

1. Dilute solutions of strong electrolytes

The theoretical problems of interpretation of the concentration dependence of the electrical conductance of dilute electrolyte solutions were considered by Onsager. The Onsager theory is based on the hypothesis that the limiting velocity v of an ion is determined by the action of three forces: 1) an external force eE; 2) average interionic forces F_r responsible for what is known as the relaxation effect; 3) forces of electrophoretic drag F_e which arise because the motion of a central ion does not occur in an immobile medium but in a medium moving in the opposite direction to this ion:

$$v = v_e + u_0(eE + F_r),$$

where v_e is the velocity of an ion under the action of the electrophoretic forces F_e; u_0 is the mobility of an ion at infinite dilution

$$u_0 = \frac{v_0}{E} = \lambda^0/zeF,$$

F is the Faraday; z is the charge of the ion.

The forces exerting the drag on an ion can be defined in terms of the distribution functions f and the pair interaction potentials U. Therefore, the theoretical problem of the electrical conductance reduces to estimating these quantities. The pair distribution functions f_{ij} and f_{ji} can be calculated by solving the continuity equation

$$-\frac{\partial}{\partial t} f_{ji} = \nabla_P f_{ij} \vec{V}_{ij} + \nabla_0 f_{ji} \vec{V}_{ji} = -\frac{\partial}{\partial t} f_{ji},$$

where $\vec{V}_{ij}$ and $\vec{V}_{ij}$ are the velocities of two particles; ∇_P and ∇_Q are the nabla operators acting in the vicinity of the points P and Q.

The continuity equation given in Ref. 10 contains the distribution functions for two, three, and four particles. A similar equation was obtained by Ebeling[11,12] directly from the Liouville equation.[13] This makes it possible to find the relationship between the Onsager approach to the problem of the electrical conductance from the point of view of diffusion and using an approach based on statistical physics.

When weak electric fields are applied to a system (as in measurements of the electrical conductance) the velocity of a charged particle can be regarded as directly proportional to the electric field E. This assumption makes it possible to solve the continuity equation by introducing the following approximations:

$$f_{ij} = f_{ij}^0 + f_{ij}',$$

$$\psi_i = \overset{0}{\psi_i} + \psi_i,$$

where ψ_i is the potential of the mean force; f^0 and ψ^0 are quantities corresponding to the equilibrium state; f' and ψ' are the contributions due to the presence of an external electric field. The relationship between the pair distribution function and the mean-force potential can be described by the Poisson–Boltzmann equation. The selection of U_{ij} and f_{ij}^0, and of the appropriate boundary conditions, for solving the continuity equation, together with the different degrees of precision of this solution are the reasons for the multiplicity of equations proposed for the concentration dependence of the molar electrical conductance, such as the equations proposed by Pitts,[14] Fuoss, Onsager and Skinner,[15] Fuoss and Hsia,[16] Quint and Viallard,[17] Chen,[18] etc.

In their most general form all the equations describing the electrical conductance on the basis of the Debye–Hückel–Onsager theory can be represented as follows:

$$\lambda = \lambda^0\left(1 + \frac{\Delta X}{X}\right) + \Delta\lambda_e, \qquad (1)$$

where $\Delta X/X$ and $\Delta\lambda_e$ represent, respectively, the relaxation and electrophoretic contributions to the electrical conductivity. We can find the interpretation of $\Delta X/X$ and $\Delta\lambda_e$ in the original papers.

One primitive model considers the behaviour of a solid charged unpolarisable sphere of radius a_j in a continuum whose permittivity ε and viscosity η are the same as in the bulk of the solvent. When equations based on this primitive model are used, it is assumed initially that an electrolyte is fully dissociated and association is considered only at the second stage using the law of mass action. Dielectric saturation is ignored and the bulk value of ε is used right up to $r = a_{ij} = R$ (which is the distance of closest approach of the ions).

Expanding $\Delta X/X$ and $\Delta\lambda_e$ as a series in terms of the concentration, we can reduce Eqn. (1) to

$$\lambda = \lambda^0 - Sc^{1/2} + Ec\ln c + I_1 c + I_2 c^{3/2} + \ldots, \qquad (2)$$

where $S = \alpha^0\lambda^0 + \beta^0$, (2a)

$$E' = E_1'\lambda^0 - hE_2', \qquad (2b)$$

$$I_1 = \sigma_1\lambda^0 + \sigma_2, \qquad (2c)$$

$$I_2 = \sigma_3\lambda^0 + \sigma_4. \qquad (2d)$$

The coefficients S and E' can be calculated from the following relationships:

$$\alpha^0 = \frac{kab}{3\sqrt{c}}\frac{1/2}{1+1/\sqrt{2}} = \frac{kab}{3\sqrt{c}}0.29282 = 8.2042\cdot10^5(\varepsilon T)^{-3/2}, \qquad (3a)$$

$$\beta^0 = \frac{Fe|z|}{3\pi\eta C}\frac{k}{\sqrt{c}} = 82.4907\eta^{-1}(\varepsilon T)^{-1/2}, \qquad (3b)$$

$$E_1' = \frac{\beta^2k^2}{24c} = 2.9437\cdot10^{12}(\varepsilon T)^{-3}, \qquad (3c)$$

$$E_2' = \frac{\beta k\beta^0}{16\sqrt{c}} = 43.3244\eta^{-1}(\varepsilon T)^{-2}, \qquad (3d)$$

$$\beta = ab = (ze)^2/\varepsilon kT = 1.6712\cdot10^{-3}(\varepsilon T)^{-1}, \qquad (3e)$$

$$\frac{k}{\sqrt{c}} = \left[\frac{8\pi N(ze)^2}{1000\varepsilon Tk}\right]^{1/2} = 5.02956\cdot10^9(\varepsilon T)^{-1/2}, \qquad (3f)$$

$$\sigma_1 = 2E_1'\Delta_1,\ \sigma_2 = 2E_2'\Delta_2,\ \sigma_3 = -ZE_1'\Delta_3,\ \sigma_4 = -ZE_4'\Delta_4,\ Z = \frac{k\beta}{\sqrt{c}}.$$

The expressions for $\Delta_1 - \Delta_4$ and the values of h obtained using various theories are as follows:

Pitt (Ref.14)

$$\Delta_1 = \frac{2}{b} + 1.7718 + \ln Z,$$

$$\Delta_2 = \frac{8}{b} + 0.01387 - \ln Z,$$

$$\Delta_3 = \frac{5.1716}{b} + 6.2928,$$

$$\Delta_4 = \frac{16}{\beta_0 b} + 1.25248,$$

$h = 1$;

Quint–Viallard (Ref.17)

$$\Delta_1 = \frac{2}{b} + \frac{2}{b^2} - \frac{1}{b^3} + 0.9074 + \ln Z,$$

$$\Delta_2 = \frac{1}{b^2} + \frac{35}{6b} - 1.6764 - 2\ln Z,$$

$$\Delta_3 = \frac{3.8048}{b^2} + \frac{4.4296}{b} + 1.6094,$$

$$\Delta_4 = \frac{34}{3b} - 3.7844,$$

$h = 2$;

Fuoss–Hsia (Ref.16)

$$\Delta_1 = \frac{2}{b} + \frac{2}{b^2} - \frac{1}{b^3} + 0.9074 + \ln Z,$$

$$\Delta_2 = \frac{22}{3b} + 0.01422 - \ln Z,$$

$$\Delta_3 = \frac{3.8284}{b^2} + \frac{4.4748}{b} + 0.6094,$$

$$\Delta_4 = \frac{4}{3b^2} + \frac{16.3906}{b} + 2.6883 - 1.2922b + \frac{\beta_0}{Z\lambda^0}\left(\frac{4}{3} - 2.2194\right),$$

$h = 1$;

Fuoss–Justice–Chen (Ref.19)

$$\Delta_1 = \frac{2}{b} + \frac{2}{b^2} - \frac{1}{b^3} + 0.9074 + \ln Z,$$

$$\Delta_2 = \frac{1}{b^2} + \frac{35}{3b} - 1.0344 - 2\ln Z,$$

$$\Delta_3 = \frac{3.8284}{b^2} + \frac{4.4748}{b} + 0.6094,$$

$$\Delta_4 = \frac{34}{3b} - \frac{2}{b^2} - 1.3693,$$

$h = 2$.

The role of the ion–ion interactions increases on increase in the concentration and on reduction in the permittivity. This leads to association of ions, which lowers the electrical conductance of electrolyte solutions. Then Eqns. (1) and (2) assume the following form if we allow for the degree of dissociation of an electrolyte α:

$$\lambda = \alpha\left[\lambda^0\left(1 + \frac{\Delta X}{X}\right) + \lambda_e\right], \qquad (4)$$

$$\lambda = \alpha\left[\lambda^0 - S(\alpha c)^{1/2} + E'\alpha c\ln(\alpha c) + I_1\alpha c + I_2(\alpha c)^{3/2} + \ldots\right]. \qquad (5)$$

However, investigators are interested more in finding not the degree of dissociation of an electrolyte but the association constant:

$$K_a = \frac{(1-\alpha)\gamma_a}{\alpha^2 c\gamma_\pm^2}, \qquad (6)$$

where γ_a is the activity coefficient of ion pairs (usually assumed to be unity): $\gamma_\pm$ is the mean-ion activity coefficient, which is usually calculated employing the Debye–Hückel theory

$$\gamma_\pm = \exp\left(-\frac{qk}{1+kR}\right), \tag{7}$$

where $q = \beta/2$.

It should be pointed out that when Eqns. (4) and (5) are used the coefficient should be interpreted bearing in mind that $c_i = \alpha c$. Fuoss[20] showed that when the series of parameters λ^0, K_a, and R are used, the values of the electrical conductance calculated from Eqn. (1) are always less than those obtained using the exact expression (2), and they agree satisfactorily with one another only up to $kR \approx 0.2$.

Justice[21] suggested making the parameter I_2 in Eqn. (5) a fitting variable and thus allowing for all the inaccuracies associated with calculation of the exponential integral. It should be pointed out that the validity of Eqns. (4) and (5) is limied to the maximum electrolyte concentration corresponding to the condition $kq \approx 0.5$.

Fuoss[22] and Lee and Wheaton[23–25] proposed equations describing the electrical conductivity on the basis of a more realistic physical picture than the primitive model described above. In the model of Lee and Wheaton it is assumed that an ion is surrounded by three different regions: in the first ($a_j < r < R_j'$, where a_j is the crystallographic radius of an ion) the solvent molecules are oriented in the electric field of an ion and the dielectric saturation effect applies; in the second region ($R_j' < r < R_j$, where R_j is the radius of the Gurney co-sphere of an ion[26]) the structure of the solvent is still modified by the field of the ion and the permittivity is not equal to the bulk value; in the third region ($r > R_j$) the properties of the solvent are the same as in the bulk.

In this way Lee and Wheaton allow for the dielectric saturation effects and also include the concept of ion association right from the beginning. This leads to the following equation

$$\lambda = \alpha\left\{\lambda_0\left[1 + C_1\beta k + C_2(\beta k)^2 + C_3(\beta k)^3\right] - \frac{\rho k}{1+t}\left[1 + C_4\beta k + C_5(\beta k)^2 + \frac{t}{12}\right]\right\}, \tag{8}$$

$$C_1 = \frac{\left(1-1/\sqrt{2}\right)\left[1\left(1+1/\sqrt{2}\right)t/2\right]}{3k_0k_3},$$

$$C_2 = -\frac{1}{24k_0k_3}\left[\frac{2\left[Tr\left(2+1/\sqrt{2}\right)t + 1/2\right]}{k_0} + \frac{H_1(t)}{k_3}\right],$$

$$H_1(t) = \left\{-1.91421356 - 1.35355t - 0.198t^2 - 3k_3Tr\left[\left(1+1/\sqrt{2}\right)t\right] + 4k_3k_2Tr(t) - k_1k_2Tr\left(t/\sqrt{2}\right)\right\},$$

$$C_3 = \frac{\left(3+1/\sqrt{2}\right)Tr\left[\left(3+1/\sqrt{2}\right)t\right]}{36k_0k_3\left(1+1/\sqrt{2}\right)},$$

$$C_4 = -\left\{H_2(t)/2 + \frac{\left[1+\left(1+1/\sqrt{2}\right)t/2\right]}{6k_0k_3\left(1+1/\sqrt{2}\right)}\right\},$$

$$H_2(t) = \left\{-Tr(t)/2 + \frac{3Tr\left[\left(1+1/\sqrt{2}\right)t\right]}{4k_3} + 0.436886 - 0.3085t\right\},$$

$$t = kR,\ \rho R = \beta_0(\alpha c)^{1/2},$$
$$k_0 = 1 + t,\ k_1 = 1 + t + t^2/2,\ k_2 = 1 + t/\sqrt{2},\ k_3 = 1 + t/\sqrt{2} + t^2/4.$$

In Ref. 27 the coefficients $C_1 - C_5$ are represented as a series in terms of t and $\ln t$, which is accurate to within 0.01% in the range $0.005 < t < 0.7$:

$$C_1 = -0.09753 + 0.08185t - 0.044144t^2 + 0.01114t^3,$$
$$C_2 = 0.11798 - 0.18737t + 0.09052t^2 - 0.02393t^3 + 0.08358\ln t,$$
$$C_3 = -0.19454 + 0.39764t - 0.37557t^2 + 0.25118t^3 - 0.07843t^4 - 0.10296\ln t,$$
$$C_4 = -0.04724 + 0.06445t - 0.07419t^2 + 0.01784t^3 + 0.12428\ln t + 0.09863t\ln t,$$
$$C_5 = 0.84185 - 0.90051t + 0.07809t^2 - 0.05333t^3 + 0.50097\ln t + 0.45252t\ln t.$$

In Refs. 22 and 28 Fuoss proposed an equation describing formation of ion pairs separated by solvent and those in direct contact:

$$M^+ + A^- \underline{K}_1 (M^+ \ldots A^-) \underline{K}_2 M^+A^-.$$

If α_1 is the fraction of free ions and α_2 is the fraction of contact ion pairs, the equation describing the electrical conductivity becomes

$$\lambda = [1 - \alpha_2(1-\alpha_1)]\left[\lambda^0\left(1 + \frac{\Delta X}{X}\right) + \Delta\lambda_e\right]. \tag{9}$$

Formation of ion pairs separated by solvent is described by the expression

$$K_1 = \frac{(1-\alpha_1)(1-\alpha_2)}{c\alpha_1^2\gamma_\pm^2},$$

whereas the formation of contact pairs from solvent-separated ones is given by

$$K_2 = \frac{\alpha_2}{(1-\alpha_2)}.$$

The association constant is

$$K_a = K_1(1 + K_2).$$

According to Fuoss, all the short-range effects can be represented by a single parameter LK_2 which can be calculated from

$$K_2 = \exp\left[\frac{\Delta E_s}{kT}\right],$$

where ΔE_s is the difference between the energies of the ions in the states $r = R$ and $r = a$.

An analysis of the experimental results using Eqn. (9) reduces to solution of the equaiton $\lambda = \lambda(c, \lambda^0, R, E_s)$. The value of K_1 is calculated on condition that R is known using the Fuoss equation for the association constant [Eqn. (28)].

Ebeling and his colleagues[29–31] used nonequilibrium thermodynamics and statistical physics in combination with the mean-sphere approximation and the law of mass action to propose the following equation for the electrical conductance:

$$\lambda = a\lambda^0[1 + S^{Rel}(t, b) + S^{Int}(t, b) + S^{Ext}(t, b)], \tag{10}$$

where

$$S^{Rel}(t,b)=\frac{1}{6\sqrt{2}tb}\left[2-2b+\sqrt{2}tb-t^2\right]-\frac{\exp(-\sqrt{2}t)}{6\sqrt{2}tb}\left[2-2b+\right.$$

$$\left.+\ 2\sqrt{2}t-\sqrt{2}tb+t^2\right]+\frac{1}{3(1+\Gamma R)^2}\left[\left(1+\frac{t}{\sqrt{2}}-b\right)\exp\left(\frac{2-\sqrt{2}t}{2}t\right)\right.$$

$$\left.-1-t+b\right]-\frac{t^2}{12b}\left(\frac{1}{3}+b\right)(1+t-b)\exp(-t),$$

$$\frac{S^{Int}(t,b)}{h}=\frac{tb}{2}E_i\left(-\frac{t}{\sqrt{2}}\right)\left[\left(\sqrt{2}-t\right)\exp\left(\frac{t}{\sqrt{2}}\right)-\left(\sqrt{2}+t\right)\exp\left(-\frac{t}{\sqrt{2}}\right)\right]-$$

$$-\frac{\exp(-\sqrt{2}t)}{t}\left[\left(\sqrt{2}+2t+\frac{t^2}{\sqrt{2}}\right)b-2\sqrt{2}-4t-\sqrt{2}t^2\right]+$$

$$+\frac{\sqrt{2}}{t}\left[\left(1-\frac{t^2}{2}\right)b-2+t^2\right]+\frac{2b^2\exp(t)}{(1+\Gamma R)^2}\left[\frac{t^2}{2}E_i\left(-\frac{t^2}{\sqrt{2}}\right)-t^2E_i(-t)+\right.$$

$$\left.+\left(1-\frac{2}{b}+\frac{t}{\sqrt{2}}-\frac{\sqrt{2}t}{b}\right)\exp\left(-\frac{t}{\sqrt{2}}\right)-\left(1-\frac{2}{b}+t\frac{2t}{b}\right)\exp(-t)\right]-t^2\left(\frac{1}{3}+b\right)$$

$$\left[\frac{t^2b}{2}E_i(-t)-\left(1-\frac{b}{2}+t-\frac{tb}{2}\right)\exp(-t)\right],$$

$$S^{Ext}(t,b)=-\frac{8tbh}{(1+\Gamma R)^2},$$

$$\Gamma R=\frac{1}{2}(1+2t)^{1/2}-\frac{1}{2},$$

$$h=\frac{\varepsilon kTN}{3\pi\eta\lambda^0\cdot 9\cdot 10^{11}}=\frac{H}{\lambda^0},\ H=1.226956\cdot 10^{-6}\varepsilon T/\eta;$$

$$E_i(-x)=0.577215665+\ln(-x)+\sum_{n=1}^{\infty}\frac{(-x)^n}{n\cdot n!},\quad b=\frac{\beta}{R}.$$

In calculation of the degree of association in this approach the constant is obtained from the Ebeling equation[32]

$$K_a=8\cdot 10^3\pi R^3N\sum_{m=2}^{\infty}\frac{q^{2m}}{(2m)!(2m-3)},\qquad(11)$$

and the mean ion activity coefficient is found from the mean-sphere approximation

$$\ln\gamma_{\pm}=-\frac{10^3t}{4\pi cNR^3}\left[1+2t-(1+2t)^{1/2}\right].\qquad(12)$$

It should be stressed that all the equations given above describe only the concentration dependences of the electrical conductance of symmetric electrolytes.

The choice of one or another theoretical equation for the calculation λ^0, K_a, and R is quite subjective. The majority of these equations give the same value of λ^0, but the values of K_a agree only to within an order of magnitude. Therefore, a correct analysis of the dependences of the conductometric parameters on the temperature of an electrolyte solution and on the ion radius should involve treatment of all the experimental data on the basis of the same equation.

In obtaining reliable values of λ^0 and K_a it is important not only to select in a reasoned manner a theoretical equation, but also a mathematical approach for its solution.

All the equations given above can be represented in the form

$$\lambda_i=f(c_i,\varepsilon,\eta,T,|z|,\lambda^0,K_a,R),$$

where λ_i is the molar electrical conductance of a symmetric electrolyte with the ion charge z and a molar concentration c_i; ε is the permittivity and η is the viscosity of the solvent at a temperature T; λ^0, K_a, and R are the unknown parameters.

The task then reduces to finding such λ^0, K_a, and R that the values of the electrical conductance calculated on the basis of theoretical equations are as close as possible to the experimental data. We shall bear in mind that an analysis of the experimental data using the above equations for the electrical conductance may be carried out only within a certain range of concentrations. Since these equations are based on the concept of formation of ion pairs, the upper limit to the concentration range is limited by that value at which associates of higher orders can be ignored. An approximate estimate of the upper concentration limit can be obtained (ignoring the degree of dissociation) using the relationship $kq \approx 0.5$,[10] which corresponds to $c_{max} = 1.4 \times 10^{-4}(\varepsilon T)^3$. The lower limit of the concentration is set by the experimental capabilities and it is usually $(0.5-1.0) \times 10^{-4}$ mol/dm^3. Moreover, it is important to stress that the values of upper and lower limits of the concentration range should differ by at least one order of magnitude.

From the mathematical point of view the finding of the unknown parameters (λ^0, K_a, R) reduces to solution of a redundant system of nonlinear equations: a) the concentration dependence of the electrical conductance [Eqns (5), (8), and (10), or others]; b) the law of mass action [Eqn. (6)]; c) the expressions for the mean ion activity coefficient [Eqns. (7) and (12)]. The solution of a system of such equations is then obtained by minimisation of the function

$$\sigma(\lambda)=\sum_{i=1}^{n}\omega_i(\lambda_i^{calc}-\lambda_i^{exp})^2/(n-m-1),\qquad(13)$$

where n is the number of experimental points; m is the number of unknown parameters; ω_i is a weighting coefficient.

The coefficient ω_i is usually assumed to be 1, but since the precision of the experimental data decreases on reduction in the solute concentration, Kay et al.[33] suggested using a weighting coefficient proportional to $c^{1/2}$. A more rigorous way of calculating the weighting coefficient for each point involves using the overall r.m.s. deviation $\omega = 1/\sigma_\lambda$.

The solution of the problem of minimisation of the function $\delta(\lambda)$ is most frequently tackled employing the nonlinear least squares method, which is not difficult when using modern computers.

One should point out however that calculations carried out by the method of least squares require the knowledge of the derivatives with respect to the parameters being sought. Analytic differentiation of such complex dependences as the equations describing the electrical conductance meets with certain difficulties. Therefore, these derivatives are frequently found by numerical differentiation but this increases the computer time. However, the derivatives with respect to λ^0 and K_a can be obtained employing the approximate equation

$$\left(\frac{\partial\lambda}{\partial K_a}\right)=-\frac{\gamma_{\pm}^2c\alpha}{(1+K_a\gamma_{\pm}^2c\alpha)}.$$

If we employ the Lee–Wheaton equation, then

$$\left(\frac{\partial\lambda}{\partial K_a}\right)\simeq\frac{E_s c\alpha}{\left(1+K_a\gamma_\pm^2 c\alpha\right)},$$

where $E_s c\alpha$ corresponds to the expression in the first square brackets of Eqn. (8).

If we use an equation of the (5) type, then

$$\left(\frac{\partial\lambda}{\partial K_a}\right)\simeq\frac{1-\alpha^0(\alpha c)^{1/2}+E_1'(\alpha c)\ln(\alpha c)+\sigma_1\alpha c+\sigma_3(\alpha c)^{3/2}}{\left(1+K_a\gamma_\pm^2 c\alpha\right)}.$$

If we employ Eqn. (1), then

$$\left(\frac{\partial\lambda}{\partial K_a}\right)\simeq\alpha\left(1+\frac{\Delta X}{X}\right).$$

We can in this way obtain derivatives with respect to λ^0 also from Eqn. (10).

In tackling such problems one may encounter cases when the derivatives with respect to K_a and R have opposite signs. Consequently, the search for a minimum may continue indefinitely. Moreover, in the case of some of the theoretical equations for the electrical conductance [Fuoss–Hsia or Fuoss (1975)] the dependence $\sigma(\lambda) = f(R)$ may have two minima in the range of physically reasonable values of R,[10] which in the opinion of these authors is related to the internal inconsistency of the equations themselves. Moreover, in solutions of specific problems it is frequently found that there is a wide range of values of K_a and R which yield practically the same value of $\sigma(\lambda)$. Difficulties are therefore encountered in an analysis of the data for such systems.

Such difficulties can be avoided either by varying R, as suggested by Fuoss[22] [then the values of λ^0, K_a, and R are selected on the basis of an analysis of the dependence $\sigma(\lambda) = f(R)$] or by reducing the problem to one with two parameters by selecting a physically reasonable value of R (it is usually the Bjerrum distance, equal to the sum of the crystallographic radii of ions and the diameter of the solvent molecule). It should be pointed out that many of these shortcomings are avoided also if the problem of minimisation is solved by the direct search method (Powell, deformed polyhedron, Rosenbrock, coordinate descent, and other methods[34]). However, in contrast to the least-squares method, the direct search methods do not yield the standard errors of the required parameters.

In tackling the task of minimisation of the function (13) we need to know the initial approximations in respect of the required parameters. In the case of λ^0 we can find this quantity approximately by: a) graphical extrapolation of the function $\lambda_i = f(c^{1/2})$ to zero concentration; b) from the Walden rule ($\lambda^0\eta_0$ = const); c) from the Fuoss–Kraus[35] or Shedlovsky[36,37] equations. The first approximation for K_a can be selected either from the Ostwald equation (if we specify λ^0 first), which gives

$$K_a=\frac{(\lambda^0)^2(1-\lambda/\lambda^0)}{c\lambda^2},$$

or from the Fuoss–Kraus and Shedlovsky equations. The first approximation for R is frequently taken to be the sum of the crystallographic radii of the ions.

We can find also other approaches to the solution of the electrical conductance equation in the published literature. They are based on a selection of an analytic relationship between K_a and R, so that the task of minimisation can be reduced to a two-parameter problem. However, we must then bear in mind that the selection should be based on the same model which underlies the theoretical equation for the electrical conductance. This approach is employed most frequently in Refs. 12, 29, 30, and 38 when the relationship between K_a and R is of the type given by Eqn. (11). On the other hand, in using the Lee–Wheaton equation the best grounded is the expression for K_a which allows for the short-range effects [Eqn. (32)]. Therefore, the number of the unknown parameters does not decrease and one of them (K_a) is simply replaced with another (U^*).

An approach developed by Justice[21] is also very popular and it involves solving equations of the (5) type. The fitting parameters are then λ^0, K_a, and I_2; the values of I_1 and $\gamma_\pm$ are then calculated on the assumption that R is equal to the Bjerrum distance (q).

The descriptions of the algorithms and the computer programs used in an analysis of conductometric data can be found in a number of original papers.[25,27,39–41]

All the equations given above describe the concentration dependence of the electrical conductance of symmetric electrolytes. In the case of solutions of asymmetric electrolytes (particularly asociated solutions) or mixtures of electrolytes the number of suggested equations is considerably less, although such solutions are encountered more frequently (they include natural water, solutions used in various technologies, etc.). The first attempts to provide a quantitative description of the electrical conductance of asymmetric electrolytes were made by Righellato and Davis,[42] and by Fuoss and Edelson.[43] The equations derived for associated 2–1 (or 1–2) electrolytes are based on the limiting Onsager law and on a number of other assumptions. Subsequently, Quint and Vialliard,[17] Murphy and Cohen,[44] and Chen[18] used the framework of the primitive model to calculate more accurately the contributions of the electrophoretic and relaxation effects to the electrical conductance of solutions of asymmetric and mixed electrolytes. The final equations for the electrical conductance can be found in the original papers. We shall give here the equation of Lee and Wheaton[23,24] obtained on the basis of their new model of a solution containing s types of charged particles:

$$\lambda(j)=\lambda^0(j)\left\{1+z_j\sum_{p=2}^{s}\chi_j^p\sum_{\nu=1}^{s}t_\nu\chi_\nu^p\left[A_\nu^p(t)(\beta k)+B_\nu^p(t)(\beta k)^2+C_\nu^p(t)(\beta k)^3\right]\right\}-$$

$$-\frac{|z_j|\beta^0 c_j^{1/2}}{(1+t)}\left[1+V_j^{(1)}(t)(\beta k)+V_j^{(2)}(t)(\beta k)^2+\Pi_j^{(3)}t/6\right], \qquad (14)$$

$$\lambda=\sum_{j=1}^{s}\left(|z_j|c_j\lambda(j)/c\right).$$

An interpretation of the coefficients in Eqn. (14) can be found in Ref. 24. However, even such a complex equation is only approximate and the expressions for C_ν^p and $V_j^{(2)}$ are incomplete.

The simplest case in which we can apply Eqn. (14) is that of 2–1 electrolytes in which ions are associated in accordance with the scheme

$$K^{2+} + A^- \leftrightarrow KA^+.$$

In the case of such a solution we find that Eqn. (14) contains five unknown parameters: the values of the limiting electrical conductance of three ions, K_a, and R. In the presence of such a

large number of unknown parameters the solution of the above equation becomes multivalued. It was shown in Refs. 27 and 45 how the number of unknown parameters can be reduced to three and in Ref. 41 an algorithm was given for calculation of the parameters of complex associated and asymmetric electrolytes.

We described above the most frequently employed theoretical approaches to the description of the electrical conductance of dilute solutions of weakly associated electrolytes. We must stress again that all these equations give practically the same value of λ^0, whereas the values of K_a are in agreement only to within an order of magnitude. As far as the parameter a (or r) is concerned, we can *a priori* expect its value to depend on the nature of the equation, because it is governed by the selection of the boundary conditions and the mathematical approximations adopted in the treatment. Moreover, we cannot expect the parameter R to have a real physical meaning if we use equations based on the primitive model because the model itself does not describe reality. Therefore, an experimentalist should bear in mind that the conductometric parameters can be compared only if they are obtained on the baiss of the same equation.

Several statistical-mechanical theories have been put forward recently and they make it possible to describe quite rigorously the transport properties of electrolyte solutions right down to the average concentrations.[30,46–49] However, the equations derived using such theories are too complex for practical use.

2. Concentrated electrolyte solutions

There is as yet no theoretically rigorous equation for the description of the electrical conductance of concentrated electrolyte solutions. Therefore, the transport properties of such solutions are being interpreted on the basis of three main approaches: 1) 'generalisation' of equations for dilute solutions by introduction of empirical terms; 2) use of the equations applicable to molten salts; 3) description of the experimental data by purely empirical or semi-empirical equations. Among the first group of equations tl most widely used is the equation of Robinson and Stokes[1], corrected for the viscosity and allowing for the influence of the relaxation effect, as estimated by Falkenhagen et al.:[51]

$$\lambda = \left(\lambda^0 - \frac{\beta^0\sqrt{c}}{1+ka}\right)\left(1 - \frac{\alpha^0 F\sqrt{c}}{1+ka}\right)\frac{\eta_0}{\eta}, \qquad (15)$$

where $F = [\exp(0.2929ka) - 1]/(0.2929ka)$.

Equation (15) describes satisfactorily the electrical conductance of some salts in water up to concentrations of 5–6 mol/litre,[52,53] whereas in the case of other salts there is no satisfactory agreement[54] even at concentrations less than 1 mol/litre. In all probability this equation works well as long as the ratio η/η_0 is small.[55] Otherwise in calculation of the coefficient β^0 [Eqn. (3b)] it is necessary to use the viscosity of a solution with a given concentration. The authors of Ref. 56 suggest extending the validity of Eqn. (15) by calculating the coefficients employing both the viscosity of a solution and its permittivity (so that the quantities β^0, α^0, and k become concentration-dependent). If calculations based on Eqn. (15) give values of the electrical conductance lower than those found experimentally, this is evidence of ion association and can be allowed for by introducing the degree of dissociation α into Eqn. (15):

$$\lambda = \alpha\lambda'(\alpha c),$$

where $\lambda'(\alpha c)$ is given by Eqn. (15) with the actual ion concentration amounting to αc; α can be found by successive approximation or by applying the law of mass action. Equation (10) allows us to describe the concentration dependence of the electrical conductance of strong (concentrated) electrolytes in water right up to a concentration of $\sim$1 M.

Among the second group of equations one should mention particularly the Vogel–Fulcher–Tammann equation describing the temperature dependence of the transport properties of glass-forming liquids and molten salts:

$$x(T) = AT^{-1/2}\exp\left(-\frac{B}{T-T_0}\right),$$

where A and B are constants, and T_0 is the ideal or theoretical vitrification temperature.

If the solubility of an electrolyte is sufficiently high, the isotherms of the composition dependence of the electrical conductance have a maximum whose position and amplitude are governed by the nature of the components of the solution. These dependences are described most frequently employing the empirical equation of Castel and Amis:[57]

$$\frac{\kappa}{\kappa_{max}} = \left(\frac{m}{m_{max}}\right)^2 \exp\left[b(m-m_{max})^2 - \frac{a}{m_{max}}(m-m_{max})\right],$$

where κ_{max} and m_{max} are the values of the electrical conductivity and of the concentration corresponding to an extremum of the dependence $\lambda = f(m)$: a and b are empirical coefficients.

Among the empirical dependences describing the electrical conductivity of electrolyte solutions, we may mention a correlation equation which allows for a whole range of the solvent and salt parameters:[53]

$$\varkappa = A\exp\{aDN(r_+)^2 + bAN/(r_-)^2 + \mu[c/(r_+)^2 + d/(r-)^2] + e/\varepsilon\}/\eta_0 V_m^{1/3}, \qquad (16)$$

where A is the coefficient of proportionality; DN is the donor number; AN is the acceptor number; μ is the dipole moment of the solvent; a, b, c, d, e are empirical coefficients.

In some cases Eqn. (16) simplifies. For example, in the case of 1 M solutions of lithium salts in aprotic solvents we can ignore the solvation of the ions, so that Eqn. (16) becomes[53]

$$\varkappa = A\exp(aDN + b\mu + c/\varepsilon)/\eta_0 V_m^{1/3},$$

where the empirical coefficients are constant for a given salt in all the aprotic solvents.

In Ref. 58 it is assumed that the electrolytic properties of electrolyte solutions are governed by the processes of association in an electrolyte

$$nA \xleftrightarrow{K_1} A_n \xleftrightarrow{K_2} aA_j^{b+} + bB_j^{a-} \qquad (17)$$

and by its interaction with the solvent

$$mA + lS \leftrightarrow A_mS_l \leftrightarrow cA^{d+} + dB^{c-}, \qquad (18)$$

which leads to equations for the iostherms of the electrical conductance of binary liquid electrolyte–solvent systems.

In the case of noninteracting systems, we have

$$\kappa\eta = \kappa_A\eta_A\left(\frac{V_A}{V}\right)^{n/2} X^{n/2}, \qquad (19)$$

where κ_A, η_A, and V_A are the electrical conductivity, viscosity, and molar volume of the electrolyte, respectively; V is the molar volume of the solution; n is the stoichiometric equilibrium coefficient of Eqn. (17); X_A is the molar fraction of the electrolyte.

The electrical conductivity of interacting systems is then

$$\kappa\eta = \kappa_A\eta_A\left(\frac{V_A}{V}\right)^{n/2} X^{n/2} + Q_i\frac{X_A^{m/2}(1-X_A)^{1/2}}{V^{(m+l)/2}}, \qquad (20)$$

where Q_i is a constant governed by the values of the equilibrium constants K_3 and K_4 of Eqn. (18), by the molar volume, and by the conductance of the resultant electrolyte A_mS_l (Q_i is found from experimental data by calculation); m and l are the stoichiometric equilibrium coefficients of Eqn. (18).

Equations (19) and (20) are derived subject to the following assumptions: 1) the mechanism of the flow of the current involves ion migration; 2) the mobility of ions is inversely proportional to the viscosity of the solution; 3) the equilibrium constants in Eqns. (17) and (18) are smaller than 1×10^{-3}; 4) the ratio of the activity coefficients of different particles in a solution varies little with the concentration.

These equations describe satisfactorily the isotherms of the electrical conductance of a wide range of systems formed by alkylammonium salts with solvents of different types in the range of concentrations ranging from molten salts to dilute solutions (the latter with 1–2 mol%).

Moreover, several more empirical and semi-empirical equations have been proposed in the literature for the description of the electrical conductivity of solutions.[59,67] Some of these equations apply only to specific systems.

3. Solutions of weak electrolytes

In the case of weak electrolyte solutions the value of λ falls steeply on increase in the concentration and this is primarily due to a strong aggregation of current-carrying particles. In the case of such systems the ionicity of the medium is low so that the Debye–Hückel–Onsager effects make a relatively small contribution and the electrical conductivity of the solution is then described by simpler equations. The best of these are the Fuoss–Kraus[35] and Shedlovsky[36,37] equations

$$\frac{1}{\lambda S(Z)} = \frac{1}{\lambda^0} + \frac{c\lambda f_A S(Z)}{(\lambda^0)^2}, \qquad (21)$$

where $Z = S\sqrt{\lambda c}/\lambda^0$, S is the limiting Onsager coefficient, described by

$$\frac{1}{S(Z)} = F(Z) = 1 - Z\left\{1 - Z\left[1 - Z(\ldots)^{-1/2}\right]^{-1/2}\right\}^{-1/2}$$

in the Fuoss–Kraus method and by

$$S(Z) = \left\{\frac{Z}{2} + \left[1 + \left(\frac{Z}{2}\right)^2\right]^{1/2}\right\}^2 = 1 + Z + \left(\frac{Z}{2}\right)^2 + \left(\frac{Z}{2}\right)^3 + \ldots$$

in the Shedlovsky method. The coefficients $F(Z)$ and $S(Z)$ can be found in Refs. 68 and 69, respectively. In the first approximation the degree of dissociation α is calculated from $\alpha = \lambda/\lambda^0$. Then, the dependence $1/\lambda S(Z)$ on $c\lambda f_{\pm}^2 S(Z)$ is linear and it can be used to find the values of K_a and λ^0. These values can then be employed as the first approximation for the association constant and the limiting electrical conductance, respectively, which can then be used to calculate a new value of the degree of dissociation from $\alpha = \lambda S(Z)/\lambda^0$. Such a calculation is carried out until the required precision of the degree of dissociation (usually 1×10^{-4}) is achieved by the method of successive approximations.

In the case of very weak electrolytes the slope of the dependence $1/\lambda S(Z) = f[c\lambda f_{\pm}^2 S(Z)]$ is so steep that the extrapolation procedure becomes uncertain and gives rise to large errors in the values of K_a and λ^0. In this case we can estimate λ^0 from the Kohlrausch law on the independence of ion migration and by combining the values of the limiting electrical conductance of strong electrolytes. For example, in the case of a solution of acetic acid in water, we can write down

$$\lambda^0_{CH_3COOH} = \lambda^0_{HCl} + \lambda^0_{CH_3COONa} - \lambda^0_{NaCl}.$$

It should be pointed out that Eqn. (21) is derived on the assumption that ion association produces only ion pairs. However, in solvents with a low permittivity we can expect also attachment of ions to an ion pair, forming ion triplets:

$$MA + M^+ \xleftrightarrow{K_1} M_2A^+,$$

$$MA + A^- \xleftrightarrow{K_2} MA_2^-.$$

These processes are most typical of solutions of electrolytes containing large organic ions.[70,71] It is usual to assume that the equilibrium constants of both processes are equal ($K_1 = K_2 = K_t$). In this case the results are usually analysed employing the Fuoss–Kraus equation[35]

$$\lambda c^{1/2} = \lambda^0 K_a^{-1/2} + \lambda_t^0 K_t K_a^{-1/2} c,$$

where λ_t^0 is the limiting electrical conductance due to ion triplets. We can find the association constant K_t representing the formation of triplets if the values of λ^0 are calculated by the method described above using the electrical conductances of strong electrolytes and λ_t^0 is obtained from the approximate expression $\lambda^0 = 3\lambda_t^0$.

Another approach to find the K_t and λ_t^0 was suggested by Beronius.[72] If we denote the equilibrium concentrations of the M^+ and A^- ions by $\alpha_1 c$ and the corresponding concentrations of M_2A^+ and MA_2^- by $\alpha_2 c$, we find that the electrical conductance is given by

$$\lambda = m(\alpha_1\lambda^0 + \alpha_2\lambda_t^0),$$

where m is a coeffficient allowing for the reduction in the conductance because of the ion–ion interaction and given by

$$m = \left(\lambda^0 - Sc_i^{1/2} + Ec_i \ln c_i + I_1 c_i + I_2 c_i^{3/2}\right)\Big/\lambda^0,$$

m can be calculated using Eqns. (2) and (3); $c_i = c(\alpha_1 + \alpha_2)$. The expressions for the association constants are:

$$K_a = (1 - \lambda_1 - 3\lambda_2)/(c\lambda_1^2 f_{\pm}^2),$$

$$K_t = \lambda_2/[c\lambda_1(1 - \lambda_1 - 3\lambda_2)].$$

However, once again we can calculate λ_t^0 and K_t only if we find first the values of λ^0 and K_a.

A combined method is suggested in Ref. 41 and a description is given there of an algorithm for the processing of conductometric data in the case of complex associated electrolytes; this is done employing the Brickley formalism to describe chemical equilibria in solutions, the modified Newton second-order method for optimisation of the required parameters, and the equation of Lee and Wheaton for the concentration of the dependence of the molar electrical conductance of an electrolyte.

III. Limiting molar ionic electrical conductance

The value of the limiting electrical conductance due to ions can be calculated using λ^0 for the electrolyte in question and the limiting transport (transference) number t^0 for one ion forming a given electrolyte. In the case of our binary electrolyte we have

$$\lambda_+^0 = t_+^0\lambda^0,$$

$$\lambda_-^0 = (1 - t_+^0)\lambda^0.$$

Similar equations can be written down if we know t_-^0.

Determination of the transport numbers of nonaqueous solvents meets with major difficulties because of the frequent use of indirect methods for calculation of λ_{ion}^0 and subject to various assumptions. An analysis of these methods can be found in Refs. 73 and 74. The author of Ref. 73 is of the opinion that a physically more justified method uses the product $\lambda^0\eta_0$ for large tetraalkylammonium ions (beginning from Bu_4N^+) in various organic solvents and at different temperatures. The physical justification is the hypothesis that large tetraalkylammonium ions do not become solvated in organic solvents at any temperature. The following indirect methods of separation into ion components are given in Ref. 73:

$$\left(\lambda_\pm^0\right)_{(CH_3)_2CO} = \left(\lambda_\pm^0\right)_{H_2O}\frac{\eta_{0\,H_2O}}{\eta_{0\,(CH_3)_2CO}},$$

$$\lambda^0_{(Pi^-)}\eta_0 = 0.267,$$

$$\lambda^0_{(Et_4N^+)}\eta_0 = 0.296,$$

$$\lambda^0_{(Bu_4N^+)}\eta_0 = \begin{cases}0.208\\0.206\\0.209,\\0.201\\0.233\end{cases}$$

$$\left[\lambda^0_{(iso-Am_3BuN^+)}\eta_0\right]_{n-PrOH,n-BuOH} = \left[\lambda^0{}_{(iso-Am_3BuN^+)}\eta_0\right]_{EtOH},$$

$$\left[\lambda^0_{(Hept_4N^+)}\eta_0{}_{n-PrOH,n-BuOH}\right. = \left[\lambda^0_{(Hept_4N^+)}\eta_0\right]_{EtOH},$$

$$\lambda^0_{R_4N^+} = ZF^2/6\pi N\eta_0[R_i - (0.0103\varepsilon + r_j)],$$

$\lambda^0_{M^+} = \lambda^0_{A^-}$, where M^+ and A^-: iso-Am_4N^+ and iso-Am_4B^-, Bu_4N^+ and BPh_4F-, Bu_4N^+ and Ph_4B^-, $MeOctN^+$ and $OcldSO_4^-$, and Ph_4B_-, Me_3PhN^+ and $PhSO_3^-$, Bu_4N^+ and Bu_4B^-, Ph_4As^+ and Ph_4B^-;

$$\lambda^0_{Bu_4N^+} = 1.08\lambda^0_{iso\text{-}Am_4N^+},$$

$$\lambda^0_{Ph_4B^-} = 1.01\lambda^0_{iso\text{-}Am_4B^-},$$

An analysis of the transport numbers of ions in a number of solvents was given in Refs. 75–77, but the results reported have been obtained mainly at 289 K. There have been only few studies of the temperature dependences of the transport numbers.[78–80]

The dependence of the limiting ionic electrical conductance on the various factors can be analysed conveniently in the form of an expression for the friction coefficient ξ (kg/s):

$$\xi_i = \frac{Z_i^2F^2}{N_A\lambda_i^0}, \qquad (22)$$

where N_A is the Avogadro number.

Different theories give the following expressions for the friction coefficients† of spherical ions of radius R_i.

Continuum models

1. $\xi = \xi_v = A\pi\eta R_i$.

In the above case only the viscous friction forces are allowed for.[1]

2. $\xi = \xi_v + \Delta\xi$, $\Delta\xi = B\dfrac{(Ze)^2(\varepsilon - \varepsilon_\infty)\tau}{R_i^3\varepsilon(2\varepsilon + 1)}$.

The viscous and dielectric friction forces are now included.[81]

3. $\xi = \xi_V + \Delta\xi$,

$\Delta\xi = \eta_0 R_{x0}\sum_{j=1}^{j=4} a_j(R_{x0})^j$ [values of a; can be found in (Ref.82)],

$R_i^4/R_{x0} \to 0$, $\xi = \xi_T = 15.624\eta R_{x0}^{1/4}$,

$R_i^4/R_{x0} >> 1$, $\Delta\xi = A\pi\eta R_i[A_1(R_{x0}/R_i^4) - A_2(R_{x0}/R_i^4)^2]$,

$R_{x0} = \dfrac{(Ze)^2}{16\pi\eta}\dfrac{\varepsilon - \varepsilon_\infty}{\varepsilon^2}\tau$.

The viscous and dielectric friction forces are included.[83–85]

3.1. $\xi = \xi_V + \Delta\xi + \Delta\xi_{DH}$,

$R_i^4/R_{x0} >> 1$, $\Delta\xi_{DH} = A\pi\eta R_i\left[A_3\dfrac{R_{x0}}{R_i^4}\dfrac{R_{HK}}{R_i^4}\right]$,

$R_{HK} = -\dfrac{\alpha(Ze)^2(\varepsilon - 2\varepsilon_\infty)}{\varepsilon^2(\varepsilon - \varepsilon_\infty)}$.

† The values of the coefficients can be found also in the original papers (the references to these papers alongside the name of the model).

The effects of dielectric saturation are included.[86]

3.2. $\xi=\xi_V+\Delta\xi+\Delta\xi_{BB}$,

$R_i^4/R_{x0} >> 1$, $\Delta\xi_{BB} = A\pi\eta R_i\left[A_4\frac{R_{x0}}{R_i^4}\frac{R_R}{R_i^4}\right]$,

$R_R=R_{x0}\eta/\eta_R$, where η_R – is the 'rotational viscosity'

$R_i^4/R_{x0}\to 0$, $\xi=\xi_T=14.089\eta R_{x0}^{1/4}$ when $R_R\to\infty$,

$\xi=\xi_T=15.624\eta R_{x0}^{1/4}$ when $R_R\to 0$.

The influence of 'rotational' viscosity is allowed for.[87]

3.3. $\xi=\xi_V+\Delta\xi+\Delta\xi_e$,

$R_i^4/R_{x0} >> 1$, $\Delta\xi_e = A\pi\eta R_i\left(\frac{b-c}{R_i^4}\right)$,

$C = A_5\frac{(Ze)^2}{4\pi\varepsilon}\left(\frac{\partial\ln\eta}{\partial P}\right)_T$,

$b = A_6\frac{C}{\beta_T}\left(\frac{\partial\ln\eta}{\partial P}\right)_T$,

The influence of electrostriction is included.[88]

4. $\xi=\xi_V+\Delta\xi$,

$\Delta\xi = A_7\frac{(Ze)^2(\varepsilon-\varepsilon_\infty)}{R_iD\varepsilon^2}$.

The Debye relaxation mechanism is supplemented by a nonlocal translational diffusion of molecules along a gradient of a nonequilibrium polarisation field.[89]

5. $\xi=\xi_V+\Delta\xi$,

$R_i^4/R_{x0} > 1$, $\Delta\xi = A\pi\eta Ry(1-g)$,

$R_i^4/R_{x0} < 1$, $\Delta\xi = x\cdot 15.624\eta R_{x0}^{1/4}$,

$xy = f\left(g, R^4/R_{x0}\right)$,

$0 > g > 1/3$.

The ion is assumed to have a finite polarisability and the polarisation changes abruptly at the surface of an ion. The solvent may have more than one relaxation time.[90]

6. $\xi = 2\pi\eta R_i\left\{\sigma+2+\frac{R_{x0}}{R_i^4}\left[\frac{1}{105}\left(56-69\sigma+59\sigma^2\right)+\left(\frac{\lambda_e}{\lambda_h}-1\right)\sigma(1-\sigma)\right]\right\}$,

$\sigma = R_i/(R_i+3\lambda_h)$.

In the above case the energy dissipation in polar liquids is allowed for. The boundary conditions on the surface of an ion are governed by electrical (λ_e) and hydrodynamic (λ_h) parameters.[91]

Continuum-molecular models

1. $\xi=\xi'_V+\xi_D$,

$\xi'_V = 4\pi\eta_0\sigma\left[1+\Delta\left(\frac{\sigma}{R_i}-1\right)\right]^{-1}$; $\xi_D = \frac{(Z_e^2(\varepsilon-\varepsilon_\infty)}{\varepsilon(2\varepsilon+1)R_i^4}\tau A_D\left[1+3\left(\frac{R_i}{\sigma}\right)_y^4\right]$,

$y = \left[\left(1+2\frac{\varepsilon}{\varepsilon_R}+\left(-\frac{\varepsilon-\varepsilon_\infty}{\varepsilon}\right)\left(\frac{\varepsilon_R}{\varepsilon_R-\varepsilon_\infty}\right)\left(\frac{2\sigma}{A_D}-\frac{3B_0}{A_D}\right)-\frac{2c\sigma}{A_D}+\right.\right.$

$\left.\left.+\frac{2\sigma}{R_i}\left(\frac{3\varepsilon_R+1}{2\varepsilon_R+1}\right)\left(1-\frac{\varepsilon}{\varepsilon_R}\right)\right]/\left[\left(1+\frac{2\varepsilon}{\varepsilon_R}\right)-2\left(\frac{R_i}{\sigma}\right)^3\left(\frac{\varepsilon_R-1}{2\varepsilon_R+1}\right)\left(1-\frac{\varepsilon}{\varepsilon_R}\right)\right.\right.$

$B_0 = \frac{\sigma}{2}\left[1+\Delta\left(\frac{\sigma}{R_i}-1\right)\right]^{-1}$, $\sigma = R_i+2R_s$,

$A_D = \frac{\sigma}{2}\frac{\eta}{\eta_{\text{eff}}}\left[1+\Delta\left(\frac{\sigma}{R_i}-1\right)\right]^{-1}$, $\Delta = \eta\rho_R/\eta_{\text{eff}}\rho(0\leqslant\Delta\leqslant 1)$,

$C = \frac{\sigma}{R_i}\frac{\eta}{\eta_{\text{eff}}}\left[1+\Delta\left(\frac{\sigma}{R_i}-1\right)\right]^{-1}$, $\rho_R, \eta_R, \varepsilon_R, \tau_R$ – for $R<r<\sigma$, ρ, η, ε, τ, – in the bulk,

$\eta_{\text{eff}} = \eta_R+\frac{\tau_R}{6M_s}\rho\left[\left(\frac{\rho_R}{\rho}\right)^2-1\right]\left(\frac{\sigma}{R_i}-1\right)\left(\rho\frac{dV(r)}{dr}\right)_{r=\sigma}$.

If $\varepsilon_R = \varepsilon$, then

$$\xi_D = \frac{1}{2}\frac{(ze)^2(\varepsilon-\varepsilon_\infty)\tau}{\varepsilon(1+2\varepsilon)}\frac{\sigma}{R_i^4}\times$$

$$\times\left\{\frac{(\rho/\rho_R)\Delta+(R_i/\sigma)^4\left[1+4\Delta(4\sigma/R_i-1)-(4\sigma/R_i-3)(\rho/\rho_R)\Delta\right]}{1+\Delta(\sigma/R_i-1)}\right\}.$$

If $\varepsilon_R = \varepsilon$ and $\rho_R = \rho$, we have

$$\xi_D = \frac{1}{2}\frac{(ze)^2(\varepsilon-\varepsilon_\infty)\tau}{\varepsilon(1+2\varepsilon)}\frac{\sigma}{R_i^4}\left\{\frac{\Delta+(R_i/\sigma)^4\left[1+\Delta(12\sigma/R_i-1)\right]}{1+\Delta(\sigma/R_i-1)}\right\}.$$

If $\varepsilon_R = \varepsilon_\infty \approx 1$, then

$$\xi_D = \frac{1}{2}\frac{(ze)^2(\varepsilon-\varepsilon_\infty)\tau}{\varepsilon(1+2\varepsilon)}\frac{1}{\sigma^3}\left[\frac{1+4\Delta(\sigma/R_i-1)}{1+\Delta(\sigma/R_i-1)}\right].$$

The local changes in the properties of the solvent near an ion are allowed for in the above expressions.[92]

2. $\xi = A\pi\eta R+\frac{2}{3}(ze)^2\frac{\varepsilon-\varepsilon_\infty}{\varepsilon^2}\frac{\tau}{R_e^3}$.

The short-range order around an ion is allowed for. The finite size of the solvent molecule is taken into acocunt.[93]

Molecular models[94–96]

1. $\xi=\frac{1}{kT}\int_0^\infty\left\langle F^R(0)F^R(t)\right\rangle dT = \xi^{HH}+\xi^{SH}+\xi^{HS}+\xi^{SS}$,

where S and H are, respectively, the soft and hard forces between an ion and the solvent molecules; ξ^{HH} is due to the hard interaction of particles considered as solid spheres and it is given by $\xi^{HH} = 4\pi\eta R_i$; ξ^{SS} corresponds to the soft interactions and is given by

$$\xi^{SS}=\frac{1}{kT}\left\langle\left(F^S\right)^2\right\rangle\tau_F;$$

$\langle(F^S)^2\rangle$ is the mean-square vibration of the soft component of the force; τ_F is the characteristic decay time; ξ^{HS} and ξ^{SH} are cross terms.

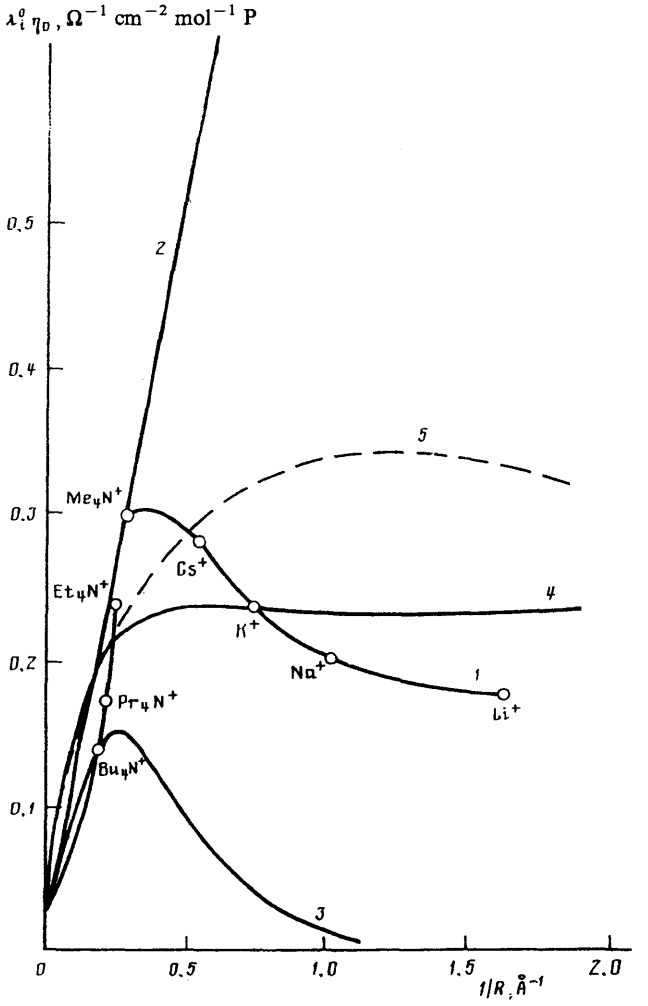

Figure 1. Experimental (*1*) and theoretical (*2*–*5*) dependences of $\lambda_i^0\eta_0$ for methanol on the reciprocal ionic radius at 298.15 K.[85] Theory: *2*, Stokes; *3*, Zwanzig; *4*, Hubbard–Onsager; *5*, Wolynes.

As pointed out in Spiro's review,[4] the Stokes equation 'does not work' until the ionic radius reaches 5.5 Å in water and 10 Å in such solvents as sulpholane. The reason for this is the hydrodynamic model, in which the solvent is regarded as a structure-free continuum. There have been many attempts to develop empirical and theoretical modifications of the Stokes theory among which we should mention the work reported in Refs. 1 and 97. It is assumed in the continuum models that an ion experiences not only the hydrodynamic, but also the dielectric friction. A moving ion orients the solvent dipoles around itself and they return back to a disordered distribution after a certain time (which is the dielectric relaxation time τ). Therefore, an additional electrostatic force acts on an ion.

The continuum models allowing for the dielectric friction have been checked for a large number of electrolytic systems, including protic, aprotic, and mixed solvents.[82,98,99] The results of such calculations are diappointing, particularly in the case of small ions for which the dielectric friction effect in the largest (Fig. 1 shows, by way of example, the experimental and theoretical dependences of λ^0 on $1/R_i$ for methanol). Introduction of dielectric saturation yields an effect which is far too small to improve the results significantly. Moreover, none of the continuum theories can account for the physical nature of the investigated phenomena.

An ideal theory of the ionic electrical conductance should account for the motion of an ion allowing for the ion–solvent interaction, for the structure of the solvent surrounding the ion, and for the motion of the solvent molecules. Wolynes started[94–96] to develop such a molecular approximation. The numerical calculations reported in Ref. 95 were carried out using only the solid-sphere radial distribution functions and the ion-dipole potentials: they showed that the calculated values of the electrical conductance due to small ions were higher than the experimental values, exactly as in the case of the continuum theories (Fig. 1). A theoretical investigation of the dielectric friction coefficient considered from the molecular positions was reported in a recent paper.[100] In principle, such an approach is analogous to that of Wolynes, but there are also some differences.

It should be pointed out that the Walden product is used widely in the interpretation of the electrical conductance data. As assumed in Ref. 101, one of the reasons for the popularity of the product $\lambda^0\eta_0$ is the erroneous view that multiplicaiton of the electrical conductance by the viscosity avoids the problem of the influence of the viscosity on the motion of an ion and makes it possible to consider the influence of other factors. However, this approach should be treated with caution. Since an ion carries a charge, the neglect of the influence of temperature, pressure, and nature of the solvent on the electrostatic interaction of an ion with the solvent may result in an unjustified stress on the structure of the pure solvent. On the other hand, the treatment given in Ref. 102 demonstrates the correctness of the use of the Walden product in diagnostics of structural features of solvents. The relationships governing the changes in the product $\lambda^0\eta_0$ with the properties of the solvent and with the ion size are investigated in Ref. 103.

It is stressed in several papers[82,101] that it is essential to analyse the conductometric data allowing for the residual friction coefficient

$$\Delta\xi = \xi - \xi_V,$$

where ξ is the overall ionic fraction coefficient [deduced from Eqn. (22)]; ξ_V is the Stokes friction coefficient under glide conditions.

In the continuum theories the quantity $\Delta\xi$ reflects mainly the dielectric friction. In the Hubbard–Onsager theory the expression for $\Delta\xi$ includes both dielectric and viscous properties of the solvent, whereas in the theory of Zwanzig only the dielectric properties are

allowed for, because of the separate description of the viscous and dielectric frictions.

The expression for the residual friction coefficient is also in agreement with the formalism of the molecular Wolynes theory. The following assumptions are made in this case: the component of the coefficient of friction due to hard collisions is equated to the Stokes friction coefficient $\xi^{HH} = \xi_V$; the cross terms ξ^{SH} and ξ^{HS} are ignored. We then have $\Delta\xi = \xi^{SS}$. However, it is shown in Refs. 100 and 104 that the neglect of the cross terms is an unjustified simplification.

In the molecular-continuum theory of Chen and Adelman,[92] in contrast to the continuum theories, the dielectric friction contribution is small even in the case of small ions. However, the function Δ introduced there to represent the degree of solvation of an ion is not determined on the basis of microscopic data but is selected to ensure agreement with the experimental conductometry results and is therefore a fitting parameter.

Since the approximation of an ion by a sphere is fairly rough, other geometric approximations have been used to describe the configuration of an ion (ellipsoid, disk, cylinder, etc.). The equations for calculation of Δ is the case of these ion configurations can be found in Spiro's review.[4]

The Hubbard–Onsager theory of dielectic friction and the Onsager–Kirkwood–Fröhlich theory of insulators are used in Ref. 105 to propose a new quantitative characteristic (θ) of the influence of an ion on the dynamic structure of the solvent. The value of θ is calculated using the limiting molar electrical conductance due to ions and it agrees well with the other characteristics of ion solvation (such as the energy of close solvation of ions proposed by Samoilov and denoted by ΔE_i and a coefficient B in the Jones–Dole equation).

One of the quantitative methods for describing the temperature dependence of the electrical conductance is the kinetic approach based on the theory of a transient state. It is shown in Ref. 106 that this theory can be used as the basis of various methods for calculating the thermodynamic characteristics of ion migration. We shall give here only one of the possible variants of such a calculation. If the motion of an ion is regarded as migration across a liquid by a series of jumps from one equilibrium position to another, the distance between which is l, we can write down

$$\lambda_i^0 = \frac{z_i e_i F l^2}{6h} \exp\left(\frac{\Delta G_{\lambda^0}^*}{RT}\right), \tag{23}$$

where h is the Planck constant and $\Delta G_{\lambda^0}^*$ is the free Gibbs energy of activation of electrical conduction.

If we assume that $l = (V_M/N_N)^{1/3}$, then differentiation of Eqn. (23) with respect to temperature and presure yields the following relationships:

$$\left(\frac{\partial \ln \lambda_i^0}{\partial T}\right)_P = \frac{\Delta H_{\lambda^0}^*}{RT^2} + \frac{3}{2}\alpha, \tag{24}$$

$$\left(\frac{\partial \ln \lambda_i^0}{\partial T}\right)_V = \frac{\Delta U_{\lambda^0}^*}{RT^2},$$

$$\left(\frac{\partial \ln \lambda_i^0}{\partial T}\right)_T = \frac{\Delta V_{\lambda^0}^*}{RT} - \frac{2}{3}\beta,$$

where α is the thermal expansion coefficient; β is the isothermal compressibility of the solvent. The first expression in the system (24) is obtained only on the assumption that the entropy of activation of electrical conduction is independent of temperature.

The electrical conductance data can also be used to calculate the number of physicochemical characteristics of solutions and then these characteristics can be useful in tackling many practical problems.[2,4] For example, using the Stokes law, we can determine the radius of a moving solvated ion (Stokes radius):

$$R_s = \frac{zF^2}{6\pi N_A \eta_0 \lambda^0} = \frac{0.82z}{\eta_0 \lambda^0},$$

and then the value of R_s can be used to calculate the solvation number of an ion

$$n_s = \frac{V_c - V_{cv}}{V_s} = \frac{1}{V_s}\frac{4}{3}\pi(R_s^3 - R_{cv}^3),$$

where V_{cv} is the volume of an ion with the crystallographic radius R_{cv} and V_c is the volume of a solvated ion of radius R_s.

It was also suggested in Ref. 97 that the radius of a solvated ion can be calculated using the semi-empirical relationship based on the Stokes law:

$$R_s = \frac{zF^2}{6\pi N_A \eta_0 \lambda^0} + 0.0103\varepsilon + r_y,$$

where $r_y = 0.85$ Å describes dipolar unsassociated solvents and $r_y = 1.13$ Å applies to protic and other associated solvents.

The limiting molar conductance of an individual ion is related to its limiting diffusion coefficient D_i by the Nernst–Einstein equation:

$$D_i = \frac{RT\lambda_i^0}{z_i^2 F^2}.$$

The limiting diffusion coefficient of an electrolyte is

$$D^0 = \frac{RT}{F^2}\frac{z_+|z_-|}{z_+|z_-|}\frac{\lambda_+^0\lambda_-^0}{|z_-|\lambda_+^0 + z_+\lambda_-^0}.$$

The electrical conductance data can be used to calculate the parameters of self-dissociation (autoprotolysis) of water ($K_w = c_H + c_{OH^-}$) and of other pure solvents. Since the ionicity of a medium in a pure solvent is low ($\lambda = \lambda^0$), we can write down

$$\kappa = \frac{\lambda^0 c_{H^+}}{1000} = \frac{\lambda^0 K_w^{1/2}}{1000}. \tag{25}$$

the value of λ^0 is obtained in the same way as in the case of electrolytes, for example, $\lambda_{HOH}^0 = \lambda_{HCL^+}^0 + \lambda_{KOH}^0 - \lambda_{KCl}^0$. By analogy with Eqn. (25), saturated solutions of low-solubility completely dissociated 1–1 electrolytes can be described, in the first approximation, by the expression

$$\varkappa = \frac{\lambda_{sat}^0}{1000} = \frac{{}^0SP^{1/2}}{1000}.$$

If an electrolyte is associated in the solution, then

$$SP^{1/2} = c_{sat} = \frac{1000\varkappa}{\lambda^0} + \left(\frac{\varkappa \times 1000}{\lambda^0}\right)^2 K_a.$$

This makes it possible to calculate the solubility product (SP) of low-solubility salts.

IV. Parameters of ion association

The association constant is introduced into the equations for the electrical conductance of electrolyte solutions using the law of mass action. Therefore, the association constant obtained by solving these equations is an experimental quantity which does not require selection of the ion association model, but depends on the selection of the ionic conductance model. We must mention straight away that the association constant obtained in this way is preferred to the molar scale of concentrations. Therefore, in comparing the ion association processes in different solvents and at different temperatures it is preferable to use the association constant referred to the scale of molar fractions $[K_a(X)]$, which is related to K_a on the molar concentration scale by

$$K_a(X) = \frac{1000\rho}{M_s} K_a.$$

On the other hand, K_a can be calculated using different theories of ion association.

The association constant is related to the distribution function which gives the distribution of ions of opposite change around the central ion. The distribution function is related to the mean-force potential by

$$W^{(s)}(\bar{r}_1 \ldots \bar{r}_s) = -kT \ln f^{(s)}(r_1 \ldots r_s).$$

There are many ways of finding the relevant distribution functions and the mean-force potentials. However, all of them are based on similar assumptions. Firstly, it is postulated that the mean-force potential can be represented as a sum of the long-range (Coulomb) and short-range parts. In fact, such a separation is justified at low concentrations. Secondly, the mean-force potential corresponding to the short-range component is replaced with the pair potential describing this interaction. The second step is again justified by the low concentrations and short distances between ions with opposite signs, when they can be regarded as ion pairs.

In connection with such a separation of the meanforce potential into components, it is usual to solve the problem of the long-range component, since it is the most significant in the formation of an ion pair, and the parameters representing the short-range part are introduced only during the second stage.[22,107,108] There have been recent treatments[23,24,109,110] in which right from the beginning both types of interaction have been allowed for. However, it must be pointed out that it is quite difficult to treat the problem rigorously in view of the mathematical difficulties which are encountered and, therefore, many authors sacrifice the physical and mathematical rigour in order to obtain easily analysable results.

Without going into details of the various theories of ion association, we can point out that for the majority of them an analytic expression for the calculation of the association constant can be represented in the form

$$K_a = \frac{4\pi N_A}{1000} \int_a^R r^2 \exp\left(-\frac{U_\pm}{kT}\right) \omega(r) dr, \qquad (26)$$

where $\omega(r)$ is a weighting function which determines the weight of a paired state of ions as a function of the distance between them. The real potential $U_\pm$ (of Fig. 2*a*) is most frequently represented by the primitive model with an apparent distance a' between the solid spheres (Fig. 2*b*) or a model potential which allows for the long- and short-range components (for example, that shown in Fig. 2*b*),

The equations for calculation of the association constants based on the primitive model allow only for the electrostatic interaction between the ions ($U_\pm/kT = 2q/r$) and they differ in respect of selection of the upper limit of integration and in respect of the expression used for $\omega(r)$. For example, in the Bjerrum theory the value of R is governed by the distance q between the ions at which the energy of the electrostatic interaction is $2kT$. The value is $\omega(r) = 1$ for $a \leqslant r \leqslant q$ and $\omega(r) = 0$ for $r > q$.

The expression for K_a then becomes

$$K_a = \frac{4\pi N_A}{1000} \int_a^q r^2 \exp\left(\frac{2q}{r}\right) dr = \frac{4\pi N}{1000} \left(\frac{|z_+ z_-| e^2}{\varepsilon kT}\right)^3 Q(b), \qquad (27)$$

where

$$Q(b) = \frac{1}{6}\left[e^2 - E_i(2) + E_i(b) - \frac{e^b}{b^3}\left(2 + b + b^2\right)\right].$$

The value of $Q(b)$ is tabulated in Ref. 1 for different values of b.

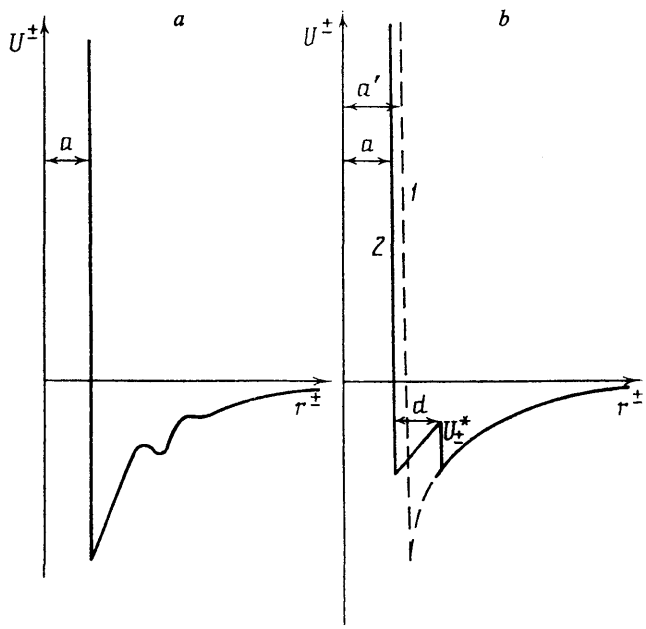

Figure 2. Representation of the cation–anion potential:[10,115] *a*, real potential; *b*, equivalent primitive model with an apparent distance a' between the hard spheres (*1*) and one of the simplest models allowing for the long- and short-range components (*2*).

In the theory of ion association proposed by Fuoss only the contact ion pairs are considered and the value of r is assumed to be $(4/3)a$. Then $\omega(r) = 1$ for $a \leqslant r \leqslant (4/3)a$ and $\omega(r) = 0$ for $r > (4/3)a$. The association constant is then given by

$$K_a = \frac{4\pi N_A a^3}{3000} e^h \cdot \qquad (28)$$

A better justified selection of the weighting function $\omega(r)$, which allows us to obtain an expression for the ion association constant using the primitive model, is made by Ebeling[12,32]

$$\omega(r) = 1 + \exp\left(\frac{2q}{r}\right) - 2\exp\left(\frac{2q}{r}\right) - \left(\frac{2q}{r}\right)^2 \exp\left(\frac{2q}{r}\right).$$

The upper limit of integration [see Eqn. (26)] is ∞. As a result, we obtain Eqn. (10).

However, the most satisfactory description of the process of ion association can be obtained by employing a model potential that allows for the long- and short-range effects. There are various ways of representing the combined potential as a function of the distance:

$$\frac{U_\pm(r)}{kT} = \begin{cases} \infty, & r \leqslant a \\ \dfrac{U_\pm}{kT} = \text{const}, & a \leqslant r \leqslant R' \\ \dfrac{2q}{r}, & R' \leqslant r \leqslant R, \end{cases} \tag{29}$$

$$\frac{U_\pm(r)}{kT} = \begin{cases} \infty, & r \leqslant a \\ \dfrac{2q}{r} + \dfrac{U_\pm^*}{kT}\left(U_\pm^* = \text{const}\right), & a \leqslant r \leqslant R' \\ -\dfrac{2q}{r}. & R' \leqslant r \leqslant R, \end{cases} \tag{30}$$

$$\frac{U_\pm(r)}{kT} = \begin{cases} \infty, & r \leqslant a \\ -\dfrac{2q}{r} + \dfrac{U_\pm^*(r)}{kT}, & a \leqslant r \leqslant R' \\ -\dfrac{2q}{R} & R' \leqslant r \leqslant R. \end{cases} \tag{31}$$

Depending on the assumptions made by the authors, one can find other designations for the quantity $U_\pm^*$: $W_\pm^*$,[110] $d_\pm$,[111] and ν_1.[112] The lower limit of integration a in Eqn. (26) is equal to the 'hard-sphere' contact distance between the ions calculated from the crystallographic radii. The upper integration limit R may be specified in a variety of ways: it may be equated to the Bjerrum distance q: it may be equal to the distance found by solving the electrical conduction equation; it may also be selected using some other approach. The intermediate distance R' is most frequently expressed in the form $R' = a + S$, where S is equal to one or several diameters of the solvent molecule or some fragment of this molecule. The effective diameter of the solvent molecule d_S can be calculated from its molar volume V_S:

$$d_S = \left(\frac{6V_S}{\pi N_A}\right)^{1/3}$$

or from the geometric parameters of the solvent molecules. If in the case of $U_\pm$ we use the model potential of the type given by Eqn. (30), we find that K_a is given by

$$K_a = \frac{4\pi N}{1000}\left[\exp\left(-\frac{U^*}{kT}\right)\int_a^{R'} r^2 \exp\left(\frac{2q}{r}\right)dr + \int_{R'}^{R} r^2 \exp\left(\frac{2q}{r}\right)dr\right]. \tag{32}$$

Then,

$$\exp\left(-\frac{U_\pm^*}{kT}\right) = \frac{K_a - (4\pi a/1000)\int_{R'}^{R} r^2 \exp(2q/r)dr}{(4\pi N/1000)\int_a^{R'} r^2 \exp(2q/r)dr}. \tag{33}$$

Eqn. (33) is frequently written in the form

$$\exp\left(-\frac{U^*}{kT}\right) = \frac{K_a - (4\pi N/1000)\int_{R'}^{R} r^2 \exp(-2q/r)dr}{(4\pi N/1000)\int_a^{R} r^2 \exp(2q/r)dr - (4\pi N/1000)\int_{R'}^{R} r^2 \exp(2q/r)dr} =$$

$$= \frac{K_a - K_a(R')}{K_a(a) - K_a(R')},$$

where $K_a(R')$ and $K_a(a)$ are calculated using either the Bjerrum equation (27) or the Ebeling equation (28).

The selection of a specific form of the functional dependence $U_\pm^*(r)$ [Eqn. (31)] of Refs. 113 and 114 widens the concentration range of the validity of this equation, but it greatly complicates the problem. Therefore, it is not used much in practical applications when an analysis is made of conductometric data.

Knowledge of the ion association constants at different temperatures allows us to calculate all the thermodynamic characteristics of the association process using the following relationships:

$$\Delta G_a^0 = -RT \ln K_a,$$

$$\Delta H_a = \frac{RT^2 d\ln K_a}{dT},$$

$$\Delta S_a = \frac{\Delta H_a^0 - \Delta G_a^0}{T}$$

If the pair interaction potential is given by Eqns. (29)–(31) then ΔG_a can be represented as a combination of the long-range (Coulomb) and short-range contributions.

It follows from our review that conductometry of electrolyte solutions can provide in a fairly reliable way of obtaining some important information on the state and mobility of ions in solvents of different kinds and in a wide range of parameters. This is largely due to a good theoretical basis of this branch of physical chemistry of solutions and the experimental capabilities of the method itself.

Line tension in the thermodynamics of thin liquid films

V G Babak
All-Union Correspondence Institute for the Food Industry, Moscow

ABSTRACT. The results of theoretical and experimental studies of line tension in thin liquid films and three-phase systems in the last 20 years have been examined and generalised. The main theories of line tension, the reported measurements of its magnitude and sign, and the results of numerical calculations of the line tension on the basis of various thermodynamic models have been analysed. The results of this analysis are discussed in terms of the generalised theory of line tension.

The bibliography contains 74 references.

I. Introduction

Line tension manifests itself as a fundamental concept of the thermodynamics of surface phenomena in the description of the mechanical equilibrium and of the energy properties of thin liquid films and of three-phase systems of finite size. The line tension can be defined either as the force $æ(H)$ acting along the boundary line (or the three-phase contact line) of a thin liquid film and tending to shorten (for $æ > 0$) or to lengthen (for $æ < 0$) the contact line, or as the specific excess free energy (referred to unit length of the contact line) of the system, i.e. its grand thermodynamic potential æ, J m^{-1}. Being (by definition) an excess quantity the line tension can take different values, depending on the idealised thermodynamic model chosen to describe the real system including a film boundary or three-phase contact line.

The line tension concept is used in surface chemistry and in colloid chemistry to describe a variety of processes: the heterogeneous formation of a new phase,[1–3] the hydrodynamics of thin liquid films,[4] the breakdown of ordinary and of Newtonian black films,[5,6] bilayer membranes,[7] the adhesion of liquid particles,[8] etc.

According to theoretical calculations[9–15] the absolute numerical value of the line tension should be $10^{-11}-10^{-10}$ N. In spite of these low values the line tension makes a substantial contribution to the free energy and to the mechanical equilibrium of thin liquid films and of three-phase systems in highly dispersed and colloid systems. In particular, the lower work of formation of nuclei of a new phase (100 Å in diameter) on solid or liquid substrates than in homogeneous nucleation has been widely attributed[1,2,14,16–20] to negative line tension effects.

Positive line tension can explain the stability of Newtonian black films towards rupture in the theory of nucleational disintegration.[7,21–24] Positive line tension is associated with the stability of ordinary black films towards rupture or towards spontaneous conversion into Newtonian black films at the contact between air bubbles or microscopic solid spheres and the air–solution interface.[5,25] Allowance for the linear tension is necessary in calculations of the force of adhesion of solid particles to the air–water interface during flotation.[26] The observed dependence of the angle of contact in the region of the film meniscus on the radius of the film (r) is attributed to the existence of an excess two-dimensional pressure $æ/r$ (where r is the radius of curvature of the line of contact).[10,16,27–39]

However, we should note that no generally accepted experimental determinations of the line tension are available at present: data from various laboratories range between -10^{-7} and $+10^{-7}$ N, even for identical systems.[1,15,16,35]

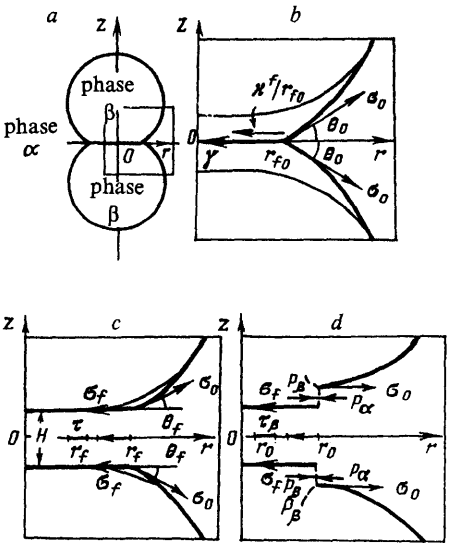

Figure 1. Different thermodynamic models of a thin liquid film used in the definition of the linear tension: *a*, contact of two identical fluid particles (phase β) in a liquid medium (phase α); *b*, membrane model of the liquid film; *c*, model of the liquid film which assumes two interfaces, used for a negative specific free energy of interaction in a film of thickness H_f; *d*, model of the liquid film for a positive specific free energy of interaction in a film of thickness H_f.

An analysis of experimental and of theoretical studies of line tension has shown[40–42] that different thermodynamic models are often used to define the line tension, and that this causes problems in comparing numerical values of æ.

The aim of this review is to analyse published work on the line tension problem in the thermodynamics of thin liquid films on the basis of the generalised theory of line tension developed by the writer.[40,42]

II. Different definitions of the line tension

All the reports on the line tension problem known to the writer can be arbitrarily divided into two groups. To the first we assign studies which have relied on the membrane approach to the thermodynamics of thin liquid films formulated by Deryagin and his co-workers.[43,44] In this approach the thermodynamic model of the thin liquid film is the interface (as defined by Gibbs,[45] i.e. a membrane of zero thickness) with respect to which the excess thermodynamic quantities are calculated (Fig. 1*b*).

Studies in which the film is treated as a layer of finite thickness H_f, bounded by two interfaces, are classified in the second group (Fig. 1*c*). This approach was proposed by Rusanov,[46–48] and has been further developed by the present writer and by others.[41,42,50–56]

In the membrane approach the condition of mechanical equilibrium of a symmetrical curved film of radius r_{f0} (see Fig. 1*b*) is defined as

$$\gamma + -\frac{æ^f}{r_{f0}} = 2\sigma_0 \cos\theta_0, \qquad (1)$$

where γ is the tension of the film, θ_0 is the contact angle corresponding to the radius of the film r_{f0}, σ_0 is the interfacial tension at the interface with the bulk phases, $æ^f$ is the line tension (in the symbols of Scheludko, et al.[1]). The term $æ^f/r_{f0}$ has the dimensions of N m^{-1} and can be interpreted as the two-dimensional pressure created by the curvature of the contact line (by analogy with the capillary pressure P_c created by the curvature of the interfacial surface). If the line of contact is straight (i.e. for $r_{f0}\to\infty$) the equilibrium equation of the film (or membrane) becomes

$$\gamma = 2\sigma_0 \cos\theta_{0\infty}, \qquad (2)$$

where $\theta_{0\infty}$ is the angle of contact corresponding to $r_{f0}\to\infty$. Ignoring the dependence of the film tension γ on its radius r_{f0} we obtain from Eqns. (1) and (2) the expression

$$æ^f = 2r_{f0}\sigma_0 (\cos\theta_0 - \cos\theta_{0\infty}), \qquad (3)$$

which is used as a basis for the experimental determination of the line tension $æ^f$ from the $\theta_0(r_{f0})$ relationship.

The line tension $æ^f$ defined in terms of the membrane approach is used, for example, by Scheludko, et al.[15,16] and by Churaev, et al.[57]

In the method of two interfaces the mechanical equilibrium condition of a symmetrical curved film is written (see Fig. 1*c*) as:[49]

$$2\sigma_f + \frac{\tau}{r_f} = 2\sigma_0 \cos\theta_f, \qquad (4)$$

where σ_f is the interfacial tension in a film of thickness H_f, which differs from the interfacial tension σ_0 and is related to it by the expression

$$2\sigma_f = 2\sigma_0 + \Delta\Omega(H_f), \qquad (5)$$

where $\Delta\Omega(H_f)$ is the specific free energy of the interaction between the interfaces in a film of thickness H_f, so that the condition for a finite angle of contact is $\Delta\Omega(H_f) < 0$; θ_f and r_f are the angle of contact and the radius of the film (note that $\theta_f \neq \theta_0$ and $r_f \neq r_{f0}$ for $H_f \neq 0$); τ is the line tension (in de Feijter and Vrij's symbols[49]).

If the thickness of the film H_f is unaffected by changes in the radius r_f we can write the expression [analogous to Eqn. (3)]

$$\tau = 2r_f\sigma_0 (\cos\theta_f - \cos\theta_{f\infty}), \qquad (6)$$

where $\theta_{f\infty}$ is the angle of contact for cylindrical films (i.e. for $r_f\to\infty$), which satisfies the condition

$$\sigma_f = \sigma_0 \cos\theta_f. \qquad (7)$$

Eqn. (6) is the basis of the experimental determination of the line tension τ from measurements of the $\theta_f(r_f)$ dependence.

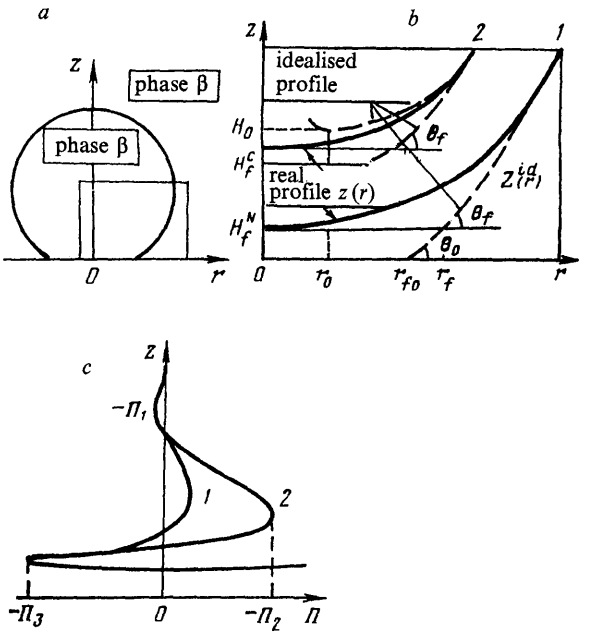

Figure 2. Definition of the parameters which characterise the profile of thin liquid films (see text).

We should stress the fact that the line tensions $æ^f$ and τ are different quantities, defined in terms of different thermodynamic models. As has been pointed out,[40,42] the difference between $æ^f/r_{f0}$ and τ/r_f is of the order of $\Delta P H_f$ (where $\Delta P = P_\beta - P_\alpha$, and P_α and

P_β are the hydrostatic pressures in the phases α and β respectively (see Fig. 1*a*), corresponding to $\sim 5 \times 10^{-6}$ N m^{-1} with $\Delta P \simeq 100$ Pa for films of thickness $H_f \sim 50$ nm thick. The error caused by identifying τ with $æ^f$ is $\sim 5 \times 10^{-10}$ N for films of radius $r_f \cong 100$ μm, and the relative error of the line tension $\tau \cong 10^{-12}$ N[49] is of the order of $\Delta P H_f/\tau = 500$. Thus failing to distinguish between the line tensions τ and $æ^f$ (as is often done in published work) can lead to serious errors in the determination of their numerical values for $H_f \neq 0$: the greater the product $\Delta P H_f$, the greater is the error.

It should be noted that the contact angles θ_f or θ_0 are determined by the following procedure (Fig. 2*a*). Since the real profile $z(r)$ of the film in the transition region of the meniscus can seldom be determined experimentally to the required precision (because of the very small size of this region) the idealised profile $z_{id}(r)$ is usually employed. This is by definition identical to the real profile $z(r)$ in the region of the main bulk of the meniscus, where the disjoining pressure is zero (Fig. 2*b*), and it can be extrapolated to the transition region of the film on the assumption that the interfaces do not interact in that region. The idealised profile of the film $z_{id}(r)$ is determined with high precision by an interference method (called the topographic method[58]). We know that the following relationship applies[49] for negative values of the specific free energy of interaction $\Delta\Omega(H_f)$ in a film of thickness H_f:

$$\Delta\Omega(H_f) = \int_{H_f}^{\infty} \Pi(H)dH, \tag{8}$$

and the idealised profile $z_{id}(r)$ must intersect the plane $z = z_f = H_f/2$, forming an angle of contact θ_f such that the condition (7) applies for cylindrical films. On the other hand if $\Delta\Omega(H_f)$ is negative and has a high absolute value the idealised profile $z_{id}(r)$ can also intersect the plane $z = 0$ (with a contact angle θ_0), and for cylindrical films the relationship (2) applies.

When $\Delta\Omega(H_f) > 0$ the idealised profile $z_{id}(r)$ passes above the plane $z = z_f = H_f/2$ (see Fig. 2*b*), and is characterised by a minimum ($z = H_0/2$) at $r = r_0$.[59–61] If the contact line is straight, i.e. if $r_0 \to \infty$, we can write

$$\Delta\Omega(H_f) = \Delta P(H_{0\infty} - H_f), \tag{9}$$

where $H_{0\infty} = 2z_{0\infty}$, and $z_{0\infty}$ is the minimum in the profile of the film for $r_0 \to \infty$.

The expression (9) was first used to determine experimentally the specific free energy of interaction $\Delta\Omega(H_f)$ in water films stabilised by adsorbed layers of polyvinyl alcohol,[62] and it was shown that under these conditions $\Delta\Omega(H_f) = +2 \times 10^{-7}$ J m^{-2}. The expression (9) was also used[63] in an experimental determination of $\Delta\Omega(H_f)$ for wetting films of aqueous solutions of electrolytes on quartz. For these films the result was $\Delta\Omega(H_f) = +2 \times 10^{-5}$ J m^{-2}.

The line tension τ_B for films with a positive $\Delta\Omega(H_f)$ was first determined by the present writer[55,64,65] as

$$\Delta\Omega(H_f) + \frac{\tau_B}{r_0} = \Delta P(H_0 - H_f), \tag{10}$$

or, using (5),

$$2\sigma_f + \frac{\tau_B}{r_0} = 2\sigma_0 + \Delta P(H_0 - H_f). \tag{11}$$

Eqn. (10) reduces to (9) for $r_0 \to \infty$. If the film thickness H_f and the difference in hydrostatic pressures stay constant, $\Delta\Omega(H_f)$ is also unchanged, and by combining (9) with (10) we obtain

$$\tau_B = r_0 \Delta P[H_0(r_0) - H_{0\infty}], \tag{12}$$

where $H_0(r_0)$ is the minimum thickness of the idealised profile of a film of radius r_0. Eqn. (12) can be used as the basis of the experimental determination of the line tension τ_B from the $H_0(r_0)$ dependence, but only under conditions of constant H_f and ΔP for changes in r_0.

In Fig. 1*c* we show a scheme which illustrates the condition of mechanical equilibrium of liquid films for a positive value of $\Delta\Omega(H_f)$.

These considerations, and the formulae for the line tensions $æ^f$, τ, and τ_B of symmetrical liquid films, can be extended to asymmetrical liquid films and three-phase systems (Fig. 3).

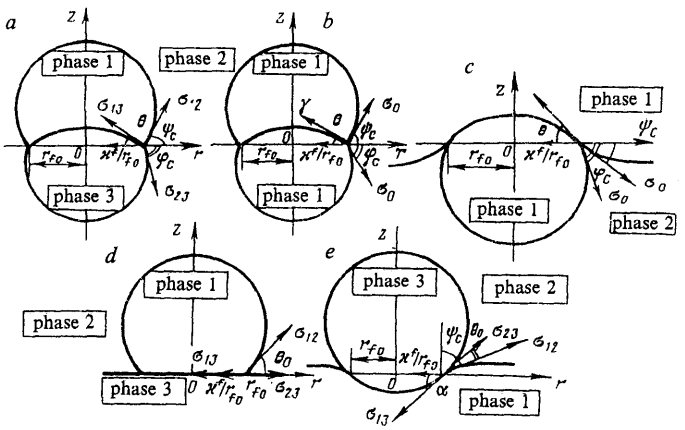

Figure 3. Definition of the line tension in asymmetric liquid films (see text).

At the contact of three fluid (liquid or gaseous) phases (Fig. 3*a*) the condition of mechanical equilibrium is

$$\sigma_{13}\cos\theta + \frac{æ^f}{r_{f0}} = \sigma_{12}\cos\psi_c + \sigma_{23}\cos\varphi_c. \tag{13}$$

If the inter-phase tensions σ_{12}, σ_{13}, and σ_{23} are known the line tension $æ^f$ can be determined by measuring the contact angles θ, ψ_c, and φ_c and the radius of the contact line r_{f0}.[18,31,39] If the interfacial tension σ_{13} is not known we must combine Eqn. (13) with the additional equilibrium equation

$$\sigma_{13}\sin\theta = \sigma_{23}\sin\varphi_c - \sigma_{12}\sin\psi_c. \tag{14}$$

When the phases 1 and 3 are identical we have $\sigma_{12} = \sigma_{23} = \sigma_0$, and $\sigma_{13} = \gamma$ (Fig. 3*b*), leading to a system of equations which describe the mechanical equilibrium of the phases and can be used to determine $æ^f$:[5,34,35]

$$\gamma\cos\theta_0 + \frac{æ^f}{r_{f0}} = \sigma_0(\cos\varphi_c + \cos\psi_c), \qquad (13')$$

$$\gamma\sin\theta_0 = \sigma_0(\sin\varphi_c - \sin\psi_c). \qquad (14')$$

If one of the phases is solid (Figs. 3*d* and 3*e*) the interfacial tensions σ_{13} and σ_{23} are unknown, and the condition of mechanical equilibrium of the three-phase line of contact of radius r_{f0} is written as follows (see Fig. 3*d* for a flat solid surface):

$$\sigma_{13} - \sigma_{23} + \frac{æ^f}{r_{f0}} = \sigma_{12}\cos\theta_0. \qquad (15)$$

On the assumption that the difference $\Delta\sigma = \sigma_{13} - \sigma_{23}$ stays constant during changes in the radius r_{f0} of the contact line we can write an expression analogous to (3):

$$æ^f = r_{f0}\sigma_{12}(\cos\theta_0 - \cos\theta_{0\infty}), \qquad (16)$$

which allows us to determine the line tension $æ^f$ from measurements of the $\theta_0(r_{f0})$ dependence.[32,38] In the case of a spherical solid surface (Fig. 3*e*) the mechanical equilibrium condition is

$$\sigma_{13} - \sigma_{23} + \frac{æ^f}{r_{f0}}\cos\alpha = \sigma_{12}\cos\theta_0. \qquad (15')$$

All these determinations of the line tension are based on the representation of the line tension as a force which stretches or compresses the line of contact. This approach to the determination of the line tension can nominally be called dynamic.

Another approach (arbitrarily termed the energy approach) depicts the line tension as the excess free energy æ referred to unit length of the contact line.[12,15,18,20] All these studies rely on the membrane model of liquid films and of three-phase systems. In particular, Rowlinson and Widom[12] determined the line tension æ by replacing the real system [including the three-phase contact line (Fig. 4*a*)], by an idealised model in which the surfaces A_{12}^{id}, A_{23}^{id}, and A_{13}^{id} have a constant average curvature and constant interfacial tensions σ_{12}, σ_{23}, and σ_{13} (up to the intersection of the surfaces with the contact line). Under these conditions the free energy (grand thermodynamic potential) of the idealised system Ω^{id} can be written

$$\Omega^{id} = -P_1V_1^{id} - P_2V_2^{id} - P_3V_3^{id} + \sigma_{12}A_{12}^{id} + \sigma_{23}A_{23}^{id} + \sigma_{13}A_{13}^{id} + æL, \qquad (17)$$

where L is the length of the contact line. The line tension æ is found from the condition of energy equivalence of the real and the idealised system, i.e. from the equality $\Omega = \Omega^{id}$, where Ω is the free energy of the real system, assumed to be known.

For the contact of a liquid drop (phase 1) with a solid surface (phase 3) in a gaseous medium (phase 2) the expression for the work of formation of the drop (assuming heterogeneous nucleation of water drops on a hydrophobic surface) can be written[1,15,20,66,67] (in our symbols) as

$$-W = \Delta\Omega = -\Delta PV_1^{id} + \sigma_{12}A_{12}^{id} + \Delta\sigma\pi r_{f0}^2 + 2\pi r_{f0}æ, \qquad (18)$$

where $\Delta\sigma = \sigma_{13} - \sigma_{23} - \sigma_{12}$; $\Delta P = P_1 - P_2$; V_1^{id} and A_{12}^{id} are the volume and surface area of the drop (for the idealised model of the drop, see above). All these workers determine the line tension æ on the basis of measurements of the work of heterogeneous nucleation of water drops from a supersaturated vapour onto hydrophobic (liquid or solid) substrates.

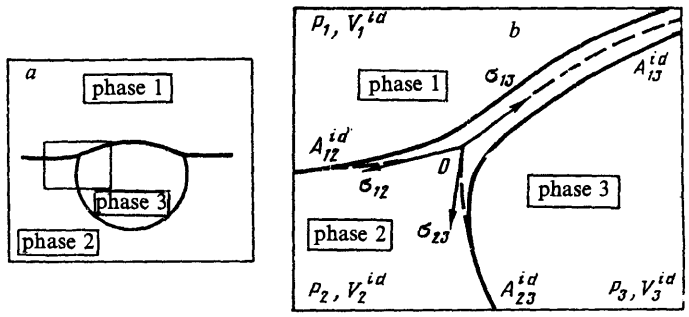

Figure 4. Definition of the line tension as the specific excess free energy of the system (referred to unit length of the contact line) which includes a thin liquid film (see text).

III. Experimental determination of the line tension

The results of experimental determinations of the line tension $æ^f$ are shown in Table 1.

The lack of correlation between the magnitude and sign of the line tension (on the one hand) and other physicochemical parameters such as the angle of contact (on the other hand) is noteworthy. Furthermore the scatter of the $æ^f$ values measured by different workers for identical systems is 3–4 orders of magnitude.[33–35] Whereas Gaydos and Neumann,[38] and also Wallage and Schürch,[39] obtained positive values by measuring the dependence of the contact angle θ_0 on the radius of the contact line r_{f0} (i.e. they noted an increase in θ_0 upon decreasing r_{f0}), Good and Koo[32] found the opposite effect (i.e. they obtained a negative value of the line tension $æ^f$). However, the latter workers[32] attributed this $\theta_0(r_{f0})$ dependence to the roughness of their solid surface, and they called the measured $æ^f$ a pseudo-line tension.

The results of experimental determinations of the line tension $æ^f$ have led some workers[14–16,68] to the following conclusions on the effect of various physicochemical factors on $æ^f$.

For a relatively small coagulation barrier Π_2 (see curve *1* of Fig. 2*c*) very thin Newtonian black films (bilayer membranes) can be formed, with a thickness H_f^N less than 10 nm (curve *1* of Fig. 2*b*) and contact angles $\theta_0 \cong 10°$. These films are formed, for example, at the contact between air bubbles in an aqueous solution of sodium dodecyl sulphate containing NaCl ($c_{NaCl} > 0.36$ mol dm^{-3}).[5,26,34,36,68] In these films the line tension $æ^f$ is negative and equals $\sim 10^{-9}$ N. Upon raising the coagulation barrier Π_2 (curve *2* of Fig. 2*c*) by lowering the concentration of the NaCl electrolyte the contact angle θ_0 monotonically decreases, i.e. the negative specific free energy of the interaction $\Delta\Omega(H_f^N)$ decreases in absolute value. For example, for $c_{NaCl} = 0.32$ mol dm^{-3} the contact

angle is ~8°, and the line tension changes sign ($æ^f = +10^{-9}$ N) [5] (see Table 1).

Table 1. Results of experimental determinations of the magnitude and sign of the line tension æ.

æ, N	System	Experimental scheme	θ_0, deg	Refs.
$\pm 6 \times 10^{-8}$	Oil/aniline/water		> 10	[31]
-10^{-6} to -10^{-5}	Air/water/solid surface		> 10	[32]
$+1.25 \times 10^{-10}$	Air/solid surface/water		~ 25	[25]
$+10^{-10}$ to 10^{-9}	Air/water/air		~ 8	[5]
-1.7×10^{-11}	Air/water/air		< 1	[33]
-10^{-9} to 10^{-9}	ditto		~ 9	[34—36]
-1.9×10^{-10}	Gas/water/hexadecane		~ 50	[1, 20]
$+3 \times 10^{-6}$	Air/oil/Teflon		40—50	[38]
$+2.4 \times 10^{-8}$	Water/dibutyl phthalate/fluorocarbon		30—150	[39]

With an even higher coagulation barrier Π_2 (curve *2* of Fig. 2*c*), when the capillary pressure P_c in the film is less than Π_2, relatively thick ordinary black films are formed (of thickness $H_f^c > 10$ nm, see curve *2* of Fig. 2*b*). If $\Delta\Omega(H_f^c)$ is negative under these conditions the contact angle θ_f is formed. If the absolute value of $\Delta\Omega(H_f^c)$ is high enough we can find the contact angle θ_0, as in curve *1* of Fig. 2*b*. According to Kolarov and Zorin's measurements[33] the contact angle for $c_{NaCl} = 0.1$ mol dm^{-3} is $\theta_0 < 0.5°$. For ordinary black films Platikanov and Nedyalkov[68] found a positive value of $æ^f$, which is incompatible with Kolarov and Zorin's value:[33] a negative line tension $æ^f = -1.7 \times 10^{-11}$ N. This value of $æ^f$ agrees well with the numerical values of the line tension τ reported[49] for ordinary black films.

Let us examine some other methods of determining the line tension $æ^f$ experimentally.

Torza and Mason[31] measured the angles of contact formed by drops of silicone oil (phase 1) and aniline (phase 3) in water (phase 2) (see Fig. 3*a*), and calculated the line tension $æ^f$ by formula (13). The results lay in the range of $\pm 6 \times 10^{-8}$ N, denoting that the precision of the method was inadequate.

In the experiment reported by Mingins and Scheludko[25] glass microspheres (phase 1) of various diameters (< 50 μm) treated with an aqueous 0.01 M solution of octyltrimethylammonium bromide fell freely in water (phase 2) towards a water—air (phase 3) interface (see Fig. 3*e*). Spheres with a radius smaller than some critical value R_c formed ordinary black films with a relatively large thickness H_f^c (see curve *2* of Fig. 2*b*) because their mass was insufficient to overcome the coagulation barrier Π_2. According to those workers[25] a positive line tension $æ^f$ (tending to shorten the contact line) prevents the rupture of the liquid water film. Microspheres with a radius greater than R_c can overcome the line tension and fracture the black film, as can be seen in the microscope. The line tension was calculated by the formula[16,25]

$$æ^f = \frac{(2\rho g\sigma)^{1/2}}{3}(1 - \cos\theta_0)R_c^2, \tag{19}$$

which gives $R = 20$ μm and $æ^f = +1.25 \times 10^{-10}$ N for the known values $\theta_0 = 25°$, $\sigma = 70$ mJ m^{-2}, and $\rho = 1.48$ g cm^{-3}.

In the experiment reported by Platikanov, et al.[5] a similar method[25] was used, but the glass spheres were replaced by microscopic gas bubbles (phase 3) which floated in an aqueous solution of sodium dodecyl sulphate (phase 2) and came into contact with a water—air (phase 1) interface (Fig. 3*c*). The diffusion of gas through the film decreased the radius of the bubble but increased the capillary pressure P_c, and for $P_c > \Pi_2$ (see Fig. 2*c*) the ordinary black films of thickness H_f^c (curve *2* of Fig. 2*b*) which had been formed initially were spontaneously converted into thin Newtonian black films of thickness H_f^N (curve *1* of Fig. 2*b*), as noted in the microscope by the sudden change in reflectance (the grey colour being replaced by black) and by the increase in the radius of the bubbles.

As reported,[5,25] the conversion of ordinary black films into Newtonian black films opposes the positive line tension tending to shorten the contact line and thus to suppress the increase in area of the film. Under these conditions the expression for the line tension $æ^f$ obtained from the mechanical equilibrium condition of the bubble becomes (in our symbols)

$$æ^f = 2\sqrt{\frac{2}{3}\rho g\sigma_0}(1 - \cos\theta_{0\infty})R_{cr}^2, \tag{20}$$

where $\theta_{0\infty}$ is the angle of contact corresponding to infinitely large films (i.e. to a straight contact line), and R_{cr} is the critical radius of the gas bubble corresponding to the rupture of the ordinary black film.

The writer has pointed out[40] that this interpretation of the role of line tension in the stabilisation of ordinary black films is over-simplified and, in general, incorrect, because the same effect (i.e. the suppression of the increase in area of the film) is produced by negative line tension: it is the effect of bulk and surface forces contributing to the free energy, and not of line forces only, as could have been thought at first sight. An alternative explanation of the results, based on the theory of adhesion of liquid particles, has been suggested.[8]

Let us examine the results of measurements of the line tension æ through measurements of the work of heterogeneous nucleation of a water phase from the supersaturated vapour onto hydrophobic substrates.[1,15,20,66,67] The authors' interpretation of the results is based on the following arguments.

From measurements of the critical supersaturation S_0 of water vapour in the chamber the radius of curvature R of the surface of the nuclei is determined by the Thompson—Gibbs formula

$$P_c = \frac{kT}{\bar{v}}\ln S_0, \tag{21}$$

where $P_c = 2\sigma_0/R$ is the capillary pressure in the water nucleus, $\bar{v}$ is the molar volume of water, and k is Boltzmann's constant. Then, on the assumption that the heterogeneous creation of a new phase on reaching the critical supersaturation S_0 of water vapour is barrierless, i.e. that the work of formation W of the nuclei is zero, Eqn. (18) is re-written (for a solid hydrophobic surface, see Fig. 3*d*) as:

$$0 = W = \frac{2}{3}\sigma_{12}\pi R^2(1+\cos^3\theta_0) + \pi r_{f0}^2\Delta\sigma + 2\pi r_{f0}\text{æ}, \qquad (22)$$

where $r_{f0} = R\sin\theta_0$ is the radius of the contact between the nucleus and the solid substrate. Eqn. (22) establishes the relationship between the line tension æ and the parameters θ_0 (the angle of contact), R (the radius of the nucleus), and also σ_{12} and $\Delta\sigma$. Then, by using (15) (which relates the line tension æ^f to the contact angle θ_0) we can solve Eqn. (22) and obtain an expression for the line tension æ on the assumption that $\text{æ} = \text{æ}^f$.

The line tension can be obtained in a similar way from data on the heterogeneous nucleation on a liquid hydrophobic substrate (Fig. 4*a*).

Scheludko, et al.[1] give the results of one experiment (S_0 = 41.9% and $R \cong 3$ nm), and also the line tension calculated from them (æ = -0.8×10^{-10} N) by using the parameters σ_{12} = 24.1 mJ m^{-2}, σ_{23} = 53.2 mJ m^{-2}, σ_{13} = 73 mJ m^{-2}, $\theta_{0\infty}$ = 28.93°, and $\varphi_{c\infty}$ = 41.59° (see Fig. 3*c*).

Scheludko, et al.[1] believe that ignoring the negative line tension (which lowers the work of heterogeneous nucleation) would make the critical supersaturation very much higher: for the example given it would be S_0 = 105%, i.e. 2.5 times higher.

The reported line tension (æ = -0.8×10^{-10} N), and also the suggestion that this method can be used to determine the line tension, have attracted critical comments by the present writer.[40,42] The main objections to the determination of the line tension by this method are the following.

1. The precision claimed for the determination of the angles of contact $\theta_{0\infty}$ and $\varphi_{c\infty}$ is unacceptably high. The error in the measurement of these angles is about 0.5° (the uncertainty in the sessile drop method), corresponding to an error in the determination of the line tension of the order of $\Delta\text{æ} \simeq \pm 10^{-10}$ N, i.e. of the same order as the measured quantity æ = -0.8×10^{-10} N.

2. For drops with a diameter of 3 nm the interfacial tension σ_{12}, σ_{23}, and σ_{13} differ from the corresponding macroscopic values since the drop size is comparable with the radius of action of the surface forces (molecular and ionic/electrostatic). In this case the drop cannot be treated as a substance in the thermodynamic sense, and the replacement of the interfacial tensions by their macroscopic values is equivalent to ascribing bulk and surface excess thermodynamic parameters to the contact line markedly different from the corresponding values for the reference phase 3 (see Fig. 4). In particular, the decrease in the critical supersaturation for nucleation S_0 can be more convincingly attributed to the decreased interfacial tension of droplets with a diameter as small as R = 3 nm than to the effect of the line tension.

In the case of wetting films only one attempt to determine experimentally the line tension τ_B has so far been reported [see Eqn. (11)].[63] Those workers used Eqn. (12) to calculate the line tension τ_B, and obtained $\tau_B = \pm 3 \times 10^{-11}$ N from the experimental $H_0(r_0)$ dependence (see Fig. 3*d*) by assuming a constant film thickness H_f (h_0 in Zorin's symbols[63]). We should stress that since the film thicknesses H_0 and H_f can be measured only to within ± 5 nm as a function of the radius r_0, and since H_f could decrease when r_0 increases (i.e. when the difference in hydrostatic pressure ΔP increases), Eqn. (12) should be replaced by

$$\frac{\tau_\beta}{r_0} = \Delta P[H_0(r_0) - H_0(\infty)] - 2\Delta\sigma_f(r_0), \qquad (23)$$

where $\Delta\sigma_f(r_0) = \sigma_f(r_0) - \sigma_f(\infty)$, and the following approximate relation applies;

$$2\Delta\sigma_f(r_0) \simeq \int_{H_f(r_0)}^{H_f(\infty)} \Pi(H)dH \simeq \Delta P[H_f(r_0) - H_f(\infty)]. \qquad (24)$$

We shall use Zorin's experimental results[63] to calculate the error in the measurement of the line tension ($\Delta\tau_\beta$) due to the failure to allow for the possible change in the actual thickness of the film ($\Delta H \simeq \pm 5$ nm). Assuming $\Delta P \simeq 150$ Pa we obtain, for a film of radius r_0 = 50 μm,

$$\Delta\tau_B \simeq r_0\Delta\sigma_f(r_0) \simeq (50\times10^{-6})\times 1.50\times(\pm 5\times10^{-9}) = \pm 3.7\times10^{-11}\text{H}.$$

Evidently, the error in the determination of the line tension is of the same order as the measured quantity.

IV. Theories of the line tension

We shall now examine existing theories of the line tension, which give a relationship between the line tension and physicochemical parameters such as the radius r and the thickness H of the liquid film, the capillary pressure P_c, and the interfacial tension σ_0, and also parameters which characterise the form of the disjoining pressure isotherm $\Pi(H)$ as a function of the local thickness of the film (H).

An analytical expression for the line tension τ [see Eqn. (4)] was first proposed by de Feijter and Vrij,[49] who used a thermodynamic model of the film based on the presence of two interfaces (Fig. 2*c*). They discussed the mechanical equilibrium of the element of volume *ABCDEFGL* of a symmetrical curved liquid film (Fig. 5*a*), and they wrote the fundamental equation for the equilibrium of this film by equating to zero the projection on the 0r axis of the resultant of all the surface and bulk forces acting on the element of volume:

$$\frac{d}{dr} = [2\sigma(H)r\cos\varphi(H) + \Delta PHr] - [2\frac{\sigma(H)}{\cos\varphi(H)} + \Delta PH] = 0, \qquad (25)$$

where $\sigma(H)$ is the local interfacial tension in a film of thickness H; $\varphi(H)$ is the local value of the angle of contact; $\Delta P = P_\beta - P_\alpha$ is the difference in hydrostatic pressure between the α and β phases respectively. Then, by invoking the mechanical equivalence (in the sense of mechanical equilibrium) of the real film (Fig. 5*b*) and of its idealised model (Fig. 5*c*) they arrived at Eqn. (4) and the following analytical expression for the line tension (see Fig. 2*c*):

$$\tau = \int_0^R \left[\frac{2\sigma(H)}{\cos\varphi(H)} + \Delta PH\right]dr - \int_{r_f}^R \left[\frac{2\sigma_0}{\cos\varphi_{id}(H)} + \Delta PH_{id}\right]dr_{id} -$$

$$-(2\sigma_f + \Delta PH_f)r_f, \qquad (26)$$

where R is the distance along the 0$_r$ axis corresponding to a zero disjoining pressure, i.e. $\sigma(H) = \sigma_0$, where σ_0 is the interfacial tension of the noninteracting surfaces and *id* indicates a quantity

relating to the idealised profile. As we have pointed out,[41,42,55] Eqn. (26) (obtained[49] for curved films, i.e. for a curved contact line) is incorrect, though it approaches asymptotically the correct expression for a straight contact line (for $r_f \to \infty$):

$$\tau = \int_{H_f}^{\infty} \sigma(H)\sin\varphi(H)dH - \int_{H_f}^{\infty} \sigma_0 \sin\varphi_{id}(H)dH_{id}. \qquad (27)$$

For the case of a straight contact line the following expression relating the line tension τ to the specific free energy of the interaction $|\Delta\Omega(H_f)|$ [see Eqn. (8) in the limit of $\Delta\Omega(H_f) \ll \sigma_0$]:

$$\tau = \sigma_0^{1/2}\left\{\int_{H_f}^{\infty}\left[\Delta\Omega(H) - \Delta\Omega(H_f) + \Delta P(H - H_f)\right]^{1/2} dH - \right.$$
$$\left. - \int_{H_f}^{\infty}\left[-\Delta\Omega(H_f) + \Delta P(H_{id} - H_f)\right]^{1/2} dH_{id}\right\}, \qquad (28)$$

or for very small contact angles θ_f (ignoring the terms containing ΔP)

$$\tau = \sigma_0^{1/2}\left\{\int_{H_f}^{\infty}\left[\Delta\Omega(H) - \Delta\Omega(H_f)\right]^{1/2} - \left[-\Delta\Omega(H_f)\right]^{1/2}\right\}dH. \qquad (29)$$

The expressions (27) and (28) were used[49] for numerical calculations of the line tension in ordinary and in Newtonian black films.

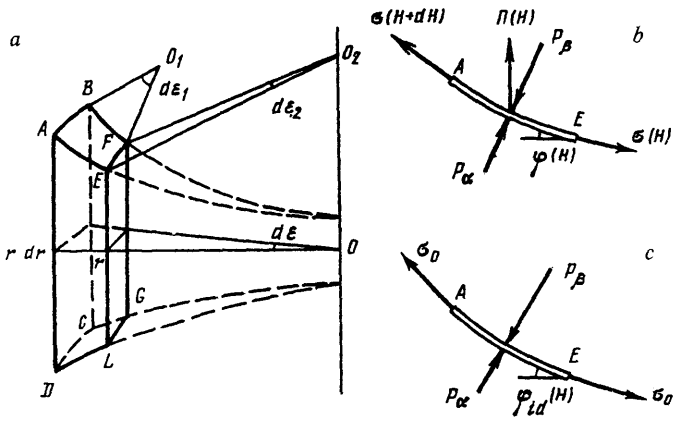

Figure 5. Formulation of the fundamental equilibrium equation of a thin liquid film [Eqn. (26)]: *a*, element of volume of a curved liquid film; *b*, equilibrium of the film surface in the transition region; *c*, equilibrium of the film surface in the Plateau region.

An approximate expression for τ, similar to Eqn. (26), was later obtained by other workers.[15,69,70]

The exact analytical expression (26) for the line tension τ was first obtained by Babak[55,64,65] in terms of the thermodynamics of the transition region of thin liquid films.[41] In particular, he showed[55] that the mechanical equilibrium of an element of volume of a thin liquid film (see Fig. 5*a*), like the element considered by de Feijter and Vrij,[49] is described by the system of equations:

$$\sigma(H)k(H) + \Pi(H)\cos\varphi(H) - \Delta P = 0, \qquad (30)$$

$$\Pi(H) = -\left.\frac{\partial\sigma(H)}{\partial H}\right|_{T,\mu_i,A} \qquad (31)$$

where $\Pi(H)$ is the disjoining pressure in the film as a function of the local thickness H, and $k(H)$ is the mean curvature of the film surface, which can be written (for a curved film)

$$k(H) = \frac{d\sin\varphi(H)}{dr} + \frac{\sin\varphi(H)}{r}. \qquad (32)$$

The Gibbs–Duhem equation (31) describes the equilibrium of the film surface in the direction of the tangent to this surface, since it can be rewritten [allowing for the fact that $dH = dl/2 \sin\varphi(H)$, where dl is an element of length of the tangent] as

$$\Pi(H)\sin\varphi(H)dl = -2d\sigma(H). \qquad (33)$$

Eqn. (30) describes the equilibrium of the film surface in the direction normal to the surface (see Fig. 5*a*) in the presence of a gradient of interfacial tension in the transition region of the film.

Eqn. (30) reduces to the well known equation for the mechanical equilibrium of a plane-parallel film of thickness H_f (which is also a definition of the disjoining pressure, proposed by Deryagin and Churaev[72]):

$$\Pi(H_f) = \Delta P = P_\beta - P_\alpha, \qquad (34)$$

allowing for the fact that in this region $k(H_f) = 0$ and $\varphi(H_f) = 0$, and that in the Laplace equation for noninteracting tension surfaces

$$\sigma_0 k_0 = \Delta P = P_\beta - P_\alpha, \qquad (35)$$

since $\sigma(H) = \sigma_0$ and $\Pi(H) = 0$.

The exact analytical expression for the line tension τ_d is[55,64,65]

$$\tau_d = r_f\left\{\int_{H_f}^{\infty}\frac{\sigma(H)\sin\varphi(H)}{r}dH - \int_{H_f}^{\infty}\frac{\sigma_0\sin\varphi_{id}(H)}{r_{id}}dH_{id}\right\}, \qquad (36)$$

where τ_d is the dynamic line tension (see Fig. 2*c*), obtained from the mechanical equilibrium condition of the element of volume of the liquid film (see Fig. 5*a*), in contrast to the energy line tension τ_e which appears in Eqn. (17) for the free energy of the film.

The expression for τ_d was obtained as follows. The integration of the fundamental mechanical equilibrium equation (30) over the thickness $H(r)$ of the real profile between the local value H and the value H_p in the Plateau region of the meniscus [where $\varphi(H_p) = \varphi_p$ and $\Pi(H_p) = 0$] leads to an invariant expression, independent of the local thickness of the film:

$$2\sigma_0\cos\varphi(H) + \Delta PH + \Delta\Omega(H) + \tau_0(H) +$$
$$+ \int_{H}^{H_p}\frac{\sigma(H)\sin\varphi(H)}{r}dH = 2\sigma_0\cos\varphi_p + \Delta PH_p, \qquad (37)$$

where the function

$$\tau_0(H)=\int_H^\infty\left[\frac{1}{2}\Delta\Omega(H)\frac{d\sin\varphi(H)}{dr}-\Pi(H)(1-\cos\varphi(H))\right]dH, \quad (38)$$

is identically equal to zero.[42]

Similarly, the integration of the Laplace equation (35) (see Fig. 5*b*) over the thickness of the idealised profile $H_{id}(r)$ between the limits H_{id} and H_p also gives an invariant, independent of the thickness of the idealised profile:

$$2\sigma_0\cos\varphi_{id}(H)+\Delta PH_{id}+\int_{H_{id}}^{H_P}\frac{\sigma_0\sin\varphi_{id}(H)}{r_{id}}dH_{id}=2\sigma_0\cos\varphi_P+\Delta PH_P. \quad (39)$$

By equating the invariants (37) and (39) we obtain a fundamental equation which was first proposed by the present writer:[55,64]

$$2\sigma_0\cos\varphi(H)+\Delta PH+\Delta\Omega(H)+\int_H^{H_P}\frac{\sigma(H)\sin\varphi(H)}{r}dH=$$

$$=2\sigma_0\cos\varphi_{id}(H)+\Delta PH_{id}+\int_{H_{id}}^{H_P}\frac{\sigma_0\sin\varphi_{id}(H)}{r_{id}}dH_{id}, \quad (40)$$

and which is valid for any values of $H(r)$ and $H_{id}(r)$ in the range of interest. This equation is universal, and it can be used to obtain all the known film equilibrium equations which have been used as the basis of the various thermodynamic models as well as the corresponding expressions for the line tensions. We shall prove this assertion with a few examples.

By inserting $H = H_f$ and $\varphi(H_f) = 0$ into the left-hand side of Eqn. (40), and $H_{id} = H_f$ and $\varphi_{id}(H_f) = \theta_f$ into the right-hand side (see Fig. 2*c*), and using the equality $\Delta\Omega(H_f) = 2\sigma_f - 2\sigma_0$, we obtain

$$2\sigma_f+\frac{\tau_d}{r_f}=2\sigma_0\cos\theta_f,$$

which is equivalent to Eqn. (4) and defines the equilibrium of the film in terms of the model of two interfaces, while the line tension τ_d is given by the exact analytical expression (36).

On the other hand if we use the membrane model of the film (see Fig. 2*b*) we must insert into the left-hand side $H = H_f$ and $\varphi(H_f) = 0$, and into the right-hand side $H = 0$ and $\varphi_{id(0)} = \theta_0$. In this case, using the definition of the film tension

$$\gamma = 2\sigma_f + \Delta PH_f, \quad (41)$$

we obtain from Eqn. (40) the condition of mechanical equilibrium of the film

$$\gamma+\frac{æ_d}{r_{f0}}=2\sigma_0\cos\theta_0,$$

which coincides with Eqn. (1), while the corresponding line tension $æ_d \equiv æ^f$ is determined by the exact analytical expression[55]

$$æ_d=r_{f0}\left\{\int_{H_f}^\infty\frac{\sigma_0\sin\varphi(H)}{r}dH-\int_0^\infty\frac{\sigma_0\sin\varphi_{id}(H)}{r_{id}}dH_{id}\right\}. \quad (42)$$

From (36) and (42) we obtain a relationship between the line tensions $æ_d$ and τ_d:[55]

$$\frac{æ_d}{r_{f0}}=\frac{\tau_d}{r_f}-\int_0^{H_f}\frac{\sigma_0\sin\varphi_{id}(H)}{r_{id}}dH_{id}. \quad (43)$$

In the case of a straight contact line (i.e. for $r_f\to\infty$) we obtain from Eqns. (36) and (42) the following expressions for the corresponding line tensions τ_d^0 and $æ_d^0$:

$$\tau_d^0=\int_{H_f}^\infty\sigma(H)\sin\varphi(H)dH-\int_{H_f}^\infty\sigma_0\sin\varphi_{id}(H)dH_{id}, \quad (44)$$

$$æ_d^0=\int_{H_f}^\infty\sigma(H)\sin\varphi(H)dH-\int_0^\infty\sigma_0\sin\varphi_{id}(H)dH_{id}, \quad (45)$$

and the following expression also applies:[55]

$$æ_d^0=\tau_d^0-\int_0^{H_f}\sigma_0\sin\varphi_{id}(H)dH_{id}. \quad (46)$$

Thus the generalised line tension theory[55,64] allows us to reconcile the various definitions of the line tension, corresponding to different thermodynamic models of a thin liquid film. This is a very valuable attribute, especially since it has been stated[15,33,57] that the line tensions τ_d [defined by Eqn. (4)] and $æ_d$ [defined by Eqn. (1)] are identical, and a good agreement has been reported between the values of æ (measured, or calculated theoretically) and of τ_d (calculated by de Feijter and Vrij[49]). Nevertheless the line tension $æ_d$ for ordinary black films can be 10^3 times greater than the line tension τ_d.[55,71] We shall examine this difference more closely below.

The following conclusion on the properties of $æ_d$ and τ_d have been formulated:[40] 1) the line tensions $æ_d$ and τ_d are different quantities; 2) $æ_d$ (unlike τ_d) depends on the film thickness H_f and coincides with τ_d when $H_f = 0$; 3) $æ_d$ is more "negative" than τ_d, since the integrals in Eqns. (43) and (46) are positive.

The writer has obtained[55,64,65] a definition of the line tension $\tau_{Bd} \equiv \tau_B$ [see Eqn. (11)], corresponding to the case of a positive $\Delta\Omega(H_f)$, for which a contact angle is not formed, and has derived an expression for this line tension:

$$\tau_{Bd}=r_0\left[\int_{H_f}^\infty\frac{\sigma(H)\sin\varphi(H)}{r}dH-\int_{H_0}^\infty\frac{\sigma_0\sin\varphi_{id}(H)}{r_{id}}dH_{id}\right], \quad (47)$$

where r_0 is the radius of the film (see Fig. 2*d*). In the case of a straight contact line Eqn. (47) reduces to

$$\tau_{Bd}^0=\int_{H_f}^\infty\sigma(H)\sin\varphi(H)dH-\int_{H_0}^\infty\sigma_0\sin\varphi_{id}dH_{id}. \quad (48)$$

The generalised line tension theory[40,41,42] also yields expressions for the "energy" line tensions, which appear in the expressions for the free energy of systems which include a liquid film. For example, for the model of a liquid film which stipulates two interfaces, the expression for the grand thermodynamic potential of the system (see Fig. 2*c*) becomes

$$\Omega^{id}=-P_\alpha V_\alpha^{id}-P_\beta V_\beta^{id}+\int_{A^{id}}\sigma(H)dA^{id}+2\pi r_f\tau_e, \quad (49)$$

where the integration is carried out over the surface of the idealised model of the film, with $\sigma(H) = \sigma_0$ on the side surface and $\sigma(H) = \sigma_f$ on the plane parallel surface.

From the condition of energy equivalence of the real film and its idealised model we obtain an expression for the line tension corresponding to a negative specific free energy of interaction $\Delta\Omega(H_f)$ in the film:[42]

$$\tau_e = \frac{1}{r_f}\int_0^R \left[\frac{2\sigma(H)}{\cos\varphi(H)} + \Delta PH\right] rdr - \int_{r_f}^R \left[\frac{2\sigma_0}{\cos\varphi_{id}(H)} + \Delta PH_{id}\right] rdr - \\ -[2\sigma_f + \Delta PH_f]r_f. \qquad (50)$$

By comparing the exact expression for the line tension τ_e [Eqn. (50)] with the approximate expression (26) obtained by de Feijter and Vrij[49] for the dynamical line tension τ we find substantial differences in spite of their structural similarity. Thus, we conclude that the first exact expression for the line tension τ_e was published in the current year.[42]

On the other hand it is clear that the dynamical line tension τ_d [defined by the expression (36)] differs from the energy line tension τ_e [defined by the expression (50)] in the case of a curving contact line. For a straight contact line the dynamical (τ_d^0) and the energy line tension coincide and are defined by the relationship (44).

The first exact analytical expression[42] for the energy line tension $æ_e$, corresponding to the membrane model of the film for $\Delta\Omega(H_f) < 0$, and the expression for the energy line tension τ_{Be}, corresponding to $\Delta\Omega(H_f) < 0$, are shown below:

$$æ_e = \frac{1}{r_{f0}}\int_0^R \left[\frac{2\sigma(H)}{\cos\varphi(H)} + \Delta PH\right] rdr - \frac{1}{r_{f0}}\int_{r_0}^R \left[\frac{2\sigma_0}{\cos\varphi_{id}(H)} + \Delta PH_{id}\right] rdr - \gamma r_0, \qquad (51)$$

$$\tau_{Be} = \frac{1}{r_0}\int_0^R \left[\frac{2\sigma(H)}{\cos\varphi(H)} + \Delta PH\right] rdr - \frac{1}{r_0}\int_{r_0}^R \left[\frac{2\sigma_0}{\cos\varphi_{id}(H)} + \right. \\ \left. + \Delta PH_{id}\right] rdr - [2\sigma_f + \Delta PH_f]r_0. \qquad (52)$$

In particular we showed that the equalities $æ_d^0 = æ_e^0$ and $\tau_{Bd}^0 = \tau_{Be}^0$ apply for a straight line of contact [see Eqns. (45) and (48) respectively].

Thus the first exact analytical expressions for the line tensions in terms of various thermodynamic models of thin liquid films have been derived from our generalised theory of line tension.[40,64] These expressions have been used[40–42,55,64,71] in numerical calculations of the line tension.

V. Calculation of the line tension by numerical methods

As was pointed out by de Feijter and Vrij,[49] the line tension τ_d^0 defined by Eqn. (27) can only be negative if the specific free energy of interaction $\Delta\Omega(H_f)$ in a film of thickness H_f is negative, i.e. when finite contact angles θ_f exist and the disjoining pressure isotherm is characterised by one coagulation minimum. This conclusion is self-evident, since in this case the product $\sigma(H)\sin\varphi$ is smaller than the product $\sigma_0 \sin\varphi_{id}$ over the whole integration range in Eqn. (27). We have shown[55,64] that under these conditions the line tension $æ_d^0$ determined in terms of the membrane model of the film [see Eqn. (1)] is even more negative if the sign of the integral in Eqn. (46) is taken to be positive. In the case of positive $\Delta\Omega(H_f)$ the line tension τ_{Bd}^0 defined by the expression (10) can only be positive[55,64] if the disjoining pressure $\Pi(H)$ is positive over the whole transition region. This obvious corollary follows from Eqn. (48) if we stipulate that the product $\sigma(H)\sin\varphi$ is greater than the product $\sigma_0 \sin\varphi_{id}$ over the whole integration region.

In the more complex disjoining pressure isotherms the sign of the line tension cannot be predicted from the form of Eqns. (44), (45), or (48). In this case the problem of the magnitude and sign of the line tensions determined on the basis of different thermodynamic models can be solved only by direct numerical calculations. The results of these calculations are examined in this section.

1. Choice of disjoining pressure isotherm for numerical calculations of the line tension

Figure 6 shows different types of disjoining pressure isotherm [$\Pi(H)$] used in line tension calculations.

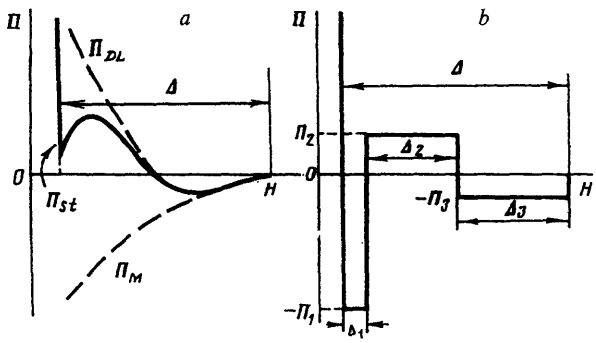

Figure 6. $\Pi(H)$ disjoining pressure isotherms used to calculate the line tension by de Feijter and Vrij[49] (*a*) and by Babak[40–42,55,64,65,71] (*b*).

De Feijter and Vrij[49] used a $\Pi(H)$ isotherm corresponding to the Deryagin–Landau–Verwey–Overbeek (DLVO) theory (see Fig. 6*a*), but including a very strong repulsion for $H \leqslant 4$ nm. This isotherm is thought to be characteristic of foam films stabilised by SAS and able to form stable Newtonian black films. The $\Pi(H)$ isotherm had the following analytical form:

$$\Pi(H) = -\frac{A}{6\pi H^3} + 1.59 \times 10^8 c \exp(-æH);\ H > 4 \text{ nm};$$

$$\Pi(H) = +\infty,\ H \leqslant 4 \text{ nm}, \qquad (53)$$

where A is the Hamaker constant, c is the concentration of electrolyte, and $æ = 3.28 \times 10^9$ s$^{1/2}$ m^{-1} is the Debye length. The line tension τ was calculated by formula (29) for several values of the parameters: $A = (0.2-4) \times 10^{-19}$ J, $c = 10^{-3}-\infty$ mol dm^{-3}, and $\Delta P = 25-100$ Pa.

As can be seen from Table 2 the line tension depends on the difference in hydrostatic pressures, on the contact angle (or specific free energy of interaction in the film), on the equilibrium thickness of the film, and on the radius of action of the molecular forces. De Feijter and Vrij[49] concluded that in ordinary and in Newtonian black films the line tension τ has a negative sign if the contact angle θ_f is finite, because varying these parameters over their actual existence range did not change the sign of the line tension from negative to positive. This conclusion is inconsistent with the experimental results of Platikanov, et al.[5,34,37,68] and of Scheludko, et al.,[16] who obtained positive linear tensions for ordinary black films.

Table 2. Line tension τ calculated[49] by the approximate formula (29) for different values of the concentration of electrolyte c, of the difference in hydrostatic pressure ΔP, of the film thickness H_f, of the contact angle θ_f, and of the specific free energy of interaction $\Delta\Omega(H_f)$ in a film of thickness H_f and radius of action of the surface forces Δ (σ_0 = 30 mJ m^{-2}).

No.	c, mol dm^{-3}	ΔP, Pa	H_f, nm	θ_f, min	$10^{-6}\Delta\Omega(H_f)$, J m^{-2}	Δ, μm	$10^{-12}\tau$, N

11	0.01	100	25	34	-2.93	4.7	-4.2

It follows from Table 2 that the effects of the parameters H_f, θ_f [or $\Delta\Omega(H_f)$], ΔP, and Δ on the line tension τ are inter-related: this prevents us from identifying the effects of the individual parameters on τ and from constructing the appropriate analytical expressions. In order to study the individual contribution of these parameters to the line tension the writer[55,64,71] has suggested using the idealised $\Pi(H)$ isotherm shown in Fig. 6*b*.

The main advantage of this isotherm over the DLVO isotherm of Fig. 6*a* is that in numerical calculations the equilibrium film thickness H_f can be kept constant, and the form parameters of the $\Pi(H)$ isotherm change in a way which keeps the angle of contact θ_f [or the parameter $\Delta\Omega(H_f)$] constant. Thus we are able to distinguish the effects of the contact angle θ_f on τ_d for constant values of the other parameters (H_f, ΔP, Δ_i, Π_i), and therefore we can establish the appropriate correlation dependences.

We should also note that the writer[64] used a $\Pi(H)$ isotherm which allows for the steric repulsion between adsorption layers of macromolecules in a liquid film, given by the Hesselink–Vrij–Overbeek (HVO) theory[73] as

$$\Pi(H) = a(1 - bH^2)H \exp(-cH^2), \qquad (54)$$

where a, b, and c are functions of the parameters which characterise the conformational state of macromolecules in the solution and their interactions.

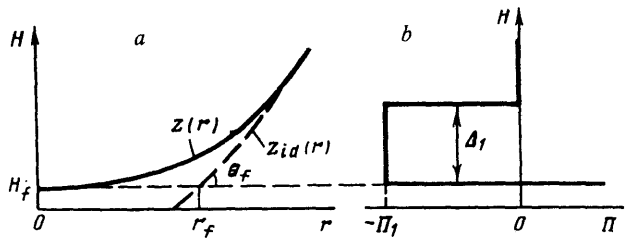

Figure 7. Idealised disjoining pressure isotherm $\Pi(H)$ with one coagulation minimum (see text).

Table 3. Line tension τ_d^0 calculated[79] by the exact formula (44) for different values of the parameters Δ_1 and Π_1 which describe the idealised disjoining pressure isotherm shown in Fig. 7, and also different values of the hydrostatic pressure ΔP, the contact angle θ_f, and of the specific free energy of interaction $\Delta\Omega(H_f)$ in a film of thickness H_f (σ_0 = 30 mJ m^{-2}).

2. Magnitude and sign of the line tension for a $\Pi(H)$ isotherm with one coagulation minimum

Let us first consider the $\Pi(H)$ disjoining pressure isotherm characterised by a single coagulation minimum (Fig. 7). It is obtained from the isotherm shown in Fig. 6*b* by the formal substitution $\Pi_2 = \Pi_3 = 0$, and it can describe Newtonian black films at relatively high concentrations of electrolyte (when the ionic–electrostatic repulsive forces in the electrical double layer are effectively suppressed and the coagulation barrier Π_2 disappears). Furthermore this disjoining pressure isotherm can describe ordinary black films (in which the radius of action of the molecular forces is much greater than the Debye length æ and the disjoining pressure Π_2 is greater than the capillary pressure in the film). The effect of the

height of the coagulation barrier on the magnitude and sign of the line tension will be discussed in depth below.

Table 3 shows the results of calculations of the line tension τ_d^0 by formula (44) as a function of the parameters Δ_1 and Π_1, which characterise the form of the idealised disjoining pressure isotherm $[\Delta P, \theta_f, \Delta\Omega(H_f)]$ for a constant interfacial tension.[40–42,55,64,71]

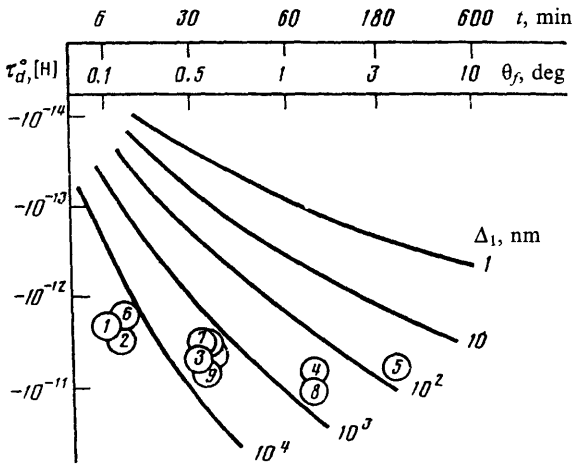

Figure 8. Plots of the line tension τ_d^0 against the contact angle θ_f for some values of the parameter Δ_1 which characterises the radius of action of the surface forces. The numbers by the curves denote the line tension value (τ) in Table 2 calculated by de Feijter and Vrij[49] by the approximate formula (29).

We note that the line tension τ_d^0 is negative for all forms of the $\Pi(H)$ isotherm, and also for the whole range of contact angles θ_f and of differences in hydrostatic pressure Δp examined. It is clear from the plots of the line tension τ_d^0 against the contact angle shown in Fig. 8 for constant values of the parameter Δ_1 (the action radius of the molecular forces) that the line tension tends towards zero as the angle of contact tends towards zero. Under these conditions the line tension is very sensitive to Δ_1, increasing as Δ_1 increases. We can see from Table 3 that the line tension τ_d^0 decreases as the difference in hydrostatic pressure ΔP increases while the other parameters stay constant.

Fundamental differences are revealed by comparing the dependences on the contact angle θ_f of the line tension τ obtained by de Feijter and Vrij,[49] and shown in Fig. 8, with the calculated $\tau_d^0(\theta_f)$ dependences.[42] For example, a change in the angle of contact from 0.5° to 3° is reported[49] to produce only a slight increase in the line tension (see the numbered points in Fig. 8). However, the line tensions in this range of θ_f actually increase by a factor of 30–100, depending on the parameter Δ_1 [see the corresponding $\tau_d^0(\theta_f)$ curves in Fig. 8]. The reason for this large difference between the calculated $\tau_d^0(\theta_f)$ dependences is self-evident when one notes that the disjoining pressure isotherm used in the calculations of de Feijter and Vrij (see Fig. 6*a*) cannot be used while keeping constant the film thickness, which decreases as the contact angle is increased (see Table 2), thus masking the true dependence of τ_d^0 on θ_f. The advantages of the $\Pi(H)$ isotherm used by the present writer[55,64,71] therefore seem obvious: it enables the film thickness H_f and the parameter Δ_1 to be held constant during changes in the contact angle θ_f, and it gives the true dependence of the line tension on θ_f.

We should also note that the use[49] of the approximate working formula (29) to calculate the line tension gives values at least 10 times too high, as can be seen by comparing the data in Table 2 with the numerical values of τ_d^0 calculated by the exact formula (44) (Table 3) for equal values of the parameters θ_f, ΔP, and Δ_1.

As was pointed out above, according to the generalised theory of the line tension[40] the tension $æ_d$, defined in terms of the membrane model of the film by Eqn. (1), differs from the line tension τ_d in the thermodynamic model, based on the assumption of a film with two interfaces [see Eqn. (4)]. The relationship between $æ_d^0$ and τ_d^0 in the case of a straight contact line is described by Eqn. (46). An analysis of the data in Table 4 leads to the important conclusion that the film thickness H_f has a marked influence on $æ_d^0$ but none on τ_d^0. Under these conditions the numerical value of the line tension $æ_d^0$ can exceed that of τ_d^0 by a factor of 10 or more.[55,71]

Table 4. Line tension $æ_d^0$ calculated[42] by the exact formula (45) as a function of the parameters Δ_1 and Π_1 which describe the idealised disjoining pressure isotherm shown in Fig. 7, and also for different hydrostatic pressures ΔP, contact angles θ_f, and specific energies of interaction $\Delta\Omega(H_f)$ in a film of thickness H_f and line tension τ_d^0 (σ_0 = 300 mJ m^{-2}).

3. Magnitude and sign of the line tension for a $\Pi(H)$ isotherm without a coagulation minimum

As we have already noted, in the case of a positive specific free energy of interaction $\Delta\Omega(H_f)$ in a film of thickness H_f the idealised profile of the film lies above the real profile (see Fig. 2*b*), and the line tension τ_{Bd}^0 is defined by Eqn. (10).[55,64,65] Table 5 shows the results of calculations of the line tension τ_{Bd}^0 by the exact formula (48) for the idealised $\Pi(H)$ isotherm shown in Fig. 9. This $\Pi(H)$ isotherm, in the form of a step, allows us to keep constant the film thickness H_f and to identify the effects of the shape of the $\Pi(H)$ isotherm (the parameters Δ_2 and Π_2) and also of ΔP and $\Delta\Omega(H_f)$ on the line tension τ_{Bd}^0.

Table 5. Line tension τ^0_{Bd} calculated[42] by the exact formula (48) as a function of the parameters Δ_2 and Π_2 which characterise the idealised disjoining pressure isotherm shown in Fig. 9, and also of the difference in hydrostatic pressure ΔP, the difference in film thickness $\Delta H = H_0 - H_f$, and the specific free energy of interaction $\Delta\Omega(H_f)$ in a film of thickness H_f (σ_0 = 30 mJ m^{-2}).

ΔP, nm	Δ_2, nm	Π_2, Pa	ΔH, nm	$10^{-6}\Delta\Omega(H_f)$, J m^{-2}	$10^{-12}\tau^0_{Bd}$, N
10^2	100	10	20	+2.0	+5.66
10^2	20	50	20	+2.0	+1.89
10^2	2	50	2	+0.2	+0.06
10^2	10	10	2	+0.2	+0.18
20	10	10	10	+0.2	+0.30
10^3	10	10	0.2	+0.2	+0.06

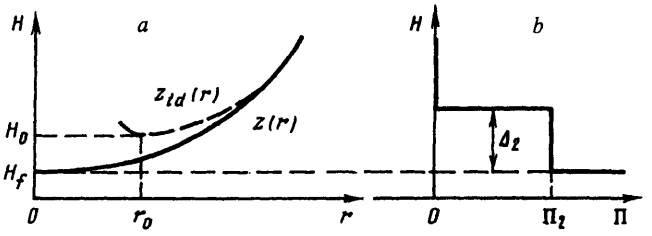

Figure 9. Idealised disjoining pressure isotherm $\Pi(H)$ without a coagulation minimum, used in calculations[41,42,71] of the line tension τ_{Bd} (see text).

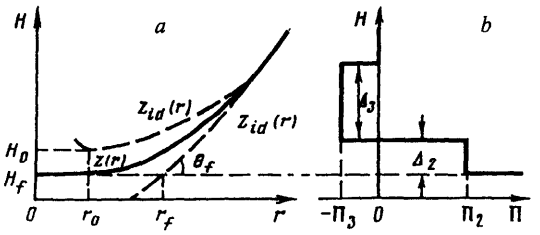

Figure 10. Idealised disjoining pressure isotherm $\Pi(H)$ with a long-range minimum and a coagulation barrier (see text).

The main conclusion from this analysis of the calculations is that the sign of the line tension τ^0_{Bd} is positive, i.e. it corresponds to the sign of $\Delta\Omega(H_f)$.[55,64] The line tension τ^0_{Bd} increases with Δ_2 and $\Delta\Omega(H_f)$, and as ΔP decreases.[55,64] More detailed results or the writer's calculations of τ^0_{Bd} as a function of these parameters have already been reported.[71]

4. Effect of the coagulation barrier on the magnitude and sign of the line tension

Let us first examine the idealised profile of the $\Pi(H)$ isotherm shown in Fig. 10, which can be used to model the change from wetting ordinary black films (which do not form a finite contact angle) to non-wetting ordinary black films (which form a finite contact angle θ_f). If the specific free energy of interaction in the film [which is equal, in our case of an idealised $\Pi(H)$ isotherm to $\Delta\Omega(H_f) = -2\Delta_3\Pi_3 + 2\Delta_2\Pi_2$] is less than zero the idealised profile $z_{id}(r)$ lies below the real profile $z(r)$ and forms the contact angle θ_f. If $\Delta\Omega(H_f) > 0$ the contact angle is not formed because $z_{id}(r)$ lies above $z(r)$. For $\Delta\Omega(H_f) = 0$ the contact angle θ_f is zero.

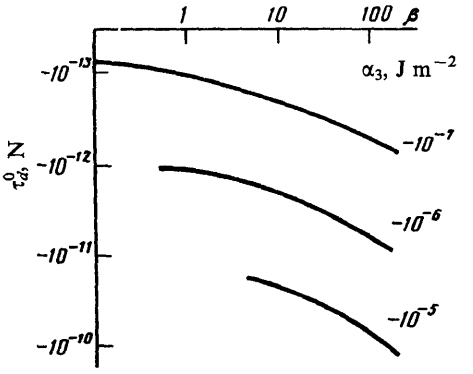

Figure 11. Dependence of the line tension τ^0_d on the parameter β for different values of the parameter α_3; ΔP = 100 Pa, σ_0 = 30 mJ m^{-2}, $\Delta\Omega(H_f) = 0$.

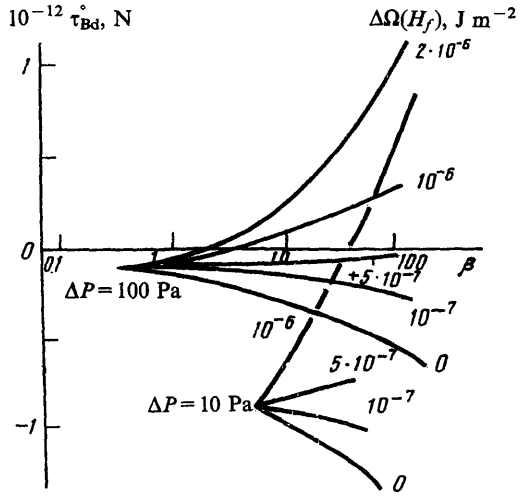

Figure 12. Dependence of the line tension τ^0_{Bd} on the parameter β for different positive values of the specific interaction energy $\Delta\Omega(H_f)$ in a film of thickness H_f and of the difference in hydrostatic pressure ΔP (σ_0 = 30 mJ m^{-2}, $\alpha_3 = -5 \times 10^{-7}$ J m^{-2}).

The latter case is illustrated in Fig. 11,[42] where the different $\tau^0_d(\beta)$ curves correspond to the condition $\Delta\Omega(H_f) = 0$ but to a different form of $\Pi(H)$ isotherm, characterised by the parameters $\beta = \Delta_2/\Delta_3$ and $\alpha_3 = -2\Delta_3\Pi_3$.

The most important conclusion suggested by the $\tau_d^0(\beta)$ curves of Fig. 11 is that the line tension τ_d^0 (and, even more, $æ_d^0$) is negative when the films have a finite angle of contact θ_f. This conclusion coincides with the results of numerical calculations of the line tension by de Feijter and Vij,[49] who obtained only negative values of τ_d^0 for ordinary black films, but is incompatible with the experimental results of Platikanov, et al.,[5,34] who obtained positive values of the line tension $æ_d$ for those films.

We also note that increasing the depth α_3 of the coagulation minimum (or the height of the coagulation barrier) for $\Delta\Omega(H_f) = 0$ (or $\theta_f = 0$) increases the absolute value of the (negative) line tension almost in proportion to the parameter α_3. This feature can be used as a criterion of the form of the $\Pi(H)$ isotherm under the conditions of a reliable experimental determination of both τ_d^0 and the contact angle θ_f.

When $\Delta\Omega(H_f) > 0$ the contact angle is not formed (see Fig. 10). In Fig. 12 we show the results of calculations of the line tension τ_{Bd}^0 as a function of the parameter $\beta = \Delta_2/\Delta_3$ for constant values of $\Delta\Omega(H_f)$ ($\alpha_3 = -5 \times 10^{-7}$ J m^{-2} in all the calculations). The upper family of curves corresponds to $\Delta P = 100$ Pa, the lower to $\Delta P = 10$ Pa.

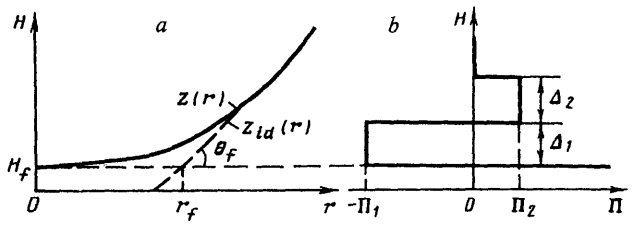

Figure 13. Idealised disjoining pressure isotherm $\Pi(H)$ with a coagulation barrier and a short-range coagulation minimum (see text).

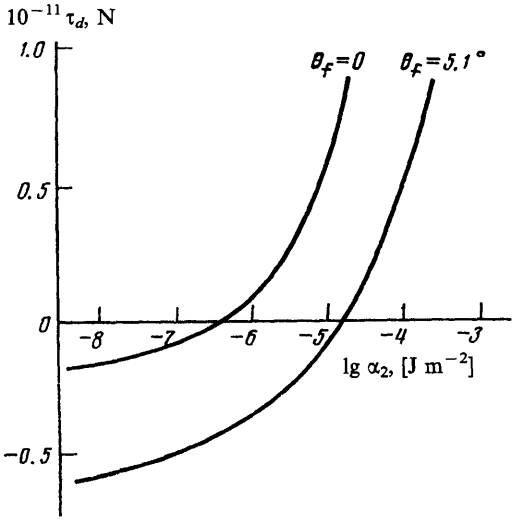

Figure 14. Dependence of the line tension τ_d^0 on the parameter α_2 for two values of the contact angle θ_f ($\Delta P = 100$ Pa, $\sigma_0 = 30$ mJ m^{-2}, $\Delta_1 = \Delta_2 = 10$ nm).

The line tension τ_{Bd}^0 determined according to Eqn. (48) can (in principle) have both negative and positive values.[42,74] However, since in ordinary black films the parameter β cannot be greater than 1 we may conclude that the line tension τ_{Bd}^0 is more likely to be negative than positive. The measured[63] positive value $\tau_{Bd}^0 = +3 \times 10^{-11}$ N for $\Delta\Omega(H_f) = 10^{-5}$ J m^{-2} and $\Delta P \simeq 100$ Pa is not incompatible with the numerical calculations of the line tension τ_{Bd}^0 shown in Fig. 12 provided that the films of aqueous solutions of electrolytes studied in that work[63] do not possess a long-range coagulation minimum, i.e. long-range molecular forces are entirely absent.

Let us now examine another generalised $\Pi(H)$ isotherm (Fig. 13), which models the Newtonian black films when the effect of the long-range coagulation barrier can be ignored. The dependence of the line tension $\tau_d^0(\alpha_2)$ on the parameter $\alpha_2 = 2\Delta_2\Pi_2$ for a constant $\Delta P = 100$ Pa is shown in Fig. 14 ($\Delta_2 = \Delta_1 = 10$ nm), where constant values of $\Delta\Omega(H_f)$ are also assumed (i.e. constant angles of contact θ_f).

We can see from Fig. 14 that upon increasing the height of the coagulation barrier Π_2 (i.e. upon increasing the parameter α_2) the line tension τ_d^0 passes from the negative into the positive region: this transition takes place at a higher value of α_2 when the contact angle θ_f is increased.

Lastly, if the effect of the long-range coagulation minimum cannot be ignored, the $\Pi(H)$ isotherm shown in Fig. 5*b* (characterised by two coagulation minima and a coagulation barrier) must be used in the calculation of the line tension.

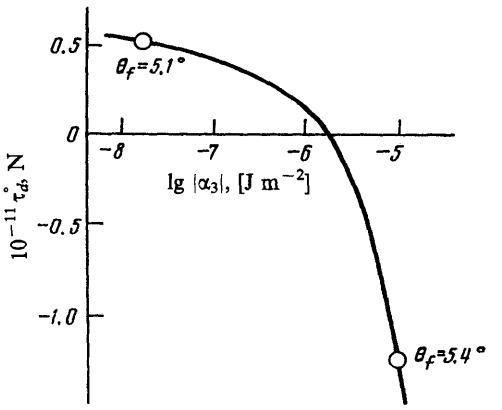

Figure 15. Dependence of the line tension τ_d^0 on the absolute value of the parameter α_3 ($\Delta P = 100$ Pa, $\sigma_0 = 30$ mJ m^{-2}, $\alpha_1 = -0.98 \times 10^{-4}$ J m^{-2}, $\alpha_2 = +1.8 \times 10^{-5}$ J m^{-2}, $\Delta_1 = \Delta_2 = \Delta_3 = 10$ nm).

In Fig. 15 we show the dependence of the line tension $\tau_d^0(\alpha_3)$ on the parameter $\alpha_3 = -2\Delta_3\Pi_3$ for constant $\Delta P = 10$ Pa, $\Delta_1 = \Delta_2 = \Delta_3 = 10$ nm, $\alpha_1 = -0.98 \times 10^{-4}$ J m^{-2}, and $\alpha_2 = +1.8 \times 10^{-5}$ J m^{-2}. Increasing the depth of the long-range coagulation minimum, i.e. increasing the absolute value of the parameter α_3, changes the sign of the line tension from positive to negative. Under these conditions the angle of contact θ_f is almost unaffected (at least,

any change in this angle is experimentally undetectable, since $\Delta\theta_f$ = 0.3° for an absolute value of $\theta_f \simeq 5°$).

Thus we may conclude that the most significant effects on the magnitude and sign of the line tension are produced by the form of the $\Pi(H)$ disjoining pressure isotherm rather than by the absolute value of the specific free energy of the interaction in the film, $\Delta\Omega(H_f)$, i.e. by the contact angle θ_f. This justifies the effort now being directed towards the experimental determination of the line tension, since a knowledge of the magnitude and sign of this parameter should provide new information on the form of the disjoining pressure isotherm.

As to the sign of the line tension τ_d^0 in Newtonian black films, in principle this parameter can be either positive or negative, depending on the form of the idealised $\Pi(H)$ isotherm. However, for real $\Pi(H)$ isotherms, for example those described by the DLVO theory, de Feijter and Vrij showed[49] that the line tension has only negative values in Newtonian black films, characterised by relatively large angles of contact. The same conclusion was reached by the present writer from the first calculations of the line tension τ_d of microscopic curved films[55] by the exact analytical formula (36).

VI. Conclusions

The following conclusions can be formulated from the analysis of the line tension problem in the thermodynamics of thin liquid films given in the present review.

Line tensions are defined by different workers in terms of different thermodynamic models of thin liquid films, and therefore they are physically different quantities. Identifying line tensions defined in different ways leads to incompatible numerical values and even signs of these parameters. The writer's generalised theory of the line tension[40] reconciles the different definitions and establishes their mutual relationships.

Exact analytical expressions for the line tension have been proposed.[40–42,55,64,65,71] In particular, it has been shown that the well known expression for the line tension [Eqn. (26)] obtained by de Feijter and Vrij,[49] which is widely used at present, is incorrect for the general case of a curved line of contact though it approaches asymptotically the correct expression as the radius of curvature of the contact line tends towards infinity.

The writer has reported[40–42,71] the first calculations of the line tension by numerical methods, and has obtained the dependence of the line tension on the form parameters of the disjoining pressure isotherm and on the capillary pressure in the film, the interfacial tension, the contact angle (the specific free energy of interaction in the film), and the film thickness. The numerical values of the line tension have been compared with known experimental results for this quantity.

The anomalous stabilisation of the oxidation state 2+ of lanthanides and actinides

N B Mikheev, L N Auerman, I A Rumer, A N Kamenskaya, M Z Kazakevich
Institute of Physical Chemistry, Russian Academy of Sciences

ABSTRACT. The present review deals with the anomalous stabilisation of the oxidation state 2+ of a number of lanthanides and actinides. This stabilisation of the oxidation state 2+ is due to the lowering of the energy of a *d*-orbital as a result of crystal field splitting in the ligand field and *d*-electron participation in chemical bonding.

I. Introduction

The lanthanides (Ln) and actinides (An) are transition *f*-elements characterised by the gradual filling of the 4*f*- and 5*f*-orbitals with electrons. The lanthanides from praseodymium to ytterbium (except gadolinium) and the actinides from plutonium to nobelium (except curium) in the ground state of the neutral atoms have the same electron configuration $f^n s^2$, so that these elements should be divalent. In fact, however, for all the lanthanides and for the actinides from americium onwards, the most stable oxidation state is 3+ (except for No, for which the most stable oxidation state is 2+). Connick[1] was the first to emphasise that the predominant oxidation state 3+ for the lanthanides is not related to the ground state of the neutral atoms, but is determined purely by the quantitative ratio of the ionisation potentials I_n and the chemical stabilisation (hydration, solvation, etc.) of the divalent and trivalent ions. A measure of the stability of the divalent state relative to the trivalent state in solution is provided by the oxidation potential $E^0_{M^{3+}/M^{2+}}$. For aqueous solutions, the standard oxidation potential can be expressed as follows:

$$E^0_{M^{3+}/M^{2+}} + 4.43 = \Delta G^\circ_{ion} + \Delta G^0_h(M^{3+}) - \Delta G^0_h(M^{2+}), \quad (1)$$

where 4.43 V is the standard electrode potential of the hydrogen electrode;[2] ΔG°_{ion} the ionisation energy, calculated from the values of the third ionisation potential I_3; and $\Delta G^\circ_h(M^{2+})$ and $\Delta G^\circ_h(M^{3+})$ the hydration energies of the divalent and trivalent ions.

Nugent and co-workers[3] obtained theoretical estimates of $E^0_{M^{3+}/M^{2+}}$ for the lanthanides and actinides. The improved theory of electron spin-pairing due to Jørgenson[4] was used in the calculations, and a correlation was found between the energy of the first electron-transfer band in the spectra of trivalent Ln and An complexes on the one hand and the energy of the first *f*–*d*-transition band of divalent Ln and An and the corresponding oxidation potentials on the other. The observed relationships are semi-empirical. Because of the lack of experimental data, the relationship between the oxidation potentials and the spectral parameters was established from a small number of points (divalent Sm, Eu, and Yb for Ln, and Cf for An) (Tables 1 and 2).

Another method for estimating $E^0_{M^{3+}/M^{2+}}$ for the lanthanides, used by Johnson,[5] is based on calculations from thermodynamic cycles. Experimental data for samarium, europium, and ytterbium were used in these calculations. The method is based on the assumption that the crystal lattice energies and the hydration energies of the ions change regularly with increase in atomic number and that the formation of a solid phase and the interaction of the ions with a solvent are not accompanied by a change in the number of *f*-electrons of the elements being considered. The calculated values of $E^0_{M^{3+}/M^{2+}}$ are given in Table 1.

The experimental data on the long familiar divalent state of samarium, europium, and ytterbium were supplemented in the late seventies by the preparation of the divalent state of many lanthanides (Pr,[6] Nd,[7] Pm,[8] Dy,[9] Ho,[10] Er,[11] Tm [12]) and actinides Am,[13] Bk,[14] Cf,[15] Es,[15] Fm[16]) and the determination of the standard oxidation potentials. The standard oxidation potentials of the M^{3+}/M^{2+} couples were determined for these elements[17] (Tables 1 and 2).

Tables 1 and 2 show that for most Ln and An the experimental values of $E^0_{M^{3+}/M^{2+}}$ agree with the theoretical estimates. From the theoretically calculated $E^0_{M^{3+}/M^{2+}}$ values, the existence of the divalent states of the elements La, Ce, Gd, Tb, U, Np, Pu, and Cm should not be expected. In fact, Tables 1 and 2 show that the calculated standard oxidation potentials of the M^{3+}/M^{2+} couples for Gd, Tb, U, Np, Pu, and Cm lie below −3 V. This oxidation potential (−3 V) is reached in the presence of the strongest known reducing agent—lithium—and a lower oxidation potential cannot be obtained in a condensed medium. Nevertheless, it has been established experimentally that these elements exist in the divalent state and that the standard oxidation potentials of their M^{3+}/M^{2+} couples are appreciably higher than the theoretically calculated values (Tables 1 and 2).

It will be shown in the present work that the anomalous stabilisation of the oxidation state 2+ of these elements is due to the participation of *d*-orbitals in chemical bonding.

II. Reduction of lanthanides and actinides to the oxidation state 2+ in chloride melts and determination of the standard oxidation potentials $E^0_{M^{3+}/M^{2+}}$

Since various actinides are available only in micro-quantities, the possibility of obtaining the *f*-elements in the oxidation state 2+ was investigated, and the values of $E^0_{M^{3+}/M^{2+}}$ determined, by cocrystallisation in the molten salt systems $(LnOCl)_{solid}-(LnCl_3-LnCl_2-SrCl_2)_{melt}$, where Ln = Pr, Nd, Sm, and Ho, the subscript solid denotes the solid phase, and the subscript melts denotes the melt. The oxide chlorides of all the actinides and lanthanides except thulium and ytterbium have the PbFCl crystal structure. Thus the cocrystallisation of micro-quantities of Ln^{3+} and An^{3+} will take place as a result of true isomorphism or isodimorphism. On the other hand, the divalent lanthanides and actinides resemble the alkaline earth elements, which do not form oxide chlorides. Thus Ln^{2+} and An^{2+} should not cocrystallise with solid LnOCl. Preliminary experiments confirmed this assumption. The entrainment of Sr^{2+} and Eu^{2+}, and also Cs^+, by the solid phase did not exceed 0.1%. This resolved the question of the possible formation of anomalous mixed crystals of the reduced forms of the elements being studied with LnOCl. In these experiments, the potential of the system was determined by the ratio Ln^{3+}/Ln^{2+} in the system. The use of the dichlorides of praseodymium, neodymium, samarium, and holmium made it possible to study the reduction of the lanthanides and actinides over a wide range of values of the oxidation potentials and, which is particularly important, at a low concentration of the elements being studied.

The method developed made it possible to determine the extent of the reduction of the *f*-element being studied and the difference between the standard oxidation potentials of the element being studied and the potential-determining element. For this it was necessary to know the equilibrium distribution of the micro-component between the solid phase LnOCl and the $LnCl_3-SrCl_2$ melt when both components are in the trivalent state:

$$D_0=[m^{3+}/m^{3+}]_{solid}[M^{3+}/M^{3+}]_{melt}, \quad (2)$$

where D_0 is the cocrystallisation coefficient, and m and M the quantities of the micro- and macro-components.

Since the micro-component in the reduced form does not cocrystallise with the solid phase, the distribution of the elements in the system containing the reducing agent, $(LnOCl)_{solid}-(LnCl_3-LnCl_2-SrCl_2)_{melt}$, will be described by the equation:

$$D_0=\left(\frac{m^{3+}}{M^{3+}}\right)_{solid}\left(\frac{M^{3+}+M^{2+}}{m^{3+}+m^{3-n}}\right)_{melt}, \quad (3)$$

where n is the number of electrons involved in the reduction of the micro-element.

From Eqns. (2) and (3) and the Nernst equation, the equilibrium state in the system is described by the equation:

$$\ln\left[\frac{D_0}{D}\left(1+\frac{M^{2+}}{M^{3+}}\right)-1\right]=\frac{-\Delta E_{M-m}}{RT/nF}+n\cdot\ln\frac{M^{2+}}{M^{3+}}. \quad (4)$$

where $\Delta E_{M-m}=E_{M^{3+}/M^{2+}}-E_{m^{3+}/m^{(3-n)+}}$, and n is the number of electrons in the reaction $m^{3+}+ne^-\rightarrow m^{(3-n)+}$. Thus if D_0 and D are known for different ratios M^{2+}/M^{3+}, Eqn. (4) can be used to

determine the value of n, that is the number of electrons involved in the reduction of the ion of the micro-element, and ΔE_{M-m}—the difference between the oxidation potentials of the couples M^{3+}/M^{2+} (for the potential-determining macro-element) and $m^{3+}/m^{(3-n)+}$ (for the micro-element).

In a large number of experimental studies,[20-27] Eqn. (4) has been used to calculate n, that is the number of electrons involved in the reduction of Ln^{3+} and An^{3+}. In all cases the value was practically equal to 1. This indicates that reduction takes place to the oxidation state 2+. This is illustrated for the reduction of Pu^{3+} in Fig. 1. The result of the reduction is independent of the reducing agent used—Pr^{2+} or Nd^{2+}. The authors cited[20-27] also calculated the difference between the oxidation potentials of the potential-determining elements and the elements being studied (ΔE_{M-m}) (Table 3).

Thus the values of ΔE in chloride melts were determined experimentally (Table 3). Subsequent studies[28,29] established how the $\Delta E_{M_1-M_2}$ values change on going to other systems, in particular aqueous solutions (Table 4). Table 4 shows that the values of $\Delta E_{M_1-M_2}$ in chloride melts, aqueous solutions, and organic solutions are similar, irrespective of the nature of the liquid phase and temperature. On this basis, the known values of $E^0_{M^{3+}/M^{2+}}$ for various lanthanides and the experimentally determined values of $\Delta E_{M_1-M_2}$ were used to calculate the previously unknown standard oxidation potentials of M^{3+}/M^{2+} couples for lanthanum, cerium, praseodymium, promethium, gadolinium, terbium, holmium, erbium, uranium, neptunium, plutonium, curium, and berkelium (Tables 1 and 2).

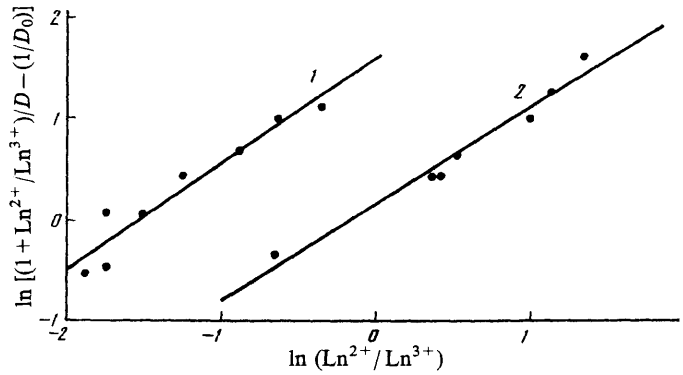

Figure 1. Determination of the number of electrons involved in the reduction of Pu^{3+} by Pr^{2+} (1) and Nd^{2+} (2).[22]

The M—MCl_3 equilibrium diagrams for many f-elements show that the metallic lanthanides and actinides are soluble to a greater or lesser extent in their molten trichlorides. This phenomenon can be regarded as resulting from the reaction

$$M + 2MCl_3 \longrightarrow 3MCl_2.$$

Since in these systems the element is present in three oxidation states (M^0, M^{2+}, M^{3+}) in equilibrium, the following equation can be written for T = 1173 K:

$$E_{M^{3+}/M^{2+}} + \frac{RT}{F}\ln\left[M^{3+}/M^{2+}\right] = E_{M^{3+}/M^0} + \frac{RT}{3F}\ln\left[M^{3+}\right]. \quad (5)$$

In this equation the values of $E_{M^{3+}/M^{2+}}$ and E_{M^{3+}/M^0} in the molten salts at 1173 K are unknown. As shown in Table 4, however, $E_{M_1-M_2}$ is independent of temperature and the composition of the liquid phase. Thus the standard oxidation potential of the M^{3+}/M^{2+} couple in the melt at 1173 K and the standard oxidation potential of the same couple in aqueous solution at 298 K $E^0_{M^{3+}/M^{2+}}$ will differ from one another by a constant quantity

$$E_{M^{3+}/M^{2+}} - E^0_{M^{3+}/M^{2+}} = a.$$

An analogous equation can be written for the oxidation potentials of the M^{3+}/M^0 couple:

$$E_{M^{3+}/M^0} - E^0_{M^{3+}/M^0} = b.$$

Replacing $E_{M^{3+}/M^{2+}}$ and E_{M^{3+}/M^0} in Eqn. (5) by the corresponding values of the standard oxidation potentials gives:

$$E^0_{M^{3+}/M^{2+}} + \frac{1173R}{F}\ln\left[\frac{M^{2+}}{M^{3+}}\right] + a = E^0_{M^{3+}/M^0} + \frac{1173R}{3F}\ln\left[M^{3+}\right] + b, \quad (6)$$

from which it is possible to calculate the quantity $a - b$:

$$a - b = E_{M^{3+}/M^0} - E^0_{M^{3+}/M^{2+}} + \frac{1173R}{3F}\ln\left[M^{3+}\right] - \frac{1173R}{F}\ln\left[\frac{M^{3+}}{M^{2+}}\right]. \quad (7)$$

Table 5 gives the mole fractions $[M^{3+}]$ and $[M^{2+}]$ found from the solubility of the metal in the molten trichloride at 1173 K,[38] and also the standard oxidation potentials of the couples M^{3+}/M^{2+} and the couples M^{3+}/M^0.[17,39,40] Table 5 also gives the values of $(a - b)$ for various lanthanides and actinides, calculated from the above data. Table 5 shows that the values of $(a - b)$ remain contant to within 45 mV.

The established correlation between the standard oxidation potentials of the couples M^{3+}/M^{2+} and M^{3+}/M^0 and the solubility of the metal in the molten trichloride is observed irrespective of whether M^{2+} is present in the melt in the configuration $f^n d^0 s^0$ or in the configuration $f^{n-1}d^1s^0$. Although the dichlorides of the lanthanides and the actinides in these two electronic states show different chemical properties, the differences between their free energies of reaction with the molten chlorides and with water are the same. All this made it possible to construct a single scale of standard oxidation potentials of the M^{3+}/M^{2+} couples (Tables 1 and 2).

III. Hydration energies of divalent lanthanides

Tables 1 and 2 show that for many of the elements, the experimentally determined values of the standard oxidation potentials of the M^{3+}/M^{2+} couples[17] agree well with the calculated values.[3,5] In the lanthanide series, the exceptions are Gd and Tb. Calculations of the hydration energies of Ln^{2+} from Eqn. (1)[47] were used to determine possible reasons for the anomalous behaviour of Gd and Tb. Fig. 2 (straight lines *1a* and *1b*) shows the dependence of the hydration energies of Ln^{2+} on their atomic number. It follows from Fig. 2 that for most of the elements the hydration energies change linearly with increase in the atomic number (Z); this is due to the linear dependence of the ionic radius on the atomic number of the element (straight line *2* in Fig. 2).[48] La, Ce, Gd, and Tb, however, do not correspond to this relationship. La^{2+} and Gd^{2+} even as the free ions have the electron configuration $f^{n-1}d^1$. When the Ln^{2+} ion is converted from the free state to the coordinated state, the d-state is stabilised by the splitting of the d-level in the crystal field of the ligands, and also by the increase in the covalent character of the chemical bonding with the ligands. The stabilisation energy of the d-level of Ce^{2+} and Tb^{2+} is greater than the fd-excitation energy of their free ions (0.406 eV and 1.112 eV respectively[18]), but on conversion into the coordinated state these elements will have the same electron configuration as the La^{2+} and Gd^{2+} ions. In this case it is convenient to calculate the hydration energies of Gd^{2+} and Tb^{2+} from Eqn. (1) using not the total ionisation energy but the energy of ionisation from the d-level, which can be calculated using the equation:

$$I_d = I_3 - E_{fd}, \quad (8)$$

where I_d is the energy of ionisation from the d-level, and E_{fd} the fd-excitation energy of the free doubly-charged ion.[18] Eqn. (1) then takes the form:

$$E^0_{M^{3+}/M^{2+}} + 4.43 = \Delta G^0_{ion}(d) + [\Delta G^0_h(M^{3+}) - \Delta G^0_h(M^{2+})], \quad (9)$$

where $\Delta G^0_{ion}(d)$ is the ionisation energy, calculated from the value of I_d.

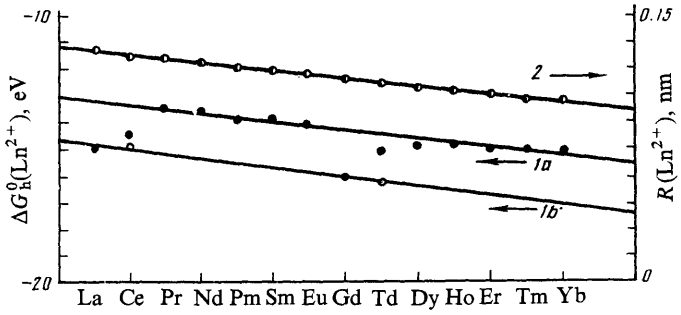

Figure 2. Hydration energies $[\Delta G^0_h(Ln^{2+})]$ (*1a*, *1b*) and ionic radii $[R(Ln^{2+})]$ (*2*) of Ln^{2+}.[47,48]

A feature of undoubted interest is that in this case the hydration energies for the neighbouring elements La^{2+}, Ce^{2+} and Gd^{2+}, Tb^{2+} have similar values, all of which lie on the straight line 1*b* (Fig. 2), lying almost parallel to straight line *1a*. This indicates that the hydrated doubly-charged ions of La, Ce, Gd, and Tb have an

electron configuration involving *d*-electrons. Moreover, the fact that the two straight lines (*1a* and *1b* in Fig. 2) are almost parallel indicates a similarity in the changes in the ionic radius of Ln^{2+} with change in atomic number in the two different electron configurations. The difference between the hydration energies of Ln^{2+} in different electron configurations might be regarded as the stabilisation energy of the *d*-level. This is true, however, only if the ionic radii of La^{2+}, Ce^{2+}, Gd^{2+}, and Tb^{2+} are independent of their electron configurations, and there is obviously no justification for this assumption. Moreover, the ionic radius of all the above elements in the $f^{n-1}d^1$ configuration should be greater than that expected if they had the electronic structure f^nd^0. Thus the stabilisation energy of the *d*-level for these elements will be greater than the differences between the hydration energies of the elements in the two different electron configurations (~1.6 eV for La^{2+} and Ce^{2+} and ~1.8 eV for Gd^{2+} and Tb^{2+}). At the same time, the order of magnitude of the values obtained for the stabilisation is consistent with the energy of splitting of the *d*-level of La and Gd in a CaF_2 matrix, obtained by Johnson and Sandoe[49] (3 eV).

In addition to Ln, yttrium was also obtained in the divalent state, and the standard oxidation potential of the Y^{3+}/Y^{2+} couple was determined (−2.82 V).[50] Yttrium is a typical *d*-element, whose doubly-charged ion has the electron configuration $4d^1$. It was therefore of interest to calculate the hydration energy of the Y^{2+} cation using Eqn. (1). The hydration energy of the Y^{2+} ion was found to lie on straight line *1b* (Fig. 2) in the range corresponding to the second half of the Ln family, confirming the electron configuration of La^{2+}, Ce^{2+}, Gd^{2+}, and Tb^{2+}.

IV. Electron configuration of divalent lanthanides and actinides

The electron configuration of hydrated Ln^{2+} ions was dealt with in a study[51] of the dependence of the standard oxidation potentials of the M^{3+}/M^{2+} couples on the *fd*-excitation energy of the free doubly-charged ion. Figs. 3 and 4 give this relationship for the first and second halves of the Ln family, and show that the standard oxidation potential of the M^{3+}/M^{2+} couple for most of the elements is linearly dependent on the *fd*-excitation energy (straight line *1*). This relationship can be explained if Eqn. (8) is used to express the ionisation energy ΔG^0_{ion} in terms of its two components. Eqn. (1) then becomes:

$$E^0_{M^{3+}/M^{2+}} + 4.43 = E_{fd} + [\Delta G^0_{ion}(d) + \Delta G^0_h(M^{3+}) - \Delta G^0_h(M^{2+})]. \quad (10)$$

The relationship $E^0_{M^{3+}/M^{2+}} = f(E_{fd})$ will obviously be linear if the quantity in square brackets does not depend or is linearly dependent on the *fd*-excitation energy. For elements such as La and Ce (Fig. 3) or Gd and Tb (Fig. 4), the standard oxidation potential of the M^{3+}/M^{2+} couple for the two elements being compared is practically independent of the *fd*-excitation energy (straight line *2*). As noted above, this is related to the fact that in these elements in the coordinated state an electron is localised in a *d*-orbital. The anomalous position of La^{2+}, Ce^{2+} and Gd^{2+}, Tb^{2+} reflects their position in the sequence of change in the hydration energies of Ln^{2+} with change in the atomic number (Fig. 2). Figs. 3 and 4 can be used to estimate the stabilisation energy of the *d*-level in aqueous solutions. It will obviously correspond to that *fd*-excitation energy of the free ion (the 4*f*-orbitals undergo practically no splitting in the crystal field of the ligands) which correspond to the point of intersection of straight lines *1* and *2* (Figs. 3 and 4). The values obtained using this approach for the stabilisation energy of the *d*-state are 1.6 eV for the first half of the lanthanide family, and 2.1 eV for the second, in good agreement with the values obtained from the hydration relationships (Fig. 2).

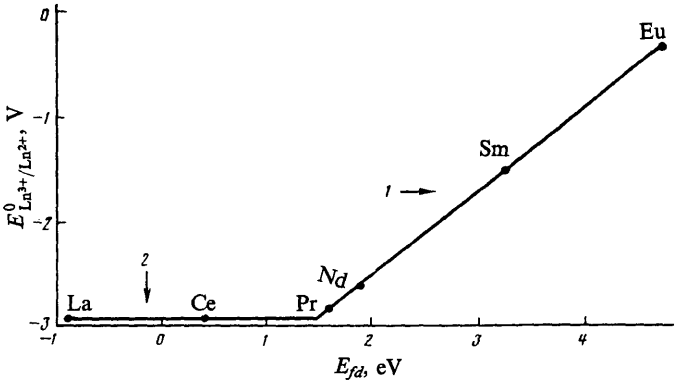

Figure 3. Dependence of the standard oxidation potentials of the Ln^{3+}/Ln^{2+} couples ($E^0_{Ln^{3+}/Ln^{2+}}$) on the *fd*-excitation energy of Ln^{2+} (E_{fd}) for the first half of the lanthanide family.[47]

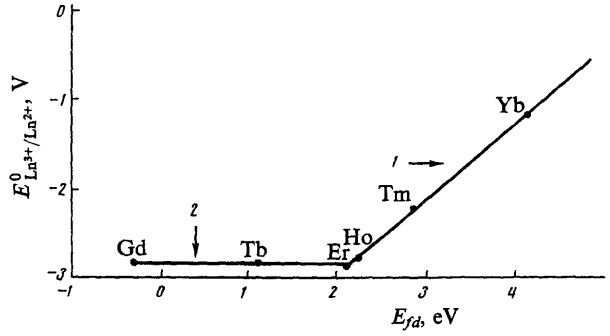

Figure 4. Dependence of the standard oxidation potentials of the Ln^{3+}/Ln^{2+} couples on the *fd*-excitation energy of Ln^{2+} for the second half of the lanthanide family.[47]

For An, the hydration energies of the An^{2+} ions cannot be calculated using Eqn. (1) as in the case of Ln, since there are no experimental values of the third ionisation potentials and hydration energies of the An^{3+} ions. The *fd*-excitation energies of the doubly-charged ions have been calculated for all An,[19] however, so that it has been possible to study the dependence of $E^0_{An^{3+}/An^{2+}}$ on the *fd*-excitation energies of the free doubly-charged ions (Fig. 5). Fig. 5 shows that the standard oxidation potential of the M^{3+}/M^{2+} couple for U, Np, Pu, and Cm is independent of E_{fd}, as already observed for La, Ce, Gd, and Tb. Thus these elements of the An family in the divalent state apparently have an electron configuration with a *d*-electron. The stabilisation energy of the *d*-state for An is 2.1 eV, which coincides with the value obtained for the second half of the Ln family.

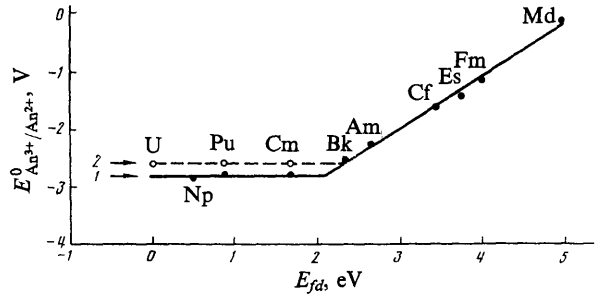

Figure 5. Dependence of the standard oxidation potentials of the An^{3+}/An^{2+} couples ($E^0_{An^{3+}/An^{2+}}$) on the *fd*-excitation energy of An^{2+} (E_{fd}) for the second half of the actinnide family.[47]

V. Characteristics of the behaviour of divalent actinides in melts

An interesting feature is that the oxidation potential of the Pu^{3+}/Pu^{2+} couple depends on the Pu concentration even in the micro-concentration range. With change in the Pu concentration from $\sim 10^{-4}$ mol% to $\sim 10^{-6}$ mol% the standard oxidation potential of the Pu^{3+}/Pu^{2+} couple changes from -2.59 V to -2.79 V (Fig. 5). In addition, the standard oxidation potential of the Cm^{3+}/Cm^{2+} couple in the presence of $\sim 10^{-4}$ mol% Pu also changes from -2.78 V to -2.59 V and coincides with the value for Pu at a concentration of 10^{-4} mol%. In addition to Cm, Pm was also added to the system; at the oxidation potential of the Nd^{3+}/Nd^{2+} couple, Pm is reduced to the divalent state. In contrast to the case of Cm, the oxidation potential of $E^0_{Pm^{3+}/Pm^{2+}}$ remained unchanged in the presence of Pu.[52] Thus Pu^{2+} is apparently able to form dimers or simple clusters. This distinguishes it from Pm^{2+} and other divalent Ln and An with the electronic structure $f^n d^0$. The probability of this process evidently depends on the Pu concentration. In addition, Cm^{2+} can also take part in the formation of clusters with Pu, and in this case its standard oxidation potential increases to the oxidation potential of the Pu^{3+}/Pu^{2+} couple. The values of the standard An^{3+}/An^{2+} oxidation potentials obtained for ponderable quantities of the elements of this family are given by straight lines *2* in Fig. 5. The "dimerisation" is an additional factor stabilising the oxidation state 2+, and was observed by us only for 5*f*-elements characterised in the divalent state by the participation of *d*-orbitals in chemical bonding.

For U there are no data on the standard oxidation potential of the U^{3+}/U^{2+} couple in the micro-concentration range ($\sim 10^{-6}$ mol%), since the experiments on its reduction were carried out using the ^{233}U isotope at a concentration of $\sim 10^{-4}$ mol%.[53] The value of $E^0_{U^{3+}/U^{2+}}$ coincides with that of $E^0_{Pm^{3+}/Pm^{2+}}$ at the same concentration (Fig. 5). Thus uranium is apparently dimerised in the divalent state in the melt. This was confirmed by subsequent studies which showed that the oxidation potential of Cm increases to -2.6 V in the presence of ponderable quantities of uranium.

The behaviour of Np is of particular interest. Change in the Np concentration from 10^{-3} mol% to trace quantities has no influence on the value of $E^0_{Np^{3+}/Np^{2+}}$ (straight line *1* in Fig. 5). Thus Np^{2+} does not form dimers in melts and in this respect differs from U, Pu, and Cm.[54]

The suggestion that dimers are formed was confirmed by studying the behaviour of Pu^{2+} during the directed crystallisation of $NdBr_2$. In contrast to the case of Am^{2+} and Eu^{2+}, for which the coefficient of cocrystallisation with $NdBr_2$ differs little from 1, the cocrystallisation coefficient of Pu^{2+} is characterised by the presence of a maximum as the crystallisation of $NdBr_2$ proceeds (Fig. 6).[52,55] The authors cited explain the appearance of the maximum as follows. As the crystallisation tube moves from the hot zone of the melt to the cooled zone, decrease in temperature is accompanied by dimerisation. The resulting dimers cocrystallise with the $NdBr_2$ matrix with a high coefficient. Thus the crystallising $NdBr_2$ as it were "draws out" Pu^{2+} from the melt. This is facilitated by the hindering of the back diffusion of dimerised plutonium into the hot zone of the melt. As a result, there is an appreciable decrease in the concentration of plutonium in the melt, so that the dimerisation stops and the cocrystallisation coefficient of Pu decreases in the final stage of the directed crystallisation. The directed-crystallisation experiments confirm the anomalous behaviour of Pu^{2+} compared with Am^{2+} and Eu^{2+}, resulting from the participation of *d*-orbitals of Pu^{2+} in chemical bonding.

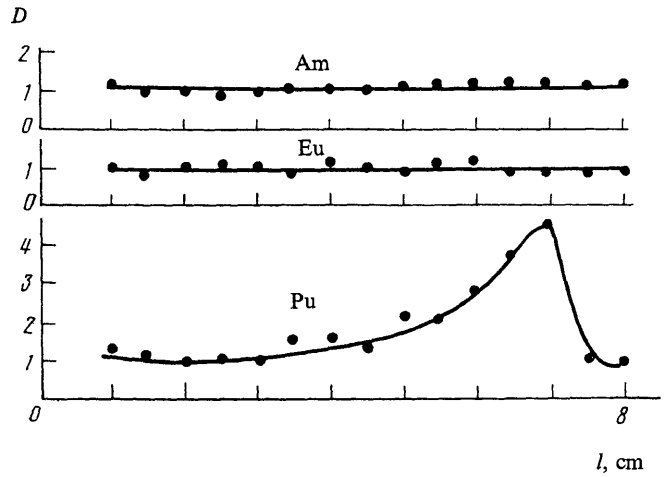

Figure 6. Distribution of Pu^{2+}, Eu^{2+}, and Am^{2+} along the crystal (*l*) in the directed crystallisation of $NdBr_2$.[55]

VI. Stabilisation of the oxidation state 2+ of lanthanides and actinides in condensed clusters

In recent years a number of condensed cluster compounds containing lanthanides having oxidation states from 1+ to 2.5+ have been synthesised.[56–61] It has been established[60] that the *d*-orbitals of the lanthanides take part in the formation of the M–M bond. The compound Gd_2Cl_3 was first obtained by the reaction of metallic Gd with molten Gd trichloride.[44] This cluster forms acicular crystals made up of chains of octahedra of gadolinium atoms joined to one another via shared edges. The mechanism of formation of the cluster has not been studied, however.

Two possible mechanisms of formation of the cluster have been proposed. The first is based on the disproportionation of gadolinium dichloride formed by the reaction of Gd^0 with $GdCl_3$:

$$Gd^0 + 2GdCl_3 \rightarrow 3GdCl_2 ,$$
$$\frac{3GdCl_2 \rightarrow Gd_2Cl_3 + GdCl_3}{Gd^0 + GdCl_3 \rightarrow Gd_2Cl_3} .$$

The second mechanism assumes reduction by metallic gadolinium sorbed on the cluster by a mechanism involving the primary sorption of the trivalent gadolinium ion:

$$Gd^0 \rightarrow Gd^{3+} + 3e^- ,$$
$$2GdCl_3 + 3e^- \rightarrow Gd_2Cl_3 + 3Cl^- ,$$
$$\frac{Gd^{3+} + 3Cl^- \rightarrow GdCl_3}{Gd^0 + CdCl_3 \rightarrow Gd_2Cl_3} .$$

The overall reaction is the same for both processes, so that it is difficult to establish the mechanism of formation of the cluster. At the same time it should be noted that a necessary condition for the first mechanism is the existence of divalent gadolinium. In this case, if a micro-component which is also reduced to the oxidation state 2+ and which like Gd^{2+} has the electron configuration $f^{n-1}d^1$ is introduced into the system, then the extent of its cocrystallisation will be proportional to the fraction of this element in the divalent state. For the second mechanism, which assumes the participation of the trivalent form of the element in the cocrystallisation, the opposite relationship should be observed, that is decrease in the cocrystallisation with increase in the fraction of the reduced form of the cocrystallising element.

Equations have been derived,[62] describing the distribution of a micro-component between solid Gd_2Cl_3 and molten $GdCl_3$ for the two mechanisms, namely

$$\ln\frac{a}{a-x} = \frac{2(1+k)}{1+k\cdot\exp\left(\frac{\Delta E^0_{M-m}}{RT/F}\right)}\lambda_1\cdot\ln\frac{2b}{2b-y} , \qquad (11)$$

for the first mechanism and

$$\ln\frac{a}{a-x} = \frac{2(1+k)\cdot\exp\left(\frac{\Delta E^0_{M-m}}{RT/F}\right)}{1+k\cdot\exp\left(\frac{\Delta E^0_{M-m}}{RT/F}\right)}\lambda_2\cdot\ln\frac{2b}{2b-y} , \qquad (12)$$

for the second mechanism of formation of the cluster, where a and b are the initial concentrations of the micro-component and the macro-component in the $GdCl_3$ melt, x and y their concentrations in the cluster Gd_2Cl_3, k the ratio of the concentrations $[Gd^{3+}]$ and $[Gd^{2+}]$ in the melt, and λ the cocrystallisation coefficient.

It can be seen that if $\Delta E^0_{M-m} = 0$, both equations become

$$\ln\frac{a}{a-x} = 2\lambda\cdot\ln\frac{2b}{2b-y} , \qquad (13)$$

and in this case the mechanism of formation of the cluster cannot be determined. Thus to establish the mechanism of formation of the cluster it is necessary to determine the cocrystallisation coefficient λ for elements which are chemically similar to Gd but which differ from gadolinium in the values of the standard oxidation potential of the M^{3+}/M^{2+} couple. This requirement is satisfied by Np, Pu, and Cm (Table 2). Since we are considering actinides with similar ionic radii, the coefficients of their cocrystallisation with Gd_2Cl_3 should be close to one another.

Table 6 gives the values of the cocrystallisation coefficients λ_1 and λ_2 for Np, Pu, and Cm with Gd_2Cl_3, calculated from Eqns. (11) and (12), which describe respectively the first and second mechanisms of formation of the cluster.[62]

Table 6. Cocrystallisation coeffcients λ_1 and λ_2 for Np, Pu, and Cm with Gd_2Cl_3.[17]

An	$E^0_{M^{3+}/M^{2+}}$, V	λ_1	λ_2
Np	−2.86	1.16	2.21
Pu	−2.59	0.072	2.03
Cm	−2.78	0.70	1.73

Table 6 shows that the values of λ_1, obtained assuming that the cocrystallisation takes place by the first mechanism, show poor agreement with one another. The situation is quite different if it is assumed that the second mechanism of cocrystallisation is correct. In this case the values of λ_2 for all three elements are close to one another, as expected for elements with similar properties It was therefore concluded[62] that the formation of the Gd_2Cl_3 cluster passes through a stage involving the sorption of the trivalent ion on the surface of the growing crystal and the subsequent reduction of Ln^{3+} to the oxidation state 1.5+.

Subsequent studies showed that not every trivalent ion can enter the Gd_2Cl_3 matrix. For example, Nd^{3+} and Pu^{3+}, which have similar ionic radii (0.0983 nm and 0.100 nm respectively) and practically identical standard oxidation potentials of the M^{3+}/M^{2+} couples (−2.62 V and −2.59 V respectively), show completely different behaviour on cocrystallisation with the Gd_2Cl_3 cluster. Plutonium cocrystallises with Gd_2Cl_3, but Nd^{2+} does not.[17] The explanation is that after sorption, the trivalent ion is reduced to the lower oxidation state by the "electron gas" in the Gd_2Cl_2 matrix. As can be seen from Fig. 5, Pu then acquires an electron configuration analogous to that of Gd, and takes part in the chemical bonding using its *d*-orbitals. In the case of Nd, the situation is quite different. As can be seen from Fig. 3, divalent neodymium does not have valence *d*-orbitals, and cannot take part in the construction of the Gd_2Cl_3 crystal lattice. Thus by studying the cocrystallisation with Gd_2Cl_3 it is possible to reach conclusions about the electron configuration of an *f*-element in the divalent state. Some elements which in the melt have the electron configuration f^nd^0, for example, Pr, Er, and Ho, cocrystallise with Gd_2Cl_3.[63,64] Figs. 3 and 4 show that Pr and Er lie at the intersection of straight lines *1* and *2*, corresponding to two different electron configurations of the ions in the divalent state, and the slight increase in the stabilisation energy of the *d*-level in the Gd_2Cl_3 crystal converts all of the above three elements into the $f^{n-1}d^1$ configuration. For Ho,

the *fd*-excitation energy is 0.13 eV greater than the stabilisation energy in melts. From this it follows that the stabilisation energy in the Gd_2Cl_3 matrix is approximately 0.13 eV greater than the stabilisation energy in the chloride melt. Our recent studies have shown that the same applies to the actinides. Thus berkelium cocrystallises with Gd_2Cl_3, whereas in the melt it has the configuration $[f^n d^0]^{2+}$. This indicates that for the actinides, the stabilisation energy of the *d*-level in Gd_2Cl_3 is 0.2 eV greater than that in the melt.

An important factor in cocrystallisation with the cluster is the ionic radius of the cocrystallising element. For example, in the series Pr–Ce–La the coefficient of cocrystallisation with the Gd_2Cl_3 cluster decreases from 0.5 for Pr to almost zero for La. The ionic radius of La^{3+}, which undergoes almost no cocrystallisation with Gd_2Cl_3, differs from that of Gd^{3+} by about 10%. According to Mitscherlich, this difference between the ionic radii should lead to a sharp decrease in the miscibility of the elements in the solid phase, as observed in the cocrystallisation of Ce and more particularly La with Gd_2Cl_3.[63] The opposite dependence of the cocrystallisation coefficients on ionic radius is observed for the actinides, however, where λ decreases in the series Pa–Np–Pu–Cm–Bk (Table 7). A possible explanation for this relationship and the comparatively high values of λ for these elements may be that in addition to *d*-orbitals, the 5*f*-orbitals are also involved in chemical bonding.

Table 7. Cocrystallisation coefficients for actinides with the cluster Gd_2Cl_3

An	Cocrystallisation coefficient λ (Ref.17)	Ionic radius of An^{3+}, nm (Ref.65)
Pa	3.00	0.104
Np	2.21	0.101
Pu	2.03	0.100
Cm	1.73	0.097
Bk	1.20	0.096

The study of the cocrystallisation of Ln and An with the Gd_2Cl_3 matrix has shown which elements of these families in the divalent state have a valence-electron configuration analogous to that of Gd^{2+}. Among the lanthanides these are La, Ce, Pr, Gd, Tb, Er, Ho, and Lu. To these can be added Y, which also has a *d*-electron in the divalent state. The actinides having an electron configuration with a *d*-electron are Pa, Np, Pu, Cm, and Bk.

Thus experimental data and information on the electronic structure of the free ions Ln and An show that a considerable number of elements of the *f*-series in the oxidation state 2+ are characterised by the participation of a *d*-electron in chemical bonding, leading to anomalous stabilisation of the oxidation state 2+, revealed by an increase in the oxidation potentials, an increase in the hydration energies, and the ability to form dimers and clusters.

* * *

The anomalous stabilisation of lantanides and actinides in the oxidation state 2+ has made it possible to reduce La, Ce, Gd, Tb, U, Np, Pu, and Cm to the divalent state. The chemical properties of these ions are similar to those of divalent yttrium. Until now it has been considered that the divalent lanthanides and actinides are analogues of the alkaline earth elements. This is true for those elements, such as Eu, for which the *fd*-excitation energy is greater than the stabilisation energy of the *d*-level. For these elements the stability of the divalent state is linearly dependent on the *fd*-excitation energy. For those divalent elements which are analogues of divalent yttrium, the stability of the divalent state is determined not by the *fd*-excitation energy by by factors stabilising the *d*-level: the splitting of the *d*-level in the crystal field of the ligands, the covalent character of the bonds with the ligands, dimerisation, and possibly others.

The elements of a given family, Ln or An, may be analogues of elements of the *s*- or *d*-groups of Mendeleev's periodic system depending on the *f*–*d*-excitation energy.[66]

The observed constant value of the standard oxidation potential of the An^{3+}/An^{2+} couples for U, Np, Pu, and Cm makes it possible to predict the value of this quantity for Ac and Pa (betwen −2.6 V and −2.9 V). There are no published data on the possible existence of Pa in the divalent state. For Ac^{2+}, the published values of its potential are −1.5 V[67] and above −1.6 V.[68] Both values are apparently too high.

Further studies will undoubtedly reveal many new and unusual features in the properties of *f*-elements showing anomalous stability of the oxidation state 2+.

Kinetic isotope effects in the enzymic reactions of tritium- and deuterium-containing substrates

G P Akulov
Khlopin Radium Institute (Scientific-Industrial Association), St. Petersburg

ABSTRACT. The kinetic differences between the enzymic reactions involving substrates containing heavy hydrogen isotopes are examined. Theoretical estimates and numerous examples of experimentally measured kinetic isotope effects in various enzymic reactions are presented. The kinetic isotope effects are widely used in studies of the mechanisms of enzymic reactions and of the structures of the enzyme–substrate complexes, for the enrichment of labelled compounds in heavy hydrogen isotopes, and also in certain fields of medicine and biochemistry.

The bibliography includes 99 references.

I. Introduction

The use of labelled compounds as radioactive tracers is based on the hypothesis of the identity of the physicochemical properties of the labelled and unlabelled molecules of the given compound.[1] This assumption is to some extent arbitrary. The introduction of an isotope label and especially of heavy hydrogen isotopes induces the appearance of isotope effects—definite changes in the physical, chemical, and biochemical, pharmacokinetic, and certain other properties of the labelled compounds.[2]

Among the numerous studies devoted to isotope effects, a large proportion referred to studies of the kinetic differences between the chemical reactions of isotopic molecules, i.e. to kinetic isotope effects (KIE).[3] KIE referring to enzymic reactions have been studied to a lesser extent, although recently there has been a continuous growth of interest in such effects, which is indicated by the constantly increasing number of published (mainly abroad) review and original (see, for example, Refs. 17–21) papers. Unfortunately, one must conclude that this field of enzyme kinetics has as yet attracted little attention by the investigators in our country.

The current interest in studies on KIE in enzymic reactions is caused, on the one hand, by the fact that the KIE may serve as a potential source of possible errors in the use of labelled compounds in radiochemical studies on enzymic reactions[22,23] and, on the other hand, KIE can serve as a powerful means of investigating a number of important problems in enzymology.[5, 11–14]

While our aim is not a detailed examination of the negative aspect of KIE, we may note, for example, that the difference between the rates of enzymic reactions of labelled and unlabelled substrates can be the cause of errors in radiometric measurements of the catalytic activities of enzymes, in the isotopic determinations of the rates of individual stages of the process, and in the establishment of the kinetic orders of the reactions of the substrates. Failure to take into account KIE in the studies on metabolism and pharmacokinetics with the aid of labelled preparations can also lead to serious errors. These and certain other complications associated with KIE become particularly significant in polyenzymic processes and also when substrates with a high degree of isotope substitution (multiply labelled compounds) are used. Comprehensive study of KIE makes it possible not only to foresee the possibility of such errors but also to avoid them by selecting conditions in the use of labelled compounds under which KIE are minimal or are fully excluded.

As regards the positive aspect of KIE, one should note in the first place the enormous importance which they have in studies on the mechanisms of enzymic reactions and the structures of enzyme–substrate complexes. One of the promising fields also involves the use of KIE for the enrichment of labelled compounds in heavy isotopes.

II. Theoretical estimates of kinetic isotope effects

The ratios of the rate constants for the corresponding pairs of isotopic molecules have come to be used for the quantitative characterisation of the kinetic differences in reactions of labelled and unlabelled compounds. Since these differences are determined primarily by the relative differences between the masses of the isotopes, the maximum KIE are to be expected for compounds labelled with hydrogen isotopes, for which the mass ratios are maximal ($^1H:^2H:^3H = 1:2:3$).

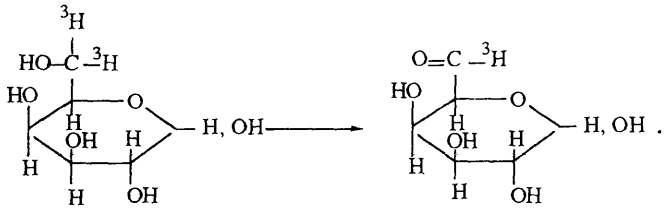
Theoretical calculations of KIE are based on the kinetic transition state theory or the theory of rate processes.[24] Without dwelling on the details of the conclusions which have been described quite fully in the familiar monograph by Melander and Saunders,[3] we shall quote the principal predictions by these authors concerning the values of the KIE for reactions involving compounds labelled with hydrogen isotopes.

The simplest calculations of KIE in which the absence of differences between the energies of the zero-point vibrations of the C–H, C–D, and C–T bonds in the transition complexes is assumed yield the quantities $k_H/k_D = 6.9$ and $k_H/k_T = 16$. In calculations where the disappearance of the deformation vibration

frequencies in the transition state is assumed, the following limiting isotope effects were obtained: from 15 to 20 for k_H/k_D and from 50 to 75 for k_H/k_T. However, the available data show that even if the deformation modes are weakened, this occurs to a very slight extent and the appreciably higher values of the KIE sometimes observed in practice compared with the above results of semiclassical calculations (6.9 for deuterium and 16 for tritium) is more likely to be attributable to quantum mechanical tunnelling. Melander and Saunders believe[3] that the isotope effects k_H/k_D below 12 and k_H/k_T below 36 may contain a definite contribution due to tunnelling, while higher values of the KIE cannot be explained at all without resorting to the tunnel effect.

The experimental protium–deuterium and protium–tritium KIE for many chemical and enzymic reactions are close to the values predicted by semiclassical calculations. There are numerous examples in the literature of a significant retardation (sometimes by several tens) of a wide variety of chemical (see, for example, Rosenberg[25]) and enzymic[26,27,34–42] reactions involving deuteriated and tritiated substrates.

As an example of such high KIE, one may quote the results of kinetic studies of the oxidation reaction of tritium-labelled galactose catalysed by galactose oxidase:[27]



It has been established that galactose doubly labelled with tritium in the 6-position is oxidised at a rate which is lower almost by a factor of 150 than the rate of oxidation of normal galactose. Such a high KIE is due both to the different isotopic composition of the bond subjected to chemical change and to the different isotopic composition of the neighbouring bond.

There exists a fairly well justified theoretical and experimentally confirmed relation between the protium–deuterium and protium–tritium KIE. It was first established by Swain, et al.[28] in the form of the equation

$$\frac{\ln (k_H/k_T)}{\ln (k_H/k_D)} = 1.44$$

or

$$\frac{k_H}{k_T} = \left(\frac{k_H}{k_D}\right)^{1.44}.$$

These relations are used widely to predict the KIE in the reactions of substrates labelled with one of the heavy hydrogen isotopes, provided that the KIE for the other isotope has been established experimentally.

The same relations can be used to confirm the reliability of the experimental results. For example, markedly different results of spectrophotometric measurements of the KIE in D-[1-^{2}H]glucose enzymic oxidation reaction have been published: the protium–deuterium KIE has been estimated as 10–15 by Bright and Gibson[29] and as 2.2–2.5 by Hauge et al.[30] Radiometric measurements of the protium–tritium KIE in a similar D-[1-^{3}H]-glucose oxidation reaction yielded k_H/k_T = 3.0–3.1.[31] When the latter was used to calculate the expected protium–deuterium effect from the equations presented above, it was found that the KIE is 2.2, which confirms the reliability of the value found by Hauge, et al.[30]

III. Classification of kinetic isotope effects in enzymic reactions

The classification adopted for chemical processes[3] can be used for the KIE in enzymic reactions. As in chemical reactions, the KIE can be divided into primary and secondary and intramolecular and intermolecular. The primary isotope effects are determined by the different isotopic compositions of the bond being dissociated with the same isotopic composition of the neighbouring bond. The secondary isotope effect is determined by the different isotopic compositions of the neighbouring bond for the same isotopic composition of the bond being dissociated. The combined isotope effect is determined simultaneously by the different isotopic compositions of the bonds being dissociated and the neighbouring bond. The intramolecular isotope effect (or the intramolecular competition factor) is determined by the different isotopic compositions of two chemically equivalent bonds in the same molecule. The intermolecular isotope effect is determined by the different isotopic compositions of molecules in the same incubation system.

The characteristic features of the kinetics of enzymic reactions, associated primarily with the multistage nature of the process and the phenomenon involving the saturation of the enzyme by the substrate, require the expansion of the classification of the KIE using special kinetic parameters which are not used in the kinetics of chemical reactions. Such a classification has been mainly developed by Northrop.[5,7]

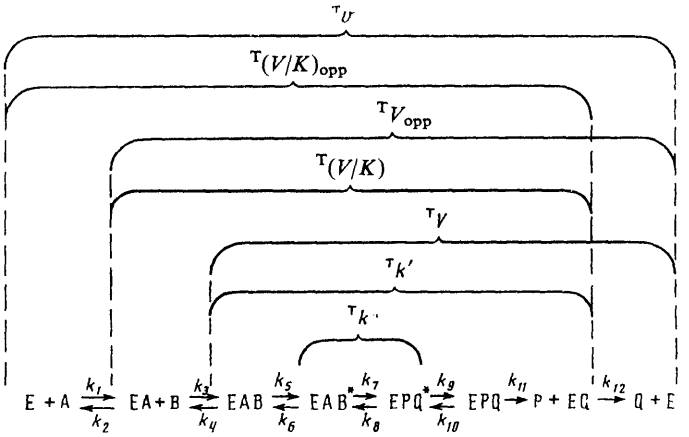


Figure 1. Classification of kinetic isotope effects in a two-substrate enzymic process.[5,7]

In the multistage enzymic process illustrated schematically in Fig. 1, the presence of a tritium (or deuterium) label in one of the substrates (for example, A) can affect the rates of individual stages

and the kinetic parameters entering into the main kinetic equation for enzymic processes (the Michaelis–Menten equation):[32]

$$v = \frac{V\,[S]}{K + [S]},$$

where v is the rate of reaction, V the maximum rate for the complete saturation of the enzyme by the substrate, [S] the substrate concentration, and K the Michaelis–Menten constant. The braces in the scheme enclose the stages in which the KIE can be determined experimentally. The symbols above the braces denote the KIE in terms of definite kinetic parameters and the superscript T means that in the given instance the isotope effect refers to tritium, i.e. one is dealing with the ratio of the corresponding parameter for the protium form to the parameter for the tritium form of the substrate.

The KIE indicated have been given the following names:[7] the isotope effect ^{T}v is the "observed isotope effect", the isotope effects $^{T}(V/K_{app})$ and $^{T}V_{app}$ are the "apparent isotope effects" (they are obtained by extrapolating the observed isotope effects to infinitely small and infinitely large concentrations of the substrate A for a fixed concentration of the cosubstrate B), the isotope effects $^{T}(V/K)$ and ^{T}V are the "limiting isotope effects" (they refer respectively to low and high concentrations of the cosubstrate B), the isotope effect $^{T}k'$ is the "internal isotope effect", and finally the isotope effect ^{T}k is the "true isotope effect" (it is analogous to the KIE in chemical reactions). The true isotope effects in the forward and reverse reactions may not be the same, which leads to the appearance of an isotope effect in the equilibrium constants.

IV. Methods for the determination of kinetic isotope effects in enzymic reactions

The observed KIE is determined from v as the ratio of the observed rates of conversion of the unlabelled and labelled substrates under identical conditions.

In order to determine the apparent or limiting isotope effects in terms of V and V/K, the concentration variations of the observed rates of conversion of the labelled and unlabelled substrates are investigated. Figure 2*a* presents typical relations of this type. For a high substrate concentration, where the enzyme is saturated by the substrate and the order of the enzyme reaction approaches zero, the labelled and unlabelled molecules are converted at the maximum rates V_H and V_T. The KIE ^{T}V corresponds to this boundary condition (Fig. 2*b*).

In the other boundary situation—at low substrate concentrations—where the process is of first order with respect to substrates, the slope of the initial sections of the curves is equal to the ratio V/K according to the Michaelis–Menten equation. The KIE $^{T}(V/K)$ corresponds to this condition.

The isotope effects in the Michaelis constants can be calculated from the KIE in terms of V and V/K obtained in this way.

Such concentration variations of the KIE can be investigated for the majority of labelled substrates and enzymes. However, limitations are possible for tritium-containing substrates. This applies to reactions for which the Michaelis constants are large and when the attainment of saturation by the enzyme requires the introduction of an appreciable amount (frequently unavailable) of the labelled substrate into the incubation system. We encountered such a case (see, for example, Akulov and Smetkova[31]) in a study of the KIE in the oxidation of glucose labelled with tritium in the 1-position in the presence of glucose oxidase. For this reaction, K has been estimated as 3.3×10^{-2} mol litre^{-1}.[33] In this case, the saturation of the enzyme by the substrate requires the use of a labelled substrate having an activity amounting to tens of Curies. Furthermore, difficulties associated with radiation processes arise under these conditions.

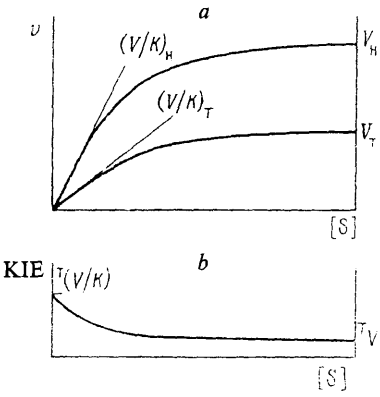

Figure 2. Determination of KIE from the concentration variations of the observed rates of reaction (*a*) and the variation of the KIE with substrate concentration (*b*).

The true ^{T}k or ^{D}k, which reflect the influence of the isotopic composition of the substrate on the true chemical reaction within the activated enzyme–substrate complex, cannot be measured experimentally but they can be calculated from the protium–deuterium and protium–tritium isotope effects in terms of V/K.[7] Thus the true protium–deuterium KIE ^{D}k can be determined with the aid of the equation

$$\frac{^{D}(V/K) - 1}{^{T}(V/K) - 1} = \frac{^{D}k - 1}{^{D}k^{1,44} - 1}.$$

The equation for the calculation of the true tritium KIE has a similar form.

Thus, in order to determine the individual KIE, it is necessary to carry out enzymic reactions of labelled substrates with complete isotope substitution at the reaction centre. Whereas for deuterium such compounds are entirely available, for tritium the production of preparations with complete isotope substitution at a given position within the molecule has begun comparatively recently. Studies in which the KIE in enzymic reactions were investigated using substrates containing exclusively tritium atoms in this position within the molecules reacting chemically in the given process began to be published only in the very latest years. However, there are still frequent claims in the literature that, owing to the absence of tritiated preparations without carriers, the protium–tritium KIE cannot be determined from the individual rates of reaction of the labelled and unlabelled substrates and that the only method which can be used in such investigations is that of competitive reactions in which the incubation system contains simultaneously labelled and unlabelled substrate molecules [Melander and Saunders (Ref. 3, p. 312) and Cleland[14]].

Owing to the difference between the rates of reaction of the labelled and unlabelled molecules, the specific radioactivity of the substrate changes in such competitive experiments. In the determination of the KIE by the competitive method, the reaction is stopped at specified time intervals and the degree of enzymic reaction and the specific radioactivity of the unreacted substrate or product are determined. The kinetic isotope effect in terms of the V/K ratio is calculated from the formula (Ref. 3, p. 105).

$$^{T}(V/K) = \frac{\lg(1-F)}{\lg[1-(FA_p/A_S^0)]},$$

where F is the extent of reaction and A_S^0 and A_p are the initial molar radioactivity of the substrate and the specific radioactivity of the product. In order to achieve the maximum accuracy, it is recommended to determine the limiting value of the function for F tending to zero:

$$^{T}(V/K) = \left|(A_S^0/A_p)\right|_{F\to 0}.$$

Thus the competitive method makes it possible to measure only the KIE in terms of V/K. This constitutes its disadvantage.

The methods for the determination of KIE examined require specially synthesised labelled substrates enriched in deuterium or tritium. However, in certain cases it is possible to use preparations with the natural isotopic composition for such purposes.

All hydrogen-containing compounds are known to contain approximately 0.015% of natural deuterium and 4×10^{-15}% of natural tritium. Unfortunately, modern experimental techniques do not allow the employment of natural tritium for the measurement of KIE; however, in the case of deuterium highly sensitive NMR spectrometers permit the measurement of the content of such deuterium in various positions within molecules and to follow its variation in chemical and biochemical processes.

It has been shown with the aid of NMR analysis that the distribution of deuterium can differ fairly appreciably as a function of the source of the preparation. For example, it has been established that specimens of synthetic and natural anethole[43] and camphor,[44] differing in their chemical history, have different distributions of natural deuterium. The cause of this difference is the KIE, which lead to the enrichment of specific positions within the molecules in deuterium. Using the NMR method based on natural deuterium, Pascal, et al.[45] established that C(10) position is appreciably enriched in deuterium in the biosynthesis of β-pinene from mevalonic acid. The KIE calculated from this enrichment proved to 2.1.

It is noteworthy that the method for the determination of KIE in terms of natural deuterium examined above is based on the competitive principle and therefore it permits the determination of KIE solely in terms of the V/K ratio.

V. Applications of kinetic isotope effects

1. Kinetic and chemical mechanisms of enzymic reactions

One of the important problems in enzyme kinetics is the determination of the kinetic mechanism of reactions occurring with participation of two or more substrates (or products), i.e. the specification of the order of the addition of substrates and of the liberation of the products. In order to estimate the kinetic order by classical methods, use is normally made of the technique involving inhibition or equilibrium exchange.[46] However, for enzyme systems, in which the conversion of the substrate into the product via a ternary complex is irreversible, such methods proved to be extremely inconvenient. Additional experimental difficulties arise when one of the substrates is oxygen and one of the products is water.

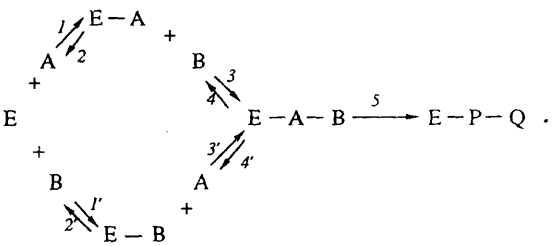
Unique possibilities in the study of the kinetic order of enzymic reactions are provided by the apparent and limiting isotope effects in terms of the V/K ratio, which are determined, as noted above, from the concentration variations of the rate of the process at a fixed concentration of one of the substrates.

Suppose that a substrate A, containing a tritium (or deuterium) label, and substrate B participate in the reaction. The order of the addition of the substrates to the enzyme involves one of the two ordered mechanisms

$$E + A \underset{2}{\overset{1}{\rightleftharpoons}} E-A + B \underset{4}{\overset{3}{\rightleftharpoons}} E-A-B \xrightarrow{5} E-P-Q, \quad (1)$$

$$E + B \underset{2}{\overset{1}{\rightleftharpoons}} E-B + A \underset{4}{\overset{3}{\rightleftharpoons}} E-B-A \xrightarrow{5} E-P-Q \quad (2)$$

or can occur at random:



Kinetic analysis of mechanism (1) yields the following expression for the KIE:[12]

$$^{T}(V/K) = \frac{^{H}k_5/^{T}k_5 + [^{H}k_5(1 + k_3[B]/k_2)/k_4]}{1 + [^{H}k_5(1 + k_3[B]/k_2)/k_4]}.$$

At an infinitely high concentration of the substrate B, the terms of the equation in square brackets become dominant and the KIE tends to unity.

On the other hand, in those cases where the addition of the substrate A precedes the addition of the substrate B [mechanism (2)], the KIE is defined by the equation

$$^{T}(V/K) = \frac{^{H}k_5/^{T}k_5 + {}^{H}k_5/k_4}{1 + {}^{H}k_5/k_4},$$

i.e. is independent of the concentration of the substrate B. In this case, the KIE can assume values from unity to the theoretical maximum value and depends on the ratio $^{H}k_5/k_4$. Here it is important that the ratio is the same for all concentrations [B]. Thus, if it has been established that the concentration of B does not affect the KIE, it follows that B is bound to the enzyme after A.

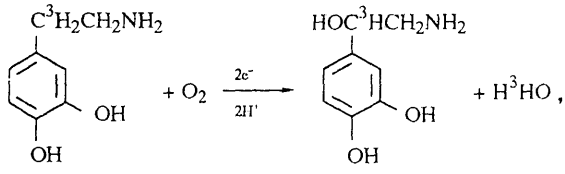
For a random sequence of the addition of the substrates A and B, the expression for the KIE becomes more cumbersome[12] but significantly simplified when the concentration [B] tends to zero:

$$^{T}(V/K) = \frac{^{H}k_5/^{T}k_5 + {}^{H}k_5/(k_4 + k_{4'})}{1 + {}^{H}k_5/(k_4 + k_{4'})}$$

or to infinity:

$$^{T}(V/K) = \frac{^{H}k_5/^{T}k_5 + ^{H}k_5/k_4'}{1 + ^{H}k_5/k_4'} .$$

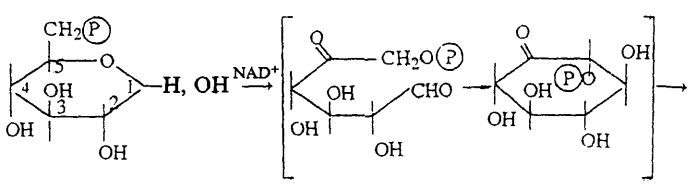
Using the KIE, Miller and Klinman established[10,47] that the oxidation of tritium-labelled dopamine catalysed by the enzyme dopamine β-monooxygenase, i.e.



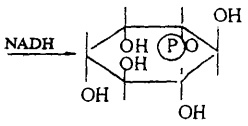
is accompanied by an appreciable KIE (V/K) which decreases from 8.8 at an oxygen concentration of 0.02 mM to 4.1 at $[O_2]$ = 1 mM. Analysis of the experimental dependences of the KIE on the oxygen concentration yielded the following limiting values of the KIE: $^{T}(V/K)_{O_2\to 0} \simeq 15$ and $^{T}(V/K)_{O_2\to\infty} \simeq 3.6$. The data obtained indicate a non-ordered kinetic mechanism of this reaction.

Analysis of the KIE in the enzyme oxidation reactions of 2-[2-^{2}H]propanol and [1-^{2}H]cyclohexanol made it possible to establish the kinetic mechanisms of processes catalysed by alcohol dehydrogenases isolated from both yeast and liver.[48–50] When liver alcohol dehydrogenase is used, the liberation of NAD from the ternary complex E–NAD–cyclohexanol takes place at a negligible rate, while cyclohexanol is liberated much faster than it reacts with formation of products, i.e. the process is ordered. In the 2-propanol oxidation reaction catalysed by yeast alcohol dehydrogenase, the liberation of 2-propanol and NAD from the complex E–NAD–propanol takes place at approximately the same rates, i.e. the reaction is random. In the study of the mechanisms of the same reactions, use was also made of secondary KIE.[51] Together with the determination of the kinetic mechanisms of enzymic reactions, the KIE can yield valuable information about their chemical mechanisms.[12,52–55]

For example, the study of the KIE in the reactions involving the conversion of *D*-[5-^{3}H]-, *D*-[3-^{3}H]-, and *D*-[4-^{3}H]-glucose-6-phosphate[34,56,57] and also *D*-[5-^{2}H]- and *D*-[G-^{2}H]- glucose-6-phosphate[58,59] into the corresponding tritiated and deuteriated isotopic forms of myoinosotol-1-phosphate, catalysed by myoinositol-1-phosphate syntheses of plant and animal origin, established the following process mechanism:



D-glucose-6-phosphate

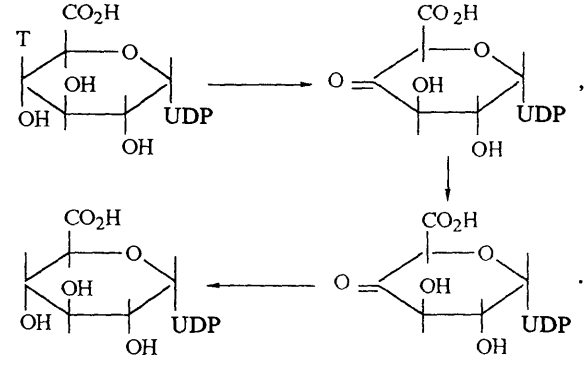


myoinosotol-1-phosphate

Isotope effects were observed only in those cases where tritium or deuterium was present in the initial substrate in the 5-position, while in the remaining cases the labelled substrates reacted at the same rate as the unlabelled *D*-glucose-6-phosphate. This shows that only hydrogen atoms in the 5-position participate in the oxidation stage and in the subsequent cyclisation of *D*-glucose-6-phosphate to myoinositol-1-phosphate.

A difference between the mechanisms of two parallel transmethylation reactions catalysed by catechol *O*-methyltransferase, involving the transfer of [^{3}H]methyl groups from the labelled *S*-adenosylmethionine to the *m*- and *p*-hydroxy-groups of dopamine, has also been established with the aid of KIE.[42] It was found that for *meta*-methylation, the secondary KIE is 1.16, whereas for *para*-methylation it is 1.35. The latter value is close to the value of 1.29 determined previously for the S_N2 transfer of the methyl group in the methylation of 3,4-dihydroxyacetophenone in the presence of the same enzyme.[60] On this basis, it was concluded[42] that the methylation of the *para*-position of dopamine proceeds via an S_N2 mechanism. The lower value of the KIE for *meta*-methylation indicates the influence of other stages on the rate of the process as a whole.

An appreciable KIE (3.1) has been observed in the decarboxylation of uridine-diphospho-*D*-[4-^{3}H]glucuronic acid in the presence of UDP-*D*-glucuronate decarboxylase, whereas the presence of the tritium label in the 3- and 5-positions in the initial compound did not affect the rate of the process.[61,62] These results show that the decarboxylation reaction is accompanied by oxidation at C(4):



Similar conclusions concerning process mechanisms have been drawn from the KIE in the reaction involving the conversion of UDP-*D*-[4-^{3}H]glucose into UDP-*D*-[4-^{3}H]galactose catalysed by UDP-*D*-glucose 4-epimerase.[63]

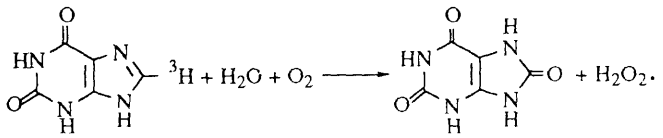
KIE have also been used in the study of the mechanisms of reactions catalysed by fumarase,[64] protease,[17] alcohol dehydrogenase,[62,65–67] aminoxidase,[68,69] chorismate synthase,[19] yeast hexokinase,[70] lacate dehydrogenase,[71] phosphoribosyltransferases,[72] succinoxidase,[73] adenosine deaminase,[74] liver monoxygenase,[75] and lipoxygenase.[54]

Useful information about the mechanisms of enzymic reactions is also provided by KIE when deuteriated solvents are used (the dependence of the KIE on the solvent).[76–78]

2. Determination of the rate-limiting stage in the enzymic process

Analysis of the principal types of KIE makes it possible to discover the rate-determining stage in enzymic reactions. An example of such use of KIE is provided by a study[21] in which kinetic

differences in the oxidation of the protium and tritium forms of xanthine catalysed by xanthine oxidase were investigated.



A marked dependence of the KIE on the xanthine concentration in the incubation mixture was observed. If the kinetic data are presented graphically using the method of the double reciprocal quantities 1/v and 1/[S], then linear relations are observed for all the cases investigated, as can be seen from Fig. 3, which is consistent with the Lineweaver–Burk equation:

$$\frac{1}{v} = \frac{K}{V[S]} + \frac{1}{V} \quad .$$

Here it is significant that all the experimental straight lines have different slopes but intersect the ordinate axis at virtually the same point at a given pH. It follows from the equation that the slopes of the straight lines are equal to the ratios K/V; the intercept on the abscissa axis is $-1/K$, while that on the ordinate axis yields $1/K$.

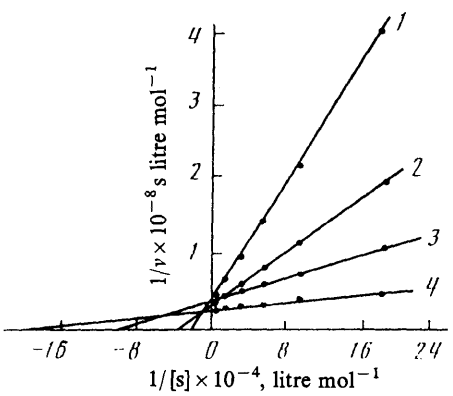


Figure 3. Graphical representation of the rates of enzymic oxidation of labelled (lines *1* and *2*) and unlabelled (lines *3* and *4*) xanthine at different pH; *1*, 10.2; *2*, 8.5; *3*, 10; *4*, 8.5.

The following conclusions can be drawn from the results: the maximum rates of oxidation of the labelled and unlabelled xanthine at the same pH are virtually identical, i.e. at high substrate concentration there is no KIE or it is insignificant; the kinetic isotope effect is manifested mainly in the value of the Michaelis constant.

The following binary mechanism has been established for the enzymic oxidation of xanthine:[79]

$$E + K \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EX \xrightarrow{k_2} E_{red} + U,$$

$$E_{red} + O_2 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E_{red}\cdot O_2 \xrightarrow{k_4} E + H_2O_2,$$

where E is the enzyme, X is xanthine, and U is uric acid. It is also known that the rate of oxidation of the reduced enzyme E_{red} is significantly greater than the rate of its formation and the rate of the process as a whole is therefore determined by the first two stages. At fairly high xanthine concentrations, [X] ≫ [E], the entire enzyme is bound in the enzyme–substrate complex EX and the rate of reaction has a maximum:

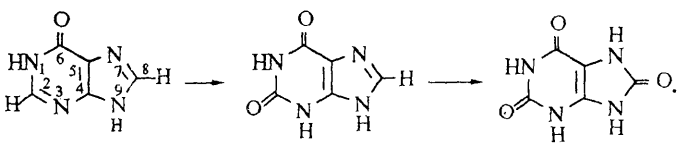
$$V = k_2[EX] = k_2[E] \quad .$$

Since the enzyme concentration was the same in the measurement of the KIE in all the experiments, the similarity of the values of V published for the protium and tritium substrates indicates a small difference between the rate constants for the decomposition of the complexes EX containing [^{1}H]- or [^{3}H]-xanthine.

On the other hand, the Michaelis constant is defined as $K = (k_1 + k_2)/k_1$. Bearing in mind that the constants k_2 have been shown to be equal, the observed difference between the Michaelis constants for the labelled and unlabelled xanthine may be explained by the difference between the rate constants for the formation and decomposition of the enzyme–substrate complexes. Thus the KIE in the reaction investigated is determined by the different rates of formation of the transition complexes of the labelled and unlabelled xanthine.

A similar discrimination between the labelled molecules was observed in the formation of enzyme–substrate complexes in the oxidation of xanthine containing deuterium in the 8-position.[79]

The rate-determining stage in the formation of the complex EX was also established in a study of the KIE in the two-stage oxidation of [2-^{3}H]-, [8-^{3}H]- and [2,8-^{3}H$_2$]-hypoxanthine catalysed by the same enzyme, i.e.



hypoxanthine xanthine uric acid

But in this case the stage involving the decomposition of the complex is partly rate-determining.[80] Isotope effects in the stage where the reaction is inhibited by the substrate were also observed under these conditions.

An effective use of KIE in order to establish the rate-limiting stages in the decarboxylation of *L*-malate catalysed by *L*-malate $NADH^+$-oxidoreductase has been reported by Schimerlik, et al.[81]

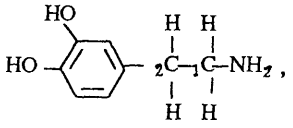
3. The structure of the transition state

The isotope effects in chemical reactions are used widely in the study of the structure of the transition state.[3] On the other hand, such use of the KIE for enzymic reaction is difficult because the chemical bond dissociation stage is usually not fully rate-determining, while other reactions such as, for example, the formation of the products or conformational changes, which precede or follow the chemical bond dissociation stage, are usually partly rate-determining. Therefore, in order to obtain information about the structure of the transition state in enzymic reactions, it is necessary to measure the true KIE, i.e. the isotope effect in the chemical bond dissociation stage. As mentioned above, this KIE can be calculated by Northrop's method. Conclusions concerning the structural characteristics of the transition state derived from the KIE

are based on theoretical considerations put forward by Melander,[3] which have been described by Cleland in relation to enzymic reactions.[11]

Unfortunately, whereas the theoretical aspect of the problem has been developed in fair detail, there have been few practical applications of KIE in the analysis of the structure of the transition state. For example, the KIE found in kinetic studies on the biosynthesis of S-adenosylmethionine from [5′-^{14}C]- and [5′-^{3}H]-ATP (catalysed by the enzyme S-adenosylmethionine synthetase) permitted the conclusion that the transition state has an S_N2-like structure in which the binding to C(5′) is symmetrical in relation to the leaving phosphate group and the arriving methionine sulphur atom.[18]

In the oxidation reactions of dopamines, chirally tritium-labelled in the 1-position {[(1*R*)-^{3}H]- and [(1*S*)-^{3}H]-dopamines}, i.e.



catalysed by ox plasma aminoxidase, strong stereochemical isotope effects were observed: 5–6 for [(1*R*)-^{3}H]- and 26–34 for [(1*S*)-^{3}H]-dopamines, which permitted a conclusion concerning the stereochemistry of the binding of dopamine to the enzyme.[68]

4. Enrichment of labelled substrates in heavy hydrogen isotopes

In those cases where the initial substrate consists of two different varieties of molecules—deuterium- or tritium-labelled molecules and the usual unlabelled molecules—the reactions of the two forms are qualitatively the same, but, by virtue of the manifestation of the KIE, are quantitatively different. The ratio of the two varieties of molecules therefore gradually changes during the reaction in favour of those labelled with heavy hydrogen isotopes.

If the initial ratio of the concentrations of the labelled and unlabelled substrate molecules $[S]_0^*/[S]_0$ is designated by R_0, while the corresponding concentration ratio after the attainment of a degree of enzymic reaction F is designated by $R = [S]^*/[S]$, the enrichment in the heavy isotope of the substrate remaining unreacted in the incubation system can be determined from the equation (Ref. 3, p. 105)

$$\frac{R}{R_0} = (1-F)^{(k^*/k)-1},$$

where k^*/k is the KIE.

When tritium-labelled substrates are used, the ratio R/R_0 in the above equation can be replaced by the ratio of the molar radioactivity of the enriched product A to the initial molar radioactivity of the substrate A_0.

This enzymic method of enriching labelled preparations in the heavy isotope is of great practical importance because the use of compounds with the maximum content of the label is of greatest interest. Furthermore, the KIE can be used to regenerate the labelled compounds after the experiments in which they were diluted by the unlabelled ("cold") compounds.

KIE have been used[20,27] in the enzymic oxidation of labelled *D*-galactose in order to increase significantly the tritium content in preparations comprising different isotopic forms of galactose. The results of these experiments are presented in Table 1.

When KIE are used to enrich substrates in heavy hydrogen isotopes, the choice of incubation conditions and primarily of the substrate concentration is important. For example, when the enzymic oxidation of xanthine is carried out at a high substrate concentration, the molar radioactivity of [8-^{3}H]xanthine does not increase appreciably since under these conditions there are virtually no KIE in terms of V.[21] On the other hand, at low xanthine concentrations, where there is an appreciable KIE in terms of V/K, it was possible to increase the molar radioactivity of the [8-^{3}H]xanthine preparations.

Table 1. Results of the enzyme-catalysed increase in the molar radioactivity of tritium-labelled *D*-galactose preparations.

Initial mixture of isotopic forms	A_0, Ci mmol^{-1}	t, min	A, Ci mmol^{-1}	A/A_0
[6-$^{3}H_1$]Gal, Gal	0.15	60	0.32	2.2
[6-$^{3}H_1$]Gal, Gal	4.6	90	20.3	4.4
[6-$^{3}H_1$]Gal, Gal	4.6	90	18.2	4.0
[6-$^{3}H_1$]Gal, Gal	4.6	240	21.3	4.6
[6-$^{3}H_1$]Gal, Gal	14.6	60	24.5	1.7
[6-$^{3}H_2$]Gal, Gal	4.2	30	6.5	1.5
[6-$^{3}H_2$]Gal, Gal	4.2	240	26.2	6.2
[6-$^{3}H_2$]Gal, [6-$^{3}H_1$]Gal	48.0	240	53.0	1.1

Note. Gal = *D*-galactose; A_0 = initial Moner activity; A = final Moner activity; t = incubation time; A/A_0 = degree of enrichment.

Examples of the analogous use of KIE in certain other enzymic reactions can be found in other studies.[31,80,82]

The observed biological fractionation of isotopes is also based on KIE.[83,84]

5. Kinetic isotope effects in pharmacology and medicine

Bearing in mind the familiar claim that enzymes are the basis of life and that the basis of biological processes is enzymic reactions, the KIE in such reactions can be regarded as the basis of the biological isotope effects, i.e. of the definite difference in the behaviour of labelled and unlabelled compounds in living organisms.

Such differences can be manifested, for example, by a change in the biotransformation of labelled products. Thus deuteriation of ethyl radicals in the anaesthetics methoxyflurane, haloctan, and enflurane leads to an appreciable slowing down of their metabolism.[85] Since the products of the biotransformation of these preparations determine to a large extent their toxicity, the weakening of the metabolism of the deuteriated compounds results in a decrease of toxicity.

The difference in the metabolic behaviour of deuteriated compounds, defined by the KIE in enzymic processes, has also been noted for certain other medicinal preparations.[86–89]

It has not been ruled out that, when deuteriated medicinal preparations are used, the KIE can in certain cases produce a greater therapeutic effect or prolong the activity of the preparations as a result of their greater concentration in certain organs.

Radioisotope diagnosis and positron emission tomography are promising fields where KIE can be applied. In such cases, it is essential to use preparations with a double isotope label: one (deuterium) label is used to achieve the KIE and the other radionuclide) label is used to investigate the distribution and location of the radiopharmaceutical preparation in the organism. In a number of instances, on the basis of the deuterium KIE it has been possible to alter the increase in the concentration in and the rate of elimination of a preparation from the test organ, achieving thereby a definite diagnostic effect. For example, such an effect has been observed by Wenzel[90] in a study of the kinetics of the process in which *N*-alkylamphetamine labelled with iodine-131 in the *para*-position was concentrated in rat and mouse brains. This radiopharmaceutical preparation is capable of being concentrated in the brain and is therefore used for various studies on this organ. It has been established that, when deuterium is introduced into the side chain of N-alkyl-*p*-[^{131}I]iodoamphetamine, the degree of concentration of this preparation in the brain increases appreciably.

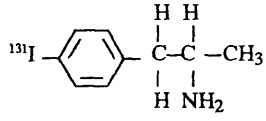


Figure 4 illustrates the kinetics of the alteration of the radioactivity in the brain of the protium form and of one of the deuteriated forms of *p*-[^{131}I]iodoamphetamine investigated by Wenzel. The figure shows that the deuteriated preparation generates a much higher concentration in the brain. This result is of practical importance, because the introduction of deuterium makes it possible to diminish the overall activity of the iodine-131 introduced into the organisms or to achieve a better diagnostic picture for the same dose. It is significant that the concentration of iodine-131 in the blood can be appreciably reduced under these conditions. The author put forward the hypothesis that the observed effect is attained as a result of the decrease in the rate of the enzymic oxidative deamination of the preparation.

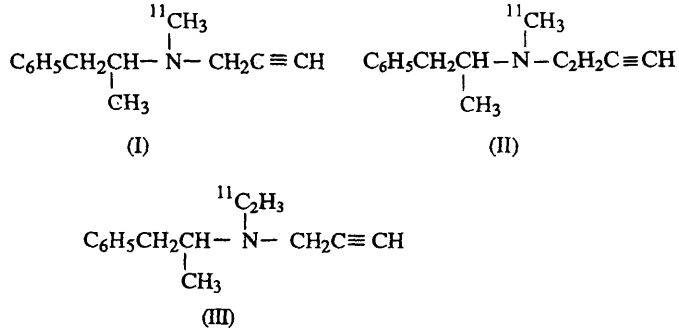
Figure 4. Kinetics of the variation of radioactivity in the brain on introduction of the protium (line *1*) and deuterium (line *2*) forms of *p*-[^{131}I]iodoamphetamine.

Analogous studies of the ruthenocene derivatives of amphetamine labelled with ^{103}Ru established that the deuteriated derivatives are also concentrated in the brain to a greater extent than the corresponding protium forms (almost to the extent of 180%).[91,92]

A decrease in the rate of metabolism in the brain has also been observed for the deuteriated preparation of *N,N*-dimethylphenylethylamine labelled with carbon-11, which is a positron emitter.[93]

In a report delivered at the VIIth International Symposium on Radiopharmaceutical Chemistry in the Netherlands in 1988, it was demonstrated that KIE can be used successfully in the solution of an important psychopharmacological problem involving the search for different kinds of monoaminoxidase inhibitors.[94] Such inhibitors include *L*-deprenyl; *L*-deprenyl containing carbon-11 is used as a radioactive tracer for the charting of aminoxidase in human and animal brains. It was postulated that *L*-[^{11}C]deprenyl is transported into the brain, where it is oxidised by monoaminoxidase. In the study of the mechanism of this inhibition process, kinetic investigations using the following three isotopic forms of *L*-deprenyl were carried out.



(I) (II) (III)

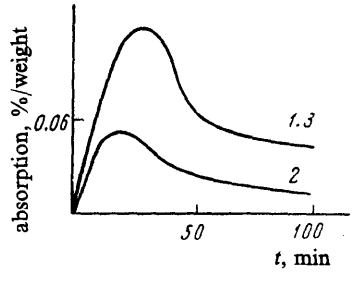


Figure 5. Kinetics of the absorption in baboon brains of the protium isotopic form of *L*-[^{11}C]deprenyl (curve *1*), the form deuteriated in the propargyl group (curve *2*), and the form deuteriated in the methyl group (curve *3*).[94]

The data for the absorption and retention of these compounds in the brains of baboons, presented in Fig. 5, were obtained by positron emission tomography.[94] An appreciably smaller absorption of ^{11}C in the brain was observed for compound (II) containing deuterium in the α-position in the propargyl group. In this case, the KIE was estimated as 3.8. The results show that monoaminoxidase

catalyses the dissociation of the C–H bond in the α-position in the propargyl group and that this is the rate-determining stage in the retention of ^{11}C in the brain.

Incubation of rat liver mitochondrial membranes in the presence of unlabelled and deuteriated serotonin showed that the activity of monoaminoxidase increases in the presence of β,β′-[$^2H_2$]serotonin, but decreases after the introduction of α,α′,β,β′-[$^2H_4$]serotonin.[85] A similar phenomenon has also been observed for dopamine. The suppression of the activity of monoaminoxidase is achieved to a greater extent in the presence of [^{2}H]phenylethylhydrazine compared with the protium form of this compound. As a consequence of this, the administration of deuteriated phenylethylhdyrazine to rats significantly increases the content of dopamine, serotonin, and *m*- and *p*-tyrosine in the brain.[95].

With the aid of fully deuteriated glucose containing simultaneously carbon-14, a significant difference was established in the distribution and metabolism of this isotopic form compared with the preparation having the usual isotopic composition.[96] This difference consists primarily in the retarded transport of deuteriated glucose into the brain, believed to be caused[96] by the isotope effects in the reaction involving glucose oxidase. The introduction of tritium instead of deuterium into glucose also alters the metabolism of this compound.[97,98] A carbon-14 KIE has been reported in the oxidation reaction of labelled *D*-glucose catalysed by glucose oxidase.[99]

There is no doubt that the examples of the use of KIE examined here do not exhaust the entire potential possibilities and that in the future kinetic differences in enzymic reactions involving labelled compounds will find new applications.

Phosphorus derivatives of salicylic acid

L V Chvertkina, P S Khokhlov, V F Mironov
All Russian Phytopathology Scientific Research Institute, B Vyazemi, Moscow Region

ABSTRACT. The present state of work on the methods of synthesis, chemical properties, and practical applications of phosphorus-containing derivatives of salicylic acid has been reviewed. The characteristics of the chemical transformations of cyclic and acyclic phosphorus derivatives of salicylic acid related to the coordination state of the phosphorus atom have been examined.

The bibliography contains 158 references.

III. Acyclic phosphorus-containing derivatives of salicylic acid 1016

I. Introduction

Acyl derivatives of salicylic acid are used as drugs and microbiocides. Particular mention may be made of the use of acetylsalicylic acid as an analgesic and antipyretic.[1] Many organophosphorus compounds show a wide spectrum of biological activity.[2] The study of compounds whose molecules contain fragments of phosphorus acids and salicylic acid is of considerable interest in the search for new substances of practical importance. Although phosphorus derivatives of salicylic acid have been the subject of a large number of studies, no reviews have been published, except for selections from the literature devoted to individual aspects of the chemistry of these compounds.[3–7] Monographs on the chemistry of phosphorus compounds contain few data on phosphorus derivatives of salicylic acid.

In our opinion, phosphorus derivatives of salicylic acid deserve detailed examination not only because of their low and varied biological activity but also because of their unique reactivity, which differs sharply from that of usual acyl derivatives of phosphorus.

The aim of the present review is to summarise and where possible systematise the results of work on the methods of synthesis and reactivity of phosphorus derivatives of salicylic acid.

Salicylic acid, unlike other hydroxybenzoic acids, contains in the *ortho*-position two functional groups capable of reacting with a central phosphorus atom to give cyclic and acyclic phosphorus-containing derivatives. The chemical properties of phosphorus derivatives of salicylic acid are determined to a large extent by their cyclic or acyclic structure, and also depend on the coordination state of the phosphorus atom. These characteristics were taken as a basis for the systematisation in the compilation of the present review.

II. Cyclic phosphorus-containing derivatives of salicylic acid

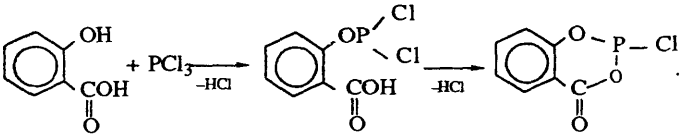
1. Cyclic phosphorus derivatives of salicylic acid containing a three-coordinate phosphorus atom

The phosphorus derivatives of salicylic acid are mixed anhydrides of phosphorus and salicylic acids. Certain features of the chemistry of these compounds are similar to those of the chemistry of acyl phosphites with an endocyclic fragment, described earlier.[8]

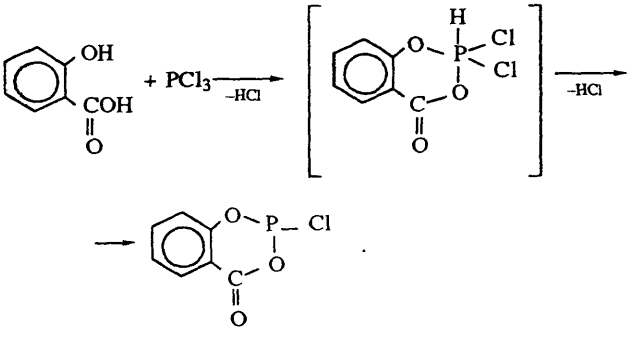
a. 4,5-Benzo-2,6-dioxaphosphorin-3-ones (BDPO)

Phosphorus derivatives of salicylic acid were first obtained by Anschütz and co-workers[9] by the reaction of salicylic acid with phosphorus trichloride. This reaction can give several products, whose structures have been studied by a number of authors.[5,6,9–16] The results of these studies have been summarised by Atherton.[4] It was established that when stoichiometric quantities of the starting materials or an excess of phosphorus trichloride are used, the chief product is 1-chloro-4,5-benzo-2,6-dioxaphosphorin-3-one (1-Cl-BDPO)—a cyclic salicyl chlorophosphite with a three-coordinate phosphorus atom in the ring. Despite the extensive practical application of phosphorylation by P^{III} chlorides in the preparation of salicyl phosphites, the mechanism of this reaction has not been studied in detail.

It has been suggested that the mechanism involves phosphorylation of the phenolic hydroxyl group, followed by ring closure:[14,15]



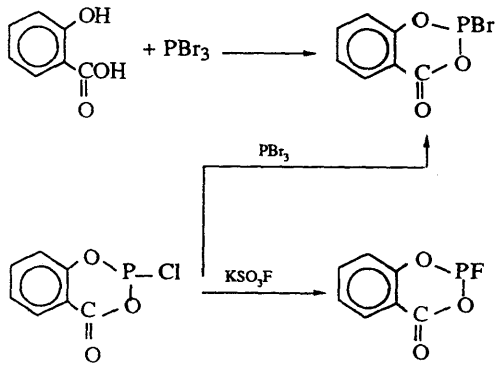
A number of authors suggest that the reaction takes place via a stage involving the formation of a phosphorane.[10,16] No spectroscopic confirmation of intermediate structures of this kind has been obtained, however.



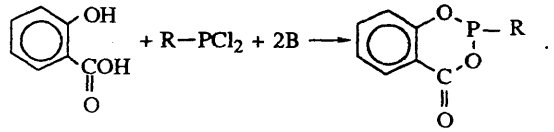
The reaction of salicylic acid with phosphorus trichloride is usually carried out by heating their mixtures in benzene, toluene, or xylene for 2–4 h,[12,14,17] or in ether with a hydrogen chloride acceptor,[15] and the product is isolated by vacuum distillation. Cooling gives a crystalline product with m.p. 36–37 °C. The ^{31}P NMR spectrum of 1-Cl-BDPO contains one signal due to the phosphorus nucleus, at 151 p.p.m.[18]

Derivatives of salicylic acid containing chlorine, bromine, iodine, methyl and nitro-groups,[11] and the hydroxyl group[19] in the benzene ring also react with phosphorus trichloride. The cyclic products were obtained in 69–90% yield.

The reaction of salicylic acid with phosphorus tribromide gives a high yield of 1-bromo-4,5-benzo-2,6-dioxaphosphorin-3-one,[14] which has also been obtained by replacing chlorine by bromine.[20] 1-F-BDPO has been synthesised by an exchange reaction.[21]



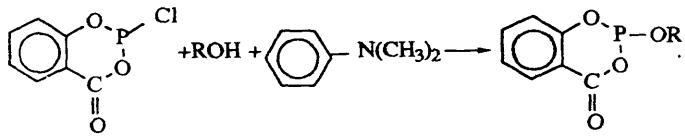
Salicylic acid undergoes a cyclisation with the dichlorides of phosphorus(III) acids in the presence of a hydrogen chloride acceptor:[15,22–24]



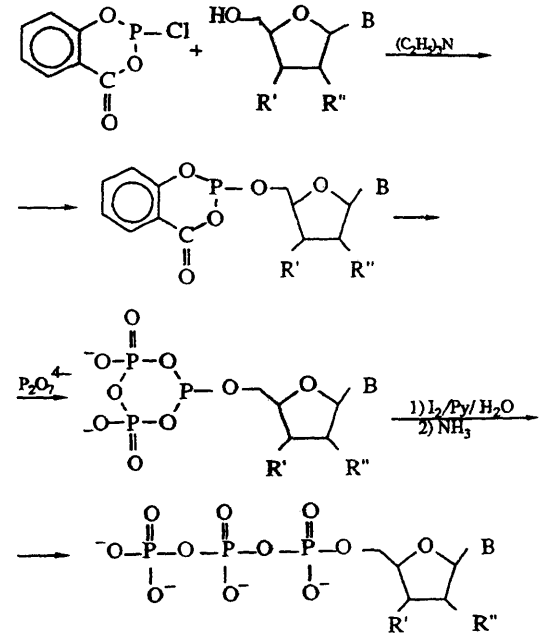
The 1-phenyl-4,5-benzo-2,6-dioxoaphosphorin-3-one formed in this reaction has been used to obtain copolymers with *ortho*- and *para*-substituted aldehydes, 4,4′-diphenoquinones, methacrylate, and acrolein.[25–27]

1-Chloro-4,5-benzo-2,6-dioxaphosphorin-3-ones react readily with electrophilic and nucleophilic reagents. These reactions can take place both with preservation and with splitting of the dioxaphosphorine ring, and with preservation or change in the coordination of the phosphorus atom. The chemical properties of these compounds have been most fully studied for 1-Cl-BDPO. As shown by Nesterov and co-workers,[28–32] this compound can serve as a key intermediate in the synthesis of various types of phosphorus derivative of salicylic acid.

The chlorine atom in position 1 of the phosphine ring has practically the same mobility as that in alkylene chlorophosphites. Thus the reaction of 1-Cl-BDPO with alcohols and phenols in the presences of a hydrogen chloride acceptor gives 1-alkoxy(aryloxy)-4,5-benzo-2,6-dioxaphosphorin-3-ones.[14,22,28–31,33,34]

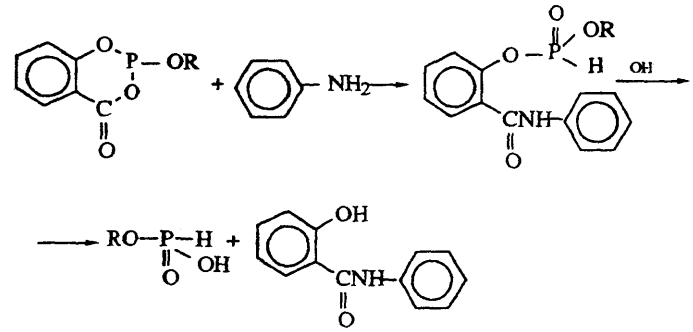


1-Alkoxy(aryloxy)-BDPO are also highly reactive, and react readily with nucleophilic reagents, with splitting of the dioxaphosphorine ring. When an excess of the alcohol or phenol is used, the chief products are salicylic acid and trialkyl(aryl) phosphites.[28,35] Carrying out this reaction in stages provided the basis for an extremely effective method for synthesising nucleoside polyphosphates.[36–39]

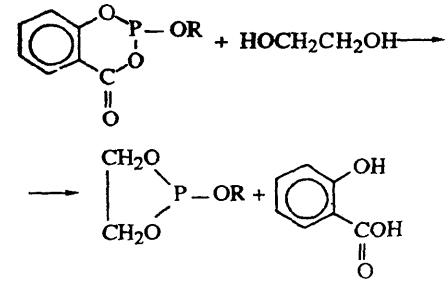


B represents nucleic bases (A^{Bz}, G^{ib}, T, C^{Bz}, U).

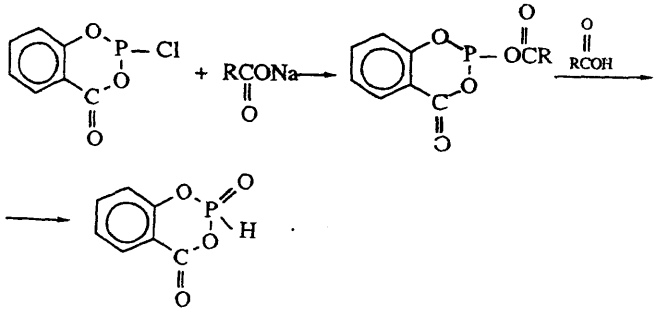
The reactions of 1-alkoxy-BDPO with amines gives monoalkyl phosphites.[40]



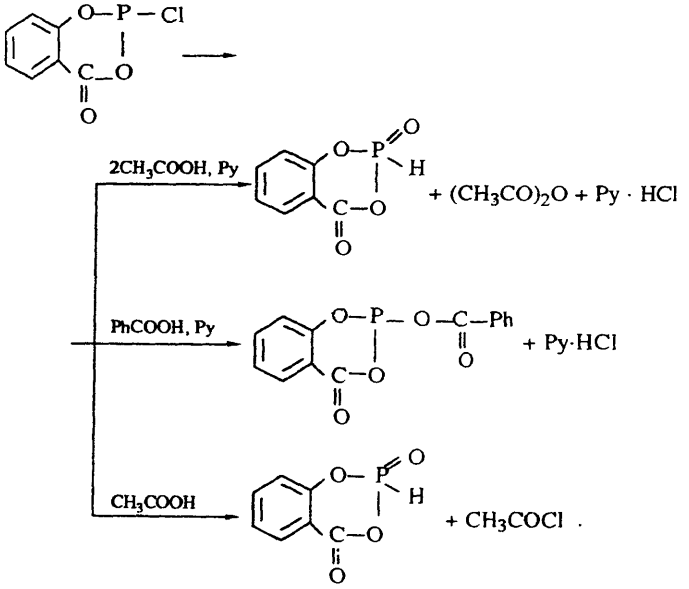
1-Alkoxy-BDPO undergo exchange reactions. With glycols, an extremely interesting reaction takes place, with recyclisation of the phosphorine ring to give a phospholane ring.[41]



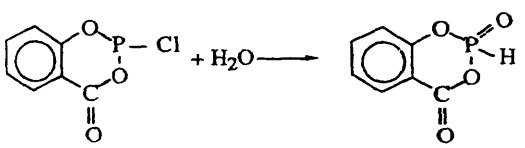
The high mobility of the chlorine atom in 1-Cl-BDPO is confirmed by the reaction with such weak nucleophilic reagents as the salts of carboxylic acids, accompanied by the replacement of the chlorine atom by the acyloxy-group[14,35] and the formation of a mixed anhydride of salicyclic, phosphorus, and carboxylic acids. With an excess of acid, the anhydride undergoes splitting, accompanied by the formation of a cyclic hydrophosphoryl compound[14,35] — 1-hydro-4,5-benzo-2,6-dioxaphosphorine-1,3-dione (1-H-BDPD):



The reaction of salicylic chlorophosphite with carboxylic acids have been studied.[14,22,35] The reaction with benzoic acid gave the acyl phosphite, but the reaction with acetic acid gave salicyl hydrogen phosphite, despite the presence of a base.

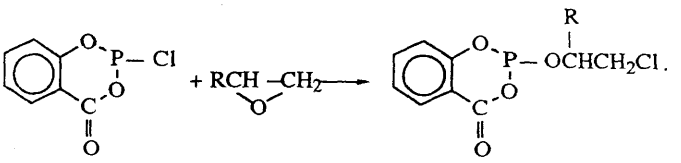


The last reaction is the most convenient preparative method for obtaining 1-H-BDPD. 1-H-BDPD can also be obtained by the reaction of 1-Cl-BDPO with water:[15,42]

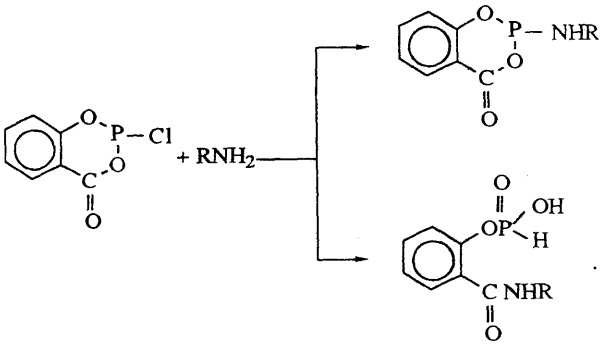


Like other hydrophosphoryl compounds, 1-H-BDPD exists in two tautomeric forms, with three-coordinate and four-coordinate phosphorus atoms, and the ^{31}P NMR spectrum correspondingly contains signals due to phosphorus nuclei at 113 p.p.m. and −4 p.p.m.[43] According to recent data,[44] however, a close structural analogue — pyrocatechol hydrogen phosphite — exists only in the oxo-form.

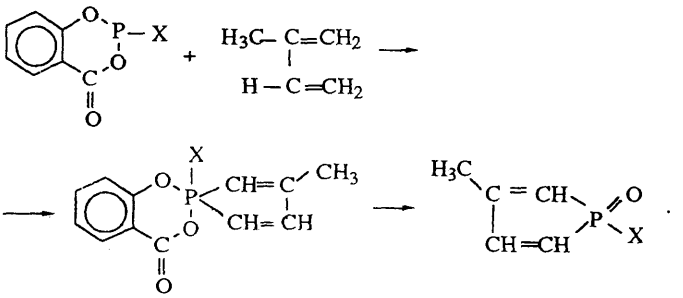
Exocyclic replacement of the chlorine atom in 1-Cl-BDPO also predominates in the reaction with alkylene oxides:[45]



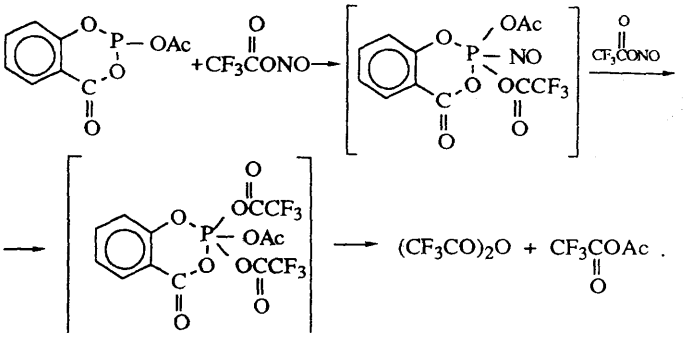
The reaction of this compound with amines is more complex. It involves not only the replacement of the chlorine atom but also splitting of the phosphorine ring:[16,46,47]



1-Chloro(ethoxy)-4,5-benzo-2,6-dioxaphosphorin-3-ones react with dienes. Their reaction with isoprene involves the intermediate formation of an unstable phosphorane, which when distilled is converted into 1-oxo-1-chloro(ethoxy)-3-methylphospholene:[48]



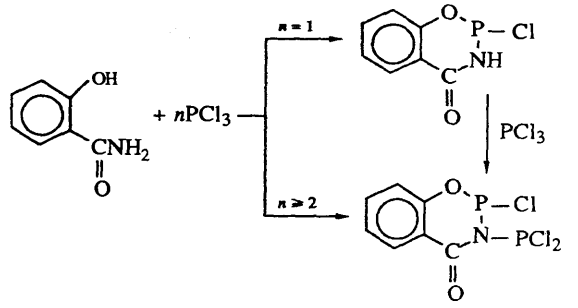
The reaction of BDPO with trifluoroacetyl nitrite gives the anhydride of trifluoroacetic acid and mixed anhydrides of trifluoroacetic acid and the acid whose residues was present on the phosphorus atom of the original phosphite:[49]



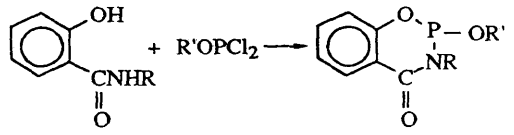
The structure of the phosphorus-containing product of this reaction has not been determined. The authors cited subsequently assigned to the organophosphorus compound formed the "general" structure $(R-COO)_3P=O$.[50]

b. 4,5-Benzo-2-aza-6-oxaphosphorin-3-ones and 4,5-benzo-6-aza-2-oxaphosphorin-3-ones

4,5-Benzo-2-aza-6-oxaphosphorin-3-ones (BAOPO) are obtained by the reaction of salicylamides with the chlorides of trivalent phosphorus acids. Salicylamides react with phosphorus trichloride in boiling benzene; the reaction is complete in several hours with the formation of a cyclic product,[51] and when there is a proton on the nitrogen atom this product can undergo further phosphorylation by an excess of phosphorus trichloride:[52]

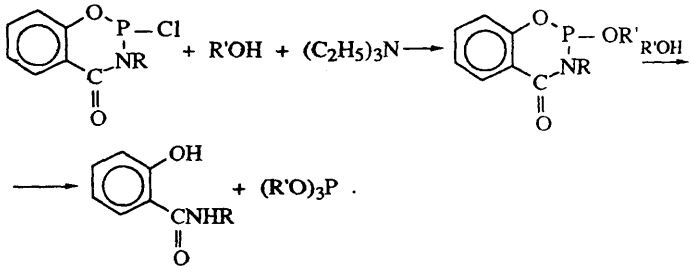


An analogous cyclisation is observed in the reaction of salicylamides with dichlorophosphites, which is complete with the formation of 1-alkoxy(phenoxy)oxa-azaphosphorin-3-ones:[51]

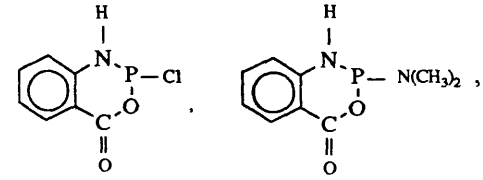


The reaction of salicylamides with amides of trivalent phosphorus acids takes place by an alternative route to give acyclic compounds[53] (see below).

1-Chloro-4,5-benzo-2-aza-6-oxaphosphorin-3-one (1-Cl-BAOPO) are highly reactive compounds. Their reactions with nucleophilic reagents can take place both with exocyclic replacement at the phosphorus atom and with splitting of the oxa-azaphosphorine ring. Thus 1-Cl-BAOPO reacts with stoichiometric quantity of an alcohol to give the 1-alkoxy-BAOPO, but in the presence of an excess of the alcohol the normal phosphite and the salicylamide are formed.[51]



Phosphorylated derivatives of anthranilic acid[54,55] with the general formula

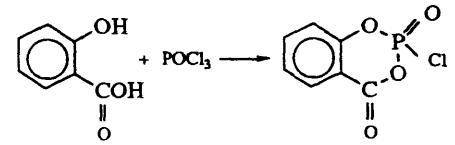


are structural isomers of 4,5-benzo-2-aza-6-oxaphosphorin-3-ones.

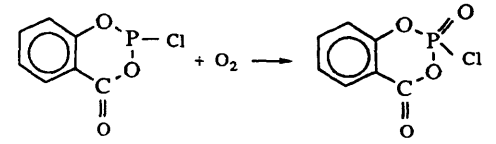
2. Cyclic phosphorus derivatives of salicylic acid containing a four-coordinate phosphorus atom

a. 4,5-Benzo-2,6-dioxaphosphorine-1,3-diones

A key intermediate in the synthesis of various 4,5-benzo-2,6-dioxaphosphorine-1,3-diones (BDPD) is 1-chloro-4,5-benzo-2,6-dioxaphosphorine-1,3-dione, for which several methods of preparation have been proposed. The simplest of these is based on the reaction of salicylic acid with phosphorus oxide chloride;[4,6,56,57]



The yield of 1-Cl-BDPD in this reaction does not exceed 50%; it can be obtained in higher yield by oxidising 1-Cl-BDPO with oxygen:[4,12]

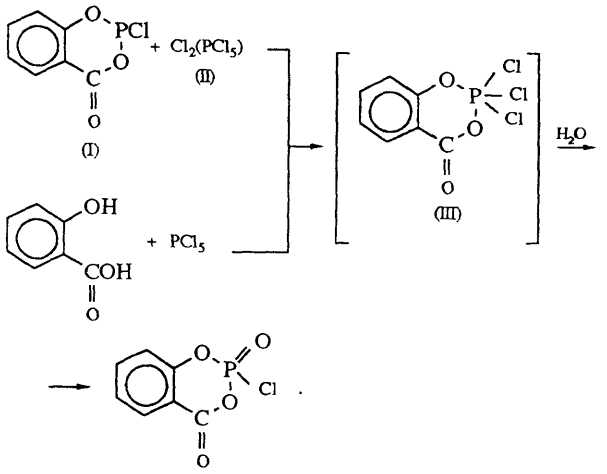


The phosphorus in 1-Cl-BDPO is only weakly nucleophilic, so that the addition of oxygen is slow, and the oxidation is not complete even on prolonged reaction.

1-Cl-BDPD, and also 1-fluoroalkoxy-derivatives of BDPD, were recently obtained in high yield (>90%) using trifluoroethyl sulphate as oxidising agent:[58]

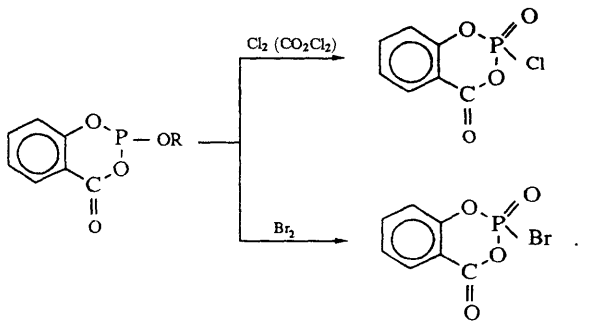
The addition of chlorine to 1-Cl-BDPO takes place more vigorously to give the trichlorophosphorane (III), controlled hydrolysis of which also gives 1-Cl-BDPO. The intermediate

phosphorane (III) can be obtained by the reaction of salicylic acid or 1-Cl-BDPO with phosphorus pentachloride:[12,59,60]



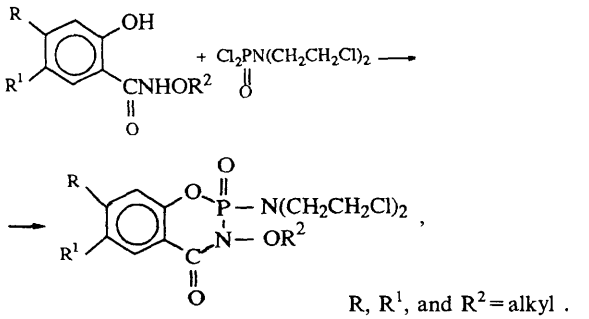
It was subsequently shown, however, that stable intermediate phosphoranes of type (III) are not formed in the reaction of the phosphite (I) with phosphorus pentachloride and chlorine.[61] The formation of stable products was observed only in the reactions of 1-chloro-4,5-benzo-2-phenylaza-6-oxaphosphorin-3-one and its 1-phenoxy analogue with chlorine.[62]

1-Cl-BDPD and 1-Br-BDPD are formed by the reaction of 1-alkoxy-BDPO with chlorine (sulphuryl chloride) or bromine respectively:[30,33]



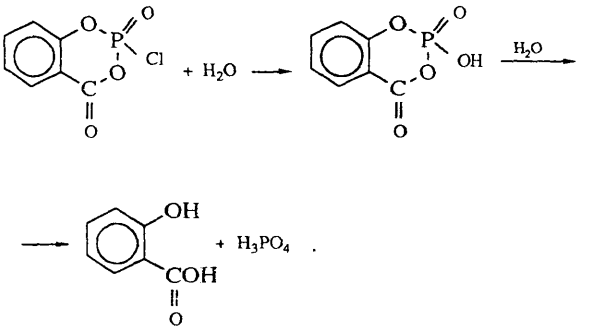
When the reaction with bromine is carried out under controlled conditions at a low temperature, ring opening takes place initially to give a product which undergoes cyclisation when the temperature is increased.[33] A similar result was obtained in a study of the reaction of 1-Cl-BDPO with halogens.[63]

Phosphorylation takes place with amidodichlorophosphates and hydroxamic derivatives of salicylic acid:[64]

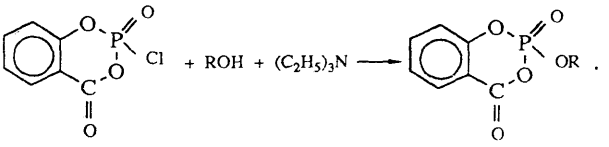


R, R^1, and R^2 = alkyl .

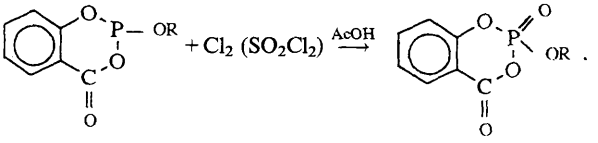
The reaction of 1-Cl-BDPD with nucleophilic reagents may involve both replacement of the chlorine atom and splitting of the phosphorine ring. On careful hydrolysis of 1-Cl-BDPD, replacement of chlorine by a hydroxyl group has been observed, but the resulting 1-hydroxy-4,5-benzo-2,6-dioxaphosphorinic acid is extremely unstable and is rapidly hydrolysed to give phosphoric and salicylic acids:[65]



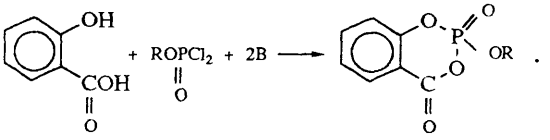
The replacement of chlorine by alkoxy and aryloxy groups takes place more selectively in the presence of hydrogen chloride acceptors to give 1-alkoxy(aryloxy)-4,5-benzo-2,6-dioxaphosphorine-1,3-diones;[6,66–68] the reaction takes place by an $S_N2(P)$ mechanism:[69]



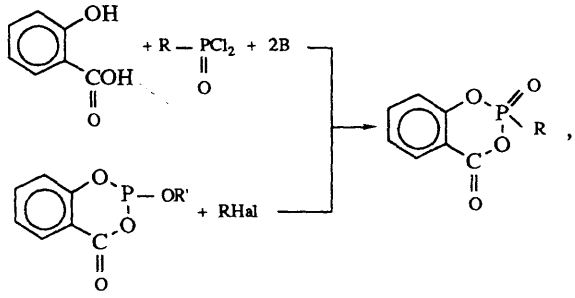
1-Chloroalkoxy(aryloxy)-BDPD have been synthesised by the reaction of 1-chloroalkoxy(aryloxy)-BDPO with chlorine or sulphuryl chloride in the presence of acetic acid:[30]

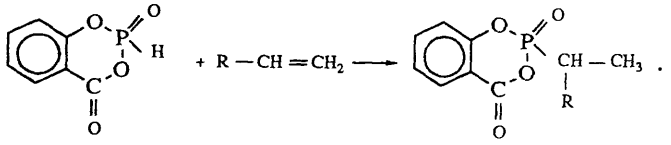


1-Alkoxy(aryloxy)BDPD have also been obtained by the counter cyclisation of the corresponding dichlorophosphates with salicylic acid:[70]



Dichlorides of phosphonic acids undergo similar cyclisation to give 1-alkyl(aryl)-BDPD, which can also be obtained by the Arbuzov[29,57,71] and Pudovik[43] reactions:



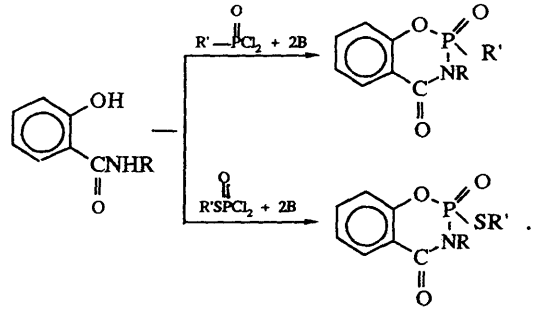


R = C_6H_5, C_2H_5, C_6H_5O, C_2H_5O

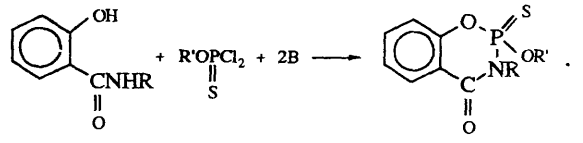
In the last case a rare non-catalysed electrophilic version of the reaction takes place.

b. **4,5-Benzo-2-aza-6-oxaphosphorine-1,3-diones and 4,5-benzo-2,6-diazaphosphorine-1,3-diones**

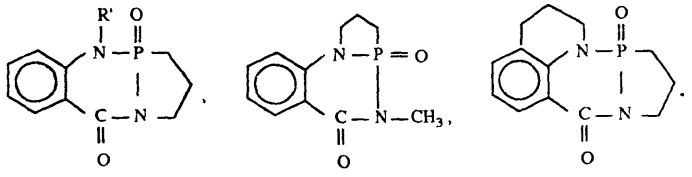
The reaction of the dichlorides of alkylphosphonic acids and alkyl dihydrogen thiophosphates with salicyliamides has been used to synthesise 1-alkyl(thioalkyl)-4,5-benzo-2-aza-6-oxaphosphorine-1,3-diones:[72–74]



The thione isomers were synthesised by the reaction of salicylamides with alkyl thiodichlorophosphates:[75]

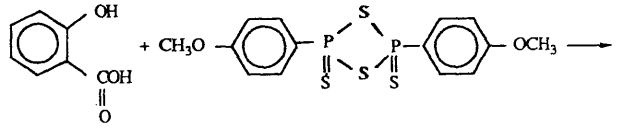


Unusual directions of the cyclisation were observed[76,77] for phosphorylated salicylamides containing a 3-chloropropyl substituent on the phosphorus or nitrogen atoms:

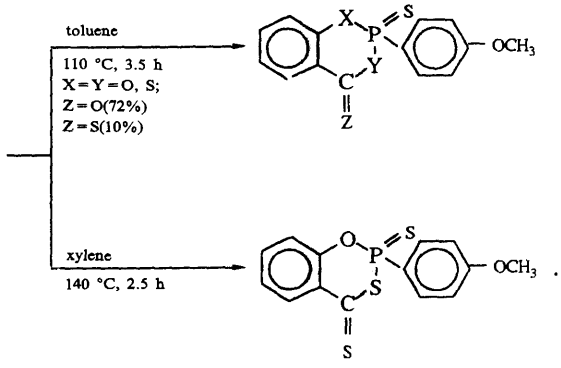


c. **1-Thio-4,5-benzo-2,6-X,Y-phosphorin-3-ones (thiones)**

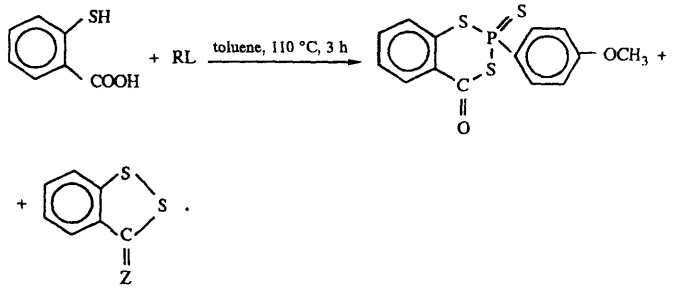
Thiophosphorus derivatives of salicylic acid have been obtained using Lawesson's reagent (RL).[78] The direction of the reaction of salicylic acid with Lawesson's reagent depends on the temperature and the solvent:



(RL)

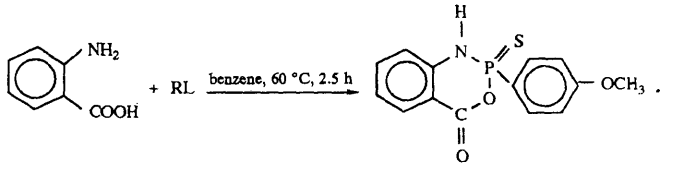


In the analogous reaction of α-mercaptobenzoic acid, phosphorylation and thionation of the original acid take place:



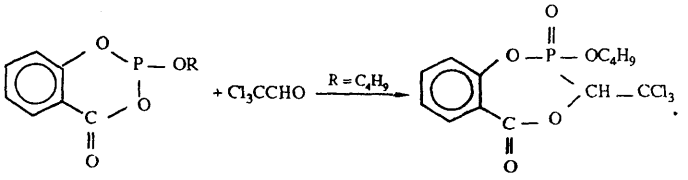
Z = O (15%); Z = S (52%) .

The reaction of anthranilic acid with Lawesson's reagent leads to only phosphorylation:

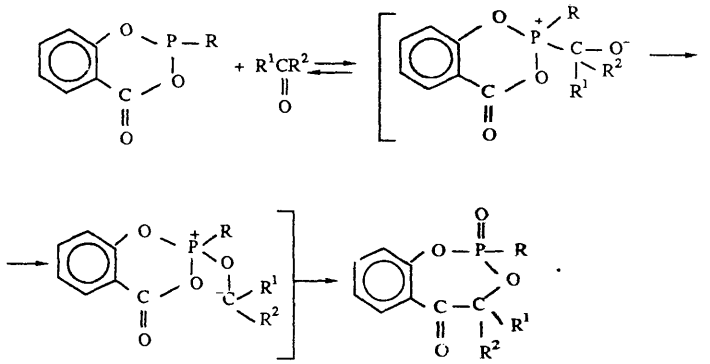


d. 5,6-Benzo-4-oxo-3,7-dioxa-1-phosphepines and 5,6-benzo-4-oxo-2,7-dioxa-1-phosphepines

An interesting feature of the reactivity of BDPO was revealed in the reactions with carbonyl compounds, in which expansion of the ring to give a phosphepine ring was observed:[79]



For R = CH_2CF_3 and $CH_2(CF_2)_2H$ the reactions were much slower, but had a high stereoselectivity, reching 95%.[80] When hexafluoroacetone and ethyl pyruvate were taken for the reaction, the expansion of the ring was accompanied by P–C → P–O–C rearrangement to give a new C–C bond:[81–83]



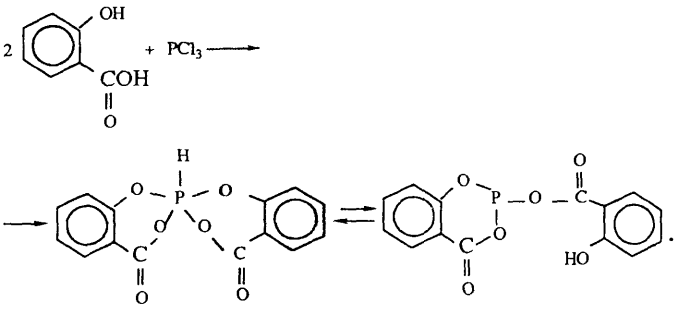
R = $N(C_2H_5)_2$, OC_2H_5, OCH_2CF_3, $OCH_2(CF_2)_2H$, $OCH_2P(O)(OC_2H_5)_2$;

$R^1, R^2 = CF_3$, CH_3, $COOC_2H_5$.

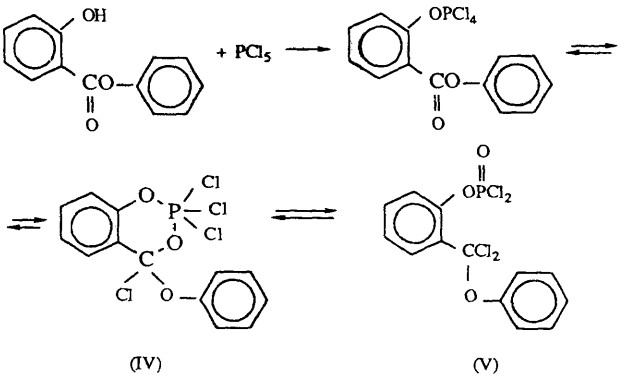
An analogous synthetic result was obtained with methyl trifluoropyruvate.[84]

3. Phosphorus derivatives of salicylic acid containing a five-coordinate phosphorus atom

The reaction of phosphorus trichloride with an excess of salicylic acid gives not 1-Cl-BDPO but a bicyclic phosphorane in equilibrium with its monocyclic form;[14,85] no ^{31}P NMR data have been published, however.



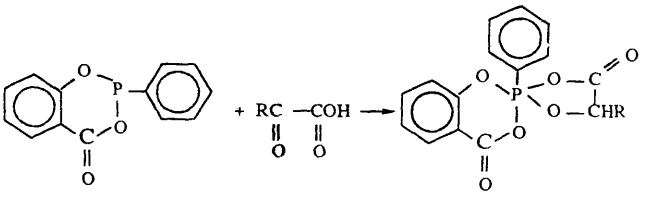
The reaction of phenyl salicylate with phosphorus pentachloride gives the monocyclic phosphorane (IV),[86] but its structure also has not been proved. The conversion of compound (V) into compound (IV) appears doubtful.



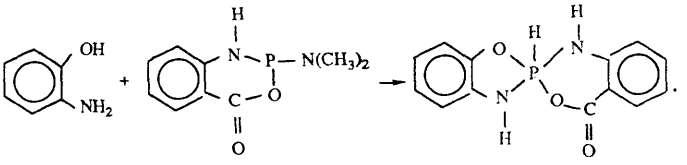
(IV) (V)

The formation of a phosphorane structure has also been assumed to take place in the careful hydrolysis of salicyl phosphate.[87] Phosphorane derivatives of salicylic acid are extremely reactive and have been little studied, and for the most part their structures have been only postulated.[60,69,87]

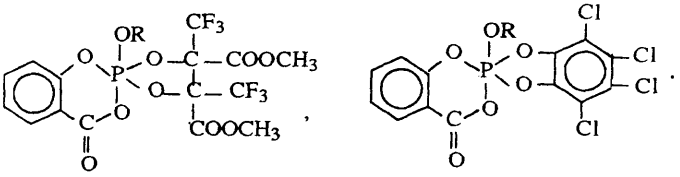
Spirodiacyloxyphosphoranes have been obtained by the reaction of 1-phenyl-BDPO with α-ketoacids, acrylic acid, and β-propiolactone, and their formation has been proved by ^{31}P NMR:[88]



A spirocyclic P–H-phosphorane based on anthranilic acid and *ortho*-aminophenol has been obtained, and its structure proved by ^{31}P NMR (δ_P 59 p.p.m., $^1J_{P-H}$ 860 Hz).[55]

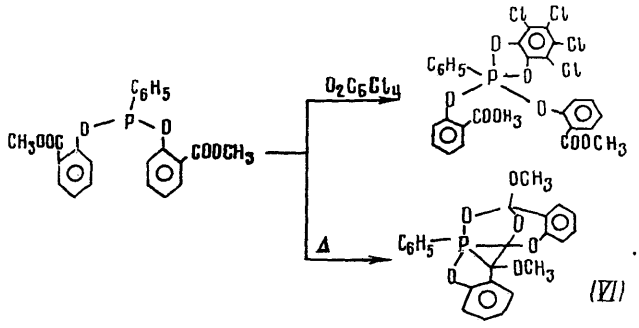


Spirobicyclic phosphoranes are also formed in the reactions with methyl trifluoropyruvate,[84] benzil, *ortho*-chloranil,[89] and phenyl azide:[83]



R = CH_2CF_3, $CH_2(CF_2)_2H$.

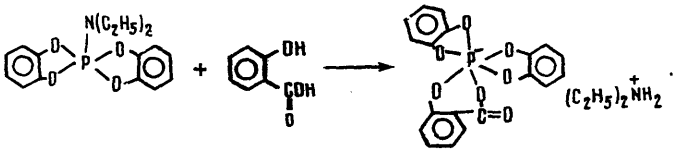
A compound of five-coordinate phosphorus has also been obtained by the reaction of an acyclic bis(2-methoxycarbonylphenyl) phosphonite with *ortho*-chloranil:[90]



(VI)

With heating, the phosphonite undergoes an unusual cyclisation to give the tricyclic phosphorane (VI).

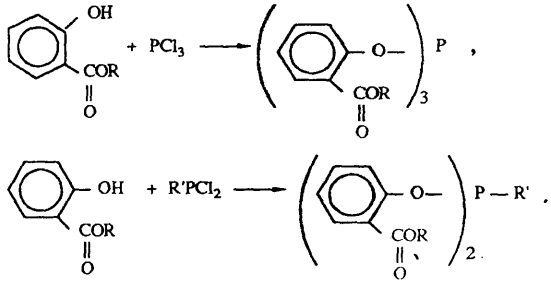
We detected the only example of a six-coordinate structure, containing a salicylate ring and obtained from diethylaminobis-(pyrocatecholato)phosphorane and salicylic acid:[91]



III. Acyclic phosphorus-containing derivatives of salicylic acid

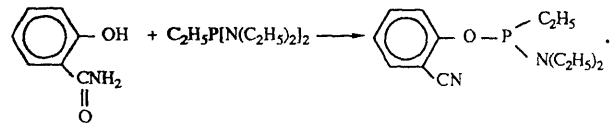
1. Acyclic phosphorus derivatives of salicylic acid containing a three-coordinate phosphorus atom

Esters of salicylic acid, like phenols, are phosphorylated at the hydroxyl group. Thus they react with phosphorus trichloride to give 2-alkoxycarbonylphenyl phosphites, and with dichlorophosphines to give the phosphonites:[92]

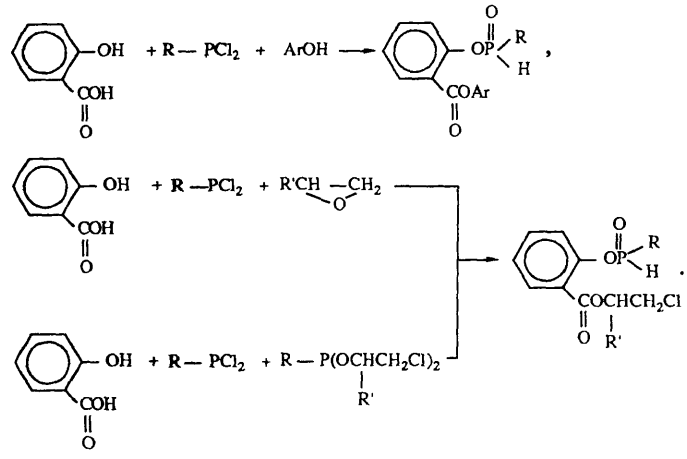


The data[92] on the synthesis of the phosphonites were later refuted[90] (see above), and it was possible to obtain these phosphonites only using bases.

Salicylamides react with phosphorus trichloride and dichlorophosphites to give mainly cyclic products,[51,52] and acyclic compounds were obtained only in the reaction with diamidophosphonites; in the opinion of the authors cited, this is due to the previous dehydration of the carbamoyl fragment of the salicylamide:[53]



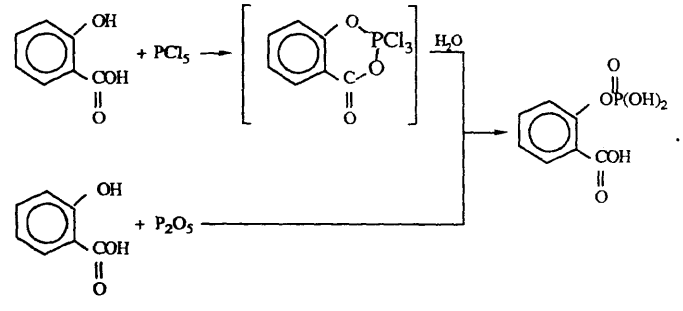
Acid esters of phosphonous acid have been synthesised by the reactions of the corresponding phosphorus chlorides with salicylic acid in the presence of phenols or alkylene oxides,[93,94] and also by an exchange reaction:[95]



2. Acyclic phosphorus derivatives of salicylic acid containing a four-coordinate phosphorus atom

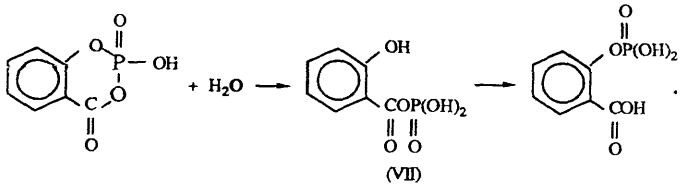
a. Phosphates and phosphonates

Phosphorylsalicylic acid is an analogue of acetylsalicylic acid, but it has not been used in medicine. Phosphorylsalicylic acid can be obtained by the direct phosphorylation of salicylic acid, and also from its cyclic phosphorus derivatives. The most convenient method of obtaining phosphorylsalicylic acid is based on the successive reactions of salicylic acid with phosphorus pentachloride and water.[59,60,61,87,96] Phosphorus pentoxide can also be used as phosphorylating agent:[97]



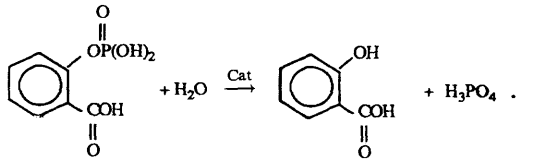
The hydrolysis of the cyclic salicylphosphoric acid to phosphoryl-salicylic acid has been said to take place via the formation of the mixed anhydride (VII),[65] but this appears doubtful, since anhydride

bonds are hydrolysed much more readily.[8] The hydrolysis of acyl phosphates, including salicyl phosphates, has been reviewed briefly.[98]



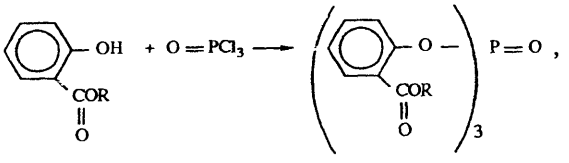
(VII)

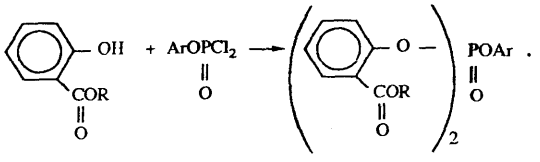
Phosphorylsalicylic acid readily undergoes further hydrolytic splitting to give phosphoric and salicylic acids.[99–104] Hydrolysis takes place more readily in a neutral medium, and is slower in strongly acidic and alkaline media.[105] The hydrolysis is catalysed by calcium ions, glyceryl phosphate, and bovine phosphatase; the hydrolysis of phosphorylsalicylic acid by bovine phosphatase is twice as rapid as that by glyceryl phosphate.[102–104]



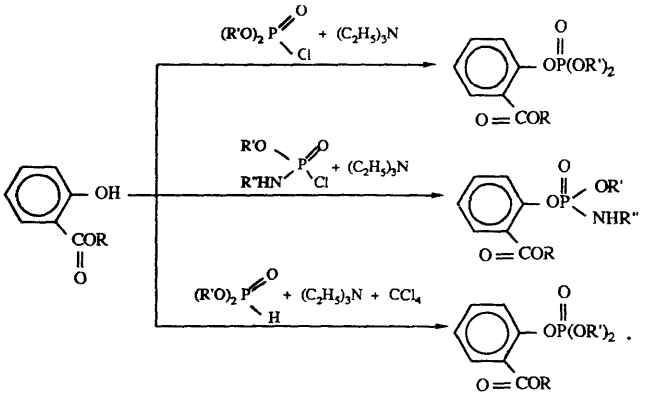
A large number of salicyl phosphates and phosphonates have been obtained in the search for biologically active substances and technically important compounds.

The reaction of salicylate esters with phosphorus oxide chloride or aryl chlorophosphates and chlorophosphonates[106,107] has been used to synthesise aromatic esters of salicylphosphoric and -phosphonic acids, proposed as polymer stabilisers:[106,107]

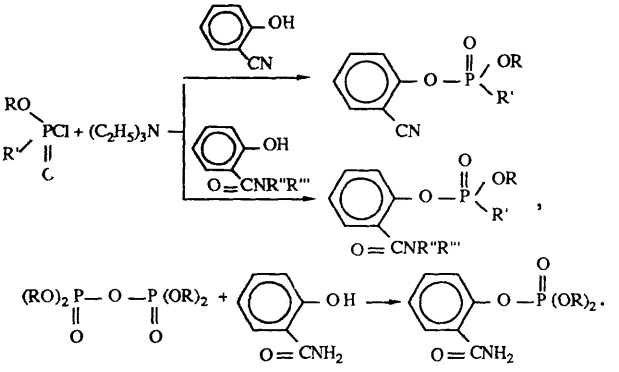




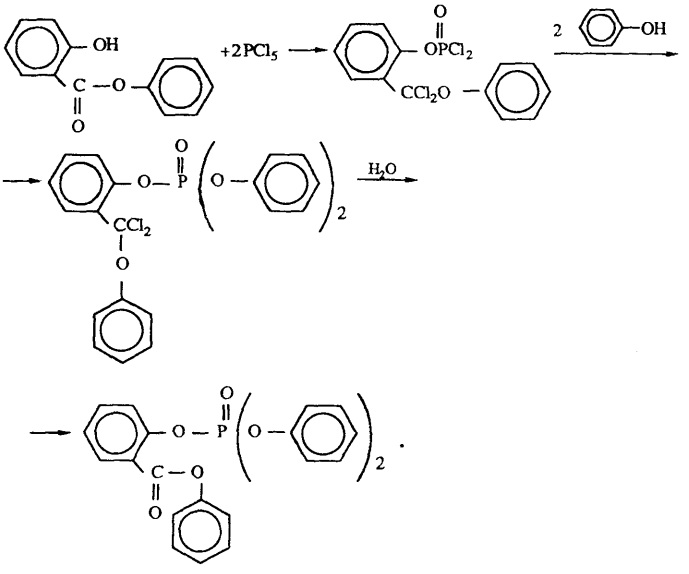
The phenolate of salicylic acid is weakly nucleophilic, and is phosphorylated by halides of phosphorus acids with difficulty.[108] Esters of salicylic acid in the presence of bases, however, are readily phosphorylated by dialkyl chlorophosphates[107–111] and amidochlorophosphates[109] to give 2-alkoxycarbonylphenyl esters of phosphorus acids, some of which are interesting insecticides and acaricides.[112] These compounds were obtained by the Todd–Atherton reaction:[113]



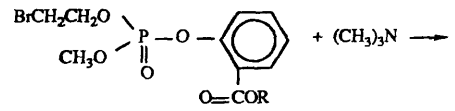
Substances with fungicidal activity have been synthesised by the reaction of salicylonitriles[114,115] and salicylamides[116] with dialkyl chlorophosphates. With salicylamides, pyrophosphates have also been used:[117]

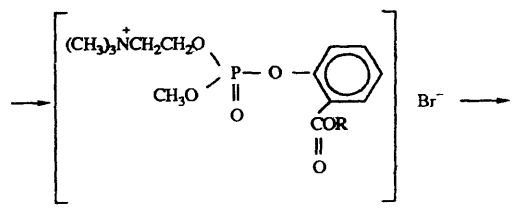


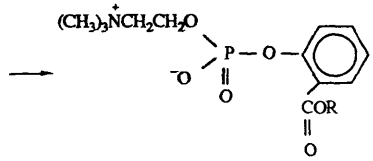
An extremely original method has been proposed for synthesising phosphorylsalicylic acid, based on the successive reactions of aryl esters of salicylic acid with phosphorus pentachloride, phenol, and water:[118]



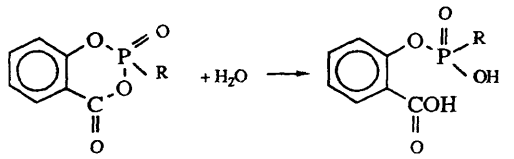
Aliphatic esters of salicylphosphoric acid can undergo dealkylation, and this has been used to synthesise salicyl phosphoxolines:[119]



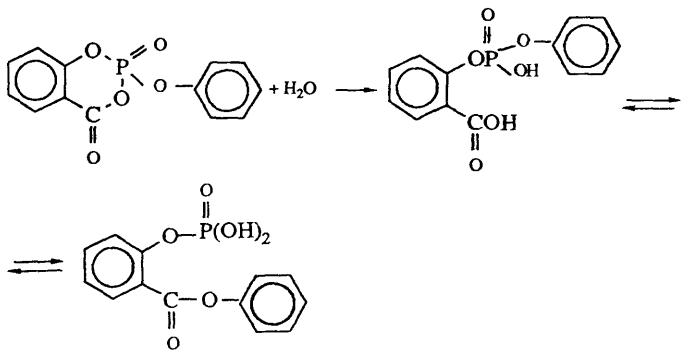




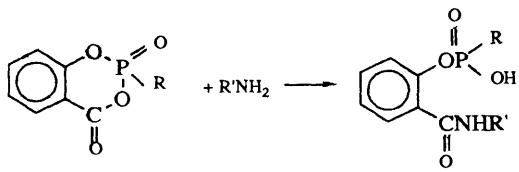
Acid esters of salicylphosphoric and -phosphonic acids are conveniently obtained by the hydrolysis of cyclic salicyl phosphates (BDPD):[68,120]



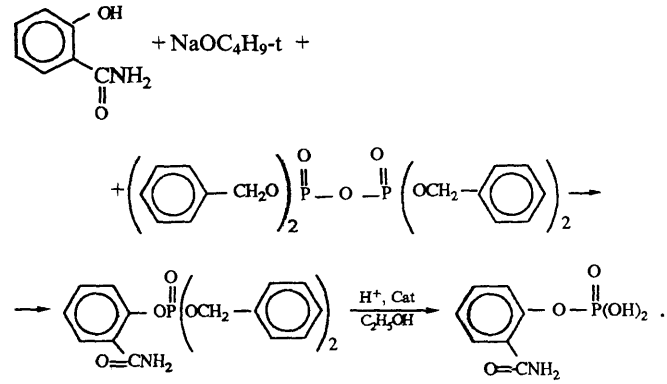
An interesting feature is that in aromatic acid esters of this type, migration of the aryloxy-group between the phosphoryl and the carboxyl groups has been observed:[65,121]



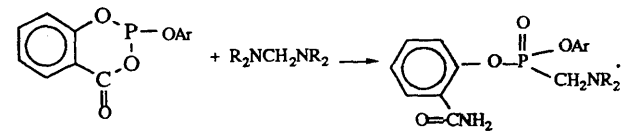
The reaction of 1-alkyl(aryl)-BDPD with amines gives 2-carbamoylphenyl esters of alkyl(aryl) hydrogen phosphates and alkyl(aryl) hydrogen phosphonates:[66,67,69,122]



Phosphorylation of salicylamide by tetrabenzyl pyrophosphate followed by hydrolysis of the dibenzyl 2-carbamoylphenyl phosphate obtained gives 2-carbamoylphenyl phosphate:[123]

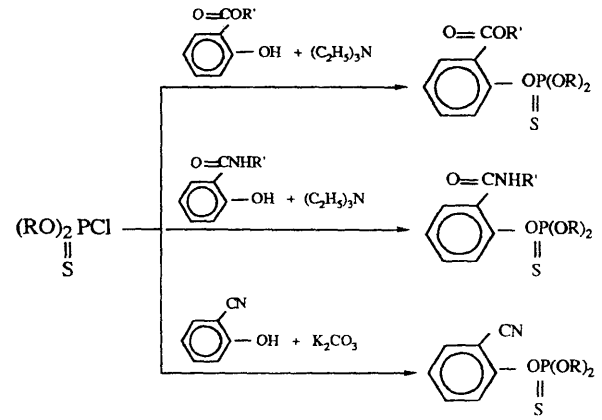


The reaction of 1-aryloxy-4,5-benzo-2,6-dioxaphosphorin-3-ones with bis(dialkylamino)methane, which gives O-aryl O-(2-carbamoyl)-phenyl aminomethylphosphonates, may be of interest:[124]



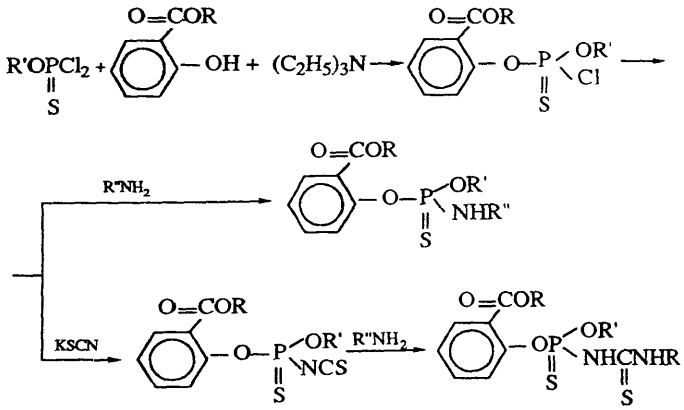
b. Derivatives of thiophosphorylsalicylic acid

The sulphur-containing phosphorus derivatives of salicylic acid include compounds with thione and thiol sulphur on the phosphorus atoms. Compounds containing sulphur in the salicylic acid fragment have not been described. The thione isomers have been synthesised mainly by the reactions of the chlorides of phosphorus thio-acids with derivatives of salicylic acid. Thus the reaction of dialkyl thiochlorophosphates with esters,[125] amides,[126,127] and nitriles[125,128–130] of salicylic acid in the presence of hydrogen chloride acceptors has been used to obtain the corresponding *ortho*-substituted phenyl esters of dialkyl hydrogen thiophosphates, which have insecticidal activity:[125–130]



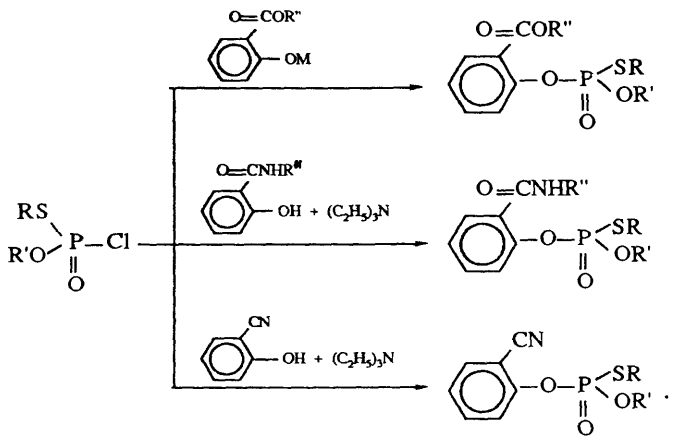
Esters,[131] amides,[126,132,133] and nitriles[134,135] of salicylic acid in the presence of hydrogen chloride acceptors also react with the ester chlorides of alkyl(aryl) hydrogen thiophosphonates to give the *ortho*-substituted phenyl esters of thiophosphonic acids, with insecticidal activity.[131–136]

An interesting feature is that in the reaction of alkyl thionodichlorophosphates with esters of salicylic acid, selective replacement of one chlorine atom by an alkoxycarbonylphenoxy-group is possible, and this has been used to synthesise amide esters[137–142] and thioureide esters[143] of thiophosphorylsalicylic acid:

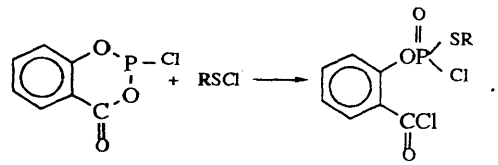


A fairly extensive group is formed by the thiol derivatives of phosphorylsalicylic acid, which are now being studied intensively in the search for pesticides with a low toxicity towards warm-blooded animals.[144–157]

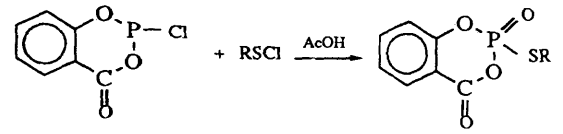
Esters,[144–151] amides,[147,152] and nitriles[153,154] of salicylic acid in the presence of hydrogen chloride acceptors react with thiolochlorophosphates to give thiol derivatives of phosphoryl-salicylic acid, many of which have been patented as insecticides and acaricides.[144–156]



An extremely interesting method of attaching a thiol group to a phosphorus atom is based on the splitting of the phosphorine ring in 1-Cl-BDPO by sulphenyl chloride to give the dichlorides of thiolo-phosphorylsalicylic acid,[158] which can be used as intermediates in the synthesis of biologically active substances:



The view that in the presence of acetic acid the reaction of 1-Cl-BDPO with sulphenyl chlorides takes place with preservation of the phosphorine ring[158] apparently requires confirmation.



* *
*

The analysis of published material shows that phosphorus-containing derivatives of salicylic acid represent an extensive group of cyclic and acyclic multidentate compounds, whose chemistry is now being intensively developed. The further development of the chemistry of acyclic phosphorus derivatives of salicylic acid is of undoubted interest in the search for new physiologically active substances.

Cyclic phosphorus derivatives of salicylic acid are highly reactive and of considerable interest as valuable synthons. The chemistry of some types of cyclic phosphorus derivative of salicylic acid has still been little studied, however. Thus there are very few data on salicyl-containing phosphoranes or proofs of their structure, although these compounds are of interest for chemical theory and as synthetic intermediates.

I. Introduction

Polycyclisation (polycyclocondensation) is a method of synthesis of numerous new generation polymers, mainly highly thermostable and heat resistant.[1] A characteristic feature of polycyclisation is that the reactions leading to the formation of macromolecules (both linear and network) are accompanied by the formation of small rings—intramolecular cyclisation. Such cyclisation can follow polymer formation or can be kinetically indistinguishable from the latter. One should not think that polycyclisation is yet another method of synthesis of polymers different from polymerisation and polycondensation, because these two processes constitute the basis of the formation of polymers. The essential feature of polycyclisation is that at the beginning of polymerisation or, more frequently, polycondensation one obtains macromolecular precursors (called in a number of instances, incorrectly in our view, pre-polymers), and then (frequently simultaneously) cyclic structures are produced:

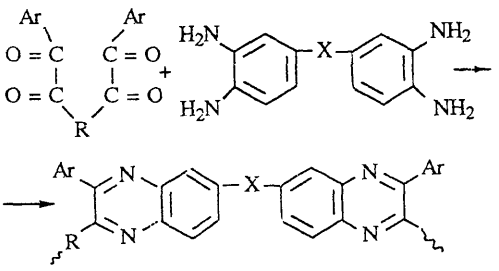
Monomer (s) ⟶	Intermediate polymer ⟶	Final polymer–
Oligomer (s)	Precursor	polyarylene,
Polymer (s)		linear or network
		polyheteroarylene

The final products, containing cyclic fragments which determine the physicochemical and operational properties of polymers, can be obtained also by the traditional procedure involving the initial synthesis of the corresponding monomers or reactive oligomers, incorporating such rings, and then the synthesis of polymers from the latter by the usual methods. This procedure is widely used for the creation of particular polyheteroarylenes, but it is important to note that these processes are no longer polycyclisation. The properties of the polymers formed can then differ markedly from those of the analogous polymers produced by polycyclisation.

Thus the simple interchange of the sequence of reaction stages ("components") alters the "sum", which is understood as the final polymer, its structure and properties. The present review is devoted to the analysis of the influence of various factors (the structure of the monomers and reaction conditions) on the formation during the polycyclisation process of polymers with a definite set of properties.

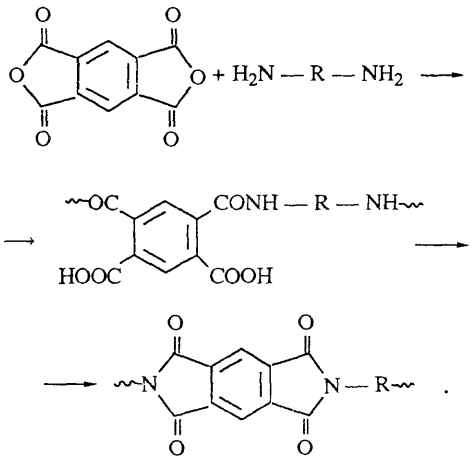
II. Polycyclocondensation of polyfunctional monomers

A series of new polymers of practical values has been obtained by polycyclisation. Here it was found essential to re-examine certain postulates of the chemistry of high-molecular-weight compounds, which have already become classical, in particular the question of the interrelation between the functionality of monomers and the structure (linear or three-dimensional) of the polymers formed.[2] If the monomers used in polycyclisation processes contain, apart from the functional group necessary for the propagation of the polymer chain, also other functional groups capable of forming cyclic fragments, linear polymers are formed also from polyfunctional polymers (trifunctional and tetrafunctional). One of the striking examples of this kind is the synthesis of polyquinoxalines from two tetrafunctional monomers: tetra-amines and tetraketones. In the presence of two amino groups in the *ortho*-positions and keto-groups in the α- positions, arranged in pairs, the six-membered quinoxaline ring is readily formed and linear high-molecular-weight polyquinoxalines are formed quantitatively under mild conditions:

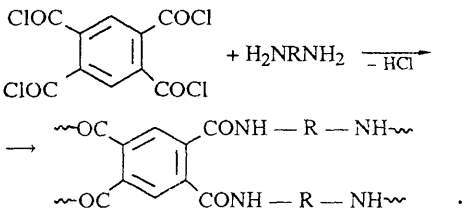


The formation of polyimides from diamines and tetracarboxylic acids is more complex and more ambiguous in this sense. When derivatives of the acids such as dianhydrides, formally regarded as bifunctional monomers, are used, linear high-molecular-weight

polyamidoacids are formed, but this entails the "appearance" of a further two functional groups—carboxy-groups, which participate in the formation of the imide ring in the next stage:



If one begins with derivatives of tetracarboxylic acids with two pairs of carboxy-groups in the *ortho*-positions, such as their acid tetrachlorides, then one obtained cross-linked network polymers instead of linear polymers:



(Naturally if the reaction centres in the polyfunctional monomers are located in positions unfavourable for ring closure, then the polymer formation reaction obeys the "classical" rules of polymer chemistry.)

Network polymers based on traditional bifunctional monomers can also be obtained by polycyclisation, for example by the polycyclotrimerisation of various monomers, which we shall consider below.

Polycyclisation processes proceed in one or several stages, frequently with formation of the corresponding intermediate polymer. As already mentioned, they are a variety of the polymerisation and polycondensation methods of synthesis of polymers and obey many of the rules governing the latter.

We shall consider certain features of linear polycyclisation occurring via the polycondensation mechanism. Thus, when the polycyclisation reactions consist of two stages, the mechanism and kinetics of the first stage hardly differ from those of the corresponding polycondensation reactions leading to the formation of linear polymers—frequently polyamides with other functional groups. Such processes can be reversible or irreversible, equilibrium or non-equilibrium, and are accompanied by the formation of low-molecular-weight products or there are no products. The methods used to carry out the reaction are also similar, although polycondensation in solution is so far usually employed for this purpose. The single stage polycyclisation reactions widely used at the present time, in which the propagation of the polymer chain and intramolecular cyclisation are kinetically indistinguishable, have much in common with the usual polycondensation processes.

The specific features of polycyclisation are manifested in the stage of the cyclisation reactions proper, which can be defined in a general form as reactions in polymer chains. Since many of the polymers formed under these conditions are infusible and insoluble, the processes are carried out on solid polymers. The main procedure involves heat treatment of the intermediate polymers over a wide temperature range. The effectiveness of the process is inferred from the degree of cyclisation of the final polymer. The "kinetic inhibition" with increase in the degree of cyclisation has been noted. It is due to the increase in the glass point of the polymer. A similar phenomenon has been observed in a number of studies in relation to the cyclisation of poly-*o*-carboxyamides, polyhydrazides, polyhydroxyamides, etc.[3–5]

At the same time, cyclisation frequently proceeds effectively in the vitreous state of the polymer and this permits the claim that the influence of the glass point of the polymer being cyclised (noted above), although significant, does not determine fully the kinetics of the cyclisation and the degree of completion of the process. The chemical structure of the cyclised group and the reactivity of the fragments which they contain are very important. The intramolecular cyclisation of polyamidoacids and their esters, which proceed effectively in the solid state, may serve as a clear example.[6–8] Although the esters are not degraded on conversion into imides, in contrast to the acids, the degree of polymerisation of the polyimides synthesised by the cyclisation of polyamidoacid esters is usually higher than that of the corresponding polyimides obtained by the thermal cyclisation of polyamidoacids. However, by virtue of the lower reactivity of the ester group compared with the carboxy-groups, the cyclisation of polyamidoacid esters is usually completed at higher temperatures in order to achieve complete conversion.

Table 1. The properties of polyimides obtained by thermal and chemical cyclisation.

Property	Ph/PM		E/PM		Ph/BP		Ph/Bphn	
	T	Ch	T	Ch	T	Ch	T	Ch
E, GPa	—	8.0	2.7	4.0	8.6	4.6	5.4	5.0
σ, MPa	—	162	112	139	321	129	154	143
ε, %	—	15	35	56	23	7	4	40
CTR, p.p.m. K^{-1}	—	5.5	31.9	22.3	31.9	8.2	18.1	25.3

Note. Ph = *p*-phenylenediamine; PM = pyromellitic dianhydrides; E = di(4-aminophenyl) ether; BP = dianhydride-3,3′,4,4′-tetracarboxylic acid; Bphn = dianhydride of benzophenone-3,3,′4,4′-tetracarboxylic acid; *E* = modulus of elasticity on extension; σ = tensile strength; ε = elongation at rupture; CTR = coefficient of thermal expansion; T = thermal cyclisation; Ch = chemical cyclisation.

Together with the degree of cyclisation, an important factor for the attainment of the optimum properties of the polymers formed on polycyclisation is their molecular weight.[9] In this sense, thermal cyclisation of the intermediate polymers, both in the solid state and,

especially, in solution, is in many instances complicated by various side reactions and leads to a decrease in molecular weight, which impairs the deformation-strength properties of the final polymeric materials. In order to eliminate or suppress the undesirable processes, the so called chemical methods, in which the aim is to carry out catalytic cyclisation under milder conditions, have been frequently used in recent years.[10–13] It is then possible to reduce to a minimum the degradative processes and to obtain polymers of a much higher quality. The improvement of the deformation-strength characteristics (Table 1) is in our view mainly a consequence of the higher molecular weight of the polymer.

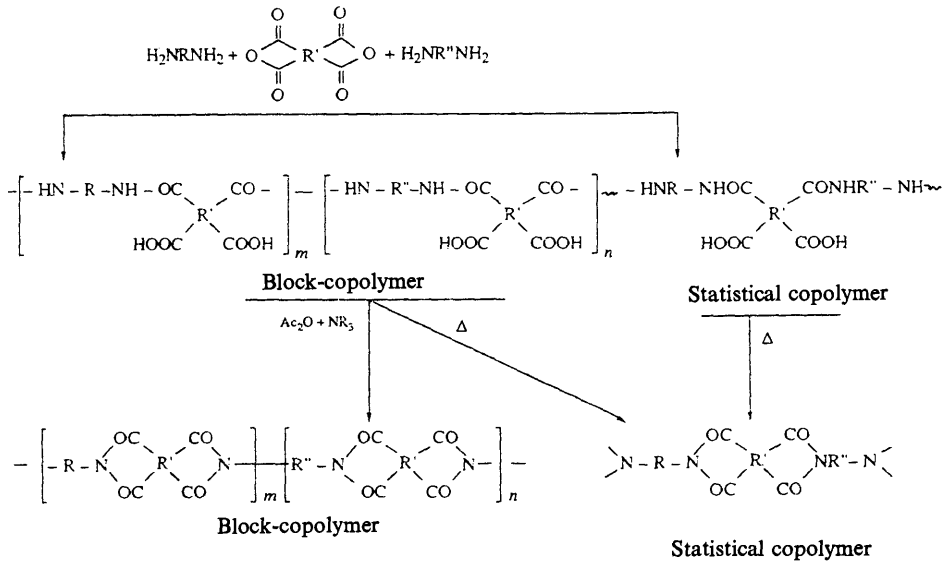
Thus in the synthesis of polymers by polycyclisation it is necessary to endeavour not only to achieve a quantitative degree of cyclisation, on which depend primarily the thermal stability, heat resistance, and other physicochemical properties of the polymers, but also it is essential to maintain a high molecular weight, which is important for the attainment of optimum deformation-strength properties of the corresponding polymeric materials. It is likewise necessary to bear in mind that the cyclisation conditions affect also the morphology of the polymers formed. Thus it has been noted that the polyimides obtained by thermal cyclisation are much less soluble in organic solvents than the corresponding polymers obtained in the presence of catalytic systems.[9] The densities of the former are lower than those of the latter.[13]

There is no doubt that the relations obtained for the cyclisation of polyamidoacids to polyimides are in general valid also for many other polymers formed as a result of the intramolecular cyclisation of intermediate polymers.

There is undoubted interest, from the standpoint of the recognition of the specific features of the polycyclisation and formation of polymers with the required set of properties, in studies directed towards the elucidation of the stereochemical and conformation characteristics of this process,[14,15] its statistics,[16] etc. However, it may be that the difficulties associated with the cyclisation processes on high-molecular-weight polymers noted above have in fact been responsible for the preferential development of single-stage polycyclisation processes, particularly in the preparation of thermoplastic and/or soluble polyheteroarylenes.

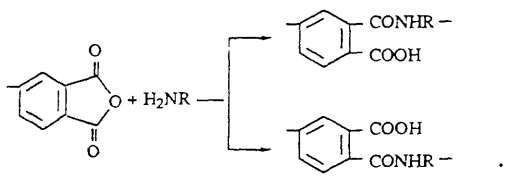
The polymers obtained by the single-state method, frequently in the presence of catalysts, are characterised by a high molecular weight and a virtually quantitative degree of cyclisation. Polycyclisation in various solvents† (high boiling organic solvents, polyphosphoric acid, etc.) have come to be most widely used. Depending on the solubility of the polymer formed, its synthesis proceeds throughout the process in solution[17,18] or is accompanied by the precipitation of the polymer at a specific stage (precipitation polyheterocyclisation), which does not prevent an increase in the molecular weight and/or degree of cyclisation of the polymer.[19–21]

Additional data concerning the specific features of polycyclisation have been obtained in the study of the formation of linear copolymers with a cyclochain structure.[22,23] In a multistage synthesis, the microstructure of such copolymers (statistical, block, or alternating) is laid down in the first stage of the reaction—the formation of the polymer chain—and is determined by factors, familiar from the polycondensation theory, namely the reversibility of the polycondensation, the ratio of the reactivities of the comonomers, the relation between the reactivities of the two reaction centres of the intermonomer, and the reaction conditions. However, by virtue of the characteristics of the second polycyclisation stage (see above), the microstructure of the copolymers can be retained or can break down. Thus in the thermal conversion into imides of copolyamidoacids with various microstructures, accompanied by their degradation, only statistical copolyimides are almost always formed. On the other hand, as a result of the catalytic cyclisation of copolyamidoacids, where there is no degradation of the polymers, the microstructures of the copolymers formed do not differ from those of the initial copolymers:



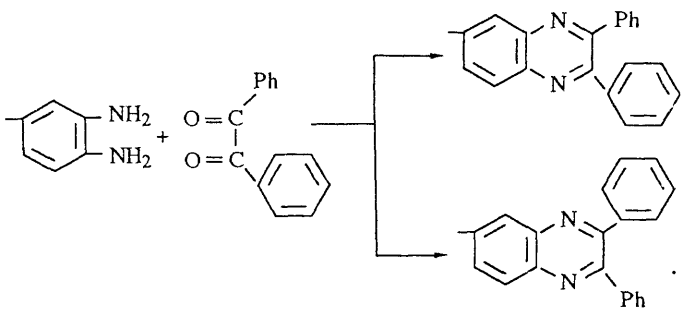
† There has been a recent growth of interest also in the synthesis of polyheteroarylenes in the melt and in the solid phase.

Proceeding now to the analysis of the relation between the physical and chemical structures and properties of polymers obtained by polycyclisation, we may note that the general laws of polymer chemistry are naturally valid for them too. The most important factor is the nature of the monomers and hence the structure of the polymers formed. The influence of various types of isomerism in polyheteroarylenes is unusual. Thus, in view of the multiplicity of the reaction centres in the monomers used in polycyclisation and a not unduly striking difference between their reactivities, the intermediate and final polymers formed contain various isomers which affect the physical structure and properties of the polymers. Striking examples are provided by the syntheses of polyamidoacids from the dianhydrides and diamines[24–26] and of polyphenylquinoxalines from bis-α-diketones and tetramines.[27–29] In the former case, the possibility of nucleophilic attack by the amine on both carbonyl carbon atoms of the anhydride ring is responsible for the formation of two isomeric fragments in the chains of the polyamidoacids:

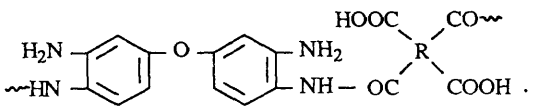


It is striking that it is not possible to obtain only one isomer by introducing different electron-donating and electron-accepting substituents even when there is a significant difference between the electrophilic properties of the above carbon atoms.[25] The heterounit structure arising in the polyamidoacids as a result of such isomerism affects their stability towards degradation.[25]

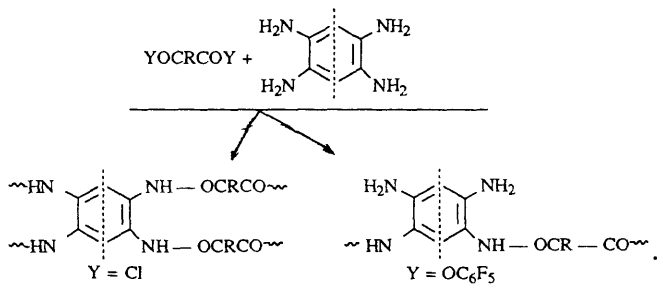
Similar factors are responsible for the appearance of isomeric fragments in the chains of polyphenylquinoxalines and hence for their amorphous structure and inadequate heat resistance, which may affect the strength parameters of the materials formed from them:



The nearly statistical distribution of different isomers in polyphenylquinoxalines as well as in many polyamidoacids is probably caused by the similar electrophilic properties of the corresponding carbonyl carbon atoms. At the same time even comparatively small differences between the basicities of the *p*- and *m*-amino-groups in tetramines (differing by approximately one order of magnitude) are found to be sufficient to ensure their selective acylation by carboxylic acid anhydrides with formation of virtually only the isomer having amide groups in the *para*-position relative to the bridging electron-donating group;[30,31]

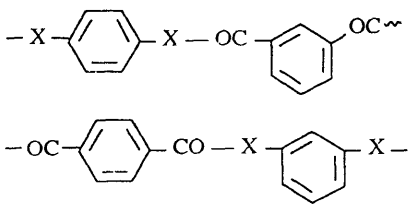


This example is also of interest because, by varying the reactivity of the acylating agent (the nature of its leaving group), it is possible to obtain both linear and network polymers. Thus, when carboxylic acid chlorides are used (as more reactive derivatives), the reaction involves all four amino-groups even under mild conditions and leads to gel formation. On the other hand, linear high-molecular weight polymers are formed on polycondensation of tetramines and activated esters (nitrophenyl, pentafluorophenyl) of dicarboxylic acids:[32]



A similar picture is observed also in acylation by tetracarboxylic acid dianhydrides. Depending on the reactivity of the latter, the mutual influence of the anhydride groups, and the nature of the bridging groups, both linear polyaminoamidoacids (reactions with relatively unreactive dianhydrides having bridging electron-donating groups—see above) and three-dimensional polymers (when the reactive pyromellitic dianhydride is used) are formed.

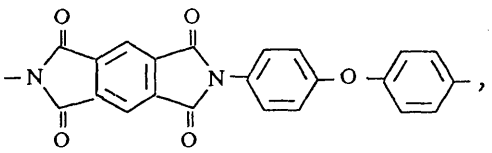
Another type of isomerism, which is manifested in an extremely unusual manner in polyheteroarylenes, is caused by the position of the bridging groups in the polymers relative to the heterocycle. In principle, this question is not new as regards heterochain polymers,[33,34] although in our view it has not been adequately considered. Thus the polyamide formed from *p*-phenylenediamine and isophthalic acid and correspondingly the polyarylate derived from hydroquinone and isophthalic acid are more crystalline than the isomeric polyamide derived from *m*-phenylenediamine and terephthalic acid and the isomeric resorcincol polyterephthalate:

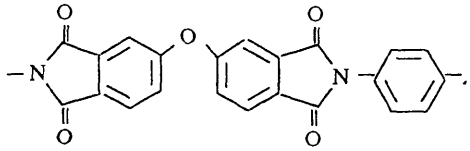


(a) X = NH
(b) X = O .

On the other hand, in the case of polyheteroarylenes the difference between the structures and properties of a series of isomeric polymers, containing bridging groups in the residues of a

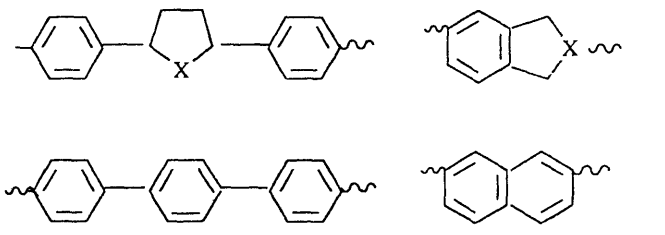
particular monomer, is in many respects associated with the different capacities for condensation of the heterocycle with fragments other than benzene rings.[35] Thus the polypyromellitimide derived from di(4-aminophenyl) ether and the polyimide obtained from *p*-phenylenediamine and di(3,4-dicarboxylphenyl) ether contain the same number of various fragments, but in the former there is a condensed system comprising three rings, while in the latter the polymer containing the phthalimide rings is a system comprising only two condensed rings:





As a result, the first polymer is significantly superior to the latter as regards heat resistance (by 50–70 °C),

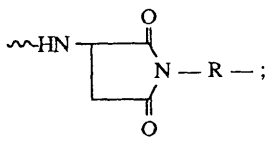
It is noteworthy that the degree of condensation of the heterocycle and other fragments of the macromolecule is a most important factor, which determines many properties of polyheteroarylenes. The latter can be arbitrarily divided into two types.[36] In the first, the heterocycles are joined by single bonds to other groups and they can be regarded as analogues of polyphenylenes. In the second, the heterocycles are condensed with other elements of the polymer chain and polynaphthalene may be regarded as their analogue. The limiting case of polymers of the second type is ladder polymers:



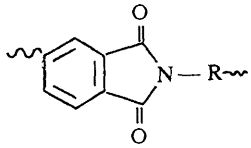
X = heteroatom

(I) (II)

Polymers of the first type (I) include poly-1,3,4-oxadiazoles, polytriazines, and polythiadiazoles, while those of the second type (II) include aromatic polyimides, polybenzimidazoles, polyphenylquinoxalines, and polybenzoxales. One may quote examples where the heterocycle enters into the composition of both types of polymers. Thus poly(asparagine imides) (A) contain isolated imide rings, in contrast to the aromatic polyimides (B), the characteristic feature of which is systems comprising two, three, and more condensed imide rings, benzene rings, and other heterocycles:



A



B

Naturally, by varying the degree of condensation of the benzene rings and the heterocycles, it is possible to vary different properties of the polymers and primarily their heat resistance.

An important factor which determines the creation of linear cyclochain polymers with the required set of properties is the size of the heterocycle in such polymers. Polyheteroarylenes with five-membered heterocycles are commonest. They include polybenzimidazoles, polybenzoxazoles, polybenzothiazoles, poly-1,3,4-oxadiazoles, and the majority of polyimides. However, representatives containing six-membered imide rings, i.e.

whose closure proceeds much more readily than that of the analogous phthalimide rings, are known for the polyimides. A specific feature of the formation of polyimides with six-membered rings is in fact that the polycyclisation cannot be arrested at the stage of the intermediate polymer — the polyamidoacid. A striking example of polymers with six-membered rings is polyphenylquinoxalines. In this case too polycyclisation proceeds in such a way that the polymer chain propagation and the closure of the six-membered quinoxaline ring occur almost simultaneously. The greater ease of closure of the six-membered ring compared with the five-membered ring (exceptions are naturally known) predetermines a series of advantages in properties, particularly the increased chemical stability. The high degree of cyclisation should have a positive effect also on the thermal stability of the polymers.

Hitherto, very many polymers have been obtained by polycrystalline reactions, polyimides being commonest among them. It is noteworthy that this is apparently due to the successful combination of thermal and mechanical properties in such polymers, the availability of the monomers, and the comparative simplicity of the synthesis. As a result of this, a vigorous development of imide-containing polymers, which already belong to the class of mass-scale polymers, can now be observed. New types of monomers for polyimides are being created and new methods of their synthesis (including catalytic methods) are being developed.

III. Polycyclotrimerisation and other methods of synthesis of polyheteroarylenes

A second important variety of polycyclisation involves the formation of linear and network poly(hetero)arylenes by the polymerisation method. This procedure has in our view a series of characteristic features, which distinguish it from both the traditional

methods of synthesis of polymers and from polycondensation. In this case polycyclic polymers are synthesised in several ways.

The first involves the polymerisation (copolymerisation) of different bi- and poly-functional compounds (monomers, oligomers, and polymers) involving the opening of multiple homo- and hetero-bonds, leading to the formation of carbocycles and heterocycles.

The second involves polycyclisation, the elementary step of which is the interaction of small (as a rule three-membered rings) with functional groups and multiple bonds, which results in the formation of new (usually five-membered) stable cyclic structures.

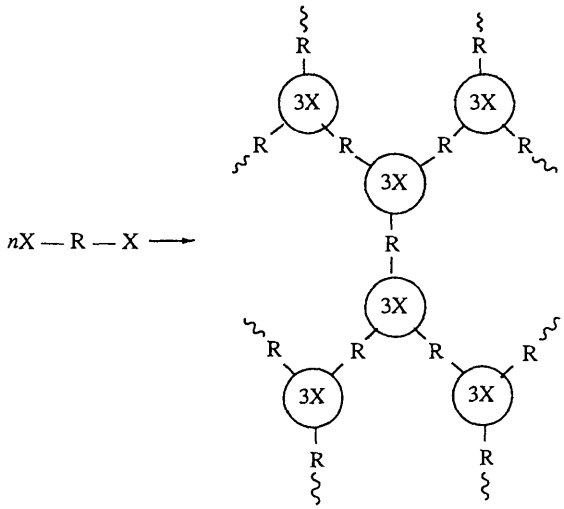
Examples of the procedures of the second type of polymerisation polycyclisation is provided by the copolymerisation of two different unsaturated rings with formation of a new cyclic structure (reactions of the Diels–Alder type), as well as the opening of unstable four-membered rings (for example, uretdione rings), with formation of stable six-membered fragments. The polycyclisation procedures listed above do not apparently exhaust the entire wide variety of the possible different versions of these reactions.

One of the most important differences between the polymerisation of different compounds with the opening of multiple bonds or strained rings and polycondensation consists in the absence of segregation of any products during the reaction. This factor determines the principal features of this polycyclisation method and makes it possible to solve the difficult problem of the processing of polycyclic polymers, which exhibit as a rule an enhanced heat resistance and thermal stability. Here not only linear cyclochain polymers but also network heat resistance structures can be made into articles directly from liquid or low-melting monomers and oligomers.

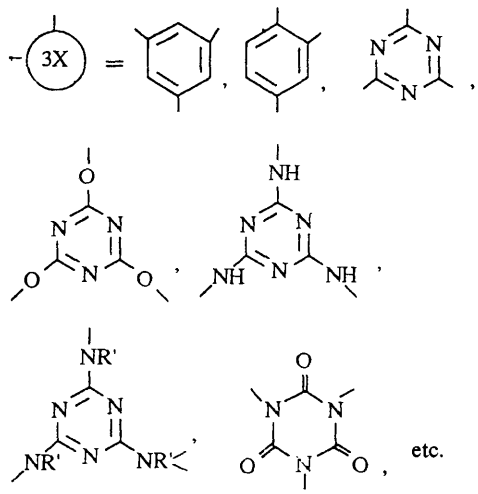
The cyclic fragments formed as a result of polycyclisation via the polymerisation mechanism may be four-, five-, and six-membered carbocycles and heterocycles, for example, polymers containing in the chain rings such as those of uretdione,[57] imino-derivatives of uretdiones,[38] 1,2,4-oxodiazole,[39] iminohydantoin,[40] oxazoline,[41], isoxazoline,[42] oxazolidinione,[43] iminooxazolidinone,[44] 1,3,5- and 1,3,4-phenylenes,[45] pyridine,[46] 2,4,6-triazine,[47] cyanurate,[48] isocyanurate,[47] etc.

Our aim was not to consider in a short review the numerous studies in this field and only certain most characteristic examples of such reactions will be surveyed with emphasis of their specific features. Polycyclotrimerisation is one of the reactions investigated in greatest detail.[47]

The polycyclotrimerisation of monomers (or oligomers and polymers) containing two and more functional groups with multiple bonds between homo- and hetero-atoms should lead to the formation of hypothetical network polymer structures with the same internodal fragments and stable six-membered aromatic carbocycles and heterocycles as network nodes:



where X = $-C\equiv CH$, $-C\equiv N$, $-O-C\equiv N$, $-NH-C\equiv N$, $-NH-C\equiv N$, $-N\equiv C=O$, $-N=C=N-$, etc,

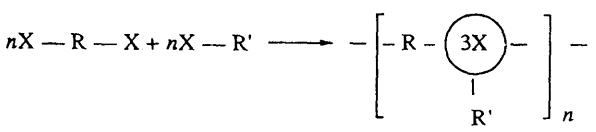


In the presence of thermostable aromatic or organoelement groups as internodal fragments in such polymers, one may expect a high thermal stability of these blends. In the case of small intermodal fragments (M_c), the thermal stability of such dense network structures should also be high.

It is noteworthy that the advantages of the polycyclotrimerisation reaction can be utilised provided that a number of conditions are fulfilled. For example, the reaction must take place stereoselectively with virtually complete conversion of the functional groups, since only in this case does the polymer structure remain undisturbed by the fragments formed as a result of side reactions of some kind or by residual non-cyclised functional groups.

There are literature data[47] on polymers obtained by the polycyclotrimerisation of compounds such as ethynyl derivatives (−R−C≡CH), nitriles (−R−C≡N), cyanates (−R−O−C≡N), isocyanates (−R−N=C=O), unsubstituted cyanamides (−R−NH−C≡N), *N*-substituted cyanamides (−R−NR′−C≡N), and carbodiimides (−R−N=C=N−R−). Other types of compounds containing multiple bonds between different atoms may be achieved in the future.

Polycyclotrimerisation is one of the examples confirming the necessity for the revision of certain classical postulates in the chemistry of high-molecular-weight compounds. Thus, whereas bifunctional monomers, for example diisocyanates form linear polyureas or polyurethanes on reaction with bifunctional amines or diols, the polycyclotrimerisation of the same diisocyanates affords dense network polymers with a regular chemical structure, illustrated in the polycyclotrimerisation scheme presented above. In "classical" polycondensation, the introduction of a monofunctional monomer leads to chain termination and the restriction (regulation) of the molecular weight of the polymer.[2] On the other hand, in polycyclotrimerisation the introduction of a monofunctional monomer can yield a linear polymer in accordance with the following scheme:



The similarity of a series of fundamental features of gel formation in the polycyclotrimerisation of dicyanates and diisocyanates, i.e. polymers of different classes, as well as the study of the molecular weight characteristics in the course of the reaction up to the gel point and of the sol fraction beyond the gel point made it possible to formulate general ideas concerning the formation of the topological gel structure in this method of synthesis of network polymers.[49−52] In a number of instances, the experimental data are close to the theoretical postulates[53] developed for the gel formation process in polycyclotrimerisation reactions. The existing differences can be explained by the failure of the theory to take into account the macrocyclisation associated with the appreciable branching of the macromolecules.[49,53]

The traditional methods of synthesis of network polymers from monomers, oligomers, or polyfunctional polymers are complicated by factors such as the differences between the reactivities of the functional groups which do not lead to branching, the proportions of the initial oligomers and polymers having different molecular weights and different types of functional groups, which are difficult to regulate, and many others. All this hinders the synthesis of network polymers with a chemically regular structure.

In the synthesis of polymers by the polycyclotrimerisation reaction, it is possible to overcome most of these difficulties and to obtain regularly cross-linked (at the molecular level) polymers. In this method of synthesis, the reaction of each functional group is accompanied by the branching of the macromolecule with the exception of the "losses" of the functional groups in macrocyclisation.

Detailed study of the gel formation process and of the molecular weight characteristics has shown[49−53] that the macrocyclisation reaction may be regulated by varying the conditions in the synthesis of the polymers. This determines in its turn the change of their topological structure. The possibility of influencing the topology (i.e. a higher level of structural organisation than the molecular level) of the networks leads to greater prospects for the directed regulation of the physical properties of network polymers.

An interesting feature discovered for a number of polymers obtained by polycyclotrimerisation is their capacity for crystallisation.[54−56] In the known[57−61] crystalline network polymers, the internodal segments are flexible aliphatic and siloxane fragments with M_c not below 2100.[57−59] The crystal structures of the cross-linked polymers is similar to that of the initial crystalline oligomers and is in essence determined by the latter.

Rigid-chain dense network polymers with a crystal structure completely different from that of the initial crystalline monomer, have been obtained in the case of polycyanurates. In other words, the crystal structure of the network polymer is formed in the course of its synthesis. In the study of the polycyanurate based on 1,4-dicyanatobenzene (M_c = 108), it was shown by X-ray diffraction that, by regulating the conditions in the synthesis, it is possible to obtain polymers with the same chemical structure but a different physical structure.[54]

A tendency towards crystallisation has been observed also in other polycyanurates based on aromatic dicyanates[47,55,56] and also in certain dense network polymers with a different chemical structure, obtained by the cyclotrimerisation of monomers with C−N multiple bonds.[47] By an appropriate selection of the initial monomers and the cyclisation conditions, similar structures can apparently be obtained in a highly crystalline state.

The capacity for crystallisation of network polyheteroarylenes obtained by polymerisation polycyclisation as well as many other unusual properties of these polymers are a consequence of their regular structure achieved as a result of the highly selective cyclisation of the functional groups of the initial monomers and its virtually quantitative completion.

When a series of polycyanurates based on dinuclear aromatic dicyanates differing in the nature of the bridging group between the phenyl groups are studied systematically, the most striking feature is that the polymers of dicyanates having a flexible bridging group and small substituents at the central carbon atom have anomalously high specific impact strengths (up to 30 kJ m^{-1}), in contrast to all the known dense network aromatic polymers. Furthermore, block specimens of aromatic and many organoelement polycyanurates have a high bending strength, a Brinell hardness of 100−170 MPa, a tensile strength of 100 MPa, a modulus of elasticity in the range 3000−5000 MPa, and a relative elongation on rupture of 3−6%. These polymers retain effective physicomechanical properties also at elevated temperatures.[47,48,63]

In order to elucidate the causes of the unusual mechanical properties of polycyanurates, a study was made of the formation of the super molecular structures of these polymers at different stages of their synthesis, starting with the initial monomer 2,2-bis-(4-cyanatophenyl)propane and ending with a regular network system and a virtually quantitative conversion of the functional groups.[64] It was found that, in the course of polycyclotrimerisation, the formation of a material with a globular structure is observed initially against the background of the characteristic cryptocrystalline structure of the monomer. The size of the globules did not remain constant in the course of the polymerisation and gradually diminished—from ~500 to 100−200 Å. The aggregation of globules, leading to fibrille-like formations in the final stage of the polymerisation (for a conversion of the N≡C−O group of ~98%) was subsequently observed under these conditions.

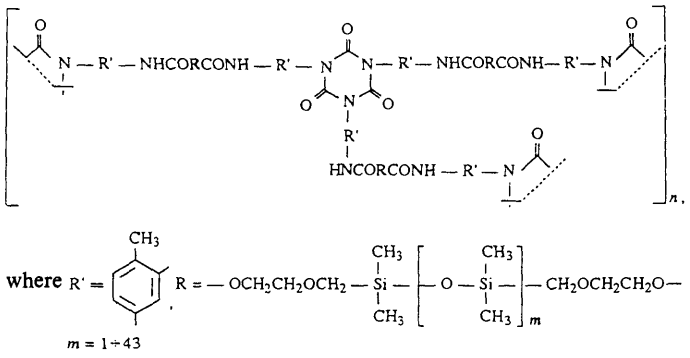
Simultaneously with the formation of the supermolecular structure of polycyanurates, the relaxation properties of the solid networks formed in different stages of the conversion of the NCO groups of the initial monomer were investigated. With increase in the degree of conversion, the relaxation curves initially shift towards higher stresses and then, beyond a ~90% conversion of the monomer, they begin to be displaced to the region of lower stresses.

The parameters of the Kohlrausch equation for different stages of the process were calculated. The data obtained show that, as the polycyclotrimerisation of aryl dicyanates advances and with the consequent increase in the regularity of the network formed, the nature of the supermolecular structure of the polymer changes, which leads in its turn to a steady variation of the mechanical properties of the network system—a decrease in brittleness and an increase in elasticity.[64] It may be that, if it becomes possible to obtain a regular defect-free network also in the case of the usual thermoreactive systems, then it will be possible to obtain also polymeric materials with increased resistance to impact influences and increased elasticity.

By introducing various organic and organoelement groups (containing B, F, and Si) into the internodal fragment in polycyanates, highly thermostable rubbers with T_g = −120 °C and highly heat-resistant systems with T_g = ~400 °C were synthesised. Carbaborane-containing polycyanates retain a large amount (~100%) of coke residues up to 900–1000 °C.[47,48,63]

Heat-resistant network polymers based on dicyanates can be designed not only by altering the structure of the initial dicyanate but also by their copolymerisation with diisocyanates, bismaleimides, oligoepoxides, and other compounds.[47,63,65–67]

The synthesis of telechelic oligomers with flexible (aliphatic and siloxane) fragments between the isocyanate functional groups has been achieved. The polycyclotrimerisation of these oligmers yielded transparent network polymers with different specifically regulated lengths between the network nodes:[68]



The combination of rigid network nodes with an aromatic framework and of flexible siloxane chains of different lengths leads to the observation of two transition temperatures. The devitrification of the siloxane and subsequently of the rigid isocyanurate fragments is reflected in the temperature variation of the tangent of the mechanism losses angle (Fig. 1).

A phase separation takes place in this system, which has been confirmed by electron microscopy and X-ray photoelectron spectroscopy data. These results show that the contents of silicon and nitrogen on the surface and within the bulk of the glass specimen differ appreciably. This shows that the siloxane phase is forced out onto the surface of the glass.[68]

Whereas the usual organic glasses have a modulus of elasticity of the order of 10^3 MPa, in this instance monomers were obtained with a wide set of moduli of elasticity, ranging from 3×10^3 to 3 MPa depending on the value of n. On the other hand, these polymers behave similarly to vitreous (elastic) polymers. This factor opens the way to new possibilities in the photoeleasticity method and in other branches of engineering.[68,69]

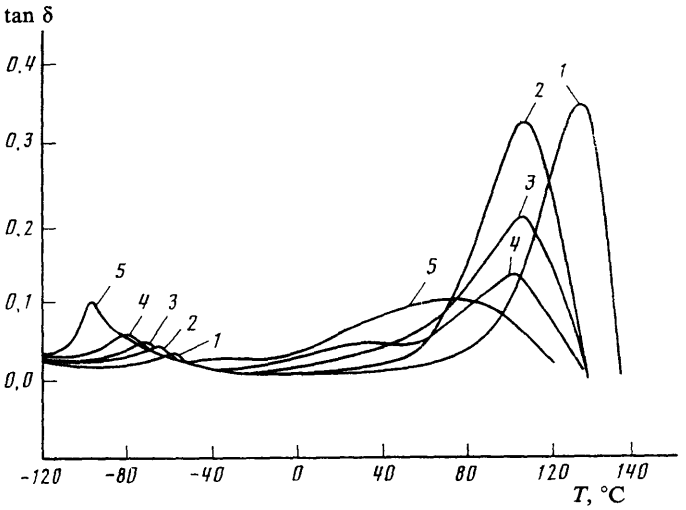


Figure 1. Temperature variation of tan δ for block specimens of polyisocyanurates with different lengths of the internodal organosilicon fragments m: *1*, 1.2; *2*, 2.1; *3*, 3.2; *4*, 5.4; *5*, 9.2.

The synthesis of linear polymers and oligomers containing in the chain regularly alternating functional groups capable of entering into the polycyclisation reaction, namely ... −X−R−X−R−X−R−..., where X is the functional group and R are aromatic, aliphatic, or organoelement substituents, constitutes a promising way of designing new polymeric structures with interesting properties.

Polycarbodiimides are representatives of polymers of this type.[47,70,71] A series of infusible (T_{soft} = 50–150 °C) oligocarbodiimides, based on bis(4-isocyanatophenyl)methane and 2,4-tolylene

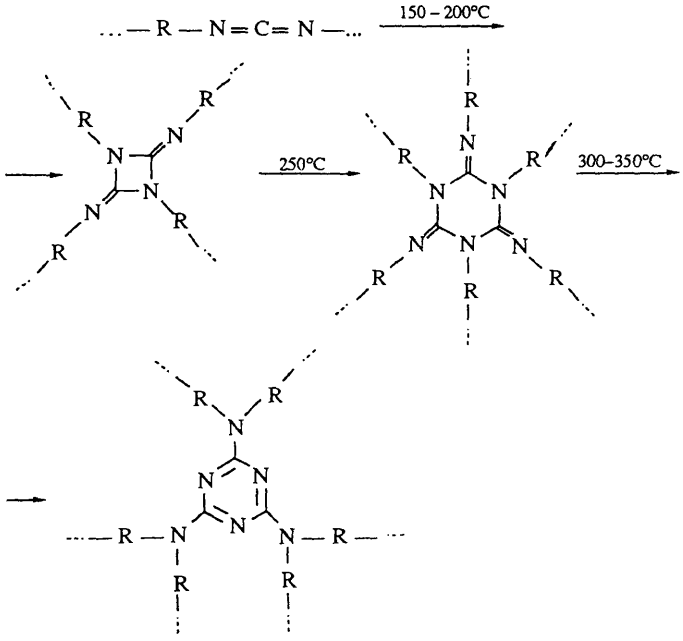
diisocyanate and soluble in organic solvents, have been synthesised:[47,70,71]

$$n\mathrm{O{=}C{=}N{-}R{-}N{=}C{=}O + 2R'{-}N{=}C{=}O \xrightarrow{\text{Cat.}}$$

$$\rightarrow R'{-}N{=}C{=}N{-}[{-}R{-}N{=}C{=}N{-}]_n{-}R' + (n+1)CO_2,$$

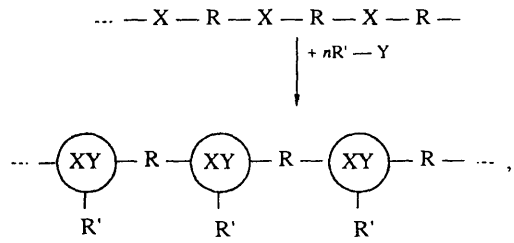
where R = 
R' = 
Cat. = 
R''' = — CH_3, Ph.

Their polymerisation at elevated temperatures yields polycyclic network structures with temperatures for the onset of decomposition of 420–450 °C and temperatures for the onset of deformation of 350–450 °C:[47,72–75]



Polycarbodiimides (polyfunctional linear polymers), used as polymer matrices for high-strength heat-resistant composite materials, combine the advantages of thermoplastics and reactoplastics.[76] Oligocarbodiimides are multipurpose thermoreactive oligomers capable of being processed into various heat resistant and thermostable composite materials for use in modern branches of engineering (Table 2).[76]

Oligomers and polymers containing functional groups of the type of carbodiimide groups alternating in the chain are capable not only of homopolymerising with formation of network polyheteroarylenes but also of entering into copolymerisation reactions with various compounds to form linear cyclochain polymers in accordance with the scheme



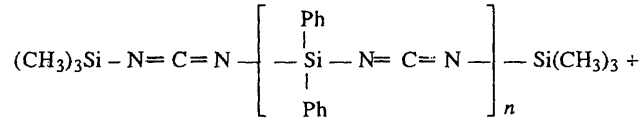
where X and Y are functional groups.

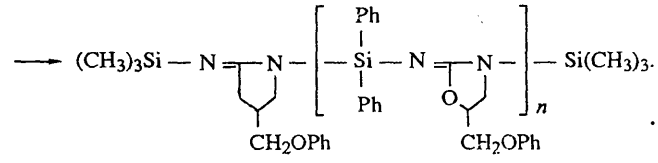
Table 2. Properties of composite materials based on oligocarbodiimides.

Property	T, °C	Carboplastic	Glass plastics	Adhesive
σ_{bend}, MPa	20	962	440	—
	300	466 (after 200 h)	390	—
	350	765	—	—
	400	452	—	—
σ_{comp}, MPa	20	900	400	—
ε	20	—	3.8—4.2	—
	300	—	3.9—4.7	—
tan δ	20	—	0.009—0.01	—
	300	—	0.020—0.025	—
τ_{sh}, MPa	20	—	—	15—18
	250	—	—	12—13

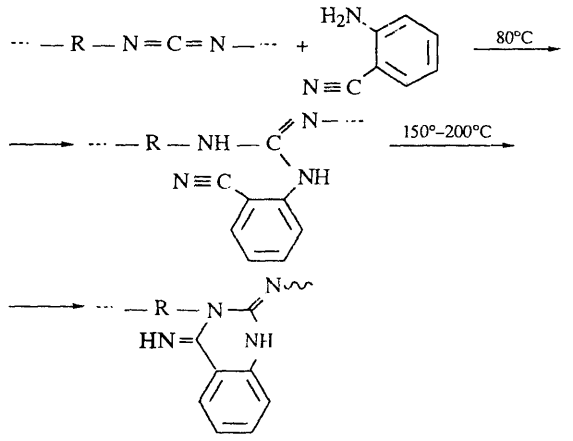
Note. ε = dielectric constant.

Thus polysilylcarbodiimides react with glycidyl phenyl ether to form polymers with iminooxazolidine fragments in the chain:[77]

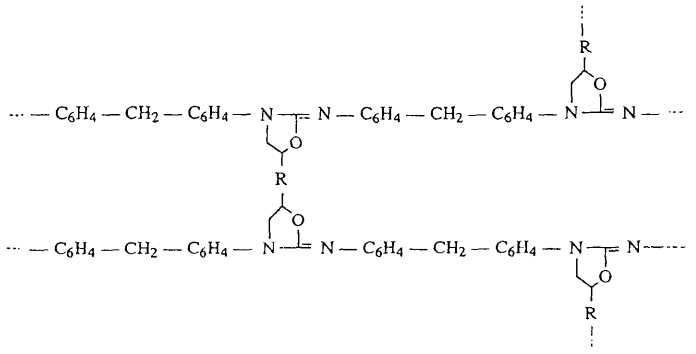




Linear polyheteroarylenes with iminoquinazoline rings in the chain have been obtained by the reaction of aromatic polycarbodiimides with anthranilic acid nitrile:



The reaction of di- and poly-epoxides with polycarbodiimides results in the formation of network polyaminooxazolidines:[44]



It has been shown[44] that, together with iminooxazolidine fragments, other heterocyclic fragments (isomelamine, uret diimine) are also obtained as a result of the homopolymerisation of the carbodiimide groups. By altering the ratio of the carbodiimine and epoxide groups in the initial mixture of oligomers, the contents of different heterocyclic fragments in the final products were regulated.[44] In the presence of an excess of oligocarbodiimides, the uret diimine rings predominate in the polymer structure, being converted into isomelamine units at high hardening temperatures (250 °C). With increase in the content of the epoxide component in the initial mixture, reactions involving the formation of iminooxazolidine rings predominate.[44]

IV. Conclusion

Since the appearance of the first publications on polyheteroarylenes, whose synthesis is based on polycyclisation reactions, more than 30 years have elapsed, but the possibilities of this interesting aspect of polymer chemistry are far from being exhausted. New monomers are being synthesised for the preparation of polymers with a specified set of properties and new methods of their synthesis, primarily catalytic methods, are being developed. Polycrystallisation processes involving parallel-consecutive reactions proceeding via the polymerisation and polycondensation mechanisms are of interest. Processes of the monomers (oligomer)–finished article and of the RIM-technological type have attracted particular attention. Finally, recent years have been marked by the appearance of data on the synthesis of polymers of the type of polycatenanes and polyrotaxanes, which are again based on polycyclisation processes.

Microbiological hydroxylation of 5α-*H*-steroids

A M Turuta, N E Voishvillo, A V Kamernitskii
Zelinskii Institute of Organic Chemistry, Russian Academy of Sciences, Moscow

ABSTRACT. The literature data on the use of microrganisms for the hydroxylation of 5α-*H*-steroids of the 5α-*H*-androstane and 5α-*H*-pregnane series and also 5α-*H*-sapogenins are surveyed. A systematic description of the influence of substitution in the steroid molecule on the specificity of the hydroxylation and the activity of the microbial enzymes is given within the framework of the enzyme–substrate interaction model.

The bibliography includes 124 references.

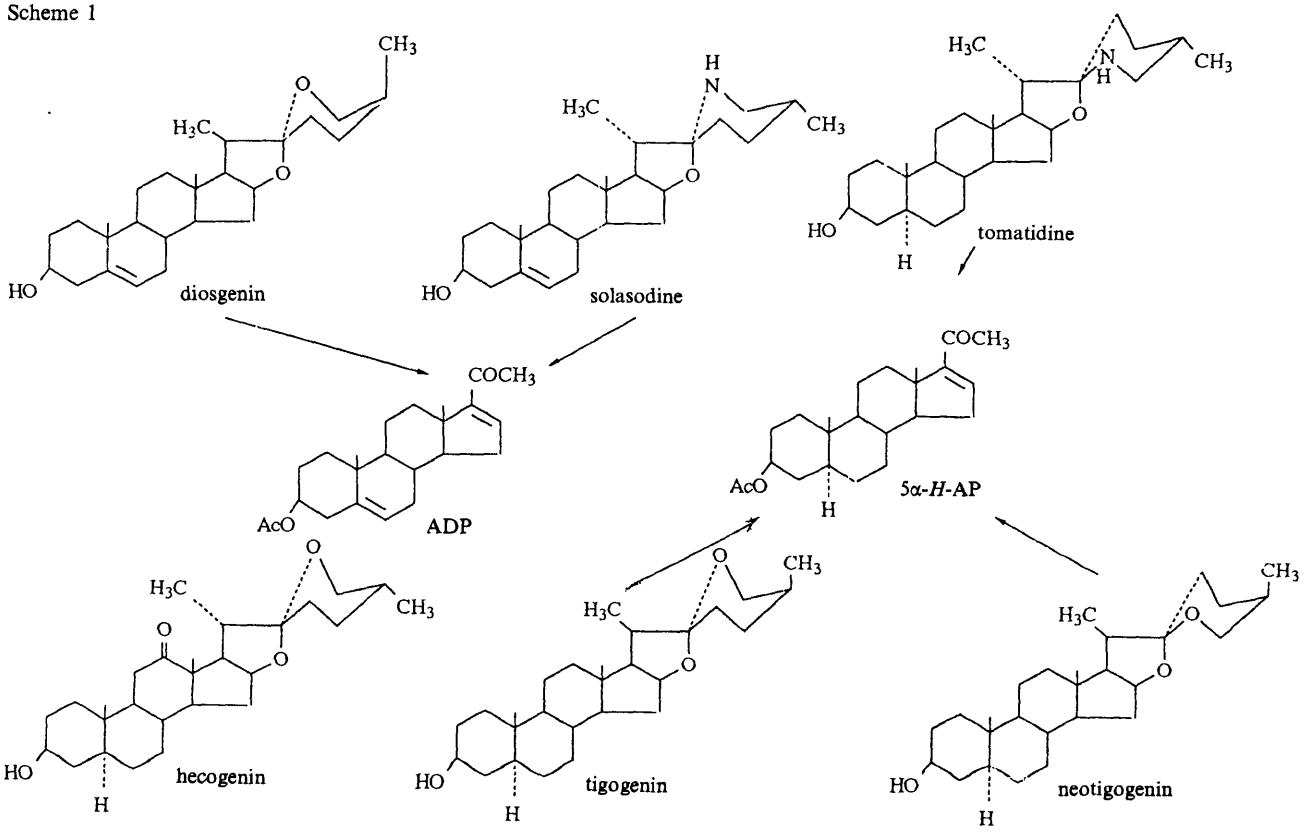
I. Introduction

The industrial manufacture of corticosteroids is based nowadays mainly on diosgen, solasodin, and their cleavage reaction intermediate 16-dehydropregnenolone 3β-acetate (DPA). The expansion of the manufacture of steroids has become a significantly more difficult in view of the sharp increase in the cost of these raw materials which are purchased in countries with a tropical climate. The only local industrial source of the steroid raw material is solasodine, the requirement for which in the CIS countries is not satisfied. For this reason 5α-*H*-steroids—hecogenin, tigogenin, neotigogenin,[1] and 3β-acetoxy-5α-*H*-Δ^{16}-pregn-20-enone (5α-*H*-AP) obtained from them—are used with increasing frequency as promising alternative sources. So far they cannot compete with their Δ^5-analogues because the *A* and *B* rings are saturated and it is difficult to transform them by chemical means into the Δ^4- and $\Delta^{1,4}$-3-oxo-substituted steroid preparations which are of practical value (Scheme 1).

Scheme 1



Data have now been accumulated concerning the possibility of microbiological methods for the effective transformation (hydroxylation and dehydrogenation) of 5α-*H*-steroids. However, they have never been treated systematically and are therefore unavailable for deliberate practical application. Furthermore, most of them refer to the 5α-*H*-androstane series and an appreciably smaller number to the 5α-*H*-pregnane series, the practical value of which is incomparably greater. Nevertheless, close examination shows that there is a close analogy between these series, which makes it possible to compare the results and permits their *a priori* transfer from the androstane to the pregnane series. The principal aim of the review is to present a systematic picture reflecting the influence of substituents in various positions in the steroid nucleus on the microbiological hydroxylation of 5α-*H*-steroids; the examination of the transformations of the *A* ring in 5α-*H*-steroids with the aid of microbiological dehydrogenation and subsequent 9α-hydroxylation effected by bacteria remains outside its framework. We believe that it is also undesirable to include in the review and to consider data on the transformation of 5β-*H*-steroids, which are not only less available but are also factually non-comparable. Thus it is known that the geometrical isomerism at the C(5) atom, which controls the junction between the *A* and *B* rings, is one of the most important factors influencing the interaction of steroid substrates with steroid hydroxylases.[2] We shall illustrate this using as an example androsterone and its 3β-hydroxy-isomer, which is hydroxylated by the mould *Penicillium* sp. in the 1α- and 12β-positions respectively. Their *A/B-cis*-analogues are hydroxylated only in the 7β-position regardless of the configuration of the 3-hydroxy-group.[3] The mould *Aspergillus tamarii* hydroxylase androsterone and its 3β-hydroxy-isomer in the 11β- and 11α-positions, whereas their *A/B-cis*-analogues are hydroxylated in the 7β-position.[4] Yet another example of compounds of the pregnane series is 16α,17α-epoxy-5α-*H*-pregnan-3-one, which is transformed with the aid of *Rhizopus nigricans* into the 11α-hydroxy-derivative (60), while its 5β-*H*-isomer is also transformed in the same way but with much difficulty.[5] The critical change in the stereochemistry of the substrate (from *A/B-trans*- to *A/B-cis*-) undoubtedly affects the steric structure of the enzyme – substrate complex; as can be seen from the foregoing, this factor becomes decisive and requires independent consideration.

Studies on the microbiological transformations of steroids refer mainly to compounds with Δ^4-3-oxo or Δ^5-3β-hydroxy-groups and have been surveyed in a number of communications.[2,6–11] The efforts of many investigators have been directed in this connection to the study of the mechanisms of the microbiological transformations and to the specificity of the action of microorganisms as a function of their positions in the classification system and on the stereochemical features of the steroid substrates. In contrast to dehydrogenation, the study of the mechanism of the hydroxylation reaction is complicated by the considerable lability of the steroid hydroxylases.[12] The question why the same culture changes the mode of hydroxylation when the steroid substrate is altered remains unelucidated. The question arises whether it is a consequence of the functioning of different enzymes in the cell. The causes of the microbiological hydroxylation of steroids have not been finally established. According to the existing hypotheses, the microbiological transformation of steroids is induced in certain cases by the need for their detoxication, while in others it occurs as a stage in the assimilation of steroids as a source of carbon. The latter has been confirmed in relation to bacterial hydroxylation. Bacteria begin to cleave the steroid molecule with hydroxylation of the 9α-, 22-, and 26-positions. However, there are no data concerning the causes of the hydroxylation in the 16α-position characteristic of streptomycetes.[6–11] With the exception of the examples of the hydroxylation by schizomycetes described, in the vast majority of cases steroids have been hydroxylated with the aid of representatives of all classes of fungi in the 1α-, 1β-, 2α-, 2β-, 3β-, 4β-, 5β, 6α-, 6β-, 7α-, 7β-, 8β-, 9α-, 10β-, 11α-, 11β-, 12α-, 12β-, 14α-, 15α-, 15β-, 16α-, 16β-, 17α-, 18-, and 21-positions.[6–11] This review, which constitutes a first attempt at a systematic treatment and analysis of the scattered data concerning the transformation of 5α-*H*-steroids, including the results published in 1992, deals with examples of the hydroxylation by fungal cultures only. All the species of fungi used for the transformation of 5α-*H*-steroids are presented in Table 1.

Table 1. The taxonomy of the fungi hydroxylating 5α-*H*-steroids.

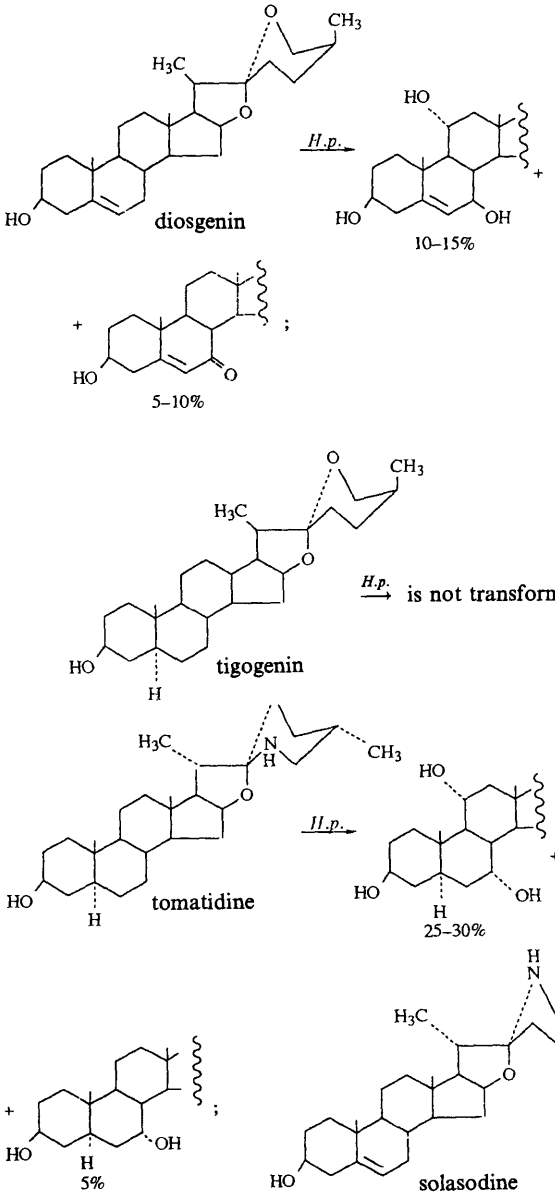
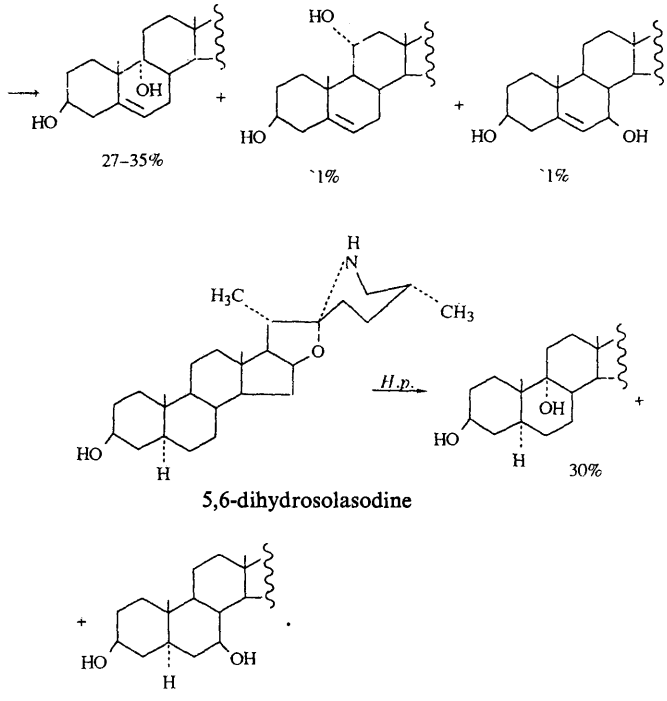
II. Hydroxylation of 5α-*H*-sapogenins

After the discovery of the ability of lower fungi to hydroxylate progesterone,[39] a number of attempts were made to obtain microbiologically hydroxylated steroid sapogenins, because they were regarded as promising initial substrates in the synthesis of steroid hormones (Scheme 1). The first result of such transformations were negative despite the fact that fairly wide ranging microorganisms and conditions in their cultivation were employed for this purpose.[40] However, later Japanese workers obtained with the aid of phycomycetes *H.p.* the hydroxy-derivatives of both Δ^5- and 5α-*H*-sapogenins (diosgenin, tomatidine solasodine, and 5,6-dihydrosolasodine.[41–46] The fact that diosgenin and tomatidine, a 5α-*H*-steroid alkaloid, undergo the same type of transformation and the complete absence of a microbiological transformation of tigogenin compared with diosgenin (Scheme 2) merits attention.[44]

Scheme 2





The principal site of hydroxylation is determined by the structure of the substrate. Diosgenin and tomatidine are transformed predominantly with formation of 11α-hydroxy-derivatives, while solasodine and 5,6-dihydrosolasodine are converted into 9α-hydroxy-derivatives.[41,46] It must be emphasised that in the transformation of tomatidine by the *H.p.* culture the nitrogen atom in the *F* ring does not hinder the 11α-hydroxylation.

A repeated attempt to obtain the hydroxy-derivatives from 5α-spirostanols was undertaken 20 years after the studies mentioned above. 1β,7β-Dihydroxy-derivatives of hecogenin were obtained with the aid of *C. el.*[47] In contrast to *H.p.* and *C. el.*, the cultures of the *Gymnoascus, Scopulariopsis, Fusarium, Dendrostibella,* and *Hypomyces* fungi do not hydroxylate 5α-*H*- and Δ^5-sapogenins, but, like bacteria, transform the *A* ring and cleave the side chain.[48–53]

III. Hydroxylation of 5α-*H*-androstanes

The hydroxylation by fungi of 5α-*H*-androstanes has been most widely investigated. Analysis of the results of the transformations of different 5α-*H*-androstanes (monoketones, diketones, ketoalcohols), chosen as the simplest model compounds for the interpretation of the behaviour of the microorganisms, permitted the main conclusions concerning the mechanism of the microbiological hydroxylation of the steroids. The hydroxylating activity in relation to 5α-*H*-androstanes has been investigated for fungi belonging to different classes of ascomycetes, basidiomycetes, deuteromycetes, and phycomycetes, which are known to be capable of hydroxylating Δ^4-3-oxosteroids in the 11α-positions (*A.o., R.n.*), the 11β-position (*C.cl.*), the 12β- and 15α-position (*C.d., P.u., P.*sp.), and the 21-position (*W.g., O.h.*).[2,6,7] Cultures of *A.t.*,[4] *D.r.*,[28] *A.r.*,[33] *L.f.*,[37] *D.c.*,[31] and *R.c.*,[24] which had not been investigated previously, were also tested. The results of these tests are presented in Tables 2 and 3.

Table 2. Hydroxylation of 5α-*H*-androstanes by fungi.

Substituents in substrate	Micro-organism	Initial compound, %	Principal hydroxylation sites	Yield, %	Secondary hydroxylation sites	Yield[a], %	Refs.

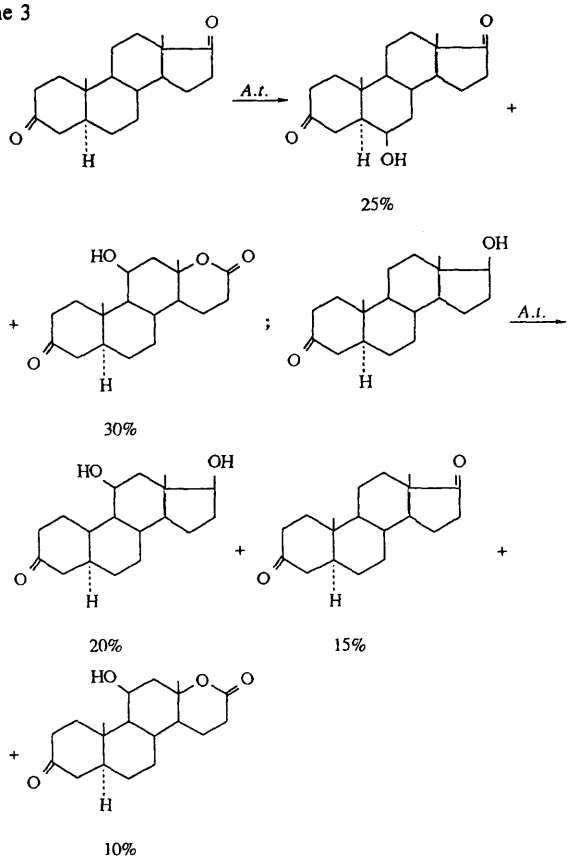
[a] Here and in the subsequent tables, the yields are quoted relative to the converted substrate.
[b] The yields of the product isolated relative to the substrate introduced into the reaction.

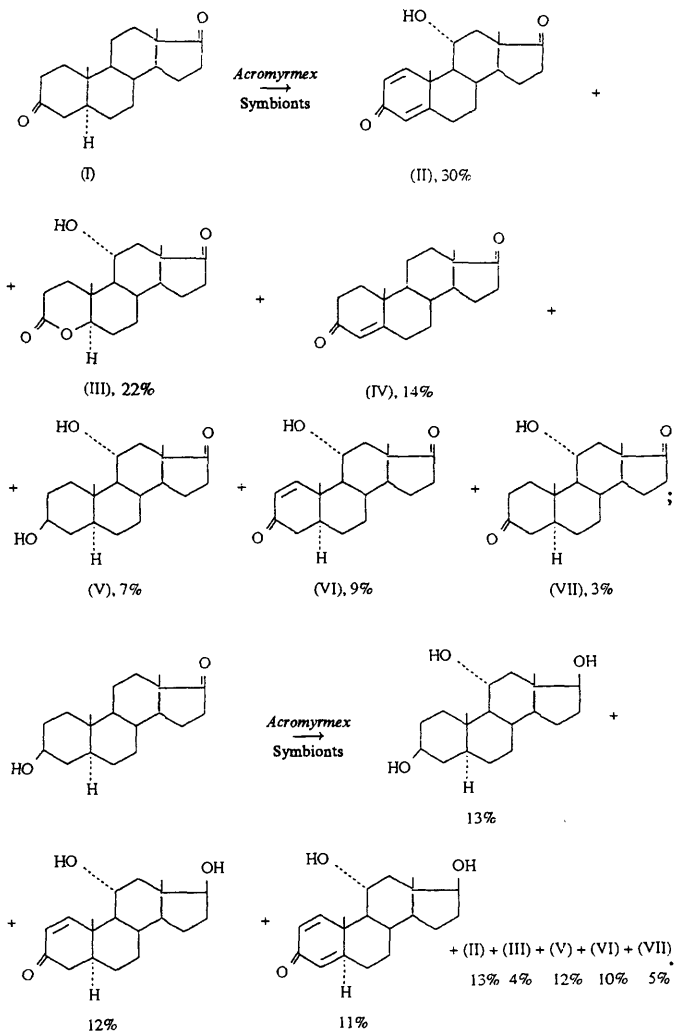
In assessing the data in Table 2, attention should be drawn to what we believe to be two important factors. Strange as it may seem, among all the species investigated, only the strain *A.t.* forms 11β-monohydroxylated compounds in the series of 5α-*H*-androstanes in a sufficiently high yield. However, the lactonisation of the *D* ring is characteristic of the culture and unfortunately this process competes with the main 11β-hydroxylation reaction. The presence of 3-oxo-group in the substrate activates the cleavage of the *D* ring with formation of the lactone, whilst in the incubation of *A.t.* with 3-hydroxy-5α-*H*-androstane *D*-homoisomerisation does not occur* (Scheme 3).

Scheme 3



The second phenomenon which merits attention refers to unidentified fungi—symbionts of ants, which have not been investigated either before the study mentioned above[32] or after it. It follows from Scheme 4 that the symbiont fungi catalyse three processes in the series of 5α-*H*-androstanes: (a) the hydroxylation of the sites specified by the directing influence of the existing substituents in the molecule; (b) the Baeyer–Villiger oxidation; (c) dehydrogenation of the *A* ring. The last two processes occur only in the presence of an oxygen-containing substituent in the 11-position. Examples comprising 5α-*H*-androstanes with oxygen-containing functional groups in the 3- and 17-positions confirm the constancy of the overall mode of the process as the nature of the oxygen-containing substituent at C(3) is varied (Scheme 4).

Scheme 4



It is regrettable that similar studies have not been made with compounds of the 5α-*H*-pregnane series, because the simultaneous activation of the *A* and *C* rings in the pregnane series appears to be an urgent task. The rare combination of the hydroxylating and dehydrogenating activities in the *Acromyrmex* fungi can be

explained, in our view, by the fact that the fungi constitute a microbial consortium whose members perform different transformations of the steroid molecule. The ability of fungi of the genus *Septomyxa* to transform 5α-*H*-steroids into the $\Delta^{1,4}$-3-oxo-compound is known in principle, but this does not entail hydroxylation.[72–74]

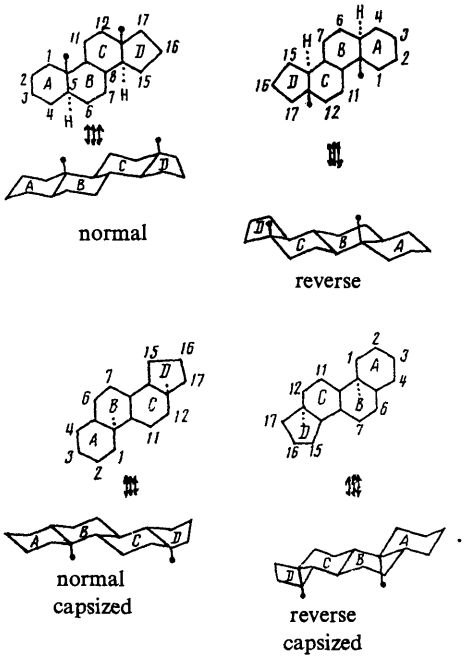
Considerable progess in the understanding of the mechanism of the hydroxylation of steroids has been achieved as a result of studies by workers at Oxford University. They investigated the influence of the functional groups of the substrate on the type of hydroxylation by different fungal cultures. In an attempt to depart from the uniformity which had arisen in connection with the use of substrates of the pregnane series with oxygen-containing substituents at C(3) (mainly CO) and to find a general model of hydroxylation, the research group led by Jones[32] investigated a very wide set of 5α-*H*-steroids (more than 300) in which the position, nature, and number of the oxygen-containing substituents were varied systematically and additional structural factors (double bonds, ring junction, the presence of a heteroatom) were excluded beforehand. This giant study, in which more than 800 hydroxysteroids were obtained and whose importance it is difficult to overestimate, was carried out in 1969—1980.[13—38] Initially the familiar microorganisms characterised by both substrate specificity and substrate independence were included in the research and were then followed by new microorganisms, not investigated previously as steroid hydroxylating biocatalysts, up to the fungi mentioned above—the *Acromyrmex octospinosus* symbionts.[32]

The data in Tables 2 and 3 show that these studies replaced the occasional and few investigations of the transformations of 3,17-disubstituted 5α-*H*-androstanes by individual cultures.[54—56,64,70,77] The workers at Oxford University investigated the influence of a wide range of substituents in 5α-*H*-androstane on the hydroxylating capacity of *A.r.*, *P.u.*, *R.a.*, *R.c.*, *W.g.*, and *O.h.* with emphasis on *C.d.*, *R.n.*, *and A.o.* The results confirmed in most cases Brannon's hypothesis[4] that the hydroxylation of the steroid molecule in different positions is catalysed by the same non-specific enzyme. The enzyme—substrate interaction model, determining the mode of hydroxylation, which was constructed on the basis of the interpretation of the results of the hydroxylation of various substrates by *R.n.*,[22,23] does not conflict with this hypothesis either. The general interpretation of the hydroxylation mechanism proposed by Jones[78] not only explained satisfactorily the results of the oxidation of steroids by the cultures listed above but was also recognised and developed by other groups of investigators.[79—96]

The proposed model of the hydroxylation reaction postulates the existence on the surface of the enzyme globule of three active centres designed for two purposes, i.e. each centre-site can perform two functions—the function involving the binding of the enzyme to the substrate and the hydroxylation function (Fig. 1). According to this model, the sites have a triangular location, corresponding approximately to that occupied by the C(3), C(11), and C(17) atoms of the steroid ring. The way in which the enzyme—substrate complex is formed and hence the result of the hydroxylation depend on whether these centres of the steroid ring carry oxygen-containing substituents (how many and what kind); the binding of the steroid to the substrate can then take place in one of the possible orientations. It is believed that four orientations of the steroid in relation to the enzyme are theoretically possible: (a) normal; (b) reverse; (c) normal capsized; (d) reverse capsized. The last two are obtained by the rotation of the steroid molecule about the C(3)—C(17) axis by 180°. The normal and reverse orientations are preferable and virtually only these are considered in Jones's hydroxylation model (Scheme 5).

Scheme 5



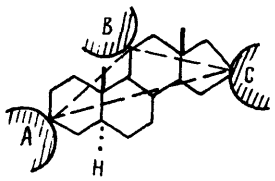


Figure 1. Jones's model of the enzyme–substrate interaction.[78]

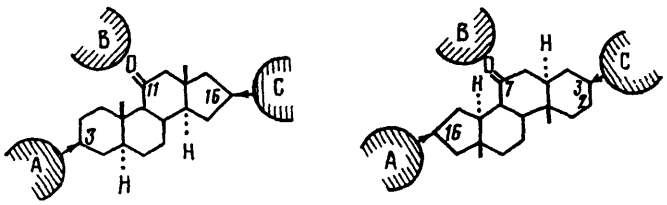

Figure 2. Site of hydroxylation of 11-oxo- and 7-oxo-5α-*H*-androstanes by a *D. r.* culture.[28]

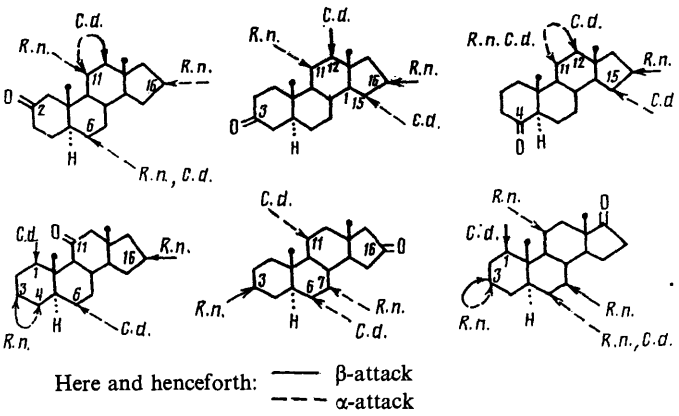
According to this model, the binding of the enzyme to the steroid substrate occurs at two oxygen centres, which is satisfactorily confirmed by data for the transformation of the monoketones of the 5α-*H*-androstane series by different cultures. Virtually all the monoketones (1-, 2-, 3-, 4-, 6-, 7-, 11-, 12-, 15-, 16-, and 17-CO) are transformed either with much difficulty—with recovery of up to 90% of the unreacted substrate—or are not transformed at all. When transformation does occur, a considerable non-uniformity of the reaction products is observed. The high percentage of the recovery can be attributed to the low solubility of the monoketones compared with other steroids and hence with the greater difficulty of their permeation into the cell. However, the main explanation of the low reactivity the monoketones and the non-uniformity of the products obtained from them is apparently that the substrate molecule, fixed on the surface of the enzyme at only one site, rotates or oscillates about the binding centre, subjecting not all the predicted positions to the action of the enzyme. The monoketones are then as a rule dihydroxylated. Fig. 2 shows how this occurs for *D.r.*

The same model explains the principle of the dihydroxylation of the monoketones by the *C.d.* and *R.n.* fungi in the following way: the keto-group of the substrate in one (or several) of its orientations is bound to one of the binding centres of the enzyme, while the other two sites perform the function of hydroxylating those C–H bonds which are in vicinal positions in relation to them. For example, the 3- and 16-ketones are dehydroxylated by *R.n.* in the 11,16- and 3,7-positions as a consequence of the binding of the keto-groups to the enzyme at the centre A in the normal and reverse ways respectively (Fig. 3). The authors explain the formation of a multicomponent mixture of the 6,11-, 3,7-, and 3,11-dihydroxy-derivatives on transformation of 17-oxo-5α-*H*-androstane by the non-uniform binding in both ways. In this case, the formation of 6,11-dihydroxy-derivatives and also of 6α,16α- and 6α,11α-dihydroxy-products rather than the 11,16-dihydroxy-derivatives on transformation of 2-oxo-5α-*H*-androstane with the aid of *R.n.* cannot be readily explained.[22]

Scheme 6



One cannot rule out the possibility that the above variants of the dihydroxylation are a consequence of the successive monohydroxylation initially in the 11α- or 16α-position and then in the 6α-position; at any rate, it is known that 6-hydroxylase can be induced in *R.n.* by 11α-hydroxysteroids on incubation with Δ^4-3-oxosteroids.[2] It may be that the 16α-hydroxy-derivatives of 5α-*H*-steroids also induce the synthesis of a second enzyme. It is noteworthy that the high percentage of the recovery of the initial substrate (17-CO and 2-CO) shows that none of the available binding methods creates a situation favourable for hydroxylation (Scheme 7).

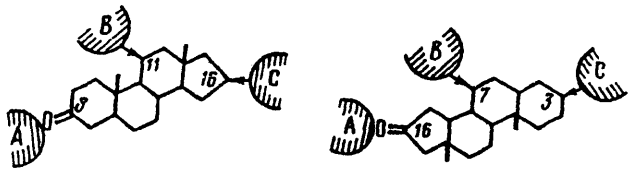


Figure 3. The site of hydroxylation of 3-oxo- and 16-oxo-5α-*H*-androstanes by the *C.d.* and *R.n.* fungi.[20,22,30]

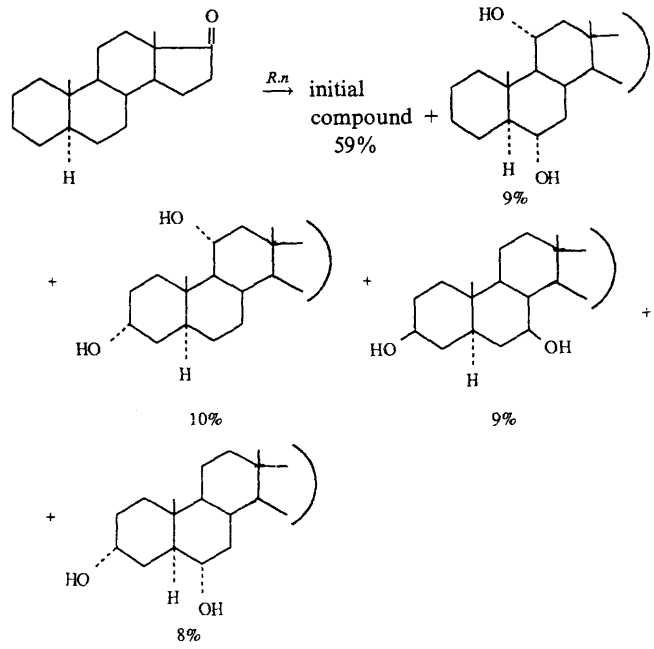
Scheme 7



We shall compare these data (Scheme 6) with the results of the oxidation of the monoketone derivatives of 5α-*H*-androstanes by a *C.d.* culture. As a result, the *C.d.* culture introduces both equatorial groups at virtually the same distances from the oxygen atom of the substrate and the distance between the attacked carbon atoms is also approximately the same (1−6 = 3.9 Å; 6−11 = 4.4 Å; 11−15 = 4.5 Å). Evidently the oxidation of the monoketones by *R.n.* is not quite so specific because, together with equatorial substitution, there is also axial substitution and the distance between the attacked centres is not quite so uniform although it is in most cases approximately 5 Å (11−16, 3−17). Appreciable conversion of the monoketones into the main product on incubation with *C.d.* takes place only when the substituent is in the terminal rings. An interesting feature of *R.n.* in relation to steroids of the 5α-*H*-androstane series is the intense hydroxylation in the 16β-position (see Table 3 above), which is never manifested in the pregnane series.[35] *R.n.* is also distinguished by a low capacity for the oxidation of monoalcohols (1α-, 3β-, 6α-, 11α-, 17β-). After incubation with the above microorganism, 75−95% of the initial substrate remains,[22] whereas *C.d.* hydroxylates at least the 3β- and 17β-alcohols (the others have not been investigated) (Table 3). The most characteristic feature of the *C.d.* species, known as the 12β,15α-dihydroxylating culture for Δ^4-3-oxosteroids,[104] is also the 12β-,15α-dihydroxylation of 5α-*H*-androstanes with 3-CO, 3β-OH, and 3α-OH substituents as well as compounds with the 3β-OH-Δ^1-, 3-CO-Δ^1, or 17-acetate groups.[13,19,29] In contrast to *C.d.*, the *R.n.* and *A.o.* moulds do not hydroxylate 3- and 17-monoacetates of 5α-*H*-androstane.[29]

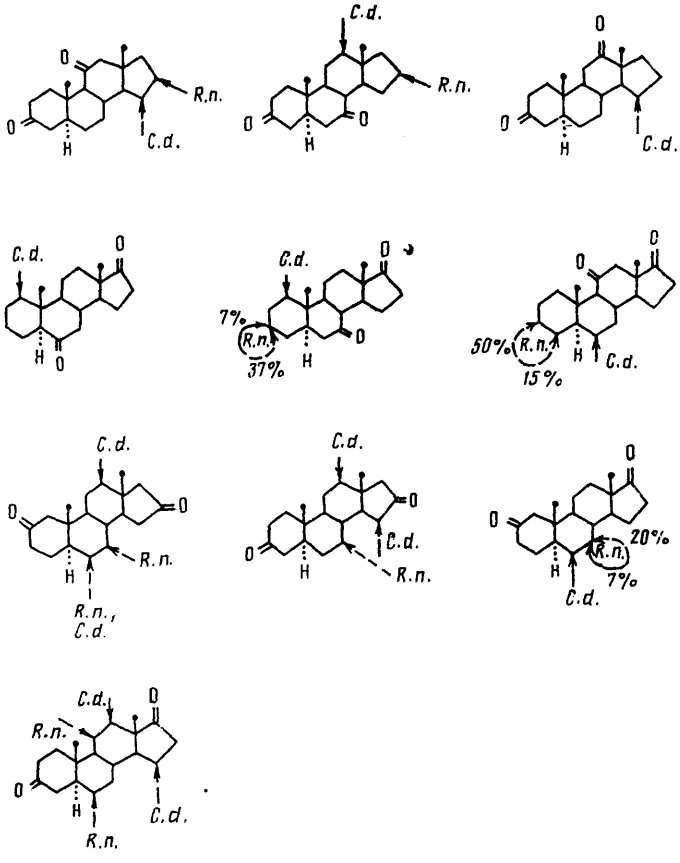
In the transformation of the monoketones with the aid of *D.r.*, the enzyme is bound to the substrate mainly with participation of the substituent at the centre of the molecule [C(7) and C(11)] with formation of 3β-,16β-dihydroxylated products (Table 2, Fig. 2). When androstanes with substituents in the terminal rings (in the 3-, 16-, and 17-positions) are used as the substrates, the recovery of the unreacted steroid is 50−90% and a complex mixture of unidentified products is formed.[28] The *W.g.*, *O.h.*, *D.c.*, *D.r.*, and *S.r.* cultures are inert in relation to the majority of monosubstituted (mainly CO-substituted) 5α-*H*-androstanes,[27] which agrees with the hypothesis of the involvement of two enzyme centres in the binding discussed here.

The *A.o.* culture does not transform the majority of monoketones. Exceptions are the 3- and 17-oxoandrostanes transformed respectively into 6β,11α-dihydroxy-derivatives with 44 and 35% conversions, 7β,11α-dihydroxy-derivatives (51 and 27%), and 11α-dihydroxy-derivatives (11 and 5%).[21] However, the formation of the dihydroxylated derivatives by the *A.o.* culture is due to the action of not just one enzyme, as for *C.d.*, but two steroid hydroxylases, the existence of which has been demonstrated in experiments with a cell-free extract.[75,76] It has been suggested that the second hydroxylase system in the *A.o.* cells is induced by the reaction product of the first enzyme, which is also the 11α-hydroxy-derivative. This leads to the formation of 6β,11α-dihydroxy-derivatives and sometimes the 6β-monohydroxy-derivatives.[28] The presence of the second oxygen-containing group (CO or OH) in the molecule in different positions facilitates the hydroxylation of 5α-*H*-androstanes with the aid of *A.o.*, but always in the 11α-position. Furthermore, whereas on incubation with monoketones the *A.o.* microorganism catalyses predominantly dihydroxylation, disubstituted androstanes are converted by this culture exclusively into 11α-monohydroxy-derivatives in 66−82% yield (Table 2). However, the functioning of two steroid hydroxylases in the *A.o.* cells and the site-specificity characteristic of this microorganism justify the assumption that it is unsuitable for the solution of the problem formulated. The research group therefore concentrated attention on *C.d.* and *R.n.*, which are capable of hydroxylating steroids in different positions depending on the structure of the substrate (Table 3), using the cultures indicated in Table 2.

Analysis of the results of the conversion of the monosubstituted 5α-*H*-androstanes has shown that the driving force determining the mode of hydroxylation is the specificity of the microorganism and the directing effect of the keto-group. The use of ketones and diketones substituted in different ways as substrates makes it possible, having increased the rate and efficiency of the transformation (by changing the hydrophilicity of the substrate, the solvent to be added to the reaction mixture, and the incubation time), to follow the competitive effect of the substituents (having restricted the monohydroxylation process as a result of the blocking effect of the second substituent) and, what is most important to discover the factors responsible for the mode of hydroxylation. It has been noted that polar groups in the terminal rings have a dominant effect on the hydroxylation process catalysed by the *C.d.* culture, as observed for monosubstituted androstanes. For example, the 3-oxo-group in 3,11-, 3,12-, and 3,7-diketones, which is common to these substrates, directs the hydroxylation to the *C* and *D* rings, while the 17-oxo-group in the 6,17-, 7,17-, and 11,17-diketones,

common to these substrates, directs the hydroxylation by the above microorganism to the *A* and *B* rings. The keto-groups in the middle *B* and *C* rings have a weak directing effect, blocking the hydroxylation in its own position and stimulating that in the neighbouring position or in a position close to it in space (Table 3, Scheme 8).

Scheme 8



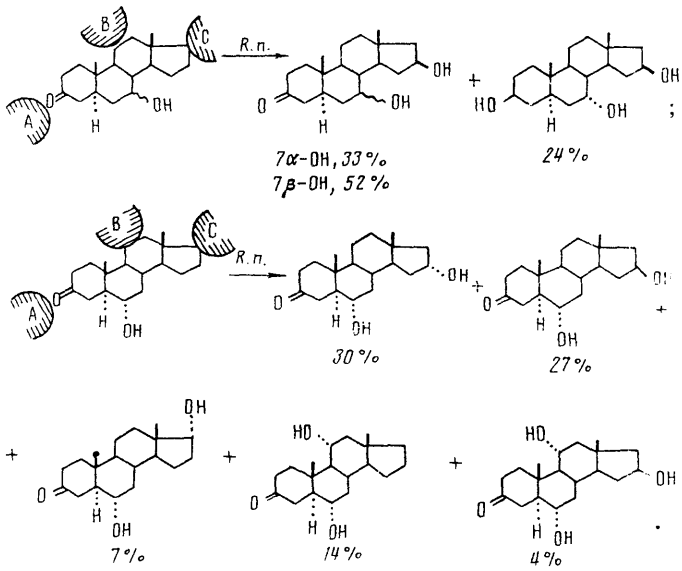
Naturally the competition between the keto-groups located in the terminal rings (the last four examples in Scheme 8) is reflected in the dihydroxylation, the mode of which is determined by the directing effect of both keto-groups. The hydroxy-groups in the main products formed as a rule assume the equatorial orientation and are at a distance of 3.5–4.5 Å from the nearest oxygen-carrying carbon atom and at a distance of 6.3–8 Å from either C(3) (substrate with a substituent in the *A* ring) or from C(17) (substrate substituted in the *D* ring). The directing force of the principal directing substituents has been estimated as follows in the analysis of the results of the oxidation reaction: 3-CO-Δ^4 (and less distinctly 5α- and 3β-OR, R = H, Me) > 17-CO > 3α-OR (R = H, Me); 3-CO-Δ^4 > 17β-OH, etc., i.e. the nature of the oxygen group is less important than its steric orientation relative to the steroid nucleus as a whole. This is an extremely important conclusion, which makes it possible to eliminate the established view, which is apparently false as shown using the *A.o.* culture, that the presence of the Δ^4-3-oxo-group, for example, in the steroid molecule is necessary for its successful microbiological hydroxylation.

According to the hydroxylation model discussed, the substrates with two oxygen-containing groups are oriented at the enzyme molecule in such a way that the maximum possible hydrophobic binding between both substituents and the corresponding enzyme centres is ensured. In this case the third catalytic centre is responsible for the hydroxylation of the nearest carbon atom.

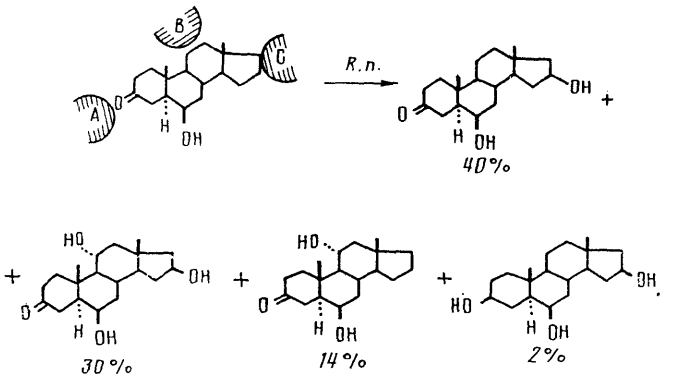
The *R.n.* enzymes hydroxylate terminally substituted substrates oriented in the normal manner in the 11-position, while those oriented in the reverse manner are hydroxylated in the 6- or 7-position. Thus, among the four terminally substituted diketones subjected to oxidation, three substrates (2,16-, 2,17-, and 3,16-) are hydroxylated only in the reverse manner (Table 3, Scheme 8).[23] The models described show that, for the first two steroids, binding in the normal manner does not permit contact between the steroid and the enzyme site B, while in the 3,16-diketone the geometrical disposition of the centres is favourable for both types of binding. The reverse type of hydroxylation observed for the 3,16-diketone indicates the preferential binding of the 16-oxo-group to the site A. Although the 3,17-diketone is in fact hydroxylated in the normal manner, the degree of conversion (32% of the starting material) and the yield of the 11α-hydroxy-derivative (23%) are low and the 6α-hydroxy-derivative is formed. It is thus legitimate to extend what has been stated above for the 17-monoketone to the 3,17-diketone. A striking result is the quantitative 11α-hydroxylation (~100%) of the 16β-hydroxy-3-ketone and the 7α-hydroxylation (90%) of the 3β-hydroxy-16-ketone bearing in mind that the corresponding monoalcohols are not transformed by the *R.n.*[23] In combination with the 3-oxo- and 16-oxo-groups, these alcohols probably constitute the optimum model for the normal and reverse hydroxylation respectively. The 17-oxo-group combined with the 3β-hydroxy group exhibits preferential hydroxylation in one particular (reverse) way (48% 7β-OH and 15% 7α-OH); on the other hand, the presence of the 3α-hydroxy-group promotes the formation of products of hydroxylation in both ways (23% of 11α-OH and 5% of 6α-OH). The presence of the 17β-hydroxy-group in 17β-hydroxy-5α-androstan-3-one not only facilitates the hydroxylation by *R.n.*, but also makes it selective. The asymmetric disposition of the substituents at C(17) probably interferes with the optimum binding of the substrate to the enzyme in this case also.

The results of the oxidation, catalysed by *R.n.*, of virtually all the ketones and ketols investigated, in which one oxygen atom is in the terminal ring and the other is in the middle ring, can be interpreted satisfactorily from the standpoint of the hypothesis of three two-target sites. As a rule, substrates with the substituent in the *A* ring are hydroxylated preferentially in the *D* ring and conversely the substrate substituted in the *D* ring is hydroxylated in the *A* ring, i.e. here too, as in the case where *C.d.* is used, the dominant influence of the terminal substituents is observed. These substituents are bound to the site A of the enzyme usually in the normal or reverse manner and are hydroxylated at the site C. On the other hand, the substituents in the central rings exert only an auxiliary influence, discussed above for *C.d.* (Scheme 9). The minor hydroxylation products can probably arise when a hydroxy-group enters positions adjoining the main hydroxylation site (for example the 4- or 17-position). One cannot fail to notice that monohydroxylation is more characteristic of disubstituted compounds even if the type of binding of the substrate molecule favours the entry of a second group. Thus in the examples presented in Scheme 10, the epimeric 7-hydroxy-3-ketones are not hydroxylated at the site *B* at all, while the epimeric 6-hydroxy-3-ketones are only partly hydroxylated at this site (Table 3).

Scheme 9

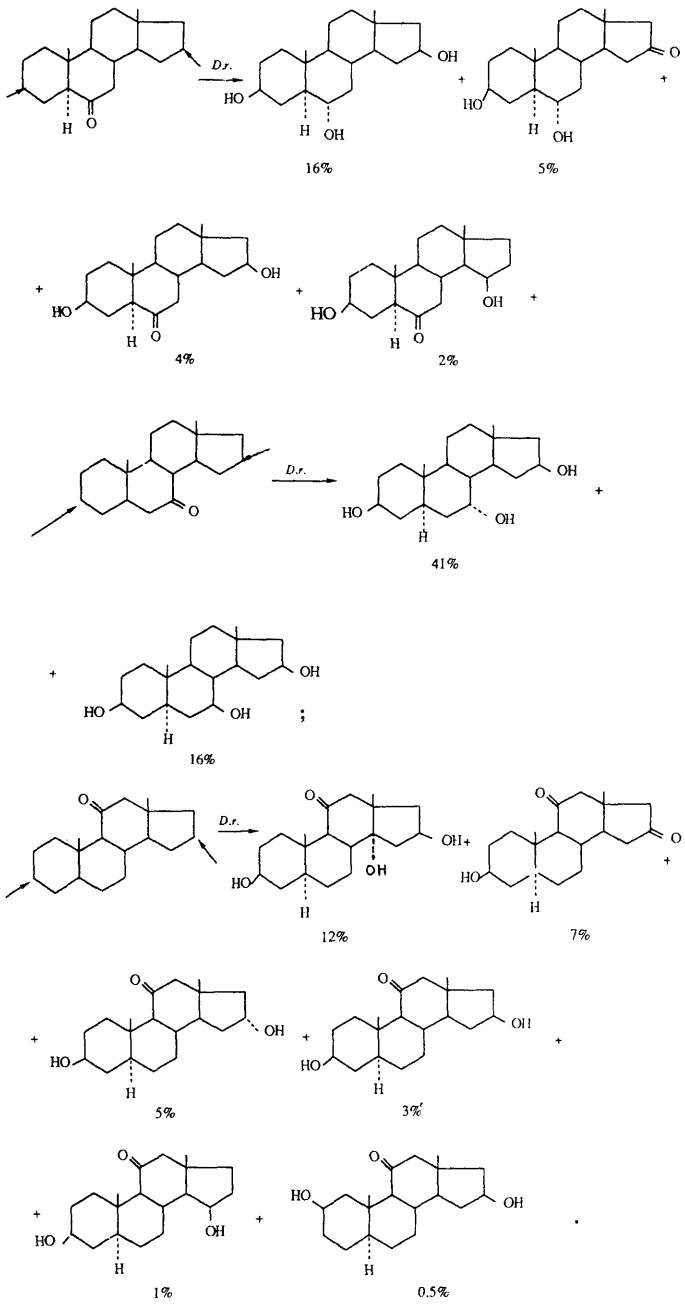


Scheme 10



In the authors' version, the proposed dehydroxylation model concentrates attention on the regiospecificity of the reactions but completely ignores their stereochemical aspects: the stereospecificity of the reactions or its absence and the influence of the stereochemistry of the substituent in the substrate. After two years, McCrindle et al.,[79] who analysed the hydroxylation of norcaranes catalysed by *R.n.* from the standpoint of Jones's hypothesis of the formation of a temporary enzyme–substrate complex, proposed a modification, which takes into account the three-dimensional nature of the steroid molecule and the protein globule. Their idea was to draw an imaginary plane through the steroid substrate molecule in such a way that the sites A and B are below it (or are coplanar with it), while the site C is above it. It is assumed that the site A binds preferentially the oxygen atoms below this plane and that hydroxylation takes place in the α-region. The site B imposes a similar requirement on the binding to the enzyme, but hydroxylation can occur both in the α-region (axial or equatorial) or in the β-region (only equatorial). The site C is bound preferentially to the enzyme above this plane and directs hydroxylation preferentially to the β-position. From the author's point of view, all the results for the stereochemistry of the hydroxylation of steroids catalysed by *R.n.* and their own data on the hydroxylation of norcaranes fit satisfactorily within the framework of this hypothesis.[79]

Scheme 11

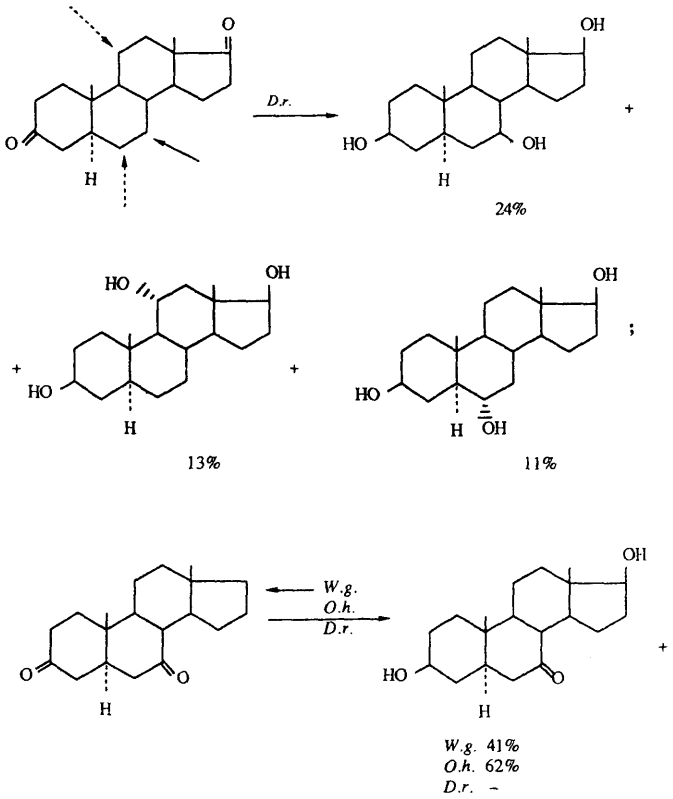


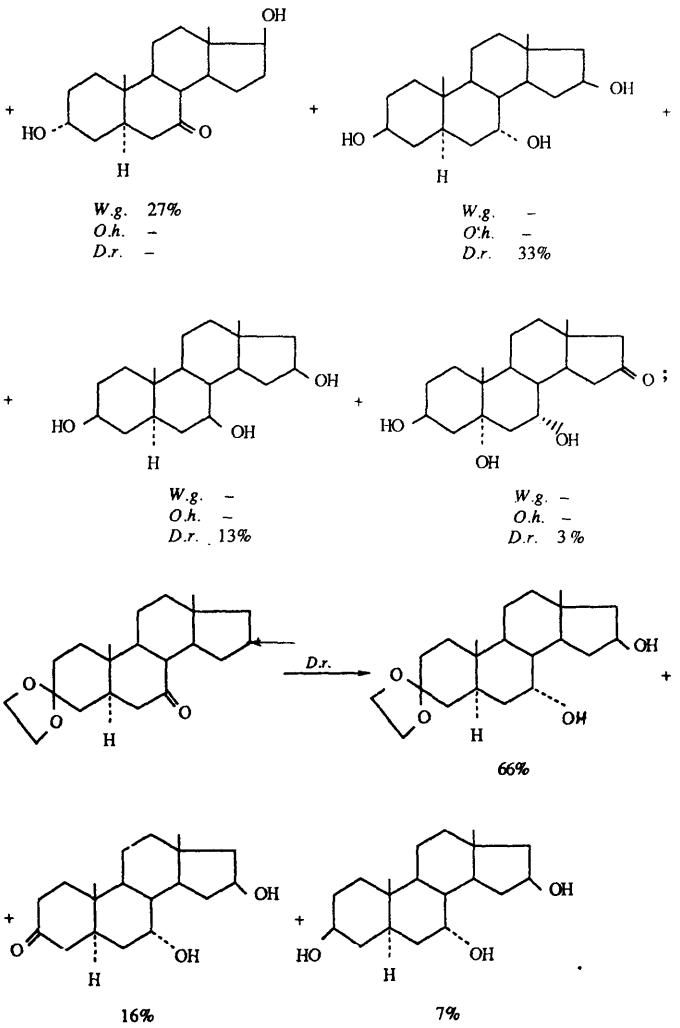
The results of the transformation of 5α-androstanes by *W.g.*, *O.h.*, and *D.r.* cultures, where the majority of monosubstituted, mainly with CO, 5α-androstanes are inert in the presence of *W.g.* and *O.h.*, are satisfactorily consistent with the proposed hypothesis. The *D.r.* enzyme system exhibits a surprising contrast between the slow hydroxylation of substrates having a carbonyl group in the terminal ring and the higher rates of conversion of substrates having this

group in the central ring. Thus 5α-androstanes with 3-CO, 16-CO, and 17-CO groups are transformed by *D.r.* only to the extent of 10–40%, forming a complex mixture of unidentified products, while their 6-CO, 7-CO, and 11-CO analogues are oxidised with 80–90% conversion at the terminal rings. The hydroxylation reactions of the 11- and 7-ketones catalysed by the *D.r.* culture are distinguished by their specificity: the former afford several hydroxylation products, while the 7-ketones are hydroxylated more unambiguously (Scheme 11, Table 2).

We shall consider in relation to these cultures (*W.g.*, *D.r.*, *O.h.*) how the results obtained with their aid fit within the framework of Jones's model. The *O.h.* enzyme system proved to be inert in relation to the terminally substituted androstanes with two oxygen-containing groups. On the other hand, the *W.g.* and *D.r.* cultures effectively hydroxylate these substrates (Table 2).[27,28] 5α-Androstanes in which one keto-group is in the terminal ring (2-, 3-, or 17-) and the other is in the middle ring (7- or 11-) are hydroxylated readily and always in the terminal ring regardless of the microorganism used, the replacement of the keto-group by a hydroxy-group having an insignificant influence on the hydroxylation reaction. The clear tendency towards preferential attack on specific positions in the steroid nucleus (usually 3-, 7-, and 16- or neighbouring positions) is characteristic of all three cultures (Scheme 12).

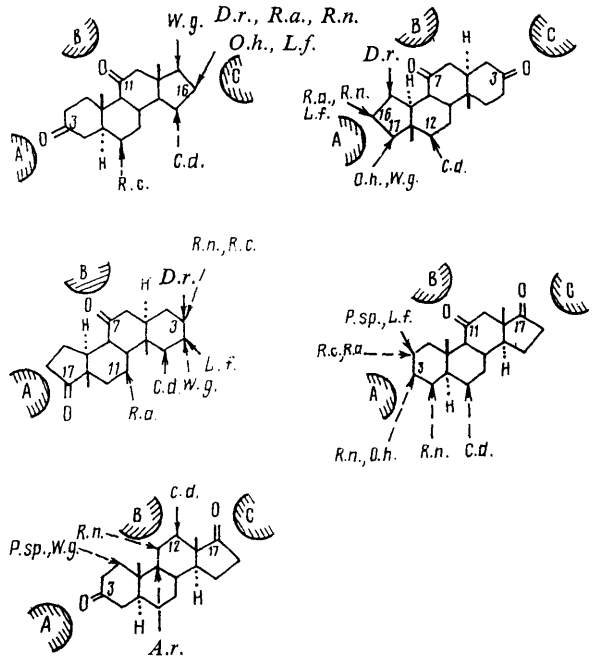
Scheme 12





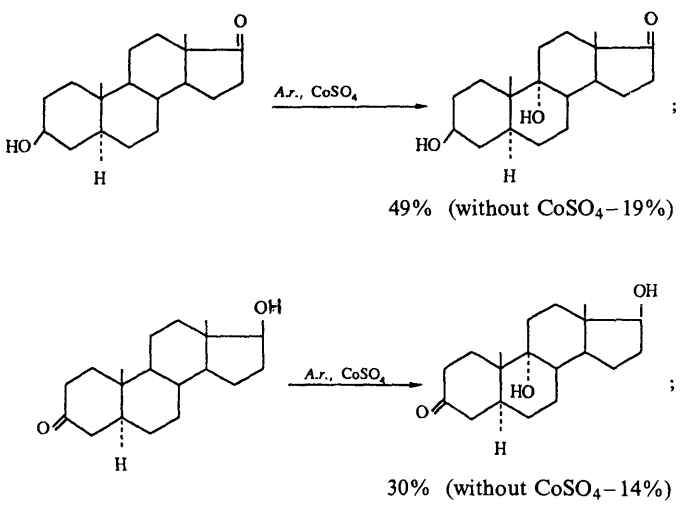
The data discussed above concerning the oxidation of 5α-androstanes and included in Tables 2 and 3 (the results of transformations catalysed by fungi of unidentified genus are not considered) are summarised in Scheme 13. In most cases, these results fit within the framework of the Jones–McCrindle model of enzyme–substrate specificity. Thus, on binding to the sites A and B or B and C, hydroxylation takes place at the sites C and A respectively [the 3,11-$(CO)_2$, 3,7-$(CO)_2$, 7,17-$(CO)_2$, and 11,17-$(CO)_2$ structures], while on binding to the sites A and C, all fungi (it must be emphasised that these represent different classes), introduce an axial hydroxy-group (with the exception of *C.d.*) in the positions within the molecule oriented towards the site B. At the same time, one of the binding sites can effect hydroxylation and in such a case dihydroxylated products are formed. On the other hand, if this does not occur, then monohydroxylated products are formed, which is observed on transformation of disubstituted androstanes in the vast majority of cases. The reactions of androstane substrates take place similarly when keto-groups are replaced by hydroxy-groups and also for 3- and 17-monoacetals and 3,17-diacetals and 2α,3α-epoxides, but not 2β,3β-, 16α,17α-, and 16β,17β-epoxides.

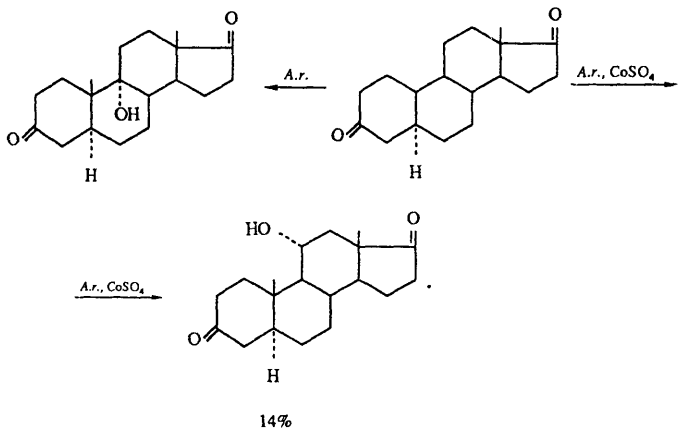
Scheme 13



The results of hydroxylation catalysed by the *A.r.* microorganism, which introduces an 11α- or 9α-hydroxy-group into the 3,17-diketone depending on the presence of divalent cobalt in the medium, are not susceptible to explanation.[33] If the substrates are 3β- or 17β-keto-alcohols, then the hydroxy-group is introduced in the 9α-position regardless of the presence of cobalt. However, in its absence the yield of the 9α-hydroxy-products is smaller by a factor of 2. The exceptional nature of these data consists also in the fact that heavy metal salts, including cobalt salts, fully inhibit the activity of 9α-hydroxylases of bacterial origin[2] (Scheme 14).

Scheme 14

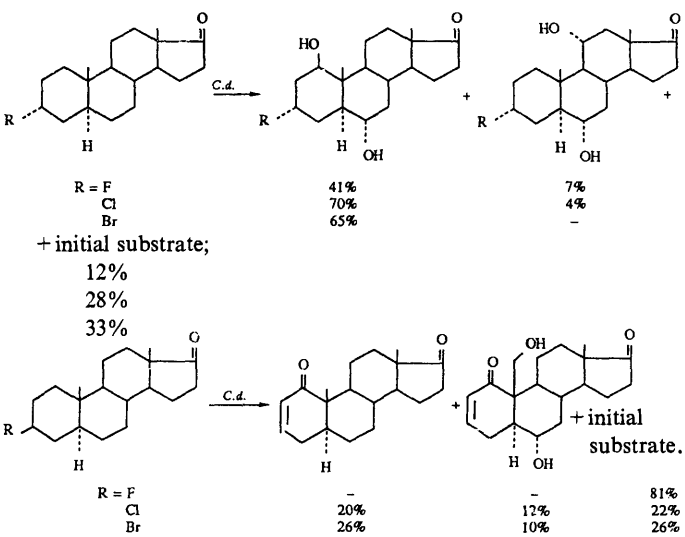




IV. Transformations of halo-5α-*H*-androstanes

In order to elucidate the influence of halo-substituents on the hydroxylation of 5α-*H*-androstanes (3-, 16-, and 17-oxo-derivatives), a number of monohalo-substituted (3-, 6-, and 17-) and *gem*-difluoro-substituted (6-, 7-, 12-, 16-, 17-) substrates were incubated under standard conditions with *C.d.*, *R.n.*, and *A.o.* micro-organisms[34,36] and the results were compared with those obtained for related unsubstituted 5α-*H*-androstanes. It was found that the catalytic properties of the biocatalysts are determined by the halogen atom: its nature, position, and configuration. This is illustrated by the results of the hydroxylation of 3α- and 3β-halo-5α-*H*-androstan-17-ones (Scheme 15).

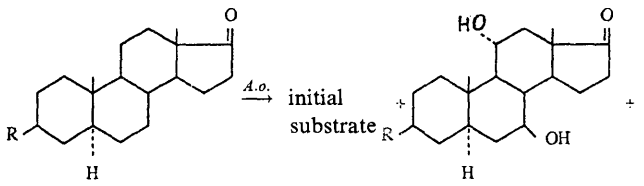
Scheme 15



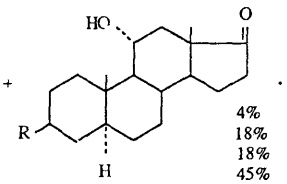
Another activity sequence in the halogenation of substrates has been observed for 17α-halogenated 5α-*H*-androstan-3-ones: in this case, the chloro-substituted derivatives are inactive in the presence of the *C.d.* microorganisms, while the fluoro-substituted derivatives undergo 12β,15α-dihydroxylation [like the unsubstituted 3-oxo-5α-*H*-androstanes (Table 3)]. A clear and very useful difference exists between the fluoro-ketones, on the one hand, and the chloro- and

bromo-ketones, on the other, in the hydroxylation of 3- and 17-oxoandrostanes catalysed by the *A.o.* microorganism. For example, 3α-chloro- and 3α-bromo-derivatives do not react, whereas the 3α-fluoroketone is effectively hydroxylated in the 11α-position by this culture. An extremely important conclusion, reached in a study of a wide range of fluorinated 5α-androstanes, is that the fluorine atom, which is remote from the site of attack specific to each 5α-androstanone (and microorganism), facilitates the hydroxylation process without altering its specificity. This can be clearly traced for the 11α-hydroxylating *A.o.* culture, which, in contrast to *C.d.* and *R.n.*, exhibits a low substrate specificity. The results presented in Scheme 16 demonstrate not only a clearly expressed induction of the hydroxylation process by the 3-fluoro-substituent but also the possibility of specific 11α-hydroxylation of 17-oxo-5α-androstanes by this culture (c.f. Table 3).

Scheme 16

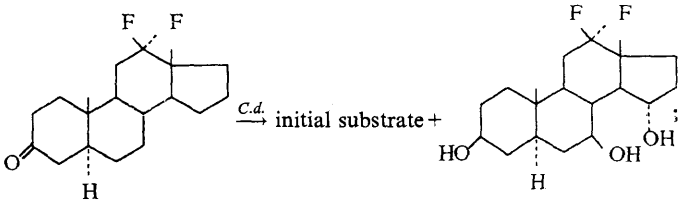


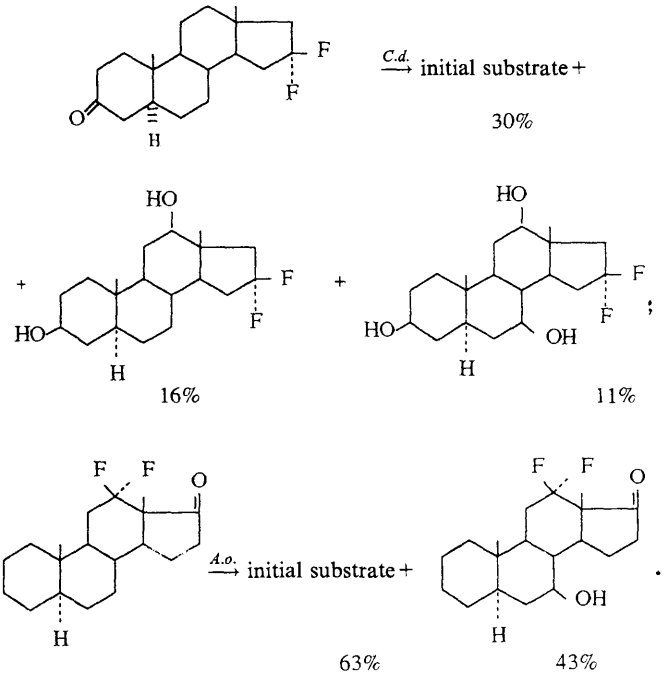
R = H	67%	34%
R = 3α-F	18%	41%
R = 3β-F	18%	40%
R = 3, 3-F_2	28%	–



On the other hand, a chlorine atom close to the standard points of attack as a rule blocks the hydroxylation process in these standard or neighbouring positions or directs it along the "reverse" pathway. For example, the 12β,15α-dihydroxylation by the *C.d.* culture, which is characteristic of 3-oxo-5α-*H*-androstanes, has not been observed in reactions with 12,12-difluoro- and 16,16-difluoro-3-ketones, where the main targets of attack are respectively the 7β,15α- and 7β,12β-atoms. A striking example of such displacement of the site attacked is provided by the result of the hydroxylation of 12,12-difluoro-17-oxoandrostanes to give the 7β-hydroxy-derivative. This result is particularly striking in the sense that the presence of the 11α-hydroxy-group is essential for the 6β- or 7α-hydroxylation by this enzyme, while monohydroxylation always takes place only in the 11α-position[76] (Scheme 17).

Scheme 17





V. Hydroxylation of 5α-*H*-*D*-homoandrostanes

In order to discover the additional factors determining the enzyme–substrate interaction, research groups in Venezuela and Great Britain[89–96] analysed the influence of the formation of *A*- and *D*-homo-derivatives in the series of 5α-*H*-androstanes on hydroxylation by three cultures—*A.o.*, *R.n.*,[80,81] and *C.el.* Comparison of the results with those for the transformation of similarly substituted 5α-*H*-androstanes permitted the conclusion that, firstly, the *A.o.* culture exhibits a narrow site-specificity also in relation to the *D*-homosteroids, hydroxylating the latter only in the 11α-position (Table 4). Secondly, compounds of this series do not induce the synthesis of a second hydroxylase, which is additionally confirmed by the absence of the hydroxylation of *D*-homo-5α-androstanes having two oxygen-containing substituents in the 3,11-positions. It is noteworthy that the same compounds are not hydroxylated by the *R.n.* culture either, which is evidence in support of the hypothesis put forward previously that two hydroxylases can also function in the *R.n.* cells but they are not quite so specific as in the *A.o.* culture. However, according to the authors,[80,81] in the main the results of the hydroxylation of *D*-homo-5α-androstanes by the *R.n.* culture fit satisfactorily within the framework of Jones's mechanism, from the standpoint of which virtually all the data obtained can be accounted for. In this series, the normal mode of hydroxylation is rarely observed and virtually all the substrates investigated are hydroxylated in the reverse manner, the reaction being accompanied to a large extent by the reduction of the keto-group. An exception is *D*-homo-5α-*H*-androstane-3,17-dione, which is hydroxylated to some extent in the normal way in the 11α-position. However, since only the 3-oxo-group is reduced to the 3β-hydroxy-group, favourably oriented for binding in the reverse manner, the process begins to proceed precisely in this direction with formation of 7β-hydroxy-derivatives. On the other hand, the 3,17*a*-*D*-homoketone (Table 4) is not hydroxylated even in the

Table 4. Hydroxylation of *D*-homo-5α-*H*-androstanes by different cultures.

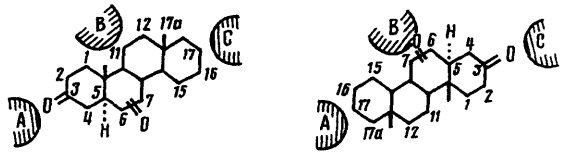
			6α	4	6α(3-CO → 3β-OH)	3	

reverse manner, because its 3α-hydroxy-derivative, having a hydroxy-group with an unfavourable orientation for binding to the site C, is formed initially. It is hydroxylated with the formation of a multicomponent mixture of unidentified products. The latter result probably justifies a general conclusion concerning the hydroxylation of steroids. If the structure of the substrate does not promote effective binding to the enzyme, then the latter is achieved with participation of molecules oriented in different ways, which leads to a non-uniform hydroxylation process or reduction of the keto-groups.

In contrast to 5α-androstanes, the 3,6- and 3,7-diketones of which are hydroxylated by *R.n.* in 16α- and 16β-positions, the corresponding homoanalogues form 17*a*α-hydroxy-products.[81] The authors suggest that the above *D*-homosteroids are hydroxylated by the reverse procedure at the site A, the formation of 16α-hydroxy-5α-androstane-3,6-dione is a consequence of the same hydroxylation pathway, while the 16β-epimer is formed in the normal way by transformation at the site C, provided, of course, that the "twisted" forms of the molecules do not participate in the process (Scheme 18).

Scheme 18

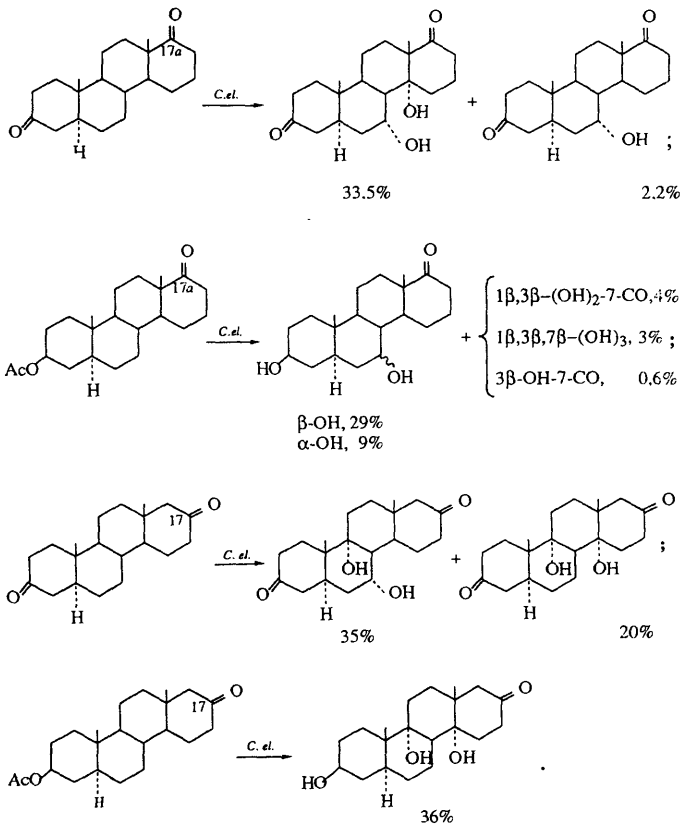


normal reverse

Unfortunately there have been no quite so systematic studies on the hydroxylation of *D*-homo-5α-*H*-androstanes by other cultures. However, one should note the different behaviour of the dihydroxylating *C.d.* culture in relation to 5α-*H*-androstan-17-one (Table 3) and its *D*-homoanalogue (Table 4): the 1β,6α-dihydroxylation in the former case and preferential trihydroxylation (7β,12β,15α- and 1β,7β,15α-) in the latter.

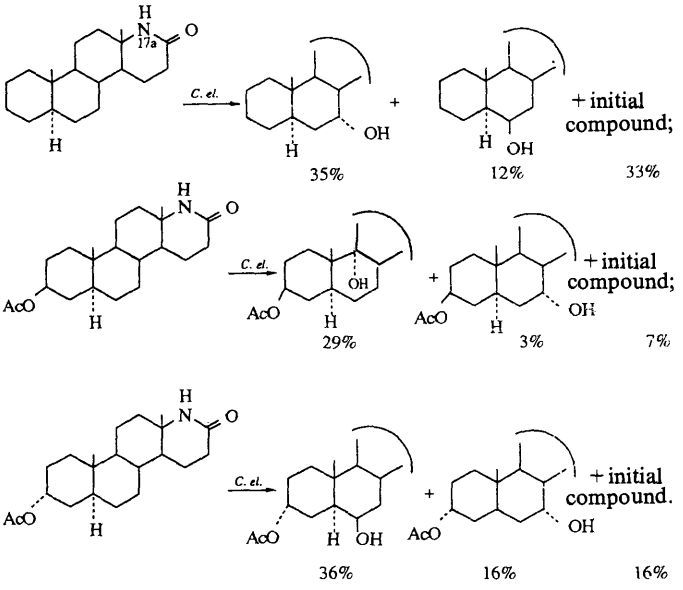
The existing, albeit few, results for the hydroxylation by the *C.el* culture of two pairs of *D*-homo-5α-*H*-androstanes 3,17-disubstituted by oxygen-containing groups (Table 4) and their comparison with data for the oxidation by the same culture of the corresponding 5α-*H*-androstane analogues (Table 2) can also be interpreted within the framework of the hydroxylation model mentioned above. The striking change, particularly notable in the series of 17*a*-*D*-homoanalogues, in the site at which *D*-homo-5α-*H*-androstan-17 (or 17*a*)-ones are hydroxylated on replacement of the 3-oxo-group by the 3β-acetate group, hydrolysing during the reaction, is noteworthy (Table 4, Scheme 19).

Scheme 19



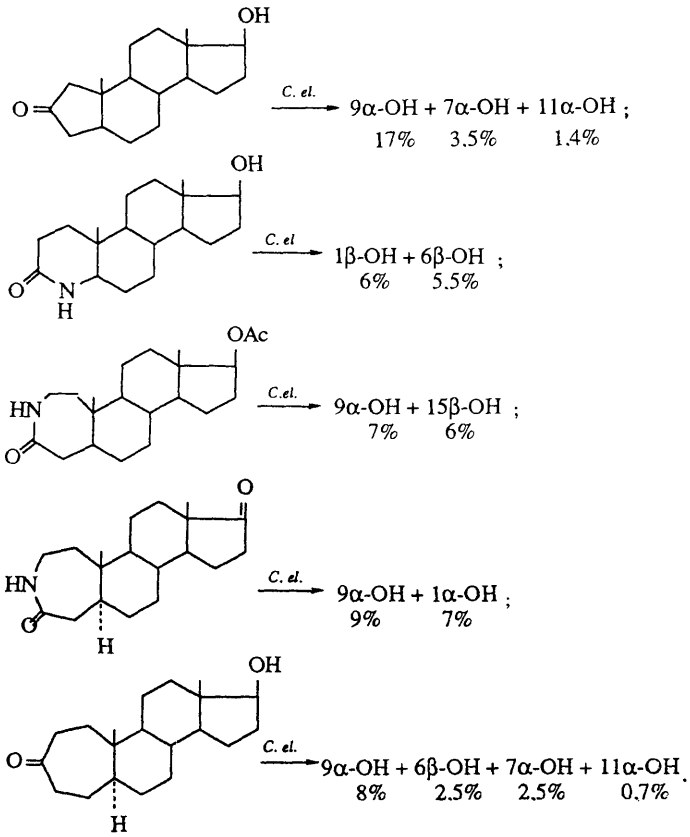
These data demonstrate convincingly also a significant dependence of the specificity of the hydroxylation on the position of the keto-group in the *D* ring. Thus, whereas the main product of the incubation of 3β-acetoxy-17*a*-*D*-homoketone is the 7β-hydroxy-derivative, the transformation of its 17-oxo-analogue affords preferentially the 9α,14α-dihydroxy-derivative. We may note that the introduction of a nitrogen atom in the 17*a*-position in *D*-homo-5α-*H*-androstan-17-one probably inhibits the 14α-hydroxylation process catalysed by this culture. Thus, only monohydroxylation, preferentially in the 9α-position, has been observed for 3β-acetoxy-17*a*-aza-*D*-homo-5α-*H*-androstan-17-one (Scheme 20), in contrast to its carbo-analogue (Scheme 19).[90,92]

Scheme 20



The influence of substitution at C(3) on the specificity of hydroxylation can be clearly traced in relation to the transformation of 17*a*-aza-5α-*H*-androstanes by the *C.el* culture. A change in the structure of the *A* ring of 5α-*H*-androstanes introduces no less significant changes into the specificity of the hydroxylation of the structure. In a series of studies by Crabb and co-workers,[86–96] the influence of the *A* and *D* rings on the hydroxylation by the *C.el.* culture was investigated. Analysis of these data did not lead to the discovery of definite correlations. One can only note that the *A*-nor-, *A*-homo-, and aza-*A*-homo-5α-*H*-androstanes, whilst exhibiting a tendency towards monohydroxylation (preferentially in the 9α-position), are nevertheless transformed with a low degree of conversion regardless of the substitution in the *D*-ring (CO or OH group) (Scheme 21). In contrast to *C.el.*, the *A.o.* culture hydroxylates *A*-homo-3,17-diketone at the site typical for this micro-organism, forming the 11α-hydroxy-product in 58% yield.[93]

Scheme 21



VI. Hydroxylation of 5α-*H*-pregnanes

The virtually specific use of 5α-*H*-pregnanes in the synthesis of corticosteroids probably determined the choice of the hydroxylating microorganism and substrates, the range of which is extremely limited compared with 5α-*H*-androstanes. In the series of 5α-*H*-pregnanes, studies have been made on cultures known to possess the ability to hydroxylate Δ^4-3-oxosteroids in the following positions: 11β-(*Curvularia, Cunninghamella, Tieghemella*), 11α-(*Rhizopus, Aspergillus*), and 12β-(*Calonectria decora*).[2,6,11] Among the 5α-*H*-pregnanes, the 9α-hydroxy-derivatives have also been obtained,[118–122] but this type of transformation should be considered separately, because it is effected by bacteria and, in contrast to hydroxylation by fungi, takes place as a stage in the microbiological cleavage of the steroid molecule after the introduction of the Δ^4-3-oxo-group.[2,6–9]

The introduction of a hydroxy-group in the C(9)-, C(11α)-, and C(12)-positions ensures their subsequent transformation into the 11β-hydroxy-derivatives by chemical methods. On the basis of the same practical considerations, 3β-hydroxy- and most frequently 3-oxo-5α-*H*-pregnanes have been mainly investigated as substrates. Studies on compounds of this series are not quite so fundamental as those on 5α-*H*-androstanes and the results summarised in Table 5, do not reveal a rigorous correlation in the enzyme–substrate interaction. However, a few systematic studies on the substrate specificity of a number of cultures are of undoubted interest.

Continuing the studies on the enzyme–substrate interaction, Jones et al.[35] turned their attention to compounds of the pregnane series assuming undoubtedly that, when the side chain is capable of rotation, certain corrections may be applied to the model constructed on the basis of data for the androstane series. They investigated the set of microorganisms most effective in the transformation of 5α-*H*-androstanes: *A.o.*, three Rhizopus species, *C.d.*, and *D.r.*[35] Unfortunately, not having at their disposal such a variable set of substrates as in the androstane series, the authors were forced to restrict their studies to 20-oxo-5α-*H*-pregnanes substituted in the 3-, 7-, and 11-positions by oxygen-containing groups (Table 5). Owing to the lack of quantitative data on the transformation of substituted 20-oxopregnanes by the *A.o.* culture, only a qualitative analysis of the results is possible. 5α-*H*-Pregnane is hardly transformed by *A.o.* or a complex mixture of unidentified products is formed. On incubation with 3,20-dioxopregnane, the transformation proceeds via the pathway usual for this microorganism with formation of the 11α-hydroxy-product. However, on incubation with its 3β-hydroxy-analogue, hydroxylation in the 1β-position, atypical for *A.o.*, is observed after the introduction of the 11α-hydroxy-group.

After prolonged incubation (6 days), 3β-hydroxy-5α-*H*-pregnan-20-one affords a mixture of the 1β,11α-dihydroxy- and 11α-monohydroxy-derivatives, the dihydroxy product being formed not synchronously but consecutively via the 11α-monohydroxy-product (Table 5). It has been noted[25] that 1β,11α-dihydroxylation is characteristic of 16β-methyl-Δ^{16}- and 16α-,17α-epoxy-analogues of 3β-hydroxy-5α-*H*-pregnan-20-one, but is not observed in the case of their 17α-hydroxy- and 16-methyl-Δ^{16}-derivatives. The behaviour of the 2,20- and 3,20-diketones[25] derived from 5α-*H*-pregnane contrasts sharply with that of the 3β-hydroxy-analogues, affording exclusively the products of 11α-monohydroxylation. Here it is noteworthy that the corresponding Δ^4-3-oxo-analogues are converted quantitatively into the 6β,11α-dihydroxy-derivatives.

A remarkable result has been achieved by hydroxylating the steroid alkaloids funtumidine (3α-NH_2) and funtumine (3α-NH_2, 20α-OH), which are hydroxylated by *A.o.* in the 12β- and 11α-positions.[98] It follows from the results that the nature and stereochemistry of the substitution at C(3) affect extremely significantly the hydroxylation of 5α-*H*-pregnanes by the *A.o.* microorganism.

The *C.d.* microorganism dihydroxylates 3-oxo- and 3β-hydroxy-20-oxo-5α-*H*-pregnane in the 12β,15α-positions. When the C(12) atom is blocked by the 11α-hydroxy-group, the attack is directed exclusively to C(15) and a similarity is thus manifested with the behaviour of this culture in the 5α-*H*-androstane series. The stability of this type of specificity of hydroxylation has been observed for various substrates of the pregnane series regardless of the presence or absence of the Δ^4- and Δ^5-double bonds and even the junction between the *A* and *B* rings.[100,102] The ability of the *C.d.* culture, indicated in Scheme 22, to effect, together with hydroxylation, the isomerisation of 3-hydroxy-Δ^5-analogues to the Δ^4-3-oxo-derivatives is striking.

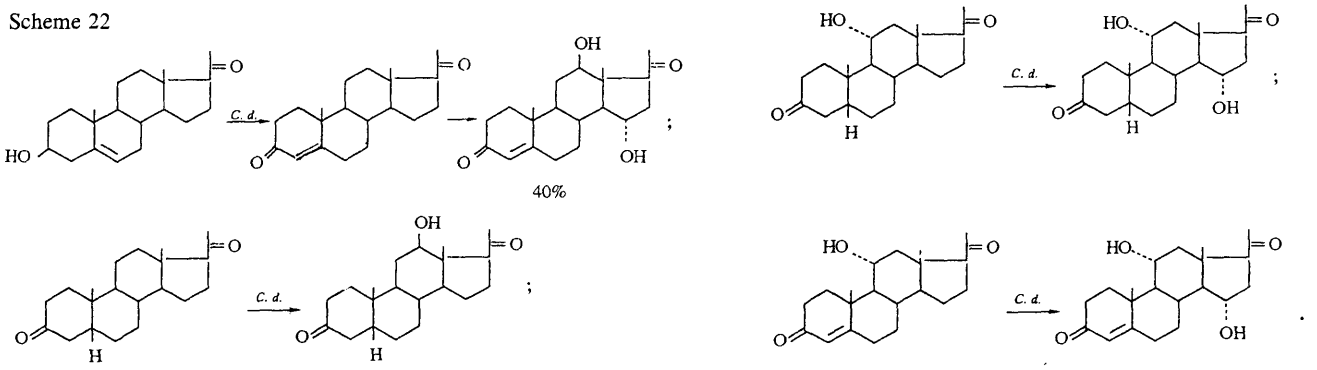
Notation. Incubation of the steroid dissolved in ethanol for 24 h (*), 6 days (**), 2 days (+), and 4 days (++).

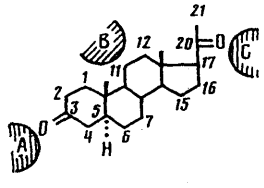
Scheme 22



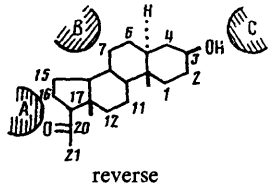
A surprising feature of *C.d.* is the 11α-hydroxylation of 3α,6α-dihydroxy-substituted derivatives, uncharacteristic of this microorganism, which is manifested only in the 5β-*H*-pregnane series.[101] Earlier data indicating 15β-hydroxylation by the *C.d.* culture[103] must be regarded as erroneous.

Three species of the Rhizopus bread fungi, namely *R.a.*, *R.c.*, and *R.n.*, have been investigated as regards the hydroxylation of 5α-*H*-pregnanes. The differences between these cultures are similar to those observed for 5α-*H*-androstanes[23,24] but are less appreciable. A tendency towards the degradation of the side chain is observed in the transformation effected by *R.n.* Analysis of the results presented in Table 5 indicates a distinct tendency of this microorganism to effect the preferential 11α-hydroxylation of 3-ketones derived from 5α-pregnane and the 7β-hydroxylation of 3β-hydroxy-5α-*H*-pregnanes: a deviation is observed only for the 3β-hydroxy-Δ^{16}-analogue, which is attacked by hydroxylase not only in the C(7) position (from the α-region) but also in the allylic 15-position. The hydroxylation in the 12β-position on incubation with 3β-hydroxy-pregnanolone is atypical for *R.n.*[35] Murray and Peterson[55] pointed out in an earlier patent that *R.n.* hydroxylates this compound, as well as its 3,20-dioxo-analogue, in the 11α-position. The general similarity in the differentiated behaviour of 3-oxo- and 3β-hydroxy-derivatives of 5α-*H*-pregnanes and 5α-*H*-androstan-17(or 16)-ones indicates probably the possibility of using the enzyme–substrate interaction model in the 5α-*H*-pregnane series, taking into account, naturally, the stereochemical possibilities of the side chain and the conditions in the binding of the 20-oxo-group (Scheme 23):

Scheme 23



normal



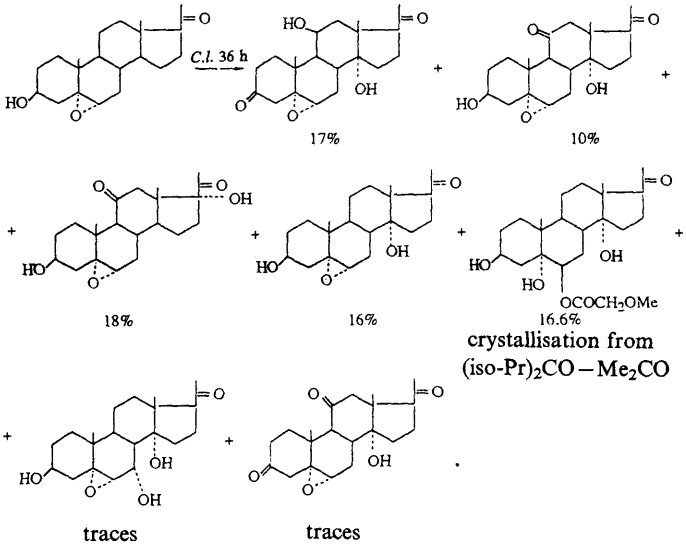
reverse

In constrast to 5α-androstanes, which are hydroxylated in the 9α-position by *C.el.*, *D.c.*, *A.r.*, *W.g.*, and *R.a.* cultures (Tables 2 and 4), only the *Circinella* sp. strain introduces the 9α-hydroxy-group into 5α-*H*-pregnanes.[67] This property is also manifested in relation to Δ^4-3-oxopregnane.[123] The series of data presented in Table 5 for transformations involving the 11α-position in 3β-hydroxy-5α,6α-disubstituted pregnanes, effected by the *C.l.* microorganism considered in the preceding context, shows that, when hydroxylation at C(7), (5,6-α-epoxy- or 6β-fluoro) is blocked, the reaction takes place exclusively at the C(11) atom. The same result casts doubt on the official view that the hydroxylation of 3β-hydroxy-derivatives of pregnanes unsaturated in the *A* ring is impossible.

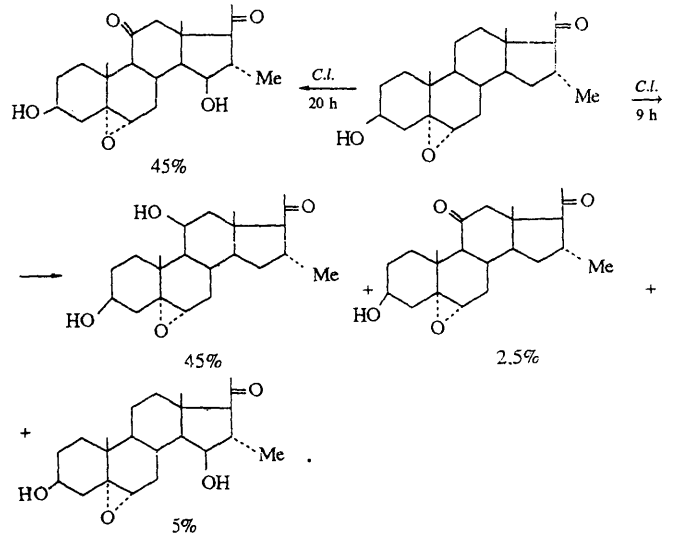
All the results presented in Table 5 concerning the transformation of 5,6-epoxides by *C.l.* are based on data obtained after brief incubation designed to achieve the maximum yield of the target product — 5,6α-epoxy-11β-hydroxy-5-pregnanones. Subsequent studies showed that this reaction proceeds with parallel formation of 14α-hydroxy-derivatives[104] and that prolonged incubation leads to a range of products[105] in which the hydroxylation site is now determined by the 11β- and 11α-hydroxy-groups and the 11-oxo-group (invariably formed by the subsequent oxidation of the 11β-hydroxy-group) already present in the molecule.[2,6]

For example, Scheme 24 presents the mixture of products obtained on transformation of 5,6α-epoxy-3β-hydroxy-5-pregnan-20-one by *C.l.* over a period of 36 h, in which the formation of 7α-hydroxy- and 17α-hydroxy-derivatives can be regarded, according to the authors, as a consequence of the directing effect of the 14α-hydroxy- and 11-oxo-groups introduced into the molecule beforehand,[105] while the formation of the 11,14α-disubstituted derivatives may be regarded as a consequence of the mutual influence of these groups. We shall show in relation to yet another example that the transformation time is an extremely important parameter in reactions of this type.[105] Here too the authors assume that the final oxidation product — the 15β-hydroxy-11-oxo-derivative — is formed as a result of the subsequent oxidation of both minor products (Scheme 25).

Scheme 24

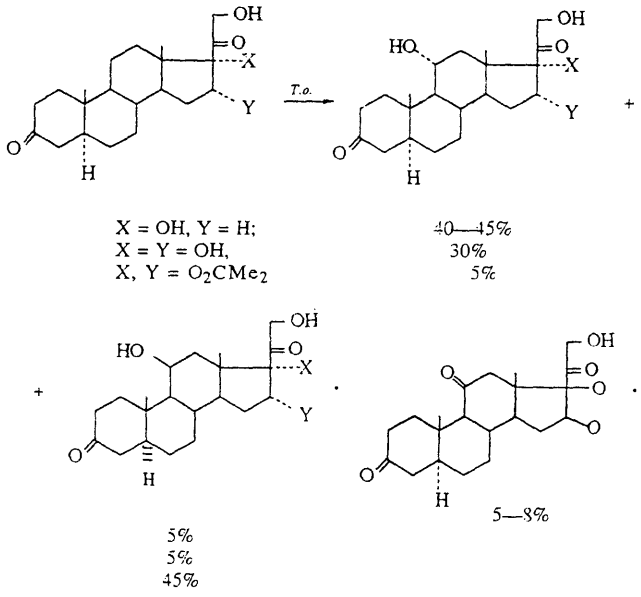


Scheme 25



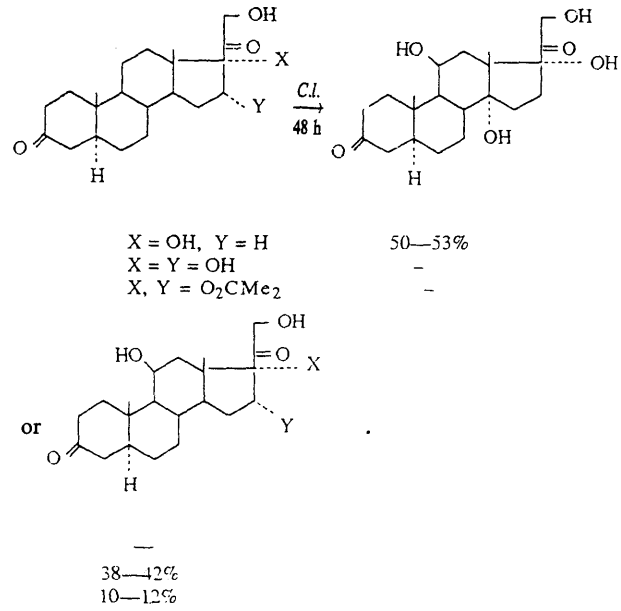
The *D* ring-substituted compounds are effectively transformed by *C.bl.* The 17α-hydroxy-, 16α,17α-dihydroxy-, and 16α,17α-dioxyisopropylidene-3,20-dioxo-5α-pregnanes are substituted preferentially in the 11α-position, the presence of an oxygen-containing 16α-substituent in the α-region of the steroid molecule stimulating the competitive 11β-hydroxylation (Table 5). The *T.o.* culture behaves similarly, but in this case the 16α,17α-acetonide group blocks 11α-hydroxylation almost completely, promoting 11β-hydroxylation (Scheme 26).

Scheme 26



All three types of substrate illustrated in Scheme 27 are hydroxylated by *C.l.* in the 11β-position, whereas in the case of the 16-unsubstituted compound (X = OH, Y = H) the subsequent 14α-hydroxylation is observed, being probably inhibited in the last two cases by the oxygen atom at C(16). Thin-layer chromatographic analysis of the reaction mixture after incubation of 17α,21-dihydroxy-5α-pregnane-3,20-dione for 24 h demonstrates the presence of 3–5% of the initial substrate, 15 and 20% respectively of the 14α- and 11β-monohydroxy-derivatives, and 30–35% of the 11β-,14α-dihydroxy-derivative, from which it follows that the 11β- and 14α-hydroxylation reactions take place consecutively. One must not fail to note that *C.l.* transforms cortexolone into a mixture of 11β- and 14α-monohydroxy-derivatives (67 and 15% respectively).[107] The authors conclude from this that 5α-*H*-steroids are sterically less hindered than their Δ^4-3-oxo-analogues. Because of this, the introduction of a hydroxy-group in one of the positions does not rule out the possibility of their reorientation relative to the enzyme, which leads to the formation of 11β,14α-dihydroxy-compounds. The authors therefore believe[107] that 16α,17α-dihydroxy-5α-pregnan-3-one is more susceptible to transformations by *C.bl.* and *T.o.*, affording 11α-hydroxy-groups in 65 and 30% yields respectively, while its Δ^4-3-oxo-analogue is not transformed by any of the cultures discussed.

Scheme 27



We do not find this view convincing; an explanation of the observed facts should probably be sought in the general model of the substrate–enzyme interaction involving pregnanes, in which the oxygen-containing functional group in the *D*-ring (its nature, position and stereochemistry) should not only participate but should also compete with the 20-oxo-group for geometrically or stereochemically favourable type of binding.

Analysing the data in Table 5 from the standpoint of Jones's model of the enzyme–substrate interaction, one may note that on the whole they agree with the postulate that three binding and simultaneously hydroxylating sites function on the surface of the enzyme. Indeed the pregnane monoketones, which can combine with the enzyme via only one centre, are hardly transformed, while in the presence of two terminal oxygen-containing groups in the steroid molecule hydroxylation at the site B takes place. In the presence of a second oxygen-containing substituent at the site B, hydroxylation can occur at the site A provided that it is not bound to a steroid molecule. When there are three oxygen-containing substituents, corresponding to the sites A, B, and C, in this case the transformation products can either not be isolated or, as happens when 11α-hydroxy-3,20-dioxopregnane is acted upon by *C.d.*, hydroxylation is apparently catalysed by one of the binding sites (Scheme 23).[102]

One should add to the foregoing that the transformation of 5α-*H*-pregnanes has also been achieved with the aid of streptomycetes of unidentified species and *S. roseochromogenes*, which introduce the 16-hydroxy-group into 3-oxo- and 3β-hydroxy-5α-*H*-pregnanes,[108,109] as in the case of compounds with the Δ^4-3-oxo-group. The mechanism of the hydroxylation of the *D* ring by these representatives of the Schizomycetes class as well as 9α-hydroxylation by *Rhodococcus*[118–122] probably differs from the mechanism proposed by Jones and co-workers for fungi.

Analysis of the data described makes it possible to trace the dependence of the specific capacity of microorganisms for hydroxylating 5α-*H*-steroids on the type of steroid and on the nature of the substituents in it (oxo-, hydroxy-, and acetoxy-groups), their

positions and stereochemistry, and their number. This makes it possible to achieve specific hydroxylation of steroids in a particular position within the molecule. Numerous examples, summarised in the tables, show that the saturation of the rings of the steroid molecule is not an obstacle to effective hydroxylation. This means that there is a possibility of altering the sequence in which 5α-*H*-steroids are converted into biologically active preparations, involving their initial hydroxylation and subsequent dehydrogenation of the *A* ring. The reverse and generally accepted sequence, involving the hydroxylation of the Δ^4-3-*H*-oxo-(or $\Delta^{1,4}$-3-oxo)-derivatives obtained initially from the 5α-*H*-steroids, is the subject of the next part of the review, in which emphasis is laid on the authors' own studies on the use of the *Rhodococcus* culture which catalyses both these processes.

Pesticides in the environment

N N Mel'nikov
Institute of Chemical Plant Protecting Agents

ABSTRACT. The most important studies on the behaviour of six classes of pesticides in objects within the environment are described systematically and discussed. General schemes for the metabolism of certain pesticides in animal organisms, plants, and the soil are presented. The principal requirements which must be met by modern pesticides and the conditions for their safe use are characterised.

The bibliography includes 250 references.

I. Introduction

Nature began to be acted upon by human society in the period when human activity changed from food gathering to farming and cattle rearing. As a consequence of the vigorous development of industry in the XXth century, the pollution of the environment proceeded most vigorously. In a simplified way, the term environment is understood to imply the upper part of the lithosphere (in the main soil) together with the biosphere and cosmic space surrounding the terrestrial globe and acting upon vital processes. The biosphere comprises all living organisms, including animals, plants, microorganisms, as well as the residues from these organisms at different stages of their decomposition and conversion into the simplest organic and inorganic compounds. The atmosphere, the hydrosphere, and the soil are included here. An enormous number of organisms live in these spheres. For example, according to the data of different investigators, one hectare of soil contains 1000–7000 kg of bacteria, 100–1000 kg of microfungi, 10–300 kg of algae, 5–10 kg of protozoa, 1000 kg of arthropods, and 300–1000 kg of earthworms.[1]

In connection with the considerable pollution due to man's economic activity, the problem of the protection of the environment has become urgent in our time.[2–5]

The scale and nature of the pollution of the environment by various products of anthropogenic activity can be inferred even from the following examples: as a result of the combustion of coal and brown coal, about 3000 tonnes of mercury enter the atmosphere annually and, when account is taken of the waste from different branches of industry and medical services about 10000 tonnes of mercury enter the environment.[6–10] Since mercury is able to accumulate in living organisms and can be converted into the ethylmercury ion, which is highly toxic and carcinogenic, it constitutes a serious danger to man.[10–12]

Many marine and river organisms already contain considerable amounts of mercury and its concentration increases every year. In view of this, the use of mercury compounds as pesticides in economically developed countries has virtually ceased despite their considerable value.

A second important pollutant of the environment is lead, which is known to exhibit a psychotropic activity. Lead compounds enter the environment in large amounts with the exhaust gases of automobiles employing petrol containing lead compounds as anti-knock additives.[13] In addition, polyhalodibenzofurans and polyhalodibenzo-*p*-dioxins, which exhibit teratogenic and blastomogenic activities, affect the skin, and are acutely toxic,[14] as well as carcinogens such as benzopyrene and benzanthracenes[18] enter the environment with exhaust gases. According to the results of some investigators,[15] the amount of the above compounds formed per kilometre of highways is 1.5 μg. We may note that the use of lead anti-knock agents has continued in many countries to this day, as a result of which lead salts and many organochlorine compounds accumulate in the environment.

One should also note that the accumulation of heavy metals such as cadmium[8,15] and chromium[17] in the environment has likewise increased.

Nitrogen and sulphur oxides, which are the products of the combustion of various types of fuel containing sulphur, are fairly serious pollutants.[19] Polycyclic hydrocarbons with blastomogenic activity are known to be formed on combustion of wood, coal, and brown coal. We may note that tobacco smoke is also a pollutant, since it contains about 800 different substances, including extremely toxic aromatic and heterocyclic compounds.

The pollution of the environment by arsenic compounds is significant.[10,20,20a] Some of them were used until the end of the 1940's as agents combating agricultural pests and also for the protection of wood against rotting. Organic arsenic compounds also continue to be used as herbicides at the present time.[21] Arsenic compounds can penetrate into plants and can migrate via their vascular systems, which frequently leads to the pollution of the products of the cultivation of plants. The soil of many countries as well as the world ocean contain nowadays very large amounts of arsenic compounds.[20,22] Up to 8 million tonnes of petroleum and petroleum products enter the world ocean annually.[22]

Polychlorobiphenyls, used in the electrical industry, as plasticisers, and in other branches of industry, polychlorodibenzofurans and polychlorodibenzo-*p*-dioxins, formed mainly on chlorination of various products and on combustion of refuse and industrial waste are also pollutants.[23] The latter compounds are so stable that they withstand heating above 600 °C.[14] Certain polychlorodibenzo-*p*-dioxins are extremely toxic and exhibit teratogenic and carcinogenic

activities and affect the skin. Thus LD_{50} for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin in relation to monkeys is only 70 μg kg^{-1}.[14] The high solubility of the above compounds in lipids leads to their accumulation in human and animal fatty tissue and also in human milk.[23,24] Polychloro-derivatives have been detected in human milk in many countries. All these compounds are extremely stable in objects within the environment and can persist for more than 10 years even under tropical conditions.

We may point out that about 55000 chemical compounds have now been detected in objects within the environment. According to our calculations, about 500 million tonnes of different products of anthropogenic activity are discharged into the environment annually.

Pesticides are physiologically active substances and therefore special requirements ensuring adequate safety in their practical application must be imposed on them. Altogether a little more than 1 million tonnes of pesticides are used annually. As the relevant data accumulate, the requirements which must be met by pesticides become more stringent. The fraction of pesticides in all the pollutants introduced by man into the environment is ~0.2%, which is less almost by a factor of 5 than the fraction of detergents.

Standards which must be satisfied by modern pesticides have been established in terms of the following parameters: persistence characterised by the half-life (or the total decomposition into simplest chemical compounds safe to man and to useful organisms); minimum chronic toxicity for man and animals; the absence of mutagenic, carcinogenic, and teratogenic activities;[25,26] the absence of negative effects when small doses of the preparations are consumed with food products by man and animals; the absence of cumulative activity; selectivity of action in relation to useful organisms; low toxicity for useful hydrobionts and many others.[27]

Together with acute and chromic toxicity and the existence of other remote effects resulting from the action of the preparation on man, animals, birds, and other useful organisms, the persistence of pesticides, which depends on their chemical stability and the rate of their metabolism in objects within the environment, is very important. The type of metabolism is also significant, since it determines the safety of the preparation.[28] The following formula has been proposed to compare the ecological stresses exerted by different preparations:[29]

$$ES = (C/LD_{50})H,$$

where ES is the ecological stress per hectare, C the norm set for the consumption of the preparation (g ha^{-1}), H the half-life (persistence) of the preparation in weeks, and LD_{50} the acute toxicity for the given organism. Naturally the above formula does not yield an absolute value, but it makes it possible to obtain comparative characteristics of individual preparations.

Despite the vigorous propaganda by the "greens" against the use of pesticides, the scale of their practical employment has continuously expanded, which is indicated by the data in Table 1. However, by virtue of the systematic improvement of the range of preparations, their tonnage has significantly decreased. This is associated with the fact that the new preparations, developed in recent years, have extremely low consumption norms which are tens of times and in certain cases hundreds of times lower than the consumption norms of the pesticides used previously. There has been not only a growth of the requirement for pesticides but also a decrease in the employment of obsolete preparations and preparations with large consumption norms and a high persistence. Thus there has been a sharp decrease in the requirement for all organochlorine insecticides and in the economically developed countries their use has ceased altogether. For example, DDT is used only in China, India, and in certain countries of Asia and Africa. The use of herbicides such as sodium trichloroacetate and dalapon has been reduced.

Table 1. The amounts of pesticides sold in 1972 and 1989 and the forecast for 1995 in millions of US dollars.[30]

Group of pesticides	1972	1989	1995 (forecast)
Herbicides	4160	9500	10940
Insecticides	4090	6200	7110
Fungicides	2525	4490	5055
Plant growth regulators	375	800	1080
Nematocides and fumigants	410	510	575
Total	11560	21500	24760

New insecticides with consumption norms up to 20 g ha^{-1},[31,32] herbicides with consumption norms of 10–50 g ha^{-1},[33–35] and fungicides with consumption norms up to 150 g ha^{-1} [36–38] have appeared and the use of insect pheromones has also accelerated,[39] which makes it possible to reduce significantly the consumption of insecticides.

Data on individual most important classes of compounds are presented below.

II. Chlorohydrocarbons

Among organochlorine insecticides, preparations such as DDT, hexachlorocyclohexane, aldrin, dieldrin, heptachlor, endrin, chlordan, mirex, kepone, endosulfan, and certain others have found practical applications in agriculture, industry, and the health service. DDT has been used on the largest scale. During 50 years (since the discovery of its insecticidal properties), approximately 5 million tonnes have been used. Hexachlorocyclohexane is employed on a somewhat smaller scale and preparations obtained by diene synthesis are used in still smaller amounts. Their accumulation in the environment is therefore significantly smaller than that of DDT.

Despite the negative attitude of many specialists to DDT, one cannot fail to note its positive role in health protection and in agriculture. In agriculture, DDT replaced extremely toxic arsenic compounds and in health protection measures it saved more than 15 million people from malaria and prevented epidemics of typhus, encephalitis, sleeping sickness, elephantiasis, the plague, tularemia, and others. However, one cannot close one's eyes also to the negative properties of this preparation, which include primarily a high persistence in a wide variety of objects in the environment and in living organisms. DDT can accumulate in the tissues of man, animals, birds, and fish.[50] In particular, DDT has been detected in human blood and fatty tissues,[40–45] in human[46,47] and cows'[48] milk, and in food products.[49]

The behaviour of organochlorine insecticides in aqueous ecosystems[51-54] and in the eggs and flesh of wild and domestic birds[54-56] has been studied. Table 2 presents data on the contents of DDT and its first metabolite—dichlorodiphenylethylene (DDE)—in the fatty tissues of inhabitants of different countries.[40]

Table 2 shows that the greatest amounts of DDT and DDE are present in the fatty tissues of the inhabitants of those countries where DDT is widely used. We may note that the content of DDT has diminished in the tissues of the inhabitants of those countries where its use has been stopped.

Table 2. The contents of DDT and DDE in the fatty tissues of the inhabitants of different countries (mg/kg of fat).

Country	Year	DDT	DDE

Czechoslovakia	1980–81	12.33	8.74
Japan	1984	1.99	1.85

The bioconcentration of DDT in various objects in the environment has also been investigated in both natural and model experiments.[57,58] The bioconcentration of DDT in biological objects is to a large extent associated with the type of its metabolism,[59] in which hydrophobic metabolites, accumulating in lipids, are formed in the first place.

Hexachlorocyclohexane accumulates in much smaller amounts in the fatty tissues of man and in milk, which is associated not only with the smaller scale of its use but also with its significantly smaller persistence.[40] Among all the isomers of hexachlorocyclohexane, the β-isomer accumulates in greatest amounts. It is distinguished not only by a lower volatility but also by a greater chemical stability.

Endosulfan,[60] toxaphene,[61] and other organochlorine insecticides[40] accumulate in objects in the environment in much smaller amounts. In view of the sharp decrease in the use of organochlorine insecticides, their content in the environment is being gradually reduced.

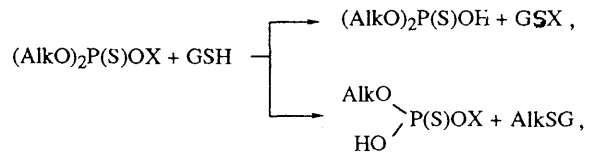
The effect of organochlorine pesticides on the soil microflora has been studied.[62-64] It has been established that, when aldrin and certain other insecticides are systematically applied, microorganisms are suppressed and the pesticide is gradually degraded.[64]

Despite the appreciable contamination of food products by organochlorine insecticides, in most cases their content in milk and other food products is within the limits of the norms established by the World Health Organisation.[65,66]

It is of interest that methoxychlor (I), whose metabolism leads to the formation of hydrophilic products, does not accumulate in the organisms of mammals and hardly contaminates milk.[67] Furthermore, methoxychlor is less toxic by an order of magnitude than DDT (for many arthropods, it is less toxic by only a factor of 1.5 than DDT).

$$CH_3OC_6H_4CHC_6H_4OCH_3$$
$$\quad\quad\quad

formation of diesters from triesters, interaction with glutathione transferase, for example[68]



degradation of the ester part of the molecule containing the carboxy-group, and the formation of conjugates with carbohydrates in plants, with glucuronic and humic acids in the soil, and with sulphates in mammalian organisms.

Some of the reactions listed above are illustrated below by individual examples. We may note that the reactions of organophosphorus compounds depend not only on the structure of the phosphorus-containing part of the molecule but also on the structure of the organic groups linked to the phosphorus atom.[68]

The methyl esters of phosphorus acids are comparatively effective alkylating agents, which also leads to their degradation and conversion into compounds with an extremely low toxicity.

About 100 organophosphorus pesticides are used nowadays on different scales.[69] In the present review, it is impossible to characterise the behaviour in the environment of all the organophosphorus compounds employed, so that only substances used on a fairly wide scale will be described.

Among phosphoric acid esters these are dichlorophos (II) and chlorfenvinphos (III); among phosphorothioic acid esters these are metaphos (methylparathion) and thiophos (parathion) (IV), chlorpyrifos (V), diazinon (VI), fenitrothion (VII), fenthion (VIII); among phosphorodithioic acid derivatives these are phorate and terbufos (IX), phosalone (X), azinphos (XI), dimethoate (XII), thiometon (XIII), carbofos (malathion) (XIV), ninosan (XV), and also kitazin P (XVI), and acephate (XVII); phosphonates include chlorophos (XVIII) and glyphosate (XIX).

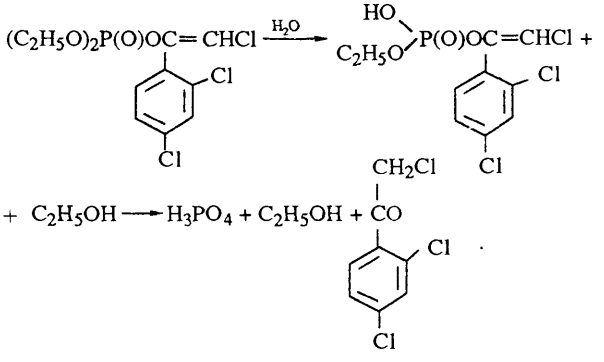
As stated above, the behaviour of pesticides in objects in the environment is influenced by numerous factors, including chemical and biological ones; the most important are the hydrolytic and oxidation reactions as well as the metabolism in various species of living organisms.

The first representative of the organophosphorus compounds listed above, namely dichlorophos, is a fairly labile substance and is readily hydrolysed by water even at comparatively low temperatures.[68,69] Thus in the tissues of the Atlantic salmon dichlorophos is not detected at all one day after entry at a water temperature of 12 °C, whilst at 4 °C only traces are found.[70] A similar picture has been observed also in milk: the preparation introduced into milk at 4–6 °C is not detected after 24 h.

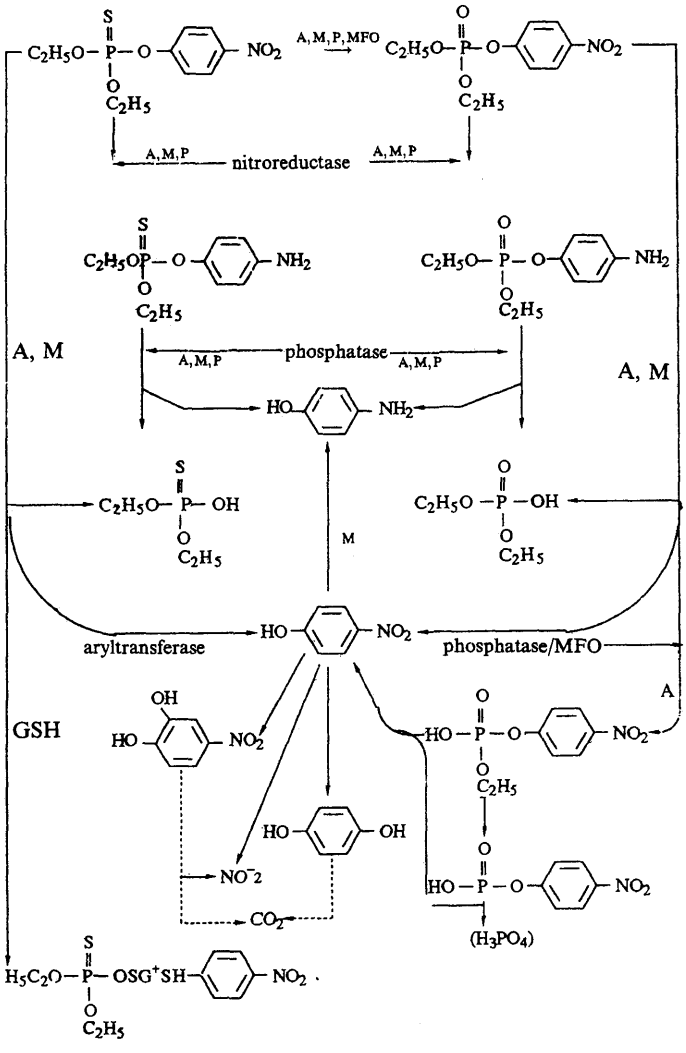
Dichlorophos decomposes to phosphoric acid and dichloroacetaldehyde and the latter is converted as a result of hydrolysis and oxidation into hydrochloric and oxalic acids.

Chlorfenvinphos decomposes in a more complex manner, forming on hydrolysis phosphoric acid and the lipophilic trichloro-acetophenone, which can accumulate in living organisms like other organochlorine compounds. For this reason, the application of this preparation is limited.



Parathion and methylparathion, whose behaviour in the environment has been studied in detail,[68,69,71–77] have found the greatest application in agriculture. The metabolism of parathion is different in different organisms, which can be clearly seen from Scheme 1.[68] We may note that the decomposition of methylparathion in the soil and other objects is significantly faster than that of parathion. Furthermore, it is less toxic and for this reason it has been successfully replacing parathion in recent years. The rate of decomposition of parathion and methylparathion depends not only on the nature of the soil, its moisture content, its content of organic substances, and the concentration of the insecticide, but also on the microflora, since different species of microorganisms will react with the preparations at different rates.[71,78]

Scheme 1

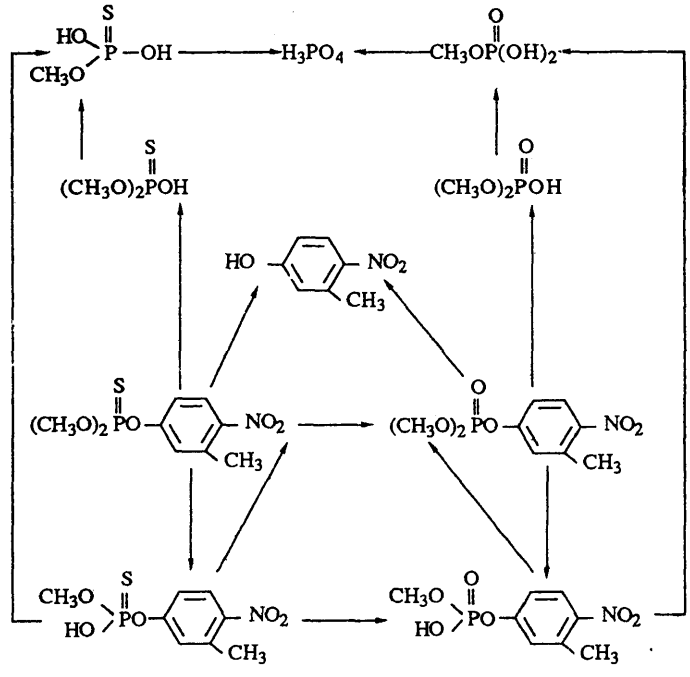


Scheme 1. Metabolism of parathion.
A = animals, M = microorganisms, P = plants, MFO = mixed function oxidases.

It is of interest to note that, in combination with toxaphene, polychlorcamphene, and oils, the duration of action of methylparathion on the cotton plant increases significantly,[77,79,80] which is apparently associated with the decrease in the rate of its hydrolysis in solutions in hydrophobic solvents such as the substances listed above. There are grounds for the assumption that a similar phenomenon may occur also in the soil. However, methylparathion decomposes in the soil in the course of 15–20 days, whilst parathion decomposes in 30–45 days, being fully converted into simple compounds (CO_2 and H_3PO_4 [71]).

We may point out that the accumulation of parathion and methylparathion in the organisms of mammals or hydrobionts has not been observed.[10,71] Special experiments on cows have shown that parathion administered in sublethal doses is almost completely eliminated from the organism in the course of 48 h.[10] The preparation does not remain in milk either.

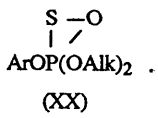
The closest homologue of methylparathion is fenitrothion, which exhibits a significantly smaller toxicity for animals compared with methylparathion.[81–83] The persistence of fenitrothion in ponds and bottom deposits,[84,85] in running water,[85] on leaves of the apple tree,[87] the poplar, and the birch,[86] and also its toxicity for fish[88] have been investigated. It has been shown that the persistence of fenitrothion is greater than that of methylparathion. The photolysis of fenitrothion[89,90] as well as its metabolism in vertebrates (mammals),[91] in the blue crab,[92] in the house fly which is resistant to the preparation,[93] and in the wheat plant,[94] as well as its oxidative dealkylation when acted upon by cytochrome P450 [95] have been studied. The general scheme illustrating the metabolism of phenitrothion in mammals is presented below (Scheme 2).



Scheme 2. Metabolism of fenitrothion in mammals.

In contrast to metabolism in mammals (rats), in which demethylation and dearylation take place, in the organisms of insects (the resistant house flies), the methyl group bound to the benzene ring is oxidised.[93] It may be that cytochrome P450 participates in this process. Many enzymes, including mixed function monoxidases, are involved in the degradation of insecticides of this type.

It has been suggested that the oxidation to oxones proceeds via a stage involving the formation of an unstable intermediate:



(XX)

We may note that soil microorganisms utilise in most cases the products of the metabolism of organophosphorus compounds as a source of carbon and phosphorus and that ultimately the majority of organophosphorus compounds decompose to CO_2 and H_3PO_4. The thione sulphur is converted into sulphuric acid, but the amount of the latter is so small that it has no practical importance as regards the acidification of the soil; in most cases the amount is only several tens of grammes per hectare.

The metabolism of fenthion is similar to that of fenitrothion,[68] but, in view of the presence of the sulphide group in the fenthion molecule, it is oxidised to a sulphoxide and a sulphone by the successive decomposition of the molecule by soil microorganisms. Fenthion is safe to a number of microorganisms and small invertebrates,[96] is moderately toxic for fish,[97] is moderately persistent in aqueous ecosystems,[98] and its toxicity is comparatively low for fungi and nitrogen-fixing bacteria and also for the little brown bat (*Myotis lucifugus*).[99]

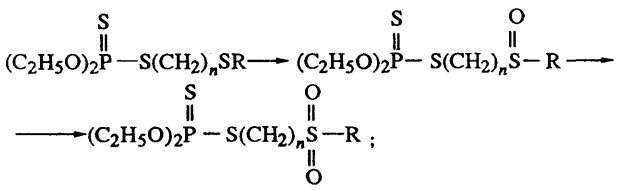
The persistence of diazinon is somewhat greater than that of the preparations described above.[100–106] Thus diazinon can be retained in organic soils for more than a year.[100] As a result of being washed out of the surface of the soil, it contaminates water bearing strata. It has been noted that diazinon is capable of being bioconcentrated by the aqueous fauna[101] but it is relatively rapidly eliminated from the organisms of fish. After 8 days, it cannot be found in the fish tissues. The metabolism of diazinon is even faster in warm blooded animals. It takes place in accordance with the general mechanism of the metabolism of phosphorothioates.[68,102,105] The principal reactions are oxidation and hydrolysis. Together with the formation of diazinonoxone derivatives, the side chains of the pyrimidine residue are oxidised at both the methyl and the isopropyl groups.[10,68,105] The main products of its metabolism in the soil are CO_2, H_3PO_4, and nitrogen. In plants diazinon also undergoes degradation. Thus, after cranberries have been treated with diazinon, the latter cannot be dectected in them after 42 days.[106]

Chlorpyrifos has similar properties.[107–118] In terms of its stability in the soil and in water, it approaches diazinon and in certain cases is superior to the latter.[107,108] The metabolism of chlorpyrifos involves, together with the hydrolysis of the ester linkages, the replacement of one or two chlorine atoms in the pyridine ring by the methylthio- and hydroxy-groups.[68,112] The hydrolysis of chlorpyrifos is fastest in an alkaline medium.[110]

It is of interest to note that phosphorothiolates (kitazin and hinosan) are hydroxylated in the aromatic ring in the course of their metabolism in plants (rice).[68]

In most cases the first product of the metabolism of organophosphorus insecticides forms conjugates with plant substances, which are sometimes fairly stable.[68] Such conjugates are obtained with carbohydrates and aminoacids. Acid sulphates are formed in animal organisms, being eliminated from them with products of their vital activity.

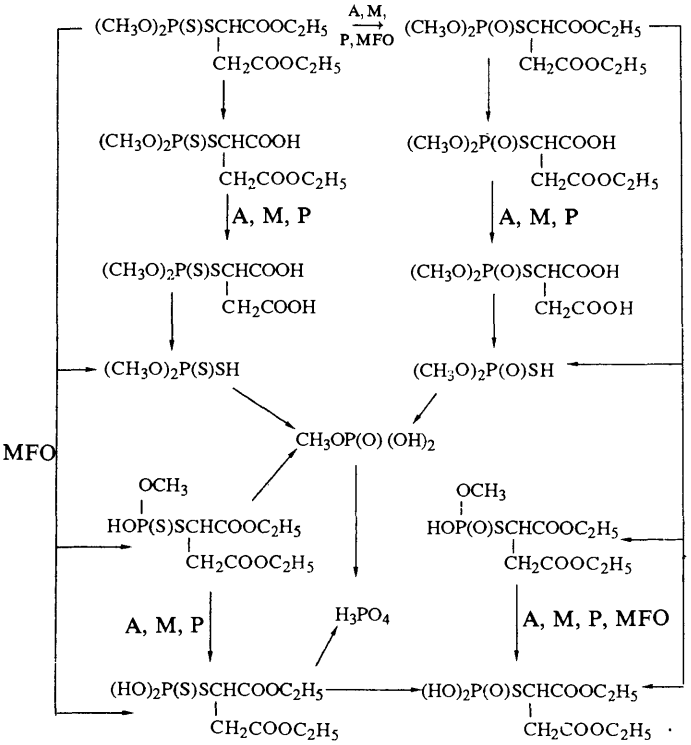
The behaviour of phosphorodithioic acid derivatives in objects in the environment depends to a large extent on the structure of the ester groups in the phosphorodithioate.[68] In this respect, the preparations phorate, terbufos, and disulfoton behave similarly.[119–125] Hydrolysis and oxidation of sulphide sulphur to the corresponding sulphoxides and sulphones are characteristic of these substances.



$R = C_2H_5$, $C(CH_3)_3$, $n = 1.2$.

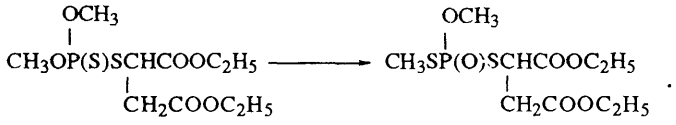
Together with the reactions described, oxidation of the thione sulphur and hydrolysis to phosphoric acid take place.[68,119] These preparations are used as soil insecticides.[121–123] Their complete degradation in the soil takes place in the course of 65–120 days, which depends to a large extent on the temperature and the nature of the soil. We may note that the preparations have a weak effect on the soil microflora.

Among phosphorodithioic acid derivatives, malathion (carbofos) has found the most extensive application as a contact insecticide.[71,126–135] A positive property of malathion is its low toxicity for mammals and its comparatively rapid decomposition in objects in the environment.[71] The metabolism of malathion is illustrated in Scheme 3.



Scheme 3. Metabolism of malathion.

Under the influence of certain inorganic substances and after prolonged heating, malathion may be converted into isomalathion, which is extremely toxic for mammals. It is sufficient to state that an admixture of 4% of isomalathion in malathion increases the toxicity of the preparation by an order of magnitude. The toxicity of malathion is also increased by an order of magnitude by an admixture of a side product of its manufacture—trimethyl phosphorodithioate.[126,131,132] The isomerisation of malathion to its toxic isomer led to the poisoning of humans in the course of its widespread application in the fight against the malaria mosquito in Pakistan.[71] The purity of the preparation used is therefore very important.

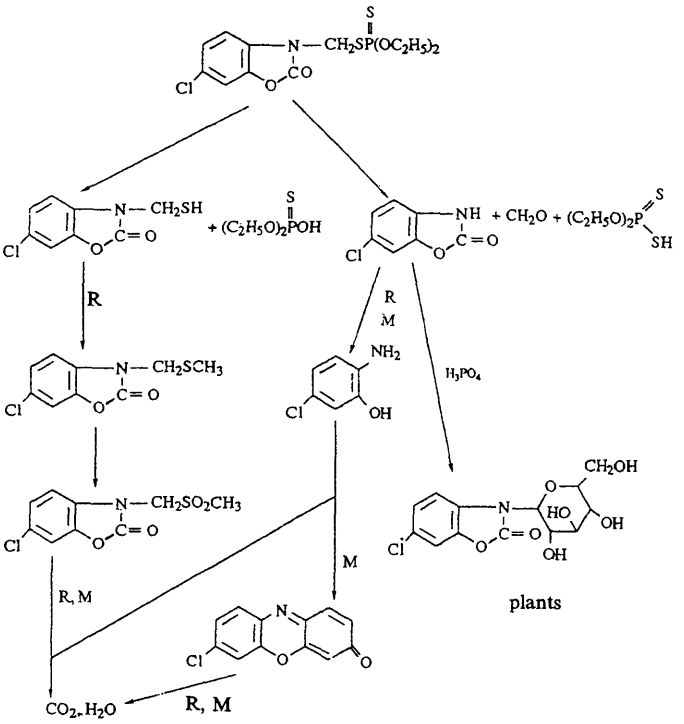


The rate of decomposition of malathion in objects in the environment is high and it vanishes rapidly from plants and animal organisms.[71,135] In the soil, malathion is also unstable and decomposes fairly rapidly. For example, in cherries, in red and black currants, and in other plants, malathion is hardly detected only 6–8 days after treatment with the preparation.[71]

Table 3. Toxicity of pyrethroid metabolites (LC_{50}) for hydrobionts (mg litre^{-1}).

Metabolite	LC_{50} (daphnia)	LC_{50} (fish)
3-(2,2-Dichlorovinyl)-2,2-dimethylcyclopropane-carboxylic acid	130	3
3-(2,2-Dibromovinyl)-2,2-dimethylcyclopropane-carboxylic acid	> 0.05	—
3-(2-Chloro-3,3,3-trifluoroprophenyl)-2,2-dimethyl-cyclopropanecarboxylic acid	100	16
3-Phenoxybenzyl alcohol	200	3–7
3-Phenoxybenzoic acid	85	13–36
2-(4-Chlorophenyl)-3-methylbutyric acid	—	10
3-Phenoxybenzaldehyde	> 0.025	—

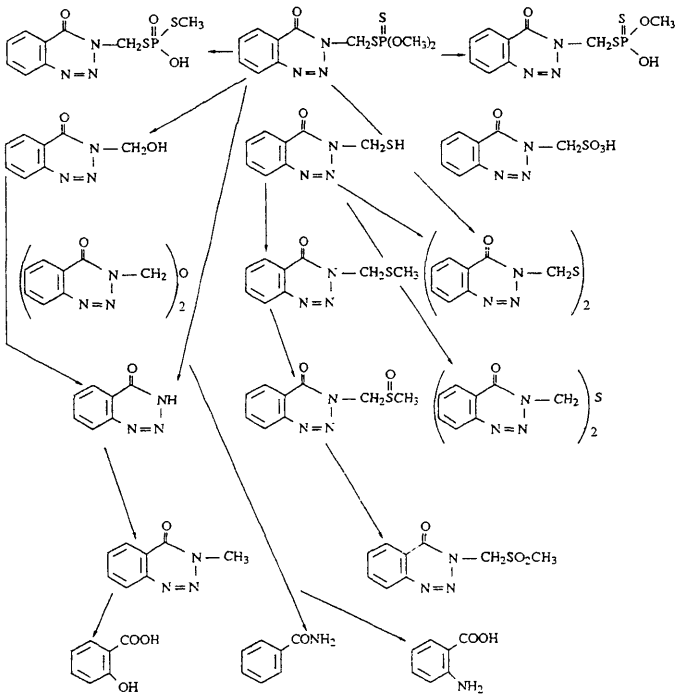
Phosalone persists in the environment for a longer time.[10] Thus it disappears from oak leaves on the twentieth day after spraying. During this period, it also decomposes in turf. Naturally, the phosalone decomposition time depends on the temperature and humidity. The higher the temperature, the faster the decomposition of the preparation. Phosalone decomposes in the soil over approximately the same period. The rate of its decomposition depends greatly on the composition and nature of the soil. However, in most cases part of the pesticide is bound firmly to the soil colloids and is included in the metabolism of organic substances.[136,137] The general direction of the metabolism of phosalone is illustrated in Scheme 4.[10,27,138]



Scheme 4. Metabolism of phosalone.
R = rats; M = microorganisms.

The final products of its metabolism in the soil under the influence of microorganisms are CO_2, H_3PO_4, N_2, etc.

Azinphos-methyl and especially azinphos-ethyl are more stable in objects in the environment. They have found fairly extensive applications in the fight against many plant pests. As can be seen from Scheme 5, even a relatively stable insecticide, such as azinphos-methyl, is almost completely decomposed by soil microorganisms.[139]



Scheme 5. Metabolism of azinphos-methyl.[139–143]

Other organophosphorus insecticides are less stable and are rapidly degraded to simple compounds.[10,27,71,68]

Among phosphonates, glyphosate, which is used nowadays in the fight against weeds, has found the most extensive application in agriculture. Numerous communications have been published on the properties of glyphosate and its behaviour in objects in the environment.[144,145]

Like all organophosphorus compounds, glyphosate decomposes almost completely in objects in the enviornment in the course of one vegetation period.[144] The decomposition products are phosphoric acid, CO_2, and other simple compounds.

It is seen from the data presented that among organophosphorus pesticides there are substances with different persistences, and from the necessary range of preparations available, it is possible to select the best substances for use under specific conditions.

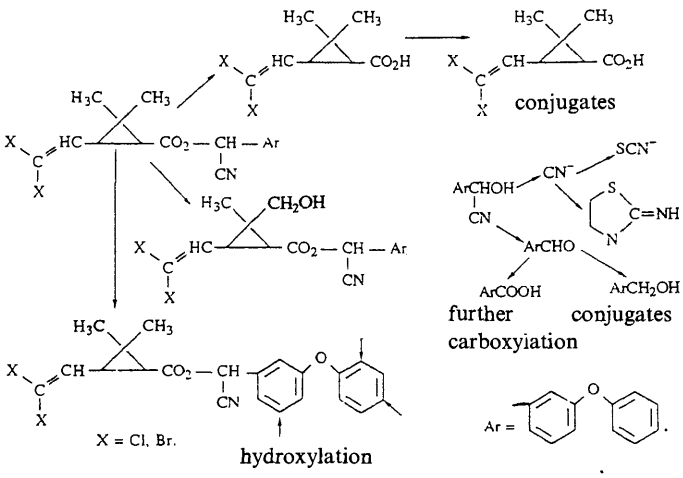
IV. Synthetic pyrethroids

The manufacture and use in agriculture of synthetic pyrethroids began only in the 1970's but at the present time they occupy a firm position in the range of modern insecticides. More than 15 preparations have found practical applications, the most important of which are permethrin, cypermethrin, and decis.

A positive property of this group of compounds is their relatively moderate toxicity for mammals and birds and also their low consumption norms, not exceeding 10–20 g ha^{-1} for a number of preparations.[146,147] Their comparatively high toxicity for hydrobionts, and in the first place for fish, must be included among the disadvantages of this group of substances.[148] Since synthetic pyrethroids are esters, they are relatively readily hydrolysed. The hydrolysis is faster in an alkaline medium. Synthetic pyrethroids decompose even more rapidly under the influence of soil microorganisms and also in animal organisms.[149,150] The rates of decomposition (%) of certain synthetic pyrethroids over a period of 8 weeks in mineral and organic soils are given below.[150]

	Permethrin	Cypermethrin	Fenvalerate	Decis
Mineral soil	94	96	88	48
Organic soil	84	84	42	26

Naturally not only the soil composition but also temperature and humidity are important for the decomposition of pyrethroids. The higher the temperature, the faster the decomposition of the preparations. The metabolism of cypermethrin and decis is indicated in Scheme 6.



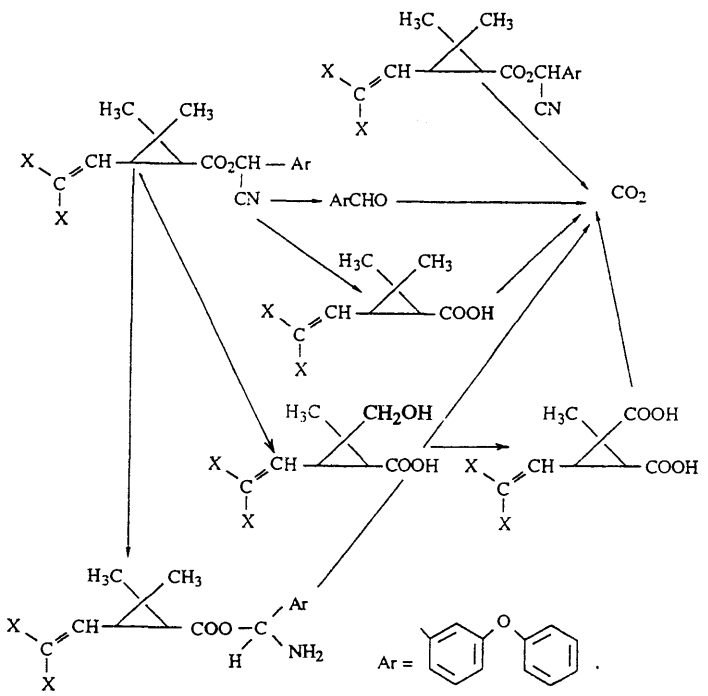
Scheme 6. Metabolism of cypermethrin and decis in animal organisms.

Since the products of the metabolism of pyrethroids are readily soluble in water, they do not accumulate in animal organisms, are rapidly eliminated with the products of their vital activity, and synthetic pyrethroids do not accumulate in milk.[148] The products of the metabolism of synthetic pyrethroids are much less toxic than the initial compounds for the majority of organisms, including hydrobionts.[151,152] Table 3 indicates the toxicity of certain metabolites of synthetic pyrethroids for hydrobionts.

For comparison we may point out that in the case of fish LC_{50} after exposure for 96 h is 0.0004–0.0007 mg $litre^{-1}$ for permethrin, 0.0004–0.002 mg $litre^{-1}$ for cypermethrin, 0.002 mg $litre^{-1}$ for fenvalerate, and 0.001 mg $litre^{-1}$ for decis.[151]

The metabolism of synthetic pyrethroids in plants also yields conjugates with glucose and other carbohydrates whose toxicity for mammals is low. However, these conjugates are incorporated in the general plant metabolism and their amount gradually diminishes.

In the soil, pyrethroids are fully decomposed to simple compounds, as shown in Scheme 7.[151]



Scheme 7. Metabolism of cypermethrin and decis in the soil.

It must also be pointed out that pyrethroids undergo photochemical transformations in the atmosphere and in an aqueous medium with almost complete degradation of the molecule.[149]

Analogues of cypermethrin and other pyrethroids which do not contain the phenoxybenzoyl fragment have now been synthesised. The study of the metabolism of the new groups of pyrethroids is being continued.[153]

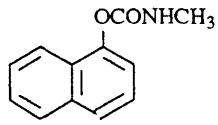
It is seen from the foregoing that synthetic pyrethroids are of great practical interest, particularly bearing in mind their extremely low consumption norms.

V. Carbamic acid derivatives

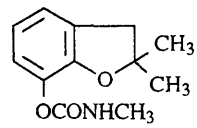
More than 40 carbamic acid derivatives have now found applications as pesticides in agriculture. They include mainly derivatives of *N*-methylcarbamic acid as insecticides[69] and arylcarbamic acid esters as herbicides.

Carbamic acid derivatives include compounds with different acute toxicities and different persistence. Despite their high toxicity, many such preparations have found fairly extensive applications in agriculture. Not being able to consider in detail all the preparations which have found practical applications, we shall examine certain typical examples.

The behaviour of carbamic acid derivatives in objects in the environment depends not only on the specific compound but also on the object in which the preparation is present. The metabolism of carbamic derivatives is most complete when the latter are acted upon by soil microorganisms.[154–165] Soil microorganisms also decompose stable preparations such as carbaryl (XXI) [154–156] and carbofuran (XXII).[157–165]

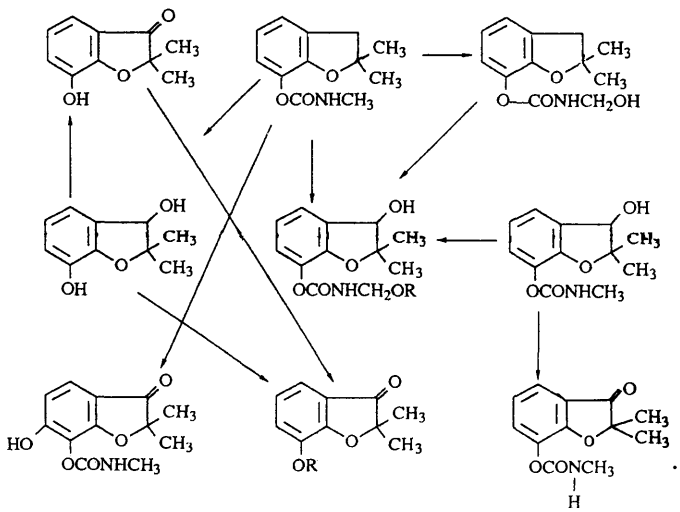


(XXI)



(XXII)

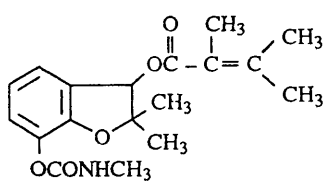
The main metabolic reactions of the carbamate insecticides are hydrolysis and oxidation.[155] The hydrolysis of the aryl esters of methylcarbamic acid leads to the formation of the corresponding phenol or other hydroxy-compound and methylcarbamic acid, which decomposes to an amine and CO_2.[155] This is accompanied by simultaneous oxidation processes which involve the methyl group and the aromatic or heterocyclic ring. Hydroxy-compounds form conjugates with organic substances (for example, humates) in the soil, with glucose in plants, and with sulphates and glucuronic acid in animal tissues. Scheme 8 presents the metabolism of carbofuran as an example.



R = glucose, glucuronic acid, or sulphate.

Scheme 8. Metabolism of carbofuran.

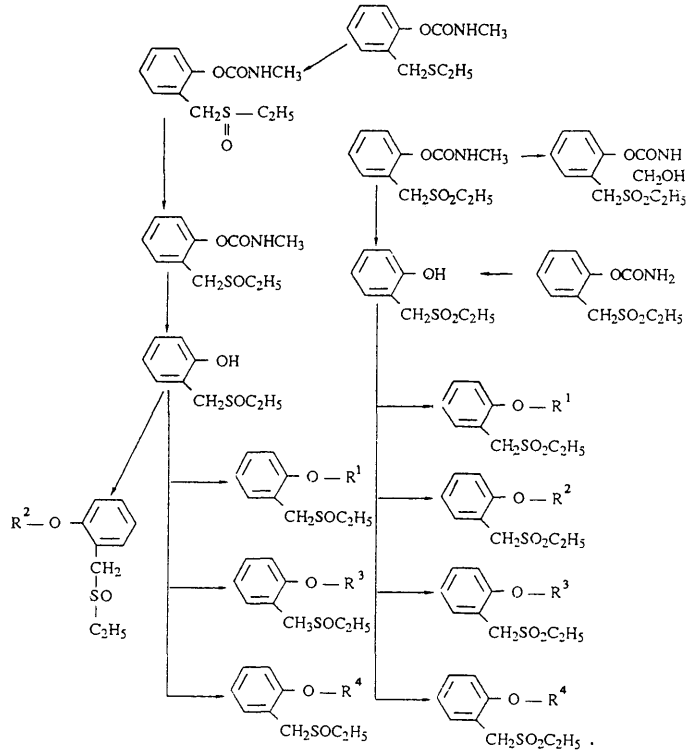
We may note that after the first stages of the metabolism shown in Scheme 8 the aromatic ring is hydroxylated and this is followed by further conversion into simple compounds. Conjugation with glucose in the 3-position takes place in plants. The carbofuran metabolites have been found in peppermint,[166] carrots,[167] ground nuts, and the cotton plant.[168] The 3-ester between carbofuran and angelic acid (XXIII) has been detected in the carrot.[167]



(XXIII)

It is of interest that the carbofuran 3-glucoside, obtained from carbofuran in plants, gives rise to glucuronides and the sulphates of the hydroxylated carbofuran metabolites in the rat organism.[169]

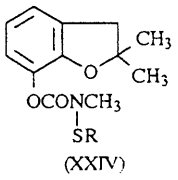
The metabolism of croneton may serve as a second example.[155] Like other preparations, croneton is fully decomposed in the soil, while in other objects it affords the products illustrated in Scheme 9.



R^1 = glucuronate, R^2 = glucoside, R^3 = condensation product, R^4 = sulphate.

Scheme 9. Metabolism of croneton.

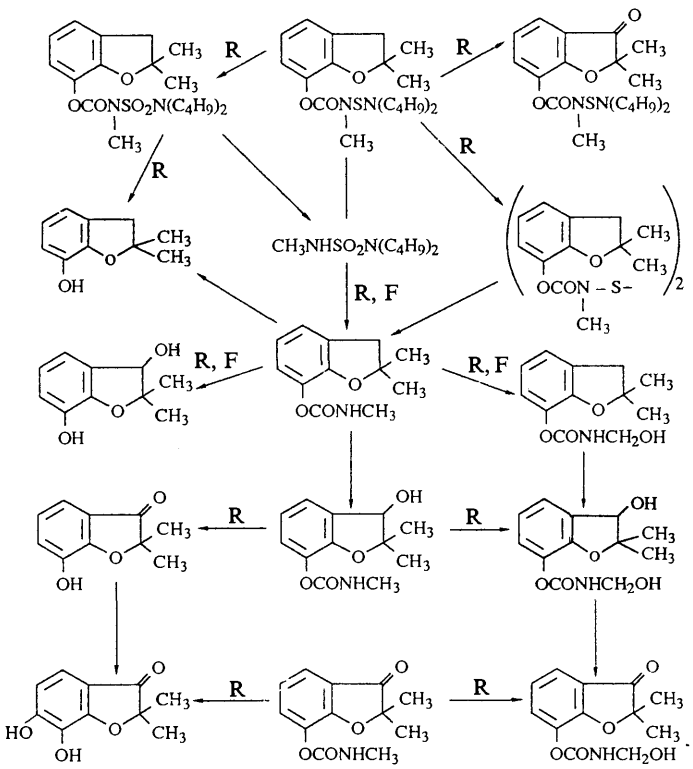
In view of the valuable properties of carbofuran as a pesticide, a new group of preparations with the general formula (XXIV) has been devised. These exhibit moderate insecticidal properties but are converted into carbofuran in the soil or in the insect organism.[170] This group of preparations has been called propesticides. Carbosulfan, promecarb, benfuracarb, and a number of others have found nowadays practical applications as insecticides. The study of the metabolism of this group of compounds showed that their metabolism in insect organisms differs somewhat from that in warm blooded animals.[170–177]



(XXIV)

R = $N(C_4H_9)_2$ (carbosulfan), $N{-}COOC_2H_5$ (promecarb), $N{-}CH(CH_3)_2$, $CH_2CH_2COOC_2H_5$ (benfunacarb).

Thus the metabolism of carbosulfan is different in the rat and fly organisms (Scheme 10). A greater amount of toxic substances is formed in flies, which results in an increase in the selectivity of the action of the preparation. A similar picture is observed also for other compounds of this type. The creation of propesticides is an example of the way in which an approach may be made to the creation of selective preparations on the basis of the study of metabolism in different species of living organisms.



Scheme 10. Metabolism of carbosulfan in the organisms of rats (R) and flies (F).[171]

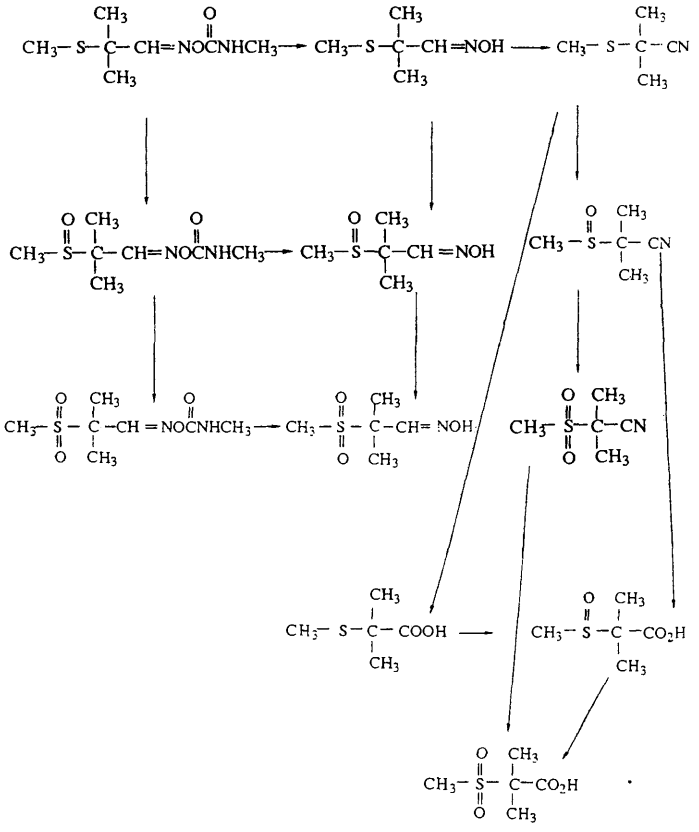
Carbosulfan is one of numerous examples. Such selective action has been observed not only in insecticides but also in herbicides and fungicides.

An important group of carbamate insecticides, which has found fairly extensive application in agriculture, is that of carbamate oximes, the commonest representative of which are aldicarb, aldoxicarb, oxamyl, and methomyl. However, the substances in this group are extremely toxic[178] and fairly stable in objects in the environment.[179–185]

One of the most toxic and stable preparations is aldicarb. In addition, its metabolites—the sulphoxide and the sulphone—are likewise highly toxic. The latter, called aldoxycarb, has found practical application as a soil insecticide. Aldicarb and its sulphoxide and sulphone are fairly stable and, when used systematically, can accumulate in the soil and can enter ground waters.[179,181–184] Even in dilute solutions, their hydrolysis is fairly slow.[186] It is of interest to note that the hydrolysis in chlorine water is faster (by 80% in 20 h).[185] The accumulation of aldicarb and of its toxic metabolites in the radish,[187] in the leaves and roots of sugar beet,[188–190], the potato, the pumpkin,[191,192] and a number of other

cultivated plants has been noted. It has been established that aldicarb and its metabolites persist in soil for up to 400 days after the introduction of the preparation in an amount of 15 kg ha^{-1},[181] but after only 10 days it is converted into the sulphoxide and the sulphone.[181] On the other hand, the sulphoxide is 99% converted into the sulphone after 120 days, the amount of sulphone by that time constituting more than 20% of the aldicarb introduced initially.[181] It has been shown with the aid of the ^{14}C-labelled preparation that ultimately aldicarb decomposes in the soil to CO_2 and other simple compounds.

The general aspects of the metabolism of aldicarb in various objects are presented in Scheme 11.[178,181,182,189] The use of aldicarb and similar preparations requires much caution and the maintenance of techniques and conditions ensuring the safety and protection of the environment. Bearing in mind the possibility of the accumulation of aldicarb and its toxic metabolites in ground waters, the use of this preparation in a number of states of the USA has been restricted. Under aerobic conditions, aldoxycarb was found to decompose in the soil in Florida after 42 days.[193]



Scheme 11. Metabolism of aldicarb.

Aldicarb can decompose photochemically with formation of methylamine, dimethyl disulphide, tetramethylsuccinodinitrile, dimethylurea, 2-methylthioisobutyronitrile, methacrylonitrile, and certain other products.[194] The aldicarb molecule undergoes almost total degradation under the influence of light. Such decomposition is possible, in particular, in an aqueous medium. Carbamate oximes such as methomyl and oxamyl are less stable and decompose faster in the environment.[155,195–201]

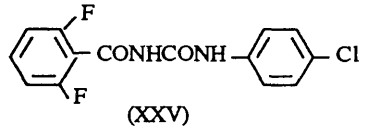
Despite the lower stability of the carbamate oximes enumerated above, work involving them requires much care and caution. This group of compounds is apparently one of the most dangerous among pesticides. However, their complete decomposition in the soil over one year does not give grounds for fear of contamination over any kind of long period.

VI. Urea derivatives

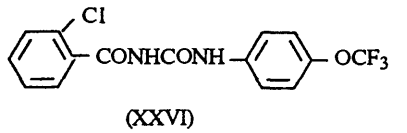
Among urea derivatives, four groups of substances have found practical application as pesticides: aryldimethylureas, arylmethoxymethylureas, benzoylureas, and sulphonylureas.[27,32,35,69]

Since the behaviour of the first groups of urea derivatives in objects within the environment has been fairly adequately described in our literature,[10,202,203] they will not be considered in this review.

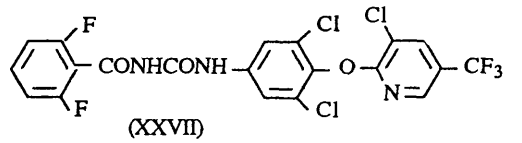
Insecticidal benzoylureas and herbicidal sulphonylureas have been vigorously investigated in recent years.[34,35,204] Among the insecticidal benzoylureas, diflubenzuron (XXV), triflumuron (XXVI), chlorfluazuron (XXVII), triflubenzuron (XXVIII), and certain others[204] have found practical applications.



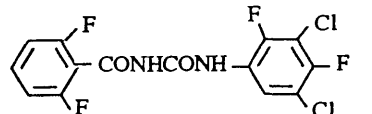
(XXV)



(XXVI)



(XXVII)



(XXVIII)

The insecticidal activity of compounds of this group is based on the inhibition of the formation of chitin during the development of insects and hence their destruction. The decomposition of these substances begins with hydrolysis accompanied by the elimination of the benzoyl group.[204–209] This may be accompanied by the simultaneous hydroxylation of the aniline ring. Next, arylurea decomposes with formation of aniline, which subsequently fully decomposes in the soil.[211]

Experiments with a carbon-labelled preparation showed that the decomposition, for example in the cotton plant, takes place over a period of two weeks.[208] The decomposition is most complete in the soil under the influence of microorganisms. In animal organisms, most of the preparation is eliminated with excrement[205] and virtually none enters milk.

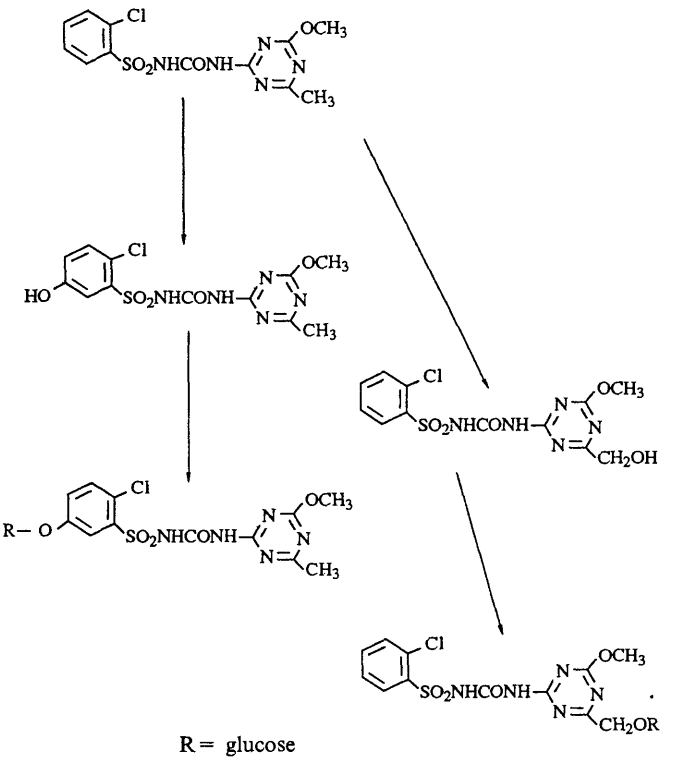
This group of compounds is of great practical interest, since they do not accumulate in objects within the environment and hydrolyse fairly rapidly in water and in the soil. A positive property of these substances is also the high selectivity of their action and low consumption norms (20 – 50 g ha^{-1}).

The herbicidal properties of sulphonylurea were discovered about 15 years ago and more than 15 preparations have now found practical applications. They are distinguished by a high selectivity of their action and low consumption norms when used to combat weeds, which is associated with their different metabolism in different plant cultures.[210] In plants resistant to sulphonylureas, their metabolism is fairly rapid and terminates after several hours,[210,212–215] whereas in plants sensitive to these compounds the metabolism is extremely slow.

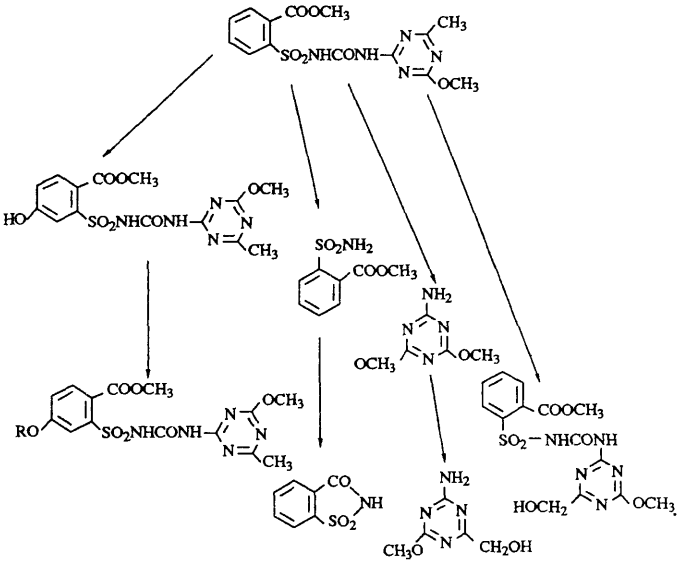
Table 4 presents certain sulphonylureas which are used as herbicides and which have found industrial or experimental industrial applications.

In the series of herbicidal sulphonylureas there are compounds with different persistence. These preparations range from those decomposing in the soil in several hours to those whose decomposition can occur over several months and even more than a year. An example is provided by chlorsulfuron. A plant culture sensitive to this compound may be damaged even a year after the preparation has been used (for a consumption norm up to 20 g ha^{-1}). A plant culture of this kind is, in particular, sugar beet.

The behaviour of a large number of derivatives of sulphonylurea in soil,[225–234] in various plant species,[210,219,235–239] and in animal,[219] bird, and fish organisms has now been studied in detail. It has been shown that the duration of their storage in the soil and their migration along the soil profile depend on the temperature and moisture content of the soil, on the pH of the medium, and on the composition of the soil. Certain sulphonylureas decompose in the soil in several hours. However, such decomposition takes place only as far as the hydrolytic stage and leads to the loss of herbicidal activity of the compound, while the complete decomposition of the majority of preparations in the soil takes place over a period of 15 – 30 days.[233,234] The complete decomposition of sulphonylureas in the soil by microorganisms takes place with total degradation of the molecule, while in plants a series of products non-toxic to the given plant are formed, as can be seen from Schemes 12 and 13 for the metabolism of chlorsulfuron in wheat and metsulfuron methyl in wheat and barley.[210,219]



Scheme 12. Metabolism of chlorsulfuron in wheat.



Scheme 13. Metabolism of metsulfuron methyl in the wheat and barley plants.

Scheme 14 presents the metabolism of thifensulfuron in the rat organisms[219] and Scheme 15 illustrates the metabolism of bensulfuron in the rat and goat organisms.[219] We may note that significant amounts of the preparations were not detected in the milk of the animals.

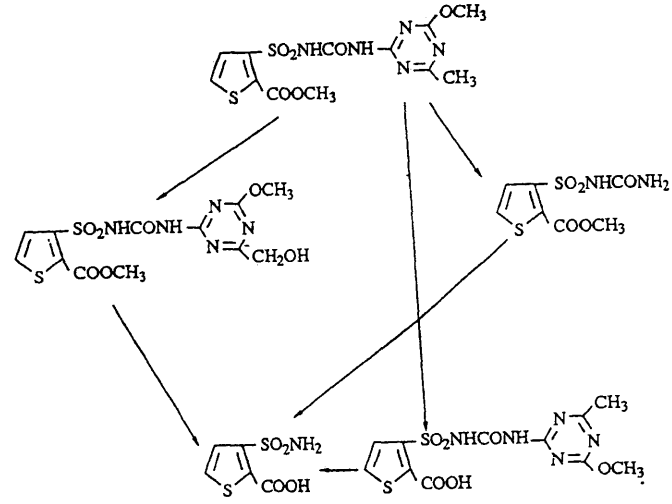
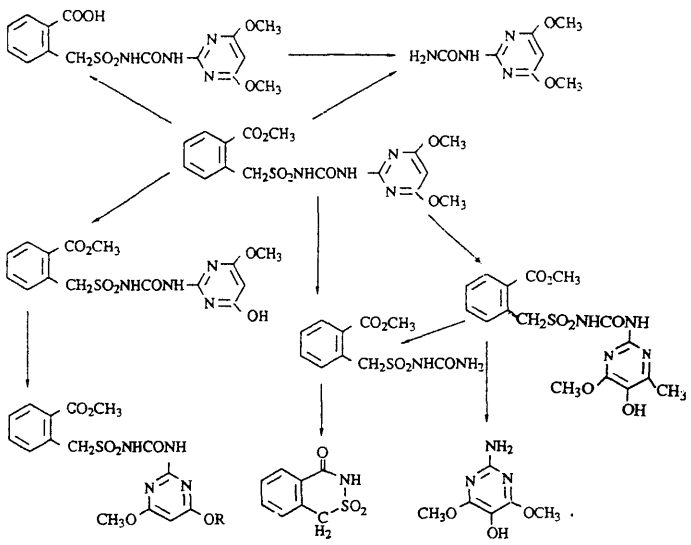


Scheme 14. Metabolism of thifensulfuron in the rat organism.



R = glucuronide

Scheme 15. Metabolism of bensulfuron in the rat and goat organisms.

We may note that, together with individual sulphonylureas, their mixtures with other herbicides, including 2,4-D salts, benzoic acid derivatives, and a number of other substances, have found extensive applications. The use of such mixtures makes it possible to reduce significantly the consumption of the preparations and to diminish the amount of herbicide applied per unit treated area, accelerating thereby its total decomposition in the soil. In addition, the use of mixtures makes it possible to reduce the amount of preparations which may enter ground waters. We may note that much attention is being devoted to this problem at the present time because certain preparations do enter ground waters when applied systematically on the same areas (like aldicarb).

The products of the metabolism of sulphonylureas are eliminated from animal organisms in most cases with excrement in the form of glucuronates and sulphates.

The photochemical decomposition of a series of sulphonylureas,[219] including sulphometuron, has been investigated in an aqueous medium.[236,237] It has been established that the main products of the photochemical conversion of sulphometuron are hydrolysis products and two other substances of unknown structure.[237] It is noteworthy that the pyrimidine and triazine rings forming part of the molecule of the majority of sulphonylureas are apparently fairly stable and decompose only slowly. Table 4 shows that virtually all sulphonylureas contain either triazine or pyrimidine rings, whose decomposition has been thoroughly investigated in relation to triazine herbicides.[240–247]

It is seen from the foregoing that sulphonylurea derivatives are of significant interest for use in agriculture and, by virtue of their low toxicity for animals, fish, and birds, they constitute no danger to the environment, particularly since the consumption norms for the majority of these substances are extremely low, as shown by the data in Table 4.

VII. Conclusion

The behaviour of pesticides in the environment has been considered in relation to several classes of chemical compounds. Analysis shows that, having at one's disposal fairly extensive knowledge, it is possible to ensure, by setting standards for the consumption of pesticides in agriculture and other fields, for example in the fight against agents transferring infectious diseases in man and animals, the use of pesticides which are completely safe both to man and a wide variety of objects in the environment can be ensured.

In order to characterise the possible contamination of food products and drinking water by pesticides, the maximum permissible levels of certain pesticides in drinking water and in food products, calculated per kilogram of human body weight per day, are

presented in Tables 5 and 6, which show that pesticides can enter the human organism in insignificant amounts. For example, if one considers diazinon, then it is found that only 0.07 mg of this substance enters the organism of a human being weighing 70 kg in 24 h, which is several times less than the amount of caffeine consumed with one cup of coffee and yet the toxicity of caffeine is approximately twice as high as that of diazinon.

Table 6. The maximum permissible levels of residual amounts of pesticides in food products (mg/kg of weight of a person per day).

A similar situation is also observed for the majority of other preparations. Despite the vigorous studies designed to create alternative methods for the protection of plants against pests, diseases, and weeds, the chemical method will undoubtedly occupy a dominant position in the foreseeable future in the integrated system for the protection of plants.[249]

When the modern assortment of pesticides is used intelligently, the latter present no danger either to man or to the environment in view of their moderate persistence and extremely low consumption limits. For example, monitoring of the content of pesticides in California (USA) in 1989 failed to detect pesticides in 80% of the samples, in 19.3% of the samples pesticides were found within permissible limits, and in only 0.7% of the samples was the content of pesticide in excess of the permissible limits.[250]

Investigation of molecular carbonium ion rearrangements by the molecular mechanics method

Yu V Gatilov, V A Barkhash
Novosibirsk Institute of Organic Chemistry, Siberian Division of the Russian Academy of Sciences

ABSTRACT. The review considers problems of the application of the molecular mechanics method in the prediction of the conversion reactions of hydrocarbon carbonium ions with a localised charge. The methods for the estimation of the heights of the activation barriers to the 1,2-shift of the migrating species, the possibilities of the method for the prediction of the transannular cyclisation of carbonium ions, and certain examples of the influence of the acidity of the medium are discussed.

V. The influence of the medium on the rearrangements 1082

I. Introduction

The foundations of the method of molecular mechanics (MM) [1] or the method of atom–atom potentials[2,3] were laid in Hill's study in 1946.[4] At the present time, this method has been widely used in a wide variety of chemical fields. This review deals with only a narrow range of applications of the method, namely the possibilities of the MM method in the study of complex multistage carbonium ion rearrangements involving carbocyclic cations (excluding π-delocalised ions, ions with a heteroatom in the α-position relative to the carbonium ion centre, and ions with the charge on a heteroatom).

The MM method deals with an isolated molecule (unless otherwise stipulated) and its results can be compared directly only with certain gas-phase data. On the other hand, carbonium ion reactions are investigated in media of different acidity, frequently under the so called long life conditions.[5] In general, the influence of the medium, for example, on the heat of formation, is enormous. Thus the heats of formation of the t-butyl cation in the gas phase and in the SO_2FCl system differ by 239 kcal mol^{-1}.[6] Direct allowance for the interaction of carbonium ions with the medium is very difficult. However, it has been shown by Arnett and Pienta,[6] who compared the enthalpies of formation in the gas phase and in SO_2FCl, that there is a satisfactory correlation (with a slope of 0.973 and $r = 0.986$) between the values of $\Delta H_f^\circ(R^+, \text{gas})$ and $\Delta H_f^\circ(R^+, SO_2FCl)$. Thus the absence of specific solvation of the cations by the medium was demonstrated in this instance, so that we can use directly the results of calculations by the MM and quantum-chemical methods.

II. Calculation of the stabilities and geometries of carbonium ions

In the early studies,[7] the MM method was used to predict the preferred carbonium ion reaction pathways, but, in order to estimate the stabilities of different cations, the values of ΔH_f° were calculated in these investigations for neutral hydrocarbons on the basis of the idea of the parallel nature of the stability series of carbonium ions and the corresponding neutral hydrocarbons. The MM method was first used directly for calculations involving carbonium ions in the study of Gleicher and Schleyer.[8] They found the parameters of the force field by the MM method and successfully compared the solvolysis rate constants and the differences between the steric energies of the carbonium ions and the corresponding hydrocarbons.

The next important step in the establishment of the MM method in the chemistry of carbonium ions was the introduction of an additive scheme for the calculation of gas-phase heats of formation,[9] which made it possible to compare quantitatively the stabilities of secondary and tertiary ions. As a result, it became possible to carry out calculations for the energetics of carbonium ion reactions, i.e. to establish whether the given process proceeds "uphill" or leads to more stable final ions.

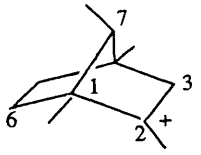
A study[10] in which the conformational analysis was carried out for tertiary (C_6, C_7, and C_8) cycloalkyl carbonium ions by the NMR method is noteworthy. The authors observed the unexpected preference (to the extent of 0.5 kcal mol^{-1}) for the twist conformation of the methylcyclohexyl cation compared with the chair conformation. This investigation was followed by a study[11] on the conformational analysis of the above tertiary carbonium ions by the MM method. According to the authors' calculations, the twist conformation of the methylcyclohexyl cation is less stable than the chair conformation by only 0.14 kcal mol^{-1} and, if account is taken of the known fact[12] that the MM method overestimates the stability of the chair form by ~0.3 kcal mol^{-1}, then the result obtained agrees well with experimental data.

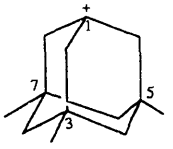
The study of Olah, et al.[13] on 1,4-bicyclo[2.2.2]octyl dication—a new pseudoaromatic system—is of interest. The causes of the surprising stability of this cation were discovered with the aid of the MM and MINDO/3 methods.

After the publication of calculations in which the force field and Allinger's MM2 method[14] were resorted to, it was natural to expect the extension of this version of the MM method also to carbonium ions, which was in fact achieved by Muller and co-workers,[15–18]

who found the necessary parameters of the MM method from kinetic data for the solvolysis of secondary[15] and tertiary[16,17] alcohols and obtained the enthalpy parameters from the experimental gas-phase heats of formation.[18] It is noteworthy that the parametrisation of the MM method for carbonium ions in the MMX program is different from that proposed by Muller.

Whilst recognising the advantages of the MM method (compared with quantum-chemical and semi-empirical methods) such as speed and reliability of the results for carbonium ions which fall within the sphere of the existing parametrisation, its disadvantages should also be noted. Firstly, at the present time the MM method cannot take into account explicitly the stabilisation of certain carbonium ions owing to the σ-delocalisation of the positive charge. The underestimation of the stability of ions with σ-delocalisation is therefore to be expected. For example, in the case of 2-norbornyl cations the underestimate is by 5 kcal mol^{-1},[9] 6 kcal mol^{-1},[19] or 7.6 kcal mol^{-1}.[20] However, it is difficult to say *a priori* for which cations such a correction should be applied, except for the thoroughly investigated 2-norbornyl cations. (We may note that there is no reliable parametrisation of the MM method for π-delocalised carbonium ions.) Secondly, X-ray diffraction studies on the salts of the 1,2,4,7-*anti*-tetramethyl-2-norbornyl[21] and 3,5,7-trimethyl-1-adamantyl[22] cations revealed an appreciable deviation of the bond lengths from the values used as a basis for the parametrisation of the MM method for carbonium ions. Thus the C(1)–C(2), C(2)–C(3), C(2)–CH_3, and C(1)–C(6) bond lengths in the norbornyl ion are 1.48, 1.48, 1.48, and 1.54 Å respectively according to the calculation by the MM2 method using Muller's parameters, while the experimental bond lengths are 1.44(2), 1.50(1), 1.47(2), and 1.74(2) Å.





In the adamantyl ion, the calculated C^+–C and (C^+)C–C bond lengths are 1.48 and 1.54 Å respectively, while the experimental values are 1.42–1.47 and 1.61–1.62 Å, i.e. the real interaction of the unoccupied orbital of the carbonium ion centre with the nearest valence bonds has not so far been incorporated with adequate accuracy in the MM method. However, it is only fair to note that the MM method reproduces the enthalpies of formation fairly reliably.[18]

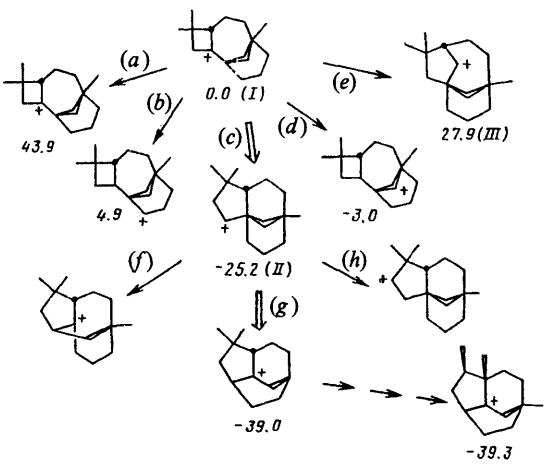
III. Estimation of the heights of the activation barriers to 1,2-shifts

One of the important problems of the chemistry of carbonium ions is that of the prediction of the heights of the activation barriers to intramolecular rearrangements. The direct procedure for the solution of this problem involves non-empirical quantum-chemical calculations (the semi-empirical method yields heats of formation for the transition states in 1,2-shifts which differ very greatly and the best results for hydrocarbon carbonium ions can be obtained with the aid of the MINDO/3 method[23]). In view of the laborious nature of these methods, the search for other approaches has been stimulated. The principal factors determining the activation barriers to the rearrangement of carbonium ions are the size of the positive charge on the carbon atom to which the migrating species moves and the difference between the thermodynamic stabilities of the rearranging and final ions.[5] If carbonium ions with π-delocalisation are disregarded, then the thermodynamic factor becomes one of the decisive ones. For example, the most probable pathway leading to the conversion of 2,3-tetramethylenebicyclo[2.2.1]heptane into adamantane has been refined[9] on the basis of the heats of formation of the carbonium ions calculated by the MM method.

However, the height of the activation barrier to the 1,2-shift of the migrating species may be influenced by specific structural factors responsible for the increased strain in the transition state. In particular, this may be the unfavourable orientation of the unoccupied orbital of the carbonium ion centre relative to the orbital of the carbon–migrating species bond (the orbital factor characterised by the torsional angle Φ between the specified orbitals). Indeed, it has been shown in relation to the solvolysis of *exo*-twistbrendan-2-ol[24] that both factors—the thermodynamic and orbital factors—are important for the prediction of the direction of the 1,2-shift. The attempt to incorporate both factors simultaneously at a qualitative level was undertaken[25] in the analysis of the mechanism of the acid-catalysed reactions of 2- and 4-homoprotoadamantanes. In this case, the pathways leading to the most stable ions and having at the same time the most favourable interorbital angles for the corresponding 1,2-shifts were recognised as the most probable.

In a later study of the rearrangement of 1-substituted caryolanes in superacids,[26] the authors encountered the situation where the pathway to the most stable ion (II) is associated with an extremely unfavourable[7] interorbital angle (Φ = 69°, Scheme 1). The heats of formation ($\Delta\Delta H_f^\circ$, kcal mol^{-1}) of the corresponding ions relative to the initial carbonium ion are indicated in Schemes 1–3 under the structural formulae.

Scheme 1



Pathway	(a)	(b)	(c)	(d)	(e)	(f)	(g)	(h)
Φ, deg	54	59	69	55	2	50	4	30
$\Delta G^{\neq}$, kcal mol^{-1}	44	24	8	17	28	20	4	12

On the other hand, the pathway which is very favourable as regards the orbital factor (Φ = 2°) leads to the highly strained cation (III). Since both these factors are important for the prediction of the rearrangements, the authors put forward the empirical hypothesis that the internal barrier (Λ) to the 1,2-shift in a degenerate

rearrangement depends on the interorbital angle in the following manner:

$$\Lambda = \Lambda_0 / \cos\Phi \,. \qquad (1)$$

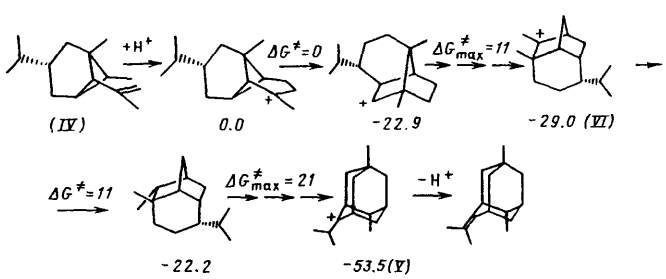
The thermodynamic factor for non-degenerate processes was taken into account with the aid of the Marcus equation, which assumes the following form for isentropic reactions:

$$\Delta G^{\neq} = \Lambda(1 + \Delta\Delta H_f/4\Lambda)^2 , \qquad (2)$$

where $\Delta\Delta H_f$ is the difference between the values of ΔH_f° for the product ion and the rearranging ion. The free energies of activation ($\Delta G^{\neq}$, kcal mol^{-1}), estimated with the aid of Eqns. (1) and (2), are presented in Schemes 1–3. They permit an unambiguous choice between the modes of rearrangement of the initial ion (I). Thus the possibility of predicting the reaction pathway, leading to the conversion of the ion (I) into the final cation with a relative heat of formation of −39.3 kcal mol^{-1} and a length equivalent to seven different 1,2-shifts, was demonstrated in the above study.

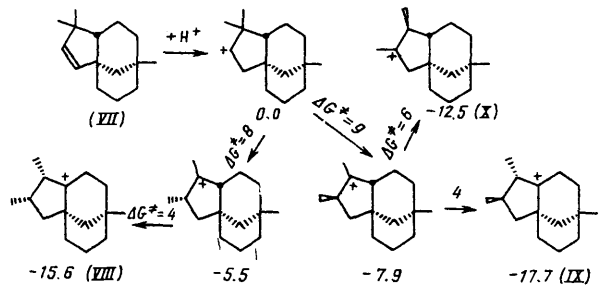
The method for the estimation of the activation barriers to 1,2-shifts examined above has been used[27] to predict the most probable reaction pathways of the sesquiterpene α-copaene (IV). The authors[27] obtained for the first time tricyclic compounds of the adamantane type from α-copaene in superacid media. About 100 structures of different carbonium ions were examined for the purpose of this prediction. Scheme 2 illustrates the fragments of the most probable pathway, consisting of 19 consecutive 1,2-shifts, leading to the rearrangement of the α-copayl ion to the adamantyl ion (V) via the intermediate isosativyl cation (VI).

Scheme 2



The above examples of the reactions of ions generated from 1-substituted caryolanes and α-copaene have in common the feature that the initial carbonium ion is converted into a much more stable ion. A different situation was observed[28] when a "map" of the possible pathways leading to the rearrangement of the cation generated from clovene (VII) was drawn on the basis of Eqns. (1) and (2). According to the prediction, the acid solution should contain in this case a mixture of the two most stable ions (VIII) and (IX) (Scheme 3). In conformity with these data, signals due to two tertiary ions were noted in the ^{13}C NMR spectrum of the reaction mixture, while olefins corresponding to the cations (VIII)–(X) were found among the products of the neutralisation of the mixture.

Scheme 3



Naturally, the simplified method for the estimation of activation barriers by Eqn. (1) has disadvantages (apart from the empirical form of the dependence on the angle Φ). Thus it has been noted in a recent study[29] that, according to the data of Bushmelev et al.,[30] the interorbital angle is not an unambiguous characteristic of the strain in the transition state due to the need for the sp^3-hybrid node of the $C(R_m)-C^+$ fragment to readjust rotationally relative to the unoccupied orbital of the carbonium ion centre, which should depend on the rigidity of the molecule. Little "tricks" such as the search for conformers with a more favourable interorbital angle Φ and the employment of the principle of microscopic reversibility cannot eliminate this disadvantage. Furthermore, the internal barriers Λ_0 to the 1,2-shifts were estimated[26] from Sorensen's kinetic data[31,32] (which include approximate and estimated quantities) for the rearrangements of δ-delocalised 2-norbornyl ions, which are specific models. The neglect of specificity leads to unduly high calculated data in the case of monocyclic and open-chain ions. It is necessary to note the very limited amount of experimental kinetic data for the rearrangements of non-arenium ions. For example, the Wagner–Meerwein rearrangement of the ions under consideration has been scarcely investigated quantitatively. This situation hinders the search for approaches to the description of the rates of the 1,2-shifts.

An attempt has been made[29] to model the strain in the transition and ground states of the 1,2-shift of the migrating species by the strains in the neutral hydrocarbons of the cyclopropane and alkane types.[29] However, it was shown that the difference between the steric energies of the components of the cyclopropane–alkane pair reflects with insufficient adequacy the changes in the quantity $\Delta G^{\neq}$ for the 1,2-shift as the molecular skeleton of the ion is altered. Other workers,[33] who investigated the reactions of 6-tricyclo[3.3.0.0^{2,7}]octyl ion, arrived at a similar conclusion. Nevertheless this approach constitutes the next step compared with the approach described by Eqns. (1) and (2) where the strain in the transition state is estimated solely from data for the ground state of the rearranging cation (i.e. an attempt is made to estimate the height of a mountain whilst standing at its base).

Further development of quantitative estimations of the activation barriers to the 1,2-shift of the migrating species in carbonium ions with a localised charge was stimulated by the successfully developing field of the chemistry of arenium ions. Thus the most general approach to the quantitative description of the rates of the 1,2-shifts of the hydrogen atom and the methyl group has been proposed[34] in relation to the degenerate rearrangement of a large series of benzenoid and non-benzenoid arenium ions. The following dependence of the energy barrier to degenerate 1,2-shifts of the

migrating species on the Hückel charge $q_{\pi x}$ on the atom to which the migrating species shifts and on the basicity constant K_i of this centre in the aromatic hydrocarbon formed after the abstraction of the migrating species was then discovered:

$$\Delta G_{\mathrm{H}}^{\neq} = 14.1 - 7.5\ q_{\pi_x} + 0.37\ \lg K_i\ (\text{kcal mol}^{-1}); \quad (3)$$

$$\Delta G_{\mathrm{CH_3}}^{\neq} = 26.5 - 23.4\ q_{\pi_x} + 0.32\ \lg K_i\ (\text{kcal mol}^{-1}). \quad (4)$$

The basicity constants can be calculated by the MM method with the aid of the relations

$$\lg K_i = -108.9 + 0.528\ PA_i\ (\text{kcal mol}^{-1}),\ \text{(Ref.34.)} \quad (5)$$

$$PA = 367.2 + \Delta H_f^0(\text{olefin}) = \Delta H_f^0(\mathrm{R}^+)\ (\text{kcal mol}^{-1}),\ \text{(Ref.35)} \quad (6)$$

where PA is the proton affinity.

Adopting $q_{\pi x} = 1$ for aliphatic and alicyclic carbonium ions, the authors[29] obtained with the aid of Eqns. (3) and (4) the free energies $\Delta G^{\neq}$, which on the whole agree quite well with experimental data. In the case of σ-delocalised carbonium ions, it was suggested that the chemical shifts (δC) of the corresponding carbon atom in the ^{13}C NMR spectrum be used to estimate the charge q^+: $q^+ = (\delta C - 115)/205$ for secondary ions and $q^+ = (\delta C - 123)/212$ for tertiary ions.

Having supplemented the basic set of the ions [for the correlations (3) and (4)] by aliphatic ions, the authors[29] obtained the following better founded relations for degenerate 1,2-shifts:

$$\Delta G_{\mathrm{H}}^{\neq} = 15.33 - 10.79\ q_{\pi_x} + 0.232\ \lg K_i\ (\text{kcal mol}^{-1}), \quad (7)$$

$r = 0.986,\ s = 0.90,\ n = 8;$

$$\Delta G_{\mathrm{CH_3}}^{\neq} = 25.74 - 21.48\ q_{\pi_x} + 0.303\ \lg K_i\ (\text{kcal mol}^{-1}), \quad (8)$$

$r = 0.995,\ s = 0.79,\ n = 7.$

Comparison of the available experimental activation energies $\Delta G^{\neq}$ and the values calculated by Eqns. (7) and (8) demonstrated that the relations are quite effective:

$$\Delta G_{\mathrm{H}}^{\neq}(\text{exp}) = 1.03\ \Delta G_{\mathrm{H}}^{\neq}(\text{calc.}) + 0.4,$$

$r = 0.943,\ s = 1.6,\ n = 23;$

$$\Delta G_{\mathrm{CH_3}}^{\neq}(\text{exp}) = 1.11\ \Delta G_{\mathrm{CH_3}}^{\neq}(\text{calc.}) - 1.2,$$

$r = 0.971,\ s = 1.7,\ n = 14.$

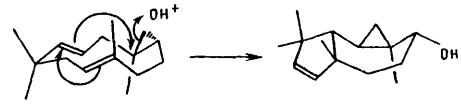
We emphasise the following advantages of this approach: (1) the use of proton affinity, which led to the indirect allowance for the orientation factor; (2) allowance for the "olefin" strain[33] arising from the Dewar representation of the transition state of the 1,2-shift in the form of the π-complex, which proved to be important for the estimation of the stability of the transition state. The "olefin" strain is also involved in the proton affinity.

It is necessary to say a few words about the disadvantages characteristic of the method under discussion. The method is unsuitable for the calculation of the free energies $\Delta G^{\neq}$ for the Wagner–Meerwein rearrangement, because in such cases it is impossible to abstract the migrating species from the skeleton in order to calculate the basicity of the corresponding olefin. Furthermore, in sterically hindered carbonium ions no account is taken of the repulsion of the migrating species (particularly the methyl group) from any other group which arises solely in the transition state of the 1,2-shift of the migrating species. Finally, this approach does not distinguish between the *exo*- and *endo*-shifts of the migrating species in 2-norbornyl cations, the difference between the $\Delta G_{\mathrm{CH_3}}^{\neq}$ for which reaches 10.6 kcal mol^{-1}.[36] We may note that semi-empirical quantum-chemical methods distinguish only imperfectly between the 2,3-*exo*- and 2,3-*endo*-shifts in the 2-norbornyl ion.[37]

IV. Transannular cyclisation of carbonium ions

The transannular cyclisation in the carbonium ion reactions of bifunctional and polyfunctional compounds, particularly of the terpene series, is fairly common. It is responsible for the possibility of the mutual approach in space of the carbonium ion centre and the double bond to a distance sufficient for effective interaction. Modelling of this process by the MM method is so far impossible owing to the lack of the corresponding parametrisation. Nevertheless, the MM method can already provide significant assistance in this case also.

The necessary mutual approach of the potential carbonium ion centre and the double bond is possible even in the ground state (or in the less stable conformer) of the neutral precursor. In this case, the appearance of the cationic centre may be accompanied by cyclisation. Such a phenomenon has been observed for the humulene 6,7-epoxide.[38] When the humulene epoxide is treated with HSO_3F, the concerted opening of the epoxide ring and transannular cyclisation are observed.

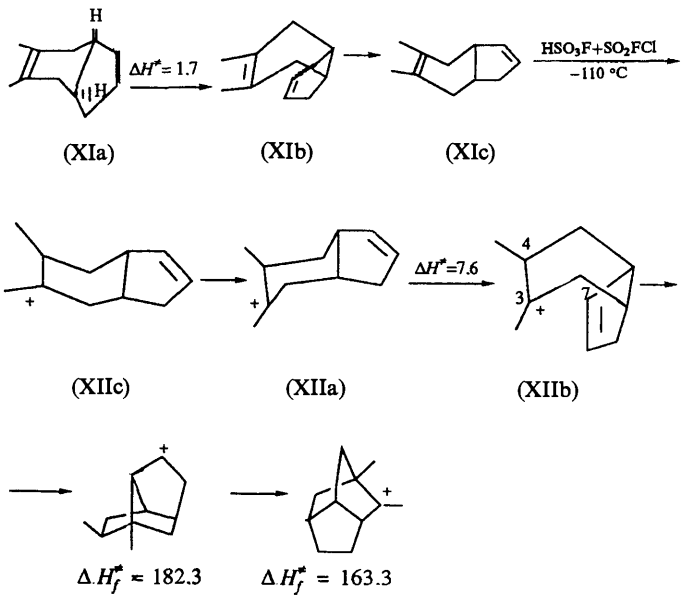


The initial protonation or opening of the epoxide ring provides an additional degree of freedom in the cation formed and hence may promote the mutual approach to the centres required for transannular cyclisation. The following method for the application of the MM method arises from these considerations: conformational analysis of the neutral precursor and of the cation formed initially and allowance for the heat of the possible cyclisation reaction.

We shall consider several examples. In a study[39] of the mechanism of the superacid transannular cyclisation of the bicyclic 1,5-diene (XI), an explanation was found for the experimental finding that the diene (XI) cyclises (Scheme 4), while the allyl ion (XIV) is formed in α-myrolene (XIII) (Scheme 5) under identical

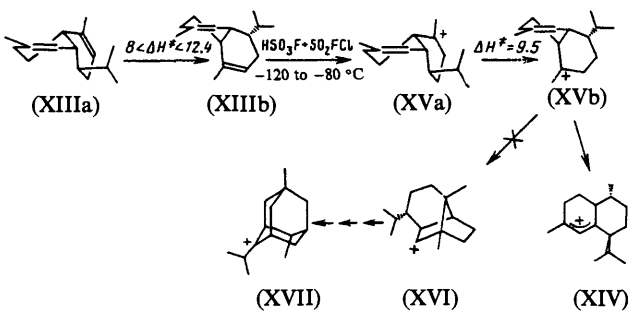
conditions. The fractions of the principal conformers (N, %) at 25 °C are indicated in Schemes 4 and 5.

Scheme 4



Conformer	(XIa)	(XIb)	(XIc)	(XIIa)	(XIIb)	(XIIc)
ΔH^0_f, kcal mol^{-1}	9.2	10.8	9.5	171.8	172.0	172.3
N, %	58.4	4.5	35.2	47.0	32.2	20.3

Scheme 5



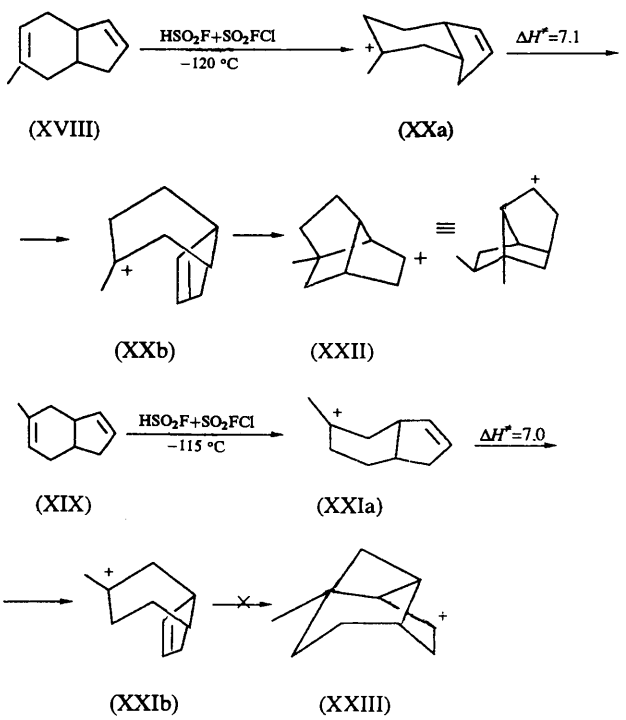
Conformer	(XIIIa)	(XIIIb)	(XVa)	(XVb)	(XVI)	(XVII)
ΔH^0_f, kcal mol^{-1}	−22.2	−20.0	145.7	150.1	150.7 (Ref.27)	102.5 (Ref.27)
N, %	82.4	18.6	99.9	0.06	–	–

Conformational analysis showed that the main conformer (XIa) of the diene (XI) can be very readily converted into the conformer (XIb), which has a geometry favourable for cyclisation. For the diene (XIII), the analogous transition requires an appreciable consumption of energy. Furthermore, one of the main conformers (XIIb), formed initially from the diene (XI), has a disposition of the interacting centres convenient for cyclisation, in contrast to the main conformer (XVa) of the initial cation formed from α-muurolene (XIII). Finally, the competing pathway operates for the ion (XV), involving conversion via the intermediate tertiary cations into the allyl ion (XIV), which constitutes a "potential well".[40]

It follows from the examination of the thermodynamics of the cyclisation of the ion (XIIb) that the quantity ΔH for this process should exceed 10.3 kcal mol^{-1}. At the same time, the cyclisation reaction in the ion (XVb) has a virtually zero heat and apparently not an unduly high activation barrier. This permits the hope that, on raising the reaction temperature, which increases the fraction of the conformer (XIIIb) or (XVb), there is a possibility of the appearance in the reaction mixture of the products of the transannular cyclisation α-muurolene. Indeed, knowing that temperature influences the composition of the ions formed on protonation of α-muurolene, Polovinka et al.[27] increased the temperature of the system (XII) + HSO_3F + SO_2FCl to −30 to −20 ° C and recorded the appearance of the tricyclic adamantyl cation (XVII).

In order to confirm the mechanism of the transannular cyclisation of the diene (XI) proposed by Tatarova et al.,[39] the behaviour of the 3- and 4- monomethyl derivatives of *cis*-bicyclo[4.3.0]nona-3,7-diene (XVIII) and (XIX) was investigated.[41] The conformational compositions of the dienes (XVIII) and (XIX) are almost indistinguishable, while there are differences (Scheme 6), albeit not very pronounced, between the ions (XX) and (XXI) formed from them initially.

Scheme 6



Conformer	(XXa)	(XXb)	(XXIa)	(XXIb)	(XXII)	(XXIII)
ΔH^0_f, kcal mol^{-1}	180.5	180.6	180.5	181.4	187.8	199.2
N, %	41.0	34.6	61.6	12.0	–	–

It is noteworthy that the distances between the interaction centres in the cyclisation reaction ($r_{3,7}$ and $r_{4,7}$) are not apparently the main factors determining the course of the reaction. In this case, the

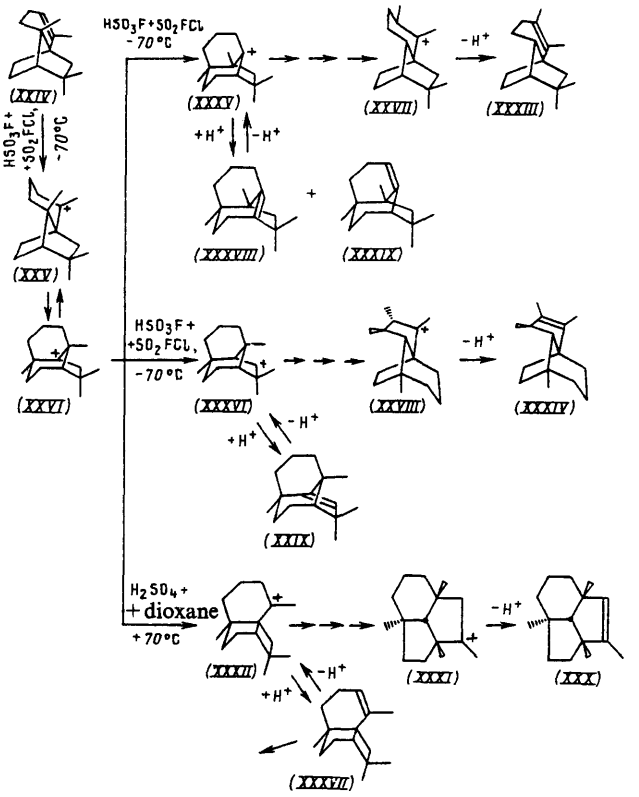
decisive factor is evidently the thermodynamic factor: the heat ΔH of the transannular cyclisation of the cation (XX) is 7.2 kcal mol^{-1}, whereas ΔH for the cyclisation of the ion (XXI) reaches 17.8 kcal mol^{-1}. An attempt may be made to estimate roughly the activation barriers to the cyclisation of the cations (XX) and (XXI) in the following way. We consider the reverse process in the carbonium ions (XXII) and (XXIII)—the dissociation of the corresponding bonds. We assume for simplicity that in the general case the degenernate bond dissociation processes and the Wagner–Meerwein rearrangement begin and proceed similarly, reaching approximately the same transition state as regards energetics. One can then use Eqn. (2) and, having assumed that $\Lambda \simeq$ 5 kcal mol^{-1},[26] the values of ΔG^{+} can be obtained for ring opening in the ions (XXII) and (XXIII)—2.0 and 0.1 kcal mol^{-1} respectively. Hence the activation barriers for the reverse transannular cyclisation in the ions (XX) and (XXI) are 9.2 and 17.9 kcal mol^{-1}.

V. The influence of the medium on the rearrangements

This problem is associated with the general problem of the possibility of predicting the preferred pathway in multistep carbonium ion reactions in the usual acids on the basis of the experimentally observed rearrangements of the carbonium ions generated in superacids from the same precursor. Sorensen[31] published previously data on the carbonium ion rearrangements of monoterpenes in various acid media. He found that, firstly, in superacids and under the conditions of acid catalysis, the sequences in which the barriers ΔG^{+} to the "ion into ion" rearrangements increase are the same and "secondly" that the stability of olefins varies in parallel with the stability of the corresponding carbonium ions. Therefore on the basis of direct observations of the rearrangements of carbonium ions in superacids one can predict the reaction pathway also under the conditions of acid catalysis. Several exceptions to this rule were found subsequently. Thus the mode of reaction in different media can be influenced by the site of the cationic centre[42] and by the nature of the internal nucleophile[43] and also by qualitative changes in the relative rates of competing intramolecular 1,2-shifts[44] and the rates of intermolecular processes.[45]

In a study of the conversion of the sesquiterpene neoclovene (XXIV) in media of different acidity, yet another interesting exception to Sorensen's observation was found.[46] When neoclovene was dissolved in the HSO_3F-SO_2FCl system at −120 °C, the authors observed the appearance of an ion, which, as shown by the application of special methods, involves partial σ-delocalisation of the charge and can be represented by two limiting resonance forms (XXV) and (XXVI) (Scheme 7) as required by the MM method in this instance. When an acid solution of the olefin (XXIV) is heated to −70 °C, the above ion is fully converted into a mixture of the new cations (XXVII) and (XXVIII). As can be seen from Scheme 7, the energy gain expected in the intramolecular conversion of the ion (XXV) into the cations (XXVII) and (XXVIII) in a superacid is 10.7 and 13.0 kcal mol^{-1} respectively.

Scheme 7



Ion/olefin	(XXIV)	(XXV)	(XXVI)	(XXVII)
$\Delta\Delta H_f^0/\Delta H_f^0$, kcal mol^{-1}	−15.6	0.0	3.9	−10.7
s, kcal mol^{-1}	39.0	43.2	52.0	32.9
Ion/olefin	(XXVIII)	(XXIX)	(XXX)	(XXXI)
$\Delta\Delta H_f^0/\Delta H_f^0$, kcal mol^{-1}	−13.0	8.4	−19.7	−2.4
s, kcal mol^{-1}	30.6	63.1	34.9	40.8
Ion/olefin	(XXXII)	(XXXIII)	(XXXIV)	(XXXV)
$\Delta\Delta H_f^0/\Delta H_f^0$, kcal mol^{-1}	6.6	−24.9	−29.8	−11.6
s, kcal mol^{-1}	49.7	30.7	25.8	36.1
Ion/olefin	(XXXVI)	(XXXVII)	(XXXVIII)	(XXXIX)
$\Delta\Delta H_f^0/\Delta H_f^0$, kcal mol^{-1}	2.7	−8.2	8.7	11.4
s, kcal mol^{-1}	38.6	46.6	65.2	45.9

It was shown in the same study[46] that neoclovene (XXIV) is almost fully converted into the olefin (XXX) in a H_2SO_4–dioxane mixture at 70 °C. It is seen from Scheme 7 that the olefin (XXX) is more stable than the initial neoclovene by 4.1 kcal mol^{-1}. The barrier to the conversion of the ion (XXV) into (XXXI) is 18.1 kcal mol^{-1}, the latter being more stable than the initial ion (XXV) to the extent of 2.4-kcal mol^{-1}. [However, experiment showed the opposite situation to be true: at −80 °C in a superacid, the ion (XXXI) is fully converted into the initial ion (XXV)]. It is noteworthy that the pathway leading to the formation of the olefin

(XXX) proceeds via the carbonium ion (XXXII) containing a four-membered ring. This fact conflicts with the postulate[47] that such iosmers be excluded from consideration since they would be very strained.

Thus the pathways in the molecular rearrangements of neoclovene in media of different acidity are completely different. The pathway (XXV)→(XXXI) does not occur in a superacid, because it would lead to a less stable ion. However, it is not clear why the reactions observed in a superacid, which could lead both to more stable ions and more stable olefins (XXXIII) and (XXXIV) than the ion (XXXI) and the corresponding olefin (XXX) actually obtained, do not occur in a usual acid.

If the rearrangements occurred intramolecularly in the usual acids, one would have to expect the same mode of rearrangement in both types of media in conformity with the relative stabilities of the intermediate and final ions. Consequently the process in a usual acid proceeds via the intermolecular protonation–deprotonation pathway. This hypothesis is confirmed by the fact that the reformation of the ion (XXV) from the olefin (XXX), obtained in usual acid, is observed in a superacid (i.e. via an intramolecular pathway). If one considers the "fork" in the rearrangements in different media [Scheme 7, the ion (XXVI)] and attention is turned to the stability of the olefins (XXIX) and (XXXVII)–(XXXIX), whose appearance is possible on deprotonation of the cations (XXXII), (XXXV), and (XXXVI), then it is readily seen that the "normal acid" olefin (XXXVII) is significantly more stable (to the extent of 1.6–19.6 kcal mol^{-1}) than the "superacid", anti-Bredt olefins (XXIX), (XXXVIII), and (XXXIX). Hence one may postulate that the mode of the rearrangements of neoclovene in a usual acid is determined by the relative stabilities of the intermediate olefins. It also follows from Scheme 7 that the principle of the parallel variation of the relative stabilities of carbonium ions and the corresponding olefins, put forward by Sorensen, breaks down in the given instance and the extent to which the variation is antiparallel may exceed 20 kcal mol^{-1}.

In the general case, the rearrangements of carbonium ions in a usual acid are regulated by the competition between several possible intramolecular 1,2-shifts and the protonation–deprotonation reaction. The methods for the estimation of the activation barriers to the intramolecular 1,2-shifts were considered above (see Section III). We shall now examine the protonation–deprotonation equilibrium under the conditions of acid catalysis where the enthalpies of formation of ions and olefins are apparently similar. In this situation, the gas-phase heats of formation calculated by the MM method are unsuitable and we attempted to resort to the concept of the intrinsic strain of the molecule (S) [1] (Scheme 7). It is seen from the values of S that the deprotonation reactions of the carbonium ions (XXVII), (XXVIII), (XXXI), and (XXXII), leading to Bredt olefins, are accompanied by the partial removal of the intrinsic strain (to the extent of 2–6 kcal mol^{-1}). On the other hand, the deprotonation of the ions (XXXV) and (XXXVI) with formation of anti-Bredt olefins increases the intrinsic strain by 10–30 kcal mol^{-1}.

Thus one may expect that the deprotonation processes in a usual acid, accompanied by an appreciable growth of the intrinsic strain in the molecule, would be difficult.

Thus the MM method makes it possible to calculate fairly reliably the stability of carbonium ions with a localised change and to estimate the heights of the activation barriers to the 1,2-shifts of the migrating species. The fruitfulness of the use of the MM method has been demonstrated in predictions of the most probable pathways in the acid-catalysed reactions of terpenoids in media of different acidity.

High-temperature X-ray diffraction: experience in the use of samples on a backing plate for studying crystalline phases mixed with the liquid

S K Filatov
St. Petersburg University

ABSTRACT. This review covers the operating procedures for X-ray diffraction studies of materials and processes in the presence of the liquid phase over a wide range of temperatures using standard X-ray diffractometers with a polycrystalline sample on a backing plate. The feasibility of using high-temperature X-ray diffraction to study materials during melting and crystallisation, to construct the supersolidus parts of equilibrium diagrams of systems, to investigate fluid crystalline materials, to find the optimum conditions for preparing materials from a solution in the melt, etc. is demonstrated.

The bibliography comprises 14 references.

I. Introduction

High-temperature X-ray diffraction has in recent decades been used successfully to study crystalline materials at different temperatures. The method has been used to determine the phase composition of a material, its crystal structure, and thermal expansion and to study high-temperature solid state transitions. Results obtained from high-temperature X-ray diffraction studies are used to construct the subsolidus parts of equilibrium diagrams of systems and as a check on the creation of technologies and materials which will function at high temperatures.[1–5]

High-temperature X-ray diffraction can also be used to study samples in the presence of a liquid.[6,7] However this facility is not often used and the results available are therefore not very complete. A choice has to be made between the two main methods of preparing a sample for investigation: packing the powder into a holder or applying the powder to a backing plate. These methods are equally laborious and similar in cost but the second fundamentally expands the potentialities of the method because it enables the material to be examined not only as a solid but also as a mixture of solid and liquid, e.g. during melting of a crystalline material.

The aim of this paper is to review and popularise the practice of using samples on a backing plate for high-temperature X-ray diffraction studies.

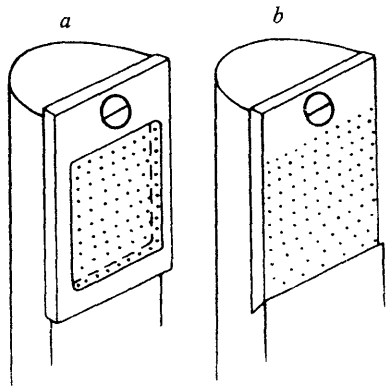

Figure 1. Powder samples for high-temperature X-ray diffraction prepared: *a*, in a holder; *b*, on the surface of a plate.

II. The sample for high-temperature X-ray diffraction

The powdered compound under investigation is usually packed into a holder made of a chemically inert material (Fig. 1*a*). Due to the geometry of the diffractometer the holder is positioned vertically and consequently on heating the material may crumble and slip down and on fusion it may run out of the holder. A more reliable specimen is obtained by depositing a thin layer of the powder on a thick plate, a backing plate,[5–7] which is not the heater (Fig. 1*b*). When this type of sample is heated above the melting point of the compound under investigation the liquid almost always wets the vertical surface of the backing plate and remains on it. An inert material, e.g. platinum, is used for the backing plate.

If the thermal expansion coefficient of the backing plate is known the latter can be used as an "internal" standard by measuring the reflection angles at all the temperatures studied. The risk of the specimen and the standard contaminating each other on heating is then less than when a powdered internal standard is used.

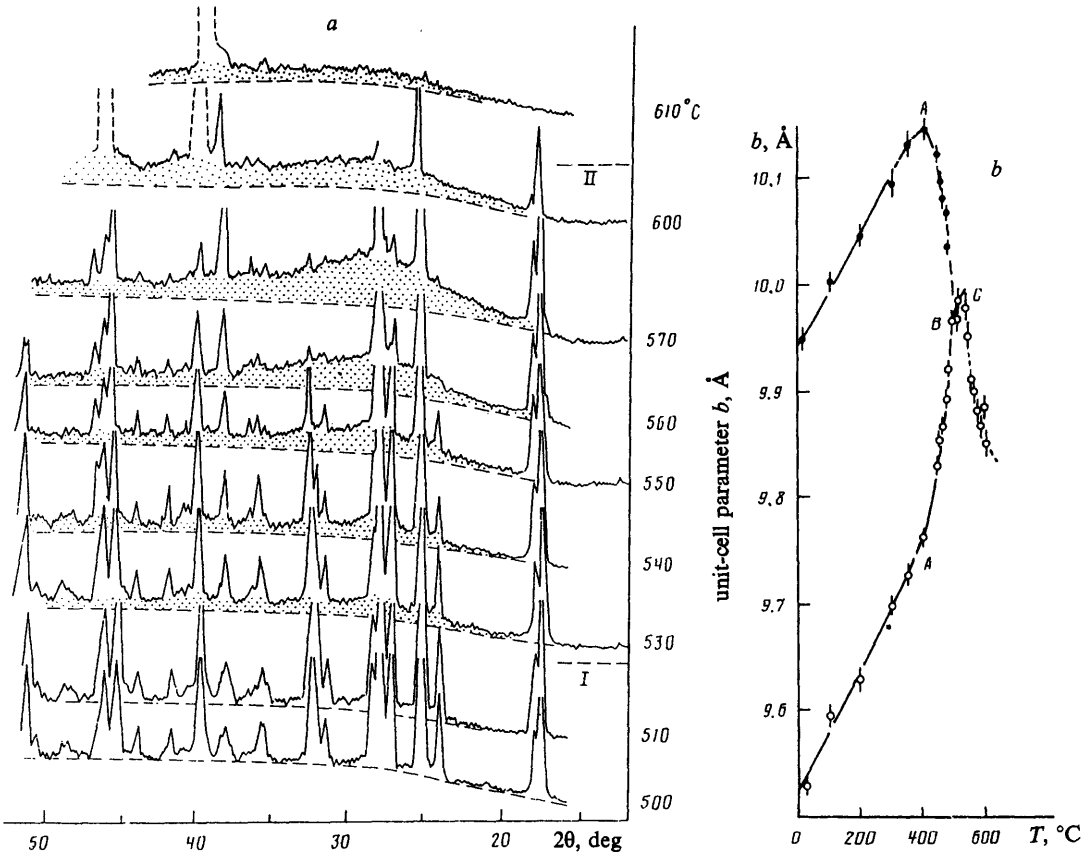

Figure 2. Typical changes with temperature in the X-ray diffraction pattern (*a*) and the unit-cell parameter (*b*) of solid solutions. Specimen composition: 80 mol% $NaVO_3$ + 20 mol% KVO_3, monoclinic phases, diopside structure type; CoK_α radiation.

A uniform thin layer (0.2–0.4 mm) of the powder on the backing plate can be obtained as follows. The plate is laid horizontally, a small quantity of the powder (some tens of milligrams) poured on to it, a few drops of alcohol added, the material levelled out with a thin (ø ≈ 0.1 mm) steel wire and kept in suspension for several minutes until all the alcohol has evaporated. If the material reacts with alcohol or the water present in it another highly volatile liquid must be used.

The thickness chosen for the layer of powder is such that the diffraction peaks from the backing plate (platinum) are completely absorbed. For inorganic compounds a layer of powder 0.2–0.4 mm thick satisfies this condition. However if the peaks from the backing plate are to be used as internal standards a thinner layer of powder is applied.

A very small amount of material is required for this type of sample, the specimen is stable at different temperatures, and solid and liquid phases can be studied concurrently.[5–13]

The representative costs of the labour and materials involved in preparing such a sample are nothing compared with the difficulties of setting up an X-ray diffractometer with a horizontal sample surface because with a geometry of that type the counter would have to rotate in a vertical plane.

III. Studies of the fusion of materials

Determinations using the halo due to the amorphous phase. Using X-ray diffraction, melting is defined by the disappearance of the diffraction maxima belonging to the crystalline phase and the appearance of a halo due to an amorphous phase (see, for example, Fig. 2*a*, 610 °C).

Melting of part of the material may be indicated by the appearance of a halo and substantial changes in the relative intensities and positions of the diffraction maxima taking place due to recrystallisation of the solid phase in the melt with a change in its chemical composition and the possible emergence of texture; compare, for example, Fig. 2*a*, 510 °C (before melting) and 560 °C (after partial melting).

If some of the melt runs off the vertical surface of the specimen holder the diffraction peaks due to the backing plate material may appear or be intensified in the diffraction pattern (see broken lines in Fig. 2*a*, 600° and 610 °C).

For a sample from the $NaVO_3$–KVO_3 system (4:1) (Fig. 2*a*) melting as defined by the criterion described starts in the region of 530 °C (line *I*) and is complete at 605 °C (line *II*).

As the halo is normally detected when there is a sufficiently large amount of the melt, there is an appreciable threshold in the sensitivity of this method to the appearance of the melt (10%).

Determinations based on the lattice parameters. The variation of the crystal lattice parameters with temperature is often a more sensitive "indicator" of melting. The onset of melting is marked by pronounced changes in the relationship. For example, for the 4:1 specimen in the $NaVO_3-KVO_3$ system melting, as defined by this criterion, starts at 535 °C (point *C* in Fig. 2*b*) and is complete at 610 °C. The detection of melting from the changes in the unit-cell parameters *b*, β, and the unit-cell volume *V* give consistent results within a few degrees.

IV. Determination of the lattice parameters of crystalline phases in mixtures with the liquid

The unit-cell parameters of a crystalline phase mixed with the liquid can be determined using a sample on a backing plate. The first such determination was made in a study of the $NaVO_3-KVO_3$ system.[12] As an example, the temperature dependence of the unit-cell parameter *b* of a 4:1 specimen from this system is shown in Fig. 2*b*. The specimen consists of two monoclinic phases of the diopside type. When these are heated, up to a certain temperature (400 °C, point *A* in Fig. 2*b*) they undergo only thermal expansion but between points *A* and *B* (~400–500 °C) the phases are homogenised, then on the section *BC* (500–530 °C) the homogeneous solid solution undergoes thermal expansion, and at point *C* (530 °C) it starts to melt.[5]

V. Studies of the supersolidus parts of equilibrium diagrams

High-temperature X-ray diffraction is widely used together with thermal analysis to study the equilibrium diagrams of systems, mainly because it is advantageous for the interpretation of transitions and identification of the phases.

It is usually used to study the subsolidus part of an equilibrium diagram. When using the method in its standard version, the formation of a liquid phase makes further investigation impossible because the material runs off the vertical plane of the sample.

Using a sample on a backing plate enables not only the solid state transformations but also the solidus and liquidus lines to be studied, i.e. a complete high-temperature X-ray diffraction study of the equilibrium diagram of a system to be made.[5,10,12,13]

Solidus and liquidus lines (plotted at various compositions). The methods described above (see Section III) are used to determine the temperatures of the commencement and termination of melting for specimens with different chemical compositions and then the solidus and liquidus lines are plotted.

Solidus line (plotted at a single composition). This is achieved using the unit-cell parameters of solid solutions. The variation of the unit-cell parameters with temperature and chemical composition is studied. The unit-cell parameters of the crystalline phases are measured at various temperatures. The dependence of these parameters on temperature and composition is used to calculate the chemical composition of the solid solutions at each temperature at which measurements are made. The points obtained are plotted on the equilibrium diagram and the interphase boundaries (solidus, binodal decomposition curve) are constructed from them.

The variation of the parameter *b* of the monoclinic solid solutions $K_xNa_{2-x}V_2O_6$ in the $NaVO_3-KVO_3$ system with temperature (*T*, °C) and potassium content (at.%) is described by the equation:

$$b = 9.478 + 0.55 \cdot 10^{-3} T + 0.0117x.$$

Part of the equilibrium diagram of the system, obtained by studying a specimen with an Na:K atomic ratio of 4:1, is shown in Fig. 3. When the temperature is raised above the solidus line this specimen breaks down into a liquid phase which is richer in potassium and a solid solution richer in sodium. In this case heating leads not only to the customary thermal expansion but also to a change in the chemical composition of the solid solution. Consequently, as is clear from Fig. 2*b*, on heating beyond point *C* the replacement of potassium ions by the smaller sodium ions leads to a marked contraction of the structure in spite of the thermal expansion that is taking place.

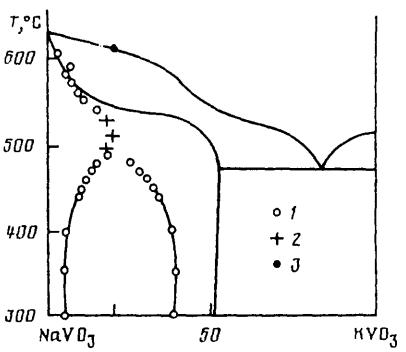

Figure 3. Construction of the equilibrium diagram of the $NaVO_3-KVO_3$ system. The experimental points were obtained using the parameter *b* for two-phase specimens (*1*) and single-phase specimens (*2*) and from the disappearance of peaks due to a crystalline phase (*3*).

The eutectic. Aspects of the X-ray diffraction study of melting in the region of the eutectic (475 °C, 83 mol% KVO_3) are illustrated in Fig. 4. When a specimen containing 80 mol% KVO_3 is heated, initially the peaks belonging to one phase (shown hatched in Fig. 4) disappear and a halo due to the liquid phase appears. There are no marked changes in the positions of the peaks belonging to the other phase or in its unit-cell parameters above the eutectic temperature (because there is no appreciable isomorphous miscibility) right up to the liquidus line, at which point these peaks disappear (*cf.* the melting of the solid solution, Fig. 2).

For compositions lying to the left of the eutectic, the diffraction peaks belonging to the right-hand phase disappear first and for those lying to the right of the eutectic, the peaks due to the left-hand phase disappear first. The composition of the eutectic is taken to be the mean between the two closest compositions at which different phases disappear. The melting point of the eutectic is the temperature at which one of the phases in the eutectic mixture

disappears. The closer the chemical composition of the specimen to that of the eutectic mixture the more melt is formed at the eutectic temperature (and hence the stronger the halo).

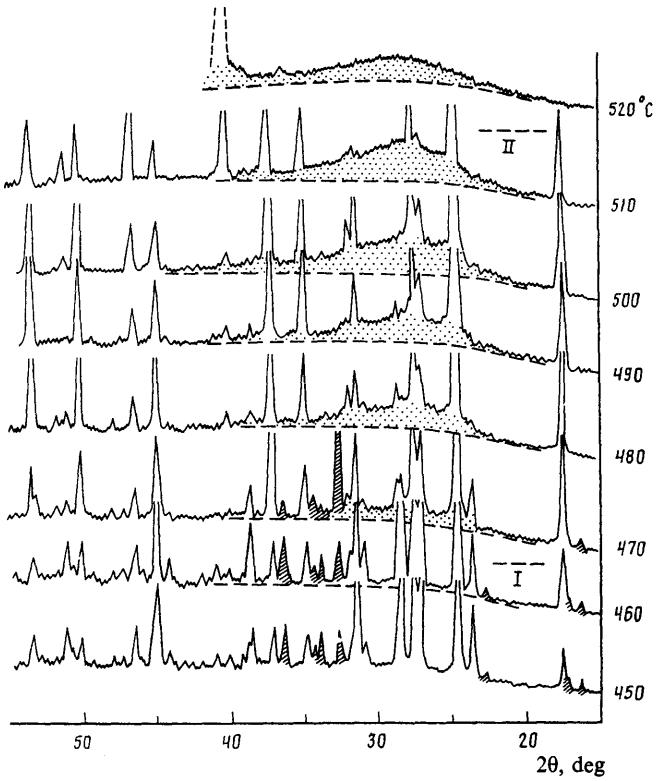

Figure 4. Typical changes in the X-ray diffraction pattern of a eutectic mixture with temperature. Specimen composition: 20 mol% $NaVO_3$ + 80 mol% KVO_3; the KVO_3 peaks are hatched and those due to $KNaV_2O_6$ are not; CoK_α radiation.

High-temperature X-ray diffraction gives some unexpected results in studies of the melting of eutectic systems. Note in particular that in the example we have been discussing (Fig. 4) the first phase disappears at a temperature (475 °C) which is 20° above (and hence later than) the appearance of the halo due to the liquid (455 °C), rather than simultaneously. Insufficiently studied premelting processes may be the cause of this.

High-temperature X-ray diffraction makes it possible to observe phases and processes at different temperatures directly and to identify them objectively. It is therefore advisable to use this method of studying equilibrium diagrams in conjunction with other methods of thermal investigation.

VI. Finding the optimum conditions for preparing materials

Reactions between substances are more rapid in the melt than between solid phases. For this reason it is helpful to introduce an easily fusible component into the mixture.

For example, in order to prepare anorthite $CaAl_2Si_2O_8$, $CaCl_2$ (m.p. 777 °C) was mixed with dickite $Al_2Si_2O_5(OH)_4$ in a 1:1 ratio, the mixture was heated, and X-ray diffraction patterns recorded at various temperatures (Fig. 5).[5] In the pattern recorded at 600 °C the diffraction peaks belonging to $CaCl_2$ are hatched. On reaching 700 °C the peaks belonging to dickite disappear due to dehydration and conversion to a metakaolinite that is amorphous to X-rays (thermographic and quenching data). The diffraction pattern recorded at 800 °C contains no peaks belonging to $CaCl_2$ either, indicating that the metakaolinite phase is in a $CaCl_2$ melt. This state also persists at 900 °C (Fig. 5).

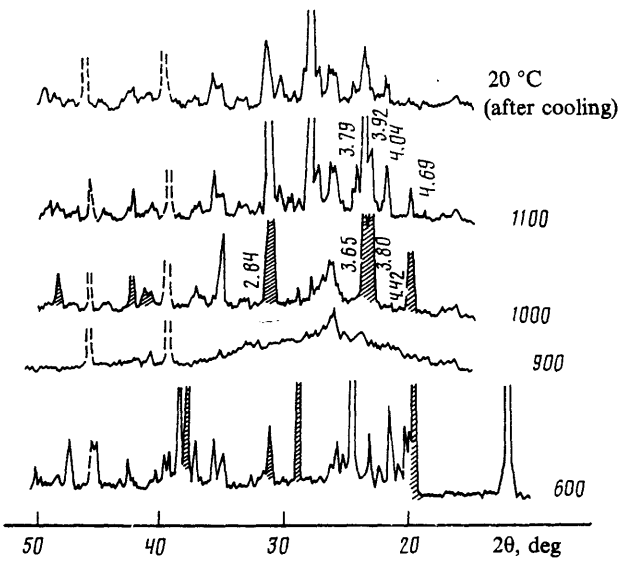

Figure 5. Preparation of anorthite: X-ray diffraction patterns of dickite mixed with $CaCl_2$ (the peaks at 600 °C due to the latter are hatched) and the products obtained by heating them (CuK_α radiation).

At 1000 °C a new structure (a layer type anorthite with the interplanar spacings d = 4.42, 3.80, 3.65, and 2.84 Å) is found in the products and when the temperature is raised to 1100 °C this is transformed to a framework modification of anorthite (with d = 4.69, 4.04, 3.92, and 3.79 Å) which is retained on cooling to room temperature.

In this experiment the film of liquid was kept on the vertical backing plate by surface adhesion forces (see Fig. 5, 900 °C). This permitted direct "observation" of the synthesis of anorthite involving the liquid phase, determination of the synthesis temperature, and the discovery that a layer-type modification of anorthite is formed initially (at 950 ± 50 °C) and is irreversibly converted to the more stable framework modification of this compound at 1050 ± 50 °C.

VII. High-temperature studies of fluid materials (taking rotational crystals — paraffins as an example)

Certain crystalline compounds display considerable fluidity, especially at temperatures near the melting point. High-temperature studies of fluid materials are not feasible on standard X-ray diffractometers with the sample packed into a vertical holder but no technical difficulties are encountered if the sample is placed on a backing plate.

Let us take as an example the normal paraffins C_nH_{2n+2}. At low temperatures these have normal crystal structures with three-dimensional periodicity but on heating they change, due to rotation of the linear molecules around their axes, to rotational crystals which have one-dimensional periodicity and finally melt, losing the periodicity. In all these states paraffins can be retained safely on the vertical surface of a sample for high-temperature X-ray diffraction.

The polymorphism of paraffins. The diffractometer traces in Fig. 6 show that the low-temperature orthorhombic modification of the paraffin with $n = 23$ changes at 40 °C to the (comparatively) high-temperature hexagonal rotational modification (the 200 and 110 peaks merge together) which melts at 47 °C. X-Ray diffraction studies of other members of the homologous series show that, contrary to the accepted opinion, the paraffins with n odd and less than 23 melt without reaching the hexagonal state.[11]

Ranges [of existence] of paraffin solid solutions. Both in nature (as concomitants of petroleum, coverings of plants) and in industries (packaging, food, electronic, and other branches) paraffins usually occur as a mixture of many homologues. For this reason studies have been made of the ranges of existence of solid solutions of different paraffins and the effect of the formation of solid solutions on polymorphism, melting, and other properties of paraffin compositions.[14]

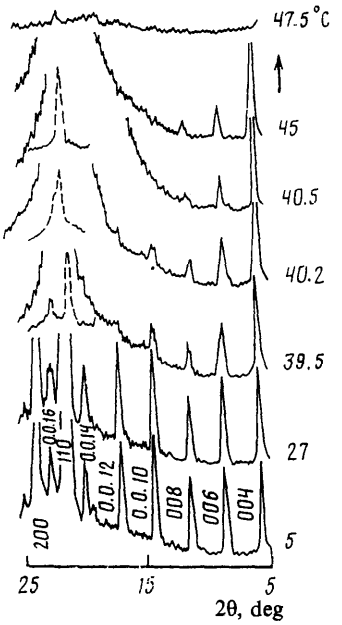

Figure 6. X-Ray diffraction patterns of the paraffin with $n = 23$ at different temperatures.[11] The peaks shown by broken lines were re-recorded using an anode current 10 times smaller; CuK_α radiation.

The data plotted in Fig. 7 show that when a homogeneous orthorhombic solid solution with the composition $C_{21}H_{44}:C_{23}H_{48} = 1:5$ is heated it breaks down at 30 °C to give two orthorhombic solid solutions, then at 34 °C the mixture of phases becomes homogeneous again, and close to 39 °C it changes to the hexagonal

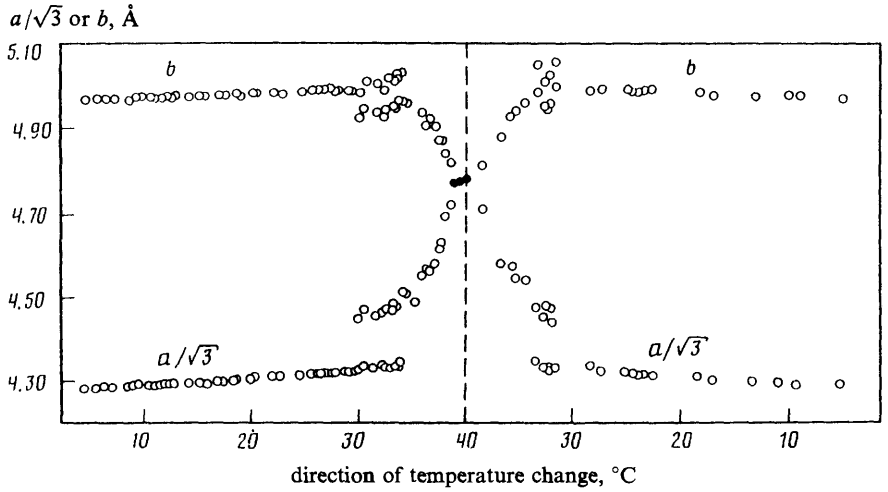

Figure 7. Variation with temperature (both heating and cooling) of the parameters $a/\sqrt{3}$ and b of the orthorhombic and hexagonal unit cells of a paraffin solid solution with the composition $C_{21}H_{44}:C_{23}H_{48} = 1:5$. The dark points relate to the hexagonal modification.

phase. On cooling these changes are repeated in the reverse sequence. This is the only example we know of where the range of the solid solution contracts on raising the temperature. It is evidently connected with the rotation of the molecules.

When the solid solution is heated the shorter aliphatic chains in the paraffin with $n = 21$ reach critical amplitudes of swinging, and possibly complete rotation around their axes, at an earlier stage and they escape from the structure of the homogeneous solid solution; at a temperature a few degrees higher when the longer molecules with $n = 23$ reach a comparable degree of oscillation or rotation, all the molecules again become comparable in energy and the mixture becomes homogeneous again.[14]

VIII. Conclusion

The high-temperature X-ray diffraction of polycrystalline samples is an objective method of studying the qualitative and quantitative phase composition of crystalline materials during a variety of solid-state thermal changes.

Using a standard X-ray diffractometer with a polycrystalline sample in the form of a thin layer of material on an inert backing plate also enables us to study crystalline materials in contact with the liquid phase, i.e. to study fusion, crystallisation, and recrystallisation processes. This provides opportunities for the complete high-temperature X-ray diffraction study of the equilibrium diagrams of systems, including their supersolidus part, and also for investigating the processes of the formation of crystalline materials from the liquid, and modelling magma and other processes involving the liquid phase.

The experience in the use of samples on a backing plate built up in the Department of Crystallography of St. Petersburg University over a period of twenty-five years shows that films of melts of various chemical compositions can be maintained on the vertical surface of a platinum backing plate by adhesion forces, so making it possible to carry out the high-temperature X-ray diffraction studies that have been described.

We can be confident that this experience will promote a wider application of high-temperature X-ray diffraction, especially with the use of a sample on a backing plate, for solving problems in crystal chemistry, physical chemistry, materials science, etc.

I am grateful to my colleagues, especially R S Bubnova and E N Kotel'nikova, for the joint research which I have quoted in this review.

Silicon-containing 1,3-alkenynes and more unsaturated compounds

M D Stadnichuk, T I Voropaeva
The Technological Institute, St. Petersburg

ABSTRACT. The methods of synthesis and characteristic features of the reactivity of silicon-containing alkenynes are treated systematically and surveyed for the first time. It is shown that the carbon–carbon double bonds are reactive in the reactions of silahydrocarbons and their functional derivatives containing the $\equiv Si-C\equiv C-C=C<$ fragments. Only aluminium, boron, and tin hydrides as well as certain weak electrophiles add preferentially or exclusively to the triple bond. The absence of a dependence of the mode of addition on the polarity of the unsaturated compound and the other reactant indicates orbital control in the reactions investigated.

Studies of the dependence of the mode of reaction (addition, desilylation, reactions of functional groups) on the structure of the silicon-containing alkenynes, the nature of the other reactant, and the experimental conditions served as a basis of the development of methods for the introduction of functional groups into the alkenynes and of a silyl protecting group method in the chemistry of acetylenic compounds and have demonstrated the extensive possibilities of the application of these procedures in the stereocontrolled synthesis of natural products and their synthetic analogues.

I. Introduction

The highly unsaturated compounds containing a conjugated double and triple bond and an organosilyl group attached to a multiply bound carbon atom exist in the form of three isomers differing in the position of the silicon-containing substituent:

$R^1_3Si-C\equiv C-CR^2=CR^3R^4$ (A)

$R^1_3Si-CR^2=CR^3-C\equiv CR^4$ (B)

$R^2R^3C=C(SiR_3)-C\equiv C-R^4$ (C)

Representatives of all these types have now been synthesised, but compounds of type (A) are historically the first and have been most thoroughly investigated. Hundreds of original articles have been devoted to the methods of their synthesis and chemical properties, but there are no reviews on the problem.

Compounds of types (B) and (C) have not been studied systematically. The communications published on this problem were devoted to the development of the methods of their synthesis and are as a rule non-systematic in character.

In the first stage, the chemistry of 1-triorganosilylalk-3-en-1-ynes (A) was indissolubly linked to the study of fundamental problems of theoretical organic chemistries such as conjugation, including $d_\pi-p_\pi$ conjugation, the relation between reactivity and structure, and the redistribution of the π-electron density of conjugated multiple bonds under the influence of the organosilicon substituent. A considerable proportion of studies in the first stage were therefore devoted mainly to the synthesis of 1-trialkylsilylalk-3-en-1-ynes and to the study of their properties. Such investigations (UV,[1] IR,[2–8] and photoelectron spectra,[9] molecular refraction,[10,11] quantum-chemical calculations,[12,13] ^1H[14] and ^{13}C[13,15–17] NMR spectra, dipole moments,[18–20] and mass spectra[21]) yield direct or indirect information about the magnitude and sign of the induction and mesomeric constants of the silicon-containing groups. The results have demonstrated unambiguously that the triorganosilyl groups attached to the triple bond exhibit an overall electron-donating effect, which is somewhat smaller than that of the hydrocarbon groups with the corresponding structures, while the basic (π-donor) properties of the triple bond in the 1,3-enyne silahydrocarbons are weaker than those of the hydrocarbons having similar structures. The spectroscopic parameters (IR, ^1H NMR, and mass spectra) have been recommended for analytical purposes in the determination of the structures of highly unsaturated organosilicon compounds.

Interest in the chemistry of enyne organosilicon compounds of type (A) increased appreciably after the development of mild desilylation methods (the removal of the triorganosilyl substituent stabilising the triple bond) as well as methods for the stereocontrolled synthesis of functional derivatives of 1-triorganosilylalk-3-en-1-ynes and the possibility of using them as synthetic units in fine organic synthesis was demonstrated.

II. Synthesis of 1-triorganosilylalk-3-en-1-ynes

The methods of synthesis of 1-triorganosilylalk-3-en-1-ynes and their carbofunctional derivatives known at present include procedures such as silylation of complete 1,3-enyne hydrocarbons and their derivatives, the creation of enyne structures as a result of β-elimination reactions of the derivatives of the corresponding acetylenic silylhydrocarbons or reactions involving the addition of silicon-containing diynes, the isomerisation (including reactions with ring opening) of unsaturated organosilicon compounds, as well as the creation of alkenyne structures as a result of the cross-coupling of silicon-containing acetylenes with the corresponding alkenes or

their precursors. As a rule, these fundamental approaches to the synthesis of a specific compound are intertwined and may involve simultaneously the formation of a double bond and the construction of the carbon skeleton and silylation.

1. Silylation of alkenynes

The most important methods for the laboratory synthesis of silicon-containing alkenynes and their derivatives is organometallic synthesis involving the interaction of the corresponding Iotsich complex with trialkylchlorosilane. 3-Methyl-1-triethylsilylpent-3-en-1-yne, the first representative of silicon-containing vinylacetylenes, was synthesised by this method in 1946:[1]

$$Et_3Si{-}Cl + CH_3CH{=}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{-}C{\equiv}CMgBr \longrightarrow$$

$$\longrightarrow Et_3Si{-}C{\equiv}C{-}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{=}CHCH_3.$$

The Iotsich reagents derived from the simplest vinylacetylenic (vinyl-,[22–24] isoalkenyl-,[25–29] alkenyl-,[25–30] and cycloalkenyl-acetylenes[25,27,28]) and more unsaturated hydrocarbons[31–34] were initially made to react with trialkylchloro- and dialkyldichloro-silanes. Trialkyl-, dialkylaryl-, and alkyldiaryl-chloro-silanes, entered into this reaction. With increase in the number of aryl groups at the silicon atom, the yield of the condensation products fell.[23,24] The attempts obtain 1-triphenylsilylbut-3-en-1-yne by the reaction of chlorotriphenylsilane and vinylethynylmagnesium bromide was unsuccessful.[23] The corresponding silylhydrocarbon was synthesised only by the reaction of the Iotsich complex with fluorotriphenyl-silane.[24] However, tri-*p*-chlorophenylsilylvinylacetylene was obtained by the reaction of the corresponding chlorosilane with the Iotsich complex, but it was necessary to heat the reaction system to a high temperature—the temperature of boiling dibutyl ether.[24]

The vinylacetylenic hydrosilanes $R_2HSi{-}C{\equiv}C{-}CH{=}CH_2$ and $RHSi(C{\equiv}C{-}CH{=}CH_2)_2$ were synthesised by the reaction of chlorohydrosilanes with vinylethynylmagnesium bromide.[23]

There are data showing the trialkyliodosilanes give rise to the corresponding vinylacetylenic silylhydrocarbons in higher yields than trialkylchlorosilanes.[25]

Alkoxysilanes, siloxanes, alkoxychlorosilanes, and triflates can be used as the silicon-containing component:

$$R^1_{4-n}(R^2O)_nSi + CH_2{=}CH{-}CMgBr \rightarrow R^1_{4-n}Si(C{\equiv}C{-}CH{=}CH_2)_n$$

(Refs. 23, 35, 36),

$$(R^1R^2SiO)_x + CH_2{=}CH{-}C{\equiv}CMgBr \rightarrow HO(R^1R^2)SiC{\equiv}C{-}CH{=}$$

$$={=}CH_2 \quad \text{(Refs. 37, 38)},$$

$$(RO)_3SiCl + CH_2{=}CH{-}C{\equiv}CMgBr \rightarrow (RI)_3SiC{\equiv}C{-}CH{=}CH_2$$

(Refs. 39, 40),

$$R_3SiCTf + CH_2{=}CH{-}C{\equiv}CMgBR \rightarrow R_3SiC{\equiv}CH{=}CH_2 \text{ (Ref.41)}.$$

A method based on the reaction of a mixture of the enyne hydrocarbon and chlorotrimethylsilane with butyllithium in hexane, presupposing the formation of lithium vinylacetylide, was developed for the synthesis of alkenyl-1-trimethylsilyl-, isoalkenyl-1-trimethyl-silyl-, and cycloalkenyl-1-trimethylsilyl-acetylenes:[30,42–44]

$$R^2CH{=}CR^1{-}C{\equiv}CH \xrightarrow[2.\ Me_3SiCl]{1.\ LiBu} Me_3SiC{\equiv}C{-}CR^1{=}CHR^2.$$

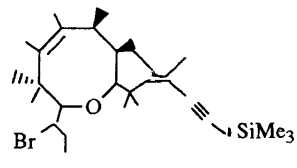
When isopropenylacetylene is treated with a mixture of butyllithium and potassium t-butoxide, the corresponding organo-potassium compound reacts with the chlorosilane:[43]

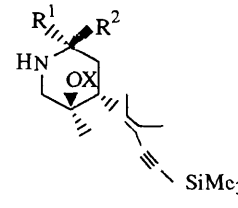
$$\underset{\displaystyle CH_3}{\overset{\displaystyle |}{CH_2{=}C{-}C{\equiv}CH}} \xrightarrow{BuLi;\ t\text{-}BuOK} \underset{\displaystyle CH_2K}{\overset{\displaystyle |}{CH_2{=}C{-}C{\equiv}CK}} \xrightarrow{Me_3SiCl} \underset{\displaystyle CH_2SiMe_3}{\overset{\displaystyle |}{CH_2C{-}C{\equiv}}}$$

$$\equiv CSiMe_3.$$

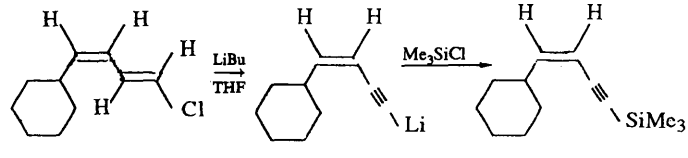
Subsequently the method of synthesis of lithium acetylides was simplified and reduced to the single-stage interaction of metallic lithium with vinylacetylene in tetrahydrofuran (THF).[45,46] Sodium vinylacetylide was obtained similarly.[47] The use of lithium and sodium acetylides makes it possible to increase the yield of the target products by 30–40% compared with the reactions of Iotsich complexes having analogous structures.[45–47]

The organolithium, organosodium, and organomagnesium syntheses of silicon-containing alkenynes can be used also for the preparation of functional derivatives of hydrocarbons subject to the condition that the functional group does not interact with the organometallic compound. Silicon-containing vinylacetylenic alcohols,[48–51] ethers,[52–54] sulphides,[55] acetals,[56,57] ketals,[41] tertiary amines,[30,42,58–60] and more complex organic compounds[61,63] were obtained in this way, for example:





An unusual version of this method involves a procedure employed in the synthesis of (*Z*)-4-cyclohexyl-1-trimethylsilylbut-3-en-1-yne:[64]



and 3-ethoxy-1-trimethylsilylbut-3-en-1-yne:[65]

$$CH{\equiv}CF + CH_2{=}C(Li)OEt \longrightarrow \underset{\displaystyle OEt}{\overset{\displaystyle |}{CH_2{=}C}}{-}C{\equiv}CLi \xrightarrow{Me_3SiCl}$$

$$\longrightarrow \underset{\displaystyle OEt}{\overset{\displaystyle |}{CH_2{=}C}}{-}C{\equiv}CSiMe_3.$$

The method involving the direct silylation of vinylacetylene with iodosilatrane was developed by Voronkov et al.:[66]

$$CH_2{=}\,CH{-}C{\equiv}CH + ISi(OCH_2CH_2)_3N \longrightarrow$$

$$\longrightarrow CH_2{=}CH{-}C{\equiv}CSi(OCH_2CH_2)_3N.$$

The same vinylethynylsilatrane was obtained by the transalkylation of triethoxyvinylethnylylsilane with triethanolamine.[67]

2. β-Elimination reactions

(a) Dehydration of silicon-containing acetylenic alcohols

This method was successfully used for the first time in the synthesis of silicon-containing alkenynes in 1957. Distillation of dimethyl(trimethylsilylethynyl)carbinol in the presence of catalytic amounts of potassium hydrogen sulphate afforded 3-methyl-1-trimethylsilylbut-1-yne in a satisfactory yield.[68] Phosphorus pentoxide,[69,70] adipic acid,[71,72] boric acid,[72] toluene-*p*-sulphonic acid,[70–75] and phosphoryl chloride[76] began to be used later as dehydrating agents.

The method yields positive results not only in the synthesis of the corresponding silylhydrocarbons[68–78] but also of their derivatives,[70,74,76] as well as bisalkenylsilanes. In the latter case, the corresponding glycols of the type $Me_2Si[C{\equiv}C{-}C(CH_3)_2OH]_2$ and $[HO(CH_3)_2C{-}C{\equiv}C{-}SiR_2]_2A$ (A = $-CH_2CH_2-$ or ) were dehydrated.[79–83]

Oxygen-containing tertiary acetylenic alcohols and glycols have also been dehydrated. The attempts to dehydrate a secondary alcohol with potassium hydrogen sulphate failed to give positive results.[84]

One should evidently note the unusual dehydration, contrary to Zaitsev's rule, of a diacetylenic ketoalcohol, which led to the formation of a "stable" enol:[74]

$$Me_3SiC{\equiv}C{-}\,C(OH)CH_3CH_2COC{\equiv}\,CSiMe_3 \xrightarrow[-H_2O]{H^+}$$

$$\longrightarrow Me_3SiC{\equiv}C-\underset{\underset{CH_2}{\|}}{C}-CH=\underset{\underset{OH}{|}}{C}-C{\equiv}\,CSiMe_3.$$

The stereochemistry of the dehydration has not been studied in most cases but there are indications that water is split off stereospecifically.[85,86]

(b) Base-catalysed elimination of hydrogen halides and other acids

The dehydrohalogenation method, widely used in the chemistry of alkenes, has been scarcely employed in the synthesis of silylhydrocarbons owing to the low hydrolytic stability of the silicon–carbon bond: the elimination of hydrogen halides is as a rule accompanied by desilylation. For example, treatment of 1,4-dibromo(bromochloro)-1-trimethylsilylbuta-1,2-diene with an alcoholic solution of alkali involves dehydrohalogenation and desilylation even in the cold with formation of the corresponding α-halovinylacetylenes:

$$Me_3SiCX{=}C{=}CHCH_2Br \xrightarrow[EtOH]{KOH} XC{\equiv}C{-}CH{=}CH_2;$$

X = Cl (Ref.87), Br (Ref.25).

The data on the dehydrobromination of silicon-containing acetylenic bromoethers are contradictory; whereas according to the data of Komarov and co-workers dehydrobromination without the cleavage of the silicon–carbon bond occurs only when triethylamine is used as the base and dehydrosilylation takes place in the presence of alkali,[88] according to Shchukovskaya and Kapustyanskaya[89] the dehydrobromination of bromoethers can be carried out also in the presence of solid potassium hydroxide:

$$R_3SiC{\equiv}C{-}\underset{\underset{OR'}{|}}{CH}CH_2Br \begin{cases} \xrightarrow[EtOH]{KOH} CH{\equiv}C-C(OR'){=}CH_2\ ; \\ \xrightarrow[\text{or KOH}]{Et_3N} R_3SiC{\equiv}C-C(OR'){=}CH_2\ . \end{cases}$$

Dehydrohalogenation without appreciable cleavage of the silicon–carbon bond has been used successfully in the synthesis of 1-trimethylsilylalk-3-ene-1,5-diynes[90] and 1,8-bis(trimethylsilyl)octa-3,5-diene-1,7-diyne.[33]

The dehyodrohalogenation (X = Cl, Br, I) of silicon-containing acetylenic and alka-1,2-diene sulphones by tertiary amines takes place particularly readily and with virtually quantitative yields (the reactions occurs at room temperature):[91–94]

$$R_3SiC{\equiv}C{-}CR'XCHR''SO_2Ar \xrightarrow[C_6H_6]{Et_3N} R_3SiC{\equiv}C{-}CR'{=}CR''SO_2Ar.$$

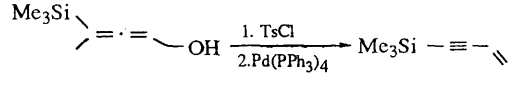
The study of the IR and ^1H NMR spectra as well as the dipole moments of the sulphones formed indicates their exclusive *trans*-structure.[20,91–93]

It has been shown in relation to the dehydroiodination of silicon-containing iodonitroacetylenes that mercury [lead?] acetate may be used as a weak base which does not cleave the silcon–carbon bond:[95]

$$R_3SiC{\equiv}\,CCHICH_2NO_2 \xrightarrow[AcOH,\ 30-40^\circ C]{Pb(OAc)_2} R_3SiC{\equiv}C-CH{=}CHNO_2.$$

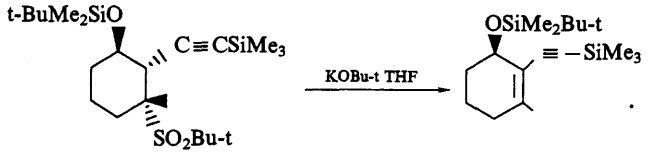
The reaction takes place stereospecifically with formation of compounds having the *trans*-configuration.

The data presented permit the claim that the base-catalysed dehydrohalogenation can serve as a convenient preparative method of synthesis of 1,3-enyne silylhydrocarbons and their derivatives but in each specific instance the solvent and base must be selected empirically. The method involving the base-catalysed (pyridine, diazabicycloundecyne) β-elimination of toluene-*p*-sulphonic acid proved to be successful in the synthesis of 1,3-enyne silylhydrocarbons and their derivatives.[85,86] Tosylates have been obtained from the corresponding secondary silicon-containing acetylenic alcohols and glycols. 4-Trialkylsilylbuta-2,3-diene-1-yl tosylate gives rise to a satisfactory yield of 1-trimethylsilylbut-2,3-en-1-yne on treatment with triphenylphosphine or the palladium complex $Pd(PPh_3)_4$:[96]



The base-catalysed cleavage of acetylenic sulphones, sulphoxides, selenoxides, and other reagents with elimination of H–X, where X = PhSO,[97] PhSeO,[98] t-$BuSO_2$,[99] and $(EtO)_2P(O)O$ [100] respectively, can also be included in this group of methods. It is of interest that

the elimination of 2,2-dimethylethanesulphonic acid on treatment with potassium t-butoxide in the example below is not accompanied by the cleavage of the silicon–carbon bond:[99]



3. Synthesis from 1-trialkylsilylalka-1,3-diynes

The 1,3-diyne silicon-containing compounds, which are available under laboratory conditions, are convenient "starters" for the synthesis of two types of the corresponding silylalkenynes containing a silicon atom attached to the triple or double bond: $R_3SiC{\equiv}C{-}CX{=}CYR'$ and $R_3SiCX{=}CY{-}C{\equiv}CR'$, which can be obtained by adding the reagent XY to one of the triple bonds of the diyne.

(a) Reduction of 1,3-diynes

The catalytic reduction of silicon-containing diacetylenic hydrocarbons was first achieved in 1964.[101] It was established that the reaction proceeds with a high chemoselectivity in relation to the triple bond remote from the silicon atom:

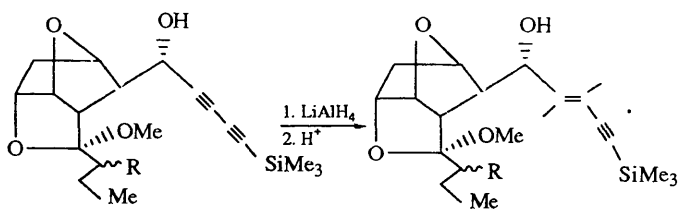
$$R_3SiC{\equiv}C-C{\equiv}C-R' + H_2 \xrightarrow{Pd/CaCO_3} R_3SiC{\equiv}C-CH{=}CHR'.$$

The stereochemistry of the process was not investigated.

The protecting effect of the trialkyl(aryl)silyl groups was used later by other investigators for the selective catalytic hydrogenation of triple bonds "unprotected" by silicon-containing groups in the synthesis of 1,3-enyne silicon-containing hydrocarbons. These studies served as the experimental basis of the method involving the "silyl protection" of the triple α,β-bond in catalytic reduction reactions, the method being widely used in organic synthesis.[102] It has been established that, regardless of the nature of the catalyst (palladium on calcium carbonate or sulphate,[32,101,103] Lindlar's platinum[104,105]) the reaction is chemoselective and stereospecific: the 1-trialkylsilylalk-3-en-1-ynes formed have the (*Z*)-configuration.

The reduction of silylalkadiynes with metallic zinc in ethanol proceeds similarly, i.e. it involves the bond remote from the heteroatom, with the preferential formation of (*Z*)-enynes.[106] The reaction takes place when zinc is activated with lithium dibromocuprate and 1,2-dibromoethane or with 1,2-dibromoethane alone.

(*Z*)-Alkenynes have been obtained exclusively also in the reduction of bis(trimethylsilyl)buta-1,3-diyne with lithium tetrahydroaluminate in THF.[107] On the other hand, the reduction of diacetylenic alcohols with lithium tetrahydroaluminate takes place stereo-specifically in the *trans*-position:[108–110]

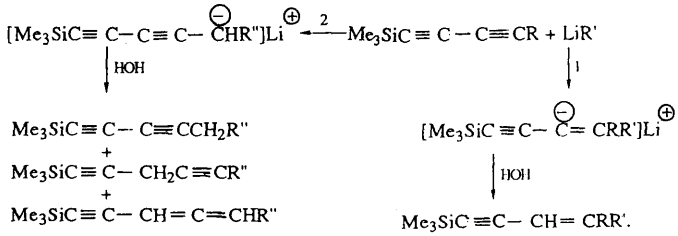


Enyne silicon-containing hydrocarbons with the exclusive (*E*)-configuration are formed in high yields (more than 90%) when lithium trialkylaluminates are used as the reducing agents:[111,112]

$$Me_3SiC{\equiv}C-C{\equiv}CR + Li[AlH(iso\text{-}Bu)_2Bu] \xrightarrow{E} Me_3SiC{\equiv}C-\underset{\displaystyle E}{\underset{|}{C}}{=}C-R.$$
$$\qquad\qquad\qquad

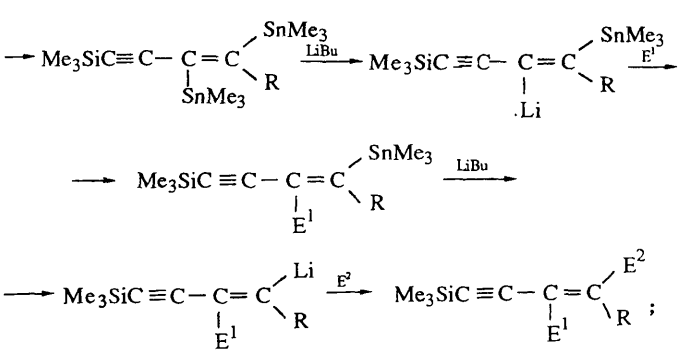
(c) Interaction with organometallic compounds

Organolithium compounds add to the triple bond of 1-trialkylsilylalka-1,3-diynes remote from the silicon atom. After the demetallation of the lithium-containing adducts with water, the corresponding vinylacetylenic silyl-substituted hydrocarbons were obtained in satisfactory yields:[119,120]



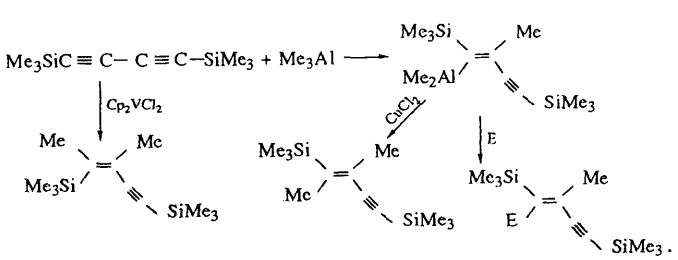
The addition reaction is accompanied by the isomerisation of the initial diacetylenes (pathway 2). Appreciable amounts of the isomerisation products were obtained in reactions of 1-trialkylsilylpenta-1,3-diyne with lithium alkyls.

The silicon-containing alkenynes $Me_3SiC{\equiv}CE^1C{=}CE^2R$ are obtained from the corresponding diacetylenic silicon-containing hydrocarbons by the successive treatment of the diyne with trimetylstannyl cuprate and the corresponding electrophile E in accordance with the scheme[121]



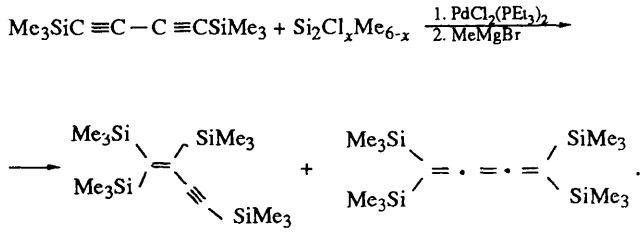
E^1 and E^2 = AlkBr.

The addition of trialkylaluminium and subsequent treatment of the alumnium-containing adducts with an electrophile E can also be recommended as a preparative method of synthesis of silicon-containing alkenynes:[122,123]



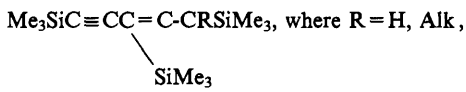
The reaction is regio- and stereo-specific and takes place only in the presence of catalysts. In the series Cp_2ZrCl_2, Cp_2TiCl_2, and Cp_2VCl_2, the best yields were obtained with the zirconium catalyst.

An interesting method of synthesis of persilylated butenynes is based on the catalytic silylation of bis(trimethylsilyl)buta-1,3-diyne with alkylchlorodisilanes[124]



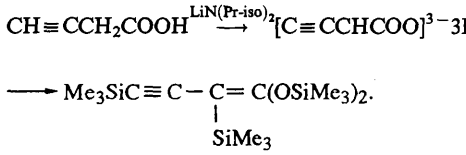
The yield and the rate of the isomeric 1,2- and 1,4-adducts are determined by the structure of the disilane as well as the temperature and duration of the experiment.

Mono- and poly-silylated alkadienynes of the type



where R = H or alkyl, are formed in the reaction of the anions or polyanions obtained from alka-1,2-diynes with chlorotrimethylsilane.[125–128]

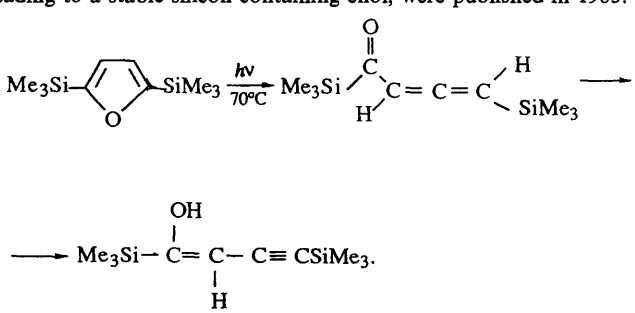
Polysilylated alkenynes have also been obtained by treating the trianion of but-3-ynoic acid with chlorotrimethylsilane:[129]



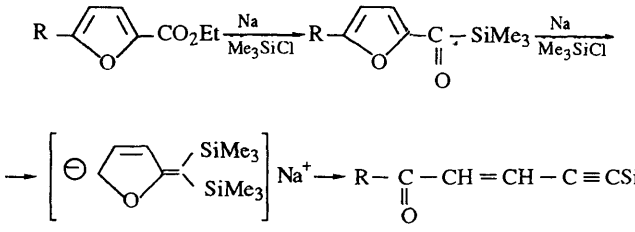
The reaction involving the addition[130–134] or cycloaddition (the Diels–Alder reaction)[135] of the corresponding reagents (bromine,[133,134] thiols,[130,131] hydrazine,[132] hydroxylamine[132]) to one of the triple bond of 1-trialkylsilylalka-1,3-diyne may be recommended as a method of synthesis of halogen-, sulphur-, and nitrogen-containing derivatives of silylalkenynes.

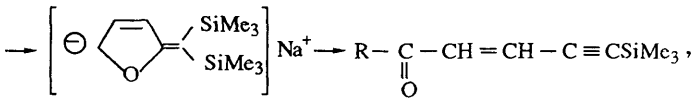
(4) Isomerisation reactions

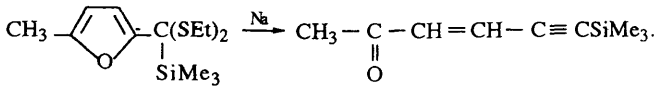
Oxygen containing functional derivatives of 1-trialkylsilylalk-3-en-1-ynes can be obtained as a result of the specific cleavage reaction of silylated furans and their sulphur and selenium analogues. Thus the results of an unusual photoinitiated opening of the furan ring, leading to a stable silicon-containing enol, were published in 1983:[136]



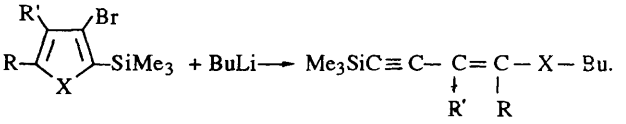
Ethyl furoates[137] and thioketals of the furan series[138] are converted into vinylacetylenic silicon-containing ketones on treatment with metallic sodium:



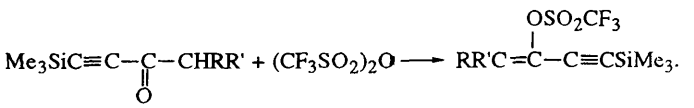




Silylated 3-bromothiophenes and 3-bromoselenophenes give rise to silicon containing alkenyne thio- and seleno-ethers with a (*Z*)-configuration in satisfactory yields on reaction with butyl-lithium:[139]



Silicon-containing triflates with alkenyne fragments are readily obtained from acetylenic ketones and the anhydride of trifluoromethanesulphonic [triflic] acid:[140–143]



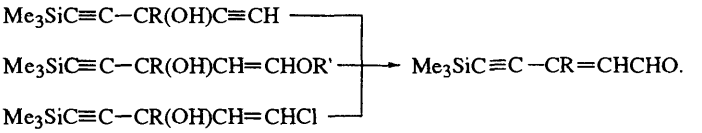
The kinetics of this reaction were investigated.[141]

Carbofunctional derivatives of 1-trialkylsilylalk-3-en-1-ynes (alcohols, aldehydes, ethers, esters, amides, etc.) are formed in satisfactory yields as a result of the acid-catalysed isomerisation of the corresponding non-conjugated vinylethynyl and diethynyl alcohols (the Claisen rearrangement). The nature of the functional group and the configuration of the substances obtained under these conditions are determined by the nature of the donor of the anion introduced into the reaction mass:[144–148]

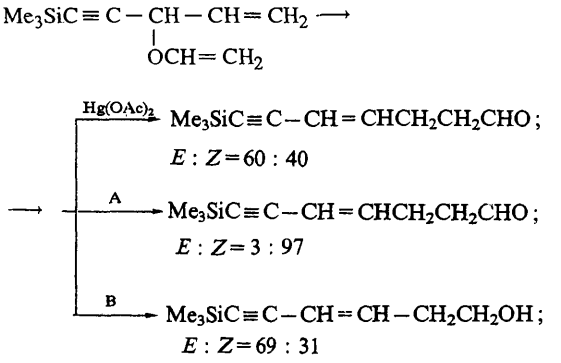
The availability of the initial vinylethynyl alcohols and the high preparative yields of the target products make this reaction one of the promising and stereocontrolled processes in the synthesis of derivatives of 1,3-enyne silicon-containing hydrocarbons.

The isomerisation of secondary alcohols proceeds stereospecifically and the reactions of tertiary alcohols afford mixtures of the (*E*) and (*Z*)-isomers, the isomers in which the substituent R is in the *trans*-position relative to the functional group predominating under these conditions.[144]

The isomerisation of diacetylenic alcohols[145] and alcohols containing substituted vinyl groups[146,149] leads to the formation of the corresponding aldehydes:

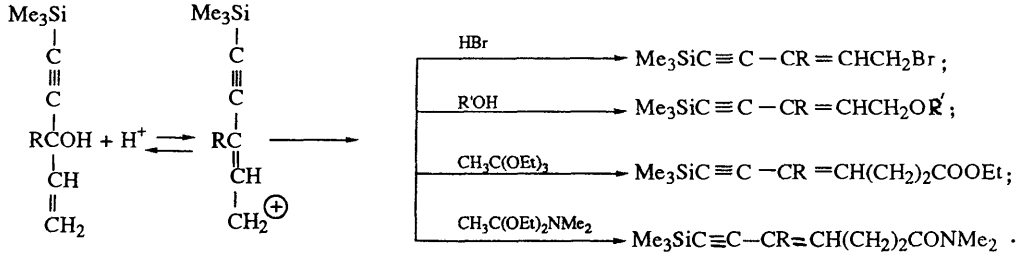


The rearrangement of the vinyl ethers (the Cope–Claisen rearrangement) also leads to the corresponding vinylacetylenic alcohols or ethers. The nature of the functional group and the configuration of the substances obtained are determined by the nature of the catalyst:[150,151]

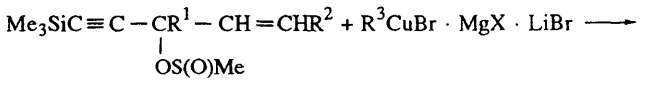


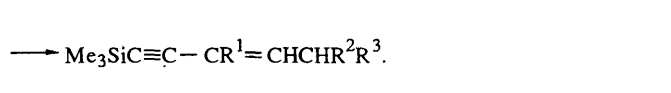
A = [2,6-(t-Bu)$_2$–4-BrC$_6$H$_2$]$_2$MeAl; B = [2,4-Ph$_2$-C$_6$H$_3$]$_2$MeAl.

Similar reactions occur also when the sulphinate of a silicon-containing vinylethynylcarbinol is treated with alkyl or aryl cuprates [the ratio of the (*E*) and (*Z*)-isomers is (4–10) : (96–89)]:[152]

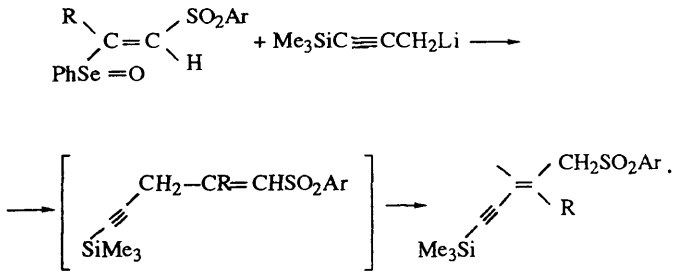


R' = H, Me, Et, Ac.

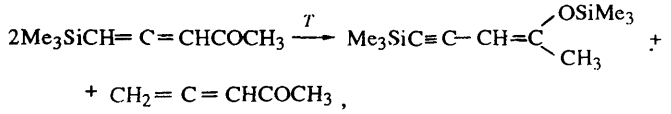




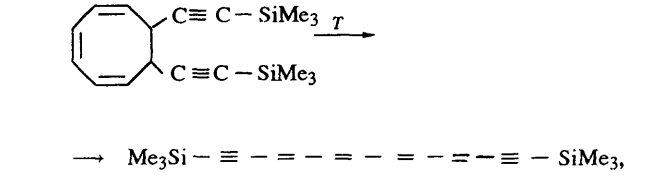
A protropic isomerisation apparently also takes place in the synthesis of vinylacetylenic sulphones by the condensation of a selenoxide with trimethylsilylpropargyllithium:[153]



The method of synthesis of silicon-containing enyne enols by the thermal disproportionation of silicon-containing allenyl ketones,[154] i.e.



and of bis(trimethylsilyl)cyclooctatetraene,[155] i.e.



can be formally assigned to the same group of reactions (isomerisation).

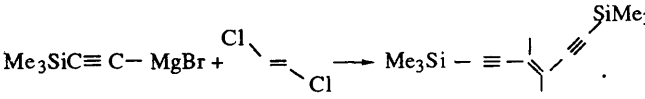
5. Construction of enyne structures from block-synthons

In the construction of enyne structures from block-synthons, use is made of methods based on the transition metal complex-catalysed reactions of organometallic compounds, condensations of the type of the Knoevenagel reaction, and the Wittig reaction and its phosphonate (the Horner–Emmons reaction) and silyl (the Petersen reaction) modifications. An obligatory feature of these methods is the formation of new single or multiple carbon–carbon bonds.

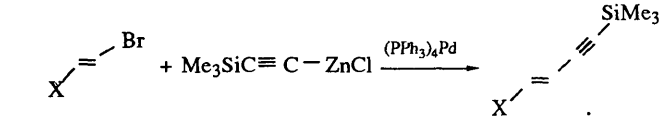
(a) Organometallic synthesis

The possibilities in the synthesis of silicon-containing alkenynes from organolithium compounds have been demonstrated solely in relation to the condensation of fluoroacetylene with α-ethoxyvinyllithium:[65]

Trimethylsilylethynylmagnesium bromide condenses with *trans*-1,2-dichloroethylene only in the presence of the nickel catalyst $NiCl_2.Ph_2P(CH_2)_3PPh_2$:[156]

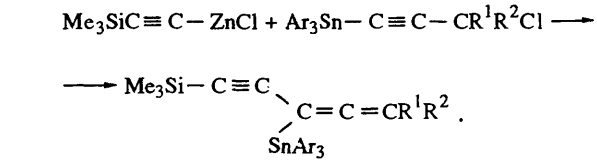


The best results were obtained in the reaction of haloalkenes with acetylenic organozinc compounds. The reactions take place only when palladium complexes are used as the catalyst.[157–162] It has been noted that *cis*- and *trans*-haloalkenes give rise to only alkenynes in these reactions:

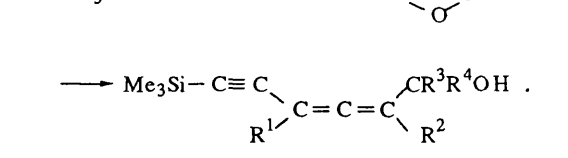


However, it has been reported[163] that the interaction of trimethylsilylethynylzinc bromide with *cis*- and *trans*-1-iodoalkenes afforded individual *cis*- and *trans*-1-trimethylsilyldec-3-en-1-ynes respectively in 74 and 75% yields.

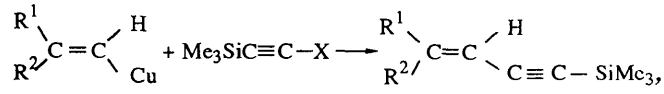
Alkenyne structures were formed somewhat unexpectedly in the reaction of trimethylsilylethynylzinc chloride with tertiary chlorides of the propargyl type.[164,165] The reaction is described by the following scheme:



The reaction of zinc acetylides with acetylenic epoxides proceeds similarly under the condition of catalysis by palladium:[166,167]



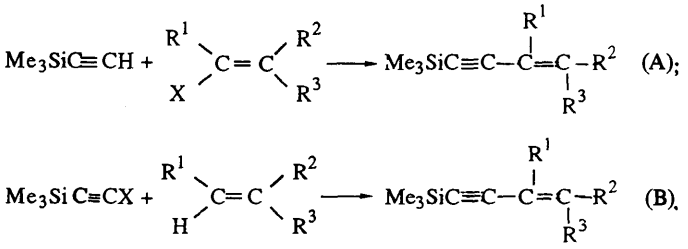
Alkenyne silicon-containing structures can be obtained by condensing silicon-containing halides (bromides, iodides) with alkenyl cuprate:[166,168–171]



where X = Br or I and R^2 and R^1 are alkyl and alkenyl groups, including groups with functional substitutents.

The cross-coupling of organic halides with an unsaturated hydrocarbon, catalysed by compounds of platinum group metals, occupies a special place in the synthesis of organosilicon alkenynes.

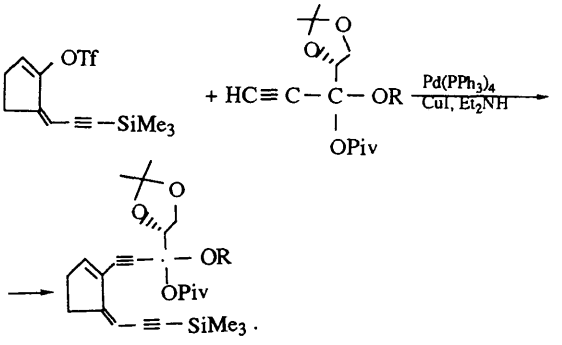
It can be achieved in two ways:



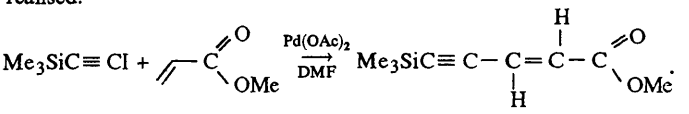
The availability of the starting compounds and the higher stereoselectivity of the processes make it possible to use method (A) on a wide scale in fine organic synthesis, including the synthesis of complex natural products and their synthetic analogues.[36,149,172–190]

$Pd(PPh_3)_4$ [149,175,176,178–180,182,186,187,189–191] or $PdCl_2(PPh_3)_2$ [36,174,175,177,183–185,188] are used as catalysts. It has been noted that *trans*-1,2-dichloro(dibromo)alkenes are much less reactive in this reaction than their *cis*-isomers.[175]

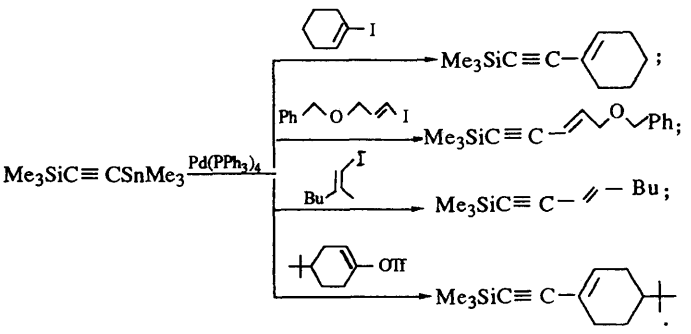
Cases are known where the corresponding triflate is made to enter into the palladium-catalysed cross-coupling reaction instead of the vinyl halide:[192–194]



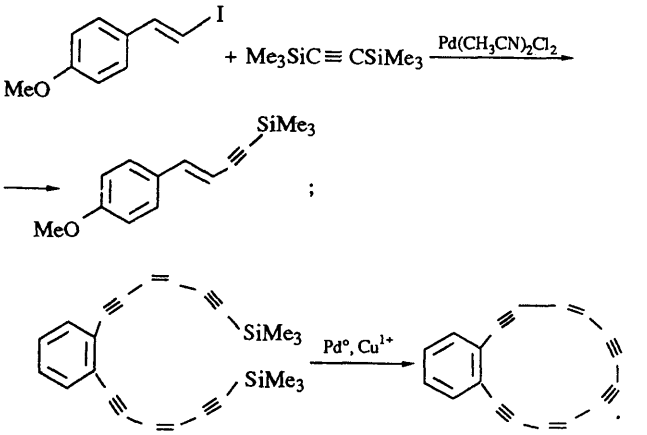
There have been only isolated instances where scheme (B) was realised:[195]



The method of synthesis of silicon-containing alkenynes by the stereospecific alkynylation of alkenyl halides[196,197] or triflates[198–200] with trialkylstannylacetylenes catalysed by a palladium complex was developed significantly during the last decade.



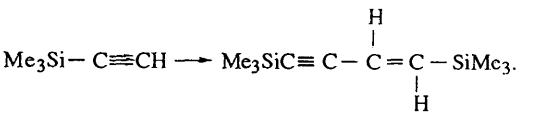
Silicon-containing acetylenes can also serve as alkynylating agents:[184,201]



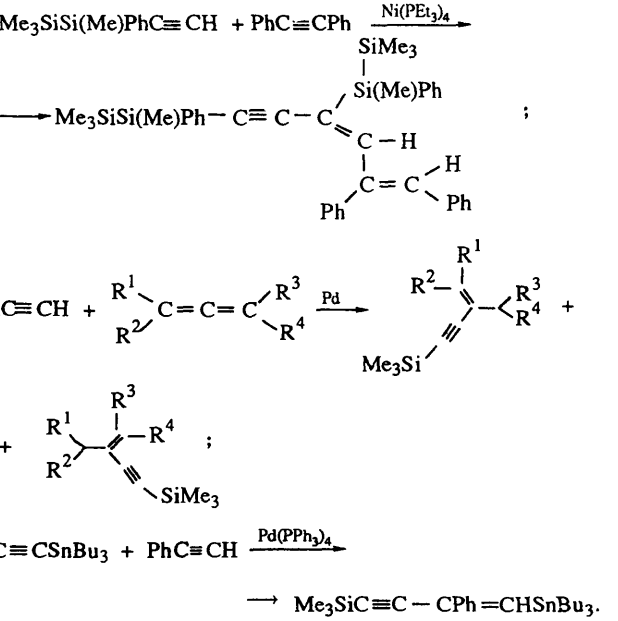
The silicon–carbon bonds are dissociated in these reactions.

(b) Dimerisation of silylacetylenes catalysed by transition metal complexes

Under the influence of the nickel complexes $Ni(acac)_2PPh_3$ [202,203] and $Ni(PEt_3)_4$,[204] the palladium complex $Pd(PPh_3)_4$,[205] the rhodium complex $RhCl(PPh_3)_3$,[206] or the titanium complex $(\eta^5\text{-}C_5H_5)TiCl_2.RMgX$ [207] as catalysts, silylacetylenes are readily dimerised with formation of the corresponding bissilylated alkenynes. The satisfactory yields (up to 90%) and controlled stereochemistry make it possible to recommend these reactions as convenient preparative methods of synthesis of alkenynes:



Under the conditions of metal complex catalysis, it is possible to carry out the codimerisation reactions of trialkylsilylacetylenes with other acetylenes or allenes:[204,208,209]



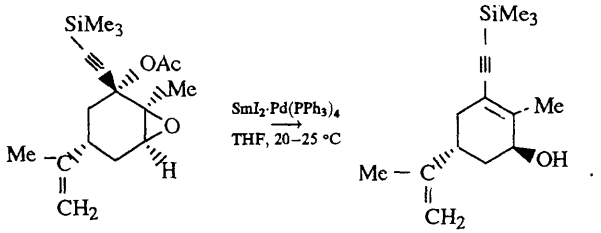
An unusual reaction involving alkynylation with silylacetylenes was described in 1978 by Japanese investigators,[210] who established that alkynylamines add to electron-deficient acetylenes with formation of silylated alkenynes containing a silicon atom attached to the double bond:

$$R^1_{R^2}\!\!>N-C\equiv C-SiR_3 + YC\equiv C-COOMe \longrightarrow$$

$$\longrightarrow R^1_{R^2}\!\!>N-C\equiv C-\underset{\displaystyle SiR_3}{\overset{\displaystyle Y}{\underset{|}{\overset{|}{C}}}}=C-COOMe\ ;$$

Y = H or COOMe.

(3*S*, 5*R*)-3-Hydroxy-5-isopropenyl-2-methyl-1-(2-trimethylsilylethynyl)-1-cyclohexene — a key compound in the synthesis of $\Delta^{9(11)}$-unsaturated vitamin D — was obtained from the corresponding epoxide using a palladium catalyst:[211]



(c) The Wittig reaction and its modifications

Silicon-containing alkenynes can be synthesised in two ways using phosphoranes: (1) by the reaction of a silicon-containing acetylenic phosphorane with a carbonyl compound:

$$Me_3SiC\equiv C-CH=PPh_3 + O=C\!<^{H(R^2)}_{R^1} \longrightarrow$$

$$\longrightarrow Me_3Si-\equiv-\underset{\displaystyle H}{\overset{\displaystyle H(R^2)}{\underset{|}{\overset{|}{\diagup\!\!\diagdown}}}}-R^1\ ; \qquad (1)$$

(2) by the reaction of a silicon-containing acetylenic aldehyde with the corresponding phosphorane:

$$Me_3SiC\equiv C-CH=O + Ph_3P=CHR^1 \longrightarrow$$

$$\longrightarrow Me_3Si-\equiv-\underset{\displaystyle |}{\overset{\displaystyle |}{\diagup\!\!\diagdown}}-R^1 \qquad (2)$$

The silicon-containing acetylenic phosphorane $Me_3SiC\equiv C-CH=PPh_3$ was first obtained by Belyaev, Stadnichuk, and Petrov in 1972.[212,213] By condensing it with cyclohexanone or benzaldehyde, it was shown that it can be used in the synthesis of silicon-containing alkenynes.[212]

Somewhat later Corey et al.[64] and then Eiter et al.[214] again described the silicon-containing propargyl-substituted phosphorane and confirmed the possibility of using it in the synthesis of the simplest vinylacetylenic hydrocarbons[64] and more complex compounds.[215] The silicon-containing propargyl-substituted phosphorane $Me_3SiC\equiv C-CH=PPh_3$ has come to be widely used in studies by other investigators.[216–223] In all these investigations, complex polyfunctional organic compounds containing the aldehyde group were employed as the carbonyl component. The condensation was stereospecific or highly stereoselective with formation of the corresponding (*E*)-alkenynes containing the trimethylsilyl protecting group at the triple bond.

The silicon-containing alkenyne-substituted phosphorane $Me_3SiC\equiv C-CH=CH-CH=PPh_3$ is frequently used in the synthesis of more unsaturated compounds, for example lipoxin[49,50] and leukotriene antagonists.[224]

The synthesis of 1-trialkylsilylalk-3-en-1-ynes and their derivatives using the second variant of the Wittig reaction was first achieved by Belyaev, Stadnichuk, and co-workers:[213,225]

$$Me_3SiC\equiv C-CH=O + Ph_3P=CHX \longrightarrow Me_3SiC\equiv C-CH=CHX;$$

X = $COOCH_3$, $COCH_3$, CN.

The stereoselectivity of the reaction depends on the structure of the phosphorane and the nature of the solvent.[225,226] The replacement of ether or THF by hexane not only increases the yield of the target products but also promotes the formation of the (*E*)-isomer in the mixture.

The phosphonate modification of the Wittig reaction (the Horner–Emmons reaction) is as a rule characterised by a greater *trans*-stereoselectivity in the synthesis of alkenes. The available data on the use of the phosphonate methods in the synthesis of silicon-containing alkenynes[49,227] agree on the whole with this claim:

$$Me_3SiC\equiv C-CH=O + (EtO)_2P(O)CH_2X \xrightarrow{Na}$$

$$\longrightarrow Me_3SiC\equiv C-CH=CHX\ ;$$

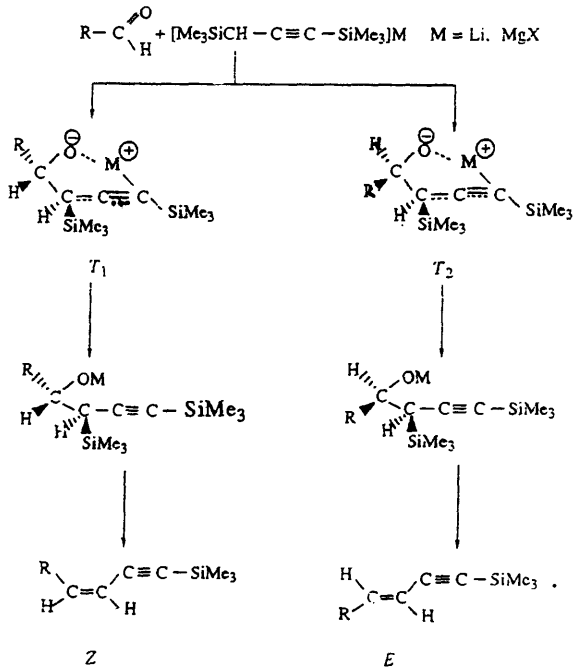
X = COOR, CN.

It is interesting that the synthesis of vinylacetylenic nitriles by the Horner–Emmons reaction produces better results (yield, stereoselectivity) than the Wittig reaction, while in the synthesis of carbonyl compounds the Wittig reaction is preferable.[213,225–227]

The conversion into silylalkenes or alkenes by the Peterson method is frequently regarded as one of the variants of the Wittig method. This procedure presupposes attack by the silicon-containing anions on the carbonyl carbon atom of the substrate. The reaction is distinguished by a high stereoselectivity. An advantage of the method (compared with the Wittig and Horner–Emmons reactions) is the fact that the hexamethyldisiloxane produced as a result of the reaction is volatile (T_b = 100 °C) and can be readily removed.

The Peterson reaction was first applied in the synthesis of silylalkenyls by a group of Japanese workers[228] in 1981 in relation to the interaction of certain aldehydes and ketones with the allene

carbanion obtained by treating 1,3-bis(trimethylsilyl)propyne with organolithium or organomagnesium compounds:



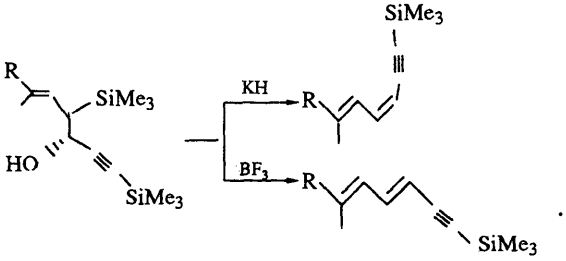
In conformity with the proposed scheme of the possible interaction pathways, the reactions of the bis(trimethylsilyl)propargyl anion with aldehydes give rise to mixtures of the (*E*)- and (*Z*)-isomers, with the latter predominating.[228–230] Judging from the yields (80–90%) and the ratio of the (*E*)- and (*Z*)-isomers, this reaction should be regarded as a convenient preparative method of synthesis of (*Z*)-alkenynes.

It follows from the available data[228–230] that the fraction of the (*Z*)-isomer increases with increase in the bulk of the SiR_3 group and also when lithium is replaced by magnesium. The replacement of magnesium by titanium[229,230] hardly affects the stereochemical result of the reaction. The authors are inclined to explain this by the steric destabilisation of the transition state T_2 compared with T_1 with increase in the bulk of the SiR_3 group.

The low level of stereoselectivity in the reactions with benzaldehyde[228,230] canot be explained. As regards the role of the counterion, the principal idea used in its explanation reduces to the fact that the ability of the cation to form the transition state T_1, possibly with the allene structure, increases in the series Li < Mg < T_1. In this transition state, the steric repulsion increases to a maximum (T_1 is more favourable on energy grounds than T_2). Therefore the allene carbanion attacks the carbonyl carbon atom preferentially, which leads to the formation of the energetically more favourable transition state T_1.[229,230]

In 1982 Corey and Ruecker[231] repeated the experiments of the Japanese workers and also showed that the reaction of lithiated 1,3-bis(trimethylsilyl)propyne with cyclohexanecarbaldehyde and trimethylacetaldehyde in THF results in the formation of the corresponding alkenynes in a satisfactory yield and with the ratio *E*:*Z* = 20:1 (as in the study of Yamakado et al.[228]). However, when the reaction is carried out in a THF–hexamethylphosphoramide (HMPA) mixture, the corresponding alkenynes are formed in proportion of 1:2.[231] The preferential formation of the (*E*)-isomer (*E*:*Z* = 7:1) when the reaction is carried out in a THF–HMPA mixture has also been observed by other workers.[232] The lithium derivative of 1-triisopropylsilyl-3-trimethylsilyl-1-propyne does not react with aldehydes under these conditions.[231] It has been suggested that the lithium derivative of bis(triisopropylsilyl)propyne exists in THF in the form of an allene, to which corresponds the energetically most favourable cyclic transition state T_1. This promotes the formation of the (*Z*)-isomer. In a more polar solvent (a mixture of THF and HMPA), an acyclic transition state is formed, promoting the formation of the (*E*)-isomers.[231]

The stereoselectivity of the elimination of trimethylsilanols also depends on the nature of the catalyst (KH or BF_3):[233]



Judging from the available data, the Peterson rection constitutes a convenient preparative method of synthesis of silicon-containing alkenynes with the (*Z*)-configuration.[234–237]

Trialkylsilylpropynals react with C–H acids (the Knoevenagel reaction) to form the corresponding derivatives of silicon-containing alkenyne hydrocarbons:[238]

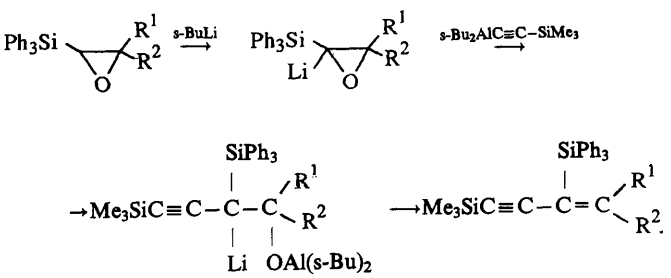
$$Me_3SiC{\equiv}C{-}CHO + CH_2XY \longrightarrow Me_3SiC{\equiv}C{-}CH{=}CXY;$$

X = Y = CN, CO_2Et; X = Ac, Y = CO_2Et; X = NO_2, Y = H.

5-Trimethylsilylbut-2-en-4-ynoic acid was obtained on hydrolysis of the diester and heating the resulting acids:

$$Me_3SiC{\equiv}C{-}CH{=}C(CO_2Et)_2 \xrightarrow[H^+]{HOH} Me_3SiC{\equiv}C{-}CH{=}C(CO_2H)_2 \xrightarrow{T} Me_3SiC{\equiv}C{-}CH{=}CHCOOH.$$

The method involving the elimination of lithium aluminate in the concluding stage, described recently,[239] can be also included formally in this group of methods:



III. Chemical properties of silicon-containing alk-3-en-1-ynes

Among the chemical reactions of silicon-containing alkenynes, three large groups can be distinguished.

1. Reactions occurring with participation of multiple bonds. They lead as a rule to the synthesis of new types of functional derivatives of alkynes or alka-1,3-dienes and alka-1,2-dienes.

2. Reactions in which the trialkylsilyl group is replaced by a proton (removal of the silyl group protecting the triple bond) or another atom or radical (halogen, acyl, etc.)—desilylation reactions.

3. Reactions with participation of the functional groups of derivatives of silicon-containing alkenynes.

1. Addition reactions

The addition of reagents of different nature of 1-trialkylsilylalk-3-en-1-ynes and their carbofunctional derivatives constitutes the most thoroughly investigated type of reactions of compounds of this class. However, their rigorous classification in terms of reaction mechanisms is impossible, since in most cases such mechanisms have not been investigated. The known types of reactions have therefore been classified in this review in terms of the type of reagent. Despite the fact that the same reagent adds via different mechanisms depending on the experimental conditions and the proposed classification principle cannot therefore be maintained throughout, this approach appears to be most acceptable at the present stage.

(a) Interaction with electrophiles

The study of the addition of electrophiles to compounds with multiple carbon–carbon bonds traditionally with the analysis of data on their reactions with hydrogen halides. Unfortunately, it is merely stated in the literature that 1-trimethylsilylbut-3-en-1-yne combines with two moles of hydrogen chloride. The structure of the reaction products was not demonstrated. The reaction could not be stopped at the stage involving the formation of monoadducts.[23]

Bromination of 1-trialkylsilylalk-3-en-1-ynes and their derivatives. Whilst describing the simplest reactions of vinylacetylenic silicon-containing hydrocarbons, Petrov, Sadykh-zade, and Egorov[22,23] noted that the addition of the first mole of bromine to 1-trimethylsilylbut-3-en-1-ynes takes place exclusively at the triple bond. However, it was later established that the bromination of silicon-containing alkenynes takes place non-chemoselectively, while the relative amounts of the dibromo-derivative formed are determined by the structure of the initial silicon-containing hydrocarbons and the conditions in the isolation and purification of the dibromo-derivatives. In the reactions of silylalkenynes in which the alkenyne fragment has the normal structure, the main products are 1,4-dibromo-derivatives, while bromination of compounds with a branched structure affords acetylenic dibromo-derivatives. Dibromo-derivatives of 1,3-dienes are either not formed at all or are present only in trace amounts.[26]

On heating, the 1,4-dibromo-derivatives readily isomerise to the bromo-derivatives of 1,3-dienes. Alkenyldimethylsilylbut-3-en-1-ynes are also brominated non-selectively,[31] the main product formed in the case of 1-dimethylvinylsilylbut-3-en-1-yne being dibromoallene. 1-Allyldimethylsilylbut-3-en-1-yne combines with the first molecule of bromine preferentially at the double bond which is not conjugated with the triple bond.

Bromine adds essentially only to the double bond also in the bromination of 1,6-bis(trimethylsilyl)oct-4-ene-1,7-diyne.[33] These data[25,26,31,33] agree well with the rule according to which bromine adds to double bonds at a rate approximately an order of magnitude higher than that of its addtion to the triple bond.[240]

The study of the dependence of the rate of bromination on the structure of the silicon-containing alkenyne[241] and the polarity of the solvent[242] and also data on the way in which 1-trimethylsilylbut-3-en-1-yne reacts with bromine in a saturated solution of lithium chloride in acetic acid[87] enabled the authors to claim that bromination, whose rate is described by a second order equation, is a two-step electrophilic process. The bromine molecule and (or) the complex Br_3^- functions as the electrophile.[242]

The functional derivatives of vinylacetylenic silicon-containing hydrocarbons $Me_3SiC{\equiv}C-CH=CH-X$, where X = NMe_2, $COCH_3$, $COOCH_3$,CN, or NO_2,[59,95,243] combines with bromine exclusively[59,95] or preferentially[243] at the triple bond regardless of the donor–acceptor properties of the substituents X. 1,4-Adducts were never detected.

The bromination of nitroalkenynes takes place only in highly polar solvents in the presence of lithium bromide and most probably via a nucleophilic mechanism.[241,244] One cannot rule out the possibility that the isotypical mode of addition of bromine to alkenynes containing the electron-donating dimethylamino-group and the electron-accepting carbonyl, carboxy-, cyano-, and nitro-groups is determined by the fact that the corresponding complexes of the reagents with bromine of the type

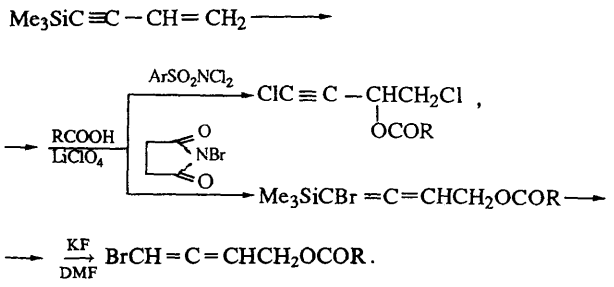
$$[R_3SiC{\equiv}C{-}CH{=}CHNMe_2{\cdot}Br]^+Br^-$$

enter into the bromine reaction.[245]

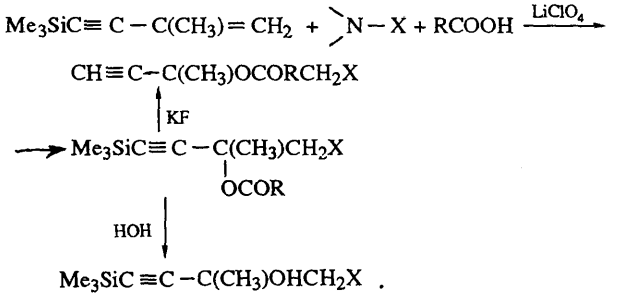
Hydroxy-, alkoxy-, and acyloxy-halogenation. The coupled hypohalogenation of silylalkenynes, where the nucleophilic solvent (water, alcohols, carboxylic acids) is involved in the concluding stage of the reaction, has not been studied systematically. It has only been stated that, when 1-trimethylsilylbut-3-en-1-yne was treated with the dichloroamide of *p*-chlorobenzenesulphonic acid or *N*-bromosuccinimide in methanol, a mixture of positional isomers of the corresponding dihalo-derivatives containing chloro- or bromo-ethers was obtained in low yields (5–10%).[246] 3-Methyl-1-trimethylsilylbut-1-yne reacts with the dichloroamide of *p*-chlorobenzenesulphonic acid and 85% formic acid to form the corresponding chlorohydrin in a satisfactory yield:[247]

$$Me_3SiC{\equiv}CC(CH_3){=}CH_2 + ArSO_2NCl_2 \xrightarrow[LiClO_4]{H_2O\ +\ HCOOH} Me_3SiC{\equiv}CC(CH_3)CH_2Cl.$$
$$\qquad\qquad\qquad

interaction of 1-trimethylsilylbut-3-en-1-yne with a dichloroamide in formic and acetic acid takes place with desilylation:

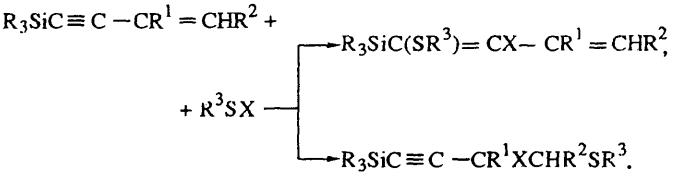


1-Trimethylsilylbut-3-en-1-yne reacts with *N*-bromosuccinimide in both acetic and formic acid to form the products of coupled 1,4-addition, uncharacteristic of the given type of reactions, with the electrophilic bromine being attached to the α-carbon atom of the triple bond. 3-Methyl-1-trimethylsilylbut-3-en-1-yne reacts with chloro- and bromo-amides to form only the products of acyloxyhalogenation at the double bond:



There is no acceptable explanation of the inversion of the electrophilic attack (at the triple bond in 1-trimethylsilylbut-3-en-1-yne in reactions with chloro- and bromo-amides and at the double bond in the reactions of an isopropenylacetylenic compound).

Interaction with the acid halides of sulphenic acids and their selenium containing analogues. The halides of sulphenic acids RSX are known to add to multiple carbon–carbon bonds via an electrophilic mechanism. These reagents belong to the category of weak electrophiles and their electrophilicity can be varied by altering the nature of the organic group. In conformity with the rule that, in reactions with electrophiles, the double bond is more reactive approximately by an order of magnitude than the triple bond, vinylacetylene[248] combines with methanesulphenyl chloride via the double (90%) and triple (10%) bonds, while its homologue 5,5-dimethylhex-1-en-3-yne combines with the above reagent exclusively via the double bond.[249,250] In contrast to hydrocarbons, their silicon-containing analogues $R_3SiC{\equiv}CCR^1{=}CHR^2$ combine with the halides of alkane- and arene-sulphenic acids exclusively or preferentially via the triple bond:[249–251]



The mode of reaction is independent of the nature of the solvent (CH_2Cl_2, $CHCl_3$, CH_3COOH, and the $CH_3COOH-LiClO_4$ mixture) and is determined by the structure of the reactants. The fraction of the minor acetylenic adduct increases with increase in the bulk of R and R^3, on passing from acid chlorides to bromides, and on passing from compounds with R^1 = H to compounds with R^1 = CH_3, and also as the electron-accepting properties of R^3 are enhanced. It has been established in relation to derivatives of vinylacetylenic silicon-containing hydrocarbons with nitro-,[252] acetyl, ethoxycarbonyl, and cyano-groups[253] in the alkenyne fragments that the introduction of electron-accepting groups increases sharply the chemoselectivity of the addition of the halides of sulphenic acids to the triple bond.

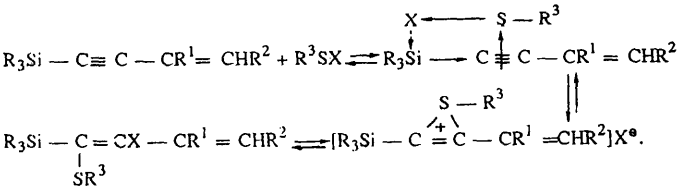
The study of the kinetics of the addition of methanesulphenyl chloride to derivatives of vinylacetylenic silicon-containing hydrocarbons[254] shows that the rate of addition to hydrocarbon and silylhydrocarbon derivatives with similar structures decreases as the electron-accepting properties of the group R^2 weaken in the sequence COR > COOR > CN, which agrees with an electrophilic mechanism of the addition reaction. This conclusion is supported also by the formation of a certain amount of solvoadducts when arenesulphenyl chlorides add to acetic acid in the presence of lithium perchlorate.[249]

However, silicon-containing alkenynes are more reactive in this reaction than the hydrocarbon derivatives of similar structure.[254] It is appropriate to recall here that hydrocarbons are more reactive approximately by an order of magnitude in electrophilic bromination reactions than their silicon-containing analogues: owing to the $d_\pi-p_\pi$ interaction, organosilicon substituents have weaker electron-donating properties than the hydrocarbon groups of similar structure.[255]

In the presence of anhydrous aluminium chloride, methanesulphenyl chloride adds to 1-trimethylsilylbut-3-en-1-yne preferentially at the double bond.[256]

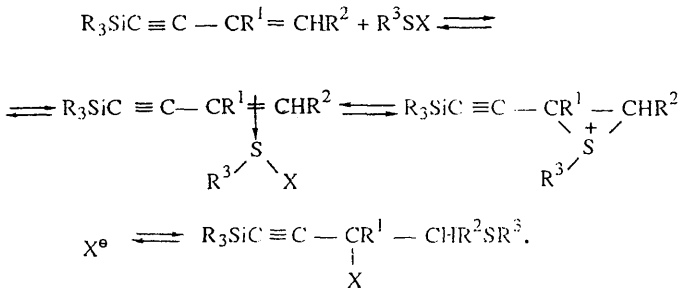
The results of the studies of the reactions of alkane(arene)sulphenyl halides with 1,3-alkenynes, their silicon-containing analogues, and their functional derivatives, examined above, made it possible to conclude that the unusual mode of reaction is due to the characteristic features of the donor–acceptor reagent–substrate interaction, in which the silicon atom with its unoccupied orbitals (a soft acid as defind by Pearson) interacts with the electron-donating end of the polar molecule of the sulphenyl halide:[249–254,256,257]

Scheme 1



This reaction should compete with the donor–acceptor interaction leading to the formation of a π-complex, which is characteristic of electrophilic addition:

Scheme 2



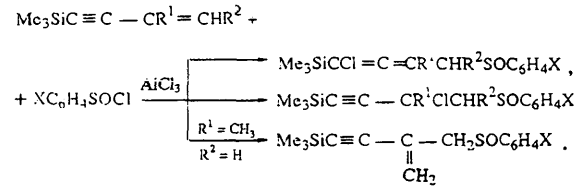
Evidently a greater bulk of R and X (the *d* orbitals are less accessible), a lower effective electronegativity of the alkenyne fragment (a smaller partial positive charge on the heteroatom), and more pronounced electron-accepting properties of R^3 (a low basicity of X) entail a greater difficulty of the realisation of Scheme 1, which presupposes the specific solvation of the substrate by the reagent, and a smaller probability of the addition of the reagent to the triple bond. The formation of molecular associated species with participation of the unoccupied *d* orbitals of silicon should facilitate the addition of the electrophile to the triple bond.[254]

The addition to 1-trialkylsilylalk-3-en-1-ynes and areneselenyl chlorides takes place similarly, i.e. preferentially to the double bond, and apparently for the same reason.[257–259] Data on the addition of sulphenyl and selenyl halides to vinylacetylenic germyl-[250,257] and stannyl-hydrocarbons[260] are satisfactorily consistent with the proposed scheme, which involves the reagent–substrate intermolecular association stage as one determining the chemoselectivity of the addition. The availability of the *d* orbitals of the heteroatoms increases in the series of silicon, germanium, and tin compounds, which is the reason for the increase in the fraction of the products of the addition to the triple bond almost to 100%.[250,257,260] It is of interest that 1-dimethylvinylsilylbut-3-en-1-yne (one of the double bonds and the triple bond are in the α,β-positions relative to the silicon atom) combines with methanesulphenyl chloride via the vinyl group non-conjugated with the triple bond:

$$CH_2{=}CH(CH_3)_2SiC{\equiv}C-CH{=}CH_2 + CH_3SCl \longrightarrow$$
$$\longrightarrow CH_3SCH_2CHCl(CH_3)_2SiC{\equiv}C-CH{=}CH_2.$$

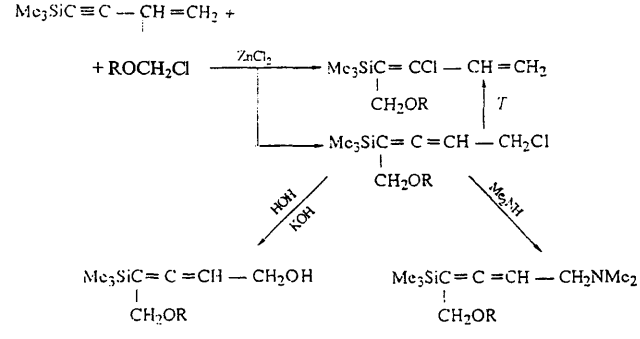
Under identical conditions, the double bond is more reactive in reactions with an electrophile.

Interaction with the halides of sulphinic acids. It has been established in relation to the interaction of the chlorides of arenesulphinic acids with 1-trialkylsilylbut-3-en-1-ynes that, in the absence of catalysts and also in the presence of zinc chloride, the reaction does not occur. In the presence of anhydrous aluminium chloride, the mode of reaction is determined by the structure of the silicon-containing alkenyne: compounds with an unbranched structure of the alkenyne fragment give rise to a mixture of the products of the addition to the double bond and in the 1,4-positions, while alkenynes having the iso-structure give rise to the products of substitutional sulphinylation:[261,262]



The corresponding vinylacetylenic hydrocarbons behave similarly in reactions with sulphinyl chlorides.[262] The chlorides of arenesulphonic acids containing electron-accepting substituents (chloro- and nitro-groups) in the aromatic ring do not react. Chlorine-containing adducts are not dehydrochlorinated when they are treated with triethylamine.[262]

Interaction with α-haloethers. There exists only one communication devoted to this problem. According to the data of Vartanyan and Tosunyan,[263] chloromethyl methyl, chloromethyl ethyl, and chloromethyl isopropyl ethers add to 1-trimethylsilylbut-3-en-1-yne at the triple bond and in the 1,4-positions in the presence of zinc(II) chloride:



It is also striking that in such cases the electrophile attacks the α-carbon atom of the triple bond, which is not characteristic of alkenynes.

(b) Interaction with radical reagents

Interaction with triphenylmethyl radicals. This was investigated in relation to their addition to 1-trimethylsilylbut-3-en-1-yne and its closest homologues — 1-trimethylsilylpent-3-en-1-yne and 3-methyl-1-trimethylsilylbut-3-en-1-yne. It was established that the introduction of the methyl group into the alkenyne fragment not only hinders the addition reaction but also alters its mode: 1-trimethylsilylbut-3-en-1-yne combines with triphenylmethyl radicals at the double bond, 3-methyl-1-trimethylsilylbut-3-en-1-yne combines with them in the 1,4-positions, and 1-trimethylsilylpent-3-en-1-yne combines with them at the triple bond.[264]

Interaction with thiols. The tertiary butyl peroxide-initiated addition of alkanethiols to 1,3-alkenyne silicon-containing hydrocarbons $R_3SiC{\equiv}C-CR^1{=}CHR^2$ (R = Me, Et: R^1 and R^2 = H or CH_3) via a free-radical mechanism involves preferentially the double bond (80–90%), the thiyl radical being attached to the α-carbon atom of the double bond and the content of allene adducts in the mixture not exceeding 15%. 1,3-Diene adducts were not

detected in the reactions of silicon-containing alkenynes. The sharp decrease in the reactivity of the alkenynes after the introduction of methyl groups at the α- and β-carbon atom of the double bond is striking.

Interaction with *N,N*-dichloroamides of arenesulphonic acids. It was noted above that treatment of silicon alkenynes with haloamides in hydroxylated solvents leads to the formation of the products of coupled halogenation. In aprotic solvents (chloroform, methylene chloride, etc.), arenesulphonic acid dichloroamides add to the double bond and in the 1,4-positions in trialkylsilylbutenynes,[246,268] which affords the compounds $Me_3SiC{\equiv}C-CR^1ClCHR^2NClSO_2Ar$ and $Me_3SiCCl=C=CR^1CHR^2NClSO_2Ar$.

On treatment with bisulphite, the adducts form the corresponding amides which are readily converted into *N*-arenesulphenylaziridines;

$$\left.\begin{array}{l} Me_3SiC{\equiv}C-CR^1ClCHR^2NHSO_2Ar \\ Me_3SiCCl=C=CR^1CHR^2NHSO_2Ar \end{array}\right\} \xrightarrow{KOH} CH{\equiv}C-CR^1(N\!<\!SO_2Ar)-CR^2$$

In all cases, the addition of the dihalo-derivative to the multiple bonds of the silicon-containing alkenynes is accompanied by side reactions involving chlorination.[246,268]

Oxidation. The oxidation of 1,3-alkenyne silicon-containing hydrocarbons and their derivatives can involve the multiple bonds or the functional groups.

The oxidation of silylalkenynes with peracids (they are usually obtained by treating the anhydrides of the corresponding carboxylic acids with concentrated hydrogen peroxide or with urea peroxide in the presence of a base) takes place chemoselectively at the double bond with formation of the corresponding acetylenic oxirans $R^1_3SiC{\equiv}C-CR^2(O)-CHR^3$.[27-29,269-273] Examples of the stereo-oxidation of *cis*- and *trans*-1-trimethylsilyldec-3-en-1-ynes have been described.[163] The oxidation of silicon-containing alkenynes with participation of functional groups was examined in subsection 2.

(c) Reactions with nucleophiles

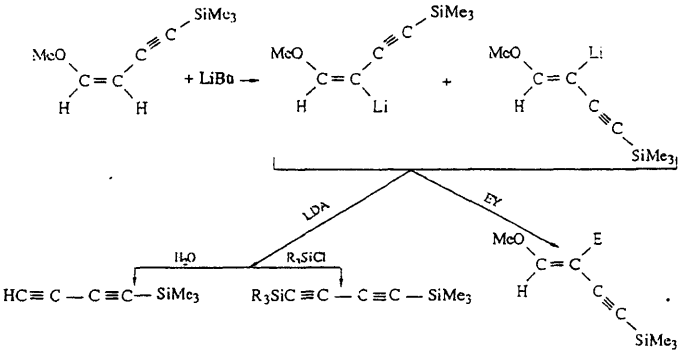
Interaction with organolithium compounds. The interaction of organolithium compounds with trialkylsilylalkenynes was first mentioned by Petrov et al.[23] According to their data, methyllithium and butyllithium add to 1-trialkylsilylbut-3-en-1-ynes exclusively at the double bond with formation, after demetallation with water, of the corresponding acetylenic silylhydrocarbons. It was later shown[274,275] that trialkylsilylalkenynes combine with organolithium compounds non-selectively at the double bond and in the 1,4-positions. The introduction of methyl groups at the α- and β-carbon atoms of the double bond hinders the addition reaction and lowers the yield of the products. It is noteworthy that 1,4-disubstituted alkenynes isomerise under these conditions with migration of the triple bond to the end of the chain.[276]

The ratio of the isomeric acetylenic and allene silylhydrocarbons depends little on the structure of the starting materials. A change in the structure of the demetallating agents also hardly affects the ratio of the isomeric reaction products: when lithium-containing adducts are treated with chlorotrimethylsilane, aldehydes, or ketones, the corresponding allene and acetylene derivatives are formed in proportions of approximately 1 : 1:

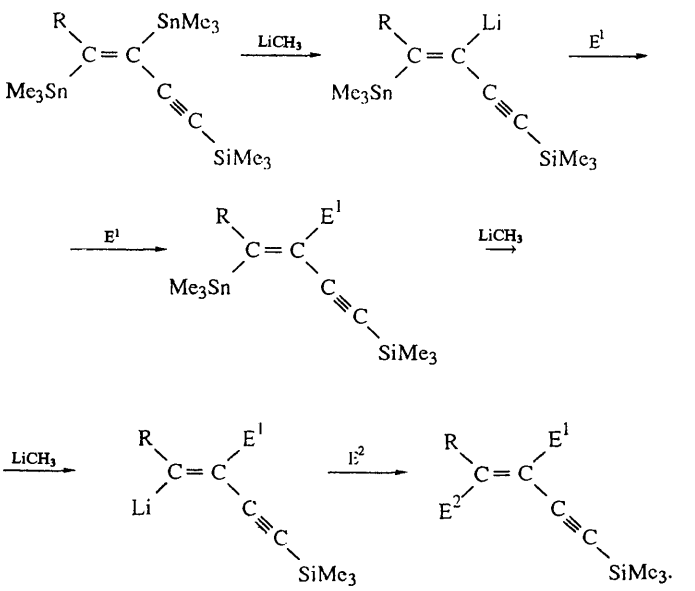
$$[R_3SiC{\equiv}C-\overset{\ominus}{C}HCH_2R']Li^{\oplus} + E^+Y^- \rightarrow \begin{cases} R_3SiCE=C=CHCH_2R' \\ R_3SiC{\equiv}C-CHECH_2R' \end{cases}$$

E — Y = Me_3SiCl; $R^2R^3C{=}O$.

1-Methoxy-4-trialkylsilylbut-1-en-3-ynes are metallated on treatment with lithium alkyls, a mixture of the *cis*- and *trans*-lithiated silylalkenynes being formed from the *cis*-ether.[53] On interaction with electrophiles, the lithiated silylalkenynes form the corresponding derivatives with the *trans*-configuration,[53] while their interaction with nucleophiles[54] affords the lithiated derivatives of 1-trialkylsilylbutadiyne:



3,4-Bis(trialkylstannyl)-1-trimethylsilylalk-3-en-1-ynes are trans-metallated on interaction with organolithium compounds. The organolithium compounds formed on treatment with the corresponding electrophiles afford derivatives of silicon-containing alkenynes in satisfactory yields:[121]



Judging from the structure of the reaction products after demetallation with water, the methyl ester of 5-trimethylsilylpent-2-en-4-ynoic acid combines with triphenyl lithiotrithioformate exclusively at the double bond (most probably via the 1,4-addition to the $-C=C-C=O$ fragment):[48]

$$Me_3SiC\equiv C-CH=CH-\underset{\displaystyle OMe}{\underset{|}{C}}=O + LiC(SPh)_3 \xrightarrow{HOH}$$

$$\longrightarrow Me_3SiC\equiv C-\underset{\displaystyle C(SPh)_3}{\underset{|}{CHCH_2COOMe}}$$

The interaction of the silicon-containing vinylacetylenic ketone with metallic sodium in chlorotrimethylsilane apparently proceeds as 1,4-addition of trimethylsilylsodium:[138]

$$Me_3SiC\equiv C-CH=CH-\underset{\displaystyle Me}{\underset{|}{C}}=O \xrightarrow[2.\ HOH]{1.\ Na + Me_3SiCl}$$

$$\longrightarrow Me_3SiC\equiv C-\underset{\displaystyle SiMe_3}{\underset{|}{CHCH_2}}-\underset{\displaystyle Me}{\underset{|}{C}}=O\ .$$

Treatment of an alkenynyl chloride with a mixture of metallic lithium and chlorotrimethylsilane followed by the demetallation of the reaction products with water afforded a vinylallene. Its formation presupposes the 1,4-addition of trimethylsilyllithium to the conjugated system of multiple bonds and dehydrochlorination:[46]

$$Me_3SiC\equiv C-\overset{CH_3}{\overset{|}{C}}=CHCH_2Cl \xrightarrow[2.\ HOH]{1.\ Li + Me_3SiCl}$$

$$\longrightarrow \begin{matrix} Me_3Si \\ \diagdown \\ \quad C=C=C \\ \diagup \qquad \diagdown \\ Me_3Si \qquad\quad CH=CH_2 \end{matrix} \begin{matrix} \\ \\ \diagup \\ \\ \\ CH_3 \end{matrix} .$$

In the absence of chlorotrimethylsilane, treatment of 1-trialkylsilylbut-3-en-1-yne with lithium and then water leads to a mixture of diacetylene and diallene hydrodimerisation products. Cross-coupling products (the corresponding allenylacetylenes) were not detected.[277]

Interaction with organomagnesium, organocalcium, and organobarium compounds. Organomagnesium compounds (Grignard reagents) are less reactive: silicon-containing alkenynes do not react with the Grignard reagent obtained beforehand under standard conditions.[278,279] However, at the instant of their formation, such reagents add fairly vigorously to 1-trimethyl- and 1-triethyl-silylbut-3-en-1-ynes,[278–280] affording, after demetallation with water, mixtures of the corresponding acetylene and allene silylhydrocarbons in proportions of 10:1 (yield about 10–15%) and oligomers.

Tris(trimethylsilyl)allene is apparently formed via the same mechanism in the reaction of 1-trimethylsilylbut-3-en-1-yne with a mixture of metallic magnesium and chlorotrimethylsilane.[46,281]

It has been shown for the reactions with phenylmagnesium bromide that silicon-containing alkenynes combine with organomagnesium compounds at the double bond in the presence of nickel(II) halides. The yield of the corresponding acetylenic hydrocarbons is 30–35%.[282] It can be increased by using other catalysts—$Fe[CH(COMe)_2]_3$, $Ni[CH(COR)_2]_2$; R = Me, Ph.[283]

Organocalcium and organobarium compounds RMI (M = Ca, Ba) add to silicon-containing alkenynes also in the absence of catalysts and, as in the reactions with organolithium compounds, mixtures of allene and acetylene silylhydrocarbons are formed after the demetallation of the adducts with water. Whereas in the reactions with organocalcium compounds the ratio of the isomers formed is 70:30,[284] in those with organobarium compounds the ratio is approximately 1:1.[285,286] Organozinc compounds (investigated in relation to the interaction of allylzinc bromide with 3-methyl-1-trimethylsilylbut-3-en-1-yne[287]) add chemo- and regio-selectively (95% *trans*) to the triple bond.

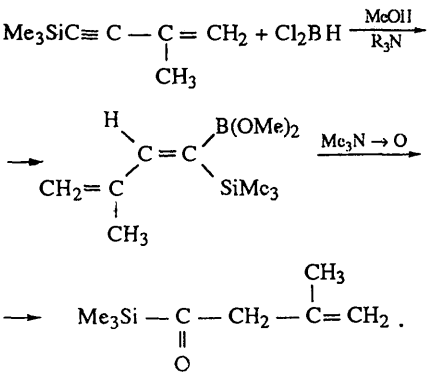
Interaction with organoaluminium compounds. Trialkylaluminium interacts with 1-trialkylsilylalk-3-en-1-ynes only under severe conditions. The reaction takes place chemoselectively at the triple bond with formation of a mixture of (*E*,*E*)- and (*E*,*Z*)-2-alkyl-1-trialkylsilylalka-1,3-dienes. The addition of bimetallic complexes of trialkylaluminium and dialkylmagnesium also takes place chemoselectively to the triple bond but much more readily:[288,289]

$$Me_3SiC\equiv C-CH=CH-C_6H_{13} + Alk_3Al\cdot Bu_2Mg \xrightarrow{H^+}$$

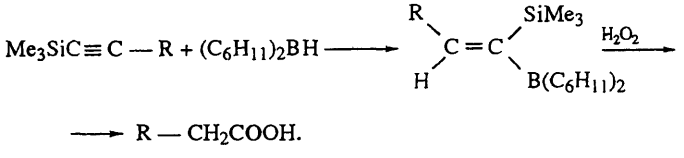
$$\longrightarrow \begin{matrix} Me_3Si \\ \diagdown \\ \quad C=C \\ \diagup \qquad \diagdown \\ H \qquad\quad C=C \\ \qquad\quad \diagup \qquad \diagdown \\ \qquad\quad H \qquad\quad C_6H_{13} \end{matrix} \begin{matrix} Alk \\ \diagup \\ H \\ \\ \\

On interaction with electrophiles, the adducts formed corresponding silylhydrocarbons or their derivatives.

Hydroboration of unsaturated compounds. This most probably proceeds via a molecular quasi-cyclic mechanism. However, it is formally analogous to hydroalumination. The first studies on the hydroboration of alkenynes were undertaken in order to develop an effective method of synthesis of silicon-containing ketones by oxidising the corresponding boron-containing adducts. It was found that the hydroboration of silylalkenynes proceeds chemo-, regio-, and *cis*-stereo-specifically at the triple bond.[292–294] The adducts formed isomerise to the *trans*-isomer on irradiation. Oxidation of the adduct with *N*-oxides leads to the formation of unsaturated silicon-containing ketones in good yields:

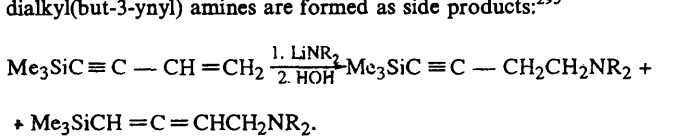


Dicyclohexylborane also adds stereo- and regio-selectively to the triple bond in silylalkenynes.[294] The adducts formed are oxidised in an alkaline medium with hydrogen peroxide to the corresponding unsaturated acids:



This method was subsequently used successfully in the synthesis of *cis*- and *trans*-6-phenyl-3-hexenoic and 5-amino-6-(4-t-butoxyphenyl)-3-hexenoic acid—key compounds in the synthesis of enkephalin analogues.[218,219]

Interaction with amines and amides. In the absence of a basic catalyst, primary and secondary amines do not interact with silylalkenynes. However, lithium dialkylamides, obtained beforehand, add under mild conditions to 1-trimethylsilylbut-3-en-1-yne with formation of a mixture of silicon-containing alkynyl- and allenyl-amines after demetallation with water. Silicon-free dialkyl(but-3-ynyl) amines are formed as side products:[295]

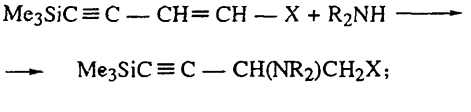


Desilylation most probably proceeds mainly at the stage involving the decomposition of the metal-containing adduct.[295] The fraction of the silicon-free alkynylamines depends on the structure of the amine: in the reaction with dimethylacetamide, they were detected only spectroscopically, while in the reaction with piperidine the yield of *N*-butynylpiperidine is 21%.

The same mixtures of silicon-containing amines derived from acetylenes and allenes are formed when an ethereal solution of the amine and 1-trimethylsilylbut-3-en-1-yne is heated to boiling in the presence of catalytic amounts of metallic sodium.[296] Desilylation products were not detected under these conditions.

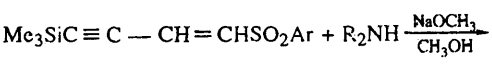
According to the results of Perveev and Afonina,[297] the silicon-containing nitriles $R_3SiC{\equiv}C-C(CH_3)=CH-CN$ are desilylated on interaction with primary and secondary amines. The nitrile of the alkenynoic acid formed combines with amines at the triple bond under these conditions. However, it was noted that, in experiments with methylamine and the nitrile of 3-methyl-1-trimethylsilylpent-3-en-4-ynoic acid, it was also possible to isolate small amounts of the product of the addition of the amine to the double bond.

Systematic study of the characteristic features of the addition of secondary amines to silyl derivatives of vinylacetylenes containing electron-accepting substituents X at the double bond showed that vinylacetylene nitriles, esters, ketones, and sulphones combine with secondary amines chemo- and regio-selectively at the double bond:[95,298–300]



In aprotic solvents (dimethyl ether of ethylene glycol), the addition takes place only after prolonged heating of the reactants at temperatures of the order of 100 °C.[298,299] In the absence of a solvent with an excess of the amine the reaction proceeds under appreciably milder conditions, ketones and ethers combining with amines even at room temperature. A decrease in temperature and reaction time in the interaction of amines with nitriles can be achieved only in proton-donating solvents (120 °C and 12 h without a solvent or 25 °C and 12 h in methanol[299]). The observed dependence of the relative reactivities of the alkenynes investigated in relation to amines has been explained by autocatalysis caused by the acid–base reagent–substrate interaction.

Silicon-containing vinylacetylenic sulphones do not combine with secondary amines in the presence of alcohols. Nor were any of the reactions of the reactants observed when their mixtures in methanol were allowed to stand in the presence of sodium methoxide at room temperature. However, on heating in the presence of methoxide, desilylation and the addition of the amine to the terminal bond take place:[300]



Reactions with thiols and thiolates. As already mentioned,[265–267] the free-radical addition of thiols to 1-trialkylsilylalk-3-en-1-ynes initiated by peroxides proceeds non-regioselectively. The attempts to add alkanethiols to silylalkenynes under the conditions of base catalysis did not yield positive results. In the interaction of 1-trimethylsilylbut-3-en-1-yne with ethanethiolate in methanol, an exothermic reaction takes place, as soon as the reactants are mixed and leads to the formation of sulphides with and without silicon in

proportions of 1 : 5.[301] The silicon-containing sulphides are products of 1,4-, 3,4-, and 1,2-addition in proportions of 4 : 1 : 2, while the sulphides without silicon constitute a mixture of 4-ethylthiobut-1-yne (12%), 1-ethylthiobuta-1,3-diene (34%) and 4-ethylthiobuta-1,2-diene (54%). Since the thiolate-catalysed addition of ethanethiol to vinylacetylene in an alcoholic solution results in the formation of only 1-ethylthiobuta-1,3-diene,[302] the formation of a mixture of silicon-free sulphides in the reaction analysed is most probably due to the desilylation of free-containing adducts.

As was to be expected, the introduction of electron-accepting groups ($COCH_3$, $COOCH_3$, CN, NO_2, SO_2Ar) into the alkenyne fragment increases significantly the rate of addition of thiols. However, when the reaction is carried out in methanol, only silicon-free products are formed from silylalkenyne derivatives even at −10 to −50 °C in the presence of thiolate:[301,303–305]

$$Me_3SiC{\equiv}C-CH=CHX + RSH \xrightarrow[CH_3OH]{RSNa} RSCH=CH-CH=CHX.$$

It has been established empirically that the silylalkenynes investigated can be made to undergo an addition reaction without appreciable cleavage of the silicon–carbon bond, provided that it is carried out in benzene or a 3 : 1 benzene–methanol mixture. Ethanethiol adds to the alkenyne both in benzene and in its mixture with methanol, while the less nucleophilic thiophenol adds only in the mixed solvent:[304]

$$Me_3SiC{\equiv}C-CH=CHX+RSH \xrightarrow[C_6H_6+CH_3OH]{RSNa} Me_3SiC{\equiv}C-CH(SR)CH_2X;$$

$R = C_2H_5$, C_6H_5.

The reaction is chemo- and regio-specific.

The silyl derivatives of vinylacetylenes investigated combine with alkane- and arene-thiols under very mild conditions, which agrees well with the nucleophilic mechanism proposed for these reactions. However, attention has been drawn to the fact[300,304,305] that the corresponding ketones react most readily, while the nitriles and sulphones react with the greatest difficulty. The antiparallel variation of the reactivity with the electron-accepting properties of the substituents X can be explained, according to the authors, by the fact that autocatalysis due to the acid–base reagent–substrate interaction plays a significant role in the reactions:

$$Me_3SiC{\equiv}C-CH=CH-\underset{\displaystyle R'}{\underset{|}{C}}=O + RSH \rightleftharpoons$$

$$\longrightarrow Me_3SiC{\equiv}C-CH=CH-\underset{\displaystyle R'}{\underset{|}{C}}=O\ldots H-SR.$$

Such interaction intensifies the polarisation of the multiple bonds and promotes the addition of the reagent to the double bond with attachment of the alkyl(aryl)thio-group to the β-carbon atom of the double bond. Aprotic solvents decompose such associated species and hinder the addition reaction, whilst proton-donating solvents themselves form associated species with the substrate and promote the addition reaction. This mechanism explains satisfactorily the decrease in the rate of addition on passing from thiophenol to ethanethiol and also the finding that in the presence of an excess of the reagent thiophenol adds to vinylacetylenic esters and ketones (X = $COOCH_3$ and $COCH_3$) at room temperature with 100% conversion in 10–15 min in the absence of a base.[305]

Interaction with arenesulphinates. This has been investigated only in relation to the reaction of 1-nitro-4-trimethylsilylbut-1-en-3-yne with sodium toluene-*p*-sulphinate. According to the available data, the addition proceeds chemo- and regio-selectively but only in the presence of an equivalent amount of acetic acid:[306]

$$Me_3SiC{\equiv}C-CH=CHNO_2 + p\text{-}CH_3C_6H_4SO_2Na \xrightarrow[CH_3OH]{CH_3COOH}$$

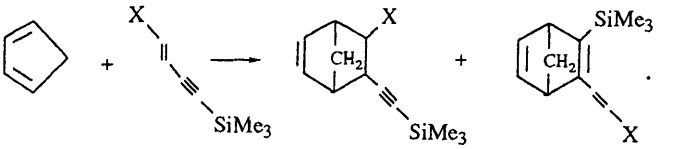
$$\rightarrow Me_3SiC{\equiv}C-\underset{\displaystyle SO_2C_6H_4CH_3\text{-}p}{\underset{|}{CH}}CH_2NO_2.$$

The silicon-containing vinylacetylenic sulphones, containing groups with weaker electron-accepting properties do not combine with sulphinates under these conditions.[307]

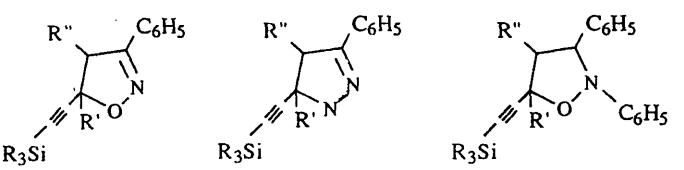
(d) Cycloaddition and cyclisation reactions

This section deals with reactions completed by the formation of carbocyclic and heterocyclic compounds as a result of intermolecular or intramolecular addition regardless of their mechanism. Shostakovskii et al.[308] showed for the first time that 1-triethylbut-3-en-1-yne is an active dienophile in condensation with hexachloropentadiene.

It has also been shown that interaction of cyclopentadiene with functional silyl-substituted derivatives of vinylacetylenes also involves the formation of a mixture of *endo,endo*, and *exo,exo*-isomers. Significant amounts of products of addition to the triple bond have been detected only in the reactions of cyclopentadiene with 1-cyano–4-trimethylsilylbut-1-en-3-yne:[309,310]

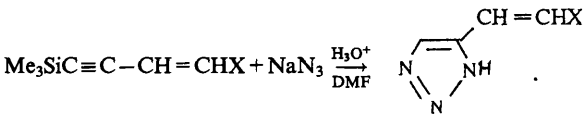


The reactions of 1,3-dipolar reagents (benzonitrile *N*-oxide, diphenylnitrile imine, α,*N*-diphenylnitrone, *C*-ethoxycarbonyl-*N*-phenylnitrile imine, 3-phenylsydnone, and sodium azide) with 1-trialkylsilylalk-3-en-1-ynes and some of their functional derivatives proceed in different ways depending on the structure of the alkenyne and the dipolar compound. Silicon-containing hydrocarbons combined in all cases with Huisgen's 1,3-dipoles at the double bond with formation of the corresponding trialkylsilylethynyl-substituted isoxazolines (I), pyrazolines (II), and isoxazolidines (III):



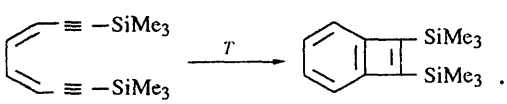
It was shown by the method of competing reactions that silylhydrocarbons are more reactive in their reactions with 1,3-dipoles than silicon-free hydrocarbons with similar structures.[311]

Sodium azide does not react with 1-trialkylsilylalk-3-en-1-ynes. However, their derivatives containing electron-accepting groups at the double bond combine with sodium azide at the triple bond on heating in dimethylformamide (DMF) at 90–95 °C. Demetallation of the adducts with water involves desilylation with formation of substituted triazoles:[312,313]

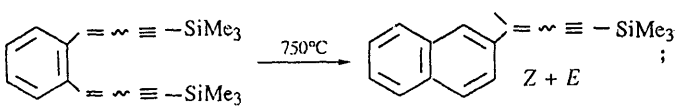


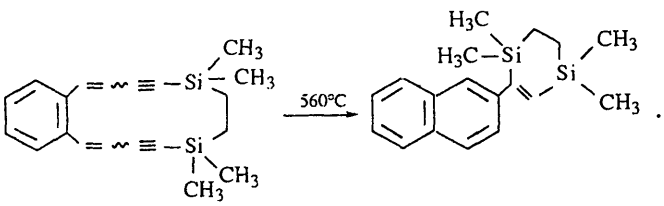
The attempts to add aryl- and trialkyl-silyl azides to silylalkenynes and their derivatives failed.[313]

The first reports concerning the intramolecular cyclisation of organosilicon compounds containing a conjugated double and triple bond appeared recently. It was shown that pyrolysis of 1,8-bis(trimethylsilyl)octa-3,5-diene-1,7-diyne *in vacuo* affords [8]annulene, which is very sensitive to atmospheric oxygen:[314]

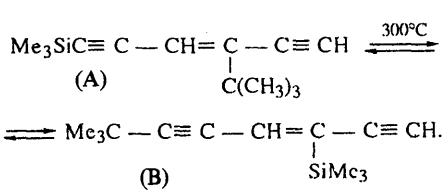


It has been established[315] that the structural analogues of 1,8-bis(trimethylsilyl)octa-3,5-diene-1,7-diyne form the corresponding naphthalene derivatives:

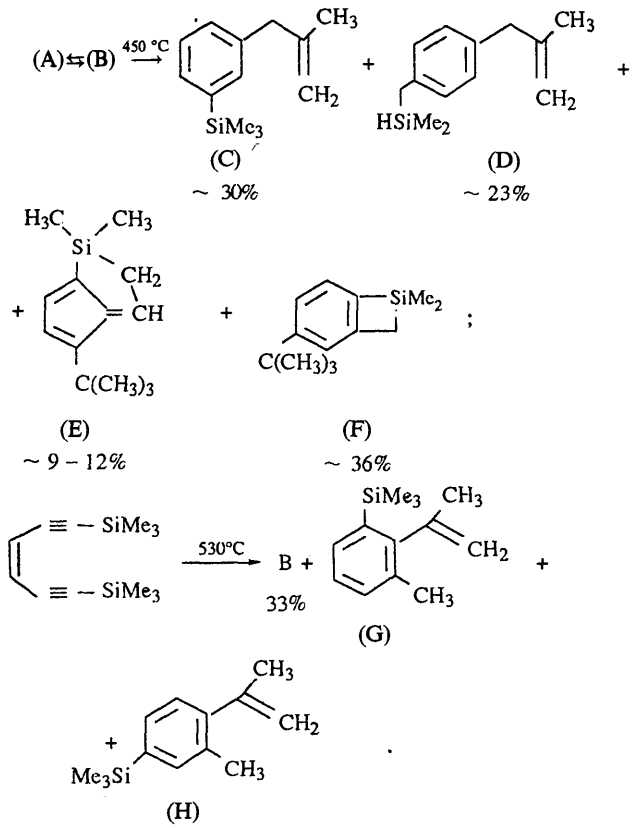




t-Butyltrimethylsilylpent-3-ene-1,4-diynes isomerise to a mixture of isomers containing only 1% of the structure (B):[90]



When a mixture of compounds (A) and (B) or each isomer separately is heated, four isomeric silyhydrocarbons are formed in an overall yield in excess of 90% regardless of the configuration (*E* or *Z*):

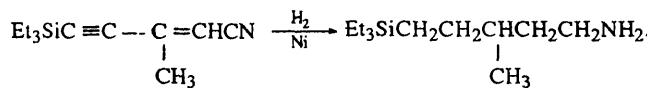


It is difficult to cyclise the disilylated alkenediyne containing the bulky trimethylsilyl groups in the 1,6-positions. The reaction takes place at an appreciable rate only at 530 °C with formation of compounds (C), (G), and (H).

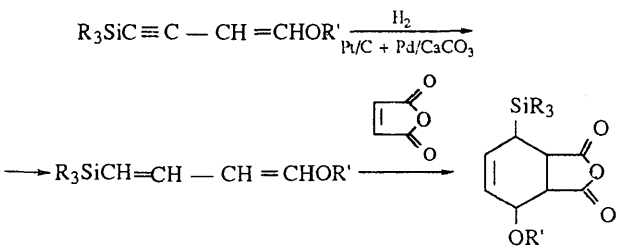
(e) Metal-catalysed homogeneous and heterogeneous reactions

Homogeneous and heterogeneous catalysis by transition metal compounds is one of the most important procedures for the activation of multiple bonds. Their characteristic feature, regardless of the mechanisms of the particular reactions occurring, is the involvement of the unsaturated ligand in intracomplex reactions of the ligands, which is as a rule the reason for a particular stereochemical result.

Catalytic hydrogenation. The catalytic hydrogenation of silicon-containing alkenynes up to complete saturation has been usually carried out in the presence of the Raney nickel catalyst,[70,78,79] the aim being to synthesise the corresponding saturated silylhydrocarbons and their derivatives. It has been noted that the nitrile of the acid derived from vinylacetylene is reduced under these conditions to the corresponding amine:[70]



Incomplete hydrogenation with the aim of determining the relative reactivities of the double and triple bonds of 1-trialkylsilylalk-3-en-1-ynes in relation to catalytically activated hydrogen was carried out by Petrov and co-workers[22,23] in the presence of a palladium catalyst. Since bands characteristic of the double bond were found in the Raman spectrum of the products obtained after hydrogenation and by analogy with data on the catalytic hydrogenation of vinylacetylene and its homologues (see, for example, Bal'yan et al.[316]), it was concluded that the first molecule of hydrogen adds to the triple bond of 1-trialkylsilylalk-3-en-1-ynes. Shostakovskii et al.,[52] who studied the hydrogenation of 4-ethoxy-1-trialkylsilylbut-3-en-1-ynes, arrived at the same conclusion:



The yield of the corresponding cyclic adduct with maleic anhydride reached only 25%. It has also been noted[52] that silicon-containing alkenyl ethers were not hydrogenated in the presence of only platinum on charcoal or palladium on calcium carbonate.

A more thorough investigation of the catalytic hydrogenation of silicon-containing alkenynes[26,244,317] showed that, in contrast to the alkenynes themselves, their silicon-containing analogues are hydrogenated non-selectively. In all cases the reaction products were mixtures of the initial silylhydrocarbon and the products of its hydrogenation in proportions of 1 : 1 (~90%) and the products of more extensive hydrogenation (5%). The products of the addition of the first molecule of hydrogen consisted of a mixture of alkyne, 1,3-diene, and allene isomers $R_3SiC{\equiv}C-CHR'CH_2R''$, $R_3SiCH=CH-CR'=CHR''$, and $R_3SiCH=C=CR'CH_2R''$ in proportions of approximately 60 : 35 : 5.[244]

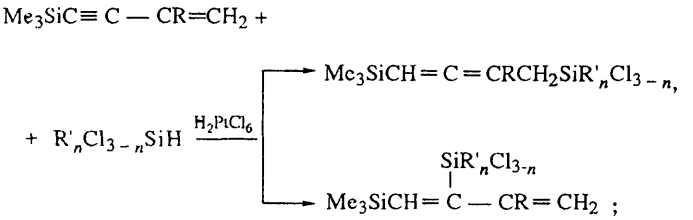
The ratio of the isomeric silylhydrocarbons varies within fairly wide limits depending on the nature of the substituents at the double bond and the silicon atom. The formation in all cases of appreciable amounts of silylallenes is striking. Their maximum amount is observed in the hydrogenation of 3-t-butyl-1-trimethylsilylbut-3-en-1-yne.[26] The addition of hydrogen in the 1,4-positions was not observed in th catalytic hydrogenation of vinylacetylenes.

It is also noteworthy that the rate of catalytic hydrogenation of silicon-containing alkenynes depends greatly on the bulk of the substituents at the silicon atom and in the alkenyne fragment.

Judging from the available data[31] allyldimethylsilylbut-3-en-1-yne is also hydrogenated in the vinylacetylene fragment, the ratio of the isomeric hydrogenation products being approximately the same as in the hydrogenation of 1-trialkylsilylbut-3-en-1-ynes.[244,317]

The data examined show that the trialkyl(aryl)silyl group at the α-carbon atom of the triple bond of the alkenyne hinders the addition of the first molecule of hydrogen to the triple bond and renders the process non-chemoselective.

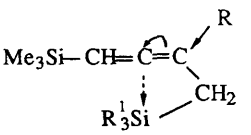
Hydrosilylation of 1-trialkylsilylalk-3-en-1-ynes. This was investigated solely in relation to the interaction of trialkyl- and alkylchloro-hydrosilanes with 1-trimethylsilylbut-3-en-1-ynes[318,319] and 3-methyl-1-trimethylsilylbut-3-en-1-yne[320] in the presence of Speier's catalyst. Chlorosilanes are more reactive in this process than trialkylsilanes and the mode of reaction depends on the structure of the alkenyne and the hydrosilane. 1-Trimethylsilylbut-3-en-1-yne combines with trimethyl- and triethyl-silanes preferentially in the 1,4-positions, while the chlorosilanes CH_3Cl_2SiH, $C_2H_5Cl_2SiH$, and Cl_3SiH combine with the above alkenyne at the triple bond:



n = 0, 1, 3; R = H, CH_3; R' = CH_3, C_2H_5.

On heating in the presence of a catalyst of the addition reaction or copper(I) chloride in an acid medium, the allene adducts isomerise almost wholly to the 1,3-diene adducts.

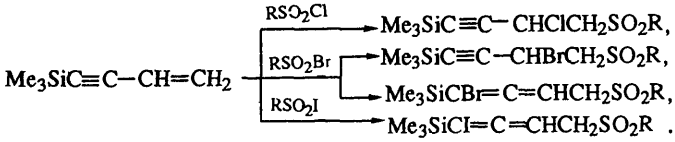
Regardless of the nature of the hydrosilane, 3-methyl-1-trimethylsilylbut-3-en-1-yne forms predominantly 1,3-diene adducts.[320] The authors suggest that the addition takes place in all cases in the 1,4-positions as an intramolecular reaction of the ligands. The ability of silicon-containing alkenynes to form "allene" complexes with platinum group metals has been demonstrated experimentally.[321,322] The allene adduct formed isomerises via a quasi-cyclic complex to the 1,3-diene adduct with migration of the trialkylsilyl group R^1_3Si:[320]



By inducing a partial positive charge on the silicon atom, the electron-accepting substituents R^1 (in the given instance chlorine) should promote the same type of isomerisation as that promoted by the introduction of a methyl group in the 3-position (R = CH_3), which increases the electron density on the C^2 carbon atom. The electron-donating substituents R^1 should hinder isomerisation. The observed dependence of the structure of the reaction products on the nature of the substituents at the silicon atom[318,320] as well as the data obtained for the hydrosilylation of 1,2,3-tris(trimethylsilyl)but-1-en-yne[117] are explained satisfactorily by the proposed mechanism. The hydrosilylation of alkenynes by trialkylsilanes is regarded[117] as a new effective preparative method of synthesis of allenes.

Intereaction with sulphonic acid halides. The relative reactivities of organic sulphonic acid halides in reactions with 1-trialkylsilylalk-3-en-1-ynes depend on the halogen; whereas acid iodides add exothermically merely on mixing the reactants, the bromides react on heating or in the presence of a catalyst, while the chlorides react only in the presence of the Asscher–Vofsi catalyst [a mixture of copper(I) halide, triethylamine hydrochloride, and acetonitrile[323]]. There are no literature data for the addition of these reagents to 1,3-alkenynes in the presence of aprotic Lewis acids.

The addition of the chlorides of alkane- and arene-sulphonic acids catalysed by copper(I) halides proceedes chemoselectively at the double bond:[91,92,94]



Regardless of the conditions (catalytic or thermal addition), the acid bromides add regioselectively to the alkenynes investigated with formation of a mixture of acetylene and allene adducts in proportions of approximately 1 : 1. In the absence of a catalyst, the acid iodides add exclusively in the 1,4-positions. The addition of the Asscher–Vofsi catalyst does not affect the mode of reaction.[93] It is of interest that t-butylvinylacetylene combines under these conditions with the acid chlorides, bromides, and iodides only at the double bond.[91,95] The introduction of a methyl group in the 3- or 4-position greatly hinders the reaction and impairs its selectivity. The chlorine-containing adducts formed in these reactions in low yields (20–30%) are mixtures of products of the addition to the double bond and in the 1,4-positions.[92]

It is also noteworthy that finely dispersed copper can be used instead of copper(I) chloride (bromide). Copper(II) hydroxide and copper oxide are inactive in the reaction.[324] It has been suggested that the reactions of the acid chlorides and bromides in the presence of copper salts proceed as intracomplex redox-initiated interaction of the ligands.[325]

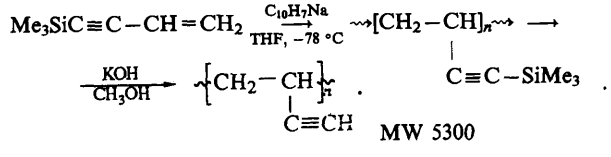
Chlorine-, bromine-, and iodine-containing products obtained in the reactions are readily dehydrohalogenated with triethylamine to form the corresponding *trans*-ethynylvinyl sulphones $R^1_3SiC{\equiv}CCR^2{=}CHR^3SO_2R^4$ in almost quantitative yields.[20]

(f) Polymerisation and copolymerisation

Trialkylsilylbut-3-en-1-ynes are known to polymerise spontaneously even at room temperature with formation of brittle vitreous masses.[23] On heating in the presence of benzene peroxides, the process proceeds at a much higher rate.[23,326] The relatively high rate of the peroxide-initiated polymerisation of dialkylhydroxysilylbut-3-en-1-yne has been pointed out.[38] There are data on the copolymerisation of 1-dimethylphenylsilylbut-3-en-1-yne with methyl methacrylate and certain physicochemical properties of the copolymers have been published.[326] The data on the structure of the polymers and copolymers obtained have not been discussed.[38,326]

In the presence of azobisisobutyronitrile, bisvinylethynylsilanes polymerise even at room temperature. The homopolymer formed under these conditions (most probably with a three-dimensional structure) is stable on heating to 400 °C.[327] The copolymerisation of bisvinylethynylsilanes with methyl methacrylate takes place at 60 °C. The influence of the ratio of the monomers on the yields, dielectric constants, and solubilities of the copolymers has been studied.

Japanese workers[328,329] have patented an effective method of synthesis of the vinylacetylene homopolymers by the naphthyl-sodium-initiated polymerisation of 1-trimethylsilylbut-3-en-1-yne and subsequent disilylation of the polymer with alkali:



Similar results were obtained using naphthyl- or butyl-lithium as polymerisation initiators.[329]

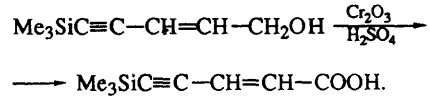
Two stages have been found in the polymerisation of 1-trimethylsilylbut-3-en-1-yne under the influence of γ-radiation: the formation of a linear polymer and the formation of three-dimensional structures in the polymer.[330] It was established that the replacement of the acetylene hydrogen by the trimethylsilyl group promotes the first stage and hinders the second.

A method has been patented for the preparation of materials for gas-permeable contact lenses from substances obtained by the polymerisation and copolymerisation of organosilicon vinylacetylene monomers of the type $CH_2{=}CR^1C{\equiv}CSiR^2R^3OSiR^4R^5R^6$ [331] or $CH_2{=}CR^1C{\equiv}CSiR^2R^3R^4$ and $[CH_2{=}CMeC{\equiv}C]_2SiMe_2$.[332]

2. Reactions with participation of functional groups

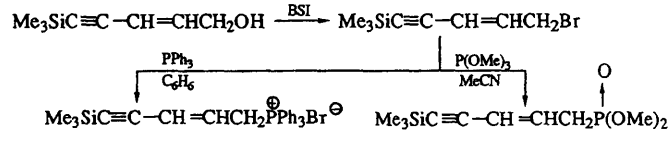
This type of chemical reaction of functional derivatives of silicon-containing alkenynes has been least investigated. However, it is known that the oxidation of silicon-containiing alkenynes with active manganese dioxide[145,186] or nickel peroxide[51] leads to the formation of the corresponding aldehydes in satisfactory yields. It has been noted that the oxidation of the (*Z*)-isomer proceeds without change in the configuration. Dimethyl sulphoxide can also be used as the oxidant.[179]

The oxidation of silicon-containing (*E*)- and (*Z*)-vinylacetylen alcohols with the Jones reagent leads to the corresponding acids, which have been converted, without purification, into methyl esters by treatment with diazomethane[48] or methanol in the presence of concentrated sulphuric acid[51]

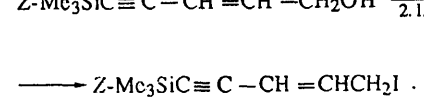


When the (*Z*)-carbinol is treated with the chlorides of acetic and (*E*)- or (*Z*)-2-methylbut-2-enoic acids,[51] the corresponding esters are produced. The configuration of the alkenyl fragments does not change under these conditions.

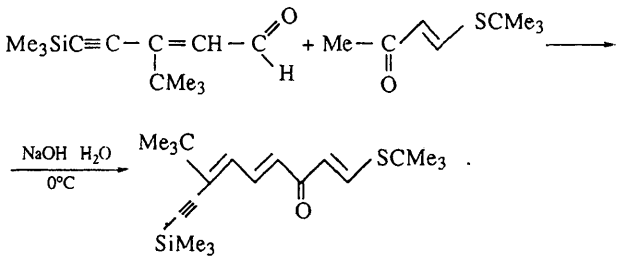
The interaction of 5-trimethylsilylpent-2-en-4-yn-1-ol with bromosuccinimide (BSI) afforded the corresponding bromide, which is readily converted into phosphoranes or phosphonates—key compounds in the synthesis of lipoxin A,[49,50,333,334,335] numerous dehydroannulenes (see Nakagawa[336] and the references quoted therein and Nakagawa and co-workers[337,338]) as well as other natural products and their synthetic analogues:[186,220,339]



A method has been developed for the synthesis of (*Z*)-1-iodo-5-trimethylsilylhex-2-en-4-yne which is used in the total synthesis of (±)-penacene:

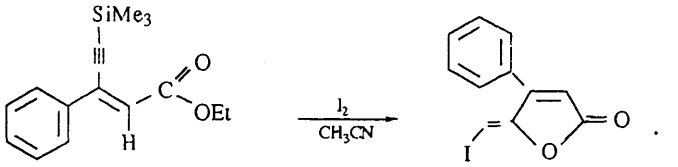


It has been shown for 3-t-butyl-5-trimethylsilylpent-2-en-4-yn-1-al[140,340] that silicon-containing aldehydes of the alkenyne series enter into aldol and crotonic condensations without the cleavage of the silicon–carbon bond:

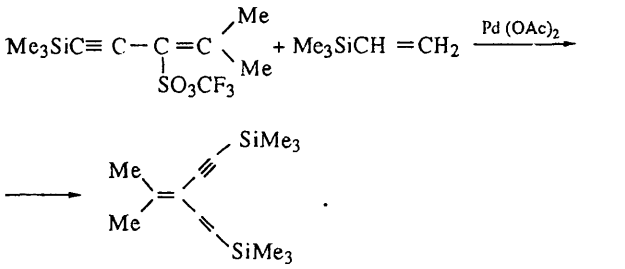


They also interact with organometallic compounds, affording the corresponding alcohols.[336,341,342]

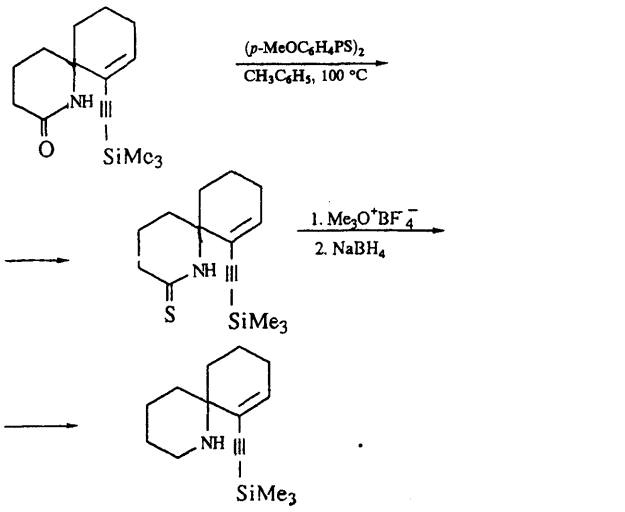
Iodolactonisation also takes place with participation of functional groups:[85]



It has been shown that 1,3-alkenyne silicon-containing triflates are capable of undergoing the palladium-catalysed cross-coupling reaction. The trimethylsilyl group is not then involved:[343,344]

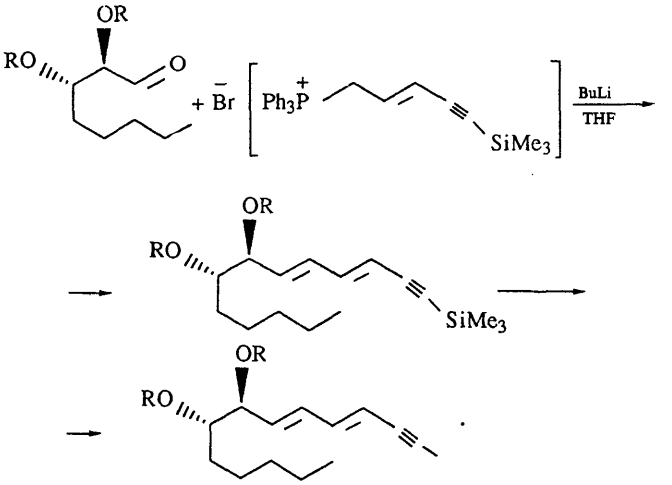


The reactions of an organosilicon lactam, described by Bultin et al.,[178] proceed with participation of functional groups:



3. Reactions with participation of the silicon–carbon bond

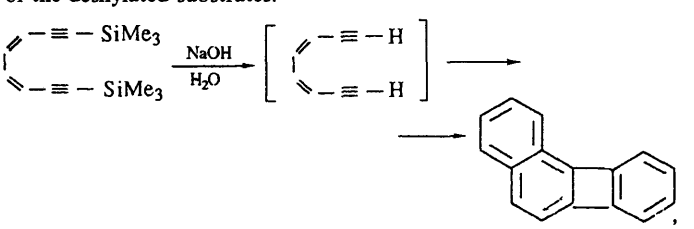
The introduction of a trialkyl(aryl)silyl group at the terminal carbon atom of the triple bond is known to increase significantly the stability of alkynes, alkenynes, and more unsaturated derivatives. The silyl protecting group is therefore used widely in the synthesis of natural products containing conjugated alkenyl fragments. As an example, one may quote the scheme for the preparation of the synthetic block (A)—the key compound in the synthesis of the four possible isomers of lipoxin B:[333,334]



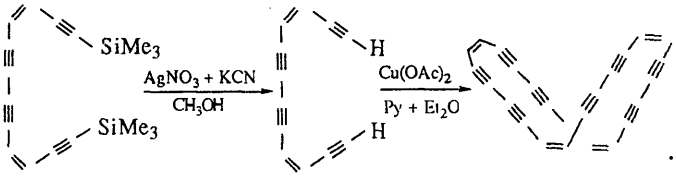
(A)

The triorganosilyl (most often trimethylsilyl) group is usually removed by the reaction of the corresponding silicon-containing acetylene with an alcoholic solution of an alkoxide,[169,170,206] an aqueous[33,85,120,155] or alcoholic[73,76,166,169,344] solutions of alkali, an aqueous solution of sodium carbonate[178] or potassium carbonate,[183] an alcoholic or aqueous alcoholic solution of a mixture of silver nitrate and potassium cyanide,[32,34,50,97,105,145,174,216,234,344] or the same reagents in a 1:1:1 ethanol–tetrahydrofuran (THF)–water mixture.[49,187,333] Desilylation takes place also when silylacetylenes are treated with methyllithium.[36,206,345] The fluorides of potassium,[30,112,141,158,159,172,201,215,224,235] sodium,[62] and tetrabutylammonium[103,104,113,173,176,182,232] have become particularly popular desilylating agents in recent years. Tetrahydrofuran, alcohol, and dimethylformamide are used as solvents in such cases. The reactions proceed as a rule at room temperature or with slight heating. The yields of the desilylation products are nearly quantitative. A method has been developed for the desilylation of silylalkenynes using phase transfer catalysts.[346] For example, the method helps to cleave the silicon–carbon bond under mild conditions without affecting the oxiran ring.

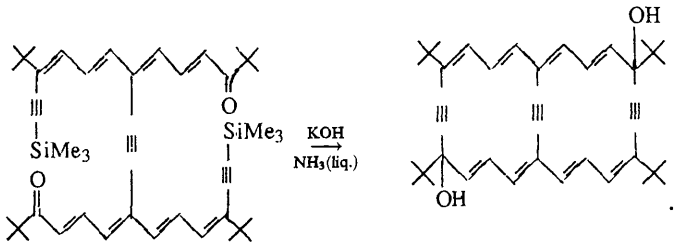
Reactions in which the removal of the silyl protecting group is completed with the formation of a new carbon–carbon bond are extremely interesting. Such processes may be due to the low stability of the desilylated substrates:[33]



or they can take place on treatment with new reagents:[34]



Japanese workers[340] developed a single-stage desilylation-alkynylation method involving the reaction of 1-trialkylsilylalk-1-ynepolyene aldehydes and ketones with alkalies in liquid ammonia. The method presupposes intramolecular or intermolecular nucleophilic attack on the carbonyl carbon atom by the acetylide anion formed on heterolysis of the silicon–carbon bond:



Subsequently this method was used widely in the synthesis of dehydroannulenes with a wide variety of structures (see, for example, Nagakawa[336] and the references quoted therein as well as Yoshikawa et al.[342]).

The reactions involving the acylation of silicon-containing alkenynes catalysed by aprotic acids,[73,107] i.e.

$$R-C(=O)Cl + Me_3SiC\equiv C-CR'=CHR'' \xrightarrow{MCl_x} R-C(=O)-C\equiv C-CR'=CHR'',$$

$$M = Al^{3+}, Ti^{4+}, Zn^{2+},$$

or by zerovalent palladium compounds are especially interesting as a method for the formation of a new carbon–carbon bond. The best yields of the corresponding ketones have been obtained using titanium chloride as the catalyst.[107] Judging from the available data,[73] the formation of ketones derived from acetylenes, which possess fungicidal activity, is also possible in the absence of a catalyst.

The heterolysis of a silicon–carbon bond can be carried out also in the presence of protic acids (perchloric, hydriodic[122]).

Desilylation of acetylenes with an aqueous alcoholic solution of silver nitrate followed by iodination leads to the synthesis of iodoacetylene:[51]

$$Z\text{-}Me_3SiC\equiv C-CH=CH-CH_2OR \xrightarrow[H_2O+EtOH]{AgNO_3+I_2} Z\text{-}IC\equiv C-CH=CH-CH_2OR.$$

Analysis of the data presented in this review permits the following conclusions:

1. The development of numerous methods for the stereospecific synthesis of readily desilylated organosilicon compounds containing the $\equiv Si-C\equiv C-C=C\lessdot$ fragments makes silicon-containing alkenynes unique synthons in the fine organic synthesis of natural products and their synthetic analogues, including sila-analogues.

2. Detailed study of the reactions involving the introduction of functional groups into 1-trialkylsilylalk-3-en-1-ynes has shown that the chemo-, regio-, and stereo-selectivities of the reactions are independent of the polarity of the reagents and substrates in all the cases investigated. The results indicate orbital control in the test reactions and to a first approximation may be generalised within the framework of the model of acid–base interaction.

The partial catalytic oxidation of methane to give oxygen-containing compounds

O V Krylov
Institute of Chemical Physics, Russian Academy of Sciences

ABSTRACT. **The three principal paths of the partial oxidation of methane, to give methanol, formaldehyde, and synthesis gas, have been reviewed. The kinetics and mechanism of the processes have been described. The possible oxidation of methane using different oxidising agents—oxygen and carbon dioxide—has been examined.**

The bibliography contains 139 references.

IV.	The oxidation of methane to synthesis gas	1125

I. Introduction

Among the various routes in the partial oxdiation of methane, the recently discovered oxidative condensation of methane to give C_2-hydrocarbons is being most intensively developed. The number of publications on this topic is much greater than the number devoted to other possible routes for the partial oxidation. A number of recent reviews deal with the partial oxidation of CH_4.[1,2]

At the same time, the practical importance of the other directions is apparently much greater than that of oxidative condensation. Among these, the oxidation of methane to methanol occupies a leading position. Methanol is an important component of oxygenate fuels for internal combustion engines. The demand for methanol amounts to millions of tons in this country, and tens of millions of tons worldwide. Thus the search for new economical methods for obtaining methanol, making it possible to replace the traditional method of preparation via synthesis gas, has become one of the most important directions in catalytic studies.

Synthesis gas ($CO + H_2$) is usually obtained by the steam conversion of methane on a nickel catalyst at a high temperature (1000–1200 K)

$$CH_4 + H_2O = CO + 3H_2.$$

In this version, however, the mixture obtained cannot be used directly for the synthesis of methanol, since this requires a different stoichiometric ratio $[CO]:[H_2] = 1:2$. This can be obtained by the direct oxidation of methane using oxygen

$$2CH_4 + O_2 = 2CO + 4H_2.$$

The oxidative transformation of methane to synthesis gas with a ratio $[CO]:[H_2] = 1:1$ is achieved by using CO_2 as the oxidising agent

$$CH_4 + CO_2 = 2CO + 2H_2.$$

This mixture can be used to obtain hydrocarbons by the Fischer–Tropsch synthesis.

The third position of economic importance is occupied by the partial oxidation of methane to formaldehyde. The discovery of selective catalysts for the direct oxidation of methane to formaldehyde would make it possible to replace by a single-stage process the multi-stage methane → synthesis gas → methanol → formaldehyde process.

Reviews of the partial oxidation of methane to oxygen-containing compounds have been published.[3–6] The present review examines publications up to and including 1991 (and early 1992). The liquid-phase homogeneous-catalytic oxidation of methane is not examined.

II. The oxidation of methane to methanol

Homogeneous oxidation. The homogeneous oxidation of methane has been studied in most detail at 673–873 K. It takes place with the intermediate formation of the free radicals CH_3, CH_3O, CH_3O_2, HO_2, HCO, and OH and the molecular species H_2O_2 and CH_3OOH. The kinetics of the formation and disappearance of the free radicals under the conditions of the reaction are often determined by freezing the free radicals in a CO_2 matrix using a trap cooled with liquid nitrogen. The use of freezing in this way combined with ESR *in situ* was first developed in the Erevan Institute of Chemical Physics.[7] A detailed scheme for the oxidation of methane, describing the principal stages of the process, has been published.[8] The reactions

determining the overall rate of the process, and the corresponding rate constants, are given below:

$CH_4 + O_2 = CH_3 + HO_2$, $k_1 = 10^{-10}\exp(-230/RT)$, (1)

$CH_3 + O_2 = CH_3O_2$, $k_2 = 4 \cdot 10^{-13}$, (2)

$CH_3O_2 + M = CH_3 + O_2 + M$, $k_3 = 10^{-14}\exp(-109/RT)$, (3)

$CH_3O + O_2 = CH_2O + HO_2$, $k_4 = 5 \cdot 10^{-14}$, (4)

$OH + CH_4 = CH_3 + H_2O$, $k_5 = 10^{-10}\exp(-35.5/RT)$, (5)

$HO_2 + CH_4 = H_2O_2 + CH_3$, $k_6 = 10^{-12}\exp(-90/RT)$, (6)

$OH + CH_2O = HCO + H_2O$, $k_7 = 1.6 \cdot 10^{-10}\exp(-10.4/RT)$, (7)

$HO_2 + CH_2O = HCO + H_2O_2$, $k_8 = 1.9 \cdot 10^{-11}\exp(-54/RT)$, (8)

$HCO + O_2 = CO + HO_2$, $k_9 = 5.5 \cdot 10^{-11}$, (9)

$H_2O_2 + M = 2OH + M$, $k_{10} = 2.8 \cdot 10^{-7}\exp(-193/RT)$, (10)

$CH_3O_2 + CH_4 = CH_3OOH + CH_3$, $k_{11} = 10^{-12}\exp(-82/RT)$, (11)

$CH_3O_2 + CH_2O = CH_3OOH + HCO$, $k_{12} = 10^{-17}$, (12)

$CH_3OOH = CH_3O + OH$, $k_{13} = 4 \cdot 10^{-15}\exp(-179/RT)$, (13)

$CH_3O + CH_4 = CH_3OH + CH_3$, $k_{14} = 10^{-12.2}\exp(-46/RT)$, (14)

$OH + CO = CO_2 + H$, $k_{15} = 1.6 \cdot 10^{-12.5}\exp(-3.3/RT)$, (15)

$H + CH_2O = H_2 + HCO$, $k_{16} = 1.6 \cdot 10^{-10}\exp(-18/RT)$, (16)

$H + CH_4 = H_2 + CH_3$, $k_{17} = 5 \cdot 10^{-9}\exp(-49.7/RT)$, (17)

$HO_2 + HO_2 = H_2O_2 + O_2$, $k_{18} = 4 \cdot 10^{-12}$, (18)

$H_2O_2 = H_2O + \frac{1}{2}O_2$, $k_{19} = 0.1$, (19)

$OH + H_2O_2 = H_2O + HO_2$, $k_{20} = 1.7 \cdot 10^{-11}\exp(-7.5/RT)$, (20)

$HO_2 + CH_3OH = H_2O_2 + CH_2OH$ $k_{21} = 1.6 \cdot 10^{-12}\exp(-60.3/RT)$, (21)

$CH_3 + CH_3 = C_2H_6$, $k_{22} = 3 \cdot 10^{-11}$. (22)

The rate constants of the unimolecular, bimolecular, and termolecular reactions have the units s^{-1}, cm^3 $molecule^{-1}$ s^{-1}, and cm^6 $molecule^{-2}$ s^{-1} respectively, and the activation energy E_a has the units kJ mol^{-1}. According to this scheme, the chain reaction is initiated by reaction (1), and chain propagation takes place mainly by reactions (2)–(9), (11), (12), and (15)–(17). The main reaction responsible for chain branching is the decomposition of the hydroperoxide CH_3OOH (13), and additional chain branching takes place by the decomposition of H_2O_2 to OH radicals in reaction (10). The principal branching agent is formed by reaction (11) in the initial stages, and by reaction (12) in subsequent stages.

The formation of various products by the oxidation of methane has been examined in a number of studies.[9–15] Reactions (2) and (3) are the forward and back reactions of the equilibrium

$$CH_3 + O_2 \rightleftharpoons CH_3O_2. \quad (23)$$

Equilibrium (23) is displaced to the left at high temperatures and to the right at low temperatures: the heat of the reaction is $Q = -\Delta H \simeq E_a = 109$ kJ mol^{-1}. Thus CH_3 radicals play an important role in the oxidation of methane at higher temperatures. The role of most of the radical reactions increases with increase in temperature. Chain termination takes place by reactions (18) and (22), but mainly by the reactions of the radicals on the walls of the reactor.

Recent studies[9–11] have shown that if later data[16] are used, the value obtained for the equilibrium constant of reaction (23) is 200 times smaller. This leads to a decrease in the previously calculated concentrations of CH_3O_2 and to an increase in the concentration of CH_3 radicals. As pointed out in a number of papers on the oxidative condensation of methane,[1,2] CH_3O_2 radicals lead mainly to extensive oxidation, and CH_3 radicals lead to the oxidative condensation of methane, that is to reaction (22).

The probability of formation of methanol is greatest at high pressures and high ratios of the concentration $[CH_4]:[O_2]$. The main reaction leading to the appearance of CH_3OH is reaction (14). At high pressures (5–10 MPa), the relative role of the different stages changes. The yield of methanol increases significantly, and that of formaldehyde decreases. According to a detailed scheme for the oxidation of methanol,[9–11] a significant contribution to the overall mechanism under these conditions is made not only by reaction (14) but also by the reaction:

$CH_3O + H_2O_2 = CH_3OH + HO_2$, $k_{24} = 2.5 \cdot 10^{-13}\exp(-16.7/RT)$. (24)

The CH_3O radical is formed not only by reaction (13) but also by the reactions

$2CH_3O_2 = 2CH_3O + O_2$, $k_{25} = 1.7 \cdot 10^{-13}$, (25)

$CH_3O_2 + CH_3 = 2CH_3O$, $k_{26} = 4.5 \cdot 10^{-11}$. (26)

CH_3OH is consumed in reaction (21) and also in the reactions

$CH_3OH + CH_3O_2 = CH_3OOH + CH_2OH$, $k_{27} = 5 \cdot 10^{-3}\exp(-60/RT)$, (27)

$CH_3OH + HO_2 = CH_2OH + H_2O_2$, $k_{28} = 1.5 \cdot 10^{-12}\exp(-60/RT)$. (28)

Considering the products of extensive oxidation, CO is formed by reaction (9) and the reaction

$HCO + M = CO + H + M$, $k_{29} = 4 \cdot 10^{-10}\exp(-71/RT)$. (29)

The disappearance of CO and the formation of CO_2 take place by reaction (15) and the reactions

$HO_2 + CO = CO_2 + OH$, $k_{30} = 2.2 \cdot 10^{-10}\exp(-96/RT)$, (30)

$CH_3O + CO = CH_3 + CO_2$, $k_{31} = 2.6 \cdot 10^{-11}\exp(-49.4/RT)$, (31)

$CH_3O_2 + CO = CH_3O + CO_2$, $k_{32} = 1.7 \cdot 10^{-10}\exp(-100/RT)$. (32)

In the high-temperature extensive oxidation of methane the most important reactions are those of the H and O atoms and the OH radical, and not the radical CH_3, CH_3O_2, and CH_3O. The reaction of the radicals with the walls of the reactor is less significant at high pressures than at low pressures.

At 5–10 MPa and 673–873 K the theoretical yield of methanol may reach several percent, calculated for the methane passed. For this purpose, mixtures with very high ratios $[CH_4]:[O_2] = 30-100$ are used. At $[CH_4]:[O_2] = 50$, the yield of CH_3OH in a pilot plant is 1% and the selectivity ~50% for 100% conversion of oxygen.

The selectivity can be increased by finding appropriate conditions for the direct recombination of the radicals

$$CH_3 + OH = CH_3OH. \quad (33)$$

The yield of methanol can also be increased by adding hydrogen to the mixture to give the reactions

$$CH_3OO + H_2 = CH_3OOH + H, \quad k_{34} = 3.6 \cdot 10^{-12}\exp(-93.3/RT), \quad (34)$$

$$CH_3O + H_2 = CH_3OH + H, \quad k_{35} = 3.6 \cdot 10^{-12}\exp(-41.8/RT). \quad (35)$$

The economics of the homogeneous oxidation of methane to methanol have been examined. For example, it has been pointed out[5] that for 100% selectivity of the oxidation of CH_4 to CH_3OH the cost of methanol would be 172 dollars per ton, compared with 248 dollars per ton for the usual method of synthesis. In Russia this process may be even more favourable, since the cost of natural gas is relatively low.

Catalytic oxidation. A catalyst should not be expected to have a marked influence on the rate of the oxidation of methane to methanol at a high pressure. Nevertheless, studies of this topic appear from time to time. For example, catalysts based on the oxides of zinc, cadmium, and nickel have been added to a high-pressure reactor (10 MPa). An increase in selectivity from 50% to 80% was reported.[17,18] The results were not subsequently confirmed, however.

In studies[3,19,20] of the oxidation of CH_4 at a high pressure (3.5–12.5 MPa), 623–723 K, and $[CH_4]:[O_2] = 20:25$, a high selectivity with respect to methanol was achieved—75–80% compared with 40–50% reported by other authors. These experiments were carried out in a stainless steel reactor. This raises the question of the possible influence of the material of the reactor on the oxidation of CH_4 to CH_3OH. Treating a stainless steel reactor with alkali (KOH) decreased the yield of CH_3OH, but did not decrease the yield of CH_3OCH_3, also present in the reaction products; Ni and Cu lowered the yield of methanol considerably. A direct study[20] of heterogeneous and homogeneous additives showed that under these conditions the reactor material has relatively little influence on the reaction rate. The best heterogeneous additive was SnO_2, and the best homogeneous additive was 2,3-dimethylbutane. The results[19,20] showing an increase in selectivity in a stainless steel reactor are not consistent with other studies. For example, other authors[21] obtained a selectivity of only 40% under similar conditions.

The initiating action of a solid catalyst on the oxidation of CH_4 at a high pressure has also been studied.[22] A platinum wire at a temperature of 520 K was introduced at a distance of 10 cm before the reaction zone in a stainless steel reactor lined with quartz, at a pressure of 4.1 MPa, a component ratio $[CH_4]:[O_2]:[N_2] = 30:1:4$, and a reaction temperature of 653–779 K. The reaction temperature was lowered by 60 K. The selectivity with respect to CH_3OH was lowered slightly, but adding 4 mol% H_2 at 673 K produced an almost two-fold increase in the selectivity. The maximum selectivity at this temperature, however, was only 34.6%. In the opinion of the authors cited,[22] the key stage corresponds to reactions (34) and (35). Hydrogen on the surface possibly reacts more effectively than H_2 in the gas phase.

A theoretical analysis and experimental data obtained using M^+ and $(M=O)^+$ ion beams showed that the direct reaction of $(M=O)^+$ with CH_4 to give CH_3OH is possible for M = Fe or Os:

$$FeO^+ + CH_4 \longrightarrow Fe^+ + CH_3OH. \quad (36)$$

The Fe^+ ions obtained can be re-oxidised using N_2O.[23]

Fe=O groups may also be present on the surface of solid catalysts, and their reaction with CH_4 may lead to the direct formation of methanol [reaction (36)] or to the additional generation of CH_3 radicals

$$MO + RH \longrightarrow \dot{M}OH + \dot{R}, \quad (37)$$

which at an increased pressure lead finally to an increase in the yield of methanol.

On the basis of this idea, the firm Sun Oil developed a catalyst for oxidising CH_4 to methanol, consisting of sodium sodalite subjected to partial ion exchange with Fe^{II}.[24] In contrast to the homogeneous process, in this case a significant selectivity in the conversion of CH_4 into CH_3OH was obtained at $[CH_4]:[O_2]$ ratios which were not very high. At 700 K, 5.3 MPa, and $[CH_4]:[O_2] = 3:1$ the selectivity increased from 44% for the homogeneous process to 77% in the presence of Fe–Na-sodalite; the conversion of CH_4 increased from 4.8% to 6.5%. Silicoferrate gave a selectivity of 66% for 5.5% conversion at 688 K.[25] The most promising catalyst is sodium sodalite containing about 13% Fe, the acidity of which had been completely removed by previous reactioin with NaN_3. The authors of a patent[25] state that non-framework cationic iron hydroxo-centres are necessary in the catalyst. Dinuclear $Fe^{II}OFe^{II}$ centres are preferable to $Fe^{III}OFe^{III}$ centres, that is over-oxidation of iron poisons the catalyst.

Data have also been published on the use of acidic catalysts, in particular superacids, for the oxidation of methane to methanol. A selectivity with respect to CH_3OH of 77% (and even 100% with respect to $CH_3OH + CH_2O$) for 3.5% conversion was obtained on the superacid catalyst $Cr^{3+} - Zr^{4+}SO_4/SiO_2$ at a low temperature (523 K). The author cited[26] considers that the reaction involves the intermediate formation of the CH_5^+ ion. The selective formation of CH_3OH from CH_4 on zeolites at increased pressures has been reported: on H-ZSM-5 at 693 K [29] and on Cu-ZSM-5 at 613 K.[28] Oxidation using N_2O gives a higher selectivity than oxidation using O_2. Fe-ZSM-5 zeolite under the same conditions gives only CO and CO_2.[28]

The problem of developing oxidation catalysts for methanol has not been solved. Many studies are not being continued, and published results are not confirmed by subsequent studies. The most promising results have been obtained using Fe-containing catalysts at high pressures and relatively low temperatures. The most probable explanation is additional generation of CH_3 radicals and their subsequent reactions to give CH_3OH.

III. The oxidation of methane to formaldehyde

Homogeneous oxidation. Unlike methanol, formaldehyde is formed with a high probability at low pressures and low concentration ratios $[CH_4]:[O_2]$. It is formed by the decomposition of the hydroperoxide CH_3OOH in reaction (13) and then from the CH_3O radical in reaction (4). The hydroperoxide precursor of formaldehyde is formed mainly by reaction (11), that is from the CH_3O_2 radical.

Calculations[8] carried out for 738 K and initial concentrations $[CH_4] = 3.2 \times 10^{18}$ molecule cm^{-3} and $[O_2] = 10^{18}$ molecule cm^{-3} gave the following maximum values of the concentrations of intermediate products (particle cm^{-3}): $[HO_2] = 4.9 \times 10^{13}$, $[CH_3O_2] = 3.9 \times 10^{12}$, $[CH_3OOH] = 2 \times 10^{14}$, $[CH_3] = 4.7 \times 10^{12}$, $[CH_3OH] = 4 \times 10^{15}$, $[CH_2O] = 2 \times 10^{16}$, $[H_2O_2] = 8 \times 10^{15}$. According to these calculations, which on the whole agree with experimental data, the yield of the desired product of the partial oxidation, that is formaldehyde, is about 1% calculated for the methane reacting, and the yield of methanol is lower by a factor of about ten. The principal oxidation products are CO and CO_2. ~2% ethane is formed. Later calculations[10,11] altered these figures slightly, giving a higher yield of CH_2O and a lower yield of C_2H_6.

Formaldehyde is also formed by the reaction

$$2CH_3O_2 = CH_3OH + CH_2O + O_2, \qquad k_{38} = 7.4 \cdot 10^{-14}, \qquad (38)$$

and is consumed mainly in reactions (7) and (8).

According to a published scheme,[13] in a flow reactor at 773–873 K, the recombination of CH_3 radicals [reaction (22)] with the formation of C_2H_6 predominates at low volume rates, and the reaction

$$CH_3 + O_2 = CH_2O + OH, \qquad (39)$$

predominates at high volume rates.

The decomposition of CH_2O under homogeneous flow conditions has been studied.[14,21] At 873 K for 20% conversion of methane, about 60% CH_2O decomposes in the empty reactor. According to experimental data,[14] the maximum yield of CH_2O (3.46%) was obtained for a mixture with $[CH_4]:[air] = 1:5$ at 923 K and 5 MPa (6.7% conversion, selectivity 51.6%). Under these conditions, filling the reactor with SiO_2 and other oxides lowers the yield of formaldehyde.

Catalysts of the oxidation of methane to formaldehyde. Dowden and co-workers[29] were among the first to study the oxidative conversion of methane into formaldehyde. According to their theoretical ideas, a catalyst for the production of formaldehyde should have the functions of dehydrogenation and the introduction of an oxygen atom. Oxides of Fe^{3+} and Cr^{3+} are best for the first function, and oxides of V^{5+}, Mo^{6+}, Ti^{4+}, and Zn^{2+} are best for the second. Of the catalysts studied,[29] the oxides of Cr^{3+} and Mn^{3+} had the highest activity; Fe^{3+} phosphate had medium activity, but the highest selectivity.

A large number of oxide catalysts were subsequently studied. An appreciable activity in the formation of formaldehyde was shown by pure SiO_2 (finely divided quartz, or silica gel).[30–32] The low selectivity of Al_2O_3[30,31] was attributed to the high rate of the successive conversion of formaldehyde to oxides of carbon both by oxidation and by the decomposition of CH_2O to $CO + H_2$. The yield of CH_2O on silica gel at 879 K was 2% (selectivity 34%, 6.1% conversion). Modifying the silca gel with B_2O_3 increased the yield to 3.5%. On an aluminosilicate modified by H_3PO_4 the yield of CH_2O was 2.9% (selectivity 48%, 6% conversion), and on an aluminosilicate modified by H_3BO_3 the yield was 2.5% (selectivity 3.5%, 7% conversion).

HCl increases both the total conversion of methane on SiO_2 and the yield of formaldehyde. According to Mel'tser and co-workers,[33] HCl poisons the centres responsible for the extensive oxidation of CH_2O to CO_2. Covering the SiO_2 with hydrogen peroxide also increases the yield of CH_2O.[34]

A large number of oxides, phosphates, and silicates have been studied as catalysts of the oxidation of methane to formaldehyde.[35–37] In the opinion of the authors cited, a high selectivity and a high yield can be obtained on catalysts with a high acidity. High yields of CH_2O were obtained, for example, at 873 K on tin phosphate $Sn_2P_2O_7$ (9.0%, selectivity 96%), on SiP_2O_7 (5.1%, selectivity 82.8%), and on an aluminosilicate treated with H_3PO_4. It was also shown that the best of the transition metal phosphates are those most difficult to reduce. It is considered[35] that on the acidic OH groups the following reaction takes place:

$$CH_4 + -OH_s \longrightarrow -OCH_3 + H_2O \xrightarrow{O_2} \begin{matrix} -O \\ \diagdown \\ \quad CH_2 \\ \diagup \\ -O \end{matrix} \longrightarrow$$

$$\longrightarrow CH_2O + O_s(-OH_s).$$

Under recirculating conditions with freezing of the products, the yield of formaldehyde reached 14–16%, and even 18% in some experiments.

Aluminosilicates containing 10–11% Al_2O_3 and modified by added oxides of iron, zirconium, vanadium, cerium, bismuth, and chromium have also been studied;[38–40] the yield of CH_2O was ~2%. The maximum yield (2.6%) was obtained on an aluminosilicate containing added 2% cerium phosphate and 0.05% P_2O_5 at 1023 K. Adding 0.2–0.5% dimethyl ether $(CH_3)_2O$ to the content zone made it possible to lower the reaction temperature by 100 K and to raise the yield of CH_2O to 5–5.6%.[40] It is possible, however, that a significant contribution to the yield of formaldehyde is made by the decomposition of dimethyl ether itself. The use of circulation of the reaction mixture with the removal of both CO and CO_2 from the mixture made it possible to increase the yield of CH_2O to 12.5% and the selectivity to 65% on one of the most active catalysts, $Mo-P-Al-SiO_2$.[39]

Almost all workers who have studied the oxidation of methane to formaldehyde have used SiO_2 or aluminosilicates as carriers. MgO and Al_2O_3 were more active than SiO_2, but gave only CO and CO_2.

Various oxides deposited on SiO_2 to concentrations of 9.2% have been studied on catalysts.[42] The highest yields of CH_2O at 923 K and $[CH_4]:[O_2] = 1$ were obtained on Ga_2O_3 (3.6%), Bi_2O_3, Al_2O_3, and ZrO_2, and the highest selectivity on P_2O_5, WO_3, B_2O_3 (>60%), Sb_2O_3, Nb_2O_5, Al_2O_3, and MgO (>30%). Here also, the acidic oxides are more active.

The largest number of studies has been carried out for the MoO_3/SiO_2 system.[42–50] On this catalyst, CH_4 is oxidised to CH_2O at 823–923 K. 85% selectivity was achieved for ~3% conversion, and 30% selectivity for 7% conversion. Formaldehyde is not formed on pure MoO_3 without SiO_2. The selectivity was increased by adding oxides of chromium[44] and copper,[46] but adding iron, chromium, cobalt, and sodium[47] lowered the selectivity of CH_2O formation compared with Mo/SiO_2, although some of them increased the degree of conversion. The catalyst $CoMoO/SiO_2$ at 873 K gave a selectivity of 50.3% for the oxidation of CH_4 to CH_3OH, and of 16.9% for the oxidation to CH_2O.[44] A system consisting of the deposited complex $MoCl_5/R_4Sn/SiO_2$ has also been studied[50] as starting material for the synthesis of a catalyst. The process was based on the ease of the replacement of the M=O group in the ligand by the carbene complex $M=CH_2$, which it is assumed could be converted directly into CH_2O. A selectivity of 80% was obtained for a low degree of conversion.[50]

A significant increase in the yield of oxygen-containing products on MoO_3/SiO_2 was achieved using N_2O instead of O_2 as oxidising

agent.[46,51–58] At 823 K the degree of conversion of CH_4 on a 1.7% MoO_3/SiO_2 catalyst increased from 0.5% to 6.0%, and the selectivity reached 55% for CH_2O and 38% for CH_3OH.[54] The highest yield of CH_2O and CH_3OH was obtained by adding water vapour to the original mixture; at P_{H_2O} = 20 kPa the total selectivity with respect to CH_3OH + CH_2O reaches 99% for 26% conversion. Other authors[56,57] also reported a high selectivity of the oxidation of CH_4 to CH_2O using N_2O, but with a much lower degree of conversion. The activation energy of this reaction is ~170 kJ mol^{-1}.[58]

At a concentration of 1–5% Mo in SiO_2, molybdosilicic acid is formed on the surface and takes part in the oxidation of methane to formaldehyde.[56] Appreciable selectivity in the oxidation of CH_4 by N_2O (up to 80% for 2% conversion) was observed[59–65] on heteropolyacids $HPMo_{12}O_{40}$ and their salts, deposited on SiO_2. A correlation between the acidity of the heteropolyacid and the yield of CH_2O has been reported.[66] A very high yield of CH_2 (12–16%) was obtained.[66] Breakdown of the Keggin structure at a temperature above 873 K leads to the loss of activity and selectivity. The activity of $H_3PMo_{12}O_{40}/SiO_2$ increased in the presence of chlorine-containing additives such as CH_2Cl_2 or CCl_4; at 799 K the degree of conversion was 12%, and the selectivity 32%.[65]

A mixed catalyst containing oxides of molybdenum, iron, bismuth, nickel, and magnesium deposited on SiO_2 showed a selectivity of 86.5% in the oxidation of CH_4 to CH_2O for 8.9% conversion at 923 K.[67]

V_2O_5/SiO_2 gave results similar to those for MoO_3/SiO_2.[49] In the oxidation of CH_4 to formaldehyde using N_2O, a 2% V_2O_5/SiO_2 catalyst gave appreciable activity at temperatures 80–100 K lower than those for MoO_3/SiO_2.[53,57] The activation energy was 88 kJ mol^{-1}. The possibility of increasing the selectivity on membrane V_2O_5/SiO_2 catalysts has been reported.[68] For 1% conversion, the selectivity with respect to CH_2O increased from 5% to 20%.

Unusual effects in both of the reactions CH_4 + O_2 and CH_4 + N_2O were detected in a study of the influence of mechanochemical activation on the catalytic properties of the systems MoO_x/SiO_2, VO_x/SiO_2, and WO_x/SiO_2.[69–72] After mechanical mixtures of Mo + SiO_2, MoO_3 + SiO_2, V + SiO_2, and V_2O_5 + SiO_2 has been ground in a ball mill or subjected to high pressure with shear in a Bridgman cell, practically no extensive oxidation was observed. The selectivity with respect to formaldehyde increased to 100% for 3% conversion at 873 K. At the same time, MoO_3/SiO_2 and V_2O_5/SiO_2 catalysts impregnated before grinding showed no change in selectivity even after grinding; a change was observed only after the mechanical grinding of a mixture of the two oxides. Electron microscopy and electron diffraction showed that under the conditions of the mechanical treatment of a mixture of the two oxides, encapsulation takes place, that is the particles of the active phases MoO_3 or V_2O_5 are covered with silica gel. This encapsulation is confirmed by a study of the Mössbauer spectra of mixtures of Fe and SiO_2 powders subjected to mechanical grinding. Encapsulated iron, covered with silica gel, remains in the metallic state under the conditions of CH_4 oxidation, whereas ordinary iron powder is oxidised to Fe_2O_3 under these conditions.

The encapsulation of the oxides of molybdenum or vanadium in SiO_2 capsules alters the fractions of the active centres involved in the partial and extensive oxidation of methane. The centres of CO_2 formation are blocked, but the CH_2O formation centres remain. The enveloping of M_xO_y by silica gel also apparently hinders the supply of electrons to the molecule being oxidised. The oxidation of CH_4 to CH_2O requires only half the number of electrons required to oxidise CH_4 to CO_2.

Active phases have also been deposited on SnO_2. On Bi_2O_3/SnO_2, methane is oxidised by oxygen with a selectivity with respect to CH_2O of ~80%. In the reaction of CH_4 with N_2O on the same catalyst, the selectivity with respect to CH_2O reaches 98.2% for 2.6% conversion.[73] Formaldehyde is also formed on an MoO_3 monolayer deposited on SnO_2.[74]

Fe-containing catalysts (like Mo-containing catalysts) have often been used to convert methane into formaldehyde.

Fe–Nb–B–O is a selective catalyst.[73] At a fairly high temperature (1023–1073 K), 70–80% selectivity was obtained for 2.7–14.3% conversion and a yield of CH_2O of 2–3.8%. The activation energy of the process is 250 kJ mol^{-1}. X-Ray photoelectron spectroscopy (XPS) detected the phases $FeNbO_4$, $FeNb_{11}O_{29}$, Fe–Nb–B–O (oxidation state of iron > 3+), and B_2O_3 on the surface. Oxidation using N_2O on the same catalyst gave the same selectivity and the same activation energy, but the activity was halved. A published study[76] of the activity of various oxides in the oxidation of methane to formaldehyde to some extent represents a continuation of other work.[75]

A high selectivity has been obtained on $MoO_3.Fe_2O_3$.[77] The same authors reported[78] a very high yield of CH_2O (22.5%) and a selectivity of 83.6% on this catalyst, but no subsequent work has been published. On $Fe_3(PO_4)_2$ promoted using $La_3(PO_4)_2$, a selectivity with respect to CH_2O or 30% was observed for 3.7% conversion at 953 K.[79] Water vapour lowered the selectivity of the transformation of CH_4 into CH_2O, as a result of the formation of HCOOH. At the same time, on pure Fe_2O_3, only extensive oxidation was observed. Adding 1% CuO and 1% Fe_2O_3 to ZnO gave the catalyst $Cu_{0.01}Fe_{0.01}Zn_{0.98}O$, which showed a selectivity of 43% for 0.02% conversion at 823 K, and a selectivity of 10% for 2.5% conversion at 1023 K.[80] XPS indicated the presence of Cu^+ and Fe^{3+} on the surface of this catalyst. Its activity and selectivity were much higher than on pure ZnO. The authors cited[80] attribute its behaviour in the oxidation of CH_4 to CH_2O to the necessity of a combination of redox properties (Fe^{2+}/Fe^{3+} and Cu^+/Cu^{2+}) and Lewis acidity (Fe^{3+}).

The results of a number of studies of iron-containing catalysts have been analysed.[14] It was concluded that the highest yields of CH_2O on these catalysts are no higher than those obtained under the same conditions in an empty reactor.

Data have also been published on metallic catalysts of the oxidation of methane to formaldehyde. According to Wang and co-workers,[81] palladium promoted with CH_2Cl_2 can bring about the selective oxidation of methane to formaldehyde. It has been shown,[14] however, that at 723–873 K only extensive oxidation is observed on Pd modified by chlorine. An increase in the selectivity of the action of anatase was observed after it was modified with CH_2Cl_2; a yield of CH_2O of 2.8% was obtained at 848 K.

The selective oxidation of methane by another oxidising agent (CO_2) was carried out on brass gauze with a specific surface of 24.3 m^2 g^{-1} which had been oxidised and reduced several times. When CH_4 + CO_2 pulses are introduced into a stream of nitrogen at 653–733 K, the only oxidation product is formaldehyde. If however methane is added to CO_2 as carrier gas, only methanol is obtained, in yields of 1.23–4.36% at 873 K.[82]

It is difficult to identify general regularities in the selection of catalysts of the oxidation of methanol to formaldehyde. Nevertheless, in the work of most authors, three groups of catalyst are clearly distinguished: 1, Mo- or V-containing deposited oxide catalysts; 2, Fe-containing oxide catalysts; 3, acidic catasyts. Despite the relationship between selectivity and acidity noted by

various workers, oxide systems deposited on SiO_2 were more active and selective than oxides deposited on Al_2O_3 or aluminosilicates.

In almost all cases the oxidation of methane to formaldehyde was carried out at temperatures 100–200 K lower than the oxidation condensation of methane, that is at 723–973 K. As in the oxidative condensation of methane, various limiting yields apparently exist; their values (3–4%) are appreciably lower than those in the oxidative condensation of methane. The individual cases where higher yields were obtained[35,40,66,77] require further study.

Mechanism of the catalytic oxidation of methane to formaldehyde. Two mechanisms of the oxidation of methane to formaldehyde are distinguished: 1, a heterogeneous–homogeneous mechanism, in which the selectivity is controlled mainly by gaseous reactions; 2, a heterogeneous mechanism, in which the selectivity is controlled by processes on the surface. The existence of limiting yields tends to support the heterogeneous–homogeneous mechanism. On the other hand, data on the chemical features of the selection of catalysts tend to support the heterogeneous mechanism. The mechanism of the oxidation of methane to formaldehyde is examined in a large number of publications.

The detection of free radicals under the conditions of the oxidation of methane to formaldehyde provides the principal evidence for the heterogeneous–homogeneous mechanism. One of the first studies proving the formation of CH_3O_2 radicals in this reaction involved freezing out the radicals in a CO_2 matrix.[30] According to the scheme given by the authors cited, however, an increase in the yield of free radicals facilitates non-selective extensive oxidation and leads to a decrease in the yield of CH_2O.

Adding C_2H_6 to a $CH_4 + O_2$ mixture increased the selectivity of the oxidation of CH_4 at 833–913 K to CH_2O on SiO_2 and decreased the yield of CO. This was attributed[83] to an increase in the formation of methyl radicals from C_2H_6. Under the given conditions, CH_3 radicals are converted into CH_3O_2 and CH_3O. A correlation has been noted[33] between the yield of CH_3O_2 radicals and the yield of CH_2O under the conditions of the oxidation of methane on SiO_2. With increase in temperature, the yield of CH_2O and the concentration of RO_2 pass through a maximum at 903 K. HCl increases the total degree of conversion, but decreases the yield of radicals, although the yield of CH_2O increases. According to the authors cited,[33] HCl poisons the centres for the extensive oxidation of CH_2O to CO_2. Depositing H_2O_2 on SiO_2 also increases the yield of CH_2O and free radicals.[34]

According to Otsuka and co-workers,[75] on an Fe–Nb–NB–O catalyst, methyl radicals are formed in the primary reaction of methane with the surface oxygen O_s, and formaldehyde is formed by the secondary reaction of CH_3 with O_s;

$$\begin{aligned} &CH_4 + O_s \longrightarrow CH_3 + OH_s, \\ &CH_3 + O_s \longrightarrow CH_2O + \tfrac{1}{2} H_2, \\ &2OH_s \longrightarrow O_s + H_2O. \end{aligned} \qquad (40)$$

It is considered[84] that the selectivity of action of catalysts of the oxidative condensation of methane can be displaced from C_2-hydrocarbons to CH_2O by changing the conditions of the process. Increase in the flow rate of a mixture with $[CH_4]:[O_2]:[Ar] = 6:1:6$ over an MgO catalyst from 1000 h^{-1} to 48 000 h^{-1} increased sharply the selectivity of the oxidation of CH_4 to CH_2O. For 9% conversion of O_2, a selectivity with respect to CH_2O of 65% was observed, but at 11% conversion of O_2 the selectivity decreased to almost zero, with a simultaneous increase in the selectivity of the transformation to CO to 65% and the appearance of ethane. With increase in the conversion the selectivity with respect to C_2H_4 and CO_2 increases. Following the scheme given by Gesser and co-workers,[19] Hargreaves and co-workers[84] examined the competition between two main reactions: the recombination of CH_3 radicals [reaction (22)] and their oxidation to CH_2O [reaction (39)]. The first reaction is kinetically of second order with respect to CH_3, and its probability is higher at low flow rates, whereas the second is of first order with respect to CH_3, and its probability is greater at high flow rates. At low pressures in the gas phase, CH_3 radicals are converted into CH_3OH.

Thus according to Hargreaves and co-workers,[84] the same catasts increase the rates of both the oxidative condensation of methane and the oxidation of CH_4 to formaldehyde and methanol. The part played by the catalyst involves the generation of CH_3 radicals, and the selectivity is determined by secondary gas-phase reactions.

The same conclusion, namely that CH_2O can be obtained at high volume rates of a $CH_4 + O_2$ mixture, was reached by other workers.[85] Under these conditions, a selectivity of 28% was obtained for the oxidation of methanol to CH_2O on silica gel at 873 K, for 12% conversion. It has been shown[76] that ethane and formaldehyde have as precursor the same intermediate product, apparently the CH_3 radical, and that the direction of the reaction is determined by the external parameters, mainly temperature and pressure.

The nature of the primary centres O_s in the catalyst, activating methane, is also important. Isotopic exchange experiments[75] showed that the oxygen of the catalyst O_s is firmly bound and does not exchange with $^{18}O_2$ under the catalysis conditions. It is lattice oxygen, and not oxygen from the gas phase, that is mainly introduced into the reaction products CH_2O, CO, and CO_2.

Additional data on the nature of the centres O_s are obtained by studying the catalysts by ESR. MoO_3/SiO_2 and V_2O_5/SiO_2 catalysts show ready reduction of the $\equiv Mo^{VI}=O$ and $\equiv V^{V}=O$ groups to the radical centres $Mo^{VI}O^-$ and $V^{V}O^-$ respectively and then to $Mo^{V}O^-$ (or $Mo^{V}OH^-$) or $V^{IV}O^-$ (or $V^{IV}OH^-$). The centres O^- detected by ESR are readily formed by the reaction of these catalysts with N_2O

$$Mo^{V} + N_2O \longrightarrow Mo^{VI}O^- + N_2. \qquad (41)$$

A mechanism has been proposed[51,52] for the subsequent reaction of CH_4 with these centres:

$$\begin{aligned} &Mo^{VI}O^- + CH_4 \longrightarrow Mo^{VI}OH^- + CH_3, \\ &Mo^{VI}O^{2-} + CH_3 \longrightarrow Mo^{V}OCH_3. \end{aligned} \qquad (42)$$

Decomposition of the surface methoxyl groups gives formaldehyde

$$Mo^{V}OCH_3^- + Mo^{VI}O^{2-} \longrightarrow Mo^{V}OH^- + CH_2O, \qquad (43)$$

and their reaction with water gives methanol

$$Mo^{V}OCH_3^- + H_2O \longrightarrow Mo^{V}OH^- + CH_3OH. \qquad (44)$$

Non-selective oxidation takes place by the reaction

$$8Mo^{VI} + 4O^{2-} + CH_4 \longrightarrow 8Mo^{V} + 2H_2O + CO_2, \qquad (45)$$

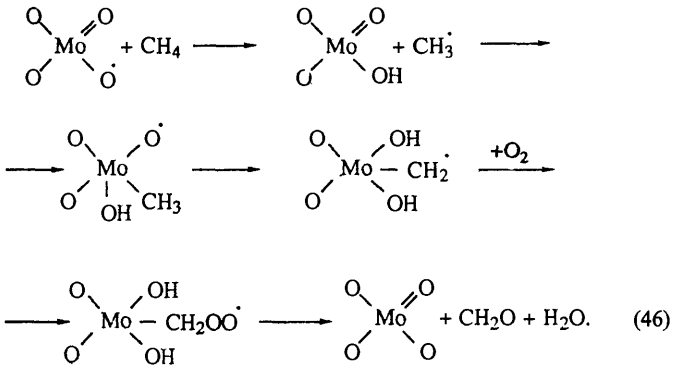
that is one-electron transfer from the centres O^- gives CH_2O, and two-electron transfer from the centres O^{2-} gives CO_2. According to this scheme there are no homogeneous stages, apart from the generation of free radicals and their reaction on the surface.

Methoxyl groups have been detected from their infrared spectra on Mo/SiO_2 and V/SiO_2 catalysts.[51,52,86,87] It has also been pointed out that on other catalysts, OCH_3 groups may be intermediate

products in the extensive oxidation of methane.[88] In contrast to the case of methane, in the oxidation of CH_3OH the activity and selectivity were lower when N_2O was used as oxidising agent than when O_2 was used.[89] O^- evidently does not take part in the oxidation of metanol.

V_2O_5/SiO_2 is one of the few catalysts in which the formation and disappearance of stabilised O^- on reduction and oxidation have been conclusively established by ESR.[90] O^- is formed by the reaction of N_2O with $V^{4+}O/SiO_2$. The reaction of O_2 with this catalyst gives O^- and O_2^-.[91]

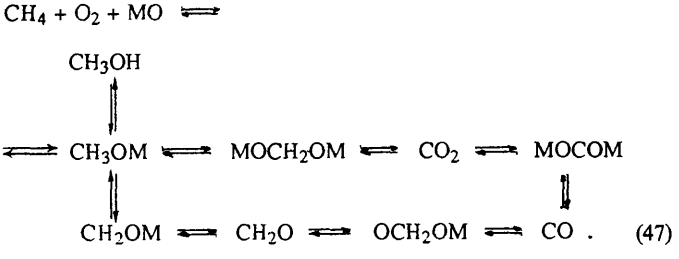
The mechanochemical grinding of $MoO_3 + SiO_2$ gives high concentrations of Mo^{5+} radical centres. The following mechanism was proposed for the oxidation of CH_4 on this catalyst:[72]



(46)

Pure SiO_2 without molybdenum or vanadium shows a fairly high selectivity with respect to CH_2O (up to 38%), but a low activity at 873 K.[92] Heating SiO_2 to 1273 K increases both the yield of CH_2O and the selectivity (to 53%). The high-temperature dehydroxylation of SiO_2 apparently leads to the formation of radical and biradical centres on the surface.

Purely heterogeneous schemes for the oxidation of methane to formaldehyde have also been published. For example, the oxidation of CH_4 on deposited MoO_3/SiO_2 and V_2O_5/SiO_2 catalysts has been modelled[50] using the rate constants, selected from the literature, of the surface stages of the parallel–consecutive scheme (only the principal steps are given):



(47)

On the whole, the scheme provides a satisfactory description of the experimental data. Here, the explanation for the limiting yields of formaldehyde is that it is an intermediate product in the oxidation to CO. The oxidation of CH_4 to CH_3OH takes place in parallel, and CO_2 is formed by two paths: directly from methane via surface transformations, and with the intermediate formation of CO in the gas phase.

Nevertheless, there are more data in support of the heterogeneous–homogeneous mechanism. The following conclusions have been established.

1. The active centre are stabilised radical centres on the surface of the oxides, probably O^-.

2. The reaction of methane with them gives CH_3 radicals, which escape into the gas phase.

3. At a temperature below 879–929 K they react with oxygen, forming CH_3O_2, CH_3O, and CH_3OOH, which finally give formaldehyde.

4. At high temperatures, long contact times, and high pressures, transformations of the radicals give other products: CO, CO_2, C_2H_6, C_2H_4, decreasing the selectivity with respect to formaldehyde.

The mechanism of the formation of CH_2O on acidic catalysts is less clear. In this case also, possibly, latent homolytic stages should be sought.

Experimental modelling of the oxidation of methane to formaldehyde. Controlled conditions can be used to establish the part played by various parameters in catalysis. Such conditions can be created photochemically and mechanochemically.

The influence of γ-irradiation on a V/SiO_2 catalyst in a $CH_4 + O_2$ mixture has been studied.[93] Subsequent thermal desorption led to the formation of up to 15% formaldehyde. In the opinion of the authors cited,[93] the most probable source of CH_2O is surface methoxyl groups formed by the reaction

$$CH_3 + O^- \longrightarrow CH_3O^-,$$

although methoxyl groups were not detected on the surface. The formation of CH_2O was also observed on ultraviolet irradiation of 5% MoO_3/SiO_2 in a mixture with $[CH_4]:[O_2] = 3:1$ at 473 K.[94] CO and CO_2 are formed at a higher temperature.

When TiO_2 [95] and MoO_3 [96] are irradiated in $CH_4 + O_2$ mixtures, small quantities of methanol are formed.

The molybdenyl bond in MoO_3 can be activated both photochemically and by thermal excitation[97–99] by the reaction

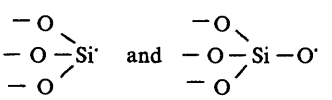
$$Mo^{VI}O^{2-} \rightleftharpoons [Mo^{V}O^{-}]^*.$$

The $Mo^{V}O^-$ pairs were not detected by ESR, because of their short lifetime, but were detected by photoluminescence. The reaction of the O^- in this pair with CH_4 can give CH_3 radicals.[100]

The phototransformations of $CH_4 + O_2$ on various oxides have been studied.[101] Two competing processes were observed: the formation of hydrocarbons and oxygen-containing products. Excitation by light in the band gap leads mainly to the formation of oxygen-containing products, and excitation of the impurity levels to the formation of hydrocarbons. The dissociative photo-adsorption of CH_4 leads to the formation of excited surface OH groups. The surface is gradually poisoned, but can be regenerated by high-temperature treatment in oxygen.

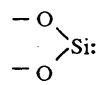
The study of the oxidation of methane by ESR *in situ* is made difficult by the very low concentration of active centres. In addition, they are situated on the surface of the oxide catalyst. This makes it impossible to study them in the presence of such gases as O_2 or H_2O. High concentrations of free-radical centres can be obtained by mechanical treatment, for example by grinding the oxides in a ball mill.

The mechanical grinding of SiO_2 gives very high concentrations of defects:[102–107] $10^{12}-10^{13}$ cm^{-2}, that is up to 1% of the number of surface atoms. Free-radical defects are formed by the homolytic splitting of siloxane bonds

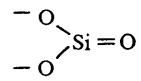


Grinding in oxygen also leads to the formation of $\equiv Si-O-O^{\cdot}$ and

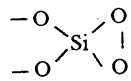
$\equiv Si-O-O-O^{\cdot}$ centres. The silicon atom is joined to three lattice oxygen atoms. A second type of defect is diamagnetic; the Si atom is joined to two O atoms of the lattice. In this set, silicone groups



silanone groups



and siladioxirane groups



have been identified. The reactions and transformations of these groups in contact with methane and oxygen have been studied.

The radical centres $\equiv Si-O^{\cdot}$ react with methane to give CH_3 radicals

$$\equiv Si-O^{\cdot} + CH_4 \longrightarrow \equiv Si-OH + CH_3. \quad (48)$$

The reaction takes place rapidly even at 78 K without significant activation energy. The CH_3 radicals are subsequently captured by diamagnetic centres; the structure of the new formations has been determined by ESR.

$$= Si: + CH_3^{\cdot} \longrightarrow = \dot{S}i-CH_3,$$

$$=Si= O + CH_3^{\cdot} \longrightarrow =Si\begin{matrix}O^{\cdot}\\ \diagdown\\ CH_3\end{matrix} \longrightarrow =Si\begin{matrix}OH\\ \diagdown\\ CH_2^{\cdot}\end{matrix},$$

$$=Si\begin{matrix}O\\ \diagup\\ \diagdown\\ O\end{matrix} + CH_3^{\cdot} \longrightarrow =Si\begin{matrix}O^{\cdot}\\ \diagdown\\ OCH_3\end{matrix} \longrightarrow =Si\begin{matrix}OH\\ \diagdown\\ OCH_2^{\cdot}\end{matrix} \quad (49)$$

Despite the high concentration of radical centres $=Si-O^{\cdot}$, practically no reaction between them and CH_3 is observed. The reaction of oxygen with the centres formed by reaction (49) gives formaldehyde

$$\equiv Si-CH_2^{\cdot} + O_2 \longrightarrow \equiv Si-CH_2OO^{\cdot} \longrightarrow \equiv Si-O^{\cdot} + CH_2O,$$

$$\equiv Si-OCH_2^{\cdot} + O_2 \longrightarrow \equiv Si-OCH_2OO^{\cdot} \longrightarrow \equiv Si-O-O^{\cdot} + CH_2O. \quad (50)$$

To complete the catalytic cycle, it is necessary to add to reactions (48)–(50) another stage, namely the dehydration of the $\equiv Si-OH$ group. This is apparently the most difficult stage.

Another possible route for the formation of CH_2O is by the thermal decomposition of the methoxyl groups, which on SiO_2 takes place at 973 K [108,109]

$$\equiv Si-O-CH_3 \longrightarrow \equiv Si-H + CH_2O. \quad (51)$$

The formation of methoxyl groups was noted in the reaction of SiO_2 with methane.[108]

Thus the mechanochemical modelling of the oxidation of CH_4 on SiO_2 shows a similarity in the homogeneous and heterogeneous radical processes. The reaction of the molecules with the radical centres of the surface takes place readily; the regeneration of the active centres is difficult.

Formaldehyde can also be obtained by the reaction of free radicals, for example CH_3O_2, with the surface. The following reaction is probable on mechanochemically treated (MoO_3 + SiO_2)-catalysts

$$CH_3O_2 + Mo^{V}OH^{-} \longrightarrow CH_2O + H_2O + Mo^{V}O^{-} (\rightleftharpoons Mo^{VI}O^{2-}).$$

This reaction explains the experimentally observed formation of CH_2O at 823–879 K,[72] when the rate of the initial formation of CH_3 radicals is fairly high, but equilibrium (23) is displaced towards CH_3O_2.

IV. The oxidation of methane to synthesis gas

The oxidation of methane by oxygen. The oxidation of methane to synthesis gas is a weakly exothermic reaction

$$CH_4 + {}^1/_2O_2 = CO + 2H_2, \ \Delta H = -44 \text{ kJ mol}^{-1}. \quad (52)$$

Reaction (52) is thermodynamically allowed ($\Delta G < 0$) over a wide temperature range, and in principle can take place with a selectivity of 100%. This process is carried out non-catalytically, for example in the synthesis gas generators of Shell and Texaco in the range 1400–1700 K.[110,11]

On catalysts, reaction (52) is usually complicated by the extensive oxidation of methane

$$CH_4 + 2O_2 = CO_2 + 2H_2O \quad (53)$$

and by the endothermic steam conversion of methane and reaction of CH_4 with CO_2

$$CH_4 + H_2O = CO + 3H_2, \ \Delta H = 207 \text{ kJ mol}^{-1}, \quad (54)$$

$$CH_4 + CO_2 = 2CO + 2H_2, \ \Delta H = 246 \text{ kJ mol}^{-1}. \quad (55)$$

Reaction (54) is displaced towards synthesis gas above 580 K, and reaction (55) above 910 K. Conversion of water gas also takes place

$$CO + H_2O = CO_2 + H_2, \ \Delta H = -35 \text{ kJ mol}^{-1}. \quad (56)$$

The value of ΔG for reaction (56) at 1100 K is negative (−25 kJ mol^{-1} at 300 K); above 1100 K the equilibrium is displaced to the left.

Deposited nickel catalysts of the steam conversion of methane are most frequently used. In a flow reactor with a nickel catalyst deposited on a refractory material, different reactions were observed in different layers of the catalyst at 1002–1173 K.[112] The exothermic extensive reaction (53) took place in the first layer, and the endothermic reactions (54) and (55) in subsequent layers. This gave a CH_4 + CO + CO_2 + H_2 mixture, corresponding to thermodynamic predictions. Different reactions taking place in different layers have been observed in other studies.[110,113,114] Stoichiometric synthesis gas was obtained in CH_4 + O_2 mixtures with an oxygen deficit on nickel deposited on mullite.[113]

The activity and selectivity of nickel catalysts deposited on various carriers: Al_2O_3, $SiO_2-Al_2O_3$, $ZrO_2-Al_2O_3$, and HY zeolite, were studied.[110] 5% Ni on a carrier in all cases gave a selectivity with respect to CO_2 + H_2 > 90% and >92.5% conversion of CH_4; for Ni/Al_2O_3 and Ni/SiO_2-ZrO_2, a selectivity and conversion of about 96% were obtained. For 1% Ni, however, appreciable activity and selectivity were obtained only on the non-acidic carriers Al_2O_3 and SiO_2-ZrO_2. It was shown[110] that nickel cations on acidic carriers are not completely reduced to metal. Non-reduced nickel gives

practically no H_2 in the reaction products. All the catalysts were active and selective at high Ni concentrations (> 5%).

The oxidation of methane to synthesis gas on 25% Ni/Al_2O_3 at 723–1173 K was studied.[114] Above 973 K the selectivity with respect to CO + H_2 reaches 95% with complete conversion of CH_4. XPS and electron diffraction studies of the catalyst showed that in the first layer of the catalyst in the reaction mixture the spinel $NiAl_2O_4$, moderately active in extensive oxidation, is formed. In the second layer, a mixture of phases NiO + Al_2O_3, which is an active catalyst of extensive oxidation, is formed. In the third layer, reactions (54)–(56) take place as far as complete thermodynamic equilibrium. Thus it was confirmed that the oxidation of CH_4 to synthesis gas takes place by the sequence of reactions (53)–(56). This combination of reactions helps to overcome the highly endothermic character of the steam conversion of methane, that is reaction (54).

A combination of the steam and oxygen conversion of methane [reactions (54) and (52)] is carried out in industry. Steam conversion is carried out in the first reactor at 973 K and $[H_2O]:[CH_4] = 2$, and oxygen conversion in the second reactor at a low CH_4 concentration and 1223 K. This gives stoichiometric synthesis gas with a lower consumption of natural gas and energy.[115]

A study of the selective oxidation of methane to CO + H_2 on palladium catalysis deposited on oxides showed[116] that the catalysts 1% Pd(γ-Al_2O_3, Y_2O_3, La_2O_3, TiO_2, ZrO_2, HfO_2, CeO_2) give synthesis gas with a selectivity greater than 90%; for Pd/SiO_2 the selectivity at 1023 K was 63.7%. The degree of conversion of CH_4 at 1023 K was 35–66%. The highest selectivity (99.5%) was obtained on Pd/γ-Al_2O_3 for 58% conversion. The selectivity is lowered by the formation of CO_2, which in the opinion of the authors cited[116] takes place in the gas phase, while CO is formed on the surface.

The oxidation of methane at 673–973 K by noble-metal catalysts deposited on γ-Al_2O_3 has been studied.[117] In a reducing medium (a gas mixture with $[CH_4]:[CO]:[O_2] = 2:1:3$) a CO + H_2 mixture was obtained, and in an oxidising medium ($[CH_4]:[CO]:[O_2] = 2:1:10$) only extensive oxidation took place. The order of activity in the oxidation of CH_4 to synthesis gas is Rh > Pd $\simeq$ Pt. Adding CeO_2 to the catalyst suppresses completely its ability to give CO. CO in the gas phase has little influence on the yield of products.

Rh/SiO_2 was the most active and selective of the noble metals deposited on SiO_2.[118] On Rh, Ru, Pd, and Ni deposited on SiO_2, the yield of synthesis gas exceeded 90%. At the same time, extensive oxidation of CH_4 took place on Fe and Co/SiO_2. Oxidised metallic catalysts have a low activity.

Synthesis gas can be obtained by oxidising methane on catalysts containing lanthanides and noble metals, even at a low temperature (777 K).[119–121] On $Ln_2M_2O_7$ catalysts, where Ln = La, Eu, Gd, Yb, and M = Ru, Ir, a yield of CO + H_2 of 92–94% was obtained with a selectivity of up to 99% at a high volume rate of 4×10^4 h^{-1}. The highest selectivity (98–99%) was observed for $Y_2Ru_2O_7$. The catalysts Ru, Pd, Ir, Ni/Al_2O_3 were also active. X-Ray data showed that under the synthesis conditions the oxide catalyst decomposes to the metal

$$2Eu_2Ir_2O_7 \longrightarrow 2Eu_2O_3 + 4Ir + 4O_2.$$

Iridium particles with dimensions of 3 nm are formed. Reaction (56) decreases the selectivity slightly. The yield of CO + H_2 decreases with increase in pressure.

Thus the highest activity and selectivity in the oxidative conversion of methane into synthesis gas are shown by the metals of the platinum group and nickel, which activate hydrogen (and correspondingly the recombination of H atoms). This ability is lost when the metals are oxidised. After the removal of the first H atom, CH_4 is apparently transformed rapidly into $CH_{2\,ads}$, CH_{ads}, C_{ads}, and then CO. The process is undoubtedly highly selective, but its practical realisation requires the special production of oxygen, and this makes the large-scale production of synthesis gas by reaction (52) less favourable than steam conversion (54).

The combination of the oxidative conversion of CH_4 into synthesis gas with other reactions is also of interest. A combination of three reactors without intermediate separation has been used[122] for the selective oxidation of methane to propanal C_2H_5CHO. The oxidative condensation of methane to ethane on $K/BaCO_3$ and the transformation of CH_4 + O_2 into synthesis gas on 1% Rh/Al_2O_3 at a high temperature (1139–1153 K) are carried out in two parallel reactors. The hydroformylation of ethane on a homogeneous Rh catalyst is carried out in a third reactor at a low temperature (993 K). A selectivity with respect to C_2H_5CHO of 27% is achieved for 49% conversion.

The oxidation of methane using CO_2. The direct reaction of methane with CO_2 on metallic catalysts has been studied by many workers, beginning with the work of Fischer and Tropsch.[123] In addition to reaction (55), reactions (56) and (57) also take place. The formation of ethane [reaction (58)] is also possible:[124]

$$CH_4 + 2CO_2 = C + 2CO + 2H_2O, \quad (57)$$

$$CH_4 + 3CO_2 = 4CO + 2H_2O, \quad (58)$$

$$2CH_4 + CO_2 = C_2H_6 + CO + H_2O. \quad (59)$$

All four reactions (55) and (57)–(59) are endothermic and take place at high temperatures (900–1200 K). At 1073 K, $\Delta G < 0$ for reactions (55)–(58), and $\Delta G > 0$ for reaction (59).

Reaction (55) often takes place as a side reaction in the steam conversion of methane. A study of its kinetics on an Ni catalyst at 1070–1173 K showed[125] that the reaction rate is described by the same equation as the steam conversion

$$r = \frac{k_1 p_{CH_4}}{1 + k_2 p_{H_2O}/p_{H_2} + k_3 p_{CO}}, \quad (60)$$

where k_1, k_2, k_3 are constants, and p_{CH_4}, p_{H_2O}, p_{H_2}, and p_{CO} the partial pressures of methane, water, hydrogen, and carbon monoxide respectively. The explanation given[124] is that CH_4 reacts first not with CO_2 but with H_2O, and the hydrogen formed reacts rapidly with CO_2 by a reaction which is the reverse of reaction (56), with the regeneration of H_2O.

In accordance with Eqn. (57), the reaction of CH_4 with CO_2 gives carbon, which poisons the nickel catalyst. It is obtained both from methane by its dissociation to C + $2H_2$ and from CO by the Boudouard reaction. Various methods are used for the industrial preparation of synthesis gas from CH_4 + CO_2. The first of Haldor Topsoe uses a CH_4 + CO_2 + H_2O mixture to decrease the poisoning of the catalyst and blocking of the tubes by carbon.[126,127] It has also developed the SPARG process (1173 K, 0.9 MPa), in which sulphur vapour is added to the reacting gases. Sulphur passivates nickel and prevents the formation of carbon.

Ni/SiO_2 was much more active than the oxides CaO and Fe_2O_3. The temperature of 50% conversion was 910 K on Ni/SiO_2, and 1200–1300 K on the oxides.[128] The oxides are covered by carbon more rapidly than nickel. At 1073 K the degree of conversion of a CH_4 + CO_2 mixture into synthesis gas was 83.1% on Ni/Al_2O_3,

74.2% on Co/Al_2O_3, and only 3.4% on Fe/Al_2O_3. The reaction rate was approximately 1.5 times lower on Ni/SiO_2 than on Ni/Al_2O_3.[129]

Metals of the platinum group are also active in the carbon dioxide conversion of methane.[130–133] The reaction takes place at an appreciable rate even at 773 K. A study of the reaction by the transverse pulse method showed that CO is formed when the CO_2 pulse is introduced. C_2H_6 and C_2H_4 are formed from the first CH_4 pulses, followed by rapid deactivation at 773 K and by slow deactivation at 823 K. Rh/Al_2O_3 and Pd/Al_2O_3 are poisoned more slowly than the others, and Ru/Al_2O_3 more rapidly. The order of specific activities in the $CO_2 + CH_4$ reaction is Rh > Pd > Ru > Pt > Ir/Al_2O_3, which corresponds to the order of the activities in the dissociation $CO_2 \rightarrow CO + O_{ads}$.[131] According to much of the data,[130,131,133] Rh/Al_2O_3 is the most active. Acidic carriers were found to be more favourable, since they facilitate the dispersion of the deposited metals.

The reversible reaction $CO_2 + CH_4 \rightleftarrows 2H_2 + 2CO$, that is the production of synthesis gas at high temperatures and methanation at low temperatures, is convenient for the creation of cells using solar energy;[132] the endothermic reaction takes place on heating by the sun, and the exothermic reaction takes place to remove the energy. The 1% Ru/Eu_2O_3 catalyst with a ruthenium particle size of 3 nm and the hexagonal ruthenium structure was found to be best for this purpose.

All the deposited noble metals studied were shown to be highly active.[134,135] Another important feature is that in almost all cases the product is a gas mixture with $[CO]:[H_2] = 1$, that is practically no side reactions take place. For a mixture with $[CH_4]:[CO_2] = 1$ at 1050 K, the yields of synthesis gas CO + H_2 were 1% on Al_2O_3, 85% on 1% Ni/Al_2O_3, 73% on 1% Pd/Al_2O_3, 89% on 1% Ru/Al_2O_3, 87% on 1% Rh/Al_2O_3, and 89% on 1% Ir/Al_2O_3. Coking was most rapid for the catalyst Ni/Al_2O_3 and Pd/Al_2O_3. The most stable to coking was Ir/Al_2O_3, which remained active for 260 h. On Ru/Al_2O_3 the yields of H_2 was greater than that of CO. In a $13CH_4 + 6O_2 + CO_2$ mixture the yield on Ni/Al_2O_3 can be increased by 91%, and the reaction becomes thermally neutral. For a $4CH_4 + O_2 + 9CO_2$ mixture the gas obtained contained exactly 50% CO and 50% H_2, and no carbon was formed on the surface.

New types of catalyst, stable to carbon formation, have been studied.[136–139] The effect of various additives on Ni/SiO_2 catalysts was studied. Of the oxides of nickel, iron, copper, chromium, and manganese, the oxides of manganese were found to be most effective. In their presence the extent of carbon formation decreased, and the degree of transformation of CO_2 increased with increase in the proportion of manganese in the nickel catalyst.

Subsequent study showed that reaction (55) can be carried out without nickel. A 5% Ca–12% Mn–O/Al_2O_3 catalyst was most effective under stationary conditions. In its presence at 1140 K at a volume rate of 900 h^{-1} with an equimolar mixture of CO and H_2, the conversion of CH_4 was 83.1%, the conversion of CO_2 62.7%, and the selectivity with respect to H_2 76.5%. At 1200 K at the start of work with a fresh catalyst, extensive oxidation of methane takes place involving the oxygen of the catalyst, and there is no transformation of CO_2. As the reaction and reduction of the catalyst take place, CO_2 is activated. The concentration of CO and H_2 increase continuously. With a catalyst operating under stationary conditions at 1200 K, the conversion of CO_2 and CH_4 is complete, and the selectivity is 99.7% for CO, and 84.6% for H_2. The activity is preserved for a long time, and practically no formation of carbon by reaction (57) takes place.

A study of the phase composition of an operating Ca–MnO/SiO_2 catalyst showed[137,138] that during the reaction the more highly oxidised phases Mn_2O_3 and Mn_3O_4 are reduced, and only the reduced phase MnO is detected in the catalyst. After the production of a stable catalyst composition, the formation of carbide and metallic manganese phases was not observed.

A study of the reaction under alternating conditions (the reaction of alternately CH_4 and CO_2 with the catalyst) showed that on the fresh catalyst, C_2H_4 and C_2H_6 are formed from methane, possibly with the participation of carbonate phases, since oxidative dimerisation takes place.[139] After reduction and phase transformation from the oxidised phases to MnO, the formation of C_2H_6 and C_2H_4 decreases and CO appears. The rates of formation of hydrogen under stationary catalysis conditions (3×10^{-3} mol g^{-1} h^{-1}) and in the reductive reaction of CH_4 with the catalyst (1.7×10^{-3} mol g^{-1} h^{-1}) are comparable. The rate of the reaction of CO_2 with the reduced catalyst (re-oxidation of the catalyst), however, is greater than the rate of reduction.

Mamedov[136] concluded that the conversion of methane to synthesis gas using CO_2 on a manganese catalyst does not take place by a redox mechanism. During the catalysis, the stationary phase MnO is not reduced and is not oxidised, but prevents carbon formation. Electron microscopy detected coke deposits as thin layers on the reduced MnO centres. CO_2 reacts with MnO and forms an intermediate carbonate complex on the surface, methane dissociates, and the carbon fragment reacts with oxygen.

$$CH_4 + MnO \rightleftarrows MnO \ldots C + 2H_2,$$
$$CO_2 + MnO \rightleftarrows MnCO_3,$$
$$MnCO_3 + MnO \ldots C \longrightarrow 2MnO + 2CO,$$
$$MnCO_3 + H_2 \longrightarrow MnO + CO + H_2O,$$
$$MnO \ldots C + H_2O \longrightarrow MnO + CO + H_2.$$

When redox additives are introduced into MnO, the reaction becomes an alternating redox reaction. Only reaction (58) is observed on a K–Cr–Mn–O/SiO_2 catalyst.

Hydroxylation of aromatic compounds with nitrous oxide. New possibilities of oxidative catalysis on zeolites

A S Kharitonov, V I Sobolev, G I Panov
Boreskov Institute of Catalysis, Siberian Division of the Russian Academy of Sciences

ABSTRACT. Studies on the use of zeolites in partial oxidation reactions are surveyed. Attention is concentrated on recent investigations of the gas-phase oxidative hydroxylation of aromatic compounds with nitrous oxide. Best results were achieved in the study of the simplest reaction of this type — the oxidation of benzene to phenol: in the presence of iron-containing ZSM-5 zeolites, the reaction proceeds with nearly 100% selectivity and a degree of conversion of benzene of 25–30%.

Further development of this method for the introduction of hydroxy-groups may lead to new possibilities for the creation of effective technologies in the field of organic synthesis.

The bibliography includes 87 references.

I. Introduction

Oxidation processes constitute one of the commonest classes of chemical reactions. This applies both to natural proceses, where oxygen effects a continuous turnover of chemical reactions, and in the field of technical catalysis carried out by man. The endeavour by investigators to create economically more effective and ecologically clean technologies has stimulated the search for new catalysts exhibiting a high selectivity.

Zeolites were not regarded for a long time as promising catalysts for oxidation reactions despite their wide scale and successful use in many other fields of catalysis. Considerable changes occurred in this respect during the last decade. They are associated with the creation at the beginning of the 1980s of titanosilicate zeolites having a structure of the ZSM-type and the discovery of their unique properties in oxidation reactions involving H_2O_2. The titanosilicate zeolites proved to be effective catalysts of a wide range of reactions occurring in the liquid phase, such as the oxidation of alcohols, epoxidation of alkenes, hydroxylation of aromatic compounds, and the conversion of cyclohexanone into an oxime.[1–5] The range of these reactions is being expanded and communications concerning the selective oxidation of lower paraffins to secondary and tertiary alcohols in the presence of titanosilicates have appeared.[6–8] Some of these reactions can be achieved also in the presence of other zeolites of the pentasil type.[9–11]

Whereas in the reviews of recent years these advances in liquid-phase oxidation have been assessed as one of the most important achievements in the field of organic synthesis,[12–15] the results obtained in the gas-phase oxidative catalysis on zeolites appear much more modest. The transfer of reactions to the gas phase has many technological advantages. However, the consequent increase in temperature precludes the use in this instance of hydrogen peroxide because of its vigorous uncontrolled decomposition. On the other hand, the employment of molecular oxygen, which is a traditional oxidant for heterogeneous-catalytic gas-phase reactions, has not so far led to major successes.

The partial oxidation of hydrocarbons is achieved as a rule in the presence of transition metal oxides.[16,17] Their activity is due to the more or less facile electron transfer and their capacity for the reversibility of their oxidation state on interaction with oxygen and the substance oxidised. Zeolites themselves cannot serve as active oxidation catalysts, but the possibility of their use as carriers is nevertheless of great interest. The regular structure, high surface area, and high adsorption potential create preconditions for the attainment of a wide variety of states of the deposited component. Indeed, numerous studies have shown that, after its introduction into a zeolite, a metal can have different states:[18] it can exist in the form of isolated ions in the tetrahedral positions within the zeolite lattice, as isolated cations serving as the counterions, as small clusters and associated species within the porous system, and as part of the composition of the highly disperse oxide phase distributed on the outer surface of the zeolite. Such a wide variety of forms is hardly possible in other systems and it would appear that it should lead to extensive prospects for the acceleration of various oxidation reactions.

However, studies carried out mainly in the 1970s and examined extremely fully in a monograph[19] have not on the whole justified these expectations. In many instances, the authors were able to demonstrate fairly effective reaction parameters on zeolites (for example, the epoxidation of ethylene on Ag/CaX [20] and the oxidative ammonolysis of toluene on Cu/ZSM-5 [21]), but such parameters do not attain the level ensured by the best traditional systems.

One of the causes of this is that the transition metals introduced into a zeolite matrix (particularly in the form of isolated ions) lose their activity. The decrease in the atomic catalytic activity can reach several orders of magnitude compared with massive oxides.[19] O_2 isotope exchange data have shown[22–24] that this is associated primarily with the loss of ability to activate molecular oxygen. To some extent, this result is natural bearing in mind that O_2 is

activated via its dissociative adsorption on the catalyst surface[25,26] involving the transfer of four or at least two electrons, which can be hardly readily achieved on small clusters let alone isolated metal cations.

A change in the structure of the zeolite lattice and also in the coordination environment can affect significantly the oxidative catalytic properties of cations introduced into the zeolite.[27–31] The oxidation of hydrocarbons on zeolites is frequently complicated by a number of side reactions occurring on the acid surface centres and deactivating the catalyst as a consequence of the deposition of coke.

During the last decade, the interest in gas-phase oxidation on zeolites has been maintained at an extremely low level. Analysis of the literature shows that only isolated reports concerning this aspect of research have appeared at major international conferences on zeolites and also at congresses on catalysis (Table 1). It is remarkable that not a single study devoted to gas-phase oxidation on zeolites was presented at the Symposia on "Heterogeneous Catalysis and Fine Organic Synthesis"[12] and "New Advances in Selective Oxidation".[33,34]

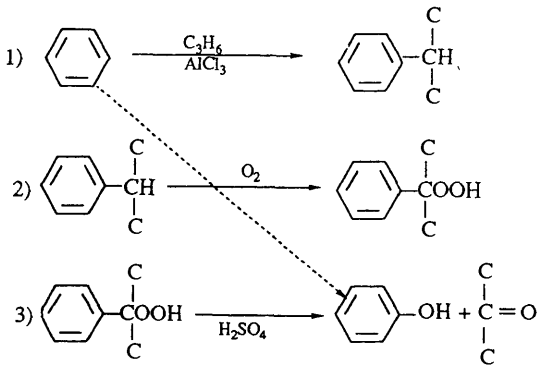
During the 1980s, a new trend arose in the field of oxidative heterogeneous catalysis. Namely it involved the use as the oxidant of not only free (molecular) oxygen but also of bound oxygen in the form of various oxygen-containing molecules.[38–45] To a large extent, this trend arose in the search for methods whereby the catalytic activation of methane and other lower paraffins could be achieved. The greatest interest among the non-traditional oxidants attaches to molecular nitrous oxide. The replacement of molecular oxygen by N_2O, including systems on zeolites,[39,40,45] frequently makes it possible to increase significantly the selectivity of the oxidation reactions.

The effective properties of nitrous oxide as a source of oxygen was manifested particularly strikingly in the study of the oxidative hydroxylation of an aromatic ring, which is a complex and difficult reaction. Studies on these lines were carried out mainly during the last 4–5 years. Although at the present stage it is difficult to reach a final assessment, nevertheless such investigations have yielded, in our view, extremely promising results and they become a basis for the creation of new ecologically clean technologies for organic synthesis and zeolites. The rest of the present review is in fact devoted to a consideration of these studies.

II. Hydroxylation of benzene in the presence of traditional catalysts

The introduction of a hydroxy-group into an aromatic ring is a difficult problem in the synthesis of organic intermediates: phenols naphthols, hydroxyamines, hydroxyacids, etc. Industrial hydroxylation procedures as a rule involve indirect multistage processes which frequently require the application of corrosive chemicals.[46,47] The simplest reaction of this type, the oxidation of benzene to phenol, is carried out via the so called cumene process comprising three stages (see the Scheme below): (1) alkylation of benzene with propene leading to the formation of isopropylbenzene (cumene); (2) oxidation of cumene to a hydroperoxide: (3) decomposition of cumenyl hydroperoxide to phenol and acetone. The first and third stages are carried out catalytically in the liquid phase using acid catalysts, which usually consist of $AlCl_3$ (stage 1) and H_2SO_4 (stage 3). Naturally this involves problems of the corrosion of the apparatus and negative environmental consequences. Furthermore, the cumene method suffers from a further disadvantage, namely the formation of each mole of phenol is accompanied by the formation of one mole of the accompanying product—acetone, which cannot always find an equivalent market for its sale because of the much smaller requirement for this product.[48] Therefore efforts have been made in numerous laboratories to seek new ways of synthesising phenol.

Scheme



The most radical procedure for the solution of this problem—the introduction of a hydroxy-group via the direct single-stage oxidation of benzene with oxygen, indicated by a dashed arrow in the Scheme, has attracted much attention by investigators. However, numerous attempts, undertaken on these lines in the course of several decades, did not lead to success. The interaction with oxygen is accompanied by the decomposition of the benzene ring and the formation of either maleic anhydride (in the presence of specially selected

catalysts) or extensive oxidation products. In the oxidation of alkylbenzenes, for example, toluene, the process involves primarily the substituent and leads to the formation of benzaldehyde or benzoic acid.[16]

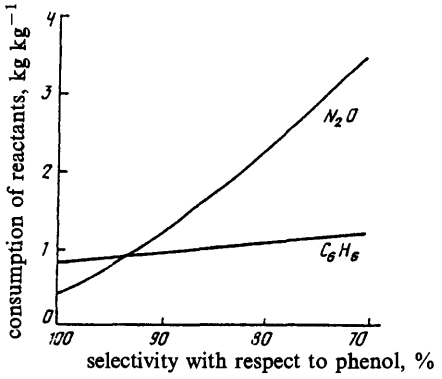


Figure 1. Consumption of benzene and nitrous oxide in the synthesis of phenol as a function of the selectivity of the oxidation of benzene to phenol.

A new reaction was discovered in 1982 — the oxidation of benzene with nitrous oxide:[49,50]

$$C_6H_6 + N_2O = C_6H_5OH + N_2. \quad (1)$$

It made it possible to achieve a fundamentally new level of selectivity with respect to phenol. Best results were obtained in the presence of deposited vanadium, molybdenum, and tungsten oxides. At 550 °C and after the addition of 30% of H_2O to the reaction mixture, the selectivity with respect to phenol on deposited catalysts reached 71% for a benzene conversion of 10%. These results aroused lively responses,[51,52] in which the environmental safety of the new process was emphasised and extremely optimistic assessments of its practical prospects were made. Plans for pilot tests in a reactor with a fluidised catalyst bed were reported. However, the process was not realised in practice.

The parameters of the vanadium catalyst proved to be inadequate and it was not possible to find better catalysts, primarily as regards their selectivity. Selectivity is the most important parameter in partial oxidation processes. On the other hand, in processes involving N_2O, this parameter assumes a particularly great importance since, in contrast to molecular oxygen, nitrous oxide is a fairly expensive oxidant, whose cost is comparable to that of benzene. Whereas the conversion of one benzene molecule into phenol via reaction (1) requires one nitrous oxide molecule, the extensive oxidation to CO_2 and H_2O via the reaction

$$C_6H_6 + 15N_2O = 6CO_2 + 3H_2O + 15N_2, \quad (2)$$

requires 15 N_2O molecules. Fig. 1 shows that the decrease in selectivity leads not only to an increase in the consumption of benzene but, and this is particularly important, also to an increase in the consumption of nitrous oxide. For 70% selectivity, the consumption of N_2O exceeds almost by an order of magnitude the theoretical consumption corresponding to 100% selectivity. Taking this into account, one can hardly speak of the practical realisation of the process if selectivity at a level of 85–90% has not been achieved.

III. The search for new systems. Zeolites

The results of Iwamoto and co-workers[49,50] stimulated the search for new more effective catalytic systems. The reaction proved to have very stringent requirements. A large number of compounds of different chemical nature, some of which are listed in Table 2, were tested. Much attention was devoted to attempts at the improvement of vanadium catalysts, which made it possible to increase appreciably their stability.[53] However, the characteristics of vanadium catalysts could not be fundamentally improved in relation to the early investigation,[50] despite the use of different methods of preparation, the introduction of modifying additives, and the employment of various oxidants (O_2, N_2O, NO, SO_2). All the other compounds presented in Table 2 proved to be either inactive or the reaction proceeded in the direction of extensive oxidation in their presence, which is particularly characteristic of platinum group metals. Only a few catalysts yielded small amounts of phenol.

Table 2. Catalytic systems tested in the oxidation of benzene to phenol.

Systems based on V_2O_5	Systems with oxides	Systems with metals	Zeolites
		Catalysts	
V_2O_5	Al_2O_3, SiO_2	Ru/Al_2O_3,	A, X, Y
V_2O_5/SiO_2,	TiO_2, Fe_2O_3	Ag/Al_2O_3,	erionite
V_2O_5/TiO_2,	NiO, ZnO,	Ag/C,	clinoptilolite,
V-Mo-O/SiO_2,	Fe_2O_3·MoO_3,	Pd/SiO_2,	mordenite,
V-W-O/SiO_2,	NiO·Cr_2O_3,	Pd/C,	$AlPO_4$-5,

		Oxidants	
O_2, N_2O	N_2O, O_2	N_2O, O_2	N_2O_2, O_2
NO, SO_2			

The results obtained in the presence of zeolites were extremely unexpected. Table 3 presents the results of tests on certain zeolites under conditions close to those in experiments with vanadium catalysts. Evidently an appreciable amount of phenol was detected in the reaction products in a number of instances. Particularly promising results were obtained for zeolites of the type of pentasil ZSM-5 and $AlPO_4$-5. Three groups of investigators concluded independently in 1988 that ZSM-5 zeolites are extremely promising catalysts for the oxidation of benzene to phenol with nitrous oxide: Suzuki et al.[54] (Tokyo Technological Institute), Hubelman et al.[55]

(The Rhone-Poulenc Company), and Kharitonov et al.[56] (Institute of Catalysis, Novosibirsk). The zeolite catalysts made it possible to reduce the reaction temperature to 300–400 °C, to abandon the introduction of water vapour into the reaction mixture, and, what is most important, to ensure a high selectivity with respect to phenol. Although the maximum yield of phenol in these investigations was low (8–16%), it became clear that a system had been found which can serve as a basis for the creation of new effective catalysts. Further studies made it possible to improve greatly the parameters of the zeolite catalysts and to extend the range of reactions.[57–62]

Table 3. Catalytic properties of zeolites in the oxidation of benzene to phenol.

Type of zeolite	$SiO_2 : Al_2O_3$ molar ratio	Specific surface, $m^2 g^{-1}$	X, %	S, %
A	2.1	580	0.5	0
X	3.1	690	2.5	10
Y	4.8	890	6	5
Erionite	4.8	460	2.5	0
Clinoptilolite	10	80	16	0
Mordenite	14.9	620	12	0
ZSM-5	260	530	7.9	100
$AlPO_4$-5	–	300	4.5	100
Al_2O_3	–	200	11	0
SiO_2	–	190	0	–

Note. Composition of the reaction mixture (mol%); C_6H_6—5; N_2O—20; He—76; T = 500 °C; contact time 2 s; X = degree of conversion of benzene; S = selectivity with respect to phenol.

IV. The nature of the catalytic activity of zeolites

1. The role of iron

It appears unlikely that a reaction as involved and as stringent in its requirements as the oxidation of benzene to phenol could be achieved as a result of the influence of the aluminosilicate skeleton of the zeolite. According to Minachev and Kharlamov,[63] certain oxidation-reduction reactions can occur on alkali and alkaline earth metal cations forming part of the zeolite. However, in this instance all investigators emphasise the importance of the conversion of the ZSM-5 zeolite into the H-form. Indeed, as can be seen from Fig. 2, with increase in the sodium content with activity of the zeolite falls appreciably. Under these conditions, the selectivity of the reaction is unaffected and remains 100% in all cases.

It appears more natural to postulate that the activity may be associated with the presence in the zeolite of admixtures of transition metals to which no importance was attached in the first investigations. This may concern primarily iron, which is the commonest impurity introduced in the synthesis of zeolites. The influence of iron has been studied in detail.[64] For this purpose, a series of zeolite specimens with the ZSM-5 structure were synthesised. They had approximately the same $SiO_2 : Al_2O_3$ = 100 molar ratio but different iron contents, varying from 0.004 to 0.72 wt.% Fe_2O_3. The specimens of this iron-aluminosilicate series were designated by Fe(Al)-*N*, where *N* is a number indicating the content of iron expressed in wt.% Fe_2O_3.

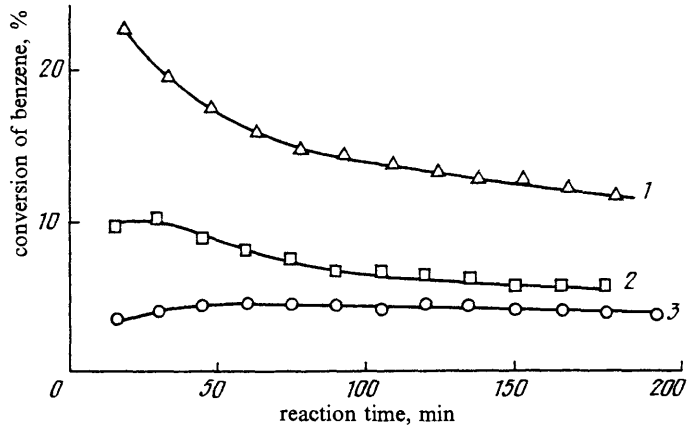

Figure 2. Dependence of the degree of conversion of benzene in the oxidation with nitrous oxide on the sodium content in the Fe(Al)-0.08 specimen (SiO_2/Al_2O_3 = 100; Fe_2O_3 = 0.08 wt.%). Na_2O content (wt.%): *1*, 0.06; *2*, 0.8; *3*, 1.1. Composition of the reaction mixture (mol%): C_6H_5—5, N_2O—20; He—75; T = 350 °C; contact time 2 s.

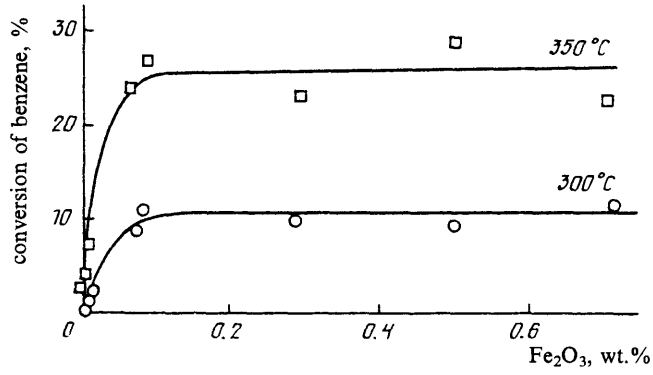

Figure 3. Dependence of the degree of conversion of benzene on the iron concentration in the Fe–Al–Si ZSM-5 zeolite specimens. The reaction conditions were the same as in Fig. 2.

Fig. 3 illustrates the dependence of the degree of conversion of benzene on the iron content in the Fe–Al–Si system plotted on the basis of the data of Panov et al.[64] Indeed, the Fe(Al)–0.004 and Fe(Al)–0.007 specimens, synthesised taking all possible precautions and virtually free of iron (0.004 and 0.007 wt.% Fe_2O_3 respectively), proved to be relatively inactive. With increase in the iron content to

0.1 wt.%, the degree of conversion of benzene increases appreciably but subsequently changes little. The Fe–Al–Si specimens containing 0.07–0.7 wt.% Fe_2O_3 exhibit such a high activity that they ensure a degree of conversion of benzene (X) at a level of 10% already at 300 °C with a selectivity with respect to phenol of 100%. At 350 °C, the degree of conversion reaches 25% for a selectivity of 95% and above on the best specimens. For higher values of X, the reaction selectivity falls owing to the further oxidation of phenol. Under these conditions, benzoquinone, catechol, hydroquinone, dibenzofuran, and cresol appear among the reaction products. The overall selectivity with respect to these substances can reach several per cent.[64]

The question of the catalytic properties of other metals is of considerable interest. Tests on specimens of the ZSM-5 zeolite containing V, Cr, Mn, Co, Ni, Cu, Ti, Zn, Sc, Pd, and Pt, which were introduced either during the synthesis of the zeolite[64] or by ion exchange,[54] showed that they are all inactive in the oxidation of benzene to phenol. It may be that iron is one of the few or even the only element capable of promoting this reaction with a high degree of efficiency. This question merits further careful study. One may note an analogy in the mechanism of the action of iron in the Fe-ZSM-5 composition and in cytochrome P-450 as well as certain artificial systems simulating its operation. These are systems which are also capable of effecting with a high degree of selectivity the oxidative hydroxylation of hydrocarbons, including the oxidation of benzene to phenol.[65]

2. The influence of aluminium

The iron introduced into the Al–Si matrix plays a decisive role in the catalytic properties of the ZSM-5 zeolite. The Fe–Al–Si specimens with the optimum iron content are greatly superior in their effectiveness to all other known catalysts, including ZSM-5 zeolites without specially added iron.[54–58] However, iron-containing zeolites with the same structure can be synthesised also in the absence of aluminium on a purely silicate base. Comparison of these two systems was of great interest from the standpoint of the influence of the chemical composition of the zeolite matrix on the catalytic properties of the added iron.

For this purpose, a study has been made[66] of a series of ZSM-5 zeolite specimens with an Fe–Si composition and a low content of the aluminium admixture (0.01–0.03 wt.% Al_2O_3) but with extensive variation of the iron content: from 0.003 to 4.8 wt.% Fe_2O_3. The formula Fe–N was used to designate these specimens. Fig. 4 shows that the influence of iron in this system is just as marked as in the Fe–Al–Si system. Thus, whereas in the presence of the Fe–0.003 specimen the oxidation of benzene with nitrous oxide occurs at a barely appreciable rate only at 500 °C, in the presence of specimens containing more than 2 wt.% Fe_2O_3 the degree of conversion of benzene reaches 25% already at 350 °C.

Although the relations illustrated in Figs. 3 and 4 are similar, attention should be drawn to the appreciable difference in the abscissa scales corresponding to the iron content. In order to represent the picture as a whole, the data concerning the influence of iron in the Fe–Si and Fe–Al–Si systems are presented in Fig.5 using logarithmic coordinates. Evidently, the relations in these two systems are appreciably displaced relative to one another in respect of the iron content. Thus, in order to attain the same degree of conversion in the case of the Fe–Si system, it is necessary to introduce 10–30 times more iron than in the Fe–Al–Si system. Conversely, for the same iron concentration, the activity of specimens containing aluminium is in many instances an order of magnitude or more higher than the activity of specimens without aluminium. Such a marked influence of aluminium suggests that the active centres for the reaction include not only Fe atoms but also Al atoms.

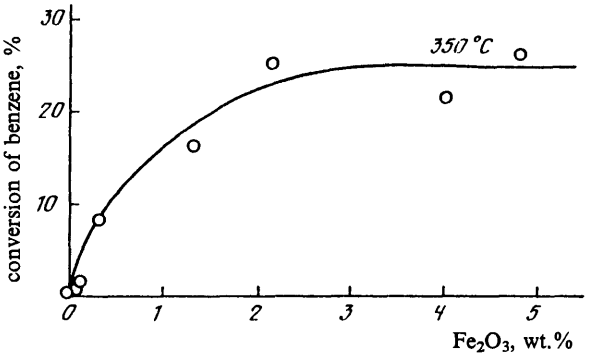

Figure 4. Dependence of the degree of conversion of benzene on the iron concentration in the Fe–Si ZSM-5 zeolite specimens. The reaction conditions were the same as in Fig. 2.

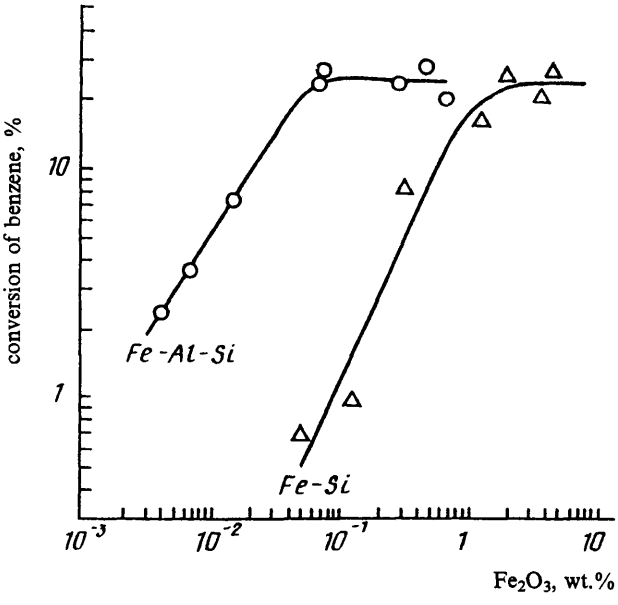

Figure 5. Dependence of the degree of conversion of benzene on the iron concentration in the Fe–Si and Fe–Al–Si ZSM-5 zeolite specimens at 350 °C. The reaction conditions were the same as Fig. 2.

This hypothesis was examined in a study[24] involving the analysis of the influence of iron on the catalytic activity of Fe-ZSM-5 specimens in the N_2O decomposition reaction. Direct comparison of

the concentration of the active centres (which can be reliably measured in these systems) with the concentration of the impurity Al atoms did not confirm this hypothesis. According to the above data,[24,66] the presence of aluminium does not affect the composition and catalytic properties of the iron-containing active centres but leads to their higher concentration as a consequence of the favourable effect of aluminium on the distribution of iron in the zeolite matrix.

V. Specific features of nitrous oxide as an oxidant. The mechanism of the hydroxylation of benzene

Iron oxide is known to exhibit a moderate activity in extensive oxidation reactions but it does not promote partial oxidation reactions.[16] The activity of the iron-containing zeolites in the oxidation of benzene to phenol therefore appears to be an extremely unexpected property of iron, manifested in the presence of nitrous oxide.

Table 4. The influence of the nature of the oxidant on the oxidation of benzene to phenol on Fe-ZSM-5 and Fe_2O_3 specimens.

Catalyst	N_2O oxidant		O_2 oxidant	
	X, %	*S*, %	*X*, %	*S*, %
Fe - 2.15	25.6	96.0	3.3	0.0
Fe(Al) - 0.08	27.0	99.0	0.0	-
Fe_2O_3	5.5	0.0	24.5	0.0

Note. Composition of the reaction mixture (mol%); C_6H_6 — 5; N_2O — 20; He — 75; T = 500 °C; contact time 2 s.

The specific features of nitrous oxide as an oxidant constitute one of the most interesting aspects of the study of the mechanism of the hydroxylation of benzene. These specific features are clearly seen on examining Table 4, which presents data for the oxidation of benzene on two typical Fe-ZSM-5 specimens with the Fe—Si and Fe—Al—Si compositions. Evidently, the replacement of nitrous oxide by molecular oxygen entails a sharp decrease in the rate of reaction. Whereas the degree of conversion of benzene on both specimens at 350 °C in the presence of N_2O is 25—27%, in the presence of O_2 and the ferrosilicate Fe—2.1 specimen it diminishes to 3% and on the ferroaluminosilicate Fe(Al)—0.08 specimen it diminishes to an infinitesimal value. [In the presence of O_2, the activity of the Fe(Al)—0.608 specimen is so low that the benzene oxidation reaction proceeds at a measurable rate only at 550 °C.] The fact that the reaction pathway changes completely under these conditions merits special attention. Instead of the formation of phenol with a selectivity of 96—99%, only total oxidation products are formed in the presence of O_2.

Such a marked influence of the nature of the oxidant justifies the hypothesis that this is associated with significant changes in the state of the surface oxygen. This stimulated a series of studies on the mechanism of the nitrous oxide decompositon reaction in the presence of the ZSM-5 zeolites,[23,24,67,68] because this particular reaction supplies oxygen to the catalyst surface. Such investigations established that the introduction of iron into the zeolite results in the formation of active centres (called α-centres), on which the decomposition of N_2O is accompanied by the formation of a new form of surface oxygen (the α-form), whose properties have been studied in detail.[23,24,67—70] The main features of this form of oxygen are that (1) it exists on iron-containing active centres of ZSM-5 but not on Fe_2O_3 and many other iron-containing specimens investigated, (2) the energy of the bond between this form of oxygen and the surface is anomalously low and close to the bond energy in the O_2 molecule, (3) is it thermally stable up to 300 °C, above which it undergoes irreversible desorption, (4) it is formed on decomposition of N_2O but not on adsorption of O_2, and (5) it is highly reactive—it participates in O_2 isotope exchange at room temperature and oxidises CO and CH_4.

α-Oxygen has been compared with the thoroughly investigated surface oxygen radical-ions O^- and O_2^-.[71] The reactivity of the α-form is close to that of the O^- radical-ion,[72—74] but it exhibits a number of significant differences which preclude the identification of these two forms of oxygen. According to Haber's classification,[26] the α-form should be regarded as an electrophilic state of surface oxygen. According to Sheveleva et al.,[66] the ability to form the α-form of surface oxygen actually accounts for the specific behaviour of N_2O as a benzene oxidant. The mechanism of formation of phenol with participation of the α-form (O) can be represented by the following stages:

(1) $N_2O + ( ) \rightarrow N_2 + (O)$,
(2) $C_6H_6 + (O) \rightarrow (C_6H_5OH)$,
(3) $(C_6H_5OH) \rightleftarrows C_6H_5OH + ( )$.

The formation of phenol is not observed in the presence of catalysts which do not contain α-oxygen. This is indicated both by the results, already mentioned, which were obtained in the presence of ZSM-5 zeolites containing different transition metals (other than iron) and the results of tests on oxide and metallic systems presented in Table 2. This is likewise confirmed by numerous unsuccessful attempts, undertaken by ourselves jointly with Krivoruchko and Skripchenko, to synthesise active catalysts by introducing iron into various non-zeolite matrices (Al_2O_3, SiO_2, TiO_2, MgO, and ZnO). Neither the existence of the α-form nor the formation of phenol were observed in any of these instances.

It has been shown[24] that the rate of decomposition of N_2O is determined by the concentration of the active centres which fix the α-form of surface oxygen, and is described by a single relation, involving direct proportionality, which is valid for all the specimens of the Fe—Si and Fe—Al—Si systems. If the mechanism of the oxidation of benzene represented by stages (1)—(3) is valid, then the above single relation should also hold for this reaction. Indeed, if the degree of conversion of benzene is represented by its dependence not on the concentration of iron (as was done in Fig. 5) but on the concentration of the active centres c_α, then we obtained a single relation for all the test specimens, which is illustrated in Fig. 6. In contrast to the decomposition of N_2O, this relation reaches a plateau at a high concentration of α-centres, which can be explained by the inhibiting effect of the reaction product—phenol.[66] Starting with a certain value of c_α, this inhibition becomes so significant that it virtually compensates for the further increase in the number of active centres.

A quantum-chemical model of the active centres, which makes it possible to account for the characteristics of α-oxygen on Fe-ZSM-5, has been described.[75]

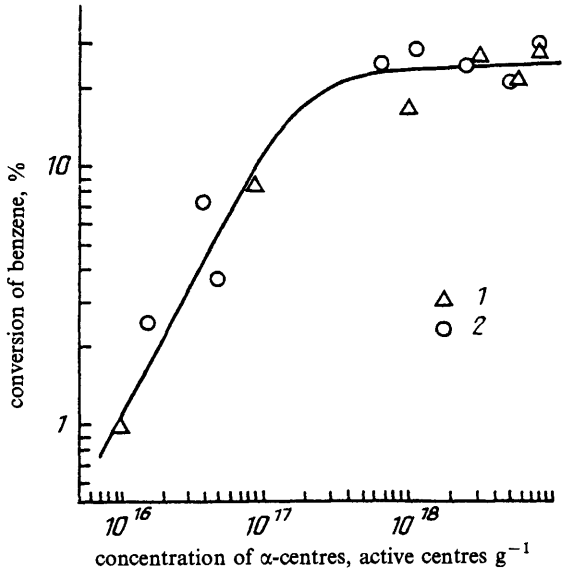

Figure 6. Dependence of the degree of conversion of benzene on the concentration of active centres on the Fe–Si and Fe–Al–Si ZSM-5 specimens at 350 °C. The reaction conditions were the same as in Fig. 2; *1*, Fe–Si; *2*, Fe–Al–Si.

Table 5. Prices of certain chemical products (USA, October, 1989).

Product	Price, U.S. dollars/tonne	Product	Price, U.S. dollars/tonne
Benzene	467	Catechol	4300
Nitrous oxide	507	Resorcinol	10000
Phenol	1091	Hydroquinone	4300

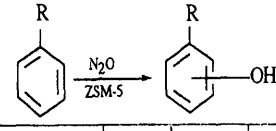
VI. Hydroxylation of benzene derivatives

The data published in the literature on the oxidation of benzene with nitrous oxide permit the conclusion that the best zeolite catalysts afford a yield of phenol up to 25–30% for a selectivity of 95–100%.[64,66] It must be admitted that, compared with numerous classical gas-phase oxidation processes, these results appear extremely modest. Thus in the oxidation of acrolein to acrylic acid[76] or of methanol to formaldehyde[77] in the presence of oxide catalysts, the yield of products reaches 95–98%. However, bearing in mind that this reaction is an alternative to the cumene process where the degree of convesion of the reactant in each of the three stages does not exceed 20–30%, the above parameters do not appear quite so bad.

According to the existing prices (Table 5), the expenditure on the raw material in the synthesis of phenol in terms of the above parameters should be 60–75% of the cost of the phenol, which can apparently ensure the competitiveness of the new process. This expenditure can be diminished somewhat by employing, instead of nitrous oxide of medical grade, a product with a lower degree of purification.

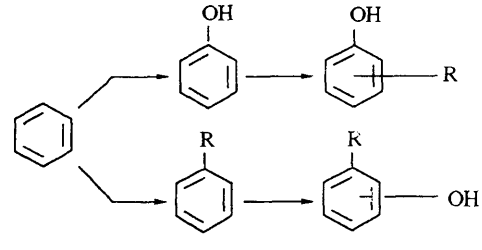
The question whether the given hydroxylation method is applicable to the preparation of more complex products which are more difficult to synthesise is important from the practical point of view. As can be seen in relation to dihydric phenols (Table 5), the cost of substituted phenols is much higher than that of phenol, so that the expenditure on nitrous oxide would no longer be significant in this case.

Table 6. Oxidative hydroxylation of benzene derivatives.



Initial compound	T, °C	X, %	S, %	Proportions of isomers, %			Refs.
				o	m	p	
Cl	330	6.7	100	58	$m \simeq p$		[54]
F	350	9.2	90.4	26.7	20.0	53.3	[55]
	400	11.0	90.4	31.1	22.7	46.2	
	450	15.2	85.3	24.4	23.7	51.9	
CH_3	350	48.1	22	$o \simeq m \simeq p$			[60]
OH	325	8.0	98	17	–	83	[60]
	350	11.5	92	18	–	82	

Two fundamentally different ways of synthesising benzene derivatives containing two substituents in the aromatic ring are possible:



These procedures differ in the sequence in which the functional groups are introduced. In view of the inadequate effectiveness of the existing hydroxylation methods, the first procedure is used nowadays in the vast majority of instances, i.e. phenol is synthesised initially and then the appropriate second group introduced with the aid of alkylation, halogenation, nitration, etc. processes.[46,47] In many cases, the processes in the second stage proceed non-selectively, require a large number of distillations, and afford a low yield of the product. For this reason, the search for effective aromatic ring hydroxylation methods, which would not involve the functional groups already introduced, is of considerable interest.

The hydroxylation of benzene derivatives with the aid of N_2O has so far been little investigated, although the possibility of such reactions in principle is not open to doubt. Table 6 presents the results of the oxidative hydroxylation of halobenzenes, toluene, and phenol. It is of interest to note that hydroxylation with the aid of nitrous oxide proceeds also when the aromatic ring contains deactivating substituents such as fluorine and chlorine, which (so far as we are aware) cannot be achieved in liquid-phase hydroxylation with the aid of peroxides.

In the oxidation of halobenzenes and toluene, hydroxylation takes place with formation of all three geometrical isomers, whereas in the oxidation of phenol, only the *o*- and *p*-isomers, i.e. catechols and hydroquinone (benzoquinone), are formed. The differences in the proportions of isomers may be associated both with the different nature of the substance oxidised and with the different chemical composition of the catalysts, the details of which are not reported in the patents.

VII. Conclusion

The earlier attempts in 1960–1970 to employ zeolites in oxidative catalysis did not yield positive results. This is because the transition metals introduced into the zeolite lose their ability to activate molecular oxygen. Although it has been possible in a number of instances to achieve effective parameters of the metal-containing zeolites, nevertheless they did not reach the level ensured by the best catalyst of the traditional type.

Studies carried out in the last decade led to a qualitative change in the situation. This was mainly promoted by two factors: the synthesis of high-silica zeolites of the type of pentasil and their metal-silicate analogues and the use of bound oxygen in the form of various oxygen-containing compounds.

The most effective among the oxygen-containing compounds proved to be H_2O_2 and N_2O. The results of the liquid-phase oxidation with hydrogen peroxide on titanosilicate zeolites are well known. They led to the development of a series of new methods for carrying out the reactions. In the present review, we attempted to draw attention to recent successes in the reactions involving gas-phase oxidation with nitrous oxide. The best parameters in this respect were achieved in the oxidation of benzene to phenol in the presence of iron-containing ZSM-5 zeolites. The uniqueness of this catalytic system is due to the existence of a specific form of surface oxygen formed on decomposition of the N_2O molecules.

Hydroxylation with the aid of nitrous oxide is particularly promising for the synthesis of complex compounds containing several functional groups in the aromatic ring. Studies on these lines are in an initial stage. The few, unfavourable data on the oxidation of benzene derivatives show that in this instance the reactions do not proceed quite so smoothly as in the oxidation of benzene itself and entail a reduced selectivity with respect to useful products. A faster deactivation of the catalysts is to be expected, although the existing patents to not report this.

Gas-phase reactions are known to have a series of important technological advantages over the liquid-phase version. However, analysis of the existing experimental data shows[78–80] that, when complex syntheses are carried out, these advantages may be lost as a consequence of the complications associated with the inadequate thermal stability of the reacting molecules and the difficulty of their desorption from the catalyst surface. Naturally, these complications must be taken into account in assessing the prospects of gas-phase oxidative hydroxylation. Nevertheless, the possibility of using an oxidant as readily available, safe, and cheap, as N_2O, which has considerable advantages over the oxidants used in the liquid phase, may significantly tip the scales in favour of this procedure. Furthermore, attention should be drawn to yet another important feature, namely the fact that the presence of deactivating substituents in the aromatic ring is not an obstacle to the introduction of a hydroxy-group with the aid of N_2O.

The importance of the search for new ways of hydroxylating aromatic compounds is so great that even the level of parameters already achieved is of practical interest. These parameters will undoubtedly be improved by a wide variety of methods for the modification of zeolites which permit a detailed adjustment of the most important characteristics of zeolites such as the chemical compositions of their internal and external surfaces, acidity, pore structure, steric selectivity, etc.[18,19,81–85] Hitherto, these procedures have not been used to optimise the catalysts of the oxidation with nitrous oxide.

An important step would also be to extend studies of this type to other classes of zeolites and zeolite-like materials, the number of which constantly grows by virtue of the advances in the adoption of new methods of their synthesis.[18,86,87] It may be hoped that further research will permit an appreciable increase in the effectiveness of this new method for the hydroxylation of aromatic compounds and probably its extension to other classes of organic substances.

The kinetics of gas-phase processes in systems containing carbon and sulphur

V S Arutyunov
Institute of Chemical Physics, Russian Academy of Sciences, Moscow

ABSTRACT. Data on the kinetics of the processes in gas-phase systems containing carbon and sulphur, which are of considerable importance in the combustion of sulphur-containing fuels, the reduction of industrial sulphur-containing gases, the industrial preparation of sulphur, etc., have been reviewed.

The bibliography contains 87 references.

I. Introduction

The kinetics of gas-phase reactions involving even basic sulphur-containing molecules have not been well studied. The principal results have been obtained in studies of the transformation of sulphur-containing compounds in the atmosphere,[1,2] their role in combustion and high-temperature corrosion,[3,4] and a number of model reactions (the oxidation of hydrogen sulphide,[5] carbon disulphide,[6] and various others). There has recently been a steady increase in the practical importance of gas-phase processes involving both sulphur-containing and carbon-containing compounds. These include the purification and processing of sulphur-containing natural gases,[7,8] the reduction of concentrated industrial sulphur-containing gases by hydrocarbons,[9,10] the production of gaseous sulphur[9,11] and carbon disulphide,[12] etc. The need to develop new industrial processes and to optimise existing ones arouses a natural interest in the kinetics and mechanism of these reactions. Unfortunately, there have been very few studies of the kinetics of gas-phase reactions involving compounds of sulphur and carbon, except for several model reactions (the oxidation of CS_2 and COS). There are very few published data on the rate constants of elementary reactions involving carbon- and sulphur-containing species.[13] Difficulties arise when attempts are made to extend generally accepted ideas about the decisive role of radical processes in complex gas-phase reactions, so clearly demonstrated in the description of the oxidation of hydrocarbons, to the kinetics of processes involving sulphur-containing molecules.

The present review attempts to summarise available data on the kinetics of gas-phase processes in systems containing compounds of sulphur and carbon.

II. The role of sulphur compounds and their transformation in the combustion and oxidation of hydrocarbons

The concentration of sulphur in different types of hydrocarbon fuel varies over a very wide range, in some cases amounting to several tens percent. The interest in the chemistry of combustion processes involving sulphur compounds is related to three basic problems: 1, the direct influence of sulphur compounds on combustion processes; 2, atmospheric pollution by sulphur-containing combustion products, principally SO_2;[3] and 3, high-temperature corrosion involving sulphur compounds, where a fundamental role is played by SO_3 molecules.[4,14]

A practically exhaustive review of work on combustion in sulphur-containing systems carried out up to 1972 has been published.[15] The presence of sulphur even in quantities less than 1%, particularly in rich mixtures, has a significant influence on all the characteristics of a process, namely temperature, rate of flame propagation, carbon formation, and the formation of NO_x. These effects are a direct manifestation of the chemistry of sulphur, primarily its influence on the concentration of radicals in the flame. The chemistry of sulphur compounds in hydrogen flames has been studied in most detail. Since the same processes predominate in hydrocarbon flames, it is appropriate to examine them briefly in this section.

Both experiments and numerical modelling show that even in rich flames, SO_2 is the predominant sulphur-containing compound, irrespective of the compound in which sulphur is introduced into the flame, although for rich mixtures the formation of H_2S, S_2, and other reduced compounds of sulphur is much more favourable from the thermodynamic viewpoint.[16] On the other hand, even in very lean mixtures it is rarely possible to detect sulphur trioxide SO_3 in quantities greater than several percent of the SO_2 concentration, and this also shows poor agreement with the result expected for thermodynamic equilibrium.[15] Elemental sulphur S_2 is the sulphur-containing species of second importance in flames, but its

concentration also does not reach the equilibrium values. The increase in the SO_2 concentration in rich flames leads to a predominant increase in the formation of S_2 from H_2S.[16]

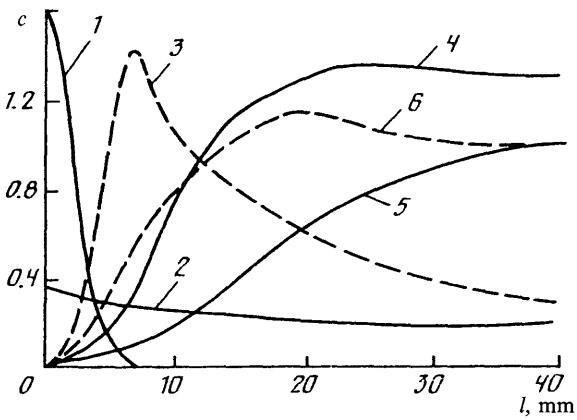

Figure 1. Experimental concentration profiles (c is the mole fraction) of the products in a laminar hydrogen flame $H_2/O_2/Ar$ containing 3% SO_2 (φ = 2.0, [Ar] = 37%, p = 150 torr);[16] *1*, 12.8[O_2]; *2*, 10[SO_2]; *3*, 400[SO]; *4*, 300[S_2]; *5*, 300[H_2S]; *6*, 4000[SH]; l is the distance along the flame.

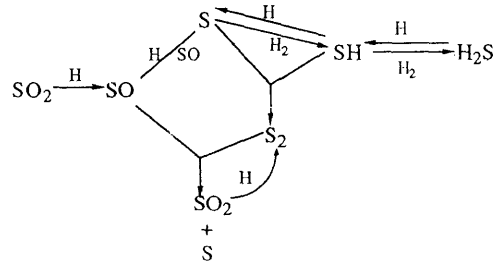
An important feature of sulphur-containing flames is their two-stage character. Even after the principal combustion processes are complete, sulphur compounds continue to undergo continuous processes of rearrangement, associated with a change in temperature and the concentration of radicals. A detailed experimental and theoretical study of sulphur-containing hydrogen flames[16] has shown that the principal intermediate product, from which all reduced compounds of sulphur are formed, is SO, which is rapidly formed in the main reaction zone in the presence of high concentrations of radicals, but its concentration decreases sharply when the main combustion process is complete (Fig. 1). Reduced compounds of sulphur (S_2, SH, H_2S) begin to be formed after the maximum concentration of SO has been passed, and the S_2 and H_2S concentration profiles are approximately the same. An important role in the chemistry of sulphur compounds in flames is played by diffusion processes. Practically all reduced compounds of sulphur formed in the later stages of the process diffuse back into the zone of lower temperatures and higher concentrations of radicals, where they undergo exothermic reactions to give more highly oxidised compounds. An important conclusion from the work cited,[16] confirmed by mathematical modelling, is that all the reduced compounds of sulphur are produced by the intermediate formation of S atoms, as shown in the diagram for the transformations of sulphur-containing compounds in a laminar hydrogen flame in the zone corresponding to the completion of the main oxidation processes



The most significant influence of sulphur on the processes in flames is related to its catalytic action in radical recombination processes. According to the proposed mechanism[17]

$$H + SO_2 + M \longrightarrow HSO_2 + M,$$
$$H + HSO_2 \longrightarrow H_2 + SO_2,$$
$$OH + HSO_2 \longrightarrow H_2O + SO_2,$$

the presence of sulphur has a significant influence on the concentration of radicals driving the chain process. Thus according to calculations,[16] the presence of up to 3% sulphur lowers the maximum concentration of H atoms by a factor of two, and their concentration in the post-combustion zone by a factor of more than ten. This naturally leads to the experimentally observed decrease in the rate of propagation of the flame and to the increase in the temperature in relatively cold rich flames by almost 100 K.[16,18]

Although the principal active sulphur-containing species S, SO, and SH have been identified experimentally in flames, attempts to record the presence in flames of the radicals HSO_2 and HSO_3, which according to existing ideas are responsible for the catalytic recombination of radicals, have as yet been unsuccessful, despite the fact that, according to calculations, HSO_2 is formed very rapidly in the flame, and the estimated $H-SO_2$ bond energy exceeds 48.5 kcal mol^{-1} and possibly reaches 63 kcal mol^{-1}.[19] Nevertheless, the real existence of these radicals can hardly be doubted. Their exclusion from the kinetic schemes gives values for the concentrations of reduced compounds of sulphur which are 10–100 times lower than the values actually observed. In addition to indications of the formation of these radicals in solid matrices, there are experimental indications of the existence in the gas phase of HSO_3 radicals with a lifetime of about 1 μs.[20] The catalytic influence of SO_2, which lowers the concentration of radicals in the flame, brings about a significant shift in the distribution of sulphur-containing species towards the formation of more highly reduced compounds of sulphur.[16]

There are experimental indications[21] of the possible existence under certain conditions of the opposite effect of promotion of slow oxidation processes by the reaction

$$HO_2 + SO_2 \longrightarrow SO_3 + OH,$$

but this requires more detailed study.

The formation and decomposition of sulphur trioxide are the most important processes in the zone after sulphur-containing flames. As already noted, even in a large excess of oxygen SO_3 is rarely formed in quantities greater than several percent of the SO_2 concentration. Nevertheless, the presence of even these small quantities of SO_3 is of considerable importance for the kinetics and

more particularly the technology of combustion processes. The principal channel for the formation of SO_3 is the reaction

$$O + SO_2 + M \longrightarrow SO_3 + M,$$

so that, for example, the quantity of SO_3 formed in the oxidation of carbon monoxide, where the concentrations of oxygen atoms are high, is much greater than in hydrogen and hydrocarbon flames. For the same reason, the addition to the flame of substances which react rapidly with oxygen atoms leads to a significant decrease in the SO_3 concentration.[15] These questions are closely related to the problems of corrosion by sulphur.

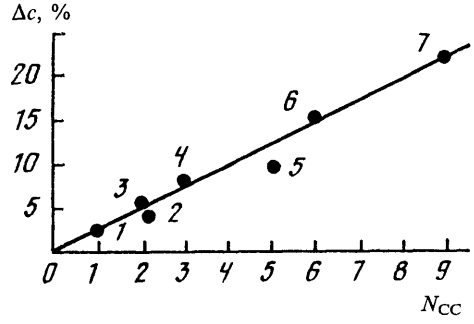


Figure 2. Influence of sulphur dioxide on the ignition limits of hydrocarbons; Δc, % is the required increase in the concentration of hydrocarbons for the addition of 20 torr SO_2 to its mixture with 200 torr oxygen (T = 700 °C);[15] N_{CC} is the number of C–C bonds in the hydrocarbon; *1*, ethane; *2*, acetone; *3*, ethylene; *4*, acetylene; *5*, n-hexane; *6*, cyclohexane; *7*, benzene.

The above processes involving sulphur-containing molecules predominate to the same extent in both hydrogen and hydrocarbon flames, and have been briefly examined here in order to give a more complete picture of the role of sulphur in oxidation processes. A specific feature of sulphur-containing hydrocarbon flames is the formation of CS_2, COS, and organosulphur compounds, and this has been much less extensively studied. Very little is known about the influence of SO_2 on the kinetics of the slow oxidation of hydrocarbons. It has been shown[22] that even at 200–250 °C the addition of SO_2 to a reaction mixture containing methane, n-hexane, methanol, or dimethyl ether leads to the formation of SO_3. In other studies of the slow oxidation of organic compounds,[23] however, only the presence or formation of oxides of nitrogen in the mixture led to appreciable consumption of SO_2, and from this it was suggested that at temperatures below 700 °C the rate of the reaction of SO_2 with oxygen-containing radicals (apart from O atoms) is negligible. The inhibiting influence of SO_2 is also revealed by the need to increase the partial pressure of the organic compounds in order to return the mixture to the ignition region.[23] In the ignition process, SO_2 apparently competes with the fuel for the chance to react with free radicals. A good correlation is observed between the quantity of added hydrocarbon required to compensate the influence of a given quantity of SO_2 and the number of C–C bonds in the molecule (Fig. 2). Since the rapid oxidative decomposition of the organic molecule must be preceded by the rupture of C–C bonds, the observed correlation suggests that SO_2 in some way is able to prevent this rupture.

The kinetics of the formation of sulphur-containing products have been studied[3] for different oxidation conditions and different hydrocarbons and sulphur-containing molecules. Flames of propane, methane, acetylene, and also hydrogen and its mixtures with carbon monoxide in the temperature range 1580–1800 K were studied. The sulphur-containing additives used were 0.23 mol% thiophen C_4H_4S and H_2S or 0.23–0.4 mol% SO_2. The relative deviation of the composition of the mixture from the stoichiometric fuel : oxidant ratio varied in the range φ = 0.6–1.7.

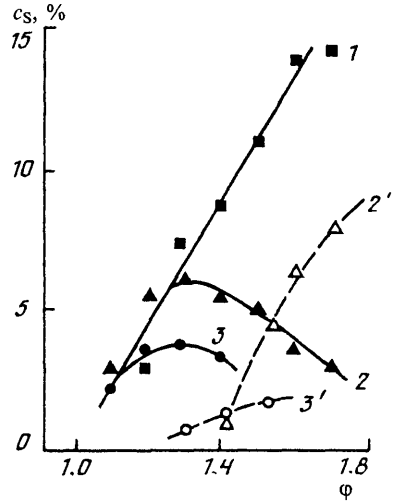

Figure 3. Concentration of sulphur (c_S) as hydrogen sulphide (*1–3*) and cabron disulphide (*2',3'*) in hydrogen and hydrocarbon flames for different values of φ (T = 1802 K, p = 0.92 atm);[3] *1*, H_2; *2,2'*, C_2H_2; *3,3'*, C_3H_8.

In the combustion of hydrocarbons with the addition of H_2S or SO_2, the following stable sulphur-containing products were detected: SO_2, SO_3, H_2S, COS, and CS_2. When C_4H_4S was used as the sulphur-containing additive, it was also detected in the combustion products. Other organosulphur molecules, including thiols, were not detected. For non-hydrocarbon flames, in addition to SO_x, only H_2S was detected. As already noted, SO_2 is always the predominant product. In lean mixtures, not more than 2–3% of the total sulphur is present as SO_3, and in rich mixtures the total concentration of sulphur in all other compounds (H_2S + COS + $2CS_2$ + C_4H_4S) does not exceed 20% (the sulphur concentration balance was determined for a propane flame at 1700 K). The type of compound containing the added sulphur had no significant influence on the yield of H_2S, CS_2, and COS. In contrast to the linear increase in the yield of H_2S in a hydrogen flame with increase in φ, in hydrocarbon flames this increase takes place only up to a certain value of φ, which corresponds to the start of the appearance of CS_2 and COS (Fig. 3). The start of the decrease in the H_2S concentration also coincides with the appearance of appreciable

quantities of unburned carbon, indicating the preferential formation of CS_2 and COS with increase in the quantity of unburned hydrocarbon in the gases. As shown below (section III), CS_2 in fact becomes the principal primary sulphur-containing product when there is a large deficit of oxygen in the system.

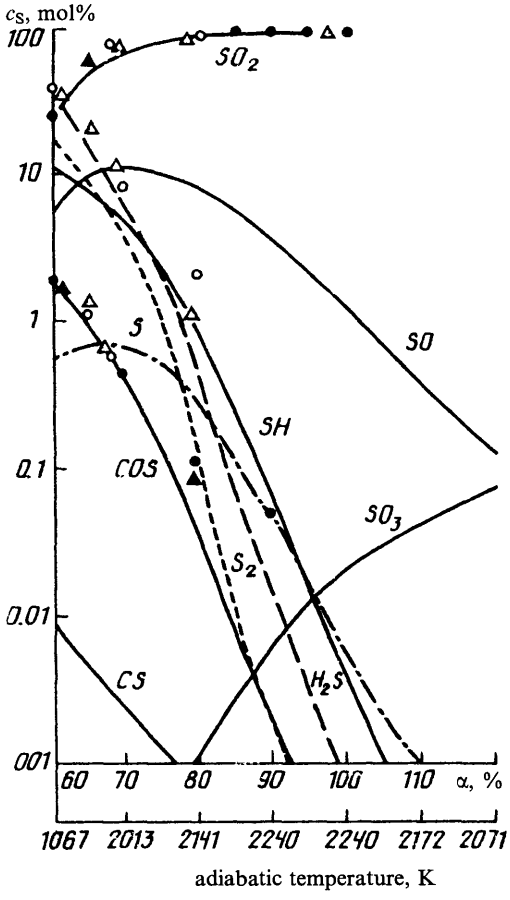

Figure 4. Equilibrium distribution of sulphur-containing components in a propane–air flame at an initial SO_2 concentration of 1%; the points correspond to the experimental data;[15,24] α is the fuel : air ratio (as a percentage of the stoichiometric ratio).

Increase in temperature naturally increases the part played by labile compounds of sulphur, so that in flames at 1500–2000 °C the equilibrium concentrations of these labile species may reach appreciable values. At these high temperatures, the attainment of the thermodynamically equilibrium composition of these products in the flames may be expected, but when the gases are cooled this equilibrium may be quenched before cooling is complete. Thermodynamic calculations of the composition of the products from hydrocarbon flames containing sulphur have been carried out.[24] The results are given in Fig. 4 as a function of the fuel : air ratio (as a fraction of the stoichiometric ratio $\varphi = 1$). Even with an air deficit of 20%, 90% of the sulphur is present as SO_2, and almost all the rest is present as SO. It is only at an air deficit of 40% that appreciable quantities of H_2S, S_2, and SH are present in addition to SO_2. With a 20% excess of air, however, less than 0.1% of the sulphur was present as SO_3. An interesting feature is that the calculation of the compositions of sulphur-containing hydrogen flames gives similar results.[4]

There have been practically no studies of the kinetics of the combined oxidation of hydrocarbons and sulphur-containing compounds at comparable concentrations. The practical interest in this topic is related primarily to the processing of natural gas with a high concentration (greater than 10%) of sulphur dioxide and the reduction of concentrated sulphur-containing gases by hydrocarbons. The marked difference in the reactivities of hydrogen sulphide and organosulphur compounds compared with that of alkanes, in particular methane, suggests that the processes involved in the oxidation of these compounds may be largely independent; this will be examined in more detail in section VI. Some data on the influence of high SO_2 concentrations on the combustion of mixtures of natural gas with air and oxygen have been published.[25] The tip of the peninsula of the range of flame propagation in a natural gas–air–carbon dioxide mixture corresponds to a concentration of 25% CO_2 in the mixture, whereas for sulphur dioxide this value is lowered to 16% SO_2. Since in the range 1100–1800 °C CO_2 and SO_2 have almost identical thermodynamic properties, the increased flame-extinguishing action of SO_2 compared with CO_2 is apparently related to the chemical inhibiting action of SO_2 on the chain process of methane combustion. For mixtures of natural gas and oxygen, the difference between the influences of CO_2 and SO_2 is even less marked, apparently because of the greater intensity of combustion of the oxygen flames.[25]

We carried out experiments to determine the range of stable combustion of methane–air mixtures containing up to 20% of added sulphur dioxide. The results agree well with published data.[25] Although sulphur dioxide shows a slightly stronger inhibiting action than carbon dioxide, the difference is not so dramatic as might have been expected from the results of studies using low concentrations of sulphur dioxide. With increase in the concentration of sulphur dioxide, the chemistry of the processes taking place evidently changes, and the role of sulphur dioxide is not limited to its participation in the catalytic recombination of radicals, particularly in the combustion of rich mixtures, where it may become the supplier of the additional oxygen required for oxidation. The results indicate that the stable combustion of methane–air mixtures containing up to 20% sulphur dioxide is possible in principle.

Unfortunately, up to the present it has apparently not even been possible to construct more or less adequate kinetic models of the transformation of sulphur-containing compounds in the combustion of hydrocarbons, and all attempts undertaken in this direction have been largely speculative in character.

III. The gas-phase reduction of sulphur dioxide by hydrocarbons

The largest group of kinetic studies of systems containing carbon and sulphur has been carried out on the reduction of industrial sulphur-containing gases by various hydrocarbons. Solid, liquid, and gaseous hydrocarbons have been used,[9] but the use of gaseous hydrocarbons (natural gas) appears to be most fully developed.

The high-temperature homogeneous reduction of concentrated sulphur-containing gases by natural gas has passed industrial tests at

the Noril'sk mining and metallurgical combine for processing waste gases from metallurgical processes with a sulphur dioxide concentration of up to 20%. The concentrated sulphur-containing waste gases are purified, and commercial sulphur is produced.[10] At the high-temperature reduction stage, the yield of sulphur is 55–60%. The total yield of sulphur with allowance for subsequent catalytic completion of reduction by the Klaus method is 80–85%. The process was first patented in 1933,[26] and tested industrially in the nineteen-forties,[27,28] but not even the most general ideas about its mechanism have been published.

Available data on the thermodynamics of the reduction of sulphur dioxide by methane show that the reaction can take place almost to completion at temperatures of 1250–1350 °C. Data on the composition of the equilibrium gaseous mixtures, found with allowance for side reactions, have been published.[29] They show that the equilibrium yield of sulphur increases with increase in temperature and with increase in the molar ratio $SO_2:CH_4$, reaching 100% at $SO_2/CH_4 = 2$ and $T > 1300$ °C. In addition, the equilibrium yield of sulphur increases with decrease in pressure.

Some of the first studies of the kinetics of the heterogeneous–homogeneous reduction of sulphur dioxide by methane were carried out by Yushkevich and co-workers,[30] Zawadzki and co-workers,[31] and Walker.[32] Yushkevich studied the kinetics of the two-stage reduction of sulphur dioxide by methanol at 700–1000 °C on bauxite with subsequent conversion of the gaseous sulphur compounds at 370 °C on the same catalyst. At a sulphur dioxide concentration of 14.7%, a ratio $SO_2/CH_4 = 2$, and a flow rate of 350 h^{-1}, the yield of sulphur was 85% at 900 °C, 82% at 800 °C, and 13% at 700 °C. According to these studies, the reaction is heterogeneous–catalytic up to a temperature of 1000 °C, and the products at thermodynamic equilibrium should be sulphur or carbon disulphide.[32] At low ratios $N = SO_2/CH_4$, that is in an excess of methane, reduction to hydrogen sulphide takes place.

Zawadzki[31] studied the process in quartz reactors at a ratio N = 2.2–3.4 and temperature of 820–1135 °C, and found that on quartz the reaction takes place only at $T > 800$ °C; up to 1050 °C the reaction is apparently heterogeneous, and above 1050 °C it takes place in the gas phase. In addition to elemental sulphur, large quantities of COS and CS_2 are formed. The formation of large quantities of COS is not consistent with thermodynamic considerations, so that the authors cited suggested that on quartz the reaction is retarded at an intermediate stage, and that carbonyl sulphide is unstable and can decompose in two directions:

$$COS \longrightarrow CO + S,$$
$$2COS \longrightarrow CS_2 + CO_2.$$

Berkman and Kushnir[33] made a detailed study of the methane process in a quartz flow reactor, and they consider that the conclusion that large quantities of COS are formed is based on unreliable methods of analysis, and that carbon disulphide is the principal and primary product of the non-equilibrium reduction of sulphur dioxide by methane. The influence of the reagent ratio $N = SO_2/CH_4$ on the composition of the products at 800 °C was also studied. The results show that the principal reduction product in all cases is carbon disulphide and that its yield is almost independent of the reagent ratio and corresponds to approximately two thirds of the reduced sulphur. The sum $H_2S + S$ is therefore also almost constant, and over a wide range of $N > 0.4$ the principal product is sulphur, and hydrogen sulphide becomes the predominant product only at very high methane concentrations ($N < 0.4$). The methane oxidation products CO and CO_2 are present in the approximate ratio 2:1.

Increase in temperature increases the extent of the reduction (at a constant rate of supply of the gases $V = 22$ ml min^{-1}) and decreases the yield of carbon disulphide.[33] The decrease in the yield of carbon disulphide at low values of N (excess of the reducing agent) leads to an increase in the yield of hydrogen sulphide for a constant yield of sulphur. At high values of N the decrease in the yield of carbon disulphide is accompanied by an increase in the yield of sulphur, and there is practically no hydrogen sulphide. The methane oxidation products are CO and CO_2; at $N < 1$, as a result of a deficit of the oxidising agent SO_2, increase in temperature leads to a marked increase in the yield of CO, whereas at $N > 2$ the yield of carbon dioxide increases. The rate (extent) of the reduction at 800 °C also depends on the type of quartz (non-transparent quartz is approximately two times more active) and on the time for which it has been used.[33] The catalytic activity gradually decreases by a factor of almost four, and neither heating in a stream of oxygen nor treatment with hot acids increases the established catalytic activity of the quartz. The relative distribution of the sulphur-containing products of the reduction of sulphur dioxide by methane, however, is not influenced by the difference in the catalytic activities of different types of quartz, or by change in the contact time, or by the decrease in the activity with time, which influence only the extent (that is the rate) of the reduction.

The methane reduction of sulphur dioxide at concentrations of 10–100% and at higher temperatures up to 1250 °C has been studied.[29] The process was carried out in quartz flow reactors with an internal diameter of 4–23 mm and a length of 38–100 mm at a constant flow rate of the mixture of 2.4 litre h^{-1}. The separation of carbon was observed in the reaction zone at 900 °C and sometimes at 1100 °C, but not at 1250 °C. Experiments were also carried out on the reduction by domestic gas, shown by chromatographic analysis to contain about 14% ethane, 80% propane, and some methane and nitrogen. The results of the experiments at 1100 °C and 1250 °C were approximately the same as those for the reduction by methane.

It has been concluded[29,32] that the rate of the reduction of sulphur dioxide by methane is controlled by the rate of its thermal decomposition. Describing the rate of the thermal decomposition of methane by the first-order equation:

$$-\frac{d[CH_4]}{dt} = K[CH_4] = A\exp(-E/RT)\,[CH_4]$$

and taking for the rate constant the value $k = 7.08 \times 10^{13} \exp(-87250/RT)$ s^{-1}, the authors cited[29] calculated the kinetics of the thermal decomposition of methane and compared them with the experimentally observed kinetics of the transformation of sulphur dioxide. Satisfactory agreement between the calculated and experimental curves was obtained.

The conclusion[34,35] that sulphur dioxide reacts with methane only after oxygen is used up is interesting. These results were obtained in a study of the kinetics of the reaction and the yield of products in the $SO_2–CH_4–O_2$ system under flow conditions in the presence of a catalyst ($T = 732–831$ °C).

Some data of interest for an understanding of the mechanism of the process were also obtained in practical work on the extraction of sulphur from rich metallurgical gases. In particular, the technological parameters of the high-temperature process depend markedly on the initial concentration of oxygen in the gases being

processed,[36] the presence in the gases of water vapour (up to 5–7% in real gases), and other factors. Increase in the oxygen concentration leads to a decrease in the degree of conversion; in addition, oxygen brings about additional heating of the reaction mixture by the heat of the reaction.[9] Published studies[36] showed that the extent of the reduction of sulphur dioxide by methane depends on the flow rate of supply of the reagents.

A detailed study of the kinetics of the reduction of sulphur dioxide by methane in the temperature range 1000–1360 K has been carried out.[37,38] The process was carried out under static conditions in quartz reactors with a diameter of 21–46 mm. The kinetics of the process were followed from the infrared and ultraviolet spectra of the reagents and products.

The following equations of first-order reactions were obtained for the maximum rate of consumption of the reagents:

$$-\frac{d[CH_4]}{dt} = 6.5\cdot10^{10}\exp(-72000/RT)\,[CH_4]\ cm^{-3}\ s^{-1}$$

$$-\frac{d[SO_2]}{dt} = 2.7\cdot10^{9}\exp(-64000/RT)\,[SO_2]\ cm^{-3}\ s^{-1}.$$

These results indicate that the rate of consumption of methane in this system and the rate of the thermal decomposition of pure methane practically coincide.[39] In any case, in the temperature range 1100–1500 K the rates of these processes do not differ by a factor of more than 2, which is much smaller than the scatter in the experimentally determined rates of the thermal decomposition of methane.[40] The activation energy of the decomposition of methane in this system (72 ± 3 kcal mol^{-1}) is close to the activation energy of the thermal decomposition of pure methane.[39,40] The good agreement between the rate of the thermal decomposition of pure methane, the rate of consumption of methane in the system and the rate of reduction of sulphur dioxide (with allowance for the stoichiometry of the reaction) shows that the thermal decomposition of methane is in fact the limiting stage of the process.

Figure 5 gives the kinetics of the reduction of sulphur dioxide by methane at a ratio $SO_2:CH_4 = 2:1$ and $T = 1200$ K. The similar behaviour of the starting materials can be clearly seen, indicating that their decompositions are limited by the same processes. As in the thermal decomposition of pure methane,[39] the kinetic curves show a section corresponding to acceleration of the reactions, that is the process is self-accelerating. The highest rate of decomposition of methane in this reaction is proportional to its concentration and depends very little on the concentration of sulphur dioxide. The maximum rate of change in the sulphur dioxide concentration is proportional to the concentration of sulphur dioxide and the concentration of methane, but only until the stoichiometric ratio $SO_2:CH_4 = 2$ is reached. At higher concentrations of methane it no longer influences the maximum rate of decomposition of sulphur dioxide.[37]

The principal primary product of the reduction of sulphur dioxide is carbon disulphide, and the start of appreciable formation of this product coincides with the end of the induction period; the highest concentration is reached at the same time as the highest rate of consumption of sulphur dioxide and methane. Its concentration subsequently decreases rapidly to almost zero. The highest concentration of carbon disulphide corresponds to almost 70% of the total change in the concentration of sulphur dioxide at that moment ($2[CS_2]_{max} \simeq 0.7\Delta[SO_2]_{t_{max}}$), and with allowance for its partial decomposition it can be stated that not less than 95% of the sulphur dioxide is converted initially into carbon disulphide. Thus carbon disulphide is not merely the principal but the only primary product of the reduction of sulphur dioxide by methane.

The formation of another sulphur-containing product, namely carbonyl sulphide, is observed much later, and its highest concentration is reached after the stage corresponding to the rapid decomposition of sulphur dioxide and methane. It is therefore a secondary product, formed most probably by the familiar reactions of carbon disulphide with other products of this process

$$CS_2 + CO_2 \longrightarrow 2COS,$$
$$CS_2 + H_2O \longrightarrow COS + H_2S.$$

In these reactions, only a small fraction of the carbon disulphide is apparently removed, since the highest concentration of COS is approximately one fifth of the highest concentration of carbon disulphide, although the concentration of carbon oxide sulphide decreases much more slowly than that of carbon disulphide, and COS is one of the stable end products.

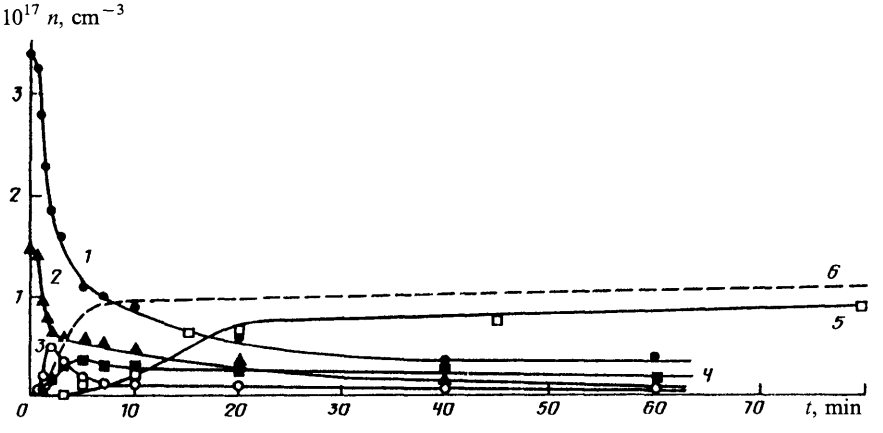

Figure 5. Kinetics of the change in the concentration of the products; $T = 1200$ K; $p = 440$ torr; $[SO_2] = 10\%$; $[CH_4]_0 = 5\%$;[38] *1*, SO_2; *2*, CH_4; *3*, CS_2; *4*, COS (relative units); *5*, H_2S; *6*, S_2 (estimated).

Hydrogen sulphide is a tertiary product of the reduction of sulphur dioxide by methane, since its formation begins after the highest concentrations of CS_2 and COS have been reached and is apparently directly related to their decomposition. In a large excess of sulphur dioxide, the formation of hydrogen sulphide is not observed at all, or takes place after a long time as a result of reactions between secondary reaction products. The highest yield of hydrogen sulphide (about 100%) is observed only with identical concentrations of sulphur dioxide and methane.

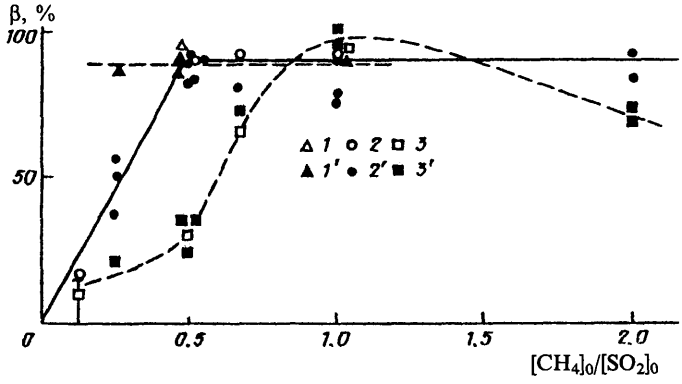

Figure 6. Dependence of the extent of the transformation of the reagents (β) on the ratio $[CH_4]_0/[SO_2]_0$; T = 1200 K; p = 440 torr;[38] *1*, $\Delta CH_4/(CH_4)_0$; *2*, $\Delta SO_2/(SO_2)_0$; *3*, $H_2S/\Delta SO_2$; reaction time: *1*–*3*, 30–50 min; *1'*, *2'*, *3'*, 60–80 min.

The formation of elemental sulphur begins at practically the same time as the formation of carbonyl sulphide. Thus sulphur is also a secondary product of this reaction, and its concentration fairly rapidly reaches a stationary level. For a ratio $SO_2:CH_4$ = 2, corresponding to the overall equation

$$2SO_2 + CH_4 \longrightarrow CO_2 + 2H_2O + S_2,$$

the distribution of sulphur in the principal products for fairly long reaction times at 1200 K is as follows: S_2 ~65, H_2S ~25, $SO_2 \leqslant 9$, and COS ~1%, that is the actual overall equation for the reaction is approximately:

$$4SO_2 + 2CH_4 \longrightarrow 2CO_2 + 3H_2O + H_2S + 5/4S_2 + 1/2SO_2.$$

At a higher concentration of methane, corresponding to a ratio $SO_2:CH_4$ = 1, the composition of the final products changes sharply towards the formation of hydrogen sulphide ($H_2S \geqslant 86\%$, $SO_2 \leqslant 9\%$, $COS \leqslant 4\%$, $S_2 + CS_2 < 1\%$), that is the relative yield of hydrogen sulphide $(H_2S/\Delta SO_2)_\infty$ tends to 100% (Fig. 6). This corresponds to the equation

$$SO_2 + CH_4 \longrightarrow CO + H_2O + H_2S.$$

With an even greater excess of methane, the relative yield of hydrogen sulphide again decreases. Here we should expect the appearance of the principal products of the thermal decomposition of methane, primarily hydrogen, C_2 hydrocarbons, and solid carbon.

Thus in the reduction of sulphur dioxide by methane, the following sequence of transformations of sulphur-containing products takes place:

$$SO_2 \rightarrow CS_2 \rightarrow COS \text{ and } S_2 \rightarrow H_2S.$$

The decomposition of carbon disulphide, which is the direct precursor of all other reaction products, is the next limiting stage of the process after the thermal decomposition of methane. It is therefore extremely important to determine the mechanism and rate of its transformation in this system. Published data[38] indicate that the decomposition of carbon disulphide involves its direct reaction with sulphur dioxide (Fig. 7). The rate of the thermal decomposition of pure carbon disulphide is one tenth of that in the $SO_2 + CH_4$ reaction. The presence of methane increases the rate of the decomposition of carbon disulphide at 1200 K by a factor of ~3, but only the reaction with sulphur dioxide can explain the observed kinetics of the decomposition of CS_2 in the $SO_2 + CH_4$ system.[38]

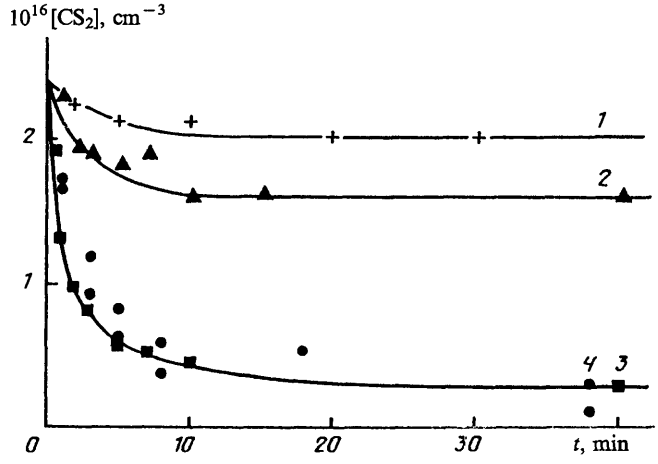

Figure 7. Kinetics of the decomposition of carbon disulphide; T = 1200 K, p = 440 torr; the initial concentrations of carbon disulphide are reduced to the same value $[CS_2]_0 = 2.4 \times 10^{16}$ cm^{-3};[38] *1*, thermal decomposition of CS_2; *2*, reaction of $CS_2 + CH_4$, $[CH_4]_0 = 1.75 \times 10^{17}$ cm^{-3}; *3*, reaction of $CS_2 + SO_2$, $[SO_2]_0 = 3.5 \times 10^{17}$ cm^{-3}; *4*, reaction of $SO_2 + CH_4$, $[SO_2]_0 = 3.5 \times 10^{17}$ cm^{-3}, $[CH_4]_0 = 1.75 \times 10^{17}$ cm^{-3}.

The extent of the transformation of sulphur dioxide in a deficit of methane increases regularly with increase in the concentration of methane in accordance with the stoichiometric ratio $\Delta[SO_2] = 2[CH_4]_0$. When this stoichiometric ratio and higher concentrations (an excess) of methane are reached, the degree of transformation of sulphur dioxide exceeds 90%.

The degree of transformation of sulphur dioxide into hydrogen sulphide (the relative yield of hydrogen sulphide) $H_2S/\Delta SO_2$ in a deficit of methane also increases regularly from $\leqslant 20\%$ at CH_4/SO_2 = 1:8 to ~30% at the stoichiometric ratio CH_4/SO_2 = 1:2 and to almost 100% at CH_4/SO_2 = 1:1, after which it

decreases again to 70% at $CH_4/SO_2 = 2:1$. Thus by controlling the ratio of methane and sulphur dioxide it is possible to control the ratio of the final concentrations of sulphur dioxide and hydrogen sulphide in the reaction products.

There are practically no published data on the kinetics of the reduction of sulphur dioxide by other gaseous hydrocarbons, except for acetylene.[41] The interest in acetylene is due to the fact that it is the principal hydrocarbon product of the thermal decomposition of methane,[39,40] and may play an important role in the high-temperature reduction of sulphur dioxide.

Studies in the temperature range 1000–1200 K[41] showed many common features in the reduction of SO_2 by methane and by acetylene, although acetylene reacts with SO_2 several times more rapidly. In this temperature range, simultaneous thermal decomposition of acetylene takes place,[42] and the rate of decomposition of acetylene under the conditions of the work cited[41] was much greater than the rate of change in the concentration of sulphur dioxide; the temperature dependence was approximately the same for these processes, and corresponded to an activation energy of ~45 kcal mol^{-1}. At lower temperatures (1000 K), a short period of auto-acceleration which is usually observed in the thermal decomposition of acetylene,[42] was noted.

The markedly different rates of the thermal decomposition of acetylene and the reduction of sulphur dioxide, together with the zeroth order of the rate of reduction of SO_2 with respect to acetylene, indicate that the reduction involves the reaction of sulphur dioxide with the thermal decomposition products of acetylene.

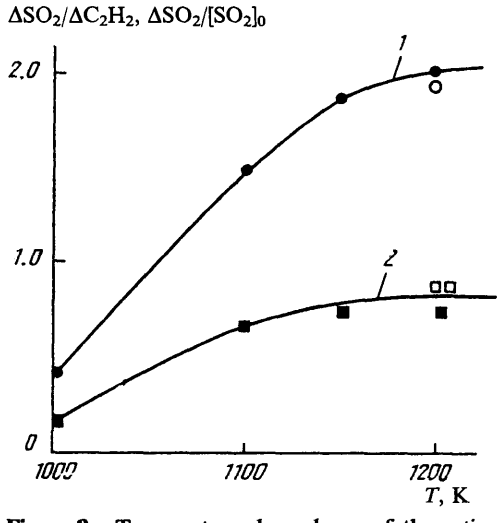

Figure 8. Temperature dependence of the ratios $\Delta SO_2/\Delta C_2H_2$ and $\Delta SO_2/[\Delta SO_2]_0$; black points—reactor with diameter 21 mm; open points—reactor with diameter 46 mm;[41] *1*, $\Delta SO_2/\Delta C_2H_2$; *2*, $\Delta SO_2/[SO_2]_0$.

In addition to sulphur, the principal sulphur-containing products of the process, recorded from their infrared spectra, are CS_2 and COS. As in the reaction of SO_2 with CH_4,[38] CS_2 is the principal and apparently the only primary product of the decomposition of sulphur dioxide. The formation of COS takes place much later, and is probably associated with the decomposition of CS_2 in the presence of SO_2. The highest concentrations $[CS_2]_{max}$ and $[COS]_{max}$ are apparently determined only by the rate of reduction of sulphur dioxide, and therefore are also independent of the initial concentration of acetylene. In an excess of acetylene, the formation of carbon is observed. Small quantities of methane are also formed, evidently by thermal decomposition.

Increase in temperature increases the ratio of the change in the concentration of sulphur dioxide to the change in the concentration of acetylene $\Delta SO_2/\Delta C_2H_2$ from 0.4 to 1000 K to 2.0 at 1200 K (Fig. 8). This may be related to a change in the mechanism and hence in the products of the thermal decomposition of acetylene, in which polymerisation products predominate at $T < 1200$ K, while at higher temperatures there is an increase in the contribution made by processes involving small radicals.[42] Another reason may be a change in the mechanism of the reaction of sulphur dioxide with the thermal decomposition products of acetylene. Evidence that the reduction of sulphur dioxide involves the thermal decomposition products of acetylene is provided by the change in the quantity $\Delta SO_2/\Delta C_2H_2$ during the reaction (Fig. 9). As the thermal decomposition products are used up, this ratio increases from zero to ~1.5 at 1100 K and ~2 at 1200 K. The degree of reduction of sulphur dioxide $\Delta SO_2/[SO_2]_0$ increases with increase in temperature is approximately the same way as the quantity $\Delta SO_2/\Delta C_2H_2$ (Fig. 8).

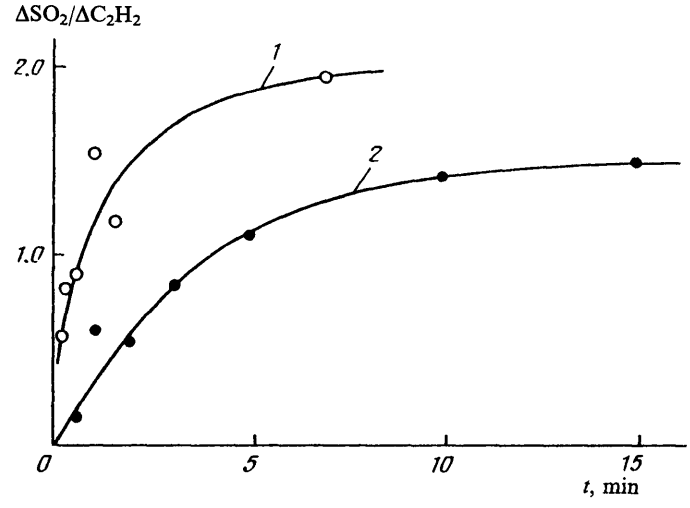

Figure 9. Time dependence of the ratio $\Delta SO_2/\Delta C_2H_2$; p = 440 torr, reactor diameter 21 mm; *1*, 1200 K; *2*, 1100 K.[41]

Thus the reduction of sulphur dioxide by acetylene and the reduction of sulphur dioxide with methane have a number of common features. From available data on the reaction of sulphur dioxide with methane and with acetylene, an attempt can be made to formulate some general conclusions about the mechanism of the reaction of SO_2 with hydrocarbons.

1. The limiting stage of the process is the thermal decomposition of the hydrocarbon.

2. The presence of sulphur dioxide does not lead to significant changes in the kinetics of the decomposition of the hydrocarbon.

3. A decisive role in the reduction is played by the reaction of SO_2 with the thermal decomposition products, primarily H_2.[43,44]

4. The rate of reduction is linearly dependent on the sulphur dioxide concentration.

5. The primary and apparently the only primary stable product of the reduction of SO_2 is CS_2. The sulphur-containing products are formed by the sequence

$$SO_2 \rightarrow CS_2 \rightarrow COS \text{ and } S_2 \rightarrow H_2S.$$

6. The subsequent decomposition of CS_2 involves its reaction with SO_2 to give COS, S_2, and other products.

7. The final degree of reduction of sulphur dioxide increases smoothly to 90–100% with increase in the hydrocarbon : sulphur dioxide ratio. At the same time the extent of the transformation of sulphur dioxide into elemental sulphur decreases.

IV. The formation of carbon disulphide and carbonyl sulphide in gas-phase processes

Carbon disulphide is one of the most important chemical products, and is required for the production of synthetic fibres, flotation reagents, vulcanisation accelerators, poisons, etc. In the nineteen-sixties, the intensive introduction of new industrial methods for obtaining carbon disulphide from natural gas and sulphur began, making it possible to establish large-scale fully automated processes.[12,45] The industrial process is carried out in the presence of a catalyst at a temperature up to 660 °C and a degree of transformation of methane up to 96%.[12] The kinetics of the process have been studied.[46] A large number of new studies are published annually on the technology of the production of carbon disulphide by this method using different modifications of the catalyst and different process conditions.[12,45] Heavier hydrocarbons containing three or more carbon atoms react readily with sulphur, and give a large quantity of carbon disulphide for every molecule of original sulphur and a correspondingly smaller quantity of hydrogen sulphide per molecule of carbon disulphide formed. The reaction of sulphur with higher hydrocarbons takes place much more rapidly with almost 100% conversion. In the catalytic process, however, the presence of propane and heavier hydrocarbons leads to the formation of carbon and tarry substances, including their formation on the catalyst, and also to the production of thiols, thiophens, and organic sulphides, so that the natural gas is purified beforehand to remove these hydrocarbons.[12]

In addition to catalytic methods, purely homogeneous methods have been proposed for carrying out this process at higher temperatures.[47–53] Patents have been published on the synthesis of carbon disulphide from paraffin hydrocarbons at 700–1300 °C,[47] accompanying petroleum gases,[48] and other hydrocarbons. A method for obtaining carbon disulphide by the reaction of saturated hydrocarbons with sulphur vapour and sulphur dioxide at 500–900 °C in 0.1–2 s has been described.[49] The disadvantages of this method are the low yield of CS_2 (42.5–50%) and the formation of side products. To eliminate these disadvantages, it is suggested that alkenes, dialkenes and heavier hydrocarbons be used as the carbon-containing starting material.[53] The process takes place at 500–900 °C at atmospheric or elevated pressure in 1.5–4 s with a yield of up to 80–91%. It is known, however, that unsaturated hydrocarbons, reacting with sulphur, give a large quantity of organic sulphur compounds as side products.[45] The kinetics of the gas-phase reaction of sulphur vapour with hydrocarbons have not been studied.

It has been suggested that carbon disulphide can be obtained by the reaction of sulphur vapour with carbon monoxide at 510–650 °C both in the gas phase[54] and in the presence of a catalyst.[55]

The use of various waste gases containing sulphur and hydrogen sulphide as the sulphur-containing starting material for the synthesis of carbon disulphide and carbon oxide sulphide is of considerable practical interest. A 26–70% yield of carbon disulphide at 1180 °C and 1280 °C without the use of a catalyst has been reported,[56] but other workers[57] obtained no carbon disulphide in the products of the homogeneous reaction in quartz tubes at temperatures of 900–1100 °C. Only the addition of a catalyst (kaolin impregnated with $K_2Cr_2O_7$) made it possible to obtain a 50% yield of CS_2,[57] so that it was suggested[45] that the quartz surface of the assembly in the work cited[56] had a catalytic action. Although the synthesis of CS_2 from methane and hydrogen sulphide has not yet found practical application, it has been suggested that this process may be promising if oxygen-containing gases or free oxygen are added to the reaction mixture.[45]

The formation of carbon disulphide and carbon oxide sulphide in the reaction of sulphur dioxide with methane was detected even in early studies.[31–33] This gas-phase process has been used with the simultaneous supply of sulphur vapour and sulphur dioxide for reaction by the hydrocarbon.[49,53] The kinetics of the formation of carbon disulphide and carbonyl sulphide by the reaction of sulphur dioxide with methane, acetylene, and carbon monoxide have been the subject of a series of detailed studies[37,38,41,58,59] (see sections III and V).

V. The kinetics and mechanism of the processes in the C–S–O system

The oxidation of carbon disulphide and carbonsyl sulphide is one of the most extensively studied gas-phase processes in the chemistry of sulphur. The available experimental data cover a wide range of temperatures (300–2000 K) and pressures (1–2000 torr) and include reactions under flow and static conditions, atomic flames, and experiments in shock tubes.[6] In addition, published data[13] on the rate constants of the elementary reactions in these processes have been used to construct a sufficiently adequate kinetic model, providing a satisfactory description of the published experiments.[6] An analysis of the kinetic model made it possible to select the most important reactions for the oxidation of CS_2:

$$CS_2 + O = CS + SO, \quad CS + O = CO + S,$$
$$CS_2 + O = COS + S, \quad S + O_2 = SO + O,$$
$$SO + O_2 = SO_2 + O,$$

and the oxidation of COS:

$$COS + O = CO + SO, \quad CO + SO = CO_2 + S,$$
$$COS + O = CO_2 + S, \quad CO_2 + S = CO + SO,$$
$$SO + O = S + O_2, \quad S + O_2 = SO + O.$$

Application of the mechanism being discussed to the conditions at low temperature $T \simeq 353$–493 K showed it to be inadequate. The calculated reaction rate was found to be too low. At low

temperatures, a fairly large contribution is apparently made by heterogeneous processes and reactions involving more complex intermediate species, not included in the kinetic scheme.

Since there is an extensive literature on the oxidation of CS_2 and COS, including reviews (see Ref. 6 and references therein), the kinetics and mechanism are examined in detail below for only one of the reactions in the C–S–O system, namely the thermal SO_2 + CO reaction.

The interest in carbon monoxide as reducing agent for sulphur dioxide is related to the fact that it is formed unavoidably when the reducing agent used is carbon or coke, whose use has been proposed for the preparation of sulphur from industrial gases containing SO_2.[60] As early as the eighteen-eighties, Berthelot and others showed that CO can reduce SO_2 slowly to give free sulphur. For example, the reaction of SO_2 and CO in a porcelain tube at 1000–1200 °C gave elemental sulphur and carbon dioxide, and also small quantities of carbonyl sulphide.[61] In the absence of a catalyst this reaction is slow, even at 800 °C, but is catalysed by almost any heated surface; the resulting reaction is of first order.[62]

Koval'skii and co-workers[63,64] showed by separate calorimetry that when Al_2O_3 is used as catalyst, the reduction of sulphur dioxide by carbon monoxide is a homogeneous reaction taking place by a chain mechanism, but chain initiation takes place on the surface of the catalyst. An appreciable quantity of carbonyl sulphide was formed in the reaction, and adding COS and sulphur increased the reaction rate.

From an analysis of the ESR spectra of the frozen products of the reaction of carbon monoxide and sulphur dioxide over bauxite at p = 1 atm and T = 600 °C it was concluded that SO is one of the species propagating the chain in the reduction of sulphur dioxide by carbon monoxide.[65] An excess of SO_2 relative to the stoichiometric ratio $CO:SO_2$ = 2 led to a decrease in the reaction rate, and an excess of CO to an increase.

The composition of a thermodynamicaly equilibrium SO_2–CO mixture at temperatures of 400–1000 K, including systems containing added water, oxygen, and carbon dioxide, has been calculated.[66] It was shown tht at 473 K almost complete reduction of sulphur dioxide by carbon monoxide is possible, but traces of water and oxygen lower the equilibrium yield of elemental sulphur.

The kinetics of the gas-phase CO + SO_2 reaction in static quartz reactors have been studied at temperatures of 1100–1360 K using infrared and ultraviolet spectroscopic analysis of the products.[58,59] Under these conditions, change in the surface:volume ratio of the reactor and in pressure in the range 60–300 torr had no influence on the reaction. The effective activation energy of the process, determined from the rate of removal of sulphur dioxide, was 46 kcal mol^{-1}. An interesting feature is that this value practically coincides with the activation energy of the formation of CO_2 in this reaction (E = 48.3 kcal mol^{-1}), obtained in shock waves at temperatures of 1770–2453 K.[67] It was established that the rate of change in the SO_2 concentration is independent of the concentration of SO_2 and is linearly dependent on the CO concentration. As in other studies,[64] the principal intermediate reaction product is carbonsyl sulphide. In contrast to the catalytic process at a lower temperature,[64] however, where the highest yield of COS reached 45%, in the gas-phase process at 1215 K and a reagent ratio $CO:SO_2$ = 2:1 the highest concentration of carbonyl sulphide was only 5–8% of the initial concentration of sulphur dioxide. At the moment when a highest COS concentration of 25–50% is reached, however, all the sulphur liberated at this stage by the decomposition of SO_2 is present as COS. An estimate taking account of the rate of decomposition of carbonyl sulphide itself showed that at least 80% of the SO_2 decomposed is converted initially into COS, and its lower concentration compared with published data[64] is due to the higher rate of its decomposition at a high temperature.

Experiments with the addition of carbonyl sulphide (up to 30% of the initial concentration of SO_2) to the original mixture showed[59] that in contrast to the catalytic process,[63,64] these additives have no significant influence on the kinetics of the decomposition of sulphur dioxide. The concentration of carbonyl sulphide itself decreased very rapidly, with practically the characteristic decomposition time of pure CO, to a quasi-stationary level close to the quasi-stationary concentration of COS in the reaction without the addition of this product. The decomposition of COS under these conditions apparently takes place to a considerable extent independently of the reduction of sulphur dioxide and does not make a significant contribution to the rate of radical initiation. The decomposition of COS in the presence of only one of the original reagents, SO_2 or N_2 (a five-fold excess relative to COS) was about three times more rapid than that in the reaction being studied. In the mixture with SO_2, a simultaneous slow decrease in the concentration of sulphur dioxide was observed. This is apparently related to the reaction of SO_2 with carbon monoxide formed by the decomposition of COS, taking place more rapidly than the decomposition of COS. The decrease in the quantity of CO_2 corresponded approximately to the stoichiometry of the reaction of SO_2 and the CO formed. Attempts to detect CS_2 in the decomposition of COS were unsuccessful, that is the reaction

$$2COS \rightleftharpoons CO_2 + CS_2$$

takes place to only a small extent, and the principal reaction is

$$COS \rightleftharpoons CO + S.$$

The extent of the decomposition of COS under these conditions was greater than 95%. The decomposition of COS is much slower in the presence of CO than in the presence of SO_2 or N_2. This may be a consequence of the influence of CO on the back reaction. Only traces of CS_2, corresponding to not more than 3% of ΔCOS, were detected. The presence of CO in the original mixture explains the slower rate of decomposition of COS in the reaction being studied, compared with the decomposition of pure COS. The extent of the decomposition also decreases as a result of the displacement of the equilibrium. Overall it can be stated that the reaction of CO and SO_2 takes place with the formation of COS and is accompanied by the subsequent and to a large extent independent decomposition of COS, mainly by the second reaction. The influence of the starting materials on the decomposition of COS reduces mainly to the influence of CO on the displacement of the equilibrium by the back reaction.

The estimated activation energy of the decomposition of COS lies in the range 30–46 kcal mol^{-1}. Since this value is approximately half the energy of the removal of a sulphur atom from a COS molecule (73.7 kcal mol^{-1}), it has been suggested[59] that the decomposition takes place by a bimolecular mechanism *via* the formation of a linear complex

$$OC-S + S-CO \longrightarrow CO + S_2 + CO,$$

which is endothermic to the extent of about 40 kcal mol^{-1}. This mechanism of the decomposition would indicate that the fact that added COS has no influence on the reaction rate is due to the absence of atoms and radicals from the reaction products.

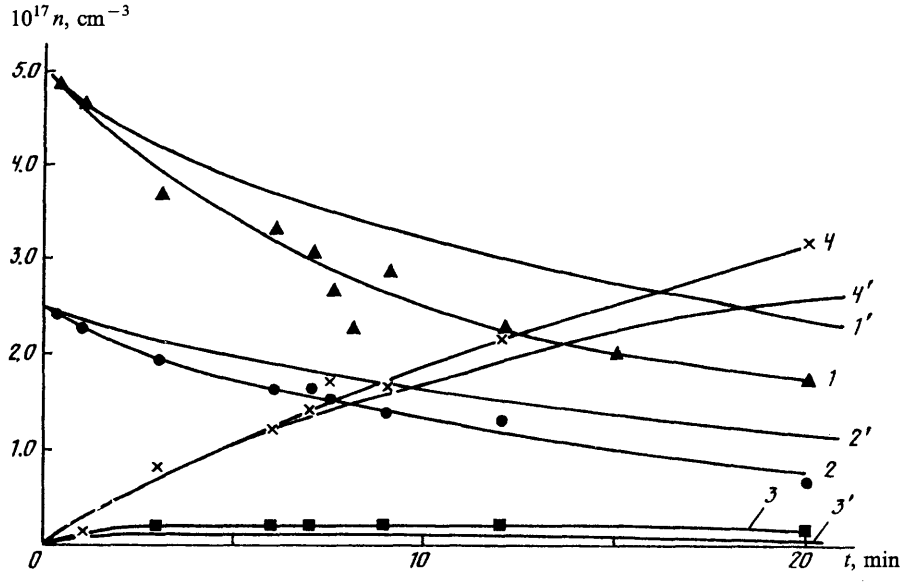

Figure 10. Kinetics of the change in the concentration (n) of the products of the reaction of sulphur dioxide with carbon monoxide at $CO:SO_2 = 2:1$ and $T = 1215$ K;[59] *1,1'*, CO; *2,2'*, SO_2; *3,3'*, COS; *4,4'*, CO_2; *1–4*, experiment; *1'–4'*, calculation.

Figure 10 gives the experimental kinetic curves for the reaction of sulphur dioxide with carbon monoxide. Attempts to detect the formation of other products, including S_2O, from infrared absorption at 679 cm^{-1} were unsuccessful. Only traces ($\leqslant 10^{15}$ cm^{-3}) of CS_2 were detected. Figure 10 also gives the results of calculations of the kinetics of this reaction using the kinetic model of the processes in the C–S–O system.[6] Satisfactory agreement was obtained between the experimental and calculated curves for all the observed products, confirming the reliability of the general model of the processes in the C–S–O system developed in the work cited.[6] Table 1[59] gives an abbreviated model of the reaction of CO and SO_2, obtained by selecting the most important reactions of the model[6] without introducing any changes to the values of their rate constants. Since the difference between calculations using the abbreviated scheme in Table 1 and calculations using the complete scheme does not exceed 15%, it can be stated that this simplified scheme gives the basic mechanism of the reduction of sulphur dioxide by carbon monoxide.

VI. The combined oxidation, photolysis, and radiolysis of carbon- and sulphur-containing compounds

The combined thermal oxidation, photolysis, and radiolysis of carbon- and sulphur-containing compounds is now being intensively studied. The aim of these studies is to find ways of processing sulphur-containing natural gas or purifying it from organosulphur compounds.

It has been shown that it is possible to carry out the chain thermal–radiation decomposition of hydrogen sulphide in the presence of carbon monoxide in the temperature range 60–650 °C;[68] the radiation-chemical yield of hydrogen $G(H_2)$ increased with increase in temperature, from 2 at 60 °C to 150 at 500 °C. According to the proposed scheme, carbon monoxide not only transfers excitation to the H_2S molecules but also reacts with the SH radical to give COS. Estimates[69] showed that it is possible to carry out the extensive purification of natural gas by the selective photodissociation of hydrogen sulphide by ultraviolet radiation to give hydrogen and elemental sulphur. This possibility was studied experimentally[70] in mixtures of hydrogen sulphide (0.5–10%) with CH_4, CO_2, and H_2 by irradiating with ultraviolet light with λ = 193 nm. Selective dissociation of H_2S took place down to concentrations lower than $10^{-3}-10^{-4}$ times the initial concentration. The formation of organosulphur compounds was not observed, and the concentration of methane remained unchanged. This result was attributed[70] to the small extent of the photodissociation of CH_4 and the low rate of the reactions of methane with the HS and S radicals formed by the photolysis of H_2S

$$HS + CH_4 \rightarrow H_2S + CH_3,$$
$$S + CH_4 \rightarrow HS + CH_3,$$

at $T < 600$ K. Because of their relatively low concentration, the reactions of S radicals with unsaturated compounds

$$S + C_2H_2 \rightarrow \text{products}$$

$$S + C_2H_4 \rightarrow \text{products}$$

have no significant influence on the purification process.

Experiments have been carried out on the combined incomplete oxidation of methane and hydrogen sulphide under static conditions at pressures of 350–440 torr and temperatures of 600–1000 K.[71] The process was carried out at concentrations of 0.3–10% hydrogen sulphide, 2.5–10% oxygen, and 5–90% methane (diluted with helium). The products were analysed from their infrared and

ultraviolet spectra (CH_4, H_2S, SO_2, CS_2, COS) and by chromatography (CH_3OH, C_2H_2, SO_2, and H_2O).

At temperatures of about 600 K it is possible to observe the kinetics of the consumption of H_2S and the accumulation of SO_2. In the absence of methane and with an excess of oxygen, practically all the H_2S is oxidised to SO_2. The presence of methane has little influence on the kinetics of the initial stage of the process, but the process becomes slower and stops at a certain residual stationary concentration of H_2S. Decrease in the oxygen concentration is accompanied by a decrease in the rate and extent of the oxidation of H_2S and the rate of formation and yield of SO_2, and by a decrease in the S_2/SO_2 ratio.

Table 1. Mechanism of the reduction of sulphur dioxide by carbon monoxide.[59]

Reaction	lg A, mol litre^{-1} s^{-1}	E, kcal mol^{-1}
$CO+SO_2 = CO_2+ SO$	9.78	55.0
$CO+SO = CO_2+ S$	9.78	10.9
$CO+S +M = COS+ M$	10.30*	1.8
$COS+M = CO+S+M$	11.28	64.0
$COS+SO = S_2 + CO_2$	8.40	8.3
$COS+S = CO + S_2$	9.23	4.0
$SO_2 + S = SO + SO$	9.78	16.8
$CO_2+S = CO + SO$	11.57	13.2

*mol^2 litre^{-2} s^{-1}.

With increase in temperature to 800 K there is a sharp increase in the rate of the decomposition of H_2S, and the SO_2 concentration passes through a maximum; both products reach stationary values of the concentration, which for H_2S correspond to half the initial value. At low concentrations (5%) of methane there is a slight decrease (~10%) in its concentration (Fig. 11). At a methane concentration of about 90% there is no change in its concentration within the accuracy of the measurements. The oxidation products contain an appreciable quantity of CS_2 and some COS; the concentrations of these products pass through a maximum when the stationary value of the concentration of SO_2 is reached. At the maximum the degree of transformation of H_2S into these products at $[H_2S] = [O_2] = [CH_4] = 10\%$ reaches the values $2CS_2/(H_2S)_0 \simeq 0.3$ and $COS/(H_2S)_0 \simeq 0.06$; the corresponding values for SO_2 and S_2 are about 0.3 and 0.35.

At even higher temperatures (900–1000 K) and concentrations $[H_2S] = [CH_4] = 10\%$ and $[O_2] = 5\%$, that is with a deficit of oxygen, H_2S decomposes completely ($t < 5$ s), but no formation of SO_2 is observed, that is the principal sulphur-containing product is now S_2.[71]

Depending on the ratio H_2S/O_2, two overall equations for the oxidation of hydrogen sulphide are possible:

$$2H_2S + O_2 \longrightarrow 2H_2O + S_2,$$
$$2H_2S + 3O_2 \longrightarrow 2H_2O + 2SO_2.$$

The fraction of hydrogen sulphide converted into sulphur dioxide naturally increases with the oxygen concentration. In the combustion of hydrocarbons containing a small quantity of sulphur compounds, practically all the sulphur is converted into SO_2.[16] Under the conditions of the work cited[71] in an excess of oxygen, the principal oxygen-containing product is again SO_2, but in the presence of methane the SO_2 formed is partly reduced to S_2 and even to H_2S, and this is a slower process than the actual oxidation of hydrogen sulphide (Fig. 11).

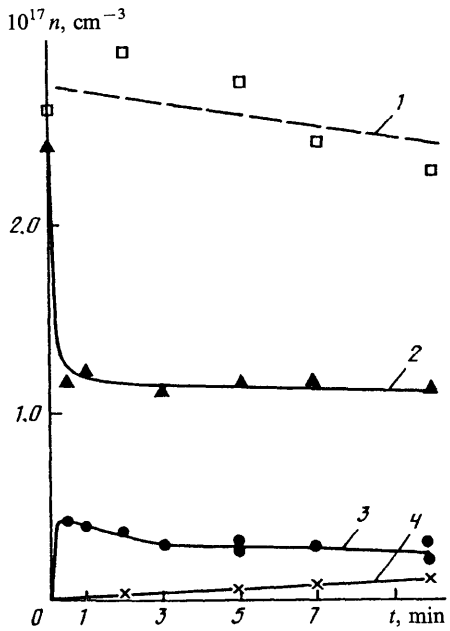

Figure 11. Kinetics of the oxidation of hydrogen sulphide in the presence of methane and the yield of products: *1*, CH_4; *2*, H_2S; *3*, SO_2; *4*, CS_2; T = 800 K, p = 440 torr, $[H_2S]$ = 5%, $[O_2]$ = 2.5%, $[CH_4]$ = 5%.[71]

Thus in the oxidation of methane containing a small quantity of hydrogen sulphide, the rapid partial oxidation of hydrogen sulphide to S_2 and SO_2, the ratio of which is determined by the oxygen concentration, is accompanied by the subsequent slower reduction by methane of the SO_2 formed to give S_2, and also by the reaction of S_2 with methane to give CS_2. It is only in a large excess of oxygen relative to hydrogen sulphide that almost complete transformation of H_2S with an almost 100% yield of SO_2 takes palce. The slow reduction of sulphur dioxide by methane (section III) limits the establishment of equilibrium in this system.

Figure 12 gives the dependence of the maximum rate of increase in the pressure W_{max} and the yield of products on the H_2S concentration. The presence of even 0.3% H_2S lowers the highest

reaction rate by a factor of 2, and 2% H_2S lowers it by a factor of about 4. The yield of methanol also decreases slightly.[71] Figure 13 gives the kinetics of the formation of the reaction products for a mixture containing 2% H_2S. In all the mixtures the concentration of methanol passes through a maximum. An interesting feature is that the transformation of H_2S is complete well before the end of the whole process.[17]

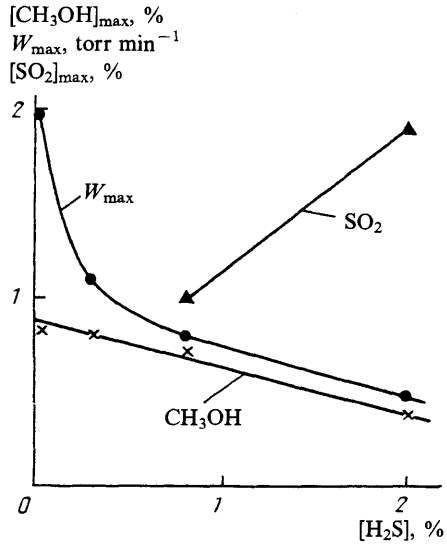

Figure 12. Dependence of the highest rate of oxidation of methane (W_{max}) and the highest yields of methanol [CH_3OH] and sulphur dioxide [SO_2] on the concentration of hydrogen sulphide; T = 723 K, p = 350 torr, [CH_4] = 80%, [O_2] = 10%, [H_2S] = 0.3–2%, remainder helium.[71]

Figure 12 shows that up to H_2S concentrations of 0.8% the highest concentration of methanol decreases by not more than 15%, indicating that it may be possible to use natural gas with a low sulphur concentration for its partial oxidation to methanol. Kinetic modelling of the incomplete oxidation of natural gas with a low sulphur concentration to give methanol at high pressures (100 atm) showed that in addition to a sharp decrease in the reaction time, even a slight increase in the yield of methanol can be expected. Even at a concentration [H_2S] $\simeq$ 1%, however, the conversion of hydrogen sulphide into sulphur dioxide is not complete. In view of the low reliability and incomplete nature of the kinetic data on the reactions of sulphur-containing compounds, however, it is difficult, without appropriate experimental studies, to evaluate the conclusions reached by modelling.

VII. The reaction of carbon- and sulphur-containing molecules in atmospheric processes

Sulphur is a relatively widespread element, and plays an important role in the circulation of the lithosphere and the atmosphere. On the earth's surface it is concentrated mainly in sulphide and sulphate ores, and in the ocean it is present mainly as dissolved sulphates. The principal sulphur-containing compounds in the atmosphere are sulphur dioxide, hydrogen sulphide, and other reduced compounds of sulphur, and also sulphate aerosols. Sulphur compounds do not accummulate in the atmosphere. Chemical cycles ensure a fine balance between the supply of sulphur to the atmosphere and its return to the earth's surface, although the increasing flux of sulphur originating from man's activities (207 million tons of SO_2 in 1976, 41.4% of the total supply of sulphur to the atmosphere[72]) is possibly displacing this equilibrium slightly.

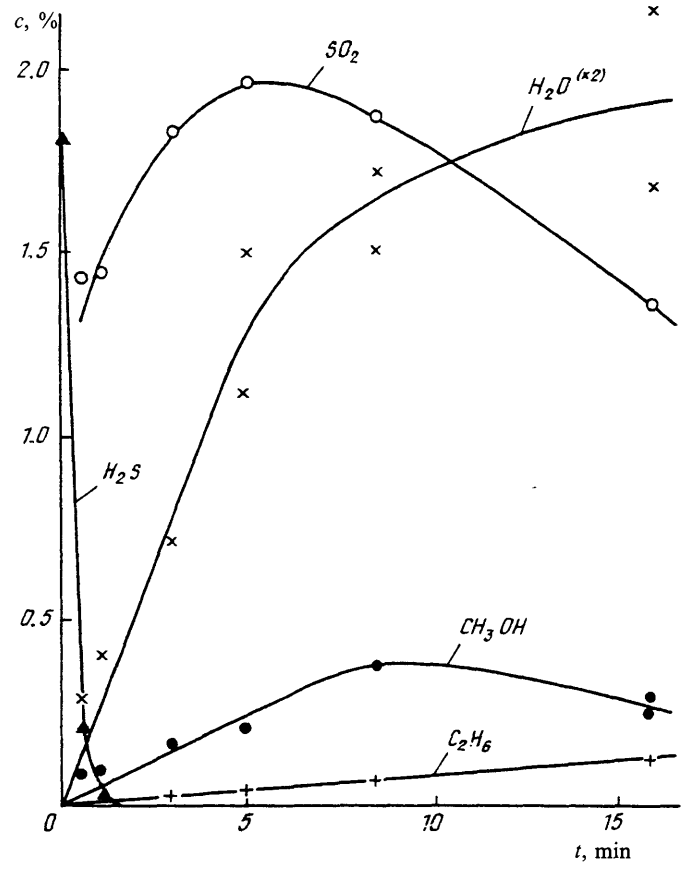

Figure 13. Kinetics of the formation of the products of the oxidation of methane in the presence of added hydrogen sulphide; T = 723 K, p = 350 torr, [CH_4] = 80%, [O_2] = 10%, [He] = 8%, [H_2S] = 2%.[71]

Most of the carbon in the atmosphere is present as carbon dioxide (~340 p.p.m.), methane (1.6–1.7 p.p.m.), and carbon monoxide (0.04–0.20 p.p.m.).[1]

Reduced carbon- and sulphur-containing molecules, whose concentration in the atmosphere is low, are oxidised mainly by

hydroxyl radicals to give finally carbon dioxide and more highly oxidised compounds of sulphur

$$OH + COS \rightarrow CO_2HS,$$
$$OH + COS \rightarrow CO + SOH,$$
$$OH + CS_2 \rightarrow COS + HS,$$
$$OH + CS_2 \rightarrow CS + SOH,$$
$$OH + CH_3SCH_3 \rightarrow \text{products}.$$

The photolysis of these compounds in the troposphere plays a relatively minor role. The hydroxyl radical is also involved in the conversion of SO_2 into H_2SO_4.

Methane also reacts initially with the hydroxyl radical to give methyl radicals

$$CH_4 + OH \longrightarrow CH_3 + H_2O,$$

which are then oxidised by O_2 in a series of reactions to give formaldehyde, whose subsequent photolysis gives carbon monoxide. Carbon monoxide from this source, and carbon monoxide entering the atmosphere directly, is oxidised further by OH radicals in a cyclic series of reactions, beginning with the reaction

$$CO + OH \longrightarrow CO_2 + H,$$

giving CO_2 as the final product. In the troposphere, about 70% of the OH radicals are used up in the reaction with CO, and 30% in the reaction with CH_4. Both processes give peroxide radicals:

$$H + O_2 + M \longrightarrow HO_2 + M,$$

$$CH_3 + O_2 + M \longrightarrow CH_3O_2 + M,$$

which can react with sulphur dioxide:

$$ROO + SO_2 \longrightarrow RO + SO_3,$$

whose concentration in the atmosphere reaches about 1.1×10^{-10}.[1] If the rate constant of the reaction

$$CH_3OO + SO_2 \longrightarrow CH_3O + SO_3$$

were about $(5-10) \times 10^{-15}$ $cm^3 molecule^{-1} s^{-1}$, as has been reported,[73,74] it might play a decisive role in the sulphur cycle. Later work,[75,76] however, gave a much lower value for the rate constant of this reaction (5×10^{-17} $cm^3 molecule^{-1} s^{-1}$), so that this reaction apparently does not play a significant part in the sulphur cycle.

Among the reduced compounds of sulphur, entering the atmosphere mainly from the ocean surface, a relatively important part in the global sulphur cycle is played by organosulphur compounds, primarily dimethyl sulphide CH_3SCH_3, which annually supplies about 40 million tons of sulphur to the atmosphere.[77] Recently, therefore, considerable attention has been paid to the mechanism of the oxidation of dimethyl sulphide, dimethyl disulphide CH_3SSCH_3, and other organosulphur compounds in the atmosphere.[77,78] As in the case of other reduced compounds of sulphur, the principal chemical process responsible for the decomposition of CH_3SCH_3 and CH_3SSCH_3 in the atmosphere is their reaction with OH, and the principal product of the complex processes involved in their atmospheric oxidation is SO_2.[78]

The reaction of carbon- and sulphur-containing molecules may play a much greater role in the atmospheres of planets such as Venus, where the concentrations reach 96.5% CO_2, 0.003% CO, and 0.015% SO_2.[1] They apparently play a predominant role in the region of the atmosphere of Venus below the cloud layer. In view of the high temperatures (732 K on the surface of Venus) and pressures (90 atm) and the proximity of the surface, which catalyses the approach to equilibrium, it may be assumed in a first approximation that the thermodynamically equilibrium composition, perturbed by vertical transport processes, is established in this region. This equilibrium is apparently in fact established at the surface, but with increase in the distance from the surface the equilibrium begins to break down to a considerable extent, increasing the part played by kinetic processes in the formation of the composition of the atmosphere. As a result, the ascending and descending streams apparently have different chemical compositions. The ascending streams contain components originating in Venus' crust (for example COS, S_2, H_2S, etc.), and the descending streams contain the products of photolysis in the upper cloud layer (SO_3, Cl_2, O_2, etc.). On the surface, chemical equilibrium is apparently established for all the gases except CO and O_2, which in the tropospheres are not in equilibrium with one another or with the COS/SO_2 system.[1] The next most important elementary stages, beginning with the formation of SO, can describe the interconversion of various components:

$$SO_2 + CO \longrightarrow SO + CO_2, \qquad CO + S + M \longrightarrow COS + M,$$
$$SO + CO \longrightarrow S + CO_2, \qquad S + COS \longrightarrow S_2 + CO,$$
$$SO + SO_2 \longrightarrow S + SO_3, \qquad SO + COS \longrightarrow S_2 + CO_2.$$

Spectroscopic data obtained by cosmic probes confirm indirectly the presence of S_2, S_3, and subsequent oligomers of sulphur S_x up to the stable S_8.[1] The photo-dissociation of these molecules

$$S_x + h\nu \longrightarrow S^* + S_{x-1}$$

may be the source of excited S* atoms capable of reacting with molecules of water and carbon dioxide

$$S^* + H_2O \longrightarrow SH + OH,$$
$$S^* + CO_2 \longrightarrow SO + CO.$$

Excited atoms and molecules play an important part in the chemistry of the atmosphere. In particular, the reaction of excited molecules of sulphur dioxide with hydrocarbons may play an important role in the formation of sulphur-containing aerosols in industrial regions with a relatively high atmospheric concentration of hydrocarbons and sulphur dioxide. The high bond energy in the SO_2 molecule practically excludes the dirct photo-dissociation of this molecule in the atmosphere, and also all other reactions except further oxidation.[79] The formation of excited SO_2^* molecules in the atmosphere may open up alternative pathways in the reaction of SO_2 with carbon-containing molecules. It has been reported[80] that a large quantity of sulphur-containing products is formed when an air/sulphur dioxide/butane mixture is irradiated.

A study of the photochemical reactions in mixtures of SO_2 with alkanes on irradiation with light with $\lambda = 3130$ Å[81] showed the absence of processes involving the rupture of C–C bonds, since the products of the photolysis of SO_2 with isobutane and n-butane did not contain methane, ethane, or propane. A small quantity of C_8 hydrocarbons was detected. Only traces of oxygen-containing compounds—alcohols, aldehydes, and ketones—were detected. The principal products include sulphinic acids RS(=O)OH and other organic acids. Their low quantum yield and the low yields of hydrogen and the products of the recombination and disproportionation of alkyl radicals show that the reaction of SO_2 with RH does not involve radical chain reactions. For the most part the mechanism of the reaction of excited SO_2^* with hydrocarbons remains unclear.

A more obvious process is the reaction of SO_2^* with carbon monoxide

$$SO_2^* + CO \longrightarrow CO_2 + SO,$$

where the spin-allowed character of the formation of SO in the triplet ground state $X^3\Sigma^-$ and the excess excitation energy make the reaction in this direction possible, although the low quantum yield shows that the removal of oxygen, even from the excited SO_2^* molecule, is difficult[81] and still requires an activation energy of 4 kcal mol^{-1}.[82]

Calvert and co-workers carried out a series of studies of the reaction of the triplet excited molecules $SO_2(^3B_1)$ with alkanes,[83,84] alkenes, and aromatic hydrocarbons.[85,86] The activation energy of the quenching of $SO_2(^3B_1)$ by paraffinic hydrocarbons decreases regularly in the order: ethane, neopentane, propane, n-butane, cyclohexane, and isobutane, which corresponds to the decrease in the strength of the C–C bond in the molecule. These and other data indicate that for these compounds chemical quenching, probably involving the removal of a hydrogen atom, predominates. The rate constants of the quenching of $SO_2(^3B_1)$ by alkenes and aromatic hydrocarbons depend little on temperature and correspond closely to the number of binary collisions. These data confirm the hypothesis that the initial act of the reaction, determining the rate of the process, is the reaction between $SO_2(^3B_1)$ and the π-system in these compounds. The subsequent addition of $SO_2(^3B_1)$ to the double bond of the alkene gives a triplet biradical as an intermediate complex,[83] as in the reaction of $O(^3P)$ atoms with alkenes.[87] The principal stable products of the reaction of $SO_2(^3B_1)$ with alkenes are sulphinic acids, formed with an efficiency of 0.14–0.5 per collision.[85]

---o0o---

The practical importance of the chemical reactions of carbon- and sulphur-containing compounds requires a deeper understanding of the kinetics of these reactions. New data in this field may lead to the improvement of a number of processes of technical importance.

The influence of metal coordination compounds on the ionic conductivity of bilayer lipid membranes

B A Bovykin, A M Omel'chenko, T V Sytnik
Dnepropetrovsk Institute of Chemical Engineering

ABSTRACT. The results of studies on the problem of the effect of metal coordination compounds on biological and bilayer lipid membranes are surveyed. The authors' later data, defining the mechanism of the action of metal complexes which are significant in the development of specific syntheses of physiologically active substances used in medicine and agriculture, are presented.

The bibliography includes 50 references.

I. Introduction

One of the most important problems in modern chemistry is that of the creation of the foundation for the specific synthesis of compounds with a specified biological activity. Its solution can be achieved only by establishing the relation between the physiological activity, on the one hand, and the molecular structure and properties of substances on the other. Despite certain advances in this field, there is at present no scientificially-based theory which would make it possible to construct effective biologically active compounds.

One of the causes of this is that the manifestation of activity is frequently inferred from the final results of the activity of substances manifested in the alteration of some kind of properties and features of the living organism as a whole (at least the living cell). The deep-seated processes at a molecular level, which are in fact the cause of the change in the normal functioning of the organism, are hardly investigated under these conditions.

The problem of creating the foundations for a specific synthesis of biologically active compounds must be solved by imparting to them properties which would enable them to act on the most important molecular mechanism among the enormous number of mechanisms of the normal vital activity of the living cell.

Among such mechanisms, it is essential to differentiate those which are linked directly to the functioning of cell membranes. Lipids, among which phospholipids predominate, constitute the structural basis of the membranes of living organisms. Bilayer lipid membranes (BLM), which are completely adequate models of the cell membranes of living organisms,[1] are therefore convenient objects for the study of the mechanisms of the action of compounds on biological membranes. Using this model, the mechanism of the action of various substances, including metal ions, has been investigated. On the other hand, only isolated studies have been devoted to the action of coordination compounds, including biologically active ones, on cell membranes.

A characteristic features of unmodified BLM is their extremely low permeability to the majority of inorganic ions, especially multicharged ions, and as a rule the absence of an appreciable selectivity among the ions. The low permeability of BLM to inorganic cations is due to the high activation energy for their transfer (of the order to 120 kJ mol^{-1} for singly charged cations[2]). At the same time, it is well known that biological membranes exhibit a high permeability (higher by 5–6 orders of magnitude than that of BLM) and manifest ion-selective properties.

The mechanisms of ionic conduction and selectivity of biological and artificial membranes have not been ultimately elucidated despite the large number of relevant studies. The accumulated literature and the authors' own data on the effect of metal cations on the lipid membranes have been surveyed[3] taking into account their physicochemical properties. It was indicated in the review that, when metal cations are bound to BLM and other membrane systems, it is necessary to take into account a series of factors: hydrolysis, the behaviour of metal compounds at different pH of the solution, in particular their solubility, their complex forming capacity, and other properties,

The subdivision of metal cations into classified groups taking into account their covalent characteristics makes it possible to estimate the sequence in which the metal cations are bound to membranes using models of the adsorption centre in lipid bilayers of different composition.

The available data suggest that the transport of metal cations through biological membranes is achieved with the aid of special transferring molecules. Evidently the transport of transition metal cations, which are important for the physiology and toxicology of living organisms, should involve the participation of organic compounds—bioligands capable of coordination interaction with these metal cations. In this connection, studies on the molecular mechanisms of the interaction of metal complexes with cell membranes have become particularly timely.

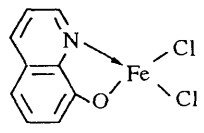
II. Interaction of metal complexes with biological membranes

Insufficient attention has been devoted hitherto to the question of coordination compounds.

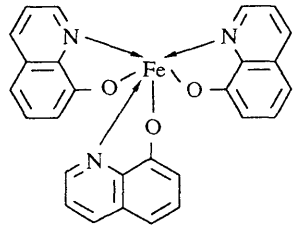
It has been assumed that the role of the metal in the complex consists in creating a suitable transport form for the ligands or, if

the metal ion itself exhibits a biological activity, then the complex is necessary for the transport of the metal through the cell membrane.[4]

Albert[5] showed that the iron(III) complex of 8-hydroxyquinoline (HQ) has the 1 : 3 composition. Neither the ligand nor the iron(III) ion possess biological activity but are very effective in suppressing pathogenic microorganisms when combined in a 1 : 1 complex.



$Fe(HQ)Cl_2$



$Fe(HQ)_3$

The author suggested that the compound containing three deprotonated 8-hydroxyquinoline molecules $Fe(HQ)_3$ is the only one among all the possible complexes which is capable of penetrating through the cell membranes of the microorganism. He believes that coordinatively unsaturated complexes are bound too strongly to membranes. After entering the cell, $Fe(HQ)_3$ decomposes with formation of 1 : 1 and 1 : 2 complexes, which exhibit a biological activity. The view that the most lipophilic complex exhibits a toxic activity on pathogenic microorganisms is supported by the fact that the introduction of hydrophobic groups into the 8-hydroxyquinoline molecule weakens the antibacterial activity of the complex.

Similar conclusions were reached in a study[6] confirming that only coordinatively saturated and neutral copper(II) complexes with low-molecular-weight lipophilic plasma components can permeate through cell membranes.

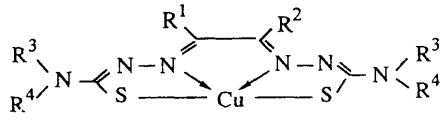
It has been shown[7] that the copper(II) complex of ceruloplasmin (CPL), which is a copper-containing serum α-2-glycoprotein, is synthesised in the liver and then enters the serum and the blood plasma. The physiological functions of ceruloplasmin involve oxidase and ferroxidase enzyme activities and participation in the iron and copper metabolisms in the organism involving transport of copper(II) ions through plasmatic membranes.

It is stated in the above monograph that bisthiosemicarbazones, which tetradentate complex-forming substances, exhibit an appreciable antitumour activity. The derivative in which R^1 = ethoxyethyl and $R^2 = R^3 = R^4 = H$ [ketoxal bisthiosemicarabazone (H_2KTS)] has been most thoroughly investigated. The effect of these compounds is due to the binding of copper(II) ions with formation of a therapeutically active complex:

$$H_2KTS + CuX_2 \longrightarrow CuKTS + H_2X.$$

This complex has been isolated and investigated in solutions and in the solid state. According to X-ray diffraction data, it has a square planar structure.

By virtue of its high stability ($\lg\beta = 18.4$), the complex is almost incapable of forming axial adducts and of entering into substitution reactions. It can therefore be regarded as coordinatively saturated.



CuKTS

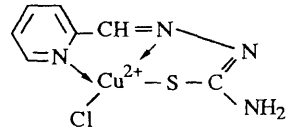
It has been demonstrated by polarographic and potentiometric methods that the compound is capable of undergoing one-electron reduction. The reaction with thiols (for example, glutathione) proceeds via a mechanism involving three stages:

$$Cu^{(II)}KTS + RSH \longrightarrow Cu^{(I)}SR + {}^1/_2RSSR + H_2KTS,$$
$$CuKTS + RS^- \rightleftharpoons CuKTSRS^-,$$
$$CuKTSRS^- + RSH \longrightarrow Cu^{(I)}SR + HKTS^- + RS^{\cdot},$$
$$2RS^{\cdot} \longrightarrow RSSR.$$

It has been noted that the rate of oxidation of thiols is correlated with the cytotoxic activity of the complexes. It is believed that H_2KTS enters the cell only as a result of the complex formation reaction with copper(II). If the reaction does not occur, then the ligand is localised in the lipophilic part of the membrane. On reduction of the complex in the cell and the formation of $Cu^{(I)}SR$, the copper is probably distributed between the cell thiols and moves to the interior of the cell, while the H_2KTS ligand emerges from the cell. This inhibits the synthesis of DNA and the mitochondrial oxidative phosphorylation, which constitutes ultimately the cytotoxic activity of the complex.

The example analysed above describes the mechanism of the action of the coordinatively saturated complex on the cell membrane, complex formation occurring on the surface of the membrane with participation of the metal ion located within the components of the tumour cell. Only as a result of this process is the physiologically active complex transported through the biological membrane.

The case of a coordinatively unsaturated complex occurs when 2-formylpyridine thiosemicarbazone (Hα) reacts with copper(II). In contrast to CuKTS, the complex $[Cu\alpha Cl]^0$, where α is the tridentate ligand



enters readily into adduct formation reactions, for example, with ethylenediamine. The stability of the complex [CuαenCl] is indicatated by $\lg\beta = 5.53$. The complex $[Cu\alpha Cl]$ is reduced on interaction with thiols within the cell, but does not decompose, in contrast to CuKTS, and affords an adduct.

The effect of platinum and platinum group metal complexes, which exhibit an appreciable antitumour activity, on biological membranes is of special interest. It was noted in 1969 that certain platinum complexes exhibit an anticarcinogenic activity. The influence of the charge, geometrical structure, stability, etc. of the complexes on their antitumour activity was investigated. It was noted that the absence of antitumour activity in charged platinum complexes is associated with their inability to permeate through cell membranes. The interaction of *cis*-dichlorodiamineplatinum(II) with a phosphate transferring agent in mitochrondia has been investigated.[8] It was suggested that the fully or partly hydrolysed complex interacts in mitochondria with a phosphate transferring agent and modifies the SH group in the latter. According to the authors, such interaction can partly account for the antitumour activity of the complex.

Interesting data have been obtained by Stetsenko et al.[9] in a study of the electrical conductivity of a NaCl solution ($c = 1 \times 10^{-2}$–0.15 M) on treatment with $[Pt(NH_3)_2Cl_2]$ isomers ($c = 3 \times 10^{-3}$ M). The reason why *cis*-$[Pt(NH_3)_2Cl_2]$ influences the electrical

conductivity of the solution is the associative interaction of the ion–dipole type between the Cl^- ions and the polar molecules (of the *cis*-isomer). The existence of a direct relation between the antitumour activity and the ability of *cis*-$[Pt(NH_3)_2Cl_2]$ to reduce the electrical conductivity of the electrolytes suggests that the association of the biologically active *cis*-isomer promotes its retention within the extracellular liquid, where the concentration of chloride ions is high, and its supply in an unchanged form through the cell membrane to the site of the reaction with the DNA of the tumour cell.[9]

Bearing in mind the size of the complex molecule (the distance between the chlorine atoms is 340 pm) and the pore radius in the cell membrane (400 pm), through which the solutes pass in either direction relative to the concentration gradient, it has been suggested[7] that *cis*-$[Pt(NH_3)_2Cl_2]$ permeates the cell as a result of passive diffusion. This mechanism has been confirmed by experiments which make it possible to distinguish passive diffusion from active transport. The rate of accumulation of *cis*-$[Pt(NH_3)_2Cl_2]$ in the cells of the Ehrlich ascites tumour has been determined and the data were analysed on the basis of the kinetic Michaelis–Menten equatiion. The hypothesis that *cis*-$[Pt(NH_3)_2Cl_2]$ passes through membranes by means of diffusion is supported by the finding that the rate of accumulation of the preparation in the cells is not affected by substances promoting membrane permeability.[7]

The biological activity of compounds is in many respects determined also by their ability to alter the functional activity of membrane structures. The complexes inhibit the activity of membrane enzymes, interacting with the surface or deep-seated SH groups of ATPase. Thus in the anionic Pt^{2+} and Pd^{2+} complexes having the composition $K_2[MX_4]$, where X = NO_2^-, Cl^-, Br^-, I^-, or SCN^-, the inhibiting properties vary in different ways with increase in the ability of the ligands to redistribute the electron density from the complex-forming ion in the above series of ligands X. For palladium(II), the inhibiting activity of the complexes increases, while for platinum(II) it diminishes. This indicates different mechanisms of the activity of the complexes. The Pt^{2+} compounds are reduced to zerovalent platinum on contact with the enzyme, forming "couplings". On the other hand, the Pd^{2+} compounds act as electron acceptors, forming complexes with the electron-donating groups of the enzyme.[10]

It has been noted that in the series of compounds $Q_2[PdBr_4]$, where Q = K^+, $(CH_3)_3NH^+$, or $N(C_2H_5)_4^+$, the inhibiting activity of the membrane ATPase diminishes with increase in the size and hydrophobicity of the cation. The large dimensions of the cations and ionic associated species probably hinder the approach through complexes to the active centre of the enzyme, as a result of which $[N(C_2H_5)_4]_2[PdBr_4]$ does not have an inhibiting activity. The same behaviour has been observed for copper(II) complexes—$[(CH_3)_3NH]_2[CuCl_4]$ and other compounds.

The intensification of studies on substances the mechanism of the biological activity of which is associated with their interaction with biological membranes has been promoted by the studies of Mueller et al.[1] They were able to develop a method for the formation of bilayer lipid membranes constituting an adequate model of the lipid matrix of the membranes in any living organisms.

A number of investigations of the effects of various reagents on BLM have been carried out using this model.[11] However, only isolated communications have been devoted to studies on coordination compounds.

Thus it has been shown[12] that, in the presence of Cu^{2+}, Zn^{2+}, Ni^{2+}, and Hg^{2+} ions as well as tetrachlorotrifluoromethylbenzimidazole (TTFB), the bilayer lipid membranes comprising brain lipids have an N-shaped voltage–current characteristic (VCC). The decrease in the conductivity of the BLM with increase in voltage has been explained by the formation of coordination compounds of the type $[M(TTFB)_n]^{2+}$ It has been suggested[13] that the agent effecting transfer through the membrane is in this case the complex of the metal cations with TTFB and the reason for the appearance of the descending section on the voltage–current characteristic is the decomposition of the complex under the influence of the potential difference between the lipid phase of the membrane and the aqueous solution.

There have also been a few studies on the transport of metal cations through the lipid bilayers of liposomes which takes place with participation of organic ligands. For example, free aliphatic acids increase the permeability of liposomes to Yb^{3+}, Tb^{3+}, Fe^{3+}, Fe^{2+}, and Co^{2+}.[14]

It has been shown[15] that hypoglycemic sulphonylureas (glibenclamide and gliclazide) increase the permeability of sonicated dipalmitoylphosphatidylcholine vesicles to Pr^{3+} and Ca^{2+}.

In view of the inadequacy of the published factual data and the lack of systematic studies of the membrane activity of coordination compounds of metals, which constitute one of the most important preconditions for the creation of a theory of the specific synthesis of biologically active substances, we undertook a study of the molecular mechanisms of the interaction of coordination compounds of metals and planar BLM to which a number of studies have been devoted.[16–30] In each specific case, the principal problem which had to be solved was that of the composition of the membrane-active form of the complex.

In order to investigate the nature of the absorbing and permeating species, use was made of the methods for the generation of a transmembrane electrical potential differences (EPD) for an asymmetric addition of the reagents to the BLM,[31] the method based on the VCC for BLM which also exist under asymmetric conditions as regards the concentration of the reagents, as well as the method involving the measurement of the intramembrane electrical potential difference based on the conpensation for the second harmonic of the alternating current.[32]

In many instances the central ion in the complex can be coordinatively unsaturated in relation to the ligand. It is then possible to postulate the formation of a membrane-transport form having the compositions central ion–organic ligand–electrolyte anion. When this is taken into account, the mechanisms of the effect of coordinatively saturated and unsaturated compounds on BLM should differ significantly. We carried out an experimental test of these hypotheses in chloride solutions and investigated the mechanisms of the transport of chloride anions by coordinatively unsaturated metal-containing compounds.

It must be emphasised that substances which function as transferring agents for chloride anions through a membrane should undoubtedly exhibit an appreciable biological activity. This is indicated by data showing the importance of maintaining a chloride homeostasis for the normal functioning of the living cell. For example, the membrane potentials of mitochondria and liver cells have a chloride basis.

III. The mechanism of the influence of coordinatively unsaturated compounds on the ionic conductivity of bilayer lipid membranes

Complexes with various biological properties were chosen as objects for the study of the activity of coordinatively unsaturated compounds. Thus the copper(II) complex of ε-caprolactam (CL)—the preparation phyton (kartocid)—exhibits a high fungicidal activity against the agent responsible for false mildew.[33]

Phyton L (a laboratory preparation) was obtained by refluxing copper(II) chloride and ε-caprolactam in molar proportions of 1 : 3 in dry alcohol over a period of 1 h. According to X-ray diffraction data, a single crystal of phyton L has an ionic structure.[34] The molecule consists of the cations $[Cu(CL)_6]^{2+}$, having a crystallographic symmetry such that the Cu^{2+} cation is a centre of symmetry, and of the anions $[Cu(CL)Cl_3]_2^-$. Thus the formula of phyton L is $[Cu(CL)_6][Cu(CL)Cl_3]_2$. ε-Caprolactam is a monodentate ligand and is coordinated to Cu^{2+} via the oxygen atom.

Phyton T (technical preparation) is dichloroaquotricaprolactamcopper(II) $Cu(CL)_3Cl_2H_2O$. Phyton T is synthesised by fusing together the initial components.

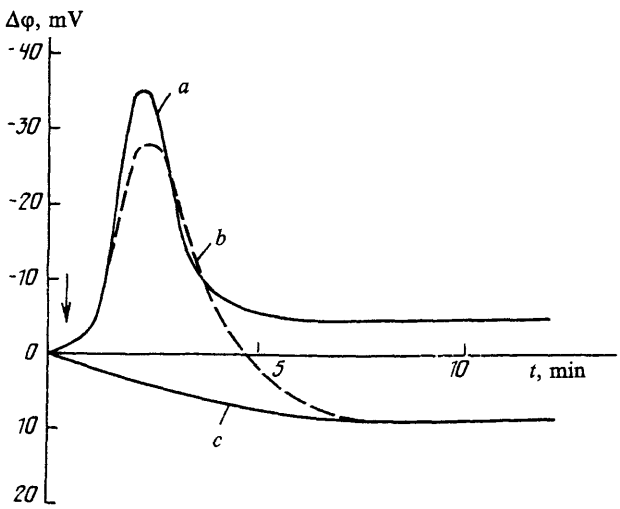


Figure 1. Typical curves for the generation of the transmembrane electrical potential difference following the introduction of reagents on one side of a brain lipid BLM; the arrow indicates the instant of the introduction of the reagents: *a*, $CuCl_2$; *b* and *c*, phyton; electrolyte—0.01 M KCl.

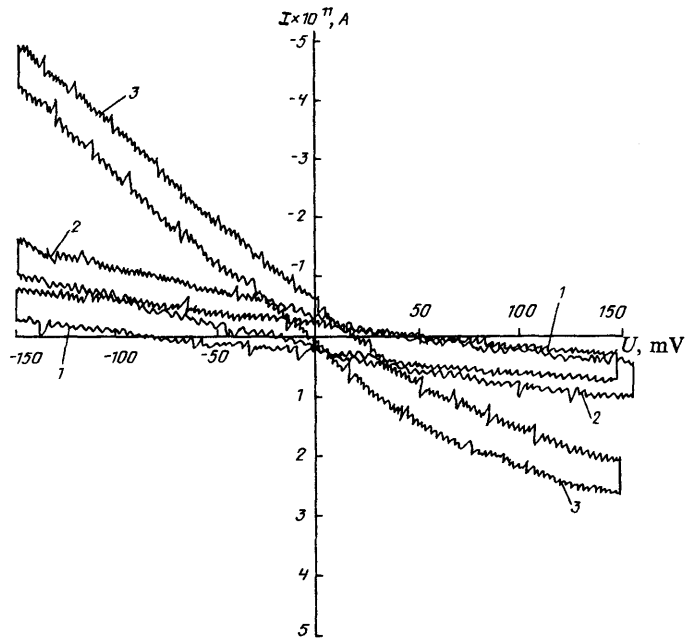

Figure 2. The voltage—current cyclic characteristics of brain lipid BLM in the presence of various concentrations of phyton on one side: *1*, in the absence of phyton; *2*, 1.7 × 10^{-4} M; *3*, 5.4 × 10^{-4} M; rate of scanning of the potential 1 mV s^{-1}; electrolyte—0.01 M KCl.

Fig. 1 presents typical curves for the generation of the transmembrane electrical potential difference when $CuCl_2$ and phyton are introduced on one side of the BLM. The introduction of ε-caprolactam did not generate a potential difference, which indicates its non-ionic nature. The nature of the transmembrane potential difference, generated on the BLM after the introduction of membrane-active agents on one side, has been studied in detail in relation to ionogenic detergents.[31,35] It was shown that the form of the potential growth—potential decrease curve depends significantly on the magnitude and sign of the charge on the adsorbing species and on the surface area of the BLM and is determined by two processes—the adsorption on the BLM of ions of membrane-active substances as well as the transmembrane transfer of these ions and the ions contained in the electrolyte solutions. The stationary potential is diffusional in nature and arises as a consequence of the transmembrane gradient of the adsorbing ions. The rate of generation of the potential is determined by the rate of adsorption of Cu^{2+} on the surface of the BLM, while the rate of dissipation of the charge is determined by the rate of the transmembrane transport (i.e. by the resistance of the membrane). The maximum on the potential growth—potential decrease curve shows that the transfer of ions through the membrane is slower than their adsorption. The existence of an excess negative charge on the BLM comprising cattle brain lipids[36] apparently determines the specific adsorption of the ions on the membrane surface.

For the asymmetric addition of dimethylformamide solutions of phytons L and T to the electrolyte surrounding the BLM, a positive charge arose also in the compartment with the phyton (Fig. 1*b*). The positive sign of the stationary potential difference indicated the preferential passage through the BLM of the negatively charged (anionic) form of phyton. Such a species was likely to have been $[Cu(CL)Cl_3]^-$. Sometimes a negative potential was recorded in the compartment with phyton and was then reversed in the course of 5—10 min (Fig. 1*c*). In this case, the curve representing the

variation of the membrane potential had a maximum, which is apparently associated with the adsorption of the coordinatively saturated complex cations $[Cu(CL)_6]^{2+}$.

The anionic nature of the membrane-transport form of phyton is indicated also by the symmetrical form of the voltage–current characteristics recorded in the presence of phyton (Fig. 2). Evidently, in the absence of the modifying agent, the voltage–current characteristic for the BLM is linear in the potential range ±150 mV. In the presence of phyton on one side, the BLM acquired rectifying properties. For the negative polarisation of the compartment with phyton, the current was greater than for the positive polarisation, which indicated the appearance of preferential anionic conductivity in the BLM.

The addition of phyton affected also the electrical conductivity of the BLM. The unmodified BLM has a low conductivity of the order of $10^{-9}-10^{-8}$ S cm^{-2}. The introduction of $CuCl_2$ diminished slightly the electrical conductivity while the addition of ε-caprolactam did not affect the conductivity of the BLM. Under the influence of dimethylformamide solutions of phytons L and T, the electrical conductivity of the BLM increased approximately by a factor of 100 (Fig. 3). The non-linearity of the dependence of the electrical conductivity of the BLM on the concentrations of the reagents is noteworthy. At a phyton concentrate close to 10^{-2} M, the structure of the BLM was affected and became unstable.

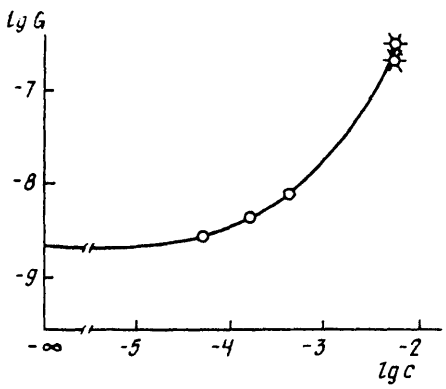

Figure 3. Dependence of the conductivity (G, S cm^{-2}) of the BLM on the phyton concentration (c, M) on one side (the points represented by stars denote the conductivity of BLM measured 20 min after the introduction of the reagent).

The solubility of the permeating anion in lipids may be imparted to it by the presence in its composition of a ε-caprolactam molecule, which exhibits definite lipophilic properties. The logarithm of the partition coefficient of ε-caprolactam in the octanol–water system, which is usually adopted as a measure of the lipophilicity, is $\lg K_{o/w} = 1.03$.[37]

The set of data obtained suggested that the coordinatively unsaturated complex between $CuCl_2$ and ε-caprolactam should be capable of combining with chloride ions and of transporting them across the membrane, whereas the coordinatively saturated complex of the above substances does not possess this property.

By altering the conditions in the synthesis, the coordinatively unsaturated compound $[Cu(CL)Cl_2(H_2O)]$ (yellow colour, lamellar form of the crystals) was isolated from the aqueous or aqueous ethanol solution with the ratio $CuCl_2$:CL = 1:3. The coordinatively saturated compounds $[Cu(CL)_6Cl_2](CL)_2$ (green colour, acicular form) was obtained from benzene solutions after adding to $CuCl_2$ an excess (more than 3 mol per mole of $CuCl_2$) of ε-caprolactam.[21] The study of the membrane activity of these compounds showed that $[Cu(CL)Cl_2(H_2O)]$ does indeed possess membrane activity similar to that of phyton T, i.e. it forms an ionic membrane-transport form having apparently the composition $[Cu(CL)Cl_3]^-$. On the other hand, the effect of $[Cu(CL)_6Cl_2](CL)$ reduced to the adsorption of the cationic complex on the surface of the BLM and did not differ qualitatively from the effect of the simple Cu^{2+} salt.

Another important biologically active compound is the zinc complex of ethylenethiourea. Ethylenethiourea (ETU) is the main product of the metabolism of metal-containing zineb and maneb,[38] which exhibit an appreciable fungicidal activity.[39] It has been suggested that, having entered the interior of the cell, zineb and maneb undergo acid hydrolysis with formation of ethylenethiourea, which exhibits a toxic activity.[40] The absence of fungicidal activity in ethylenethiourea itself can be explained by its poor capacity for permeation through cell walls. Zineb and maneb are regarded as a kind of depot of ethylenethiourea. On the other hand, no account has been taken whatsoever of the role in transport through the cell membrane of the metal cations in the $ZnCl_2$–ethylenethiourea complex.

Up to a concentration of 2 mM, ethylenethiourea does not alter the conductivity and capacity of the BLM. It has been shown by the method of trial hydrophobic ions[41] that ethylenethiourea molecules are incorporated in the solution/BLM boundary.[25]. Under these conditions, the ethylenethiourea dipoles are oriented parallel to the dipoles of the phospholipid molecules, which increases the dipole-induced jump in the BLM potential.

The study of the complex formation reaction between $ZnCl_2$ and ethylenethiourea in aqueous solutions by spectrophotometric and conductimetric methods showed[26] that, at an ethylenethiourea concentration below 10^{-4} M, the complex is not formed even in the presence of a 60-fold excess of zinc ions. At $ZnCl_2$ and ethylenethiourea concentrations of 10^{-3} and 10^{-4} M respectively, the tetrahedral complex $[Zn(ETU)Cl_2]$, in which ethylenethiourea is a bidentate ligand, is formed. At higher ethylenethiourea concentrations, a second ethylenethiourea molecule adds to the zineb ion with formation of the tetrahedral complex $[Zn(ETU)_2Cl_2]$. Under these conditions, ETU behaves as a monodentate ligand.

The study of the effect of the complex on the BLM established[27] that it induces an appreciable growth of membrane conductivity (Fig. 4). This occurs at a concentration of the complex close to 10^{-3} M, so that, in combination with data obtained in the study of the complex formation reaction with ethylenethiourea in aqueous solutions, this shows that at a concentration less than 10^{-3} M the complex decomposes in the solution into its component parts and that the increase in the conductivity of the BLM is induced by the effect of the complex species. The threshold character of the dependence of the electrical conductivity of the BLM on the concentration of the complex suggested the possibility, in principle, that a membrane-active complex is formed from $ZnCl_2$ and ethylenethiourea directly in the electrolyte solution. The results for the influence of $ZnCl_2$ on the properties of the BLM formed in the presence of ethylenethiourea are presented in Fig. 4. Evidently, as in

the case where the complex is catalytically active, here too the conductivity of the BLM increases after the attainment of a $ZnCl_2$ concentration of about 10^{-3} M. This indicates the formation of permeating complex ions directly from simpler species either in the bulk of the electrolyte or at the membrane/solution interface.

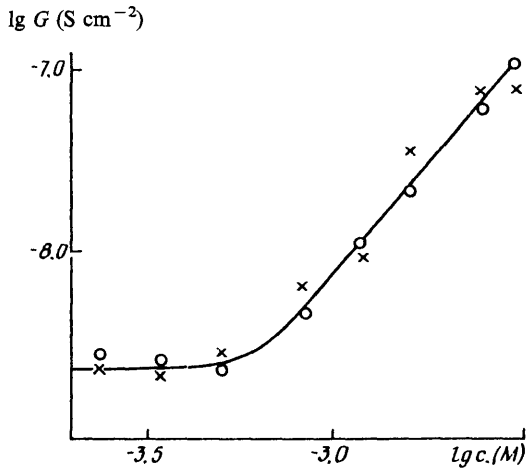

Figure 4. Dependence of the conductivity of the BLM on the concentration of the complex (circles) and $ZnCl_2$ in the presence of 2.4×10^{-3} M ethylenethiourea (crosses).

In order to determine the sign of the charge of the permeating species, a study was made of the voltage–current characteristics of BLM under asymmetric conditions. The BLM was then formed in the presence of ethylenethiourea on either side of the membrane, while $ZnCl_2$ was added on one side. Under these conditions, the voltage–current characteristics had an asymmetric form, the current being higher at a negative potential in the $ZnCl_2$ compartment. This showed that the permeating species are anions.

Measurement of the intramembrane potential difference with the aid of the second harmonic of the alternating current made it possible to determine the sign of the charge of the adsorbing species. It is seen from Fig. 5 that the position of the current I minimum (II) does not change under the influence of ethylenethiourea. This showed that ethylenethiourea does not by itself alter the intramembrane potential difference and confirmed its non-ionic nature. When $ZnCl_2$ is introduced at a concentration of 6.8×10^{-4} M in the cell compartment where ethylenethiourea had been added previously, a difference between the boundary potentials amounting to +14 mV is generated. This indicates a change in the surface charge on the *cis*-side of the BLM in the positive direction as a result of the adsorption of the Zn^{2+} cations. On subsequent increase of the $ZnCl_2$ concentration to 7.5 mM, the sign of the intramembrane potential difference is reversed, which indicates a change in the sign of the charge and hence in the nature of the species adsorbed on the membrane surface.

In this case, the anionic transport complex is apparently formed as a result of the addition of chloride anions to the coordinatively unsaturated complex $[Zn(ETU)Cl_2]$ with formation of the anion $[Zn(ETU)Cl_3]^-$. The most characteristic coordination number for Zn^{2+} cations is 4. The coordinative unsaturation of $[Zn(ETU)Cl_2]$ is associated with the impossibility of altering the denticity of the ligand. Thus one can postulate that the permeating charged species is the anion $[Zn(ETU)Cl_3]^-$. The presence of ethylenethiourea in the complex imparts a certain lipophilicity to the latter (for ethylenethiourea, $\lg K_{o/w} = 0.35$ [37]), whilst chloride anions impart to the complex a negative charge, which is more favourable for transport across the BLM. It is well known that lipophilic anions have a much greater permeating capacity than cations, because the hydrophobic region of the BLM is subject to the influence of a positive electric potential.[42]

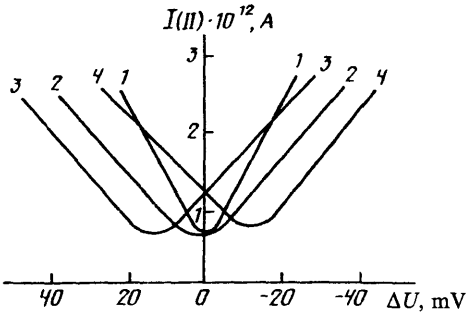

Figure 5. Dependence of the current of the second harmonic and the applied potential in the presence of 1.7×10^{-3} M ethylenethiourea on the *cis*-side: *1*, BLM in the absence of modifying agents; in the presence of modifying agents on one side: *2*, 1.7×10^{-3} M ethylenethiourea; *3*, 6.8×10^{-4} M $ZnCl_2$; *4*, 7.5×10^{-3} M $ZnCl_2$; brain lipid BLM; electrolyte—0.01 M KCl + 0.002 M acetate buffer.

Coordination compounds of cobalt(II) with *o*-phenanthroline (phen) have aroused much interest among the series of new biologically active substances.[43,44] Their appreciable catalytic activity in the oxidation reactions of biological substrates and their influence on the respiratory electron transport chain in mitochondria and on the photosynthetic apparatus of chloroplasts have been observed. Growth regulating and bactericidal activities have been found for a number of complexes. However, the membrane activity of these compounds has not been studied. At the same time, *o*-phenanthroline is appreciably lipophilic ($\lg K_{o/w} = 1.83$ [37]). This suggests a definite possibility of transmembrane transport of cobalt ions as part of coordination compounds with *o*-phenanthroline.

We investigated the effect of *o*-phenanthroline and of its coordinatively unsaturated compounds $[Co(phen)(H_2O)_2](NO_3)_2$ and $[Co(phen)Cl_2].HCl$ on BLM made up of ox brain lipids.[23,29] It was shown that, in the presence of simple salt $CoCl_2$, at a concentration of 10^{-3} M, the electrical conductivity of the BLM is reduced by 20%. On the other hand, the effect of *o*-phenanthroline or the coordination compounds $[Co(phen)(H_2O)_2](NO_3)_2$ and $[Cl(phen)Cl_2].HCl$ on BLM led to an increase in the electrical conductivity of the latter. The kinetics of this change are illustrated in Fig. 6. The effect of *o*-phenanthroline is apparently a consequence of its

lipophilic properties. In order to determine the site of location of *o*-phenanthroline in the BLM structure, the method of trial hydrophobic ions was used. It demonstrated, that, in constrast to ethylenethiourea, *o*-phenanthroline molecules do not have a particular location relative to the normal to the BLM plane. This is probably associated with the more pronounced lipophilic properties of *o*-phenanthroline compared with ethylenethiourea. The protonated form of *o*-phenanthroline, formed in the weakly acid electrolyte (pH 4.5) surrounding the membrane, is apparently the carrier of electricity through the BLM. *o*-Phenanthroline plays the role of the protonophor in this system.

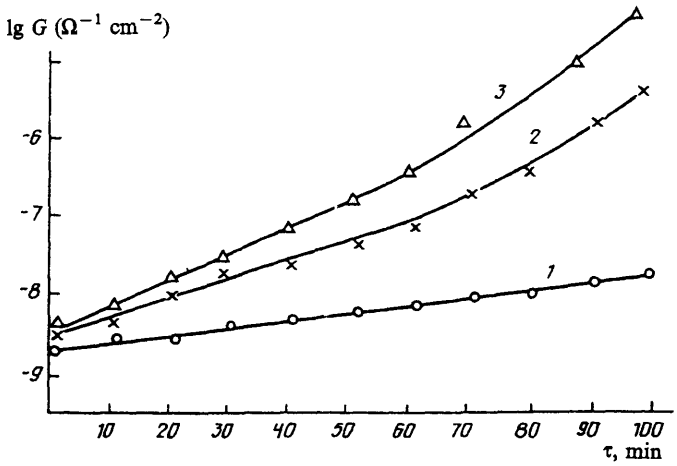

Figure 6. Kinetics of the variation of the conductivity of the BLM after the introduction of 2×10^{-4} M reagents on one side of the membrane: *1*, *o*-phenanthroline; *2*, $[Co(phen)(H_2O)_2](NO_3)$; *3*, $[Co(phen)Cl_2]HCl_2.HCl$; electrolyte—0.01 M KCl + 0.002 M acetate buffer.

The increase in the electrical conductivity of the BLM in the presence of $[Co(phen)Cl_2].HCl$ and $[Co(phen)(H_2O)_2](NO_3)_2$ is apparently induced by the passage through the BLM of lipid-soluble membrane-transport forms comprising coordination compounds.

In order to establish the sign of the charge of the permeating species, a study was made of the voltage–current characteristics of the BLM under asymmetric conditions. Fig. 7 shows that the voltage–current characteristics are asymmetric and that for $[Co(phen)Cl_2].HCl$ the current is greater at a negative potential in the cell compartment where the reagent had been added (*cis*-compartment), while in the case of $[Co(phen)(H_2O)_2](NO_3)_2$ the current is greater at a positive potential in the cell compartment. This shows that anions and cations are the permeating species in the former and latter cases respectively.

As stated above, the complexes investigated are coordinatively unsaturated. The maximum coordination number of cobalt(II) is 6, while in the given complexes it is 4, since *o*-phenanthroline is a bidentate ligand. There is therefore a possibility of a further addition to the central ion of chloride ions, a large number of which are present in the electrolyte. However, here it is necessary to bear in mind that the permeating capacity of the ions through the BLM diminishes greatly with increase in their charge, i.e. the transport of a singly-charged ion is preferred to that of a doubly-charged ion. In the case of $[Co(phen)Cl_2].HCl$, the permeating species are probably the anions $[Co(phen)Cl_3]^-$, while in the case of $[Co(phen)(H_2O)_2].(NO_3)_2$ they are the cations $[Co(phen)(H_2O)_2Cl]^+$. In the latter case, the coordination of a single chloride anion diminishes the positive charge of the ion transported. Such forms of the complex ions probably exhibit an enhanced stability in the membrane phase, i.e. in a medium with a low dielectric constant, whereas in the bulk of the electrolyte they are less stable and dissociate with elimination of chloride anions. Thus, under the influence of the electric field gradient there may be induced transport of chloride anions from one side of the membrane to the other. The greater electrical conductivity of BLM in the presence of $[Co(phen)Cl_2].HCl$ compared with $[Co(phen)(H_2O)_2](NO_3)_2$ is apparently associated with the difference between the charges of the permeating ions.[42]

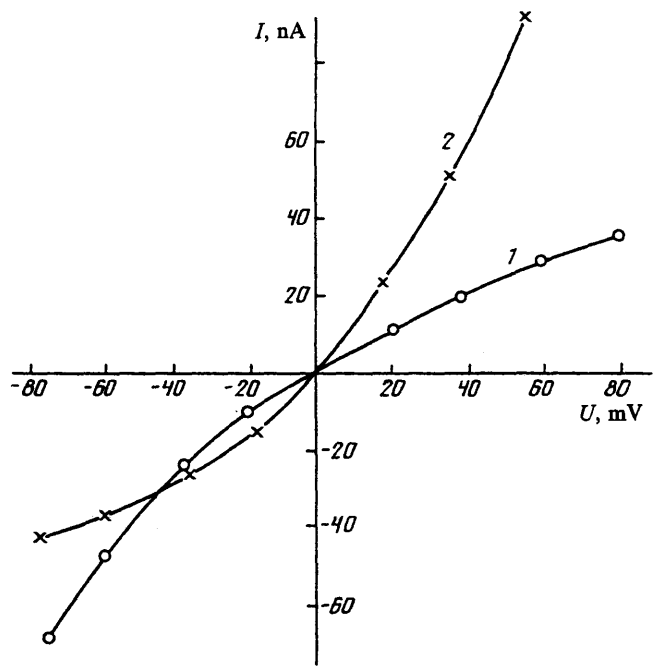

Figure 7. The voltage–current characteristics of a BLM in the presence of $[Co(phen)Cl_2].HCl$ (curve *1*) and $[Co(phen)(H_2O)_2].(NO_3)_2$ (curve *2*) on one side; the sign of the potential is indicated relative to the cell compartment to which the reagent has been added; electrolyte—0.01 M KCl + 0.002 M acetate buffer.

The chloride selectivity of BLM in the presence of the given complexes is indicated by measurements of the potential arising when a transmembrane electrolyte concentration gradient is established. For example, in the presence of 2×10^{-4} M $[Co(phen)(H_2O)_2](NO_3)_2$ with the ratio of the concentrations of the

KCl electrolyte on the two sides of the membrane amounting to 10, an ionic potential of 53 mV is developed, which corresponds to the transport number of the anions $t_{Cl^-} = 0.91$.

The influence of the coordinative saturation of the Co^{2+} ions and of the lipophilic properties of the ligands on the membrane activity of the complex compounds was investigated with the aid of the coordinatively saturated complex $[Co(phen)_2Cl_2].3.5(H_2O)$ and the coordinatively unsaturated complex $[Co(dimphen)Cl_2].HCl$, where dimphen is 2,9-dimethylphenanthroline. The lipophilic properties of 2,9-dimethylphenanthroline are more pronounced ($\lg K_{o/w} = 2.49$ [37]) than those of *o*-phenanthroline. It is striking that, in the presence of the coordinatively saturated complex $[Co(phen)_2Cl_2].3.5H_2O$, the electrical conductivity of the BLM does not increase. It is also seen that the more lipophilic cobalt(II) complex of the dimethyl derivative of *o*-phenanthroline is more effective than $[Co(phen)Cl_2].HCl$. In the presence of $[Co(dimphen)Cl_2].HCl$ on one side of the membrane, the voltage–current characteristics of BLM are asymmetric (the membrane current at a negative potential in the *cis*-compartment is greater than at a positive potential).

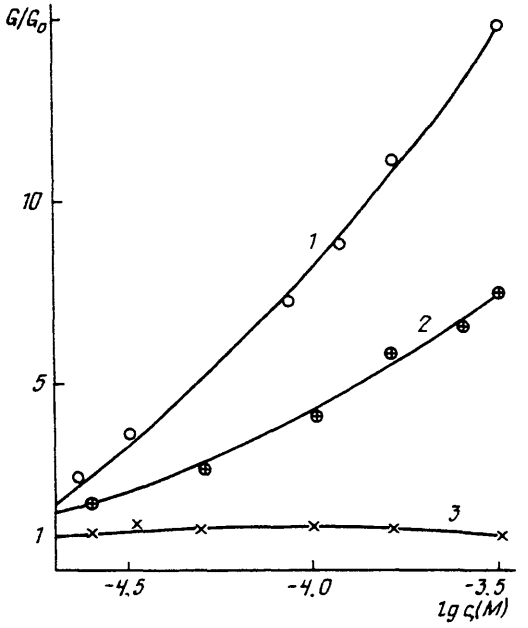

Figure 8. The influence of cobalt(II) complexes of *o*-phenanthroline and its dimethyl derivatives on the relative conductivity of the brain lipid BLM: *1*, $[Co(dimphen)Cl_2].HCl$; *2*, $[Co(phen)Cl_2].HCl$; *3* $[Co(phen)_2Cl_2].3.5H_2O$; electrolyte—0.01 M KCl + 0.002 M acetate buffer.

The study of the ionic selectivity of BLM in the presence of the given complexes by the method involving the measurement of the diffusion potential under conditions where a transmembrane chloride ion gradient has been established demonstrated the chloride selectivity of BLM in the case of coordinatively unsaturated complexes (the Cl^- transport numbers were 0.91–0.93) and the absence of ionic selectivity in the case of the coordinatively saturated complex. The results permit two conclusions: firstly, the coordinatively saturated complexes are unable to transport chloride ions through BLM and, secondly, an increase in the lipophilicity of the coordinatively unsaturated complexes improves their membrane-transport properties in relation to chloride anions.

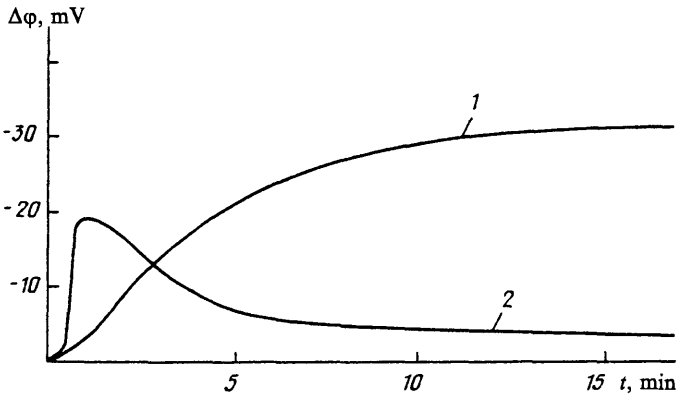

Figure 9. Generation of the transmembrane potential difference after the introduction of 2.7×10^{-6} M $[Zn(BMC)_2Cl_2]$ (curve *1*) and 2.5×10^{-4} M $ZnCl_2$ (curve *2*) on one side of the membrane.

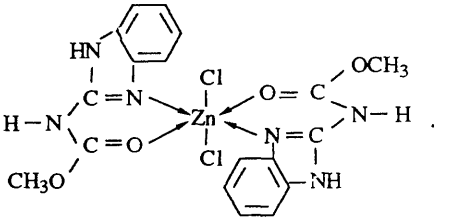
IV. The mechanism of the influence of coordinatively saturated metal complexes on the ionic conductivity of bilayer lipid membranes

The coordinatively saturated complex of $ZnCl_2$ with *N*-methyl-(2-benzimidazolyl)carbamate (BMC) exhibits a fungicidal activity.[45] Its structure and properties have been described.[46] The complex $[Zn(BMC)_2Cl_2]$, where BMC is a bidentate ligand, has an octahedral configuration:



In order to determine the sign of the charge of the membrane-active species, a study was made of the generation of the transmembrane potential difference after the introduction of $[Zn(BMC)_2Cl_2]$ and $ZnCl_2$ on one side of the BLM (Fig. 9). When both reagents were added, the potential difference had a minus sign in the *cis*-compartment. The form of the curve in the case where $ZnCl_2$ was introduced indicated a facilitated adsorption of the cations and a negatively charged surface of the BLM made up of ox brain lipids. The absence of a maximum following the introduction of $[Zn(BMC)_2Cl_2]$ indicated the retardation of the stage involving the adsorption of ions formed on dissociation of the above complex compared with the stage involving their transport. The sign of the generated potential difference shows that the permeating ions are cations.

Additional evidence indicating that the permeating species are cations on exposure of the membrane to $[Zn(BMC)_2Cl_2]$ was provided by the voltage–current characteristics of the BLM recorded after the introduction of the reagent on one side only. They had the rectification form—the current corresponding to positive polarisation in the *cis*-compartment was higher than that corresponding to the negative polarisation. The cationic transport complex is apparently formed as a result of the hydrolysis involving the elimination of a chloride ion:

$$[Zn(BMC)_2Cl_2] + H_2O \rightleftarrows [Zn(BMC)(H_2O)Cl]^+ + Cl^- .$$

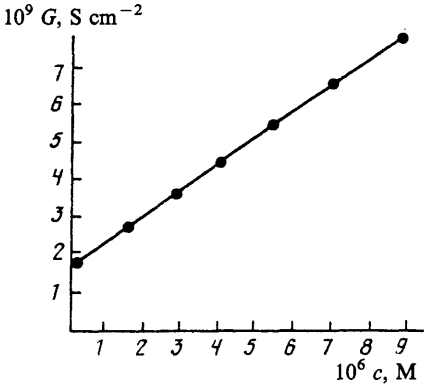


Figure 10. The influence of the $[Zn(BMC)_2Cl_2]$ concentration on the conductivity of the ox brain lipid BLM; electrolyte—0.01 M KCl + 0.002 M acetate buffer.

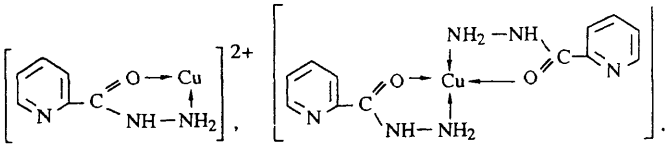
The transport of cations is ensured by the lipophilic properties of the BMC molecules ($\lg K_{o/w}$ = 0.35 [37]) and also by the low electric charge on the complex (+1) and apparently proceeds via a mechanism involving the direct passage of hydrophobic ions through the BLM. Evidence for this mechanism of the transmembrane transport of the cations $[Zn(BMC)_2(H_2O)Cl]^+$ is provided by the linear dependence of the conductivity of the BLM on the concentration of the cations (Fig. 10). Such linear dependence is characteristic of the direct passage of hydrophobic ions through the BLM.[41]

The complex of gallium(III) chloride with isonicotinic acid hydrazide (INAH), having the formula $[Ga(INAH)_3]Cl_3.H_2O$, is coordinatively saturated. Isonicotinic acid hydrazide (isoniazide) inhibits the growth of tuberculosis bacteria. The main side effect of isoniazide therapy is liver damage. On the other hand, the use of isoniazide in a complex with copper ions makes it possible to reduce greatly the negative side effect of the preparation. The copper(II) complex of INAH is an active antitumour agent. The protonated forms of the complex exhibit a biological activity:



It is believed [7] that the role of the metal reduces to creating a liposoluble compound which enhances the transport of the physiologically active ligand through the biological membrane. The use of isoniazide in a complex with the triply charged gallium cation can probably lead to new effects in therapy using this preparation.

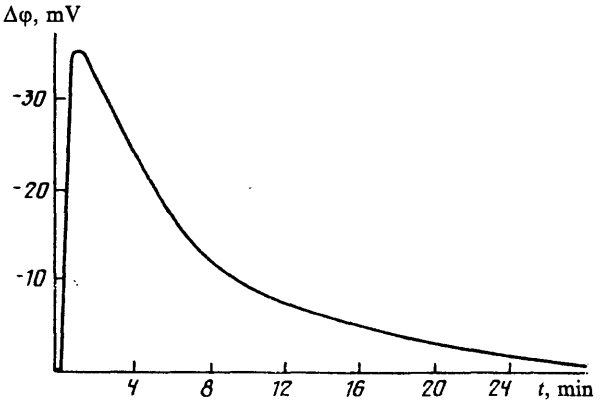


Figure 11. Generation of the transmembrane potential difference following the introduction of 1.6×10^{-6} M $[Ga(INAH)_3]Cl_3$ on one side of the membrane; the instant of the introduction of the reagent was adopted as the zero time; electrolyte—0.01 M KCl + 0.002 M acetate buffer.

We investigated the membrane activity of the $GaCl_3$ complex with isoniazide in relation to ox brain lipid BLM.[28] A typical potential difference generation curve after the introduction of the complex on one side of the BLM is illustrated in Fig.1. The minus sign of the potential difference in the *cis*-compartment of the cell indicates the adsorpton of the positively charged complex species on the BLM surface. It is seen that the residual (diffusion) potential diminishes almost to zero, which indicates the absence of the transmembrane transport of any kind of ionic form of the reagent. The maximum on the curve indicates an appreciable adsorption capacity of the complex, which is associated with the presence in its composition of the complex cation with the +3 charge.

The presence of the lipophilic isoniazide organic ligand ($\lg K_{o/w}$ = −0.5 [37]) leads to an increased adsorption capacity of the complex compared with the simple gallium salt $Ga(NO_3)_3$ (Fig. 12). When account is taken of the equality of the charges on the adsorbing species (+3), the higher value of $\Delta\varphi$ corresponds to a greater amount of cations bound to the BLM surface.

Studies on the ionic selectivity of BLM in the presence of the $GaCl_3$ complex with isoniazide demonstrated the absence of the ability of the latter to combine with and transport chloride anions to the BLM. On the other hand, comparison of the concentration variations of the relative conductivities and capacities of the BLM formed from n-octane and n-tetradecane solutions of lipids showed that, with increase in the concentration of the reagent, the properties of the BLM vary as a consequence of structural rearrangements in them (Fig. 13). It is essential to note the qualitative difference between the concentration variations of the capacities of the

membranes formed from n-octane and n-tetradecane lipid solutions, which is due to the different contents of the hydrocarbon solvent in the BLM.[22]

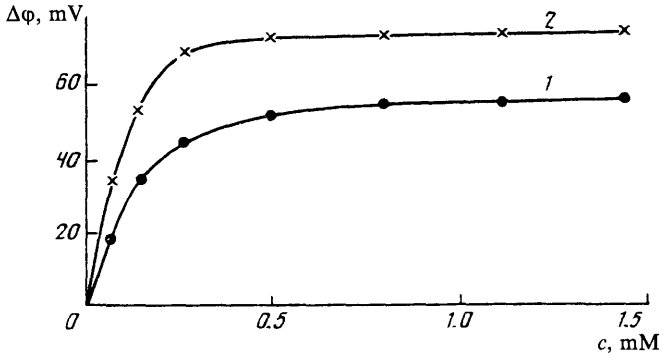

Figure 12. Dependence of the difference between the boundary potentials of the brain lipid BLM on the concentrations of $Ga(NO_3)_3$ (curve *1*) and $[Ga(INAH)_3]Cl_3$ (curve *2*); electrolyte—0.01 M KCl + 0.002 M acetate buffer.

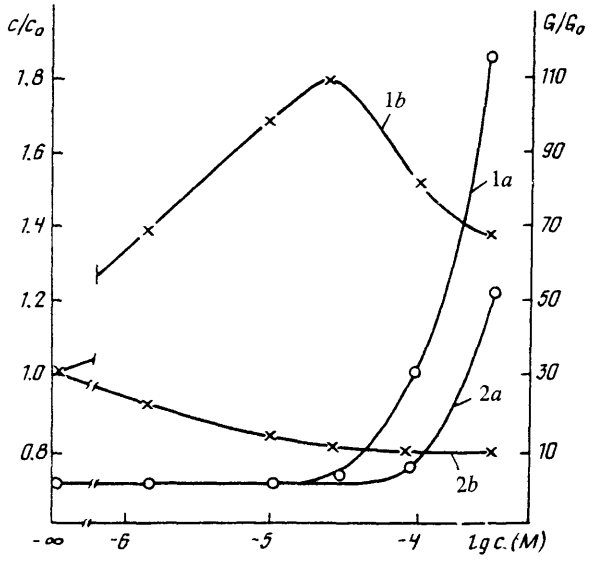

Figure 13. Dependence of the change in the relative conductivity (*a*) and relative capacitance (*b*) of the BLM in n-octane (curve *1*) and n-tetradecane (curve *2*) on the $[Ca(INAH)_3]Cl_3$ concentration; c_0 and G_0—the capacitance and electrical conductivity of the unmodified membranes.

V. Conclusion

The systematic studies which have been carried out make it possible to put forward the following considerations concerning the mechanisms of ion transport through biological membranes with participation of metal coordination compounds. There is no doubt about the validity of the hypothesis that the complex species is more favourable as a transport form for the transfer of both heavy metal ions and lipophilic ligands through the cell membrane.

However, the mechanisms of their action depend on a number of factors: coordinative unsaturation, charge, and stability of the complex, the lipophilicity of the ligands, etc. Under these conditions, the mechanism of the actual interaction of the complexes with the biological membrane, frequently accompanied by a change in its structure, is quite distinct.

Allowance for these phenomena is a necessary precondition for the specific synthesis of physiologically active substances with a wide range of therapeutic activities.

Experimental data for the effects of different complexes on BLM have shown that the most important factor in the interaction is the coordinative saturation of the complexes and the lipophilic ligands. It is known that the effect of hydrophilic heavy metal salts is associated with adsorption on the surface of the biological membrane. An increasing number of data have appeared recently showing that the specific chemical properties of the metal cations as well as the structure and properties of the adsorption centres are strongly manifested in this kind of binding process. Here it must be emphasised that in the case of BLM the above interaction does not entail an increase in the conductivity of the BLM.

However, an increase in the lipophilicity of the reagent should lead to an increase in the membrane activity of the heavy metal salts. Thus on coordination of the lipophilic ε-caprolactam, the complex $[Cu(CL)Cl_2(H_2O)]^0$ causes an appreciable increase in the activity of the BLM.

The use of the lipophilic 8-hydroxyquinoline ($\lg K_{o/w} = 1.13$) as the ligand and the formation of the compound $[Cu(HQ)_2]^0$ increase the electrical conductivity of BLM approximately by an order of magnitude. The membrane activity of the trichlorophenol (TCP) complex of copper(II) $[Cu(TCP)_2]^0$, where the lipophilicity of each TCP molecule is $\lg K_{o/w} = 3.7$, increases even further.

All the complexes indicated are coordinatively unsaturated but even the coordinatively saturated compound $[Zn(BMC)_2Cl_2]^0$, in which the BMC molecule has a definite lipophilicity $\lg K_{o/w} = 0.35$, constitutes an energetically favourable transport form whereby transfer through a biological membrane is effected.

On the other hand, the complexes which do not include lipophilic molecules do not exhibit a membrane activity. Thus in the presence of $[Cu(NH_3)_4]SO_4$ there is no change in the electrical conductivity and capacity of BLM up to a concentration of 2 mM. The lipophilicity parameter for ammonia molecules is low, amounting to $\lg K_{o/w} = -1.5$. The low membrane activity of $[Cu(NH_3)_4]SO_4$ compared even with $CuSO_4$ is associated with the stability of the complex ion whose instability constant is 10^{-12}.

The effect of ligands (ethylenethiourea, BMC, 8-hydroxyquinoline, ε-caprolactam, *o*-phenanthroline, etc.) does not alter the permeability of BLM to K^+ and Cl^- ions, which is associated with their non-ionic nature and probably with the absence of a marked surface activity of such species. On the other hand, polar molecules are able to be incorporated in the BLM structure. The dipoles of such molecules are then oriented in a different manner relative to the dipoles of the lipid molecules. By becoming incorporated similarly in BLM, polar molecules alter the dipole-induced potential jump at the BLM/aqueous solution interface, which may affect the change in the permeability of membranes to metal cations.

A significant difference between the mechanisms of the action of coordinatively unsaturated and saturated complexes is that, as

observed for the first time by ourselves, the coordinatively unsaturated complexes become transferring agents for chloride anions and probably other anionic substrates via a diffusional mechanism.

The substance synthesised as the agent transferring chloride anions through membranes must possess a number of properties which make possible, firstly, the addition of chloride anions to the complex-forming ion via a coordinate bond and, secondly, the transport of the chloride ions through the internal hydrophobic region of a BLM as a part of the composition of the lipophilic transport complex. This imposes definite requirements on the central ions and ligands which are determined by calculating the energy of the transport of species through BLM. The theoretical foundations of the specific synthesis of biologically active substances, inducing the transport of chloride anions through BLM, have been described in detail.[24,30] We shall describe only the main ones.

The principal property of the ligand molecules in the process indicated is their ability to impart lipophilic properties to the transport complexes formed, which enables them to permeate through the internal hydrophobic region of the BLM. On the other hand, it has been shown[48] that the permeability of the membrane to extremely hydrophilic and extremely hydrophobic molecules is very low. The optimum partition coefficient $\lg K$ in the organic solvent/water system, adopted as a measure of the hydrophobicity of the molecule, is in the range $-1 \leqslant \lg K \leqslant 1.5$.

The coordinatively unsaturated complex species, with which the anionic substrate combines, must have a positive electrical charge or, in the absence of the latter, a dipole moment. On the basis of electrostatic considerations, a +1 charge is optimum. In the absence of electrostatic attraction of chloride anions to the coordinatively unsaturated complex, one can assume, taking into account the non-equivalence of the coordination, that combination with chloride ions does not occur. This is indicated by the results of a study[9] where it was shown that the addition of chloride anions is observed for the polar *cis*-$[Pt(NH_3)_2Cl_2]$ and is not observed for the non-polar *trans*-$[Pt(NH_3)_2Cl_2]$ if it is assumed that both compounds are coordinatively unsaturated.

One can postulate that the mechanism described plays a definite role in the transport systems of biological membranes. A complex transport form having the composition coordinated ion–lipophilic ligand–hydrophilic substrate is then created. Aminoacids, polypeptides, as well as purine and pyrimidine bases, which are components of protein molecules, can play the role of ligands.[7] By virtue of their lipophilic and polar properties, the above ligands can be incorporated in the lipid bilayer and, furthermore, are able to interact with transition metal cations. This results in the formation of a compound, coordinatively unsaturated by the ligand, which can combine with chloride anions and effect their transfer. In a real biological system, other hydrophilic substrates (dihydrogen phosphate, hydrogen carbonate, carboxylate, etc. anions) can also take the place of chloride ions.

Hydrolytic enzymes, in particular carbonic anhydrase and carboxy- peptidase, which are coordinatively unsaturated compounds of zinc and histidine or with histidine and glutamic acid, can probably serve as examples of such systems in living organisms. Proof of the direct binding of a chloride anion to zinc in carbonic anhydrase was obtained from line broadening in the ^{35}Cl NMR spectra.[49] Similar results have been obtained for other anionic substrates and in the case of carboxypeptidase.

Another mechanism of the interaction of coordination compounds with cell membranes is that involving a change in the structure of the membranes. The change in the structure of membranes, in particular BLM, is associated with the charge of the active complex species. It is noteworthy that anionic complexes do not interact with BLM because of the presence of a negative charge on its surface. In the presence of highly lipophilic ligands, the latter can only be incorporated in the lipid bilayer.

Coordination compounds with a +2 charge and above are adsorbed on the BLM surface and the adsorption is stronger the higher the charge of the adsorbing species for identical lipophilicities of the ligands in the coordination sphere of the complex.

We have shown,[22,28] in relation to the interaction of the gallium complex of isonicotinic acid hydrazide $[Ga(INAH)_3]^{3+}$ with BLM, that the properties of the bilayers change as a consequence of the compaction of their structure caused by the decrease in the electrostatic forces repelling the polar heats of the lipid molecules in the adsorption of complex cations on the BLM surface. The concluding stage of the increase in the electrical conductivity of BLM with increase in the concentration of the complex involves the phase transition of the BLM from the liquid-crystal to the gel state. The increase in the permeability of bilayers in such phase transitions has been pointed out.[50] This results in an increase in the thickness of BLM, which do not contain the solvent, this being explained by the transition from the *gauche*-conformation to the fully *trans*-conformation in the lipid molecules. The increase in the conductivity of BLM under the influence of a cationic complex in the phase transitions can be induced by the local formation of micellar and hexagonal phases, whose permeability is high, and also by the appearance of lipid domains at the boundaries of which there is a possibility of the diffusion of ions. For the BLM obtained from individual lipids, the change in conductivity during the phase transition has a discrete character. In our case, the change becomes more marked slowly and smoothly, which is a characteristic feature of the phase transitions in BLM formed from a mixture of lipids. Under these conditions, the conductivity increases significantly only in the region of high concentrations of the complex.

The data obtained for the mechanisms of the action of complexes are important for the development of the specific synthesis of biologically active substances and must be taken into account in discussing the physiological properties of such compounds.

Some problems in the stereochemistry of nitrogen compounds in the gas phase

N I Sadova, L S Khaikin, L V Vilkov
Moscow State University

ABTRACT. Data on the geometry of free molecules containing a nitrogen atom have been reviewed. Most attention has been paid to compounds of amines with a nitrogen–metal bond, nitro-compounds, and complex compounds. The applicability of various ideas on the relationship between the electronic structure and geometry of molecules has been analysed.

The bibliography contains 193 references.

I. Introduction

The stereochemistry of nitrogen compounds is rich in different forms of valence state of the nitrogen atom and different types of bond between nitrogen and other elements. A large number of publications[1–8] have been devoted to the systematisation of data on the geometry of molecules in the gas phase and the discovery of structural regularities. The present review is restricted to a few classes of nitrogen compound, and most of the data systematised are not in the works cited above.

The analysis was based on two sections of Landolt–Bornstein[9] containing the results of electron diffraction (GE) and microwave (MW) studies of the structure of molecules in the gas phase up to and including 1985, and original publications for the following year. For the values of the parameters given in the text, the following dimensions are used: bond lengths in Ångstrom units (Å) and valence and dihedral angles in degrees (°). Their experimental errors in the last significant figures are given in brackets.

Since different methods of studying the structure were used, the geometric parameters, in particular the bond lengths, have slightly different physical significance, because of the slight (generally up to ~0.01 Å) influence of vibrational corrections (see for example Ref. 2).

II. Amino-derivatives

1. Amines with hydrocarbon substituents and halogenoamines

In the examination of the structure of amines, particular attention is usually paid to the geometry of the amine fragment, that is to the configuration of the bonds formed by the nitrogen atom and the lengths of the "nitrogen–substituent" bonds.

Table 1. Geometric parameters of alkylamine molecules.

Compound	N–C, Å	C–N–C, °	Method,* type of parameter	Refs.
CH_3NH_2	1.472(3)	–	GE+MW, r_g	[10]
$(CH_3)_2NH$	1.455(6)	111.8(8)	GE, r_a	[11]
	1.462(7)	112.2(5)	MW, r_s	[12]
$(CH_3)_3N$	1.458(4)	110.9(6)	GE, r_α	[13]
$(CF_3)_3N$	1.426(6)	117.9(4)	GE, r_0^δ	[14]
$C_2H_5NH_2$	1.470(10) *trans*	–	GE+RC+NC, r_g	[15]
	1.475(10) *gauche*			
$(CH_3)_3CNH_2$	1.493(6)	–	GE, r_g	[16]
$CH_2CH_2CHNH_2$	1.452(7)	–	MW, r_s	[17]
$(CH_3)_2NC_2H_5$	1.452(6)	111.3(10)	GE, r_a	[18]
$CH_2N(CH_3)_2$	1.449(4)	110.7(10)	GE, r_α	[19]
$[(CH_3)_2CH]_2NH$	1.470(4)	120.1(10)	GE+VS+MM, r_g	[20]
$[(CH_3)_3C]_2NH$	1.467(15)	135(3)	GE, r_a	[21]
$(CH_3)_3CNHCH_2CH_3$	1.476(1) (C″)	117.6(11)	GE+VS+NC, r_g	[22]
	1.465(1)			
$(CF_3CF_2CF_2)_3N$	1.459(8)	120.0(2)	GE, r_g	[23]

*Notation: GE = gas-phase electron diffraction, MW = microwave spectroscopy, RC = rotational constants, NC = non-empirical calculations, VS = vibrational spectroscopy, MM = molecular mechanics.

The geometric parameters of a number of alkylamines are given in Table 1. The bonds formed by the nitrogen atom in ammonia and methylamines have a pyramidal configuration. The replacement of the hydrogen atoms in NH_3 by CH_3 groups increases the average valence angle α_N by ~3°:

Amine	NH_3	CH_3NH_2	$(CH_3)_2NH$	$(CH_3)_3N$
$\bar{\alpha}_N$, °	106.7	110	108.6	110.9

In the methylamine series the N–C bond length tends to decrease on going from the primary to the tertiary amine. This trend is also observed in a series of alkylamines with heavier substituents, such as $C_2H_5NH_2$ [N–C 1.472(10) Å] and $C_2H_5N(CH_3)_2$ [N–C 1.452(6) Å].

On going from CH_3NH_2 to $C_2H_5NH_2$ the N–C bond length remains unchanged, but the presence of the bulky t-butyl substituent in $(CH_3)_3CNH_2$ increases the N–C bond length to 1.493(6) Å.

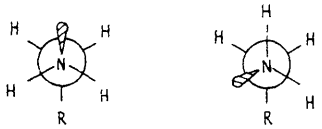
Replacing the electron-donor CH_3 groups in the trimethylamine molecule by the electron-acceptor CF_3 groups leads to flattening of the configuration of the nitrogen atom [the CNC angle is 117.9(4)°]. At the same time the N–C bonds are shorter [1.426(6) Å] than those in methylamines.

On going from $(CF_3)_3N$ to $(CF_3CF_2CF_2)_3N$ the configuration of the bonds formed by the nitrogen atom becomes completely planar, with a CNC angle of 120.0(2)°, and the N–C bond length increases by ~0.03 Å.

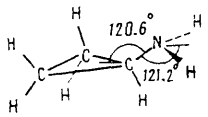
The steric interactions between the t-butyl groups in the $HN[C(CH_3)_3]_2$ molecule increase the CNC angle to 135(3)° compared with the corresponding angle [120.1(10)°] in $NH[CH(CH_3)_2]_2$, indicating that the steric repulsion of the t-butyl groups is greater than that of the isopropyl groups.

Thus the configuration of the bonds formed by the amine nitrogen atom in alkylamines depends on the type of substituent and on steric factors.

In the study of the structure of more complex aliphatic amines such as $CH_3CH_2NH_2$, $CH_2CH_2CHNH_2$, $(CH_3)_2CHNH_2$,[24] $(CH_3)_2NC_2H_5$, $NH[C(CH_3)_3]_2$, $NH[CH(CH_3)_2]_2$, and $CH_2[N(CH_3)_2]_2$, the conformations of the molecules, in particular the rotational isomerism about the N–C bond, is also examined in detail. It has been shown, for example, that ethylamine consists of a mixture of *gauche*- and *trans*-isomers (~1:1) and that $\Delta H(gauche-trans)$ = 306(200) cal mol^{-1}.



In cyclopropylamine the amino-group is in the staggered "perpendicular" conformation relative to the cyclopropane ring†.



The conformations of the molecules of secondary amines are characterised by the two angles of rotation about the N–C bonds. For the $NH[CH(CH_3)_2]_2$ molecule these angles are the same and equal to 52(4)°, whereas in $NH[C(CH_3)_3]_2$ the t-butyl groups are rotated slightly differently (19° and 30°) relative to the N–C bond, and the axes of symmetry of these groups deviate from the direction of the N–C bonds by 2.5 ± 1.5°.

†According to the definition given by the authors cited, the term "perpendicular" conformation indicates that the lone pair of electrons of the nitrogen atom is situated above the three-membered ring and is projected on to the bisector of the CCC angle.

The geometric parameters of a number of halogenoamines are given in Table 2. A distinguishing feature of halogenoamines compared with ammonia and methylamines is the decrease in the valence angles XNX and XNY, and hence in the average valence angle at the nitrogen atom.

Table 2. Geometric parameters of halogenoamine molecules.

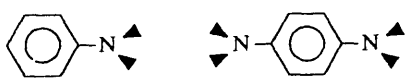
*Accepted value.

The N–C bond lengths decrease systematically in the fluoroamine series CF_3NF_2 > $(CF_3)_2NF$ > $(CF_3)_3N$ (Tables 1 and 2).

The configuration of the bonds formed by the nitrogen atom in aromatic amines is sensitive to the influence of substituents. According to microwave data, the molecule of aniline $C_6H_5NH_2$ (A) is non-planar.[34] The angle of displacement of the N–C_{arom} bond from the plane NX_2 (Φ) is 37.5°, and the angle HNH is 113°, indicating that the configuration of the bonds formed by the nitrogen atom is pyramidal:

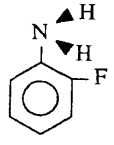


(A) (B)

For the related molecule of *p*-diaminobenzene (B),[35] the angle Φ characterising the pyramidal character of the configuration of the bonds formed by the nitrogen atom is slightly greater [43(4)°] than that in aniline (37.5°), but the conformation of the molecule (B) is similar to that of aniline. Of the other geometric parameters of these molecules, the N–C bond lengths [1.402(2) Å in (A) and 1.424(5) Å in (B)] and the $CC_{NH_2}C$ valence angles [119.4(2)° in (A) and

119.8(2)° in (B)] are noteworthy. The N–C bond length in arylamines is much shorter than that in alkylamines and halogenoalkylamines. The deformation of the valence angle in the benzene ring at the amine nitrogen atom is slight.

Microwave data have been published, characterising the configuration of the bonds formed by the amine nitrogen atom in the molecules of *o*-, *m*-, and *p*-$XC_6H_4NH_2$ (X = F,[36–38] Cl[39–41]), *p*-$FC_6H_4NHCH_3$,[42] $C_6H_5NHCH_3$,[43,44] and $C_6H_5N(CH_3)_2$‡.[45] The complete structures of these molecules have not been determined, however. Of all the fluorine-substituted anilines, *o*-$FC_6H_4NH_2$ [36] is the one for which the parameters characterising the geometry of the amino-group are closest to those for non-substituted aniline; it is followed by *m*-$FC_6H_4NH_2$,[37] and the greatest deviations are observed for *p*-$FC_6H_4NH_2$.[38] It is suggested[36] that since an intramolecular hydrogen bond H...F may be formed, the conformation of the *o*-$FC_6H_4NH_2$ molecule probably differs from that of aniline.



When one or two H atoms in the amino-group of *p*-$FC_6H_4NH_2$ are replaced by a CH_3 group, the configuration of the bonds formed by the nitrogen atom is flattened considerably.

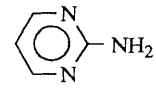
Molecule	$C_6H_5NH_2$	*m*-$FC_6H_4NH_2$	*n*-$FC_6H_4NH_2$	*n*-$FC_6H_4NHCH_3$	*n*-$FC_6H_4N(CH_3)_2$
Angle HNX, ° (X=H, CH_3)	113.1(2)	115.0	112	115.6	114
Angle of displacement of the N–C_{arom} bond $\bar{\phi}$, °	37.5(2)	36.2	46.4	18.3	27

In the series of chloro-substituted anilines, on going from *o*-$ClC_6H_4NH_2$ [39] to *p*-$ClC_6H_4NH_2$ [41] the angle Φ characterising the pyramidal nature of the configuration of the bonds formed by the nitrogen atom increases from 34.5° to 41.4°.

The structure of another two arylamines, $(C_6H_5)_3N$ [47] and $C_6H_5NCH_2CH_2$,[48] can be considered. In the triphenylamine molecule the valence angles at the nitrogen atom are 116(2)°, that is the configuration of the bonds formed by the nitrogen atom is flattened considerably, as in N-fluoromethylamines, but in the N-phenylethyleneimine molecule the nitrogen atom, firmly fixed in the ring, has a pyramidal structure, and the angle of displacement of the N–C_{arom} bond from the plane of the three-membered ring is ~55°. The conformation of the $C_6H_5NCH_2CH_2$ molecule is similar to that of aniline and dimethylaniline. The electron diffraction studies of the $(C_6H_5)_3N$ and $C_6H_5NCH_2CH_2$ molecules, however, were carried out in the sixties, with an accuracy lower than that now attainable.

‡ The $C_6H_5N(CH_3)_2$ molecule has also been studied by electron diffraction,[46] but the accuracy of the determination of the parameters is low.

2-Aminopyrimidine



is stereochemically similar to arylamines.[49] The molecule of this compound is flatter than the aniline molecule, and the angle of displacement of the N–C_{arom} bond from the plane of the NH_2 group is 27°. The N_{amine}–C bond length [1.33(1) Å] is shorter than that in $C_6H_5NH_2$.

Thus the configuration of the bonds formed by the nitrogen atom in arylamines varies from pyramidal to almost planar, depending on the substituents on the nitrogen atom and to some extent on the substituents in the benzene ring.

Comparison of aliphatic and aromatic amines shows that $r(N-C)_{aliph} > r(N-C)_{arom}$ and $\bar{\alpha}_N(aliph) < \bar{\alpha}_N(arom)$ ($\bar{\alpha}_N$ is the average value of the valence angle at the nitrogen atom).

There are almost no published data on enamines of the type $R^1R^2N-CR^3=CR^4R^5$ in the gas phase. In a microwave study of vinylamine $CH_2=CHNH_2$,[50] the complete structure could not be determined. By making a number of assumptions it was possible to obtain, with a low accuracy, only the N–C bond lengths [1.397(30) Å and the C=C–N angle [125.2(20)°], and also the angle between the N–C bond and the continuation of the bisector of the HNH angle [θ = 34(5)°].

The amides of carboxylic acids $RC(O)NH_2$ and their derivatives form a separate class of compound. The central fragment in amide molecules contains the N–C(O) bond. A knowledge of the geometry of this fragment is of considerable importance for establishing the structure of the peptide group in polypeptides.

The geometry of the molecules of the simplest amides has been studied by spectroscopic and diffraction methods and in considerable detail. The nitrogen atom in the >NC(O) group has a planar bond configuration. The N–C(O) bond is ~0.1 Å shorter than the N–CH_3 bond. The bond lengths in the molecules are different in the gas phase and in the crystal; the N–C(O) bond is 0.07 Å longer, and the C=O bond ~0.4 Å shorter, in the gas phase than in the crystal.

Detailed data on the structure of amides in the gas phase are given in a book by Naumov and Kitaeva.[51]

2. Monomeric compounds of amines with metals

Electron diffraction studies, carried out mainly abroad in the late eighties, provide material for generalising the characteristics of the geometric structure of monomeric compounds of amines with metals, chiefly compounds in which the metal has a low coordination number (CN).

A large proportion of these data relate to compounds containing two-coordinate metals of groups II (the *s*-elements Be and Mg, and the *d*-elements Zn, Cd, and Hg), VII, and VIII (the *d*-elements Mn, Fe, and Co), and also to compounds with the *p*-elements of group IV Ge, Sn, and Pb (Table 3). Data have also been published on compounds of amines with three-coordinate Sc, La, Ce, and Pr (*d*-elements of group III and lanthanides), and on tetra-amino-compounds of Ti, Zr, and V, a penta-amino-compound of Ta, and a hexa-amino-compound of W (*d*-elements of groups IV–VI, Table 4).

The two-coordinate state is not characteristic of the atoms of the lighter group II metals. Their compounds with amines tend to associate to give bridged systems, and the CN of the metal may reach four or more. In the compounds studied, the stability of the two-coordinate states of the atoms of these metals is ensured by the

large volume of the substituent $N[SiMe_3]_2$. Only the Hg atoms are distinguished by their inability to extend greatly their coordination sphere. The following mechanism has been proposed[61] to explain this difference in the coordination properties of the *d*-elements of group II. If the nitrogen atoms form σ-bonds with the sd_{z^2}-hybrid orbitals of the two-coordinate atoms of these elements, then since the 6*s*- and 5*d*-energy levels of the Hg atom are close to one another, there is more complete mixing for this atom, so that the Hg–N bonds are stronger than the Zn–N or Cd–N bonds. When adducts are formed, however, the degree of mixing of the *s*- and *d*-orbitals of the Hg atom decreases, the primary Hg–N bonds become weaker, and there is probably no energy gain as a reuslt of additional coordination to the metal atom, that is the structure of the adduct is unstable.

Table 3. Parameters (r_a) of monomeric amino-derivatives of two-coordinate metal atoms, obtained by gas-phase electron diffraction.

*The parameter r_g is given.

The presence of bulky substituents is apparently no less important for the stabilisation of monomeric structures with the two-coordinate *d*-atoms Mn, Fe, or Co and *p*-elements of group IV. The tendency of these compounds to associate is revealed by the formation of dimers in the crystal and in the gas phase. The gas-phase structure of one of these compounds, namely the dimer of the amino-derivative of tin(II) $\{Sn[NMe_2]_2\}_2$, will be examined in Section V.

For the atoms of group III metals (Sc, La, and the lanthanides), the usual CN are 7, 8, and 9, and with small bidentate ligands such as the nitrate group, even CN of 10 and 12 are possible. The bulky nature of the $N(SiMe_3)_2$ ligands is also of decisive importance for stabilising the fairly uncommon three-coordinate states of the atoms of these elements.

a. Amino-derivatives of *s*- and *d*-elements of group II and *d*-elements of groups VII and VIII

Important common characteristics of these compounds are the linearity of the N–E–N fragment, the planar configuration of the bonds formed by the amine nitrogen atom, and the orthogonal arrangement of the two pairs of terminal substituents $SiMe_3$ in the stable molecular form.

For the structures of the *d*-elements of group II (Zn, Cd, and Hg), the first two of these characteristics also follow from an analysis of the vibrational spectra of solutions[62] and the utlraviolet spectra of the gas phase.[63] The spectral data, however, do not make it possible to make a choice between the orthogonal (D_{2d}) and planar eclipsed (D_{2h}) conformations of the $Si_2N-E-NSi_2$ core. Electron diffraction data show that the equilibrium form has D_{2d} symmetry. At the same time there is a torsional motion of large amplitude round the linear chain N–E–N. The heights of the potential barriers (V_2) in the planar transition state D_{2h}, obtained for amino-derivatives of Mg, Zn, Cd, and Hg, are relatively small [3(1), 2.5(1.5), 1–2, and 2(1) kcal mol^{-1} respectively] and practically constant, at least for the derivatives of the *d*-elements.

The production of the barrier to rotation in this case might be due to the presence of dative π-bonds in the N–E–N fragment, van der Waals interactions between the ligands, or a combination of these factors. Force field calculations based on the vibrational spectra[62] show that in the molecules being considered the E–N bonds should be essentially single bonds. At the same time, if it is assumed that the other geometric parameters (other than the angle of rotation) remain unchanged in the process of internal rotation, then in the planar form D_{2h} the shortest of the distances between the Me groups, although shorter than those in the equilibrium form D_{2h}, are nevertheless greater than the sum of the van der Waals radii. Thus the existence of the barrier to internal rotaiton could be attributed to the effects of dative π-interaction rather than to steric factors. Although these electronic effects are very small, in this case they are apparently responsible for the stabilisation of the linear form of the N–E–N fragment.

It is possible to take as a geometric criterion of the multiplicity of the metal–nitrogen bond the difference between its length and that of the corresponding metal–chlorine bond.

	Be	Mg	Zn	Cd	Hg	Cl
r(E–Cl), Å	1.75	2.18	2.06	2.21	2.25	1.99
r(E–N), Å	1.56	1.91	1.82	2.03	2.01	1.76
Δ, Å	0.19	0.27	0.24	0.18	0.24	0.23

Since the nitrogen and chlorine atoms have equal electronegativities, the polar corrections for the corresponding bonds with a metal should also be equal. Since the accuracy of the determination of the Be–Cl, Be–N, Cd–Cl, Cd–N, and Hg–N bond lengths is low, it can be taken that the effect of replacing the chlorine atom by the nitrogen atom remains practically constant, and the actual changes Δ can be related to the difference between the covalent radii of the chlorine and nitrogen atoms. For metal chlorides, significant multiplicity of the metal–chlorine bonds is unlikely, since the chlorine atom cannot be a strong electron donor for a metal atom.

From the general principle that the atomic radius increases on going from a lighter to a heavier element in a group, the changes in the bond lengths E–N in the compounds of the group II elements show two anomalies (Table 3), on going from the *s*-atom Mg to the *d*-atom Zn and on going from the Cd atom to the Hg atom. Thus the Mg–N bond is 0.35 Å longer than the Be–N bond, and the Cd–N bond is 0.2 Å longer than the Zn–N bond. However, since

the effective charge on the nucleus of the Zn atom, which has a full *d*-level, is much larger, the Zn–N bond length is ~0.1 Å shorter than the Mg–N bond length. The Hg–N bond length in turn differs little from the Cd–N bond length, apparently due to a combination of the effects of *d*-contraction, *f*-contraction, and relativistic concentration.

The relatively short Be–N bond is possibly a consequence of a slight increase in dative π-interaction, if the small radius of the Be atom and its fairly high acceptor power are taken into account. Together with the increase in the inter-ligand interactions, this should lead to an increase in the barrier to internal rotation in the $Be[N(SiMe_3)_2]_2$ molecule compared with the amino-derivatives of the other group II metals.

In the compounds of the group VII and VIII metals of period IV, the change in the E–N bond lengths corresponds to the change in the atomic radius on going from a lighter to a heavier element. A characteristic feature is that within the large experimental errors the Mn–N bond length still approaches the Mg–N bond length, whereas the Fe–N and Co–N bond lengths are almost the same as the Zn–N bond length.

For the parameters of the ligand $N(SiMe_3)_2$, the Si–N bonds in some of the compounds examined are shorter than that in the $HN(SiMe_3)_2$ molecule [r_a = 1.738(5) Å[64]], whereas in others they are almost equal to this value. The observed decrease in the Si–N bond lengths is usually attributed to an increase in the polarity of the corresponding E–N bonds, which leads to an increase in the dative π-interaction between the N and Si atoms. The changes in the SiNSi valence angles in the amino-derivatives of the metals being considered relative to $HN(SiMe_3)_2$ [131.3(15)°] are slight. The large value of this angle, characteristic of these compounds, in this case is apparently determined chiefly by intra-ligand steric factors. Comparison of the data being considered with the dimeric structures of amino-derivatives of Mn and Co in the crystals shows that dimerisation is accompanied by a considerable increase in the length of the terminal E–N bonds and a decrease in the Si–N–Si valence angles in the terminal ligands by ~10°.

b. Structures with two-coordinate atoms of *p*-elements of group IV

It was noted above that the use of the bulky substituents $N(SiMe_3)_2$ makes it possible to obtain more stable monomeric compounds with two-coordinate Ge, Sn, or Pb atoms in the gas phase and in crystals. When $N(SiMe_3)_2$ groups in an Sn^{II} derivative are replaced by NMe_2, the concentration of the monomer in the gas phase decreases to 76 ± 1%.

Unlike the amino-derivatives of metals of groups II, VII, and VIIII, the monomers of the *p*-elements of group IV contain non-linear N–E–N fragments (Table 3). At the same time, the planar configuration of the bonds formed by the amine nitrogen atom is preserved. Both NY_2 planes are practically perpendicular to the NEN plane.

The valence angles NEN do not exceed 101°. They decrease regularly with increase in the atomic number of E, as is characteristic of many other compounds of the elements of the main sub-groups. This corresponds to the familiar Bent's rule, according to which an increase in the difference between the electronegativities of the atom E and the substituent is accompanied by an increase in the *s*-character of the non-bonding orbitals of the atom E. It is also possible that a decisive role is here played by inter-ligand steric repulsions which are weaker for longer E–N bonds. Steric effects, however, probably have a greater influence on the E–N bond lengths. Thus the Sn–N bond in the $Sn(NMe_2)_2$ molecule is almost 0.1 Å shorter than that in the $Sn[N(SiMe_3)_2]_2$ molecule, whereas the NSnN valence angles are almost equal in the two molecules. The difference between the E^{II}–N and E^{IV}–N bond lengths obtained for Ge and Sn derivatives is half of this value (see Table 3 and Ref. 2). Comparison shows that the Sn–N bond in the $Sn(NMe_2)_2$ molecule is only ~0.05 Å shorter than that in the $Sn(NMe_2)_4$ molecule. Overall, the change in the E^{II}–N bond lengths in the structures being considered reflects the gradual increase in the atomic radius on going from a lighter to a heavier element.

In the crystalline phase the E–N bond lengths of the monomers are practically the same as those in the molecules in the gas phase, whereas the NEN angles are larger by 10° or more and become less sensitive to the nature of the atom E. This is probably related to a change in the orientation of the ligands in the crystal, since the form of the molecule produced in the gas phase is not favourable for effective packing. This change leads to the production of shorter intramolecular contacts, and the resulting strain is compensated by an increase in the angle NEN. The relative ease of the change in the orientation of the $N(SiMe_3)_2$ groups on going from the gas to the crystalline phase may indicate that the potential function of the internal rotation is flat.

c. Amino-derivatives of *d*-elements of group III and the lanthanides

X-Ray diffraction data show that the amino-derivatives of group III elements $E[N(SiMe_3)_2]_3$ are monomeric. All the compounds $E[N(SiMe_3)_2]_3$ can be divided into two groups differing in the configuration of the EN_3 fragments. This separation also corresponds to the characteristics of the electronic structure of the metal atom. The derivatives of the *p*-elements (Al, Ga, In, Tl) have a planar core EN_3, and D_3 symmetry for the molecule as a whole. In the derivatives of the group III *d*-elements and the lanthanides studied, the configuration of the EN_3 fragment is pyramidal, with valence angles NEN equal to 115.5 (Sc), 117.8(1) (Nd), and 116.6° (Eu).

On going to the gas phase there are appreciable changes in the configuration of the environment of the atoms of the group III *d*-elements and the lanthanides (Table 4).

Electron diffraction data show that in the Sc derivative the configuration of the ScN_3 fragment becomes almost planar, whereas in the compounds of La, Ce, and Pr (nearest neighbours of Nd in the periodic table) the EN_3 fragment is much more pyramidal than in the crystal. The measured dipole moments and the infrared spectra also indicate that the solutions contain molecules with a planar ScN_3 fragment,[72] and the vibrational spectra of the derivatives of the lanthanides Pr and Nd confirm that their structures are non-planar in the crystal, in the gas phase, and in solutions.[73] The values of the valence angles NEN found in the crystal are very close to one another, and possibly determine the molecular form most favourable for crystal packing. The relative ease with which changes take place in these angles with change in the state of the substance apparently indicates a flat form for the potential function of the inversion of the central atom E in these systems.

The pyramidal configuration of the ScN_3 fragment, produced in the solid phase by the effects of crystal packing forces, is accompanied by a change in the geometry of the ligands. The Si–N bonds become much longer [1.751(2) Å], and the angle SiNSi

Table 4. Parameters of monomeric amino-derivatives of metals with coordination numbers from three to six, obtained by gas-phase electron diffraction.

Note. The prefixes anti- and *syn*- are used to characterise the relative arrangement of the $SiMe_3$ groups and the atom of the metal E relative to the N_3 plane in the triamino-derivatives of Ce and Pr; ax. and bas. denote the axial and basal Ta–N bonds in the pentakis(dimethylamino)tantalum molecule and the valence angles between them; 2-fold and 4-fold denote the two-fold and four-fold valence angles NEN in the tetra-amino-derivatives of Ti, Zr, and V (S_4 symmetry); the difference between them is that the S_4 axis lies in the planes of the two-fold angles.

becomes much smaller [121.6(4)°]. These changes are apparently due to Me...Me contact repulsion between neighbouring $N(SiMe_3)_2$ groups.

A consequence of the steric requirements of the bulky $N(SiMe_3)_2$ ligands may be their propeller-like configuration, found in the gas phase, relative to both the planar EN_3 fragment in $Sc[N(SiMe_3)_2]_2$ [angle of rotation 55(2)°] and the pyramidal EN_3 fragment in the derivatives of Ce [42(5)°] and Pr [47(5)°]. In the crystalline phase the configuration is practically unchanged, and the angle of rotation is ~50°.

d. Amino-derivatives of *d*-elements of groups IV–VI

The stability of the monomeric structures of the derivatives of the *d*-elements of groups IV–VI decreases on going from a lighter to a heavier element in a group, and this is usually related to the change in the covalent radii. Studies of benzene solutions of amino-derivatives of Ti and Zr showed, in particular, that the $Ti(NMe_2)_4$ molecules are monomeric in solution, whereas $Zr(NMe_2)_4$ gives an equilibrium monomer–dimer mixture.

Many derivatives of tantalum and tungsten in higher oxidation states also exist as binary or pseudo-binary compounds. Data on the structure of the stable monomeric amino-derivatives of these elements are therefore of considerable interest. The study of the structure of $V(NMe_2)_4$ is also important in relation to the influence of change in the configuration of the electron cloud of the central atom on the structure on going from the d^0-compounds of Ti and Zr to the d^1-compound of V.

One of the most significant characteristics of the state of amine nitrogen atoms, namely the bond configuration, is practically planar in all the structures studied (Table 4); this is apparently determined by the $p_\pi - d_\pi$-interaction of the nitrogen atom with the metal atom. At the same time, changes in the covalent radius of the metal atoms and also in their coordination numbers may have a significant influence on the form of the potential function of the wagging–inversion motion of the amino-group, which may be more or less flat, depending on steric factors.

The covalent radius of the Zr atom (1.45 Å) is much larger than those of the atoms of Ti (1.32 Å) or W (1.30 Å). The flatter potential function of the inversion of the amino-group in the $Zr(NMe_2)_4$ molecule compared with $W(NMe_2)_6$ is indicated by the much larger mean amplitude of the vibrations for the distances Zr...C [0.162(8) Å] compared with W...C [0.085(1) Å], whereas the amplitude of the vibrations for the C...C distances is almost the same in the two molecules.

The observed difference in the Zr–N and Ti–N bond lengths (0.154 Å) corresponds closely to the difference between the covalent radii given above. At the same time, for the bonds Zr–N and W–N the value of this difference obtained experimentally (0.036 Å) is much smaller than the estimated value. Thus the actual radius of the W atom in the $W(NMe_2)_6$ molecule is underestimated, and the

deviation is possibly due to inter-ligand steric interactions. The W–N bond length in the gas phase [2.035(5) Å] agrees with that found in crystalline $W(NMe_2)_6$ [2.032(25) Å[71]]. The $W(NMe_2)_6$ molecules in both phases have core symmetry T_h, with orthogonal planar $C_2N-W-NC_2$ fragments and linear N–W–N chains.

The molecular structures of the tetra-amino-derivatives of Ti, Zr, and V studied have S_4 symmetry. The configuration of the EN_4 fragment in these derivatives deviates considerably from T_d symmetry, particularly in the V compound. This is confirmed by spectral data.[74] The dihedral angles NENC characterising the rotation of the plane of the amino-group relative to the NEN plane containing the S_4 axis varies in these structures from 51(1) (Ti) to 69(9) (Zr) and 71(2)° (V).

The increase in the radius of the central metal atom on going from Ti to Zr possibly explains the slightly smaller deviation of the NZrN valence angles from the tetrahedral value (109.47°). It has been pointed out[69] that the deviation of the symmetry of the core of the $Zr(NMe_2)_4$ molecule from T_d cannot be regarded as statistically significant. Moreover, the large error in the determination of the valence angles of the ZrN_4 fragment and the fact that changes in these angles (not exceeding ±2°) have no influence on the values of the other parameters suggest that the ZrN_4 fragment is appreciably non-rigid and easily deformed.

The results of the X-ray diffraction study of the diamagnetic d^2-structure of $Mo(NMe_2)_4$ are of interest.[75] The crystal cell contains two independent molecules having symmetry close to D_{2d} (angle N–Mo–N–C ~90°). The value of the NMoN angles in these molecules, however, varies completely arbitrarily from 107.3(2)° to 112.5(2)° [average value 109.5(19)°], that is it is determined chiefly by intermolecular forces. The influence of the d^2 electron configuration of the central Mo atom on the structure of $Mo(NMe_2)_4$ is apparently less significant.

Table 5. Microwave and electron diffraction data for imino-derivatives.

Molecule	Method	Parameter	N=C, Å	X–N=C, °	Refs.
$HN=CH_2$	MW	r_s	1.273	110.4	[76]
$FN=CF_2$	MW+GE	r_α^0	1.274(6)	107.9(2)	[77]
$ClN=CCl_2$	GE	r_α^0	1.266(5)	117.1(4)	[78]
$Me_3CN=CH-CH=NCMe_3$	GE	r_a	1.283(6)	122.8(15)	[79]

In the opinion of authors cited,[68,69] the conclusion that the EN_4 core of tetra-amino-derivatives of Ti, Zr, and V undergoes deformations of large amplitude is confirmed by the appreciable values of the mean amplitudes of the vibrations obtained for the N...N distances [0.22(3), 0.14(3), and 0.19(4) Å in the derivatives of Ti, V, and Zr respectively]. However, the large experimental error most probably reflects the fact that the contribution of the N...N distances to the diffraction pattern is too small to be determined reliably against the background of the stronger or more numerous E...C, C...C, and N...C contributions.

The same feature apparently makes meaningless the discussion of the observed differences in the ratios between the values of the two-fold and four-fold valence angles NEN in the compounds studied (see Table 4), including the discussion of the possible influence of change in the configuration of the electron cloud of the central atom.

The $Ta(NMe_2)_5$ molecule has C_{2v} symmetry, and the TaN_5 fragments form a distorted square pyramid. A characteristic feature of the structure is that the axial Ta–N bond is 0.1 Å shorter than the basal bonds.

**The authors cited[80] assume that the equilibrium value of the Si–N=C valence angle is 180°, so that the Si–N=C=N–Si fragment is linear.

III. Imino-, carbodi-imido-, and azino-derivatives

In the imino-derivatives (Table 5) the N=C bond length changes little under the influence of substituents. The valence angle at the nitrogen atom, however, increases considerably on going from the $FN=CF_2$ molecule to $ClN=CCl_2$ and then to $Me_3CN=CH-CH=NCMe_3$, because of the appreciable steric interactions.

In the carbodi-imides (Table 6) the carbon atom forms bonds of the cumulene type, so that the N=C bonds in these compounds are shorter than those in the imines. The marked increase in the valence angle X–N=C (X = Si, Ge, P) compared with that in the imines may be due to the steric and electronic effects of the attachment of the Si, Ge, and P heteroatoms to the nitrogen atom. An interesting feature is that on going to the bulkier $SiMe_3$ and $GeMe_3$ substituents the X–N=C angle becomes much smaller than that in the SiH_3 and GeH_3 derivatives. Thus the observed increase in the valence angles Si–N=C and Ge–N=C is apparently due to the stereoelectronic effects of the Si and Ge atoms.

The cumulene bond system in allene $H_2C=C=CH_2$ has D_{2d} symmetry, with a dihedral angle H–C=C=C–H of 90°. In the carbodi-imide derivatives, however, the arrangement of the terminal groups is characterised by a much smaller dihedral angle. The investigation of this feature requires more systematic studies and quantum-chemical calculations.

Azino-derivatives (Table 7) are diene systems, that is classical conjugated double bond systems. As in derivatives of butadiene, the central N–N bond in these compounds is shorter than that in hydrazine [1.449(2) Å[88]]. The decrease in the length of the N–N bond in the molecule of the azine of formaldehyde $H_2C=N-N=CH_2$ (~0.05 Å), however, is smaller than the decrease in the length of the C–C bond in butadiene compared with ethane (0.07 Å^2). This can be attributed to the smaller coordination number of the N atom. The experimental average values of the N–N bond lengths (r_g, r_a) in halogen-substituted azines of formaldehyde (Table 7) were determined with a fairly large uncertainty, so that regularities in the changes cannot be established.

Table 7. Electron diffraction data for azino-derivatives.

*The value of the dihedral angle at the minimum of the potential function of the internal rotation is given (the angle 180° corresponds to the planar *anti*-form). For $H_2C=N-N=CH_2$, an MP2/6-31GF** calculation[84] gave another shallower minimum at an angle C=N–N=C of ~90° (see text).

**The effective value corresponding to averaging with respect to the twisting vibration of large amplitude relative to the N–N bond is given (see text).

Non-empirical quantum-chemical calculations in the Hartree–Fock approximation with 6-31GF** [85] and 6-31GF* [84] basis sets indicate a regular decrease in the length of this bond in the equilibrium *trans*- or close to *trans*-conformations of the azine of formaldehyde and its tetrafluoro- and tetrachloro-derivatives (from 1.40 to 1.39 and 1.37 Å respectively). According to these calculations, the change in the N–N bond length in the internal rotation is 0.04 Å. In the case of the azine of formaldehyde, the N–N bond length is shortest in the *gauche*-form (1.37 Å), and in the planar *cis*- and *trans*-forms with a predisposition towards conjugation it increases to 1.41 Å and 1.40 Å, whereas in the halogen derivatives there is a regular change from the smallest value in the *cis*-form to the largest value in the *trans*-form.

The conformation of C=N–N=C is of considerable interest. The results of experiments and calculations indicate that the potential functions of the internal rotation of the azine of formaldehyde and its halogen derivatives have a fairly flat surface in a wide region close to the *trans*-form and a high barrier in the *cis*-position. The height of the barrier is 14.6 kcal mol^{-1} for the molecule of the azine of formaldehyde (MP2/6-31GF** calculation), and 14.2 kcal mol^{-1} and 26.5 kcal mol^{-1} for the tetrafluoro- and tetrachloro-derivatives (MP2/6-31GF*//6-31GF*).[84] Calculation at the Hartree–Fock level gives a value for the barrier which is only 2 kcal mol^{-1} higher. These values are 2–3 times the values obtained by calculations at the Hartree–Fock level for the heights of the barriers in butadiene, glyoxal, and their fluoro-derivatives (see Ref. 85 and references therein). The form of the potential curve in the flat region and the position and number of the minima on it depend to a significant extent on the substituents present in the molecule. Thus for the molecule of the azine of formaldehyde, in addition to the principal minimum corresponding to the planar *trans*-form, non-empirical calculation[84] also gives a weak minimum in the region of the *gauche*-form (the dihedral angle C=N–N=C is ~90°), with an energy 0.75 kcal mol^{-1} higher. The barrier to the transformation from the *trans*- to the *gauche*-form is very low, only 0.85 kcal mol^{-1}.

In contrast to this, according to the calculations,[84] for the $F_2C=N-N=CF_2$ molecule the minimum corresponding to the *trans*-position is the only one. An electron diffraction study of the fluorinated azine of formaldehyde[85] gave for the angle C=N–N=C the effective value 153(5)°, due to averaging with respect to a twisting vibration of large amplitude. This non-planarity of the average configuration is related to the fact that the equilibrium *trans*-form has planar symmetry. In the twisting vibrations, rotation through the same angle in different directions from the plane of symmetry leads to two equivalent configurations. Thus the averaging with respect to configurations which is obtained in the analysis of the electron diffraction data without allowance for the vibration of large amplitude (using the so-called static model) leads to an effective non-planar configuration of the molecule.

The potential function of the internal rotation of the $Cl_2C=N-N=CCl_2$ molecule has a minimum in the region of the *gauche*-form. The experimental value of the dihedral angle C=N–N=C at the positon of the minimum [139(7)°], obtained by analysis with allowance for the twisting vibration of large amplitude (using the so-called dynamic model), shows good agreement with the value obtained in a quantum-chemical calculation.[84] Estimation of the height of the barrier in the transition state corresponding to the planar *trans*-form, however, gives a value not exceeding 0.1 kcal mol^{-1}.

According to electron diffraction data, the height of the barrier to rotation in the planar *trans*-form [1.4(12) kcal mol^{-1}] in the $Br_2C=N-N=CBr_2$ molecule should be much greater than that in the chlorine analogue, and the minimum of the potential function in the *gauche*-position corresponds to a greater deviation from the *trans*-form [121(9)°].

In the *trans*-conformations of the Cl- and Br-derivatives of the azine of formaldehyde there is considerable steric repulsion between the Cl or Br atoms and the lone pairs of the N atoms in the *cis*-position to them. The importance of steric factors is indicated by the appreciable increase, found by calculations,[84,85] in the N–N=C valence angles on going from the *trans*- to the *cis*-form for the azine of formaldehyde and its tetrafluoro- and tetrahcloro-derivatives (by 10, 15, and 20° respectively).

IV. Nitro-compounds

C-, N-, and O-nitrocompounds, with CNO_2, NNO_2, and ONO_2 groups, are distinguished. Structural data on nitro-compounds, obtained up to 1979, have already been reviewed.[89] The present

Table 8. Principal geometric parameters of the molecules of various nitro-compounds in the gas phase, from gas-phase electron diffraction data (r_g structure).

*X is the substituent in addition to the NO_2 group (X = Cl, Br, I, CH_3, OH, SeBr, SCl).

review gives the results of the study of the structure of molecules of nitro-compounds of all three types, published in recent years. Among the C-nitro-compounds, most attention has been paid to aromatic halogeno- and polynitrobenzenes, and also nitrobiphenyls.

1. Aromatic C-nitro-compounds

The principal geometric parameters of a number of nitrobenzene derivatives in the gas phase are given in Table 8.

As noted earlier,[4,5,90] the geometry of aromatic nitro-compounds is determined by the mutual influences in the nitro-group – benzene ring – substituent system. Subsequent studies have confirmed this conclusion.

All compounds of this type show deformation of the benzene ring under the influence of the nitro-groups and other substituents (Cl, Br, I, CH_3). The addition of electron-acceptor groups to the benzene ring leads to an increase in the valence angle of the *ipso*-carbon atom.[90,91] This is shown most clearly in *para*- and *meta*-substituted nitrobenzenes. In the molecules of 1-chloro- and 1-bromo-2,6-dinitrobenzenes, the nitro-groups are responsible for the deformation of the benzene ring, and the influence of the chlorine and bromine atoms is slight. The competing influence of the nitro-groups and the chlorine (bromine) atoms is shown most clearly in the *sym*-trihalogenonitrobenzenes. Unfortunately, the experimental errors do not make possible a more detailed discussion of this question.

The greatest deformation of the benzene ring is observed in the *sym*-$C_6(CH_3)_3(NO_2)_3$ molecule, where the electron-acceptor NO_2 groups and the electron-donor CH_3 groups supplement one another. This can be seen by comparing the data in Table 9.

Table 9. Valence angles CC_XC (°) in the molecules of $C_6X_3(NO_2)_3$ and $C_6H_3X_3$.

*The values of the angles $CC_{NO_2}C$ are given in square brackets.

In the series of aromatic nitro-compounds given in Table 8, the C⩬C bond lengths in the benzene ring are shorter than in non-substituted benzene. This applies to *o*-chloro and *o*-bromonitrobenzenes (this feature was previously noted for *sym*-trinitro- and *p*-dinitrobenzenes[111]). In *sym*-$C_6Cl_3(NO_2)_3$, however, where the accuracy of the determination is fairly high, there is no decrease in the C⩬C bond length (in non-symmetrical nitro-derivatives, some non-equivalence of the C⩬C bonds may be assumed, but it is impossible to detect it experimentally by gas-phase electron diffraction). The average C⩬C bond length in nitrobenzenes is independent of the number of NO_2 groups.

Analysis of the parameters of the nitro-group shows that the scatter in the N=O bond lengths (average value 1.228 Å) does not exceed 0.015 Å. The average value of the angle ONO is 125°, but the values of this angle in nitrobenzene derivatives differ considerably.

The C–NO_2 bond lengths have been determined with fairly large errors. The average value of r(C–NO_2) is 1.47 Å. Because of the relatively large errors in the determintion of r(C–NO_2) and the small changes in this quantity, it is difficult to establish the influence of substituents on the length of this bond or the dependence of r(C–NO_2) on the angle of rotation of the nitro-group. The changes in r(C–N) and the angle φ_{NO_2} for halogenonitrobenzenes (Table 8) show no definite relationship between them.

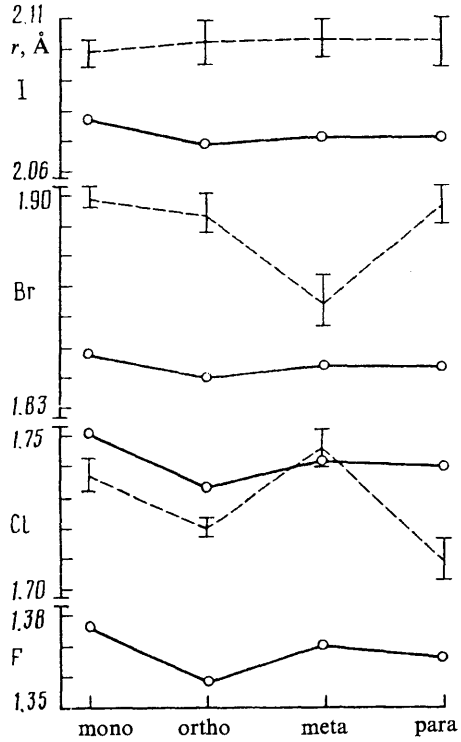

Figure 1. Dependence of the experimentally determined bond length r_g(C–X) (broken line) and the corresponding bond length r_e(C–X) (continuous line) obtained from non-empirical calculations on the position of X in halogenonitrobenzenes; the calculations were carried out using the basis sets 6-31GF for X = F, 3-21GF* for X = Cl, and STO-3GF* for X = Br and I respectively; the notation "mono" refers to the halogenobenzene, and "ortho", "meta", and "para" to the positions of the substituents X = F, Cl, Br, and I in the halogenonitrobenzenes.

Figure 1 gives the dependence of the C–X bond lengths (X = F, Cl, Br, I) on the positions of the substituents X in halogenonitrobenzenes.

Under the influence of the nitro-group in the molecules of chloronitrobenzenes there is a slight decrease in the length of the C–Cl bond in the *ortho*- and *para*-substituted nitro-derivatives compared with chlorobenzene [1.737(6) Å [112]]. This decrease in the C–Cl bond length is not observed in *m*-chloronitrobenzene.

The decrease in the C–Cl bond length in the *o*-chloronitro-derivatives is confirmed by the data for 1-chloro-2,6-dinitrobenzene, *sym*-trichloronitrobenzene, and 1,3,5-trichloro-2,6-dinitrobenzene.

The C–Br bond lengths in *o*- and *p*-bromonitrobenzenes are practically the same as that in bromobenzene [1.899(3) Å].[113] This is confirmed by the data for 1-bromo-2,6-dinitrobenzene. The shortest C–Br bond length was found experimentally in *m*-$BrC_6H_4NO_2$; this does not correspond to the trend detected for other molecules and by *ab initio* calculations.[102]

For iodonitrobenzenes, the changes in the C–I bond lengths are very small. As in the case of the C–Br bond, nitro-groups in the *ortho*- or *para*-positions have no influence on the C–I bond length.

Figure 1 also gives the results of *ab initio* calculations for the molecules of fluoro-, chloro-, bromo-, and iodonitrobenzenes. The largest changes in the C–X bond lengths were obtained for fluoronitrobenzenes, and the smallest for iodonitrobenzenes.

It is of interest to follow the influence of nitro-groups on the C–Cl, C–Br, and C–CH_3 bond lengths (in Å) by comparing the data obtained for the symmetrical 1,3,5-derivatives:

	C–Cl	C–Br	C–CH_3
1.3.5-$C_6H_3X_3$	1.734(2)	1.877(4)	1.509(2)
1.3.5-$C_6(NO_2)_3X_3$	1.699(4)	1.886(6)	1.482(11)

The C–Cl and C–CH_3 bond lengths decrease on going to the nitro-derivatives. Because of the relatively large experimental errors, the difference for the C–Br bond is statistically insignificant.

According to microwave data,[114] the potential of the internal rotation of the NO_2 group in the nitrobenzene molecule has a minimum at φ_{NO_2} = 0°, that is for the planar configuration of the molecule. The barrier to the rotation is 2.9 kcal mol^{-1}. Electron diffraction study makes it possible to determine the average value of the dihedral angle between the planes of the benzene ring and the nitro-group; for $C_6H_5NO_2$ the value does not coincide with the equilibrium value, and is equal to 13°.[92] The same situation apparently arises for the *meta*- and *para*-derivatives of nitrobenzene, where the minimum of the potential of the internal rotation of the NO_2 group corresponds to 0°, and the non-planar conformations, detected by electron diffraction, are related to the twisting vibrations of the nitro-groups. Allowance for these vibrations leads to planar equilibrium models with a barrier to rotation $V_2 \simeq 4-5$ kcal mol^{-1}.[115]

In the molecules of the *ortho*-derivatives of nitrobenzene there is considerable steric hindrance, and the equilibrium configurations are appreciably non-planar. Thus in the *ortho*-dinitro-derivatives and 1-halogeno-2,6-dinitro-derivatives the experimentally determined conformations are close to the equilibrium ones.

In the *sym*-trinitro-substituted benzenes $C_6(NO_2)_3X_3$ (C = Cl, Br, CH_3) the average dihedral angles are ~80°. If the equilibrium configuration corresponds to an angle φ_{NO_2} = 90°, it may be expected that vibrational effects will destroy the high symmetry of the equilibrium configuration, leading to a decrease in the dihedral angle φ_{NO_2}. Thus *ortho*-substituted nitrobenzenes are sterically "crowded" molecules, and the greatest steric strain is produced in the *sym*-tribsubstituted nitrobenzenes.

The decisive factor lowering the steric strain is the rotation of the nitro-group through the angle φ. Comparison of the shortest distances Cl...O, Br....O, CH_3...O and correspondingly Cl...N, Br...N, CH_3...N with the sums of the van der Waals radii for *sym*-hexasubstituted nitrobenzenes shows that the distances between the

non-bonded atoms X...O are close to the sums of the van der Waals radii, whereas the X...N distances are much smaller than the corresponding sums.

The molecules of *o*-$(NO_2)C_6H_4SCl$ and *o*-$(NO_2)C_6H_4SeBr$ are planar, with internuclear distances O...S (2.36 Å) and O...Se (2.39 Å) shorter than the sums of the van der Waals radii [3.13 Å (O...S) and 3.30 (O...Se)]. The planar conformations of these molecules, in which the S and Se atoms approach the NO_2 group, may be the result of conjugation of the lone pairs of S and Se with the electronic system of the nitro-group (donor–benzene ring–acceptor system), and also of intramolecular coordination of the oxygen of the nitro-group to these atoms.

The planar conformation has also been established for the $C_6(OH)_3(NO_2)_3$ molecule. This result is consistent with earlier data obtained for the molecules of *o*-nitrophenols in the crystalline phase, in which an intramolecular hydrogen bond is assumed. By analogy, the existence of a bond of this type may be expected for the molecules in the gas phase. The distance $r(O_{NO_2}...H_{OH})$ [1.55(5) Å] between neighbouring NO_2 and OH groups is much shorter than the sum of the van der Waals radii of the H and O atoms (2.45 Å), and the angle O–H...O is 116°.

The very few structural data for nitro-derivatives of biphenyl relate mainly to the crystals. Until recently only one compound, 6,6′-dinitrobiphenyl-2,2′-dicarboxylic acid, had been studied in the gas phase.[116]

As in the case of non-substituted biphenyl,[117] a characteristic feature of the molecules of nitro-derivatives of biphenyl is the rotation of one benzene ring relative to the other round the central  bond. Thus in the "free" molecule of 6,6′-dinitro-biphenyl-2,2′-dicarboxylic acid the angle of rotation of the rings φ_{C-C} is 71°, and the angle of rotation of the nitro-group φ_{NO_2} is 30°.

Among the nitro-derivatives of biphenyl studied in the crystalline state, 2-nitrononafluorobiphenyl[118] shows the largest angle of rotation of the rings (86°). In this compound there is also appreciable rotation of the nitro-group (56°). Compounds with nitro-groups in the *para*-positions (4-nitrobiphenyl[119] and 4,4′-dinitrobiphenyl[120]) show an almost coplanar arrangement of these groups and the benzene ring, that is their conformation is analogous to that of *para*-derivatives of benzene. Within the experimental error, the length of the central C–C bond in the nitro-derivatives of biphenyl is close to that in non-substituted biphenyl (1.49 Å).

A series of electron diffraction studies of the biphenyl derivatives 4,4′-dinitrobiphenyl, 2-nitrobiphenyl, and 2,2′-dinitro-4,4′-dichloro-biphenyl has now been carried out.[121–123]

The results are compared with data for biphenyl and nitrobenzene in Table 10. For 4,4′-dinitrobiphenyl, the electron diffraction data are also compared with X-ray diffraction data.

The results supplement and confirm the previously noted geometric characteristics of the structure of nitrobiphenyls. In particular, comparison of the angles of rotation φ_{C-C} indicates that the introduction of nitro-substituents in the *para*-position to the central  bond has no statistically significant influence on the conformation of the biphenyl fragment.

At the same time the introduction of an NO_2 group in the *ortho*-position to the  bond increases by 20° the angle of rotation of the benzene rings relative to one another (~65°), compared with non-substituted biphenyl. The highest value of the angle φ_{C-C} is observed in 2,2′-dinitro-4,4′-dichlorobiphenyl (87°), that is in the molecule with the greatest steric strain.

Table 10. Geometric parameters of the molecules of biphenyl, nitrobenzene, and nitro-derivatives of biphenyl.

*Determined in agreement with experiment.

The principal difference between the structural parameters of 4,4′-$NO_2C_6H_4C_6H_4NO_2$ in the free molecule and in the crystal is observed for the central torsional angle φ_{C-C}. The other structural parameters are comparable, within the experimental error. The same conclusion was previously reached by comparing the geometries of non-substituted biphenyl in the gas phase and in the crystal.

As in the case of mono-substituted benzene derivatives, the addition of a nitro-group to the biphenyl ring leads to an increase in the endocyclic angle at the carbon atom joined to the nitro-group, compared with the trigonal value.

2. N-Nitramines (N-nitro-compounds)

In N-nitramines there is a direct interaction between the electron-donor amino-group and the electron-acceptor nitro-group. The geometry of the molecules of these compounds depends significantly on the substituents on the amine nitrogen atom.[89] We are speaking primarily of the changes in the N–N bond lengths and the pyramidal nature of the amine nitrogen atom.

Despite the fairly large number of published experimental studies of N-nitramines,[89] however, there is still no clear picture of the regularities in their structures and the energy parameters of the intramolecular motions involving inversion of the amine nitrogen atom and internal rotation about the N–N bond. The answers to many problems are not obtained by structural methods, and the unambiguous interpretation of the results is often difficult.

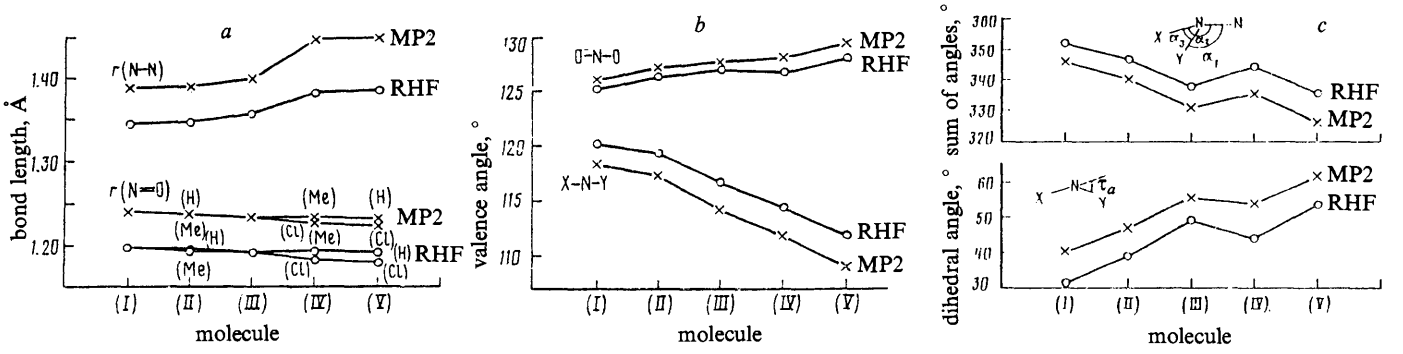

Figure 2. Influence of change in the electronegativity of the substituents on the amine nitrogen atom on the N–N and N=O bond lengths (*a*), the valence angles ONO and XNY (*b*), and the pyramidal character of the configuration of the amine nitrogen atom [the change in the dihedral angle between the NNX and NNY planes (τ_a) and the sum of the valence angles at the nitrogen atom ($\Sigma\alpha_N$)] (*c*) in the N-nitramines (I)–(V), from the results of RHF/6-31GF* and MP2/6-31GF* calculations.

a. Non-empirical quantum-chemical calculations for N-nitramines

These compounds, which are important for theoretical and practical chemistry, can now be studied systematically using another powerful instrument, namely quantum-chemical calculations. The results of calculations for five N-nitramines, H_2NNO_2, $MeNHNO_2$, $ClNHNO_2$, $MeNClNO_2$, and Me_2NNO_2,[124,125] carried out by the restricted Hartree–Fock (RHF) method with allowance for electron correlation using second-order Möller–Plesset theory (MP2), are of interest. The standard basis set 6-31GF*, which has proved effective in similar studies,[8,126–128] was used.

Many structural parameters of amino-derivatives, including the valence angles at the nitrogen atom, are reproduced with this basis set within the experimental error of their determination, even at the RHF level. Allowance for electron correlation in the MP2 approximation largely removes the discrepancies between the calculated and experimental lengths of multiple bonds and neighbouring bonds. Simultaneously, however, the pyramidal nature of the amine nitrogen atom is overestimated slightly.

Analysis of the results reveals a trend towards a coordinated change in the geometric parameters with change in the effective electronegativity of the substituents on the amine nitrogen atom. With increase in the electronegativity of the substituents, that is with decrease in the electron-donor properties of the substituted amino-group, there is an increase in the N–N bond length, a decrease in the N=O bond length, an increase in the pyramidal character of the bond configuration of the amine nitrogen atom, and an increase in the non-planarity of the nitro-group. All this can be regarded as a consequence of a decrease in the $p-\pi$ conjugation between the lone pair of electrons of the amine N atom and the π-system of the NO_2 group.

This is clearly demonstrated by the graphs in Fig. 2 giving the changes in the geometric parameters, where the discrete points on the abscissa correspond to the positions of the compounds in order of increasing electronegativity of the substituents: Me_2NNO_2 (I), $MeNHNO_2$ (II), H_2NNO_2 (III), $MeNClNO_2$ (IV), and $ClNHNO_2$ (V). The greatest difference in the N–N bond lengths (up to 0.06 Å) is observed on going from molecule (I) to (V) (Table 11).

An interesting feature is that with increase in the electronegativity of the substituents X and Y on the amine nitrogen atom the valence angles ONO and XNY change synchronously, but in opposite directions away from the value 120°; the angle ONO increases with increase in the electronegativity of the substituents X and Y (this can be related to the change in the electron density distribution with decrease in the N=O bond length), whereas the angle XNY decreases.

Table 11. N–N bond lengths in N-nitramines, from experimental data and the results of non-empirical quantum-chemical calculations for the equilibrium structures (ES) and the transition states of the inversion (TS_{inv}) of the amino-group and internal rotation (TS_r) (in Å).

The systematic increase in the dihedral angle τ_a between the planes NNX and NNY and the simultaneous decrease in the sum of the valence angles at the amine N atom, together with the changes in the angle XNY, indicate that the pyramidal nature of the amine nitrogen atom increases with increase in the electronegativity of the substituents.

Unlike the experimental data (Table 12), the results of the calculation give a pyramidal bond configuration for the amine nitrogen atom for all the molecules studied. Thus the interaction of

the amine nitrogen atom with the nitro-group, unlike that for other functional groups (the acyl group and the nitrosyl group[126–128]), does not lead to a planar bond configuration for the amine nitrogen atom in the equilibrium state of the molecule.

Table 12. Dihedral angle NNX/NNY in N-nitramines (τ_a, °), from experimental data and the results of non-empirical quantum-chemical calculations of the equilibrium structures (ES) and the transition states of internal rotation (TS_r).

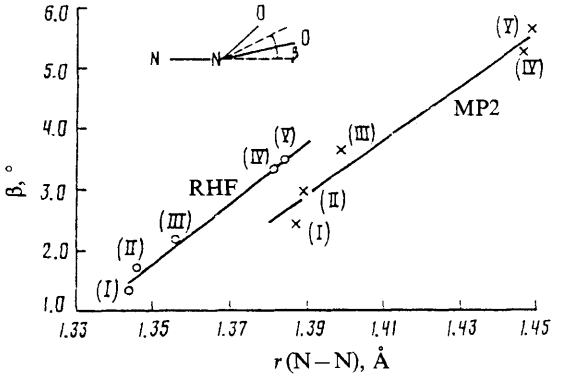

Figure 3. Relationship between the N–N bond length and the angle of displacement of the N–N bond from the ONO plane (β) in the N-nitramines (I)–(V), from the results of RHF/6-31GF* and MP2/6-31GF* calculations.

The deviation from the planar configuration of the nitrogen atom of the nitro-group is defined by the angle of displacement of the N–N bond from the ONO plane (β), the change in which is practically proportional to the change in the N–N bond length. Figure 3 give the dependence of the angle β on r(N–N) for the N-nitramines studied. It is consistent with the concept of $p-\pi$-conjugation: the greater the conjugation and the shorter the N–N bond becomes, the greater the flattening of the bond configuration of the nitrogen atom of the nitro-group. An equally simple relationship is not obtained for the angle of displacement of the N–N bond from the plane of the amine nitrogen atom XNY. This may indicate that change in the steric factors has a significant influence on the configuration of the amine group.

To characterise the potential function of the displacement of the N–N bond from the plane of the nitro-group, the geometry of the molecules Me_2NNO_2, $MeNHNO_2$, and $ClNHNO_2$ was optimised for a fixed planar configuration of the NNO_2 fragment. The total energies of the optimised models were greater than that of the equilibrium form. It is significant that in all cases there were no imaginary normal-vibration frequencies. This indicates that the planar form of the nitro-group in the N-nitramines studied does not correspond to transition states. Cordell[133] obtained for the Me_2NNO_2 molecule the potential curve for the displacement of the N–N bond from the ONO plane, which has a single minimum at an angle of displacement of the N–N bond from the plane of the nitro-group equal to 1.2°, and which can be approximated by a function close to harmonic. Thus the motion being considered is the wagging vibration.

Analysis of the results of the calculation of the transition states for the inversion of the amino-group (TS_{inv}) and internal rotation about the N–N bond (TS_r) leads to the following important conclusion. The flattening of the bond configuration of the amine nitrogen atom during inversion, and the deviation of the structure of the molecule from the equilibrium form during internal rotation, are accompanied by a significant change in the other geometric parameters. Particularly marked changes are undergone by the N–N bond lengths, which are 0.06–0.08 Å longer in TS_r than in the equilibrium forms (see Table 11).

In addition, the transition state of the inversion shows a decrease in the N–N bond length, an increase in the valence angle XNY, and a slight increase in the N–O bond lengths, and the transition state of the internal rotation shows a significant increase in the pyramidal nature of the configuration of the amine nitrogen atom (see Table 12) and a decrease in the N–O bond lengths.

Roughly speaking, the planar transition state of the inversion of the amino-group should promote an increase in $p-\pi$-conjugation, whereas the perpendicular form of the transition state of the internal rotation is unfavourable for this interaction. In this connection it is of interest that the observed relaxational changes in the N–N bond lengths and other parameters during inversion or internal rotation take place in coordinated fashion and in accordance with the concept of $p-\pi$-conjugation. Moreover, the coordinated nature of the changes in the parameters in the intra-molecular motions observed in this case apparently has the same basis as the changes examined above in the parameters of the same structures as a result of the influence of the electronegativity of the substituents on the electron density distribution.

In contrast to the equilibrium forms of molecules (I)–(V), where the N–N bond lengths change regularly with change in the extent of the conugation, in TS_{inv} and TS_r the lengths of these bonds are determined almost entirely by the presence or absence of the Cl-substituent.

The graphs in Fig. 4 give the dependence of the heights of the barriers to inversion (V_i) and rotation (V_r) in the N-nitramines (I)–(V) on the electronegativity of the substituents on the amine nitrogen atom. Both methods of calculation (RHF and MP2) reveal the same trend in the changes in V_i and in V_r; the RHF calculation gives higher values than MP2 for V_r, and lower values for V_i. The height of the barrier to inversion in the H_2NNO_2 molecule, obtained by the MP2 calculation (3.1 kcal mol^{-1}), effectively reproduces the

experimental value of 2.7 kcal mol^{-1}.[135] The last value is at present the only experimentally determined energy characteristic of intramolecular motion in N-nitramine molecules.

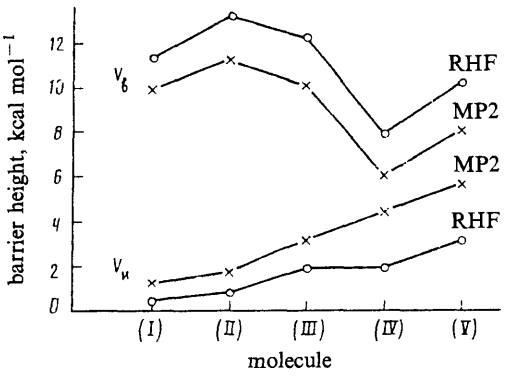

Figure 4. Changes in the heights of the barriers to inversion of the amine nitrogen atom (V_i) and internal rotation about the N–N bond (V_r) in the nitramines (I)–(V), from the results of RHF/6-31GF* and MP2/6-31GF* calculations.

The results show that the greater the pyramidal nature of the amino-group in the equilibrium state of the molecule, the higher the barrier to pyramidal inversion and in general the lower the barrier to internal rotation about the N–N bond.[8] The relationship is more complex for the barrier to rotation, however. This may reflect changes in the contributions of steric factors to the rotation potential. All estimates of the barriers to inversion of the amine nitrogen atom lie in the range 0.4–6.0 kcal mol^{-1} (for comparison, the barrier to inversion has the values 5.8 for ammonia, 2.0 for cyanamide, and 10.3 kcal mol^{-1} for diethylochloroamine[134–136]). The barriers to internal rotation in N-nitramines are 6–13 kcal mol^{-1}, that is they are 1.5–2 times lower than those for amides and N-nitrosamines.[127,128,137–140]

The existence of conjugation in the equilibrium forms of nitramines, as in other amino-derivatives with unsaturated substituents, may be indicated by the flattening of the pyramid of the bonds of the amino-group and the decrease in the N–N bond length. This is accompanied by a lowering of the barrier to inversion of the amine nitrogen atom and a raising of the barrier to internal rotation about the N–N bond. The effect of conjugation in nitramines, however, is less marked than that in amides and nitrosamines.[8] The appreciable change in the geometric parameters in the transition states compared with the equilibrium state may indicate an increase in conjugation during inversion, and breakdown of the $p-\pi$-conjugation on rotation about the N–N bond.

Finally, another interesting result of the calculation may be noted. The inversion of the amine nitrogen atom is coordinated with the flattening of the nitro-group. For a fixed planar configuration of the amino-group, optimisation of the other geometric parameters invariably leads to a planar configuration of the bonds formed by the nitrogen atom in the nitro-group. In the equilibrium states, however, as already noted, the configuration of the bonds formed by the nitrogen atom of the nitro-group is slightly pyramidal, and the degree of pyramidal character correlates well with the change in the N–N bond length.

b. Electron diffraction data

Work on the determination of the structure of the simplest N-nitramines in the gas phase includes gas-phase electron diffraction studies of the molecules of $(CH_2Cl)_2NNO_2$ and $CH_3(CH_2=CH)$. $.NNO_2$ (Table 13). For comparison, Table 13 also gives the parameters of the $(CH_3)_2NNO_2$ and $(CH_2Cl)CH_3NNO_2$ molecules.

In all these molecules the effective configuration of the amine nitrogen atom is planar. The CNC angle in these molecules is much larger than that in alkylamines. The influence of the Cl atom of the chloromethyl groups in $(CH_2Cl)_2NNO_2$ and $(CH_2Cl)CH_3NNO_2$ on the nitroamine fragment is slight.

In the examination of the conformation of these molecules, the following should be noted. In the $(CH_2Cl)CH_3NNO_2$ molecule, the chloromethyl group is oriented in such a way that the ClCN plane is approximately perpendicular to the CNC plane. The same orientation of the CH_2Cl group is observed in the $(CH_2Cl)_2NNO_2$ molecule, and the C–Cl bonds are on different sides of the C_2NNO_2 plane. For the $CH_3(CH_2=CH)NNO_2$ molecule, the most probable conformation is that with the *trans*-arrangement of the NO_2 and $CH=CH_2$ groups. In this molecule, conjugation between the vinyl and nitroamine fragments apparently does not influence the geometric parameters.

Until recently there were no published data on the structure of cyclic nitramines in the gas phase. Electron diffraction data have now been obtained on the structure of 1,3,5-trinitro-1,3,5-triazacyclohexane [$(CH_2NNO_2)_3$, RDX], 1,3-dinitro-1,3-diazacyclopentane [$CH_2(CH_2NNO_2)_2$, DDCP], and N-nitropyrrolidine [$(CH_2)_4NNO_2$, NP].[144] These molecules are of interest since in their five- and six-membered rings the possibilities for change in the endocyclic angles are limited, and this may lead to appreciable deviation from the planar bond configuration of the amine nitrogen atom. The actual conformation of the rings is also of interest.

The results (Table 14) show that the six-membered ring in the RDX molecule has the "chair" conformation with the nitro-groups in the axial position. The assumed C_3 symmetry is consistent with the experimental data.

Table 14. Structural parameters of cyclic N-nitramines.[144]

Parameters	RDX	DDCP	NP

ONO	125.5(10)	128.2(18)	126.3(19)

*Sum of the valence angles at the nitrogen atom.

The five-membered ring in DDCP has the "half-chair" conformation (assuming C_2 symmetry for the molecule), and that in NP has the "envelope" conformation. In both molecules (DDCP and NP) the nitro-groups are in the equatorial positions. The angles of displacement of the N–N bond from the CNC plane vary from ~20° in RDX to ~40° in DDCP and NP.

Comparison of the principal geometric parameters of the cyclic nitramines studied and of dimethylnitramine shows that the CNN angles in all four molecules are the same within the experimental error. At the same time the CNC angle in RDX is slightly smaller than the corresponding angle in $(CH_3)_2NNO_2$, and those in DDCP and NP show an even sharper decrease. This leads to a change in the bond configuration of the amine nitrogen atom from almost planar in dimethylnitramine to pyramidal in the five-membered cyclic molecules of DDCP and NP. The RDX molecule occupies an intermediate position in this series.

In the cyclic nitramines studied, no increase in the N–N bond length with increase in the pyramidal nature of the bond configuration of the nitrogen atom is observed.

3. O-Nitrates (O-nitro-compounds)

The molecular structures of O-nitro-compounds in the gas phase have been less extensively studied than those of C- and N-nitro-compounds. The geometric parameters of the $HONO_2$, O_2NONO_2, CH_3ONO_2, and $C_2H_5ONO_2$ molecules are given in Table 15.

A difference in the parameters is observed only for the N_2O_5 molecule. In this molecule, the two NO_2 groups joined through the central oxygen atom undergo twisting vibrations of large amplitude. The potential energy minimum corresponds to equal torsional angles $\tau_1 = \tau_2 = 30°$ (measured from the planar conformation). The torsional movements are correlated so that an increase in one of the angles τ is accompanied by a decrease in the other.

Table 15. Geometric parameters of the O-nitro-compounds $XONO_2$ (X = H, NO_2, CH_3, C_2H_5).

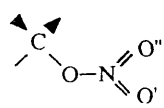
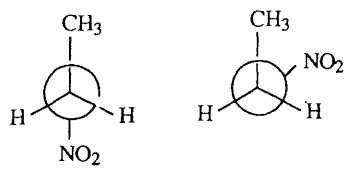
**Ab initio* calculation, MP2/6-31GF*.
**Assumed structure.
***The average value is given.

The nitric acid molecule is planar. In methyl and ethyl nitrates, the core also has a planar structure:



In $HONO_2$, CH_3ONO_2, and $C_2H_5ONO_2$ the valence angles O–N=O are different; the angle O–N=O″ is larger than the angle O–N=O′. In methyl and ethyl nitrates the difference between these angles is 6°.

The structure of ethyl nitrate in the gas phase has been studied by gas-phase electron diffraction and microwave, infrared, and Raman spectroscopy. The data obtained by all these methods show that ethyl nitrate is a mixture of two rotational forms (*trans* and *gauche*), if rotation about the C–O bond is considered; the *trans*-form is more stable, by ~0.6 kcal mol^{-1}.



According to GE data, the concentration of the *gauche*-form is about 20%. The angle of rotation about the C–O bond in this form is about 100° (if the angle of rotation for the *trans*-form is taken as 0°).[148]

A separate group of O-nitro-compounds is formed by the metal nitrates. The monovalent metal nitrates MNO_3 (M = Cs, Rb, Tl) (Table 16) in the gas phase contain a planar bidentate NO_3 group, and the metal atom lies on the bisector of the angle O(1)NO(1′):

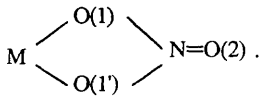


Table 16. Geometric parameters of metal nitrates.

Compound	N–O(1), Å	N=O(2), Å	O(1)NO(1′), °	Refs.
$RbNO_3$	1.252(3)*		115(6)	[150a]
$CsNO_3$	1.252(5)*		117(5)	[150b]
$TlNO_3$	1.254(8)*		114.(5)	[150c]
$Cu(NO_3)_2$	1.298(3)	1.205(5)	113.5(6)	[151]
$Zr(NO_3)_4$	1.284(7)	1.184(10)	—	[152]
$Sn(NO_3)_4$	1.281(5)	1.179(8)	—	[152]
$CrO_2(NO_3)_2$	1.254(4)	1.193(4)	112.2(4)	[153]
$Be_4O(NO_3)_6$	1.298(4)	1.185(5)	117.0(9)	[154]

*The average of the N–O(1) and N=O(2) bond lengths is given.

The $MONO_2$ fragment is also planar in the nitrates of copper $Cu(NO_3)_2$, zirconium $Zr(NO_3)_4$, and tin $Sn(NO_3)_4$. In $Cu(NO_3)_2$ the copper atom lies in the plane of the square formed by the oxygen atoms of two bidentate NO_3 groups. The ligand atoms round the central atom in Zr and Sn tetranitrates give a distorted tetrahedral configuration.

In the $CrO_2(NO_3)_2$ molecule (C_2 symmetry) the coordination of the Cr atom is best described as a distorted octahedron, since the bidentate nitrate groups are joined asymmetrically to the Cr atom. The Cr–O–NO_2 group is slightly non-planar, with a dihedral angle between the CrON and NO_2 planes of ~16(3)°. There is apparently weak torsional motion round any of the single bonds in the –O–NO_2 groups.

The structure of $Be_4O(NO_3)_6$ deviates slightly from T_d symmetry, probably as a result of a complex intramolecular motion.

In the molecules of $Cu(NO_3)_2$, $Zr(NO_3)_4$, $Sn(NO_3)_4$, $CrO_2(NO_3)_2$, and $Be_4O(NO_3)_6$, the N–O bonds are non-equivalent; the N=O(2) bond is ~0.1 Å shorter than N–O(1). For the monovalent metal nitrates, only the average N–O bond length has been obtained. The O(1)NO(1′) valence angles in the ring are smaller than 120°.

V. Complex compounds of nitrogen

A large amount of interesting material has now been accumulated on the structure of donor–acceptor compounds of nitrogen in the gas phase. A large proportion of the structural data relates to adducts of the type $Y_3E{\leftarrow}NX_3$, where E is a group III element (B, Al, Ga). The experimental data for pyridine-containing complexes in the gas phase are fundamentally new, particularly in view of their low stability. Dimeric and trimeric amino-compounds of group III elements, lithium, and tin(II), and various derivatives of the anthrane type with an intramolecular donor–acceptor bond, have also been examined.

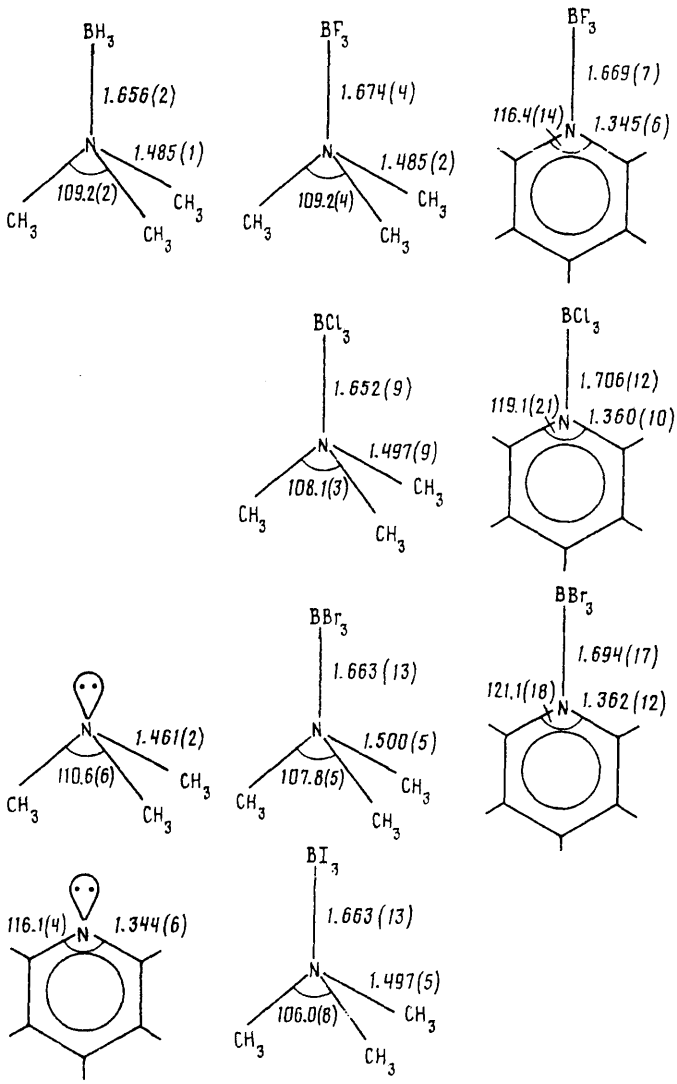

Figure 5. Comparison of the parameters of the r_g-structure of the free molecules of trimethylamine[13] and pyridine[169] and their boron adducts (see Table 17).

A new approach to the classification of the donor–acceptor bond as a unique type of bond has been proposed by Haaland,[7] who showed from an analysis of various physicochemical properties (including the geometric structure) that the donor–acceptor bond differs from a simple covalent bond.

1. Adducts containing a nitrogen–boron bond

Table 17 gives the parameters of complexes $Y_3B.NX_3$ studied in the gas phase by microwave spectroscopy (r_s, r_0) and electron diffraction (r_α^0, r_α, r_g, r_a) and by both methods. The differences between the data obtained by these two methods may be extremely large, because of the difference in the physical significance of the parameters obtained. Thus for one of the most interesting parameters, namely the NB bond length, the differences reach 0.03 Å, corresponding to the level of structural effects. In the subsequent analysis, therefore, we shall try to use comparable quantities.

When an adduct is formed, the lone pair of electrons of the nitrogen atom is partly transferred to the unoccupied orbital of the boron atom. This is accompanied by changes in the geometry of the original monomers, and the changes in the molecular parameters of the acceptor BY_3 are much greater than those for the donor NX_3.[6] We are interested primarily in the structural characteristics of the NX_3 fragment. The comparison in Fig. 5 shows that the participation of the trimethylamine molecule in complex formation as a donor leads to a significant increase in the length of the N–C bonds and a decrease in the CNC valence angles. In the adducts with boron trihalides these changes increase in the order

$$F_3B \cdot NMe_3 < Cl_3B \cdot NMe_3 < Br_3B \cdot NMe_3 < I_3B \cdot NMe_3.$$

A similar trend is observed in the change in the parameters of the nitrogen fragment of the pyridine ring on complex formation, the only but extremely significant difference being that the intra-cyclic CNC valence angle does not decrease, but increases.

The replacement of some substituents on the boron atom by others, however, does not have such a clear and systematic influence on the N–B bond length (Figs. 5 and 6). The N–B bond in the adduct $F_3B.NMe_3$ is slightly longer, whereas that in the corresponding adduct with pyridine is shorter, than those in the other members of the corresponding series of derivatives.

Although microwave studies have not given an accurate value for the N–B bond length in the adduct $Me_3B.NMe_3$ (indirect estimates give the value 1.70–1.80 Å [6]), the available data suggest that the methyl substituents in the amino-group lead to a decrease in the N–B bond length, whereas the same substituents in the acceptor fragment lead to an increase (Table 17).

The geometric parameters of adducts of the type $Y_3.B.NMe_3$ in the crystalline phase differ considerably from those in the gas phase. The B–Y and N–C bond lengths become larger, and the YBY angles and, which is most important, the N–B bond lengths are smaller than those in the gas phase. For the N–B bond the difference reaches 0.05–0.10 Å.[6] This shows that in the crystal the degree of charge transfer increases considerably, and the N–B donor–acceptor bond becomes stronger. The molecules of the adducts $Y_3B.NX_3$ have the staggered conformation (C_{3v} symmetry) in both phases.

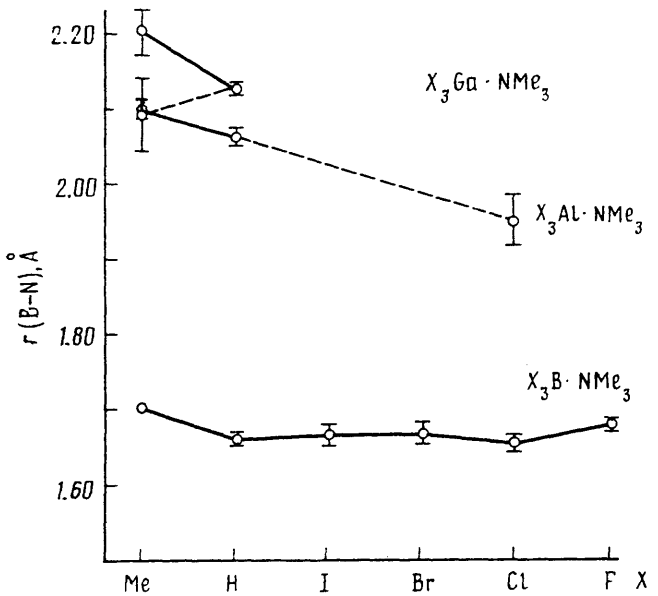

Figure 6. Influence of substitution in the acceptor group of the adducts $X_3E.NMe_3$ on the E–N bond lengths (E = B, Al, Ga; X = Me, H, I, Br, Cl, F).

The determination of the heights of the potential barriers is of considerable interest in relation to possible internal rotation about the N–B bond. Apart from anything else, these parameters are important for characterising the strength of the dative bond. The heights of the potential barriers in $Y_3B.NX_3$ cannot be estimated from the infrared and Raman spectra, however, since the twisting vibrations are not active in these spectra. The possibility of obtaining the heights of the potential barriers from an analysis of electron diffraction data using available spectral information is therefore of interest. The results of this analysis, and some microwave data, are given in Table 18.

Table 18 shows that the barriers to rotation are apparently higher in the $Cl_3B.NMe_3$ and $Br_3B.NMe_3$ molecules than in the other molecules, although the accuracy of the determination is low. The change in the height of the barriers, and also the change in the N–B bond length, most probably depend not only on the electronegativity of the substituents but also on steric factors.

2. Adducts containing nitrogen–aluminium, nitrogen–gallium, and nitrogen–halogen bonds

The structural parameters of donor–acceptor complexes containing N–Al and N–Ga bonds (mainly from electron diffraction data) are given in Table 19. They reflect more clearly the regularities established above from the analysis of the parameters of their boron analogues.

Table 18. Barriers to rotation about the dative bond N→B in the adducts $Y_3B.NX_3$.

Molecule	Height of the barrier to rotation, kcal mol^{-1}	Method	Refs.
$H_3B.NH_3$	2.03	MW	[155]
$H_3B.NMe_3$	3.4	MW	[157]
	>5	GE	[158]
$F_3B.NMe_3$	4.3(3)	GE	[162]
	6.2	GE	[164]
$Cl_3B.NMe_3$	18	GE	[165]
	13.7	GE	[164]
$Br_3B.NMe_3$	12	GE	[165]
$I_3B.NMe_3$	3.5	GE	[166]

Table 19 clearly shows the tendency for the N–Al bond length to decrease with increase in the electronegativity of the ligands on the Al atom in the order Me < H < Cl (see Fig. 6). Increase in the acceptor power of the aluminium fragment also leads to an increase in the N–C bond lengths in the donor fragment NMe_3. In turn, increase in the electronegativity of the substituent on the N atom (Me < H) is accompanied by an increase in the N–Al bond length, that is by a decrease in its strength as a result of the decrease in the donor power of the nitrogen fragment.

A characteristic feature of adducts containing N–Al and N–Ga bonds, distinguishing them from the corresponding adducts containing an N–B bond, is that complex formation leads to an increase in the CNC valence angles of the donor fragment NMe_3 (see Fig. 5). The reason apparently is that the overall increase in the N–Al and N–Ga bond lengths compared with the N–B bond lengths (by ~0.3–0.5 Å) leads firstly to a decrease in the strength of the repulsion between the bonding electron pairs of the donor and the electrons involved in the formation of the coordinate bond, and secondly to a decrease in the steric interactions between the ligands of the donor and the acceptor. In the boron complexes these factors have a more significant influence not only on the N–B bond lengths and the CNC valence angles but also on the parameters of the potential functions of the internal rotation. These interactions may determine the differences in the structural regularities examined above for the boron–nitrogen adducts with trimethylamine and pyridine (see Fig. 5).

The only results not agreeing with the other data examined in this section are those obtained in the study of the $Me_3Ga.NMe_3$ molecule.[180,181] In this compound the two key parameters characterising the structure of the adduct {the N–Ga bond length

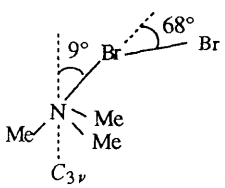
*Accepted value.

[2.09(5) Å] and the CNC valence angle (104.0°)} clearly do not correspond to the regularities examined above. Without going into details of the electron diffraction analysis, we may note that the deviation in this case is due to the unreliability of the determinaiton of the N–Ga bond length. The complexities of its determination were related to two factors: 1, the large amplitude of the vibrations for this distance, characteristic of a donor–acceptor bond, and 2, the possible decomposition of the substance on heating during the electron diffraction experiment, since dative bonds become weaker on going to the elements of the lower part of group III.[6]

An interesting feature is that the summary of the preliminary results of the structural analysis[181] gave what are apparently better justified values of these parameters, namely r(N–Ga) = 2.20(3) Å and angle CNC = 109.6°. In the crysalaline Al and Ga adducts, the molecular core also has C_{3v} symmetry, and the N–Al and N–Ga bonds, like the N–B bonds, are ~0.1 Å shorter than those in the molecules in the gas phase,[6] corresponding to an increase in the extent of charge transfer.

In the study of the structure of the double adduct $H_3Al.2NMe_3$ in the gas phase it was not possible to obtain information on the form of the molecule, apparently because of its partial dissociation. The value found for the N–Al bond length is more than 0.1 Å greater than that for the 1 : 1 adduct.

There are as yet only isolated data on adducts of trimethylamine containing a halogen atom as acceptor. The conformation of the Br_2NMe_3 molecule in the gas phase differs considerably from that found in the crystal for I_2NMe_3 (C_{3v} symmetry). The Br atom closest to the nitrogen atom deviates by 9(2)° from the three-fold axis of the NMe_3 fragment. The second Br atom deviates from the N–Br bond by a further 68(3)°.



3. Dimers and trimers of amino-compounds of various non-transition elements.

Anthrane compounds

Dative bonds involving the nitrogen atom as donor stabilise the molecular structure of the derivatives of various non-transition elements.

These structures include *n*-meric amine systems. The structures of some of the compounds have been studied in the gas phase (Table 20).

Monomeric lithium amines $LiNR_2$ with a three-coordinate nitrogen atom are extremely rare. Most lithium amines form *n*-meric cyclic systems in which the nearest lithium atoms are joined by amide bridges with four-coordinate nitrogen. Crystallographic data indicate that the $(LiN)_2$, $(LiN)_3$, and $(LiN)_4$ rings are invariably planar.[184,185]

Table 20. Dimers and trimers of the amino-derivatives of various non-transition elements.

The only electron diffraction data for dimeric $[LiN(SiMe_3)_2]_2$ in the gas phase also indicate a planar cyclic system. The molecule as a whole has D_2 symmetry. The cores of the bridging ligands $N(SiMe_3)_2$ lie in a plane perpendicular to the plane of the ring, and the $SiMe_3$ groups of each of the ligands are arranged in a staggered conformation relative to one another. An interesting feature is that the Li–N bond length found in this case is indistinguishable from the corresponding distances in the crystalline trimeric and tetrameric lithium amines (1.97–2.00 Å [184,185]), whereas the Li–N bonds in the crystalline dimers studied show a tendency to increase, apparently as a result of the presence of the additional ligands on the Li atom.

Comparison of the electron diffraction data with the X-ray diffraction also shows that the intra-ring valence angles at the Li atom are influenced more strongly than the angles at the N atom by the dimensions of the ring. Thus the LiNLi angles change from 80° to 100° on going from the dimers to the trimers, whereas the NLiN angles change from 100° to ~170°.[184,185]

A consequence of the tetrahedral coordination of the N atom in the dimer $[LiN(SiMe_3)_2]_2$ is the slight decrease in the N–Si bond length compared with that in the $HN(SiMe_3)_2$ molecule [r_a 1.738(5) Å [64]]. The SiNSi angle in the dimeric Li amine is practically the same as the corresponding valence angle in $HN(SiMe_3)_2$ [131.3(15)° [64]].

For all the elments of the boron sub-group, the cyclic dimers $(Me_2NEH_2)_2$ are more characteristic than the monomeric structures $Me_2N{=}EH_2$ containing a multiple bond. This is due to the greater stability of the dimeric form. Experimental data obtained by various methods show that structures in which the NMe_2 groups form bridges producing a four-membered N_2E_2 ring exist in the gas phase, in solution, and in the crystalline phase.

The electron diffraction data for the Al and Ga derivatives (Table 20) are consistent with a molecular model having a planar ring and effective D_{2h} symmetry of the core $(C_2NEH_2)_2$. Since the nitrogen atoms in these compounds become four-coordinate by using their lone pair of electrons for bond formation, it is of interest to compare the E–N bond lengths in the four-membered rings and in the adducts $Y_3E.NX_3$ (see above). The comparison shows that the change to the cyclic system and the changes in the coordination spheres of the atoms lead to an appreciable decrease in the E–N bond lengths. Thus the B–N bond in aminodiborane $H_2N{\rightarrow}BH_2{-}H{\ldots}BH_2$ is ~0.1 Å shorter than in any of the adducts $Y_3B.NX_3$ studied. The Ga–N bond in the dimer $(Me_2NGaH_2)_2$ is ~0.1 Å shorter than that in the $H_3Ga.NMe_3$ molecule. The Al–N bond length in the four-membered ring of $(Me_2NAlCl_2)_2$ coincides (within the large error of the determination) with that found in the $Cl_3Al.NMe_3$ molecule, but is shorter than the dative bonds in other acyclic aminoalanes. The available X-ray diffraction data also indicate a decrease in the E–N bond lengths in the rings on going from the gas to the crystalline phase.[187,189]

The intra-ring valence angles at the Al and Ga atoms in the dimers $(Me_2NAlCl_2)_2$ and $(Me_2NGaH_2)_2$ being considered are only slightly smaller than the angles at the N atoms, so that the four-membered rings are practically square. In the six-membered ring of the aminoalane $(Me_2NAlH_2)_3$ the valence angles at the N atoms are

Table 21. Electron diffraction data for compounds of the anthrane type.

Molecule	Parameter	Bond lengths, Å			Valence angles, °		Refs.
		E–N	E–R	N–C	ENC	NSiO NZnC	
	r_g	2.453(17)	1.853(15)	1.458(6)	103.4(16)	79.0(15)	[190]
	r_g	2.324(14)	1.568(6)	1.481(8)	103.2(4)	81.3(3)	[191]
	r_a	2.392(15)	1.991(6)	1.467(3)	101(2)	82(2)	[192]

increased to a much greater extent than the angles at the Al atoms. In these rings the steric repulsion between the Al or Ga atoms is apparently greater than the interaction between the N atoms. The valence angles at the latter are greater than those found in the dimeric Li amine or aminodiborane.

Studies of trimeric aminoalanes in the gas phase (Table 19) and in the crystals[188] indicate that the valence angles at the nitrogen atoms are more easily altered parameters of the ring than the angles at the Al atom. Electron diffraction data for the $(Me_2NAlH_2)_3$ molecule show that the six-membered $(AlN)_3$ ring in it is non-planar and has the "chair" conformation (C_{3v} symmetry). Although the Al–N bond lengths found are only slightly longer than those in the chloro-substituted dimer $(Me_2NAlCl_2)_2$, the direction of the change corresponds to the influence of substituents on the E–N bond lengths observed for adducts of the type $Y_3E.NX_3$. As in the case of the dimers examined above, the Al–N bond in $(Me_2NAlH_2)_3$ is ~0.1 Å shorter than that in the adduct $H_3Al.NMe_3$. Moreover, the value obtained is 0.03–0.05 Å larger than that in various crystalline trimeric aminoalanes.[188]

The bis(dimethylamino)tin(II) dimer is less stable than the corresponding monomer (see section II). A study of this compound in the gas phase showed that its concentration in the mixture is 24 ± 1%. The Sn–N bond length in the cyclic dimer is 0.3 Å larger than that in the monomer. The four-membered $(Sn-N)_2$ ring is planar, and, as in the case of the dimeric amines of the boron sub-group, the intra-ring valence angles at the nitrogen atom are slightly greater than the angles at the tin atoms. An X-ray diffraction study, carried out in parallel with the electron diffraction study, showed that the structures of the dimer in the gas phase and in the crystal differ considerably.

The study of the structure of compounds of the anthrane type in the gas phase is also of considerable interest. At the present time, data of this kind are available for Me- and F-substituted silatranes and a chelate spiro-structure with two dative N→Zn bonds (Table 21).

Silatranes are biologically active molecules in which the properties of the substituent on the Si atom have a marked influence on the strength of the dative bond. This is confirmed by electron diffraction data. Thus electronegative substituents (for example the F atom) lead to a decrease in the N→Si bond length of more than 0.1 Å, compared with the Me-derivative. The N–C bonds in the ring systems of the F-silatrane become longer by more than 0.02 Å, as in the adducts $Y_3E.NMe_3$. The identical donor–acceptor nature of the interaction of the nitrogen atom in the silatranes and in the other classes of compound examined in this section is also revealed by the decrease in the N→Si bond length on going from the gas to the crystalline phase,[193] which is more clearly defined in the silatranes (~0.3 Å). Simultaneously, the length of the bond formed by the Si atom with the ring substituent increases by 0.02–0.05 Å.

The donor–acceptor interaction of the Zn atom with the amine nitrogen atom in its diorgano-derivatives is much weaker than that in the adducts of boron, aluminium, or gallium. Thus according to electron diffraction data, the monoligand complex $Me_2Zn.NMe_3$, which exists in the liquid phase, is completely dissociated in the gas phase even at 30 °C to $ZnMe_2$ and NMe_3,[192] and the diligand complex $Me_2Zn(NMe_3)_2$ is not known.

Nevertheless, N→Zn dative bonds are fairly stable in diorgano-derivatives of Zn with N donor atoms in the δ- or ε-positions of the substituent chain, in particular in the $Zn[(CH_2)_3NMe_2]_2$ molecule. The $(CH_2)_3NMe_2$ substituents bend to form rings, bringing the N atoms closer to the Zn atom, to give additional intramolecular coordination of the N atoms to the Zn atom with the production of a chelate structure.

A possible explanation for the instablity of the simplest adducts of Zn examined above may be that the increase in entropy associated with their dissociation plays a more significant role than the energy effect of complex formation. In contrast to this, on intramolecular coordination the entropy changes are minimal, and even a relatively low energy of complex formation is sufficient to stabilise the donor–acceptor bonds.

The weakness of the dative interaction of the N and Zn atoms is revealed by the increase in the N→Zn bond length by 0.6 Å compared with the length of the Zn—N covalent bond in the monomeric amine $Zn[N(SiMe_3)_2]_2$ (see Table 3). This is also indicated by the high value of the mean amplitude of the vibrations of the N→Zn bond [0.17(3) Å]; the amplitude of the vibrations of the Zn—C bond in the chelate ring system is only 0.073(6) Å. The transfer of the Zn-derivative from the gas to the crystalline phase is accompanied by a decrease in the N→Zn bond length (by 0.085 Å)[192] which although not so great as that in silatranes is nevertheless considerable. The bond lengths and valence angles in the five-membered rings of the chelate system of $Zn[(CH_2)_3NMe_2]_2$ are very close to those found in silatranes (Table 21).

VI. Summary

Systematic experimental studies of series of compounds are required to determine the relationships between the geometry of molecules and their chemical properties. Unfortunately, complete systems of data often are not available. This is due both to problems of synthesis and to the limited possibilities provided by the methods of studying structure. In these cases the use of non-empirical quantum-chemical calculations at a high level becomes extremely effective.

The structural data given and the regularities found reveal the important role of steric repulsion in compounds with bulky substituents. This conclusion is naturally very simple. In some cases, however, it is difficult to distinguish an interaction having a decisive influence on the configuration of a molecule. Thus the CNC valence angle at the amine nitrogen atom in methyl- and chloro-substituted N-nitramines is appreciably greater (by ~15°) than that in $(CH_3)_3N$ (~110°). At the same time, in metal amines this angle is not increased (~111°), although the configuration of the bonds formed by the nitrogen atom in these compounds, as in the Me-derivatives of N-nitramine, is planar or close to planar.

In di-imides with the cumulene bond system $\diagdown N=C=N\diagup$ the expected orthogonal configuration of the bonds formed by the nitrogen atom with substituents is not observed. This emphasises the important role of the interaction of non-bonded atoms (even at appreciable distances).

Data on nitro-aromatic derivatives and N-nitramines indicate that conjugation has an extremely limited influence on the configuration of the molecule, since the $C-NO_2$ bond length is practically independent of the angle of rotation of the NO_2 group about the C—N bond. The same appreciable pyramidal character of the bonds formed by the amine nitrogen atom in pyrroles does not change in the N—N bond length.

In complex compounds containing a "pure" donor—acceptor bond involving the nitrogen atom, the stereochemistry of the donor and acceptor fragments is consistent with Gillespie's ideas. The almost square structure of the planar four-membered rings in the dimeric complexes of metal amino-derivatives is difficult to explain, however, because of the differences in the elastic constants of the valence angles at the atoms of nitrogen and the acceptor metal.

The effect of alternation in chromatographic retention relationships

M S Vigdergauz, E I Petrova
Samarskoe State University

ABSTRACT. The effect of the alternation of the chromatographic retention values has been examined for homologous series of sorbates and stationary phases (the even–odd effect) and for other series formed by the successive addition of identical functional groups to the repeating fragments of an aliphatic molecule or ring, as well as by the displacement of functional groups or alkyl groups along a chain or a ring. Particular attention has been paid to the manifestation of this effect when liquid-crystalline stationary phases are used. It has been shown that the diffference in the concentrations of given substances in natural materials may be partly due to the alternation of the sorption characteristics.

The bibliography contains 70 references.

I. Alternation of the physicochemical characteristics of homologues

In the study of the regularities of the change in the physicochemical properties of substances which are members of homologous series, attention is drawn to the role of the structural factor determined by the characteristics of the configuration of molecules with even and odd numbers of carbon atoms.[1] As a consequence of this influence, the relationship between the physicochemical characteristics and the number of carbon atoms z is given by a zigzag curve, that is alternation of the quantities being studied, depending on the parity of z, is observed.

The influence of the parity of z was first revealed in the study of the regularities of the change in the melting point in the homologous series of n-alkanes.[2,3] The relationship between the melting point and the number z was found to be different for the even and odd homologues. A similar effect was later observed for the aliphatic acid series.[4] Data have been published[5] on the effect of alternation in the change in the melting points and solubilities of dicarboxylic acids. The values of the melting points and solubilities of the numbers of the series with odd values of z are higher than those for the even homologues.

For liquid crystals, the effect of alternation is revealed not only by the melting points but also by the temperatures of other phase transformations: smectic–nematic and nematic–isotropic liquid.[6–11] In addition, in the nematic phase of N-(4-alkoxybenzylidene)-4′-toluidine specimens oriented by a magnetic field, an even–odd effect was detected in the temperature dependence of the parameters of the orientational ordering.[11]

Published data[4,12–15] and their own data were used by a group of authors[16,17] to study the regularities in the influence of the parity of z on the values of the dipole moments, refraction, heats of crystallisation, refractive indices, and size of the crystal cells of aliphatic acids, their methyl esters, and the dimethyl esters of dicarboxylic acids. It was later shown[18] from published data[12,19–22] that a fairly clearly defined alternation of such characteristics as the melting point, density, refractive index, dipole moment, and even boiling point is observed for homologous series of alkylamines, alkylbenzenes, ketones, and esters of carboxylic acids.

One of the possible factors responsible for the alternation of the physical properties of substances (such as the melting point or heat of fusion) is apparently the nature and stability of the packing of the molecules in the crystal.[23] The stability of the packing of the molecules in the crystal in turn depends on their geometry. For example, X-ray diffraction shows that the zigzag chains of the molecules of saturated non-branched hydrocarbons in the crystal are arranged parallel to one another, and that the "convex" parts of one chain enter the "dents" in the other. The physical properties of these substances depend on the parity of the number of carbon atoms, since the symmetry of the individual molecules influences the way in which one layer of molecules in the crystal is superimposed on another. Molecules with an odd value of z have a plane of symmetry passing through the central carbon atom, and the terminal methyl groups are directed in the same direction relative to the axis of the molecule. A chain with an even number of carbon atoms does not have this plane of symmetry, but acquires a centre of inversion, situated between the two central carbon atoms. The terminal methyl groups in these molecules are directed in different directions with respect to the axis of the molecule. This difference in the arrangement of the methyl groups is responsible for the difference in the packing of the layers of molecules.

On crystal formation, hydrocarbons with an even value of z are arranged in such a way that each layer repeats the previous layer (with a slight sideways displacement), whereas in the crystals formed by hydrocarbons with an odd value of z, every second layer has the same arrangement of molecules.

Increase in the chain length eliminates the advantage of one type of packing over another, and for hydrocarbons the even–odd effect gradually decreases, disappearing completely when the number of carbon atoms is sufficiently large.

Similar arguments can be used to explain the even–odd effect in carboxylic and dicarboxylic acids.

II. Alternation of the gas-chromatographic retention values in homologous series of sorbates (even–odd effect)

The possibility of the effect of alternation appearing in the change in the temperatures of the phase transformations in liquid crystals is evidently related to their structural ordering in the solid and liquid states. Since the chromatographic characteristics are also related to the phase transformations, the changes in these characteristics should also show the effect of alternation. The probability of this is greater if the liquid phase has a fairly rigid structure. Kovats[24] initially determined the retention index by a logarithmic interpolation based on the logarithms of the retention volumes of the n-alkanes of the even series, but since the alternation effect was not detected, this was later recognised as unnecessary, and the interpolation began to be carried out on the basis of the retention characteristics of neighbouring n-alkanes.

In the subsequent development of chromatography, when highly efficient columns were introduced (this increased considerably the sensitivity of the determination of the retention characteristics), it was established that the relationship between the retention values and the number of carbon atoms in the molecules of sorbates in a homologous series, previously assumed to be linear, often shows deviations from linearity.[25–29] These deviations may be due to either anomalies in the properties of the sorbates or the corresponding sorption properties of the stationary phases. Detailed study of this question established that the deviations from linearity are related primarily to the characteristics of the molecular structure of the first members of the homologous series and are also determined by the non-constant nature of the increment of the repeating fragment of the molecule. These deviations can be seen particularly clearly when polar sorbates and(or) polar stationary phases are used.

The authors cited[29] also showed that for different stationary phases the difference between (ratio of) the retention values in the series of n-alkylbenzenes and n-alkylcyclohexanes is greatest for the n-propyl-substituted/ethyl-substituted pairs (a similar relationship was found for such physicochemical characteristics as the dielectric constant and surface tension). Sojak and co-workers[30] established that the n-propylbenzene/ethylbenzene pair also has the smallest value of the increment in the retention index on a column containing squalane. This effect was later called the "propyl" effect.[31]

The importance of the parity of z was a factor influencing the retention of homologues was first revealed[32] in a study of the n-alkane–polyethylene glycol system. An experiment carried out on a highly efficient capillary column showed that the relationship between the retention and the number z is given by a broken line, that is alternation of the chromatographic retention values is observed on going from an even to an odd member of the homologous series. Thus strictly speaking this relationship should be represented by two curves, one corresponding to even values of z and the other to odd values. Two anomalous effects, namely the "propyl" effect and the even–odd effect, are shown simultaneously by data on the retention of alkylbenzenes on squalane, acetyl tributyl citrate, and 1,2,3-tris(β-cyanethoxy)propane.[33–36]

The relationship between the chromatographic retention and the number of carbon atoms in the molecule z, with allowance for alternation, can be described by the equation:[37]

$$\lg t'_{R_z} = a_t + b_t z + c_t z^2 + d_t z^3 + D_t \varphi_z. \qquad (1)$$

where t'_{R_z} is the reduced retention time of the member of the homologous series with z carbon atoms in the molecule; a_t, b_t, c_t, D_t are constants; and $\varphi = +1$ for even values of z, or -1 for odd values.

Since the effect of alternation is fairly fine, it can be detected by examining not the retention time but the ratio of the reduced retention times

$$\sigma_\Gamma = t'_{R_z}/t'_{R_{z-1}}$$

or the difference between the retention indices ΔI of neighbouring homologues. In the study of the change in the retention characteristics with change in z for substances belonging to different homologous series, it is necessary to examine the ratio of the reduced retention times or the difference between the retention indices of substances having the same number of carbon atoms in the molecule but belonging to different homologous series. The quantity σ_Γ is related to the difference between the molar free energies of volatilisation from the stationary phase $\delta(\Delta G^\circ)_z$ of two molecules with numbers of carbon atoms in the molecule z and $z-1$ by the equation

$$\delta(\Delta G^\circ)_z = RT \ln \sigma_\Gamma, \qquad (2)$$

where R is the universal gas constant, and T the absolute temperature of the column.

Thus the contribution of the parity of the number of carbon atoms to the retention can be expressed in energy units.

On the graph, the distance between lines corresponding to series of homologues with even and odd values of z is characterised by the alternation criterion A_z:[16,17,37]

$$A_z = \lg \sigma_{\Gamma_{z+1}} - \lg \sigma_{\Gamma_z} = \lg t'_{R_{z-1}} + \lg t'_{R_{z-1}} - 2\lg t'_{R_z}, \qquad (3)$$

where σ_{Γ_z} and $\sigma_{\Gamma_{z+1}}$ relate to homologues with numbers of carbon atoms z, $z-1$ and $z+1$, z respectively. The sign of A_z depends on the parity of z and changes on going to each subsequent homologue.

The influence of the parity of z on the retention of n-alkanes, 1-bromoalkanes, and 2-alkanones by a stationary phase of medium polarity, namely triethylene glycol dibutyrate, was revealed using a highly efficient capillary column.[37] The study was carried out at temperatures of 40 °C and 80 °C. The alternation effect increases in the order: n-alkanes < 1-bromo-alkanes < 2-alkanones. This is clearly demonstrated by the plot of $\sigma(\Delta G^\circ)_z = f(z)$. The clearly defined zigzag character of this relationship for the 2-alkanones disappears on going to the 1-bromoalkanes and then to the n-alkanes. The $\sigma(\Delta G^\circ)_z = f(z)$ relationship for the n-alkanes is given by an almost straight line. The data obtained also indicate that in this case the temperature effect is slight; the influence of temperature is shown only by a displacement of the points on the graph, and the form of the curve giving the dependence of the chromatographic retention characteristics on z remains unchanged. An interesting feature is that the value of $\sigma(\Delta G^\circ)_z$ for 1-bromoalkanes with even values of z is smaller than that for the odd compounds, that is the change in these quantities is the opposite of that for the n-alkanes. This effect can be attributed to the role of the bromine atom in position 1, which makes the hydrocarbon chain longer, that is the number of "chain-forming" atoms in the 1-bromoalkanes with z carbon atoms must be regarded as $z+1$.

Fig. 1 gives graphs showing the influence of the parity of the number of carbon atoms in the molecule on various properties of n-alkanes.[37] It can be seen from Fig. 1 that the general curvature of the dependence of the retention values on z is determined by the regularity of the change in the values of the saturated vapour pressure of the sorbates (curve *1*). The influence of the parity of z on the retention of n-alkanes (curves *2* and *3*) is revealed to a greater extent when polyethylene glycol 400 is used as the stationary phase than when triethylene glycol dibutyrate is used; this is a consequence of the more rigid molecular structure of the first of these stationary phases. The similarity between curves *3* and *4* proves the close relationship between the retention values and the molecular structure of the compounds being considered.

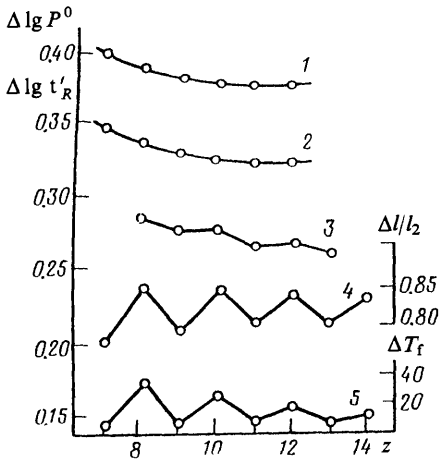

Figure 1. Dependence of various properties of n-alkanes on the number of carbon atoms in the molecule;[37] *1*, homologous difference between the logarithms of the saturated vapour pressures $\Delta \lg P^0$ at 80 °C; *2,3*, homologous difference between the logarithms of the reduced retention times at 80 °C on columns containing triethylene glycol dibutyrate (*2*) and polyethylene glycol 400 (*3*); *4*, the quantity $\Delta l/l_2$, where Δl is the difference between the terminal carbon atoms in the molecule for neighbouring homologues, and l_2 the length of the C–C bond; *5*, homologous difference between the melting points ΔT_f.

The influence of the parity of z on the functional group increment in the molecules of compounds of different homologous series has been studied.[38] The sorbates chosen were n-alkanes, bromoalkanes, aldehydes, and ketones. The study was carried out on a capillary column with triethylene glycol dibutyrate as stationary phase. The retention characteristic was the partial Henry coefficient (the capacity coefficient) $\Gamma' = t'_R/t_0$, where t_0 is the retention time of a substance which is not sorbed. The dependence of $\lg \Gamma'$ on z has the form of a broken line and can be described by an equation analogous to Eqn. (1).

Calculation of the retention increments from published data[39] shows that alternation of the values of ΔI is also observed for homologous series of methyl and chloromethyl esters of n-C_5–C_{12} chlorocarboxylic acids on capillary columns with the stationary phases SE-30 and Carbowax 20M.

The effect of alternation in the chromatographic retention of n-alkanes (C_6–C_{11}) is also observed on packed columns containing trifluoropropylmethylsilicone SKTFT-100 and pentaphenyl ether.[40] The $\sigma_\Gamma = f(t)$ relationship is given by a zigzag line. In particular, for the stationary phase SKTFT-100 the value of σ_Γ lies in the range 1.40–1.58 (uncertainty in the determination 0.01–0.04), and the quantity $\Delta\sigma_\Gamma = \sigma_{\Gamma_{z+1}} - \sigma_{\Gamma_z}$ characterising the range of alternation for following pairs of homologues has the values −0.11, 0.18, −0.14, 0.14.

The effect of alternation becomes particularly marked for polar sorbates and polar stationary phases. The alternation may be clearly defined even for packed columns with medium efficiency. In particular, this phenomenon has been studied in detail for aliphatic acids and their esters.[16,17,41] The regularities in the retention of the methyl esters of aliphatic acids were studied at different temperatures on four stationary phases with different polarity: Apiezon L, Triton X-305, Carbowax 20M, and diethylene glycol succinate (DEGS). The ratios of the retention indices of the sorbates studied on columns containing DEGS and Apiezon L showed a tendency to alternate. The alternation of these quantities is observed in the range $z = 3$–12, and the tendency disappears with further increase in the length of the alkyl group.

The retention of the dimethyl esters of aliphatic dicarboxylic acids on a column containing the high-temperature liquid-crystalline stationary phase bis(*p*-ethoxybenzylideneamino)biphenyl has been studied.[42] Clearly defined alternation of the retention values is observed for the C_4–C_8 series, after which it disappears with increase in the number of CH_2 groups in the molecule.

To investigate the alternation of the t'_{R_z} values, the alternation criterion A_z was calculated. The values of A_z were calculated for a temperature of 190 °C on two stationary phases: the polar DEGS and the non-polar Apiezon L. Alternation of the values of t'_{R_z} is observed only on the polar liquid phase in the range $z = 3$–6 for the dimethyl esters of dicarboxylic acids (t_0 = 190 °C, stationary phase DEGS); alternation of the retention characteristics is also observed in the range $z = 4$–10 for the free aliphatic acids (t_0 = 190 °C, stationary phase diethylene glycol adipate + H_3PO_4).

In the study of the chromatographic behaviour of free aliphatic acids it was shown that lowering the temperature of the column to 160 °C leads to disappearance of the alternation effect, and that the effect is preserved when the temperature is raised to 200 °C.

The alternation of the properties in the series of normal aliphatic acids is attributed to the difference between the configurations of the molecules of the even and odd homologues. In the monocarboxylic acids, the carboxyl group at one end of the molecule is opposite a methyl group for odd values of z) or a methylene group (for even values of z). For dicarboxylic acids, the carboxyl group is opposite a second carboxyl group or a methylene group, depending on whether the value of z is even or odd. Thus if the alternation is determined by the configuration of the molecule, it should be more clearly defined for the dicarboxylic acids and their derivatives. This is confirmed by the results obtained.[16,17] Thus if the range of alternation of the retention values is characterised by the difference

$$\Delta A_z = |A_{z+1}| - |A_z|,$$

then the range will be about 0.01–0.07 for free aliphatic acids, 0.06–0.08 for the methyl esters of aliphatic acids, and 0.16 for the dimethyl esters of dicarboxylic acids. The authors cited[16,17] consider that a definite role in the phenomenon of alternation may also be played by the polymorphism of the aliphatic acids (there exist forms

A, B, and C whose molecules differ in the magnitude of the angle at which the carbon atoms are arranged).

The effect of alternation has been observed[5] in the dependence of the relative retention of n-alkyl-substituted carboxylic acids (n-C_5 – n-C_{16}) on their melting points on a column containing a silicon + 15% stearic acid as stationary phase, the dependence of the relative retention of the methyl esters (n-C_8 – n-C_{18}) on the melting points of the corresponding aliphatic acids on a column containing a silicone grease as stationary phase, and the dependence on the melting points of the absolute specific retention volume of n-alkanols (C_1 – C_8) in a column containing the stationary phase SE-30.

A statistical estimation of the alternation effect has been carried out.[18] For this purpose, the uncertainty in the determination of the quantity used to characterise the chromatographic retention was established. This quantity was the retention increment ΔI equal to the difference between the retention indices I of neighbouring members of a series of sorbates differing in the number of repeating fragments. It was shown for a number of examples that the regularities of the change in the retention values in the series of sorbates studied are preserved when account is taken of the uncertainties in the determination of these quantities. Thus in the range of alternation $\Delta(\Delta I)$ for cycloalkanes on squalane in the range 3 – 13 I units, the uncertainty in the determination of I varies in the range 0 – 1.5 I units. Thus the alternation effect observed in a number of cases is not a consequence of the uncertainty in the determination of the retention indices, but is determined by the characteristics of the structure of the sorbates and the nature of their interaction with the stationary phase.

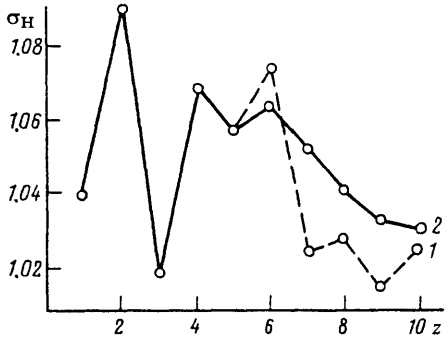

Figure 2. Dependence of the selectivity coefficient on the number of carbon atoms in the lateral alkoxy-group of symmetrical azoxy-ethers for smectic (*1*) and nematic (*2*) meso-phases.

The alternation effect is also revealed by the regularities of the chromatographic behaviour of liquid crystals when they are used both as sorbents and as stationary phases. For example, the alternation effect was detected in a chromatographic study of the thermodynamics of the solution of monohydric aliphatic alcohols in the cholesteryl ester of myristic acid.[43] The authors cited[43] consider that the probable reason for this effect is that when the molecules of non-mesogenic additives are introduced into the structure of a meso-phase there is a difference in the efficiency of the coupling between the molecules and individual sections of the meso-phase. The coupling reduces mainly to an end-type interaction between the molecules of the liquid crystal and the non-mesogenic additive. Increase in the length of the hydrocarbon group of the alcohol will lead to a decrease in the smectogenic character of the cholesteryl myristate molecules.

The selectivity of the stationary phases *p,p'*-methoxyethoxyazoxy-benzene (MEAB) with respect to isomeric alkanes (C_{10} – C_{17}) has been studied;[9,44] geometric isomers and positional isomers were examined. The dependence of the selectivity coefficient σ_H, which is the ratio of the reduced retention times of *trans*- and *cis*-isomers with double-bond position 2 – 8 or the ratio of the reduced retention times of neighbouring *cis*- and *cis*-isomers and *trans*- and *trans*-isomers, on the number z has a zigzag form. This confirms the influence of the parity of z on the ratio of the retention parameters of sorbates having the same number of carbon atoms in the molecule but belonging to different homologous series.

III. Even – odd effect in the retention of sorbates by homologous series of stationary phases

The effect of alternation in chromatography can also be detected by studying the retention of the same sorbates on a number of stationary phases which are members of one homologous series. In particular, this effect has been observed in a study of the separation of close-boiling isomers on columns containing nematic liquid crystals, namely azoxy-ethers. The influence of the parity of z can be examined from different viewpoints; thus it is possible to consider firstly the total number of carbon atoms in the molecule of the liquid crystal, and secondly the number of carbon atoms in both lateral parts; the influence of parity in one side chain on the chromatographic retention can also be examined. Thus symmetrical azoxy-ethers have been used as stationary phases for the separation of *m*- and *p*-xylenes.[45–47] The dimethoxy-derivative (azoxyanisole) has a low selectivity, the diethoxy-derivative (azoxyphenetole) a higher selectivity, and the subsequent homologues approximately the same or a lower selectivity (Fig. 2). If however the asymmetric ether *p,p'*-methoxyethoxyazoxybenzene is used as the stationary phase, the *m* – *p*-selectivity increases considerably and becomes greater than that for azoxyphenetole and its eutectic mixture with azoxyanisole.[48]

The change in the *m* – *p*-selectivity in a series of symmetrical and asymmetrical azoxy-ethers has been studied.[9,49] The value of the selectivity coefficient σ_H, which in this case is the ratio of the reduced retention times of the *m*- and *p*-xylenes, shows alternation not only with change in the number of carbon atoms in the side chains of the azoxy-compounds but also in the dependence on the symmetry of the molecules of the liquid crystals as a whole. The asymmetric azoxy-ethers on the whole have a greater *m* – *p*-selectivity than the symmetrical ones. In the series of asymmetric homologues, MEAB has the greatest *m* – *p*-selectivity.

An even – odd effect has been detected[50,51] in the retention of standard sorbates (ethanol, methyl ethyl ketone, benzene, and nitromethane) on liquid-crystalline stationary phases belonging to the homologous series of nitroazoxybenzenes. Alternation is shown by the values of the linear retention indices of the sorbates studied and the chromatographic polarity factors. The values of the retention parameters are greater for the odd than for the even substituents.

When asymmetric azoxy-ethers are used as stationary phases,[32] alternation is also shown by the values of the universal polarity factors—quantities which are proportional to the reduced retention times of the sorbates and which characterise the chromatographic polarity of the stationary phase with allowance for its sorptive capacity and the duration of the chromatographic analysis.

IV. Even–odd effect in liquid–liquid chromatography

The influence of the parity of z on the sorptive properties of petroleums is related to the corresponding regularities of their composition. Thus the ratio of odd and even n-alkanes in recent sediments and petroleums is different.[53–56] In sediments, molecules with an odd number of carbon atoms predominate, whereas in petroleums, molecules with an odd value of z are present in very small quantities or are not detected at all. It has been proposed[57] that this relationship be characterised by the odd-parity index, which is the ratio of the number of molecules of n-alkanes with odd values of z [odd molecules (O)] to the number of molecules of n-alkanes with even z [even molecules (E)]. The corresponding values of O/E are -5.6 in recent sediments, and $0.9-1.2$ in petroleums.

The odd-parity index is used by many authors as a characteristic of petroleum which makes it possible to identify its origins. Another characteristic of petroleum used for identification is the ratio of the concentrations in it of two alkanes with an isoprene structure, namely pristane (2,6,10,14-tetramethylpentadecane) and phytane (2,6,10,14-tetramethylhexadecane).[58,59] For a long time, however, the predominance of even or odd alkanes (with normal or branched structures) in different petroleums was related in the literature only to the organic origin of the petroleum, and no account was taken of the fact that a change in its composition may take place during the migration of petroleum through rocks which are adsorbents. This was first pointed out by Vigdergauz and co-workers.[60] It is confirmed by the results of investigations[61,62] in which the effect of the alternation of the sorptive properties of n-alkanes was studied under liquid–liquid chromatographic conditions. When a mixture of n-alkanes is passed through a column containing silica gel moistened with hexane, a fraction richer in hydrocarbons of the even series will leave the column first, followed by a fraction richer in those of the odd series.

Fig. 3 shows the change in the ratios of the concentrations of neighbouring n-alkanes (containing z and $z-1$ carbon atoms in the molecules) in a comparison of the initial and final fractions of the eluate with the original mixture. The total coefficient of enrichment of the initial fraction of the eluate in n-alkanes of the even series was 1.24 for the chosen conditions.

Studies carried out with different adsorbents moistened with different organic substances gave initial fractions enriched sometimes in the even and sometimes in the odd homologues.

In the work cited,[62] the changes in the compositions of the petroleums were studied by gas–liquid and thin-layer chromatography. It was shown that the process of filtration of the petroleum through rock is accompanied by a change in the even : odd n-alkane ratio and in the pristane/phytane ratio compared with the ratios in the petroleum taken initially.

Finally, a detailed study has been made[63] of the effect of change in the composition of a mixture of hydrocarbons with the isoprene structure on filtration through moistened porous media. The work was carried out under the conditions of frontal liquid–liquid chromatography, which approach most closely the natural conditions of the migration of fluids. The porous medium used was activated silica gel moistened with n-hexane. The studies showed that an even–odd effect is also observed in this case. The concentration of pristane in the initial fractions increases, compared with the concentration of phytane. In subsequent fractions this sorption effect gradually decreases, and the composition of the filtrate approaches the original composition. The effect of change in the composition of the mixture of isoprene hydrocarbons under these conditions is determined both by the solubility of the hydrocarbons studied in the n-hexane wetting the adsorbent and by the adsorption surface of the polar activated silica gel used as the adsorbent.

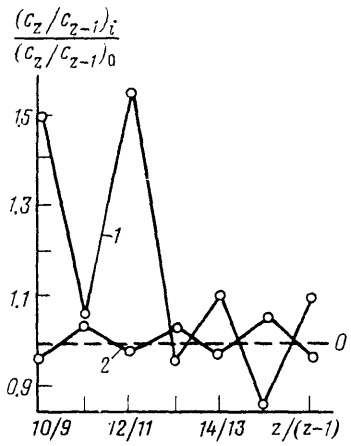

Figure 3. Change in the ratios of the concentrations of neighbouring n-alkanes (with numbers of carbon atoms in the molecules z and $z-1$) in a comparison of the initial (*1*) and final (*2*) fractions of the eluate with the original mixture (0).[60]

V. Other forms of alternation of retention values

A detailed examination of published data showed that the even–odd effect is only a particular case of alternation in chromatography. It is therefore of interest to examine the problem of alternation as a whole, and in particular the position occupied by the even–odd effect in alternation phenomena.

Study of the regularities of retention in different series of sorbates and stationary liquids makes it possible to consider seven cases of alternation of retention values.

1. With increase in the length of a molecule as a result of an increase in the number of repeating fragments (with a functional group on one or both ends of it). The even–odd effect, determined by the number of methylene groups in alkyl chains, is here a particular case.

2. On the successive addition of identical functional groups (or alkyl groups) to the repeating fragments of an aliphatic molecule or the aliphatic part of a molecule.

3. The analogous effect of a cyclic molecule (naphthenic or aromatic rings) and in per-substituted rings or heterocycles.

4. On displacement of a functional group (including hydrocarbon groups), joined to the alkyl chain of a molecule, along the chain.

5. The analogous effect for substituents in a cyclic molecule.

6. On the displacement of a functional group or a more complex fragment (or multiple bond), situated in a chain, along this chain (succession of metamers).

7. The analogous effect in heterocycles containing two heteroatoms.

Thus three types of alternation can be distinguished.

I. On the successive addition of identical fragments to a molecule (point 1).

II. On the successive addition of identical functional groups (or alkyl groups) to the fragments of an aliphatic chain or ring (points 2 and 3).

III. On the "displacement" of these fragments along alkyl chains and aromatic (or naphthenic) rings (points 4–7).

The initial data for the study of the relationships characterising the different types of alternation were the retention index values given in various sources,[64–69] and the published[45] and our own[10,70] values of the *m*–*p*-selectivity coefficients.

The retention characteristics used were the differences between the retention indices of neighbouring compounds in the series of sorbates selected

$$\sigma I = I_{N+1} - I_N,$$

where N is the sequence number of the compounds, and for the case of alternation in a series of liquid-crystalline stationary phases the selectivity coefficient σ_H, representing the ratio of the reduced retention times of *m*- and *p*-xylenes.

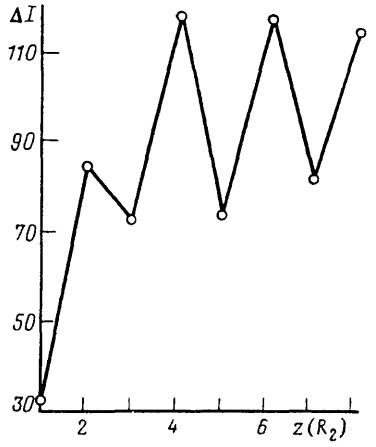

Figure 4. Dependence of ΔI on the number of carbon atoms in the substituent for n-alkyl acetates $CH_3-COO-C_zH_{2z+1}$ (z = 1–9) on a column containing OV-351.[64]

The graphical relationships which we obtained can illustrate the following classification of series of sorbates and stationary liquids in which alternation of the retention values takes place.

1. Series formed by an increase in the length of the aliphatic chain of a molecule as a result of an increase in the number of repeating fragments (structural units); the members of the series are homologues or polymer–homologues $R_1-\varphi-R_2$, where R_1 and R_2 are alkyl groups, and φ a functional group;

a, increase in length on one side of a functional group (or counting from a terminal methyl group); R_1 = const, $R_2 \neq$ const (Figs. 4–6);

b, increase in length in both directions away from a functional group; $R_1 \neq$ const, $R_2 \neq$ const; the side chains may increase in length to equal or different extents (Figs. 2 and 7).

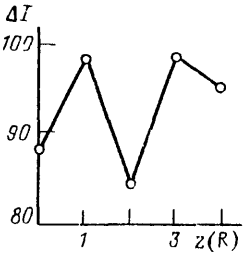

Figure 5. $\Delta I = f(z)$ relationship for n-alkyl derivatives of cyclohex-1-ene  (z = 1–5) on a column containing Apiezon L;[65] temperature of the experiment 100 °C.

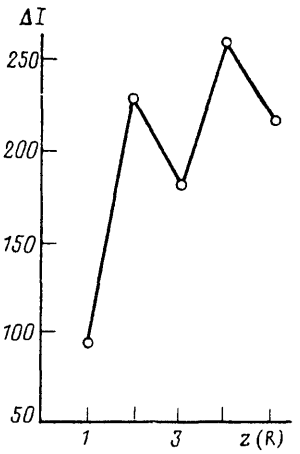

Figure 6. $\Delta I = f(z)$ relationship for di-n-alkylnitrosamines $(n\text{-}C_zH_{2z+1})_2N-NO$ (z = 1–6) on a column containing SE-30;[66] temperature of the experiment 125 °C.

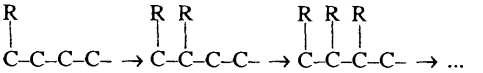
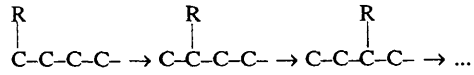
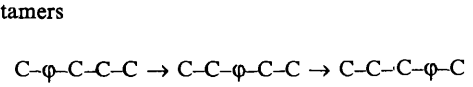
2. Series formed by the successive addition of identical functional groups (or alkyl groups) to the repeating fragments of an aliphatic molecule (or the aliphatic part of a molecule) or to a ring (formation of a polysubstituted chain or poly-substituted ring) (Figs. 8 and 9)



3. Series formed in the movement ("displacement") of functional groups or alkyl groups along a chain or ring (Fig. 10)



Series formed by "displacement" of insertion, that is a sequence of metamers



are included here.

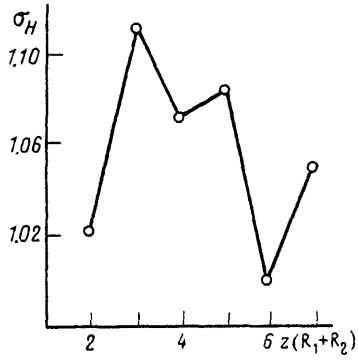


Figure 7. Dependence of the coefficient of $m-p$-selectivity σ_H of dialkoxyazoxybenzenes  on the total number of carbon atoms in both side chains of azoxy-ethers symmetrical and non-symmetrical structures.[10]

4. Obviously, alternation is also observed in isologous series, that is on going from saturated aliphatic hydrocarbons to alkenes and alkynes, and also from alicyclic to aromatic.

Studies have shown that the probability of the appearance of the alternation effect in chromatographic retention relationships is higher, the more polar the sorbates and stationary liquids studied. Thus in the study of retention on non-polar or slightly polar stationary phases (squalane, Apiezon L, SE-30, etc.), alternation is observed for such sorbates as alkyl-substituted cycloalkanes, aldehydes, ketones, and various esters, and is not observed for alkanes, alkenes, alkynes, or alkyl-substituted aromatic hydrocarbons. The range of alternation, defined as the difference between neighbouring values of ΔI in the selected series of sorbates, varies in the ranges 1–20 I units (sorbates—substituted cycloalkanes, aldehydes, ketones, esters of carboxylic acids; stationary phases—Apiezon L, SE-30, DS-550, OV-1), 1–50 I units (sorbates—substituted cycloalkanes, ketones, esters of carboxylic acids, alcohols, alkyl-substituted phospholans, substituted amines; stationary liquids—squalane, Apiezon L, SE-30, DS-550), and 1–100 I units (sorbates—substituted adamantanes, substituted amines; stationary phase—SE-30). On going to polar stationary phases, the effect of alternation becomes stronger and can also be observed for non-polar and weakly polar sorbates. For example, the range of alternation reaches 40 I units for such sorbates as alkylbenzenes, alkylamines, esters of carboxylic and benzoic acids, and alkyl-substituted cycloalkanes on columns containing PEG-4000, OV-351, XF-1150, dibutyl tetrachlorophthalate, and 1,2,3-tris(β-cyanethoxy)propane, 80 I units for alkyl-substituted cycloalkanes, cycloalkenes, and naphthalenes, esters of carboxylic acids, and alkylamines on columns containing PEG-1000, PEG-4000, PEGA, OV-351, and tricresyl phosphate, and 400–200 I units for alkylbenzenes, ketones, and esters of carboxylic acids on columns containing OV-351, XF-1150, tricresyl phosphate, and Reoplex.

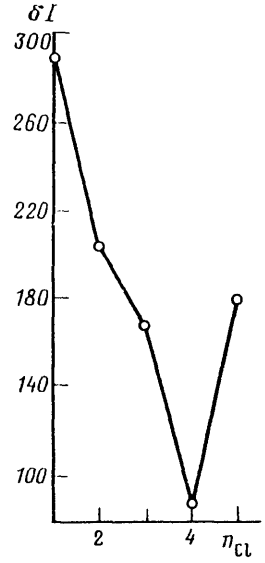

Figure 8. Dependence of δI on the number of chlorine atom for a series of chloro-derivatives of benzene: chlorobenzene, 1,2-dichlorobenzene, 1,2,3-trichlorobenzene, 1,2,3,4-tetrachlorobenzene, pentachlorobenzene, and hexachlorobenzene on a column containing Carbowax 20M.[67]

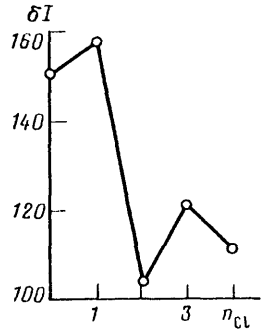

Figure 9. Dependence of δI on the number of chlorine atoms for a series of methyl esters of chloropropionic acids: $C_2H_5-COO-CH_3$, $CH_3-CHCl-COO-CH_3$, $CH_2Cl-CHCl-COO-CH_3$, $CH_2Cl-CCl_2-COO-CH_3$, $CHCl_2-CCl_2-COO-CH_3$, and $CCl_3-CCl_2-COO-CH_3$ on a column containing OV-101;[68] temperature of the experiment 80 °C.

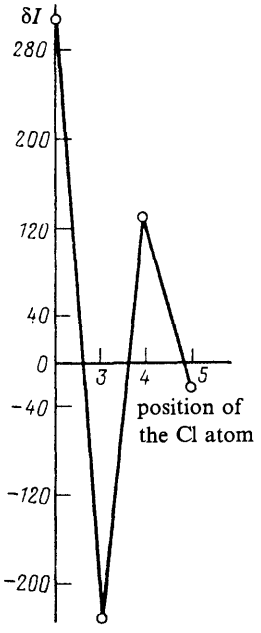

Figure 10. Dependence of δI on the position of the chlorine atom for a series of chlorinated salicylaldehydes on a column containing OV-351;[69] temperature of the experiment 140 °C.

It will be possible to determine more precise dependences of the retention values on the number of carbon atoms in the molecule and other physicochemical characteristics for identification, when more selective stationary phases appear. For a deeper understanding of the reasons for the production of the alternation effect it is necessary to study its relation to the structure of the molecules of the sorbates and stationary phases and the intermolecular interactions in the chromatographic column.

***

Thus the effect of alternation of chromatographic characteristics is observed both in homologous series of sorbates and stationary phases (the even–odd effect) and in other series (for example on the "displacement" of a functional group along an aliphatic chain). The scale of the alternation for a sufficiently rigid molecular structure may reach 10–13 retention index units. The effect is detected in distribution and adsorption chromatography. Further studies may reveal this effect in other forms of chromatography (supercritical fluid, thin-layer, etc.). Different forms of alternation will possibly be detected.

Characteristic features of the chemical kinetics of the formation of interpenetrating polymer networks

Yu S Lipatov, T T Alekseeva
Institute of the Chemistry of Macromolecular Compounds, Academy of Sciences of the Ukraine, Kiev

ABSTRACT. Data on the kinetics of the formation reactions of interpenetrating polymer networks (IPN) are surveyed. They are formed in the course of the simultaneous cross-linking in the reaction system of two three-dimensional networks which do not react chemically. It was established that the kinetics of the formation of the network components forming part of the IPN differ from those for the "pure" networks. The mutual influence of the networks formed on the kinetics of their formation depends on the composition of the IPN, the ratio of the rates of the component reactions, and the order in which the reactions are carried out.

A characteristic feature of the formation of the IPN is that, even in the early stages of the reactions of the system, a thermodynamic incompatibility of the molecular fragments of the component networks arises as a rule.

I. Introduction

It has now been established that the properties of polymeric materials based on interpenetrating polymer networks (IPN) depend on the thermodynamic compatibility of the constituent networks and the kinetics of the chemical reactions which establish the microphase separation at a particular level.

Analysis of the literature data shows that an increasing number of studies are now being published on this problem. Whereas the structure and properties of the IPN were previously studied mainly in the laboratories of Frisch, Sperling, and Lipatov, which led to the discovery of their principal structural features and a set of properties determined by the microheterogeneity of the IPN, nowadays Hourston, Meyer, Widmaier, and Hsu are engaged in the problem of the creation and study of the IPN. Investigations by Japanese and Chinese investigators have been published. Many polymer compositions for the production of IPN have been tested. For example, Kim et al.[1] investigated modern IPN based on polyurethane–polystyrene or polyacrylates, Hourston and co-workers[2] studied by the ^{13}C NMR method the structure and properties of IPN based on polyurethane-polyphenylsiloxane, Djomo, Morin, and co-workers[3] investigated the mechanical properties of IPN based on polyurethane–poly(methyl methacrylate), Bi Xiping, Li Binyao and co-workers[4,5] studied those based on poly(vinyl acetate)–poly(methyl methacrylate), and Burford et al.[6] investigated by mechanical dynamic spectroscopy IPN based on a cross-linked butadiene or butadienestyrene elastomer and polystyrene. Visscher et al.[7] studied by differential scanning calorimetry and IR spectroscopy new class of IPN based on polyorganophosphazenes and poly(methyl methacrylate), which are biocompatible and resistant to oil. The majority of studies were devoted to the synthesis and investigation of the mechanical and viscoelastic properties[8–11] and the morphology[12–14] of the materials obtained. However, in order to be able to employ the IPN in different technologies, it is essential to understand in detail the kinetics of the hardening reaction and the microphase separation processes in polymeric two-phase systems and the influence of these parameters on the viscoelastic and mechanical properties of such systems.[15,16]

A characteristic feature of interpenetrating networks is that the phase separation processes occur as a result of the formation of heterogeneous networks from an initially single-phase system, so that the degree of microphase separation is determined by the kinetics of the formation of the components. IPN can be obtained in two ways: with simultaneous and consecutive formation of polymer networks. The initial system is usually single-phase—in the simultaneous formation process it is a solution of components forming two networks, while in the consecutive formation process it consists of a swollen gel. Since microphase separation begins simultaneously with the chemical reaction at a certain degree of conversion, the properties of the IPN are determined by the differences between the rates of formation of individual networks, which can be varied within wide limits by altering the hardening temperature for each component, the catalyst concentration, the concentration of the cross-linking agent, the hardening sequence using thermo- or photohardening, and the component ratio in the IPN formed. It is also essential to take into account the fact that in the case of both consecutively and simultaneously formed IPN the formation reactions of one of the networks take place in the matrix of the other.

In the simultaneous formation of IPN, the kinetics of the formation reactions of the constituent networks are different and the reactions proceed via different mechanisms (polyaddition–polymerisation), one of the networks being formed usually at an earlier stage and serving as the matrix for the formation of the other. The network formed first (the matrix network) alters significantly the

conditions in the formation reaction of the second network, becoming segregated as a microphase as a consequence of the resulting thermodynamic incompatibility of the chains of the constituent networks. This affects the diffusion parameters of the formation reaction of the second network.

Although the factors listed above provide grounds for the hypothesis that there are differences between kinetics of the formation of the interpenetrating networks and the individual polymer networks, sufficient attention has not yet been devoted to the study of this problem. Vigorous investigation of the kinetics of the reactions, occurring simultaneously and consecutively via different mechanisms and influencing one another, has begun only in recent years.

II. The influence of the components of one network on the kinetics of the formation of the second network during the consecutive generation of interpenetrating networks

Studies on the formation of IPN began comparatively recently. This is associated primarily with the fact that, on passing from the study of individual polymer networks to IPN, the kinetics become more complex, apparently as a consequence of the rapid increase in the viscosity of the reaction medium during both polycondensation and radical polymerisation and the mutual influence of the two processes occurring in the IPN produced.

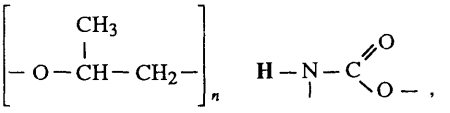
The first studies on kinetics of the formation of IPN were carried out by Djomo et al.[3] in relation to two network polyurethane–poly(methyl methacrylate) polymers. The polyurethane (PU) network was formed from a flexible polyoxypropylene glycol (POPG) block with a molecular weight of 2000 and an aromatic triisocyanate adduct. The catalyst was tin octanoate (OcSn). The poly(methyl methacrylate) (PMMA) network was obtained by copolymerising methyl methacrylate (MMA) and tri(hydroxymethyl)-propane trimethyacrylate using a radical polymerisation initiator 2,2-azobisisobutyronitrile (AIBN). The PU network was formed first at room temperature and this was then followed by the formation of the PMMA network at 50 °C. The influence of all the components of the PMMA network on gel formation in the PU network was studied in succession and a similar study was made of the influence of the components of the PU network on gel formation in the PMMA network. The influence of the OcSn catalyst on the rate of formation of the PMMA network was investigated. It was observed that the components of the PMMA network do not affect the gel formation in the PU network, whereas the components of the PU network diminish the gel formation time from 180 to 30 min. This is induced by the increase in viscosity of the reaction medium, which increases the rate of formation of the PMMA network (V_p) in the presence of the components of the PU network as a result of the decrease in the termination rate constant (K_t) in accordance with the equation[17]

$$V_p = \frac{K_p[M]\sqrt{V_{in}}}{\sqrt{K_t}}, \qquad (1)$$

where [M] is the monomer concentration, K_p the chain propagation rate constant, V_p the rate of chain propagation, V_{in} the rate of initiation, and K_t the termination rate constant.

The influence of the OcSn catalyst on the rate of formation of the PMMA network was studied in greater detail by Meyer.[18] Data for the electrical conductivity of the system led the author to the conclusion that the catalyst does not affect the rate of decomposition of the initiator but does accelerate the polymerisation and copolymerisation of the methacrylates as a result of the polarisation of the monomer double bonds and facilitates the addition of radicals to the latter, inducing thereby an acceleration of the formation reaction of PMMA in the presence of the OcSn catalyst.

The possibility of the formation of a chemical bond between the PU and PMMA networks has also been studied. The presence in the reaction medium of two components of the PU network–polyoxypropylene glycol and the triisocyanate adduct, i.e.



containing a mobile hydrogen atom which can be abstracted by a radical, suggests a possible way in which the reaction may be transmitted, which can be represented schematically as follows:

Stage I:

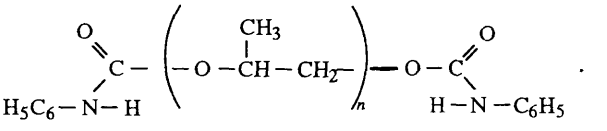
$$Ac^{\cdot} + T \longrightarrow Ac + T^{\cdot}.$$

Stage II:

a) $T^{\cdot} + Ac \rightarrow T \sim Ac^{\cdot}$;

b) $T^{\cdot} + Ac^{\cdot} \rightarrow T \sim Ac$,

where Ac is the MMA monomer, T the component containing the oxypropylene or urethane group, and $Ac^{\cdot}$ and $T^{\cdot}$ are the corresponding radicals. If reactions (IIa) and (IIb) occur, then a chemical bond is formed between PU and PMMA. To confirm this hypothesis, a mixture of methacrylate monomers with different amounts of the α,ω-phenylurethane–POPG adduct was polymerised under the experimental conditions described above:



The products were extracted with a solvent and were analysed by IR spectroscopy. It was observed that the PU component is extracted to an extent greater than 90% (of the amount introduced). For the system containing 20% PU and 80% PMMA, 1.8% PU remained after extraction in the poly(methyl methacrylate) network. This is a low value, so that even if a chemical graft does exist, it is so small that its influence on the macroscopic properties of the IPN is insignificant.

The above study[18] constituted the first step in the investigation of the complex IPN systems. The author showed that it is essential to take into account the influence of each component of one network on the formation of the second network, and conversely, as well as the possibility of side reactions, which may disturb or prevent the formation of one of the networks.

The influence of the concentration of the cross-linking agent and the initiator for the polyacrylate network, of the NCO/OH ratio, and of the component ratio PU/PMMA on the transparency and the viscoelastic properties of the resulting IPN and semi-IPN was demonstrated in subsequent studies.[19–22] Fourier transform IR

spectroscopy[23] was used to investigate the kinetics of the formation of IPN and semi-IPN based on PU and PMMA, obtained as described by Meyer.[3] The method makes it possible to study the kinetics of the simultaneous formation of IPN (the NCO group absorbs in the region of 2275.5 cm^{-1}, while the C=C bond absorbs at 1639 cm^{-1}). The authors[23] studied the influence of the various factors (temperature, concentration of the cross-linking agent, concentration of PU in solution) on the formation of individual PU and PMMA networks forming part of the composition of the IPN. In the study of the PU network in ethyl acetate (EA) with the concentration ratio PU/EA = 25/75 wt.%, the rate of formation of PU increased with increase in the OcSn catalyst concentration from 0.38 to 1.0 wt.% but a further increase in catalyst concentration to 2 wt.% did not affect the rate of formation of PU. It has also been shown that an increase in the PU content in ethyl acetate for a constant catalyst content increases the rate of formation of the PU network and that the temperature at which the PU network is formed has a similar effect. In the study of the formation of PMMA it was observed that the cross-linking agent accelerates the formation of the network structure of the PMMA compared with the linear polymer and that under these conditions the onset of autoacceleration shifts towards shorter times, whilst the presence of the OcSn catalyst intensifies the copolymerisation effect.

The study of the simultaneously formed IPN having the composition PU/PMMA = 34/66 (wt.%) by Fourier transform (FTIR) IR spectroscopy showed that the nature of the PU and PMMA kinetic curves does not differ from the initial curves and it was concluded on this basis that there is no chemical interaction between the two IPN networks.

Subsequently the IPN network based on the same PU–PMMA system was investigated by FTIR spectroscopy[24] under conditions of stepwise polymerisation. Polyurethane was polymerised at room temperature, while PMMA was polymerised at 60 °C. The influence of the catalyst concentration and of the PU/PMMA ratio on the rate constants for the urethane formation reaction in the IPN at room temperature was investigated. In the study of the kinetics of the formation of the PU network in the IPN for the component ratio PU/PMMA = 34/66 (wt.%) with the reactions occurring simultaneously, it was observed that the rate of urethane formation increases by a factor of 8 when the temperature is raised to 60 °C. The order of the reaction was found over a wide range of NCO conversions. The authors believe that the equation

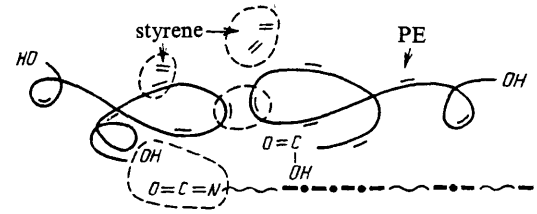
$$d[NCO]/dt = K[OcSn][NCO]^{1.5},$$

describes satisfactorily the formation of the PU network in the IPN under the conditions of both stepwise and simultaneous formation of both networks.

The search for new ways of synthesising IPN led Derrough et al.[25] to a simple but novel solution of the problem of synthesising IPN via a radical mechanism *in situ*. The butyl acrylate or methyl methacrylate (MMA) and diallyl carbonate–bisphenol A (DACBA) monomers were used to repair the IPN. The novelty of the method of synthesis consists in the choice of compounds which initiate the reaction only in a specific temperature range. AIBN, which operates at temperatures above 50 °C, was chosen for butyl acrylate or methyl methacrylate, while t-butylperoxy-3,5,5-trimethylhexanoate (TBPTMH), which initiates the reaction above 95 °C, was chosen for bisphenol A. The polymerisation mixture of MMA and DACBA in proportions of 50/50 (wt.%), containing the AIBN and TBPTMH initiators, was investigated by FTIR spectroscopy. The degree of conversion in the reaction was calculated from the change in the absorption band in the region of 1639 cm^{-1} characteristic of the C=C bond in MMA, with a shoulder at 1649 cm^{-1}, which corresponds to the allyl monomer. At 50 °C, the intensity of the 1639 cm^{-1} peak diminishes and reaches the base line, which corresponds to more than 95% conversion of the C=C bond in methyl methacrylate over a period of 2 h. With increase in temperature, the shoulder is unexpectedly transformed into an isolated peak, the intensity of which does not change so long as the temperature of the reaction medium does not reach 95 °C. After the attainment of this temperature, the peak intensity diminishes, indicating the polymerisation of the second component. After the introduction of the cross-linking agent, it is also possible to obtain the full IPN.

The influence of the methacrylate radicals on DACBA in the polymerisation of methyl methacrylate at 50 °C was investigated. UV analysis did not reveal the presence of the aromatic DACBA rings in the PMMA polymer chain. The nature and concentration of the radicals produced during the formation of the IPN were also investigated by the EPR method.[25] The results of this investigation agreed with the IR spectroscopic data. Consequently the authors clearly showed that the half-IPN or IPN can be obtained via a single mechanism (a radical mechanism) using different initiators. It would be of interest to have information about the phase state of the given IPN.

Hsu and Lee[26] investigated experimentally and theoretically the kinetics of the formation of IPN from polyurethane and an unsaturated polyester (PE). The PU component was obtained from a diisocyanate, a polyol, and a diol containing rigid and flexible segments; the PE component was obtained from an unsaturated polyester with styrene as the cross-linking agent involving the C=C bond in the polyester. The formation of a graft between the two PU and PE phases via the reaction of the NCO groups with the terminal OH or COOH groups of the PE molecules is possible. Such systems can be classified as graft IPN, which are illustrated schematically below.



The studies were carried out on an DSK-2S differential scanning calorimeter under isothermal and adiabatic conditions. The kinetics were studied for IPN obtained as a result of the RIM process (reaction injection moudling) and the usual casting. The kinetic measurements on the formation of the IPN by differential scanning calorimetry under isothermal conditions demonstrated that, as a consequence of different reaction mechanisms (polyaddition and radical polymerisation), the formation of urethane always begins after mixing the components and takes place under conditions where the PE phase does not yet react or only partly reacts, the PU being formed in solution in the components of the PE network, while the PE phase is frequently formed under conditions where the PU has been already fully or partly formed, i.e. the radical polymerisation of the polyester takes place fully or partly in the polymerised PU phase. However, the question of phase separation was not considered in the above study.

Fig. 1 shows that, with increase in the PU content in the IPN from 25/75 to 75/25 (wt.%), the peak for the PE reaction shifts to the right, which characterises the increase in the induction period due to the formation of the PE network, while the broadening of the peak indicates an increase in reaction time. This means that the diffusion of the PE reagents becomes hindered as the content of the PU network increases.

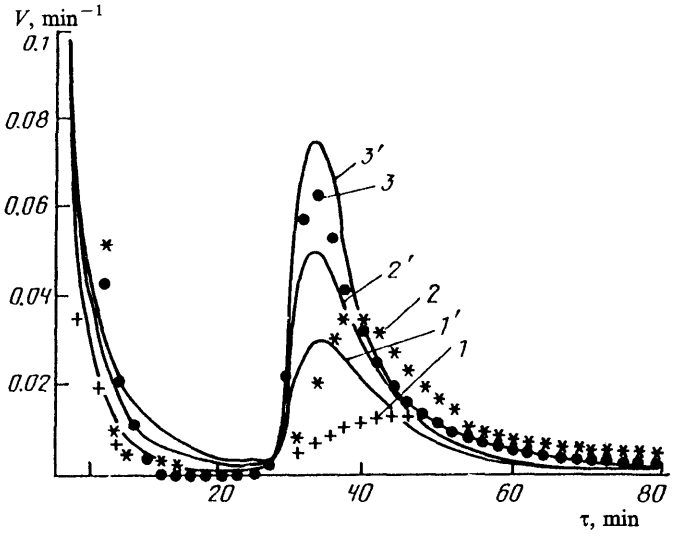


Figure 1. Time (τ) variation of the rate of reaction (V) for different ratios PU/PE in the IPN at T = 80 °C obtained experimentally (curves *1*–*3*) and calculated theoretically (curves *1'*–*3'*); PU/PE (wt.%): *1*, 75/25; *2*, 50/50; *3*, 25/75.[26]

The study of the formation of IPN under adiabatic conditions, modelling the RIM process, showed that the reaction takes place consecutively and the time variation of the degree of conversion of the components has the S shape characteristic of radical polymerisation for the component ratio PU/PE = 50/50 (wt.%). With increase in the fraction of the PU component in the IPN to 75/25 wt.%, the form of the curve changes, since the urethane formation reaction predominates in the overall process.

Using models based on the additive contributions of the initial components of the IPN, the authors[26] carried out a theoretical calculation for the model reaction under isothermal and adiabatic conditions involving the IPN investigated. In the calculation for the model reaction, use was made of the Arrhenius equation and a number of assumptions which disregarded the mutual influence and interaction of the two polymer network structures formed in the system, were made.

The kinetic parameters of the PU reaction were calculated from the increase in the temperature of the reaction system under adiabatic conditions using the equation

$$\ln\frac{dT_u}{dt} = \ln\left[\frac{\Delta H_u A_u}{P_u C_{pu}}\right] + \frac{E_u}{RT_u} + n\ln\left[\frac{T_{ad} - T_u}{T_{ad} - T_{uo}}\right] ,$$

The variables dT_u/dt, $1/T_u$, and $[(T_{ad} - T_u)/\Delta T_{ad}]$ can be calculated from the time variation of the temperature in the adiabatic polymerisation. Using the multilinear regression method, the order of the reaction n, the activation energy E_u, and the pre-exponential factor of the rate constant A_u were calculated.

The kinetic parameters of the radical polymerisation of the polyester were calculated by Lee's method[27] from the equation

$$\left(2fI_0A_p\right)\exp\left(-\frac{E_p}{RT}\right) = \frac{K_d\exp[-K_d(t_m - t_z)]}{1 - \exp[-K_d(t_m - t_z)]} ,$$

where f is the effectiveness of the initiator, I the concentration, K_d the decomposition rate constant, and t the induction period.

The authors concluded that the theoretical calculations for the reactions of pure PU and PE agree well with experimental data obtained by differential scanning calorimetry under isothermal conditions. Slight discrepancies between the theoretical calculation and experiment are observed for the IPN having the composition PU/PE = 25/75 (wt.%), while an increase in the content of the PU network in the system to 50/50 (wt.%) increases the discrepancies, which become appreciable for the ratio PU/PE = 75/25 (wt.%). The authors attribute this to the fact that in the theoretical calculations no account was taken of the interaction between the components. Discrepancies with experiment are observed particularly for the PE polymerisation, which is probably associated with the effect of diffusion in the region of high conversions. The mathematical description of the model reaction for the IRM process under adiabatic conditions agrees well with experimental results, which can be explained by the high rate of the reaction under adiabatic conditions.

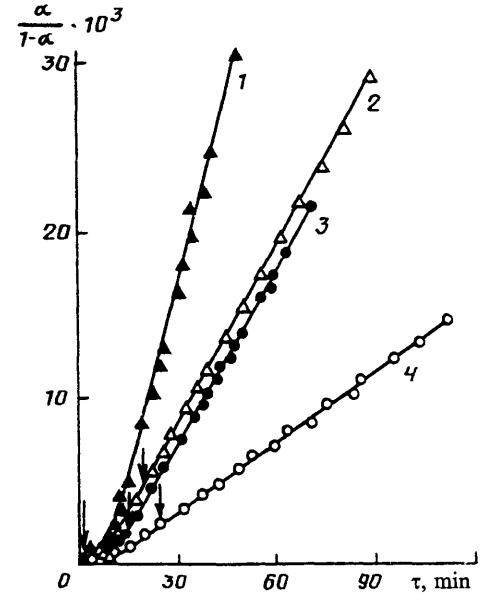

Figure 2. Transformed kinetic curves for the copolymerisation of styrene with divinylbenzene in a semi-IPN; the arrows indicate the onset of phase separation; PBMA content at T = 90 °C (wt.%): *1*, 40; *2*, 15; PBMA content at T = 80 °c (wt.%): *3*, 30; *4*, 15.[28]

III. Kinetics of the formation of interpenetrating polymer networks taking into account the interrelation between the processes and the influence on the microphase separation

The mutual influence of the kinetics of the formation of the polystyrene–divinylbenzene copolymer in the presence of poy(butyl methacrylate) (PBMA) and the microphase separation in the resulting IPN was investigated for the first time[28] in relation to a semi-IPN. Fig. 2 illustrates the linear forms of the kinetic curves for the copolymerisation of styrene with divinylbenzene in the semi-IPN for different proportions of the PBMA. The authors explain the absence of a break in the kinetic curves at the phase separation point by the fact that the microphase separation process in the semi-IPN produced proceeds via a spinodal mechanism, whereupon no visible volume effects are observed[29] and under such conditions the microphase separation (MPS) does not affect the rate of reaction. It has been established that, with increase in the content of PBMA in the mixture, the time of the onset of the MPS diminishes significantly, while an increase in temperature by 30 K likewise shortens the time of the onset of the MPS, the degree of conversion of the copolymer increasing under these conditions. It has also been shown that phase separation begins for low conversions of styrene in the range 0.1–8.0%. The authors conclude that there is a close relationship between the reaction kinetics, the degree of conversion, and the MPS in the system, the kinetics of the formation of the IPN exerting a significant influence on MPS processes, determining the onset of MPS.

Table 1. Physicochemical characteristics of the polyurethane network in the semi-IPN with the composition PBMA/PU = 15/100 (%).[30]

No. of specimen	Composition	T_h, °C	c_{ct}, wt.%	$10^4 K_r$, kg mol^{-1} s^{-1}	τ_{MPS}, min	α_{MPS}
1	PU	60	0.005	3.46	—	—
2	PU	60	0.010	7.63	—	—
3	PU	40	0.010	1.90	—	—
4	semi-IPN	60	0.005	1.30	100	0.13
5	semi-IPN	60	0.010	2.62	43	0.23
6	semi-IPN	60	0.050	8.10	28	0.39
7	semi-IPN	80	0.010	7.05	30	0.56
8	semi-IPN	40	0.010	0.73	290	0.48

Notation: T_h is the hardening temperature, c_{ct} the catalyst concentration, K_r the reaction rate constant, τ_{MPS} the time of the onset of the MPS, and α_{MPS} the degree of conversion at the instant of the onset of the MPS.

A study[30] of the formation of polyurethane in the presence of 15% PBMA was devoted to the establishment of the relationship between the kinetics of the hardening of the half-IPN and the MPS during the formation of the polymeric two-phase system. Analysis of the results, presented in Table 1, shows that the onset of the MPS depends directly on the rate constant of the urethane formation reaction. Variation of the rate of reaction achieved by varying the catalyst concentration alters the degree of conversion at which phase separation begins from 23 to 39%, while variation of the rate of reaction effected by varying the temperature (40–80 °C) leads to the considerable scatter in the degrees of conversion (from 23 to 56%). The transformed kinetic curves presented in Fig. 3 are characterised by the presence of two sections, which indicates a change in the rate of reaction in the system after the attainment of a definite degree of conversion. Comparison of experiments 1 and 4, 2 and 5, 3 and 8 reveals a decrease in the rate of urethane formation by a factor of 3 in the presence of PBMA, but the nature of the transformed kinetic curves remained qualitatively the same as before. The degree of conversion at which MPS begins does not agree with the degrees of conversion at which a break is observed in the transformed curves (except for experiment 8). The results do not indicate a change in the reaction kinetics when MPS begins or in the vicinity of the degree of conversion corresponding to this process, which indicates the occurrence of MPS via the spinodal mechanism in the half-IPN formed.[31] Consequently the results agree with those of Lipatov and Grigor'eva,[28] confirming unambiguously that the MPS depends significantly on the reaction kinetics, regardless of the type of reaction (radical polymerisation or polyaddition) and that a change in the kinetics of the formation of the two-phase system influences its viscoelastic properties.

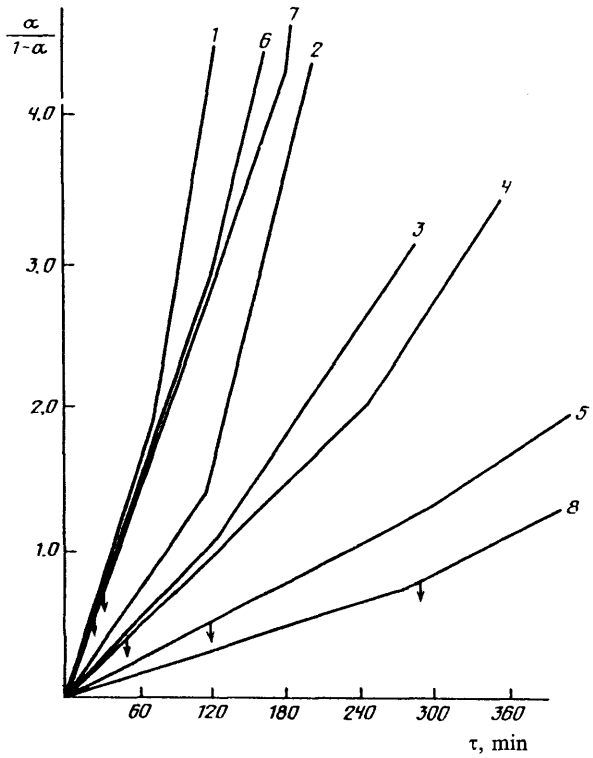

Figure 3. Transformed kinetic curves for the polyurethane network (curves *1–3*) in the semi-IPN based on polyurethane and PBMA (curves *4–8*); the significance of the symbols is indicated in Table 1.[30]

The kinetics of the formation of IPN based on polyurethane and polyurethane acrylate (in the IPN) were investigated for the first time by the method of distorted total internal reflection (DTIR) in the IR region with simultaneous hardening for different PU/OUA ratios (OUA = oligourethane acrylate). The transformed kinetic curves for the formation of polyurethane were linear up to a degree of conversion of 50%, which shows that the urethane formation reaction obeys a second-order equation. The initial slope of the curves (Fig. 4) depends significantly on the amount of oligourethane acrylate in the reaction mixture. Differentiation of these curves yielded the dependence of $|\partial\alpha/\partial\tau|$ on the composition, characterising the influence of the component ratio in the reaction mixture on the rate of the urethane formation reaction (Fig. 5). Fig. 5 shows that small amounts of added OUA play the role of an inhibitor of this reaction. For comparable amounts of the components in the OUA mixture, the formation of polyurethane is initially accelerated sharply, but, after the elapse of 45–60 min, the rate of formation of PU in the presence of PUA falls to values lower than in the individual PU.

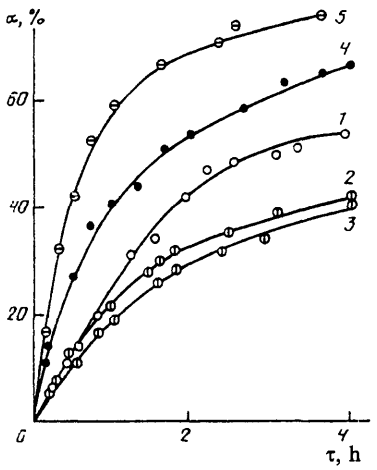

Figure 4. Kinetic curves for the hardening of pure polyurethane (curve *1*) and polyurethane in the IPN system; PUA (wt.%): *2*, 1; *3*, 5; *4*, 50; *5*, 70.[32]

Spectroscopic studies showed that the observed effect is not associated with the chemical interaction between unlike networks, since the spectra of the hardened IPN of different composition can be obtained by superimposing the spectra of the individual networks. On the other hand, some deviations from additivity, observed in the region of the stretching vibrations of the C=O and NH groups, indicate a redistribution of the network of physical bonds as the composition of the IPN is altered.

In IPN with comparable amounts of the components, the MPS process begins usually before the onset of gel formation in the individual networks, is fairly rapid, and is characterised by a high extent of completion. For both low and high OUA contents in the mixture, gel formation begins during the first 5–6 min of the reaction. The rapidly growing PUA network, segregated in the course of the MPS, displaces the reacting components of the first network (PU), intensifying their self-association and increasing the concentration of the reactants in the microregions, which accelerates the formation of polyurethane. Furthermore, the PUA segregated as a separate phase can play the role of a filler, which exerts an orienting influence on the components of the first network adsorbed on its surface, which can also accelerate its formation. The retardation of the polyaddition reaction at later stages of the formation of the IPN having this composition can apparently be explained by the fact that, as the reacting components are exhausted in the PU microregions, the process is controlled by the rate of diffusion of the components through the interface.

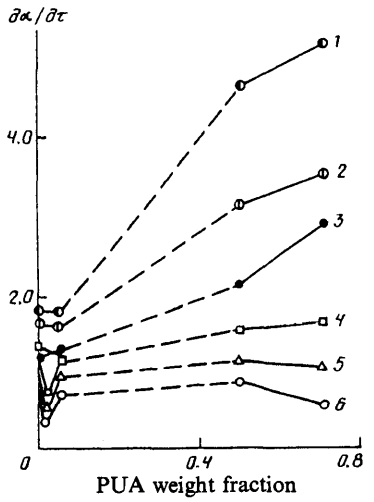

Figure 5. Concentration variation for the IPN; hardening time (min): *1*, 10; *2*, 20; *3*, 30; *4*, 45; *5*, 60; *6*, 90.[32]

For low contents of one of the components of the IPN, the MPS process is much slower. During the period investigated, the OUA has insufficient time to become segregated as a separate phase and the weakening of the bonds between the urethane groups and the appearance of free C=O groups (shoulder at 1740 cm^{-1}) indicates a significant redistribution of the intermolecular interactions after the introduction of small amounts of OUA.

These investigations showed that, in the formation of the IPN, the same component (OUA) can accelerate or retard the formation of the PU network depending on its fraction in the reaction mixture. We believe that this phenomenon is based on the dependence of the rate and the degree of completion of the MPS process on the composition of the reaction mixture. However, it has been shown[28,30] that the degree of MPS is a function of the rate of reaction. The onset of the MPS has been determined[30] during the reaction by the method of the appearance of turbidity points on an FPS-3 photocalorimeter. The experimental data (Table 1) show that, with increase in the rate constant for the formation of the PU network, the time of the onset of the MPS diminishes synchronously, which confirms unambiguously the dependence of the MPS on the reaction kinetics, whereas no breaks, which would indicate a change

in the rate of urethane formation at the instant of the onset of the MPS, are observed on the transformed kinetic curves for the formation of polyurethane at the point corresponding to the onset of the MPS (indicated by an arrow in Fig. 3).

The mutual influence of the kinetics of the formation of two unlike interpenetrating networks has been investigated in recent studies.[33–36]

Interpenetrating networks based on network polyurethane and an unsaturated polyester with styrene in molar proportions of 1 : 2 have been studied by FTIR spectroscopy[33] for simultaneous and consecutive reactions at 60 °C. Styrene served as an agent cross-linking polyester chains via the C=C bonds. Fig. 6 presents typical curves for the time variation of the degree of conversion for two phases (PU and PE) in the case of simultaneously produced IPN with a low-temperature radical polymerisation initiator for the component ratios PU/PE = 50/50 and 30/70 (wt.%). Similar kinetic curves are presented in Fig. 7 for the stepwise polymerisation of IPN with a high-temperature initiator.

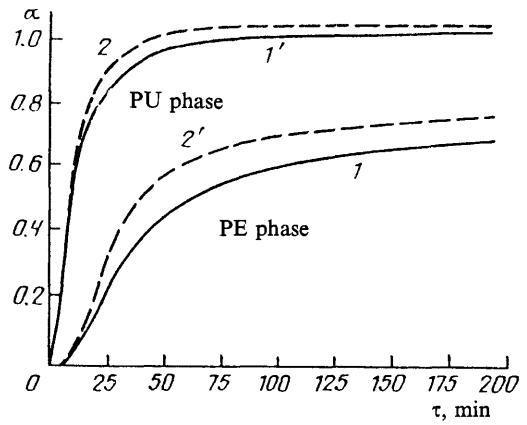

Figure 6. Time variation of the degree of conversion (α) for different PU/PE in the case of simultaneously formed IPN at T = 60 °C: *1*, 50/50; *2*, 30/70 (wt.%) (for polyurethane); *1′*, 50/50; *2′* 30/70 (wt.%) (for polyester).[33]

The use of the latter at 60 °C decreases the rate of reaction of the polyester component with the consecutive formation of IPN. It is of interest to note that, for both consecutively and simultaneously formed IPN, both reactions are accelerated with increase in the content of the polyester component 50 to 70 wt.%. The authors attribute this effect on the reaction of the polyester phase to the increased concentration of double bonds and, for the reaction of the polyurethane phase, to the fact that the rate of consumption of the NCO groups increases with the increase in the amount of the polyester component, since the NCO groups react with the OH groups of the polyol in the polyurethane phase and with the terminal OH groups of the unsaturated polyester. Consequently the degree of conversion in the polyurethane phase increases in proportion to the concentration of the polyester in the IPN, which indicates chemical interaction between the unlike polyurethane and polyester network structures and the given system can be classified as a graft IPN.

The polymerisation of the polyurethane in the IPN takes place in solution in the initial components of the polyester which have not yet reacted or have only partly reacted. On the other hand, the polymerisation of the polyester frequently takes place under conditions where the polyurethane network has been partly or fully formed, i.e. the polyester network is formed in the presence of the hardened second network, which is believed[33] to be in the solid state. Thus, when the IPN is created, there exists a "solvent effect" in the formation of the polyurethane network and a "solid effect" in the formation of the polyester network, which can influence the mechanism of the reactions occurring.

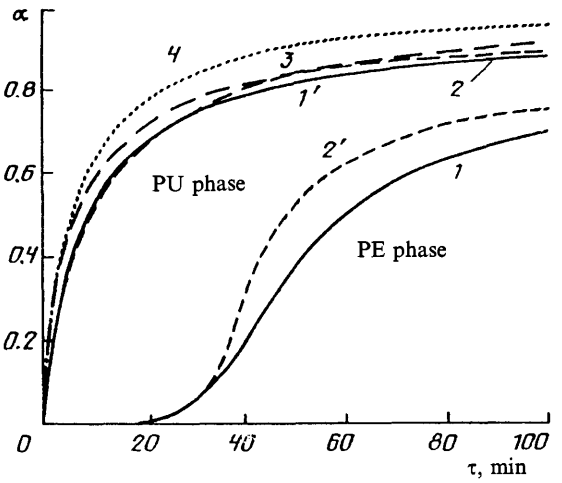

Figure 7. Time variation of the degree of conversion for different PU/PE in the case of consecutively formed IPN at T = 60 °C: *1–4*, for polyurethane; (*1′*, and *2′*) for polyester; *1*, PU/PE = 50/50; *2*, PU/PE = 30/70; *3*, PU/PE = 30/70; *4*, PU/PE = 50/50 (wt.%) [NCO/OH stoichiometric proportions (curves *1* and *2*)].[33]

Within the framework of formal kinetics, the authors obtained an equation for the overall rate of reaction in three possible versions: styrene–styrene, styrene–PE, PE–PE. The rate of reaction of the styrene monomer, the rate of conversion of the C=C bonds in the unsaturated polyester, and the rate of conversion of all the double bonds can be expressed thus:

$$-dc_S/d\tau = k_{SS}\cdot c_S\cdot c_S + k_{ES}c_E\cdot c_S,$$

$$-dc_E/d\tau = k_{SE}c_S\cdot c_E + k_{EE}\cdot c_E\cdot c_E,$$

$$-dc/d\tau = -(dc_S/d\tau + dc_E/d\tau) = k_{SS}\cdot c_S\cdot c_S + k_{ES}c_E\cdot c_S + k_{SE}c_S\cdot c_E + k_{EE}\cdot c_E c_{E'},$$

where S represents styrene, E represents the C=C bonds in the unsaturated polyester, S˙ and E˙ are the radicals in styrene and the polyester, c is the concentration, and k the rate constant. The rates of reaction can be determined experimentally from IR spectra.

Since the structure of the network in the polyester phase depends on the copolymerisation mechanism, information about the dependence of the degree of conversion of the polyester in the polyester phase is very important. Fig. 8 illustrates such dependences. If it is assumed that the contribution of the rate of the PE–PE

reactions to the overall rate is insignificant, then the rate of reaction of the styrene monomer can be expressed as follows relative to the rate of reaction of the C=C bonds in the polyester:

$$\frac{dc_S}{dc_E} = 1 + r_S \frac{c_S}{c_E}, \quad r_S = k_{SS}/k_{SE}.$$

If the copolymerisation takes place under azeotropic conditions, i.e.

$$c_E/c_S = 1 - r_S ,$$

then

$$\frac{dc_S}{dc_E} = \frac{c_S}{c_E} , \qquad \text{(curve 1)}$$

while for the alternative copolymerisation we have

$$\frac{dc_S}{dc_E} = 1 . \qquad \text{(curve 2)}$$

Experimental data for IPN show (Fig. 8, curve *3*) that the PE–PE reaction in the polyurethane network is more favourable at low conversions than the styrene–PE and styrene–styrene reactions. This is probably associated with the fact that the polyurethane phase can intensify the intermolecular reactions of the polyester molecules. On the other hand, at high conversions the styrene–styrene reaction is more favourable than the reaction involving the C=C bonds in the polyester.

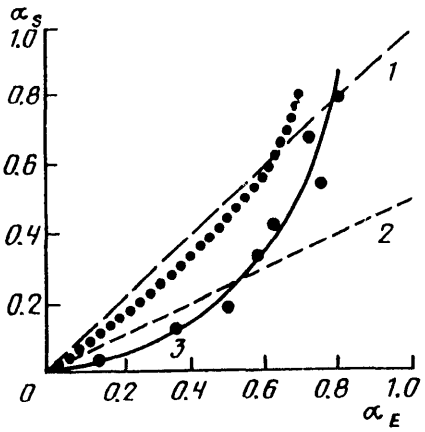

Figure 8. Dependence of the degree of conversion of styrene on the degree of conversion of C–C bonds for the PU–PE reaction in the IPN at T = 60 °C calculated theoretically for copolymerisation under azeotropic conditions (curve *1*) and for alternating copolymerisation (curve *2*) and determined experimentally for the 30/70 (wt.%) composition.[33]

The authors[33] concluded that the kinetics of the urethane formation reaction in bulk differ from the kinetics of the reaction in solution. However, if the IPN is created, the "solvent effect" operates in the formation of the polyurethane network and the "solid effect" operates in the formation of the polyester network, the two effects altering the mechanisms of both reactions. However, as regards the formation of the polyurethane in the presence of the polyester component, the authors do not take into account the "solvent effect" in their explanation of the increase in the rate of urethane formation with increase in the content of the polyester component in the IPN.

Fully grafted, half-grafted, and non-grafted IPN have been obtained[34] for three unsaturated polyesters and a polyurethane. The kinetics of the formation of the IPN as well as the rheological and morphological properties of the IPN obtained were investigated by differential scanning calorimetry, electron microscopy, and dynamic mechanical spectroscopy. The polyurethane component was obtained from diphenylmethane diisocyanate (MDI) and polycaprolactonetriol. The polyester component was obtained from the unsaturated polyester in the presence of styrene. The unsaturated polyester was synthesised from maleic anhydride and propylene glycol. The industrial non-block polyester contained terminal OH and COOH groups, the synthesised polyester contained only COOH groups, and the third type of unsaturated polyester was blocked using phenyl isocyanate.

Consequently fully grafted IPN were obtained on the basis of the industrial polyester, since there is a possibility of the interaction of the terminal OH and COOH groups with the NCO groups of the diisocyanate. Half-grafted IPN were obtained from the synthesised polyester as a result of the reaction of the COOH and NCO groups, while the blocked polyesters yielded non-grafted IPN.

Studies on such complex systems have shown that a better phase compatibility is characteristic of the fully grafted IPN, in contrast to the grafted and non-grafted IPN. It is manifested in the temperature variations by a broad peak in the range between 60° and 120 °C. The half-grafted IPN have three distinct peaks at 38°, 74°, and 120 °C, while the non-grafted IPN exhibit a high and broad peak at 50 °C and a shoulder at 99 °C. As the chemical interaction between the phases intensifies, the modulus of shear G' increases under these conditions. Thus the authors concluded that the interaction between the two phases plays an important role in decreasing the spreading of the phase separation between the polyurethane and polyester networks and also affects the kinetics of the formation of the IPN itself.

The relation between the kinetics of the formation of the two unlike three-dimensional structures in the IPN was also investigated for polyurethane–polyester acrylate.[35] The rate of hardening of polyurethane was determined by the ratio of the tri(hydroxymethyl)-propane–tolylene diisocyanate adduct and the oligoglycol, while the rate of hardening of polyester acrylate (PEA) was specified by the concentration of the initiator AIBN (0.01% for series I, 0.5% for series II, and 3.0% for series III). The kinetics of the formation of the IPN were investigated by the DTIR method. Figs. 9 and 10 illustrate the kinetic curves for the hardening of the polyurethane and PEA networks separately and in the blend. Judging from the slopes of these curves, the rates of cross-linking of unlike networks in the IPN, obtained by the single-stage method, are not independent.

Special experiments showed that the mutual influence is not associated with the chemical interaction between the networks. The authors determined the rate of hardening $\partial\alpha/\partial\tau$ of polyurethane or PEA at each point on the curve from the dependence of $\partial\alpha/\partial\tau$ on the composition of the IPN for different contents of the initiator at fixed time intervals elapsed since the beginning of the reactions. It was shown that the rate of urethane formation in the IPN depends, especially in the initial stages, on the concentration of the oligoester

acrylate and on the rate of its hardening. In the presence of small amounts of additives, the PEA network retards the cross-linking of the polyurethane. The oligoester acrylate inhibits the cross-linking in the series I specimens, where it is hardened at a lower rate than the individual polyurethane. In the series II specimens, the oligoester acrylate hardening at a higher rate inhibits the cross-linking of the matrix network less effectively. In series III, the retardation of the urethane formation reaction is observed over a wide range of compositions.

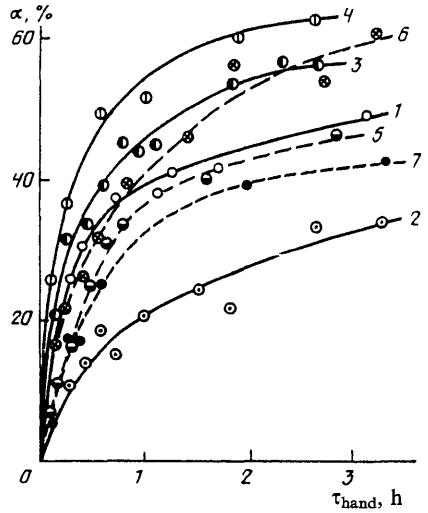

Figure 9. Kinetic curves for the hardening of pure polyurethane (curve *1*) and the polyurethane in the IPN for different PEA contents (wt.%): *2*, 0.5; *3*, *6*, and *7*, 2; *4*, 20; *5*, 0.3; curves *1*–*4* refer to series I, curves *5* and *6* to series II, and curve *7* to series III;[35] τ_{hard} = hardening time.

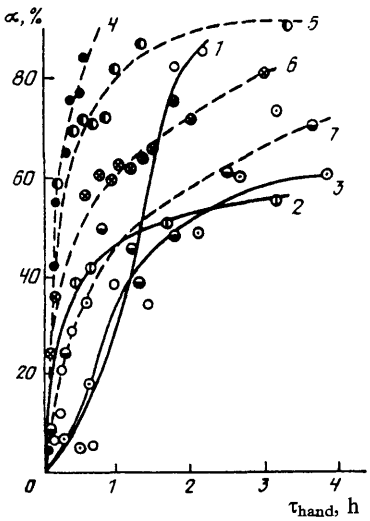

Figure 10. Kinetic curves for the hardening of pure PEA (curves *1* and *4*) and the PEA in the IPN for different PU contents (wt.%): *2*, and *6*, 30; *3*, and *7*, 50; *5*, 10; curves *1*–*3* refer to series I and curves *4*–*7* to series II.[35]

In the range of average compositions, the oligoester acrylate (OEA) accelerates the cross-linking of the polyurethane already in the initial stages of the reaction and the effect depends on the rate of hardening of the OEA. The rate of formation of PEA in the IPN is determined in its turn both by the initiator concentration and by the content of polyurethane. In the series I IPN, the polyurethane hardening at a higher rate initiates the cross-linking of the OEA in the experimental range of compositions. On the other hand, in series II, where the rate of its hardening is lower than that of the OEA, it behaves as an inhibitor of this process.

As the reaction mixture is hardened, the chemical composition and the system of intermolecular interactions continuously change. At a certain degree of conversion, the growing networks become thermodynamically incompatible. Following the onset of microphase separation, the influence of the PEA network on the hardening of the polyurethane should weaken. Indeed, the rate of hardening of the adduct in the IPN approaches the rate of hardening of the pure polyurethane as the reaction develops. After a time, microregions of the "rigid block" type arise in the segregated polyurethane phase, which is indicated by the appearance in the spectrum of bands due to the self-associated urethane groups at 1710 to 1720 cm^{-1}.

On the basis of the results, the authors conclude that, for the simultaneously formed IPN, the rates of hardening of unlike networks are related via the microphase separation process. In IPN with small amounts of the second network, the time of the onset of microphase separation increases sharply and the hardening of the IPN having this composition is characterised by a low degree of segregation of the components and by diffuse phase boundaries.

It is of interest to investigate the kinetics of the formation of simultaneously produced IPN based on polyurethane and polystyrene (PS) by IR spectroscopy.[36] The effects of temperature, of the concentrations of the catalyst, the initiator, and the cross-linking agent for polystyrene, and of the PU/PS ratio on the rates of the formation reactions of polyurethane and polystyrene were investigated. The kinetic results for the urethane formation reaction obtained spectroscopically agree with data obtained by chemical titration. It was shown that, with increase in the ratio PU/PS, the rate of formation of polyurethane increases and the rate of formation of polystyrene diminishes. The variation of the concentration of the catalyst (OcSn) affects the rate of formation of polyurethane but not the rate of formation of polystyrene in simultaneous reactions. The radical polymerisation reaction behaves similarly.

The authors observed that the rate of urethane formation and the rate of the radical polymerisation of styrene are higher for the pure systems than in the IPN. The results obtained for the polymerisation of styrene are surprising, since the catalyst and initiator concentrations in the polyurethane–polystyrene system investigated were chosen in such a way that the rate of formation of polyurethane should be much higher than the rate of formation of the polystyrene. Consequently the polystyrene in the IPN is formed when the degree of conversion of the polyurethane reaches 40–60%, depending on the conditions in the formation of the IPN, and the viscosity of the medium is high. The rate of termination of radical polymerisation is known to diminish sharply with increase in the viscosity of the medium and the rate of formation of polystyrene in the IPN after autoacceleration should therefore be higher than the rate for the pure polystyrene, which was not observed in the above study.

One should also note that the authors[36] do not attempt to explain the influence of the catalyst of initiator, when they are varied, on the formation of polystyrene or polyurethane. However, it has been shown[35,37] that these two processes are so interrelated that a change in the rate of urethane formation is reflected in the rate of formation of polystyrene in the IPN.

A more detailed study of the kinetics of the formation of IPN and semi-IPN confirmed the close relation with microphase separation.[37] It was shown that the rates of formation of the two three-dimensional structures via different mechanisms (polyaddition and radical polymerisation) in the IPN and the formation of the network and linear polymers in the semi-IPN are interrelated: a change in the formation of one of the networks affects significantly the rate of hardening of the second network or the linear polymer. In addition, two processes are superimposed under these conditions: the physical microphase separation process is superimposed on the chemical IPN formation processes.

Table 2. Composition and parameters of the microphase separation in the semi-IPN based on polyurethane and PBMA.[37]

PU/PBMA, wt.%	$I \times 10^2$, M	$K \times 10^3$, % s^{-1}	τ_{MPS}, min	α_{MPS}	
				PU	PBMA
75/25	0.74	0.7	70	0.57	0.034
75/25	0.48	0.83	65	0.50	0.040
75/25	2.96	2.66	55	0.38	0.062
75/25	5.40	3.80	45	0.36	0.080
75/25	10.80	6.60	35	0.21	0.091
65/35	5.40	2.20	65	0.37	0.110
85/15	5.40	5.50	60	0.45	0.28

Notation: I is the initiator concentration and K the rate constant for polymerisation to PBMA before autoacceleration.

The objects of study were semi-IPN and IPN. The semi-IPN was obtained by the method involving the formation of the network polyurethane from polyoxypropylene glycol with a molecular weight of 2000 and an adduct [the product of the interaction of tri(hydroxymethyl)propane with tolylene diisocyanate in proportions of 3 : 1] in the presence of butyl methacrylate (BMA), in which the radical polymerisation initiator (AIBN) had been dissolved beforehand. The catalyst concentration for the urethane formation reaction was constant in all the experiments and equal to 1.4×10^{-4} M. The kinetics of the formation of polyurethane and poly(butyl methacrylate), individually and as part of the composition of the semi-IPN, were investigated at 60 °C using a DAK-1-1A differential calorimeter. The onset of the MPS during the reaction was determined simultaneously for the same systems and under the same kinetic conditions by the method of turbidity points using an FPS-3 photocalorimeter. The composition of the semi-IPN obtained and the time of the onset of the MPS are given in Table 2. Assuming the additivity of the contributions of the heats of formation of each component of the semi-IPN to the overall heat evolution in the reaction, the heat evolution area corresponding to the formation of PBMA in the semi-IPN and the degree of conversion into the PBMA in the half-IPN were determined. The area under the heat evolution curve corresponding to urethane formation was calculated from the degree of conversion obtained by an independent method (back titration of the NCO groups).[38] The kinetic curves for the formation of polyurethane and PBMA in the half-IPN thus obtained for the ratios 75/25 wt.%) in the presence of different initiator concentrations (Fig. 11) show that, for simultaneously occurring reactions, the rate of formation of the polyurethane diminishes with increase in the initiator concentration as does the rate of formation of PBMA compared with the rate of formation of the individual polyurethane network. Evidently the retardation of the polyurethane network formation reaction in the semi-IPN formed can be attributed to the increase in the viscosity of the PBMA reaction system. The rate of polyurethane formation is lower, the higher the rate of formation of PBMA (Fig. 11). Polymerisation to give PBMA takes place in a matrix consisting of a mixture of the polyurethane formed at the given instant and the components from which it is synthesised, i.e. the polymerisation reaction takes place, as it were, in a "dilute" system, as a result of which the initial rate of formation of PBMA is diminished compared with the pure polymer. However, subsequently the rate of formation of PBMA in the semi-IPN becomes higher than for the pure PBMA, which is clearly seen from the variation of the reduced rates of formation of the initial PBMA and the PBMA in the IPN (Fig. 12). This increase in rate may be associated with the overall increase in the viscosity of the reaction system.[17] During the formation of the semi-IPN, the viscosity increases so much that it leads to a sharp decrease in the termination constant (K_t) relative to the propagation constant (K_p) and hence to an increase in the ratio K_p/K_t and in the rate of chain propagation V_p in accordance with Eqn. (1).[17]

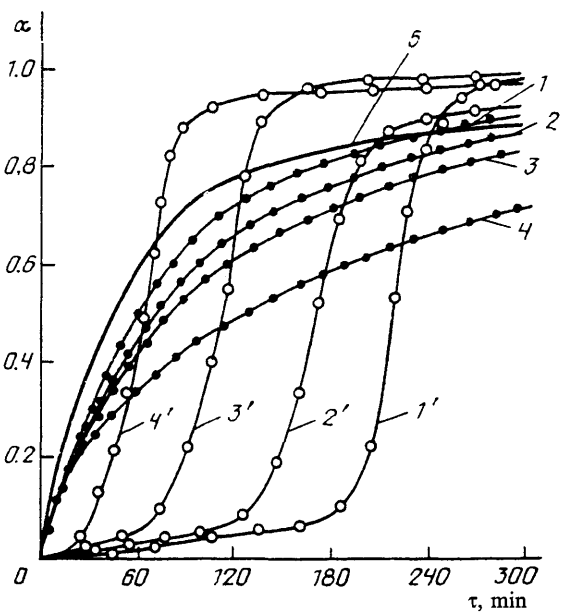

Figure 11. Kinetics of the formation of polyurethane (curves *1–4*) and PBMA (curves *1′–4′*) in the semi-IPN with the composition PU/PBMA = 75/25 for different initiator concentrations $I \times 10^2$(M): *1*, 0.74; *2*, 1.48; *3*, 2.96; *4*, 10.8; *5*, polyurethane.[37]

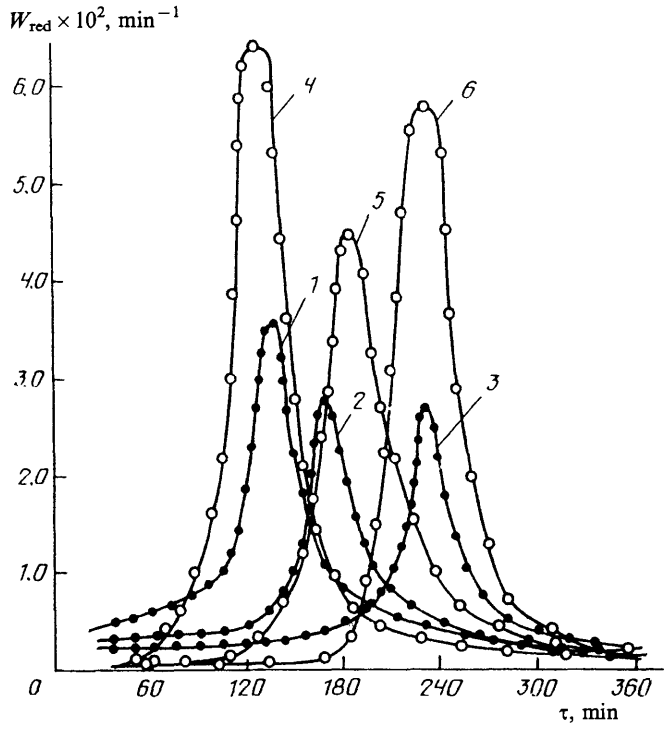

Figure 12. Time variation of the reduced rate of polymerisation (W_{red}) of butyl methacrylate at different molar initiator concentrations $I \times 10^2$ for the pure methacrylate (curves *1*–*3*) and the methacrylate in the semi-IPN with the composition 75/25 (curves *4*–*6*): *1*, and *4*, 2.96 M; *2*, and *5*, 1.48 M; *3*, and *6*, 0.74 M.[37]

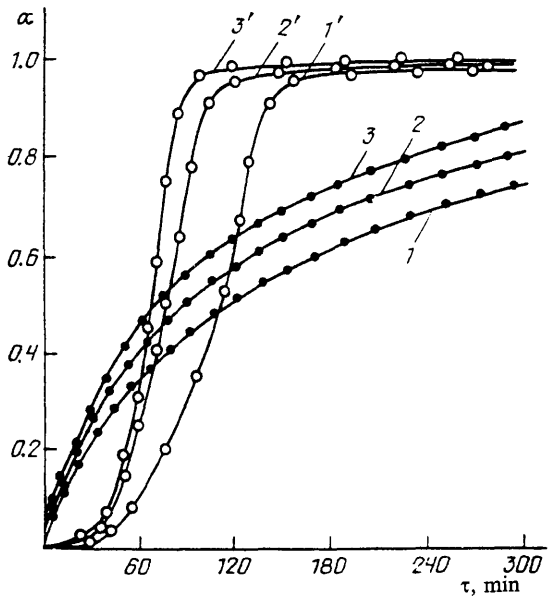

Figure 13. Kinetics of the formation of polyurethane (curves *1*–*3*) and PBMA (curves *1′*–*2′*) in the semi-IPN for $I = 5.4 \times 10^{-2}$ M and different component ratios (wt.%): *1*, and *1′*, 65/35; *2*, and *2′*, 75/25; *3*, and *3′*, 85/15.[37]

Fig. 13 presents kinetic curves for polyurethane and poly(butyl methacrylate) in different proportions in the blend at constant initiator and catalyst concentrations. The calculated reduced rates (W_{red}) for PBMA in the blend show that the rate of formation of PBMA increases in the sequence 65/35 < 75/25 < 85/15 compared with the initial rate, which is associated with the increase in the viscosity of the system. In the experiment with the 85/15 (wt.%) ratio, the viscosity was higher than in the experiment with the 65/35 (wt.%) ratio. Hence K_t diminished and K_p and V_p increased. As can be seen from Fig. 13, the rate of formation of polyurethane under these conditions in the blend diminishes in the sequence 85/15 > 75/25 > 65/35 compared with initial rate.[37]

If one adopts the concept already formulated and assumes the existence of a relation between the kinetics of the formation of the IPN and the microphase separation processes, then it is evident that there exists a distinct relation between the kinetics of the formation of the IPN and its structural characteristics. Such a relation has been established for semi-interpenetrating networks based on cross-linked polyurethane and PBMA formed in a polyurethane network matrix by the radical polymerisation of the monomer.[39]

Table 3 presents some data concerning the conditions in the formation of networks and their structural characteristics determined from low angle X-ray scattering data.[40] The polyurethane formation reaction in the given system begins before and terminates after the butyl methacrylate polymerisation reaction. As can be seen from the data in Table 3, with increase in the initiator concentration and hence in the overall rate of reaction, the heterogeneity distance l_s and the extent of the transition layer also increase. These data can be interpreted as follows. The increase in the rate of formation of PBMA leads to a faster onset of the thermodynamic incompatibility of the components of the interpenetrating network considered (we neglected here the differences between the molecular weights of the PBMA associated with the differences in the rate of initiation). There is then a rapid increase in the viscosity of the reaction system. Against the background of the simultaneous formation of the polyurethane network, these factors retard the microseparation process as a consequence of both the increase in viscosity and the fixation of the microphase separation regions arising on formation of the polyurethane network. The larger dimensions of the inhomogeneity regions and the greater extent of the transition layer are "quenched" as a result.

Table 3. Composition of the semi-IPN based on polyurethane and PBMA and their structural parameters.[39]

No. of specimen	PU/PBMA	$I \times 10^2$, M	Method of synthesis of the IPN	l_s, Å	E^2, (Å)^2
1	75/25	0.74	simultaneous	68	38
2	75/25	5.4	" "	70	27
3	75/25	10.8	" "	75	60
4	85/15	5.4	" "	65	37
5	65/35	5.4	" "	81	61
6	75/25	5.4	stage I–photopolymerisation, stage II–thermopolymerisation	66	21
7	75/25	5.4	stage I–thermopolymerisation at 25 °C, stage II–photo-polymerisation	72	65

Notation: l_s is the heterogeneity parameter and E^2 the thickness of the transition layer.

Indeed it is known[41] that, on spinodal separation, the boundary between the microphase regions in the initial stages is diffuse, but subsequently the differences between the compositions of these regions and the boundary become more distinct. Judging from the experimental data for the structure of the IPN, the observed structural parameters are consistent with this finding. The sooner is the structure of the IPN fixed as a consequence of the inhibition of the microphase separation process, the greater are the micro-heterogeneity distances and the thickness of the transition layer. Indeed, for the same rate of initiation but for a different PU/PBMA ratio [85/15 and 65/35 (wt.%)] in those cases where the content of PBMA is higher, separation is evidently slower, the transition layer is more extensive, and the heterogeneity distance is longer. We also observed a difference between the structural characteristics of consecutively formed IPN, based on the same components, under the conditions of the polymerisation of butyl methacrylate in the matrix of a polyurethane network formed previously.

Thus one may claim that there exists a relation between the structure of the hardened IPN and the kinetics of the formation of the constituent networks, the latter determining the possibility of the occurrence of the microphase separation process. However, since, apart from the factors which we have examined, the microphase separation is influenced also by others (including the change in the thermodynamic compatibility as a function of the composition and the degree of conversion which we did not take into account), a more detailed treatment of the above data does not appear desirable.

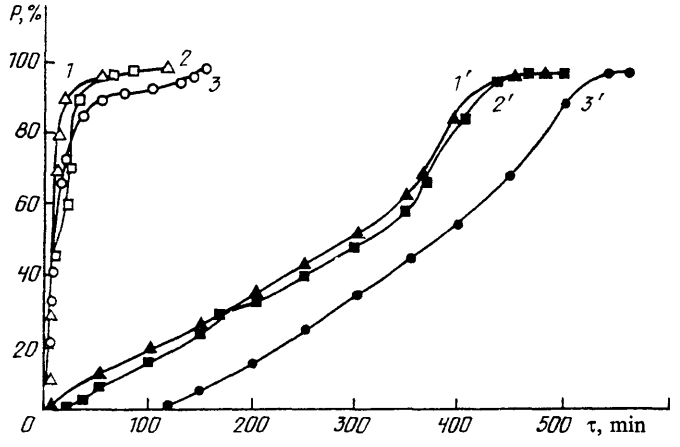

Figure 14. Time variation of the degree of conversion (P) in the formation of the semi-IPN with the composition PU/PS = 30/70 (wt.%) for different polyurethane formation times before the onset of the radical polymerisation of styrene: *1*, and *1′*, 5 min; *2*, and *2′*, 15 min; *3*, and *3′*, 2 h; *1*–*3*, polyurethane; *1′*–*3′*, polystyrene.[42]

The kinetics of the formation of polyurethane and polystryene as part of the composition of a semi-IPN as well as the influence of different kinetic conditions in the formation of the half-IPN on the phase separation in the system have been investigated[42] by FTIR spectroscopy. In order to obtain the half-IPN with the composition PU/PS = 30/70 (wt.%), a mixture of the initial components was maintained at room temperature for different times τ (5 min, 15 min, and 2h) and then the temperature was raised to 70 °C and the mixture was polymerised until the complete disappearance of double bonds. Fig. 14 presents kinetic curves for the formation of polyurethane and polystyrene. Evidently, for times of 5 and 15 min, the polyurethane network and polystyrene are formed simultaneously but at different rates, whereas for τ = 2 h polystyrene is formed in the fully polymerised polyurethane network. The different kinetic conditions in the formation of polyurethane influenced the phase separation in the system, which is clearly seen from the time variation of the transmittance (T, %) (Fig. 15). The system loses transparency on simultaneous formation of polyurethane and polystyrene (τ = 5 min) when the degree of conversion into polystyrene is about 2%. When the semi-IPN is obained consecutively (τ = 2 h), the system remains transparent, but for τ = 15 min a tendency towards a decrease in transmittance (T, %) is observed at later stages in the formation of the half-IPN.

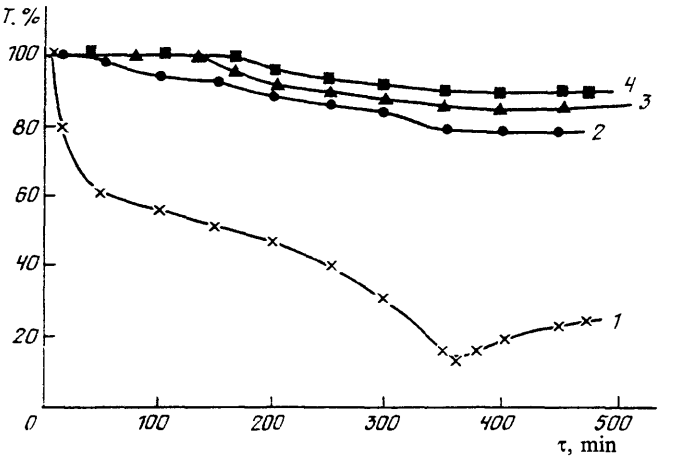

Figure 15. Transmittance (T) curves for the semi-IPN with the composition PU/PS = 30/70 (wt.%) at 70 °c for different polyurethane formation times before the radical polymerisation of styrene: *1*, 5 min; *2*, 15 min; *3*, 2 h; *4*, 6 h.[42]

The introduction of polymerised polystyrene and polyurethane in an amount of 0.5–1% in the first minute induces phase separation in the reaction system. The authors also showed that, with increase in M_n for polystyrene, phase separation is manifested sooner and becomes explicit (Fig. 16). Thus the authors conclude that, when the reaction mixture is separated before the onset of gel formation in polyurethane, the half-IPN are turbid. If separation takes place after gel formation, then transparent IPN are produced, i.e., using certain kinetic parameters it is possible to obtain materials with a wide range of properties.

In order to investigate further the influence of the kinetics of the formation of IPN on the microphase separation, a study was made of IPN based on two networks: polyurethane and a loosely cross-linked butyl methacrylate in the presence of triethylene glycol dimethacrylate (TGM-3).[43] The composition of the IPN and the concentrations of the cross-linking agent (TGM-3), the initiator, and the catalyst are presented in Table 4. The kinetics of the formation

of the IPN were investigated by the calorimetric method described above. The kinetic curves for the initial polyurethane and PBMA and the copolymer with the cross-linking agent TGM-3 having different contents of the latter are presented in Fig. 17. Fig. 17 shows that the initial section on the kinetic curves for the radical polymerisation of butyl methacrylate and the butyl methacrylate–TGM-3 copolymer remains unchanged, so that the introduction of a small amount of the cross-linking agent (up to 0.15 M) does not affect the initial rate of polymerisation of butyl methacrylate but does influence the degree of conversion (α_a) at which autoacceleration begins. With increase in the concentration of TGM-3, the degree of conversion falls, but, after the attainment of a definite value of α_a, the rate of formation of the copolymer increases with increase in the amount of cross-linking agent. This is usually explained by the decrease in the rate of the chain termination reaction when the rate of initiation and the rate of chain propagation are altered slightly. Kinetic curves for polyurethane and PBMA have been obtained by the method described for simultaneously produced IPN with the compositions 75/25 and 65/35 (wt.%) (Fig. 18) in the presence of different concentrations of the initiator and cross-linking agent (Table 4). The experimental data show[43] that the rate of formation of the butyl methacrylate–TGM-3 copolymer in the IPN diminishes in the initial stage owing to the dilution by the components of the polyurethane network but subsequently increases compared with the initial value and the degree of conversion at the onset of the autoacceleration (α_a) diminishes under these conditions. It has been observed that the rate of polymerisation of the copolymer in the IPN changes after the start of autoacceleration with increase in the initiator concentration (Fig. 18, curves *2* and *3*) and a slight decrease in the degree of conversion after the onset of autoacceleration is observed. Under these conditions, the rate of urethane formation also diminishes slightly (curves *1*–*3*). The change in the rate of formation of the loosely cross-linked PBMA in the IPN owing to the variation of the initiator and cross-linking agent concentrations is manifested more markedly on the kinetic curves for the formation of polyurethane in the IPN for the component ratio 65/35 (wt.%) (Fig. 19).

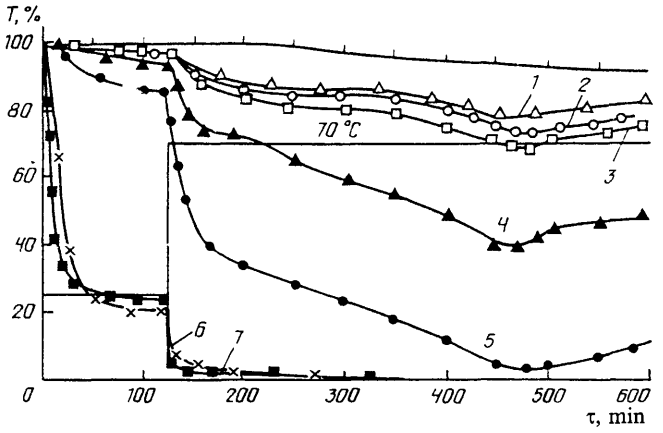

Figure 16. Transmittance (*T*) curves for the semi-IPN with the composition PU/PS = 30/70 (wt.%) at 70 °C with 0.5% polystyrene having different molecular weights M_n: *1*, 2000; *2*, 4900; 3, 22 000; *4*, 27 000; *5*, 40 300; *6*, 52 000; *7*, 105 000.[42]

Kinetics of the formation of polyurethane (curve *1*) and PBMA (curve *2*) and of the copolymerisation of butyl methacrylate with triethylene glycol dimethacrylate: *2*, $I = 2.96 \times 10^{-2}$ M; *3*, PBMA + TGM-3; $I = 2.96 \times 10^{-2}$ M, [TGM-3] = 0.031 M; *4*, PBMA + TGM-3, $I = 2.96 \times 10^{-2}$ M, [TGM-3] = 0.156 M.[43]

Table 4. Physicochemical parameters of the IPN based on polyurethane and PBMA.[43]

PU/PBMA (wt.%)	$I \times 10^2$, M	[TGM]*, M	τ_{MPS}, min	α_{MPS}	
				PU	PBMA
75/25	2.96	0.031	60	0.51	0.045
75/25	2.96	0.156	56	0.47	0.050
75/25	5.40	0.031	57	0.44	0.200
65/35	2.96	0.031	60	0.47	0.030
65/35	2.96	0.156	56	0.42	0.050
65/35	5.40	0.031	38	0.28	0.070
50/50	2.96	0.156	70	0.37	0.040

*[TGM] is the concentration of the cross-linking agent.

The calculated reduced rates (W_{red}) for PBMA in the blend for different component ratios show that the rate of formation of PBMA increases in the sequence 50/50 < 65/35 < 75/25 (wt.%). Under these conditions, the dependence of the maximum reduced rate on the PU/PBMA ratio is linear (Fig. 20) and is correlated with data obtained for the semi-IPN. The explanations are similar: with increase in the viscosity of the system, the termination constant diminishes and the chain propagation constant increases with the corresponding increase also in the rate of formation of the copolymer in conformity with Eqn. (1) presented above. The rate of formation of polyurethane diminishes in the sequence 75/25 > 65/35 > 50/50 (wt.%).

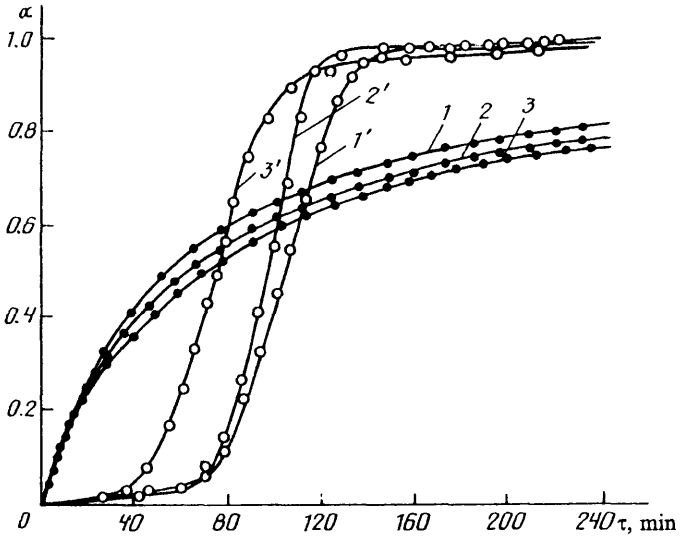

Figure 18. Kinetics of the formation of polyurethane (curves *1*–*3*) and of the cross-linked PBMA (curves *1'*–*3'*) in the IPN for PU/PBMA = 75/25 (wt.%) and different TGM-3 and initator concentrations: *1*, and *1'*, $I = 2.96 \times 10^{-2}$ M, [TGM-3] = 0.031 M; *2*, and *2'*, $I = 2.96 \times 10^{-2}$ M, [TGM-3] = 0.156 M; *3*, and *3'*, $I = 5.4 \times 10^{-2}$ M, [TGM-3] = 0.031 M.[43]

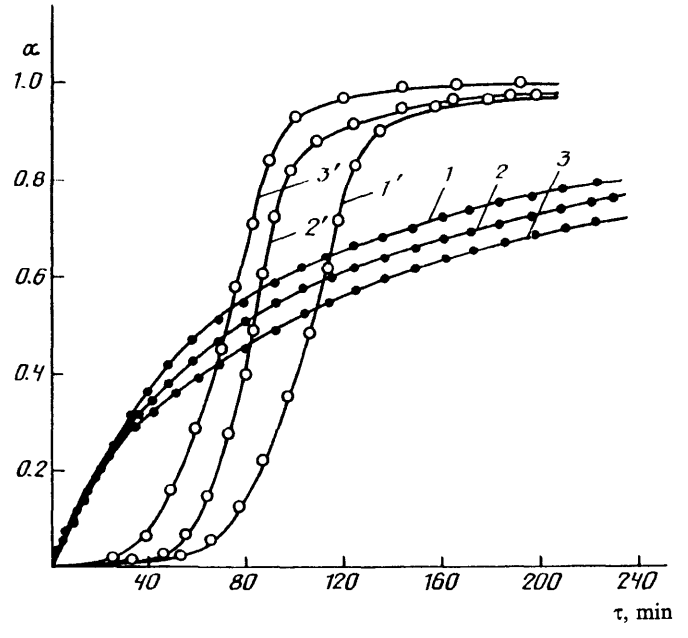

Figure 19. Kinetics of the formation of polyurethane (curves *1*–*3*) and of the cross-linked PBMA (curves *1'*–*3'*) in the IPN for the ratio PU/PBMA = 65/35 (wt.%) and different TGM-3 and initiator concentrations: *1*, and *1'*, $I = 2.96 \times 10^{-2}$ M, [TGM-3] = 0.031 M; *2*, and *2'*, $I = 2.96 \times 10^{-2}$ M, [TGM-3] = 0.156 M; *3*, and *3'*, $I = 5.4 \times 10^{-2}$ M, [TGM-3] = 0.031 M.[43]

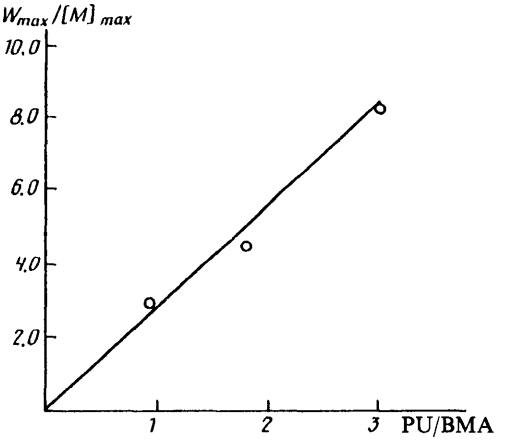

Figure 20. Dependence of the maximum reduced rate of polymerisation of butyl methacrylate in the presence of TGM-3 in the IPN on the component ratio.[43]

Analysis of the data obtained on the kinetics of the formation of polyurethane and PBMA in the case of the simultaneously produced semi-IPN and IPN leads to the conclusion that the introduction of the cross-linking agent for the second polymer network accelerates the formation of the second network, which is reflected directly in the kinetics of the formation of the first network. This is manifested more strikingly with increase in the amount of the second network. The features of the kinetics of the formation of the two networks remain unchanged as the component ratio PU/PBMA varies both in the IPN and in the semi-IPN.

We shall now consider the influence of microphase separation in semi-IPN and IPN and the kinetics of the reactions in the given system. The onset of the MPS was determined simultaneously for the same systems and under the same kinetic conditions in the course of the reaction by the method of turbidity points on an FPS-3 photocalorimeter.[37,43] Tables 2 and 3 present data characterising the microphase separation occurring during the formation of the semi-IPN and the IPN. Analysis of the data presented shows that the time to the onset of the MPS diminishes almost linearly with increase in the concentration of the initiator of the polymerisation of PBMA in the semi-IPN. Calculation of the rate of reaction of PBMA along the initial section (up to the onset of autoacceleration) shows that there is also a linear relation between this quantity and the time of the onset of the MPS. It follows from Table 2 that, for a constant initial composition of the system, the degree of conversion into the polyurethane diminishes at the instant of phase separation with increase in the rate of polymerisation, while the degree of conversion of PBMA increases. The weight fractions of the components in the phase separation were determined from the initial system composition for different rates of polymerisation.[37] Evidently the fraction of polyurethane then falls while that of PBMA increases, which is associated with the influence of the initiator concentration, examined above, on the ratio of the reaction rates. Compatibility is known to be determined not only by the component ratio but also by the ratio of the molecular weights. Evidently the amount of polymer formed at the instant of phase separation, and not the molecular weight, plays a decisive role in the appearance of

incompatibility. We may note that the weight fraction of polyurethane in the semi-IPN at the instant of phase separation is significantly greater than its value in the initial system (of the order of 0.9), which also suggests that the accumulation of PBMA is the decisive factor in the PMS. The higher the rate of polymerisation leading to PBMA, the higher the degree of conversion into PBMA at the phase separation point, and the lower the fraction of polyurethane for which separation begins, while the time up to the onset of the MPS in the system diminishes.

The onset of the MPS depends also on the ratio of the polyurethane and PBMA components in the semi-IPN. For the component ratio 85/15 (wt.%), the degree of conversion up to the onset of MPS is indeed higher for both components than for the ratio 75/25 wt.%, while in the case of the ratios 65/35 and 75/25 wt.%) the degrees of conversion are similar. At the same time the weight fraction of the polyurethane at which MPS begins proved to be smallest for the 65/35 ratio and greatest for the 85/15 (wt.%) ratio. Account must be taken of the fact that the rate of MPS in a highly viscous medium is clearly lower than the rates of the reactions and may therefore lag in time behind the degree of conversion at which this would have occurred under equilibrium conditions uncomplicated by the reaction occurring in the previous period.

The study of the influence of microphase separation on the kinetics of the formation of IPN showed that, for a constant composition of the components, the degree of conversion into polyurethane at the instant of phase separation falls with increase in the rate of formation of PBMA and the degree of conversion into PBMA increases, the influence of the initiator concentration being more marked compared with that of the cross-linking agent. Such behaviour can be traced for two component compositions — 75/25 and 65/35 (wt.%). The time up to the onset of MPS in the system diminishes sharply only for the component ratio 65/35 (wt/%) with increase in the initiator concentration to 5.4×10^{-2} M. When the component ratio is altered at constant initiator and cross-linking agent concentrations, the time of the onset of MPS increases to 70 min and the degree of conversion into polyurethane diminishes from 0.49 to 0.37 and that into PBMA varies in the range 0.04 – 0.05.[43]

Consequently, an increase in the rate of polymerisation, which increases the degree of conversion into PBMA, reduces the time before the onset of phase separation. However, the most significant conclusion arising from the analysis of the rates of reaction and the times of the onset of MPS is as follows. As can be seen from the kinetic data, both before the onset of MPS and afterwards, the nature of the kinetic curves remains unchanged, i.e. the MPS is not reflected in the rates of the continuing reactions. This means that, in the region becoming segregated, the MPS alters the composition to one close to the average composition of the system, i.e. in each segregated phase the ratio of the reacted and unreacted components is approximately the same. This situation can occur only in the case of a microphase separation which proceeds via the spinodal mechanism and is in its initial stage. Evidently, the microheterogeneous system, arising as a result of the formation of the network, is then chemically "quenched",[44] which prevents further phase separation after the attainment of a definite degree of conversion. Otherwise the microphase separation would have progressed further and deviations of the rates of reactions from those in the initially separating system should have been observed, and this is not the case up to high degrees of conversion.

Thus one may conclude that the simultaneously occurring chemical formation reactions of polymer molecules constituting the semi-IPN and the IPN and the physical microphase separation processes take place under non-equilibrium conditions.

This makes it possibile to represent in the following way the process leading to the formation of the IPN. When the IPN is synthesised, the initial reaction system consists of a homogeneous mixture of components capable of forming two independent three-dimensional networks in the course of the chemical reactions occurring via different mechanisms. After the attaiment of a definite degree of conversion, as a rule before the attainment of the sol – gel transition point, the growing fragments of the constituent networks become incompatible in the system. The condition for this is the attainment by the thermodynamic interaction parameter χ_{23} of the critical value predicted by the theory. The initial phase separation conditions are specified by the conditions for the transition of the parameters χ_{23} from negative (region of compatibility) to positive (region of incompatibility) values or by the conditions under which χ_{23} becomes zero for the given system composition and at the given temperature. In most cases, this takes place in the initial stages of the reaction in the kinetic region. However, phase separation takes place from the very beginning under non-equilibrium conditions, because it occurs simultaneously with the developing chemical reaction, altering the parameter χ_{23} and thus the phase separation conditions. The rate of attainment of the critical value of the parameter χ_{23} is determined by the rates of the two independent reactions, while the phase separation process begins before the completion of gel formation in the constituent networks.

In the initial period of the reaction (low degrees of conversion), the onset of phase separation is determined solely by the rate of reaction, i.e. by the rate of formation of the polymer and the increase in its molecular weight. However, the cross-linking of sections of the growing chains into a continuous network and the rapid increase, as a consequence of gel formation, in the viscosity of the system have an inhibiting effect on the phase separation, which thus becomes possible only in a definite range of conversions and in a time interval which is a function of the rates of the constituent reactions. Since the cross-linking reactions continue in the time interval $\Delta\tau$, the phase separation then proceeds under non-equilibrium conditions, because the composition of the phases and their proportions vary with time in the reaction system. Thus the real situation arising in the formation of the IPN differs significantly from the case of "chemical quenching" examined theoretically by Frisch and Binder, in which it is assumed that the hardening time is much shorter than the relaxation time of the system in the phase separation.[44]

Both processes — the chemical reaction and the phase separation — take place simultaneously. This determines the nature of the structures which develop and are transformed at different stages of the reaction in the phase separation. The structure produced as a result of the reaction is characterised by a periodicity and order typical for structure arising in phase separation via the spinodal decomposition mechanism[45] The kinetics of the phase separation are described approximately in the initial stages by the linear Cahn – Hilliard theory despite the fact that this entails continuous changes in the degree of conversion, i.e. a drift of the system along the phase diagram implying continuous variation of the parameter χ_{23} and of the composition of the phases being separated. Thus yet another fundamental feature of the formation of the structure is established. It consists of a continuous sequence of structures differing in composition not only in the early stages of the phase separation but, according to the theory, also as a

consequence of the chemical reaction.[46] Thus the structure arising during the reaction is a result of a non-equilibrium phase transition of the liquid–liquid type and the final result of this transition is determined by the system composition (the ratio of the networks, the rates of the reactions, and the degree of the non-equilibrium phase separation during the time interval $\Delta\tau$).

It follows from the foregoing that, from the thermodynamic point of view, IPN are non-equilibrium systems. However, phase separation microregions, which can be described as quasi-equilibrium regions, are manifested in them. Indeed, each of the two experimentally observed phases has a glass point different from the glass points of the constituents. Each given phase contains both constituents. We can consider such a phase as a region in which the state of the molecular blending of the components (compatibility), corresponding to the equilibrium conditions preceding the given state of the entire system, has been "frozen". Overall, this is a thermodynamically non-equilibrium two-phase system whose state is determined by the conditions for incomplete microphase separation. However, each phase is in a quasi-equilibrium state. The structure of the IPN is microheterogeneous and molecular blending of the components takes place in the constituent phases.

IV. Conclusion

Analysis of the data presented shows that the principal experimentally demonstrated fact in the formation of IPN is at the present time the influence of the kinetics of the formation of the constituent networks in the IPN on the kinetics of the microphase separation and also the occurrence of the MPS under non-equilibrium conditions in the chemically varying system. However, this postulate has been formulated in a qualitative form.

The previous literature describes no attempts at a formal analysis of the kinetics of the network formation reactions taking into account the factors which influence the kinetics and which were examined above.

Numerous data essential for the understanding of the mechanisms of the formation of IPN are lacking. Thus, in radical three-dimensional polymerisation, the role of the reaction involving chain transfer to the second network, being formed via a non-radical mechanism or already formed (consecutive hardening), was not established. An appropriate study of the kinetics of the formation of the network in the matrix already produced (consecutively formed IPN), which strictly speaking should have preceded the investigation of the kinetics of the simultaneous reactions, was not carried out.

Although the fundamental role of MPS in the kinetics and their mutual influence has been established, the fundamenal problems arising in this connection have still not been studied. These include the following. Despite the fact that the degree of the MPS in the IPN may be estimated quantitatively,[41] it has not been estimated at different degrees of conversion of the systems for which the kinetics have been investigated. It is not clear in which stage and at what degree of conversion the MPS is frozen as a function of the kinetic conditions in the formation of the networks (rate, composition, and temperature). There are no data on the kinetics of the MPS after its onset.

It is also not clear in what way the reaction takes place after the MPS in MPS regions of different composition and how the chemical interaction between the phases is achieved. We have no information about the influence of the constituent networks and the MPS on the conversion at the gel point. Accordingly, and this is very important for the estimation of mechanical properties, the density of the constituent network is unknown under the conditions of the mutual influence of the kinetics of the reactions and the kinetics of the MPS on the formation of the IPN.

From the standpoint of the phase state, three cases of the formation of IPN are possible. The first arises when one network is formed much faster than the other, i.e. it is formed virtually in the liquid phase comprising the components of the second network, which results in a microphase structure with a fairly high degree of segregation. The second case occurs when the formation reactions of both networks are rapid and there is insufficient time for the occurrence of the MPS, whereupon the structure of the system characteristic of the single-phase state is frozen. The third, commonest case obtains when the rates of formation of both networks are comparable. The MPS begins in the course of the reaction and its continuation is inhibited as the network structure is produced. Among the three versions specified above, the formation kinetics as well as the relation with the microphase separation in the IPN have been studied in greatest detail for the third, commonest case, leaving the first two cases without due attention. All this demonstrates how far we are from a true understanding of the mechanism of the formation of IPN.

Aliphatic organophosphorus nitro-compounds

G M Baranov, V V Perekalin
Gertsen Russian State Pedagogic Institute, St. Petersburg

ABSTRACT. The review presents data on the methods of synthesis and properties of aliphatic organophosphorus α-, β-, γ-, and δ-nitro-compounds. They are arranged in conformity with the structural types of the compounds, since there are no general methods of synthesis characteristic simultaneously of all the groups of organophosphorus nitro-compounds.

The bibliography includes 109 references.

I. Introduction

The interest in the study of aliphatic organophosphorus nitro-compounds is due primarily to the wide variety of their reactions involving the electron-accepting groups (the nitro-group and the phosphoryl group) linked to alkyl and alkenyl residues, which is the reason for the great importance of such compounds in synthetic and theoretical organic chemistry.

The synthesis of aminoalkylphosphonic acids with functional group substituents via the nitro-derivatives opens the way to certain compounds which are otherwise difficult to obtain. Thus organophosphorus nitro-compounds can become important intermediates in the synthesis of pharmaceuticals, fungicides, herbicides, antibiotics, glutamate-ergic neuron blocking agents, etc.

In discussing the data, the aim was to trace (in so far as this was permitted by the published results) the dependence of the mode of the reactions on their experimental conditions and on the structure of the reactants, to demonstrate the relation between the physicochemical properties and structure of organophosphorus nitro-compounds, and also to describe their possible subsequent reactions.

Certain reactions, discovered as a result of the search for ways of synthesising organophosphorus nitro-compounds, are of fundamental importance in organic synthesis.

II. Organophosphorus α-nitro-compounds

1. Methods of synthesis of organophosphorus α-nitro-compounds

The use of the most reactive trivalent phosphorus compounds for the synthesis of organophosphorus nitro-derivatives was hindered by the occurrence of numerous oxidation-reduction processes involving phosphorus(III).[1-3]

The first representative of organophosphorus α-nitro-compounds was obtained by nitrating with ethyl nitrate potassium benzyldiphenylphosphine oxide metallated with the aid of potassium t-butoxide:[4]

$$Ph_2P-CH_2PH \xrightarrow[2)\ EtONO_2,\ 0\ ^\circ C]{1)\ t\text{-}BuOK} Ph_2P-CHPh(O)(NO_2).$$

Nitration of alkylphosphonates with alkyl nitrates in the lithium isopropylamide–tetrahydrofuran (THF) system leads to cleavage products (nitroalkanes and trialkyl phosphates) together with nitrophosphonates:[5]

$$(R^1O)_2P(O)-CH_2R \xrightarrow{(iso\text{-}Pr)_2NLi-THF-n\text{-}PrONO_2} (R^1O)_2P(O)-CHR(NO_2) + RCH_2NO_2 + n\text{-}PrOP(O)(OR^1)_2;$$

R = Bu, C_5H_{11}.

The attempt to suppress the cleavage of the initial ester by using bulky substituents at the phosphorus atom (for example, isopropoxy-groups) failed and the yield of the nitroalkylphosphonates is also low in this case.

The interaction of phosphorylated aldehydes and ketones with acetyl nitrate in acetic anhydride at 30–35 °C also leads to nitromethylphosphonates.[6,7] It has been suggested[8] that the reaction proceeds via an enol formation stage in accordance with the mechanism

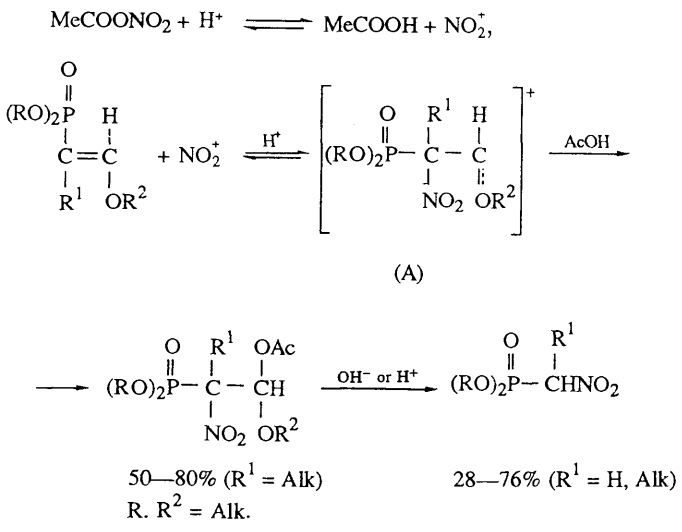
$$(RO)_2P(O)CH_2C(O)R^1 \rightleftharpoons (RO)_2P(O)CH=C(OH)R^1 \xrightarrow{AcONO_2} \left[(RO)_2P(O)CH(NO_2)C(OAc)(OH)R^1\right] \xrightarrow{HX} (RO)_2P(O)CH_2NO_2;$$

R = Alk; R^1 = H, Me; X = OH^-, AcO^-.

The introduction of electronegative substituents into the methylene group in β-ketophosphonates prevents this reaction. Thus diethyl

1-chloro-2-oxoalkylphosphonate does not react with acetyl nitrate at 33–35 °C, while at a higher temperature it decomposes under the reaction conditions.

A more convenient method of synthesis of 1-nitroalkylphosphonates involves the interaction of 2-alkoxyvinylphosphonate with acetyl nitrate. The final products can be readily separated from the initial reactants by converting them into the aci-form with subsequent acidification.[6,9] The reaction is catalysed by sulphuric acid (apparently as a consequence of the enhancement of the electrophilicity of the reagent $MeCOONO_2.H^+$).[7] The addition of acetyl nitrate is not stereospecific—diastereoisomers are formed in proportions of 45:55. The reaction apparently proceeds via a stage involving the addition of the nitronium cation to the vinylphosphonate with subsequent nucleophilic attack on the relatively stable planar carbonium ion (A) by acetic acid or the acetate ion, the attack being directed with equal probability "from the front and from the rear".

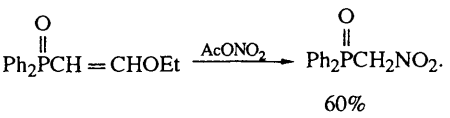


50—80% (R^1 = Alk) 28—76% (R^1 = H, Alk)
R. R^2 = Alk.

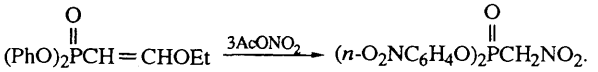
In the presence of an alkyl group in the α-position relative to the phosphonate group, the adduct is stable and on treatment with bases (sodium alkoxide, alcoholic alkali) or hydrochloric acid gives rise to 1-nitroalkylphosphonate.[10]

The stability of the adducts formed by the addition of acetyl nitrate to 2-alkoxy-1-alkylvinylphosphonates can be accounted for by the presence of the alkyl group, which causes steric hindrance to the conjugation between the C–C bond and the π-system of the nitro-group. The stability of the carbonium ion (A) is also affected by the 2-alkoxy-group, which hinders the nucleophilic attack: in its absence (diethyl 1-ethyl-2-oxoethylphosphonate), the ion (A) is cleaved in the instant of reaction. Thus slight changes in the structure of phosphonates affect the course of the reaction with acetyl nitrate and the structure of the products. For example, nitration products cannot be obtained from diethyl 2-ethoxy-2-methylvinylphosphonate.

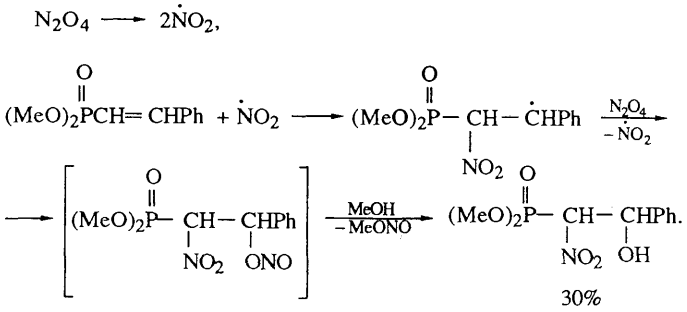
Nitration with acetyl nitrate of the corresponding 2-alkoxyalkenylphosphinates and 2-alkoxyalkenylphosphine oxides also leads to nitromethylphosphinates and nitromethylphosphine oxides.[11] The authors explain a certian passivity of phosphine oxides in the reaction by the competing protonation of the phosphoryl group, and not acetyl nitrate, by sulphuric acid, which lowers the activity of the catalyst. Only nitromethyldiphenylphosphine oxide, in which the phosphoryl group is less basic, is obtained in a high yield.



In the case of diphenyl esters of 2-ethoxyvinylphosphonic acid, acetyl nitrate nitrates simultaneously both the double bond and the benzene ring:[11]

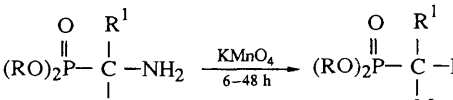


Nitration of 2-phenylvinylphosphonate with dinitrogen tetroxide leads to an organophosphorus α-nitroalcohol.[12] The reaction is accompanied by the cleavage of the C–P and C–C bonds, which was confirmed by the isolation of 2-nitrostyrene and 2-nitrophenol from the reaction mixture.



According to IR spectroscopic data, organophosphorus α-nitroalcohols form intermolecular hydrogen bonds in the crystal [ν(OH) = 3280 cm^{-1}], which are readily ruptured on dissolution with formation of free molecules [ν(OH) = 3590 cm^{-1}]. The chemical shift of the hydroxyl proton (δ_{OH} = 2.93 p.p.m.) in the ^1H NMR spectra also corresponds to the virtually free state of the OH group.

1-Aminoalkylphosphoantes substituted in the 1-position are oxidised by potassium permanganate or hydrogen peroxide to the corresponding α-nitroalkyl phosphonates:[6,13]



30—53%

1-Nitroalkylphosphonates have also been obtained by oxidising with *m*-chloroperbenzoic acid 1-*N*-hydroxyiminoalkylphosphonates synthesised beforehand from 1-oxoalkylphosphonates, which were

obtained in their turn by the reaction of acyl chlorides with triisopropyl phosphite.[14]

$$(\text{iso-PrO})_3\text{P} \xrightarrow{\text{RCOCl}} (\text{iso-PrO})_2\text{P}(\text{O})\text{C}(\text{O})\text{R} \xrightarrow[\text{2) m-ClC}_6\text{H}_4\text{COOOH/CH}_2\text{Cl}_2]{\text{1) NH}_2\text{OH·HCl/C}_5\text{H}_5\text{N}} (\text{iso-PrO})_2\text{P}(\text{O})\text{CH}(\text{NO}_2)\text{R};$$

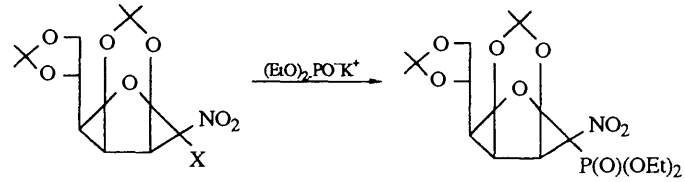
The methods of synthesis of α-nitroalkylphosphonates have been used in carbohydrate chemistry to obtain phosphorus-containing derivatives.[18] Thus (1-*C*-nitroglycosyl)phosphonate was obtained from X-nitromannofuranose and potassium diethyl phosphite.



21—67%

X = Cl, *p*-$MeC_6H_4SO_2$.

The structure of organophosphorus α-nitro-compounds has been investigated by IR and NMR spectroscopy, which made it possible to discover the specific mutual influence of the nitro- and phosphoryl groups.

The ^{31}P chemical shift for α-nitroalkyl phosphonates (δ_P = 11–12 p.p.m.) is significantly lower than for other (β, γ, δ)-nitroalkylphosphonates. This can be explained by the strongly electron-accepting influence of the nitro-group.[12]

The characteristic absorption bands in the IR spectra of α-nitroalkyl phosphonates[5,6] at 1550–1560 [$\nu_{asym}(NO_2)$] and 1330–1360 [$\nu_{sym}(NO_2)$], 1260–1270 (P=O), 1120 and 1165 (POC), and 710 cm^{-1} (P–C bond) hardly differ from those for nitroalkanes and alkylphosphonates.

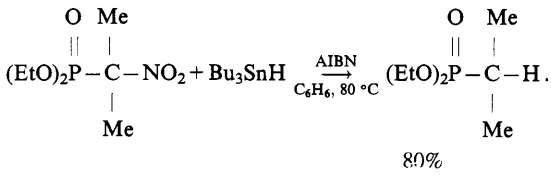
2. The chemical properties of organophosphorus α-nitro-compounds

The chemical properties of organophosphorus α-nitro-compounds are determined by their functional groups — the nitro-group and the phosphonate group. It is therefore useful to examine initially the chemical reactions associated with the nitro-group and then with the phosphonate group and finally other reactions specific to organophosphorus α-nitro-compounds.

Organophosphorus dialkyl nitro-compounds can be titrated potentiometrically in an aqueous medium with alkalis as weak monobasic acids.[6,7] Their ability to form sodium salts permits their purification via nitronic acids.[7,15]

The high CH acidity of organophosphorus α-nitroalkyl compounds is the cause of their reduced capacity for nucleophilic reactions. Thus they add with difficulty to derivatives of acrylic acid (the Michael reaction) and do not react with benzophenone.[19]

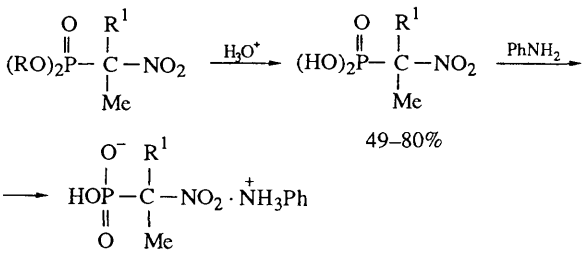
The nitro-group in tertiary organophosphorus α-nitro-compounds is readily substituted by hydrogen when the nitro-compound is treated with tributyltin hydride in the presence of azobisisobutyronitrile (AIBN).[20]



The interaction of diethyl (2,3 : 5,6-di-*O*-isopropylidene-1-nitro-α-D-mannofuranosyl)phosphonate with tributyltin hydride in the presence of AIBN leads to (2,3 : 5,6-di-*O*-isopropylidene-β-D-mannofuranosyl)phosphonate in 78% yield.[18]

Organophosphorus α-nitro-compounds are readily reduced catalytically in the presence of Raney nickel[4] and also with tin and hydrochloric acid[17] to the corresponding amino-derivatives.

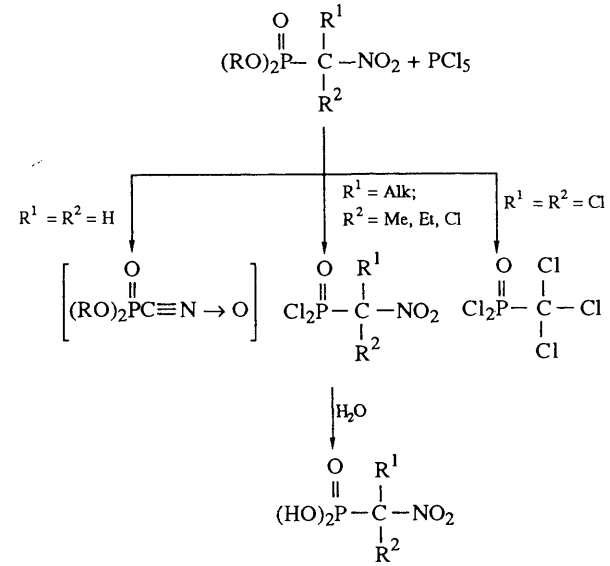
Acid hydrolysis of α-nitroalkylphosphonates not containing hydrogen atoms at the carbon atom linked to the nitro-group leads to high yields of the corresponding organophosphorus α-nitroacids, which were isolated in the form of monoanilinium salts.[6,13]



R, R^1 = Me, Et.

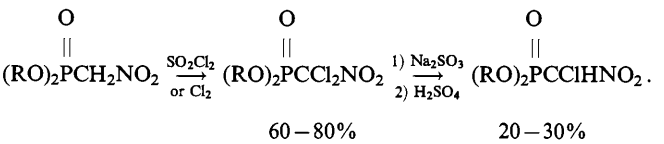
Hydrolysis of α-nitroalkylphosphonates containing hydrogen atoms at the α-carbon atom leads to their decomposition with formation of hydroxylamine hydrochloride (75%) and phosphoric acid.[7]

α-Nitroalkylphosphonates unsubstituted at the α-carbon atom, for example, diethyl nitromethylphosphonate, react with phosphorus pentachloride to form phosphonocyanidate *N*-oxide or its decomposition products, while the substituted derivative afford high yields of the hydrochlorides, which are then hydrolysed to the corresponding acids.[6,13] α-Nitroalkylphosphonates monochloro-substituted in the α-position,[21] for example, dimethyl 1-chloro-1-nitropropylphosphonate, react with phosphorus pentachloride to form the dichloride of 1-chloro-1-nitro-propylphosphonic acid in 72.5% yield. Its hydrolysis leads to the corresponding acid, which was isolated as the anilinium salt (64.8%). The interaction of dichloro-substituted diethyl nitromethylphosphonate with phosphorus pentachloride leads to the substitution not only of the alkoxy-group but also of the nitro-group by a chlorine atom, which results in the formation of the dichloride of trichloromethylphosphonic acid in 80% yield.



α-Nitroalkylphosphonates are readily brominated via the lithium salt to give the corresponding bromonitroalkylphosphonates.[5]

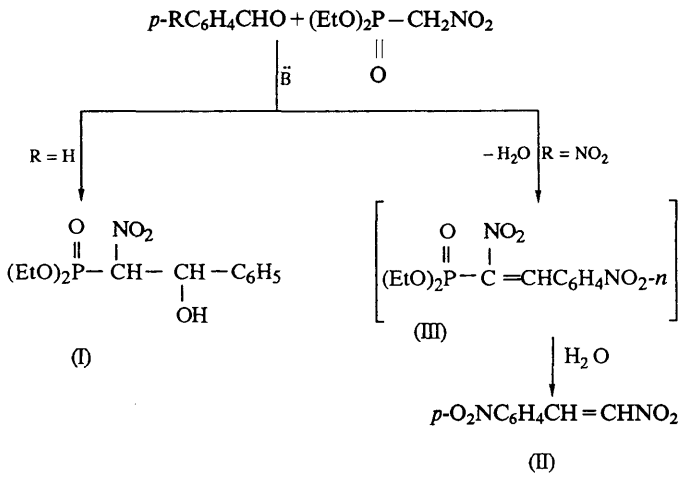
On treatment with sulphuryl chloride or chloride, the mobile hydrogen atoms in the methylene or methylidyne groups in α-nitroalkylphosphonates are substituted by a chlorine atom, which results in the formation of dichloronitroalkylphosphonates. These are readily converted into monochloro-derivatives on treatment with sodium sulphite.[21]



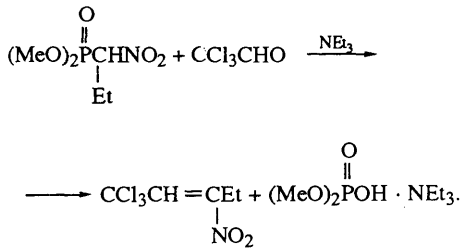
Chloronitromethylphosphonates behave in aqueous alcoholic solutions as weak monobasic acids. The IR spectra of these compounds are characterised by the presence of absorption bands at 1575 and 1350 cm^{-1} (NO_2), 1280 cm^{-1} (P=O), and 710 cm^{-1} (Cl). With increase in the number of chlorine atoms at the α-carbon atom, there is some increase in $\Delta\nu = \nu_{asym} - \nu_{sym}$ for the nitro-group: the corresponding frequencies ν_{asym} and ν_{sym} are 1560 and 1375 cm^{-1} for $(EtO)_2P(O)CH_2NO_2$, 1575 and 1350 cm^{-1} for $(EtO)_2P(O)CHClNO_2$, and 1600 and 1335 cm^{-1} for $(EtO)_2P(O)CCl_2NO_2$.

Diethyl nitromethylphosphonate reacts with benzaldehyde in the presence of piperidine to form diethyl 2-hydroxy-1-nitro-2-phenylethyl phosphonate (I) in 67% yield.[22] However, the reaction with *p*-nitrobenzaldehyde under the same or even milder conditions afforded 1-(*p*-nitrophenyl)-2-nitroethene (II) (80%). This course of the reaction is due to the presence of the electron-accepting nitro-group in the aromatic ring, which promotes the formation of the

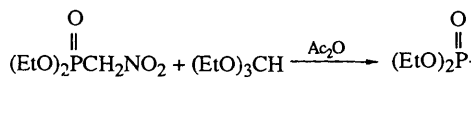
alkene (III), the latter being subsequently dephosphorylated to the more stable nitroalkene (II).



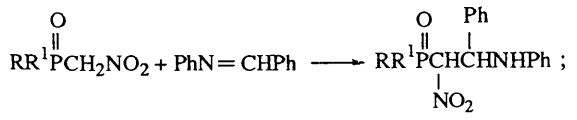
Similar elimination of the phosphonate group with formation of 1,1,1-trichloro-3-nitropent-2-ene is observed in the reaction of the highly electrophilic chloral with dimethyl 1-nitropropylphosphonate in the presence of triethylamine.[19]



Condensation of diethyl nitromethylphosphonate with triethyl orthoformate in acetic anhydride leads to diethyl 2-ethoxy-1-nitrovinylphosphonate in the form of a mixture of the (*E*)- and (*Z*)-isomers.[19]

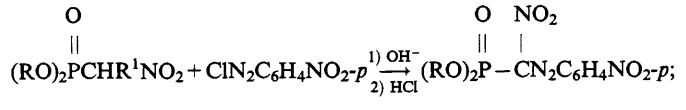


Organophosphorus α-nitro-compounds interact with benzylideneaniline in the absence of a catalyst.[19]



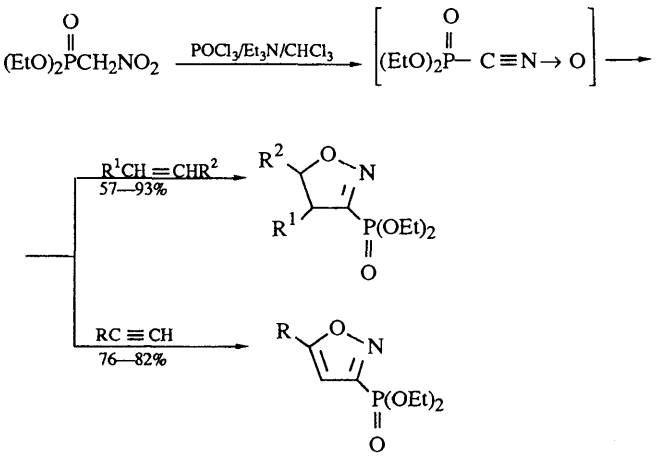
R, R^1 = OMe, OEt, Et, Ph.

α-Nitroalkylphosphonates enter into the azo-coupling reaction in an alkaline medium with *p*-nitrobenzenediazonium chloride.[19]



R = Me, Et; R^1 = H, Et.

On treatment with phosphoryl chloride in the presence of triethylamine, diethyl nitromethylphosphonate gives rise to a phosphorocyanidate *N*-oxide which at the instant of formation adds via the 1,3-dipolar cycloaddition mechanism to alkenes and alkynes with formation of the corresponding 3-diethoxyphosphoryl-4,5-dihydroizoxazoles and 3-diethoxyphosphorylisoxazoles.[23]

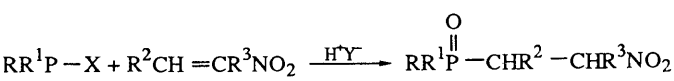


III. Organophosphorus β-nitro-compounds

1. Methods of synthesis of organophosphorus β-nitro-compounds

The study of the reactions of the full phosphites with nitroalkenes by a set of physicochemical methods demonstrated that the process proceeds via several competing pathways with formation of phosphoranes, alkenylphosphonates, β-nitroalkylphosphonates, oximes, nitriles, etc.[24]

The reactions of the full phosphites with nitroalkenes in proton-donating solvents lead mainly to organophosphorus β-nitro-compounds.[24–26]



R, R^1 = AlkO. PhO. Alk. Ph; R^2 = H. Alk. Ph;

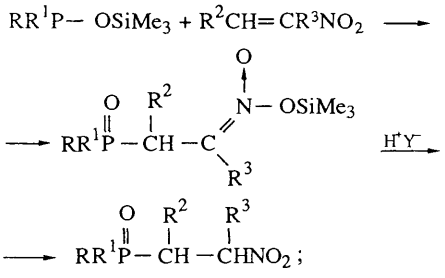
R^3 = H. Br. Et; X = AlkO; Y^- = OH^-. AcO^-.

The target products contain admixtures of α,β-unsaturated compounds. In order to reduce their content, appropriate protonating compounds and mixtures are selected: methanol,[27–29] phenol,[30] t-butyl alcohol–benzene,[31,32] water,[33,34] water–dioxane,[25,35,36] water–tetrahydrofuran,[37,38] water–dimethoxyethane,[39] acetic acid,[25] and *N*,*N*-diethylaniline hydrochloride in acetonitrile.[40]

The formation of the 1-nitroprop-1-ene radical-anion in the reaction of methyl diphenylphosphonite [methyl phenyl phenylphosphonite?] with 1-nitropropene was detected by the EPR method.[41,42] This reaction proved to be a convenient model for the determination of the thermodynamic parameters of the $P^{III} \leftrightarrows P^{V}$ equilibrium.[43]

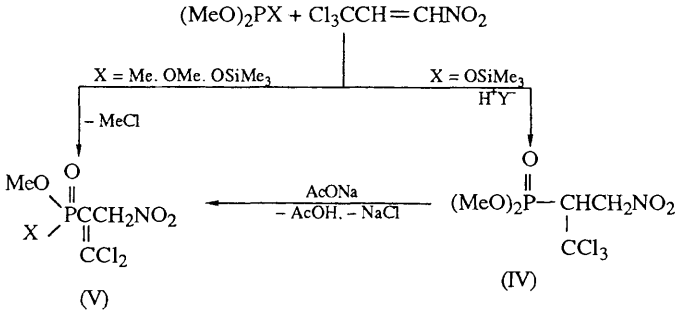
The reaction of silicon-containing derivatives of phosphorus(III) acids with nitroalkenes proved to be a more convenient method of synthesis of organophosphorus β-nitro-compounds. The first stage of this reaction involves the formation of the trimethylsilyl

esters of phosphorylated nitronic acids, which are then readily decomposed by water[34,44,45] and other proton-donating reagents (water-tetrahydrofuran,[37,38] dilute hydrochloric acid[46]).



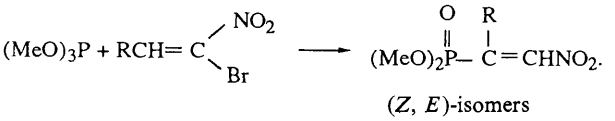
R = Alk. Ar. AlkO; R^1 = Alk; R^2 = Alk. CCl_3; R^3 = H. Br.

The reaction of the full esters of phosphorus(III) acids with 3,3,3-trichloro-1-nitroprop-1-ene proceeds under mild conditions.[47,48]



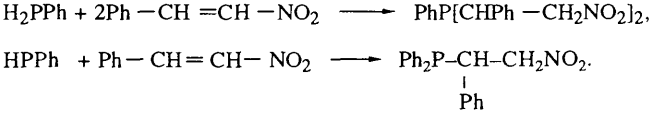
When the product of the interaction of dimethyl trimethylsilyl phosphite with 3,3,3-trichloro-1-nitroprop-1-ene[48] is treated with proton-donating reagents (water, methanol, acetic acid, and hydrogen chloride), dimethyl 2,2-dichloro-1-nitromethylvinylphosphonate (V) is formed together with dimethyl 1-trichloromethyl-2-nitroethylphosphonate (IV). This shows that the presence of the strongly electron-accepting trichloromethyl group at the α-carbon atom of the organophosphorus compound increases significantly the mobility of the α-CH proton, which is able to compete even with the trimethylsilyl group in terms of its capacity for migration. In aprotic solvents, 2,2-dichloro-1-nitromethylvinylphosphoryl derivatives (V) are formed exclusively. Since the chloride anion behaves more readily as a leaving group than the nitrite anion, in this case 1-trichloromethylvinylphosphoryl compounds are not formed. The nitro-derivative (IV) is readily dihydrochlorinated with sodium acetate in ether, affording the product (V).

(*Z*) 1-Bromo-1-nitroalk-1-enes[36,49,50] react with trialkyl phosphite to form nitroalkenylphosphonates. Thus the reaction of trialkyl phosphite with (*Z*)-1-bromo-1-nitro-3-methylbut-1-ene results in the formation of a mixture of the (*Z*)- and (*E*)-isomers of 2-nitroalkenylphosphonates and other compounds.

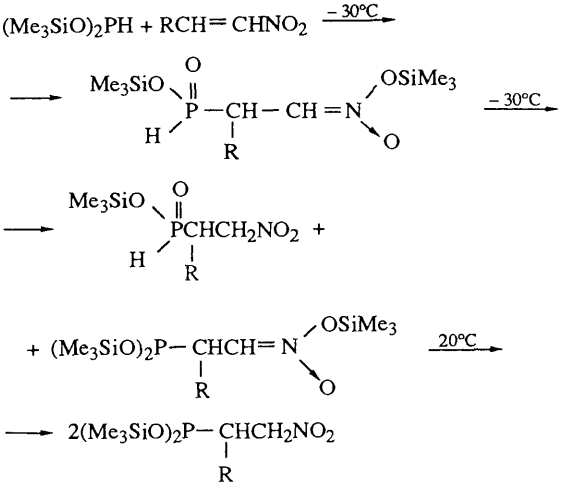


(*Z*, *E*)-isomers

One of the most thoroughly investigated methods of synthesis of organophosphorus β-nitro-compounds involves the nucleophilic addition of hydrophosphoryl compounds to conjugated nitroalkenes. Thus the interaction of phenylphosphine and diphenylphosphine with nitrostyrene leads to the formation of the corresponding di- and mono-adducts.[51]

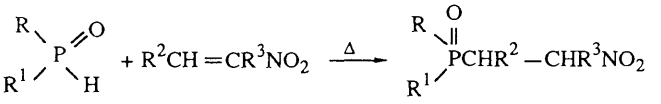


The interaction of bis(trimethylsilyl) hypophosphite with 1-nitroprop-1-ene and nitrostyrene is a multistep process. When the reaction is carried out at temperatures in the range −30 − 35 °C, trimethylsilyl 2-aci-nitroalkylphosphonites are formed. The latter are converted at room temperature into bis(trimethylsilyl) phosphonites.[52]



R = Me. Ph.

Dialkylphosphinties,[53,54] alkyl alkylphosphonates,[54] dimethyl phosphite,[54–56] and diethyl phosphite[57] add to conjugated nitroalkenes after prolonged heating at 100 °C in the absence of catalysts to form organophosphorus β-nitro-compounds.



19—96%

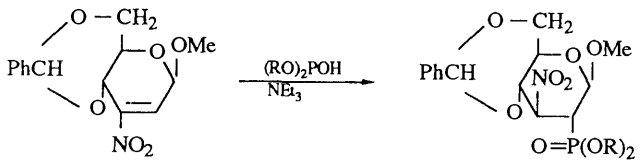
R, R^1 = Ph, $PhCH_2$, C_6H_{13}, OMe; R^2 = Me, Ph, Pr, Et, iso-Pr;

R^3 = H, Me, COOEt.

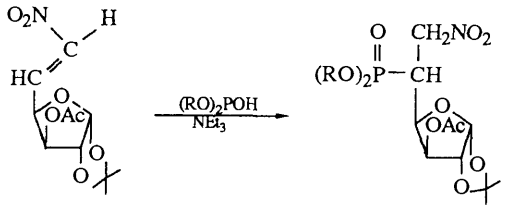
An attempt was first made to carry out this reaction in the presence of basic catalysts, but the competing polymerisation reaction of the nitroalkene reduced the yield of the organophosphorus β-nitro-compound or altogether prevented its formation.[58] The polymerisation of nitroalkenes was partly suppressed by using an excess of dialkyl phosphite and a polymerisation inhibitor.[59]

The addition of dialkyl phosphites to unsaturated nitrosugars is one of the ways of modifying the latter.[60] Phosphonites and phosphines have also been used to modify sugars.[61] Thus the addition of methyl ethylphosphonite to 3-*O*-acetyl-5,6-dideoxy-1,2-isopropylidene-6-*C*-nitro-α-D-xylohex-5-enofuranose takes place on heating at 70 − 80 °C for 7 − 10 h, the yield of the adduct being

90%. When phenylphosphine is used, monoadducts (63%) and diadducts (34%) are formed.[61]

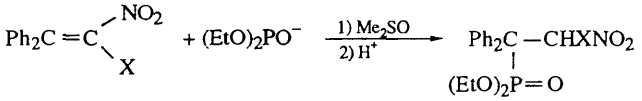


R = Me (69%); Et (3.4%)



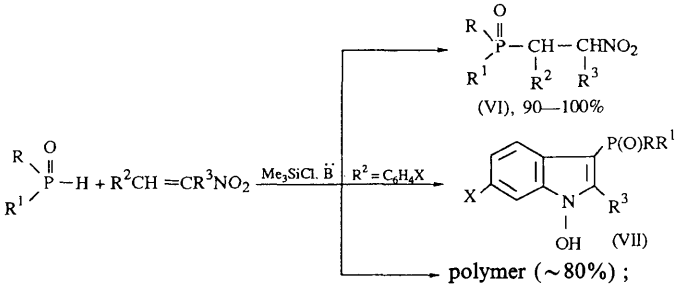
R = Me (43%); Et (3.4%)

The interaction of 1,1-dinitro-2,2-diphenylethene[62] and its derivatives[63] with one equivalent of diethyl phosphite in dimethyl sulphoxide leads to the corresponding adducts on acidification.



X = H, PhS, t-BuS, NO_2.

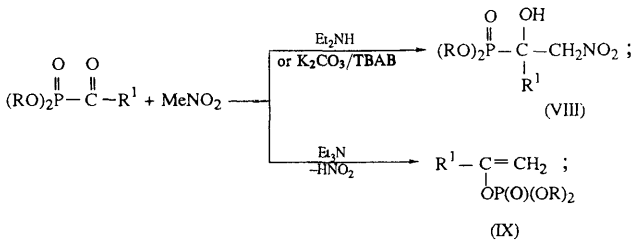
Reactions of partly esterified phosphites with nitroalkenes in the presence of trimethylsilyl chloride and a base, which proceed via a stage involving the formation of dialkyl trimethylsilyl phosphite, lead to organophosphorus β-nitro-compounds in almost quantitative yields.[64] It was later shown that, depending on the nature of the nitroalkene, the reactant ratio, and the reaction conditions, organophosphorus nitro-compounds (VI), *N*-hydroxyindoles (VII), and polymers are formed.[65,66]



R, R^1 = Alk, Ph, AlkO; R^2 = H, Alk, Ph, *p*-HOC_6H_4; R^3 = H, Me.

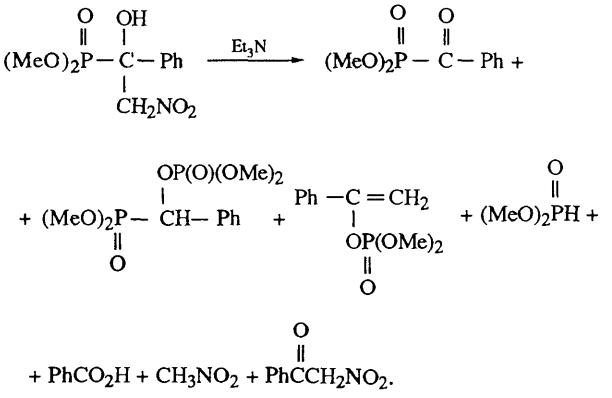
Thus polar solvents promote the formation of the organophosphorus compounds (VI). In terms of their effect on the formation of compounds (VI), the solvents can be arranged in the following sequence : DMF > Me_2CO > MeCN > CH_2Cl_2 > THF > Et_2O > C_6H_6.[65] When aromatic nitroalkenes with electron-donating substituents in the benzene ring, weakly polar solvents, and highly basic acid-binding reagent are used, the reaction proceeds mainly via the pathway leading to the formation of the indole derivative (VII). (The structure of *N*-hydroxyindoles was established by NMR spectroscopy and X-ray diffraction[65]). The formation of the polymeric adduct is promoted by inorganic bases.

The interaction of organophosphorus α-carbonyl compounds with nitroalkanes to form the corresponding organophosphorus β-nitro-compounds (VIII) takes place successfully in the presence of diethylamine and Triton B (OH)[67–69] and also under the conditions of phase transfer catalysis in the K_2CO_3–tetrabutylammonium bromide (TBAB) system.[70] When triethylamine is used, the enol phosphate (IX)—the product of the phosphonate–phosphate rearrangement of compound (VIII)—is formed preferentially.



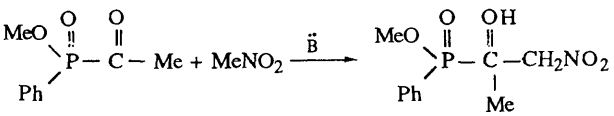
R = Me, Et, iso-Pr; R^1 = Me, Et, Pr, *m*-MeC_6H_4, *o*-MeC_6H_4, *p*-MeC_6H_4, *p*-FC_6H_4, *m*-FC_6H_4, *o*-FC_6H_4, *o*-ClC_6H_4, *p*-ClC_6H_4, $PhCH_2$, $PhCH_2CH_2$, *p*-$FC_6H_4CH_2$, C_6H_{11}.

Apart from the enol phosphate (IX), other products were also identified in the reaction mixture when the reaction was carried out in the presence of triethylamine, which indicates the reversibility of the reaction and the capacity for the cleavage of the C–C and C–P bonds in the initial compound (VIII).[70]

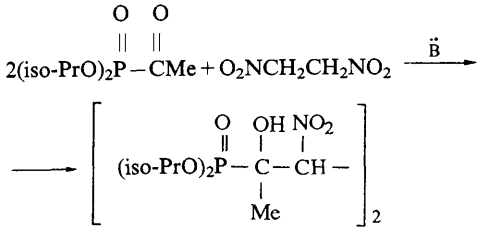


Thermographic studies showed that, in the absence of catalysts, the phosphonate–phosphate rearrangement does not occur, compound (VIII) being decomposed with rupture of the C–P bond and subsequent oxidation.[71]

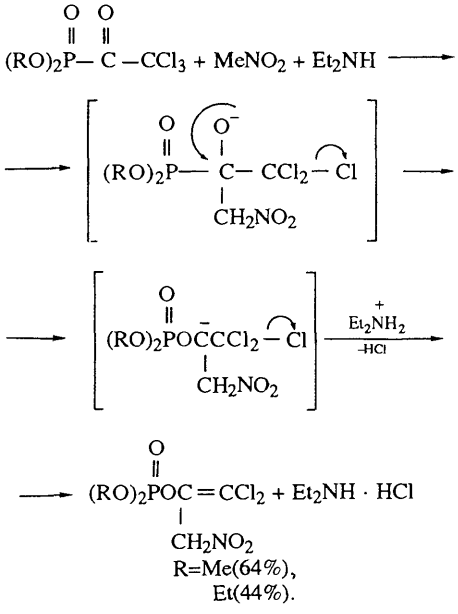
Apart from the α-carbonyl derivatives of phosphonates, acylphosphinates also react with nitroalkanes. Thus the reaction of nitromethane with methyl acetyl(phenyl)phosphinate affords methyl 2-hydroxy-1-nitropropyl(phenyl)phosphinate.[72]



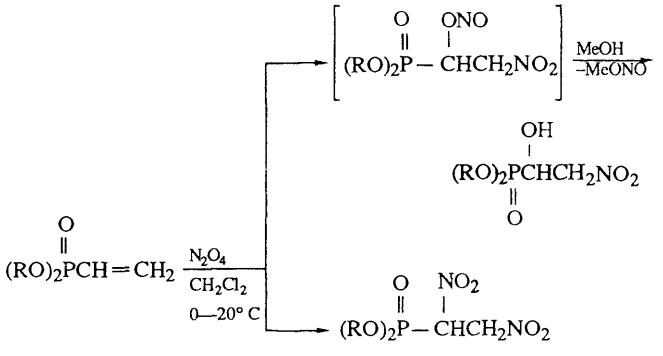
The vicinal dinitroethane reacts with diisopropyl acetylphosphonate in any molar proportions to form only the diadduct.[73]



The reaction of trichloroacetylphosphonate with nitromethane[74] affords the products of the phosphonate–phosphate rearrangement — dialkyl 2,2-dichloro-1-nitromethylvinyl phosphates.



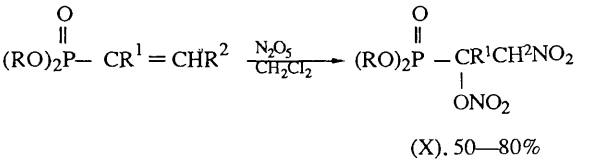
Nitration of unsubstituted vinylphosphonates with dinitrogen tetroxide leads predominantly to dialkyl 1-hydroxy-2-nitroethylphosphonates and dialkyl 1,2-dinitroethylphosphonates in a very low yield.[75,76]



R = Me, Et, iso-Pr, CH_2CH_2Cl.

Alkyl-substituted vinyl phosphonates could not be nitrated.

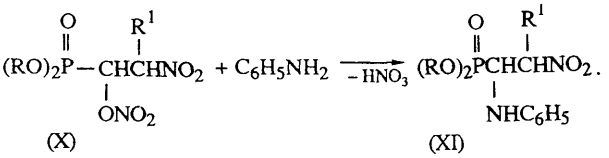
Dinitrogen pentoxide interacts with vinylphosphonates to form the relatively unstable dialkyl 2-nitro-1-nitroxyalkylphosphonates (X).[77] Certain alkyl-substituted vinylphosphonates also enter into this reaction.



(X). 50—80%

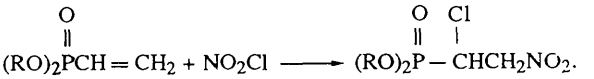
R = Me, Et, iso-Pr, CH_2CH_2Cl' R^1 = H, Me; R^2 = H, Ph.

In the nitration of dimethyl-2-phenylvinylphosphonate with dinitrogen pentoxide, the nitro-group adds to the β-position (δ_P = 21 p.p.m.) , in contrast to its nitration with dinitrogen tetroxide.[77] Compounds (X) react with aniline to form the stable crystalline products (XI):[77]



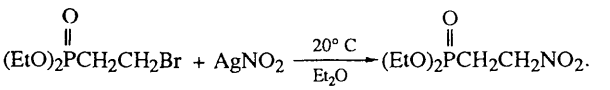
The reaction apparently proceeds via the intermediate formation of nitroalkenes.

The reaction of nitrosyl chloride with dialkyl vinylphosphonate results in the formation of 1-chloro-2-nitroalkylphosphonates.[78]



It is noteworthy that the interaction of nitrosyl chloride with the dichlorides of α-chloro-β-ethoxy- and β-chloro-β-ethoxy-vinylphosphonates and their full esters takes place in a complex manner and does not lead to organophosphorus nitro-compounds.[79]

2-Nitroethylphosphonates are also obtained by Kornblum's method from 2-bromoethylphosphonate and silver nitrite.[80]



2. The structure of organophosphorus β-nitro-compounds

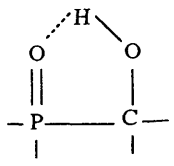
The structure of organophosphorus β-nitro-compounds has been investigated by IR and NMR spectroscopy and by X-ray diffraction.

The ^{31}P chemical shift for β-nitroalkylphosphonates (δ_P = 17–22 p.p.m.) is greater than for α-nitroalkylphosphonates (δ_P = 11–12 p.p.m.), which indicates a decrease in the influence of the nitro-group on the magnetic characteristics of the phosphorus atom.

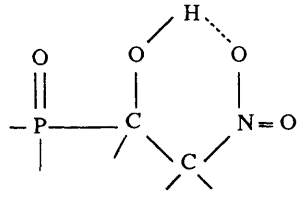
The absorption bands of the nitro- and phosphoryl groups in the IR spectra of organophosphorus β-nitro-compounds do not differ from the analogous bands in the spectra of organophosphorus and nitro-compounds.

The stereochemistry of α-aryl-β-nitroalkylphosphinates has been studied in greater detail.[66] The compounds were separated by recrystallisation into two pairs of diastereoisomers and the structure of each pair was determined by X-ray diffraction.

The structure of the organophosphorus β-nitroalcohols was also of theoretical interest. On the basis of their geometrical structure, one may postulate the formation of two types of hydrogen bonds: via the phosphoryl oxygen with closure of a five-membered ring [structure (A)] and via the oxygen of the nitro-group with closure of a six-membered ring [structure (B)].

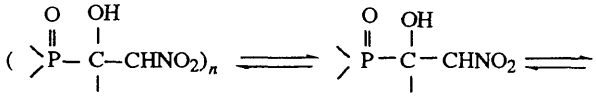


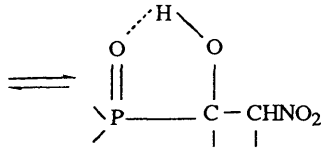
(A)



(B)

It has been shown by IR spectroscopy[81] that in the solid state β-nitro-alcohols form intermolecular hydrogen bonds [ν(OH) = 3220–3280 cm^{-1}] between the OH and P=O groups, whereas in solution an equilibrium is established between the free [ν(OH) = 3550 cm^{-1}] and associated molecules of the phosphonates.





In inert solvents, organophosphorus nitroalcohols form an intramolecular hydrogen bond via the oxygen of the phosphoryl group [structure (A)] with a very low interaction energy in the five-membered phosphorus-containing ring.

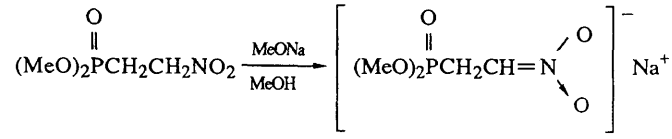
A hindered *gauche*-conformation with a transoid orientation of the phosphoryl and nitro-groups has been established for tertiary organophosphorus nitroalcohols by NMR. It is stable in the temperature range from −40 °C to 100 °C in various solvents.[12]

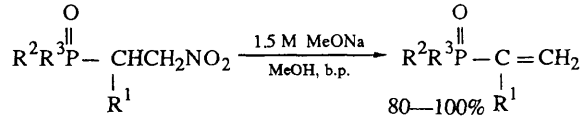
3. Chemical properties of organophosphorus β-nitro-compounds

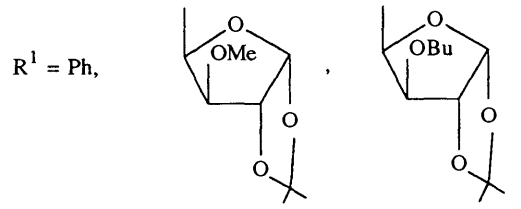
It is natural to expect that chemical reactions involving the nitro-, phosphoryl, and other functional groups as well as isomerisation processes and reactions involving cleavage at the C–P bond are characteristic of organophosphorus β-nitro-compounds.

(a) Reactions with participation of the nitro-group

2-Nitroethylphosphonates are converted into sodium nitronates in the reaction with sodium methoxide in methanol at room temperature,[31] whilst on boiling they afford the corresponding vinylphosphonates, vinylphosphinates, and vinylphosphine oxides.[82]



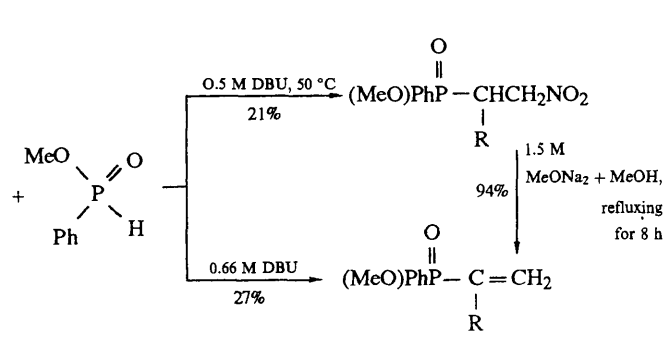


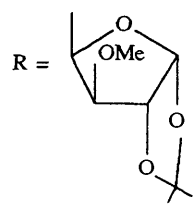


R^2, R^3 = OMe. Ph.

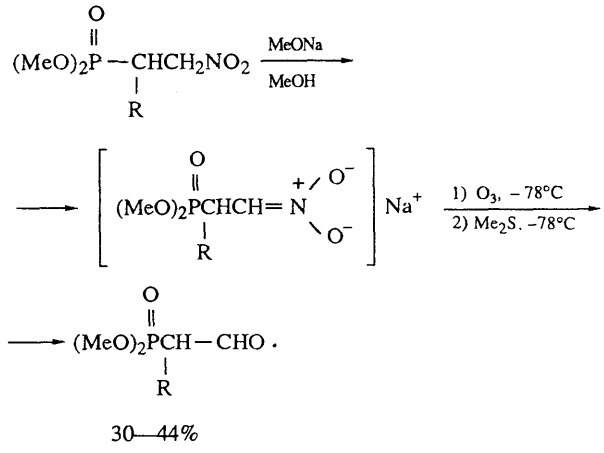
Proton exchange in the sodium methoxide–methanol system has been observed by the ^1H NMR method. It was demonstrated unambiguously that only the hydrogen atom at the β-carbon atom is acidic, whereas this was not observed for the hydrogen atoms at the α-carbon atom.[31]

Nitrovinyl-containing sugars have been converted into vinyl-substituted phosphorus-containing sugar derivatives either by the addition of the hydrophosphoryl compound in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) followed by denitration with sodium methoxide or by heating the initial reactants at 60 °C in the presence of DBU.[82]



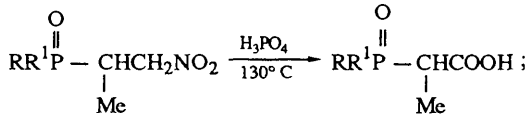


Treatment of sodium nitronate with ozone at −78 °C leads to the corresponding aldehyde:[55,56]



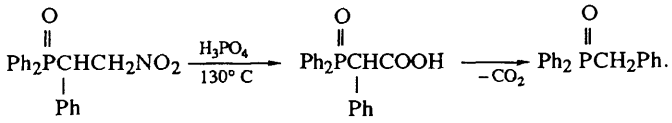
30—44%

When 2-nitroalkylphosphine oxides are heated to 130 °C with 85% orthophosphoric acid, the nitro-group is readily converted into a carboxy-group.[53]

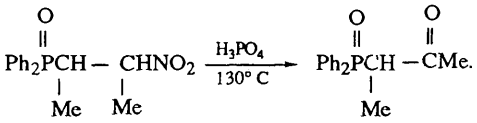


R, R^1 = Ph, $PhCH_2$, C_6H_{13}.

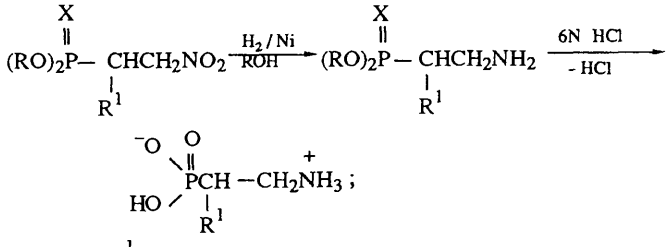
In the presence of a phenyl substituent at the α-carbon atom, the carboxy-group formed on treatment with orthophosphate decarboxylates under the reaction conditions. Thus benzylidiphenylphosphine oxide is formed from β-nitro-α-phenylethyl(diphenyl)phosphine oxide.[53]



The nitro-group in β-alkyl-substituted 2-nitroalkylphosphine oxides is converted into a keto-group under analogous conditions.[53]

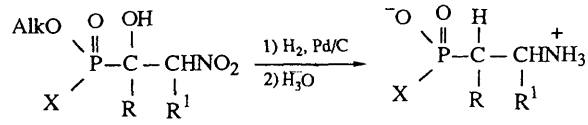


Organophosphorus β-nitro-compounds are reduced with hydrogen in the presence of the Raney nickel catalyst.[59,83,84] Subsequent acid hydrolysis of the 2-amino-derivatives leads to the corresponding aminoacids.



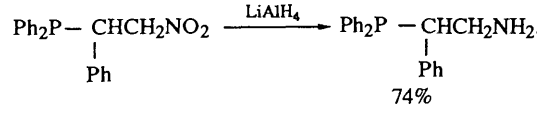
R = Alk; R^1 = Alk, Ph; X = O, S.

The reduction of 1-hydroxy-2-nitroalkylphosphonates with hydrogen in the presence of Raney nickel is accompanied by their partial decomposition at the C—P and C—C bonds.[72,85] Hydrogenation on palladium catalysts[72,86] or on Raney nickel in the presence of acetic acid[87] is more suitable. The reduction products are either isolated as picrates or are converted by acidic hydrolysis into the corresponding acids.[72,86–88]

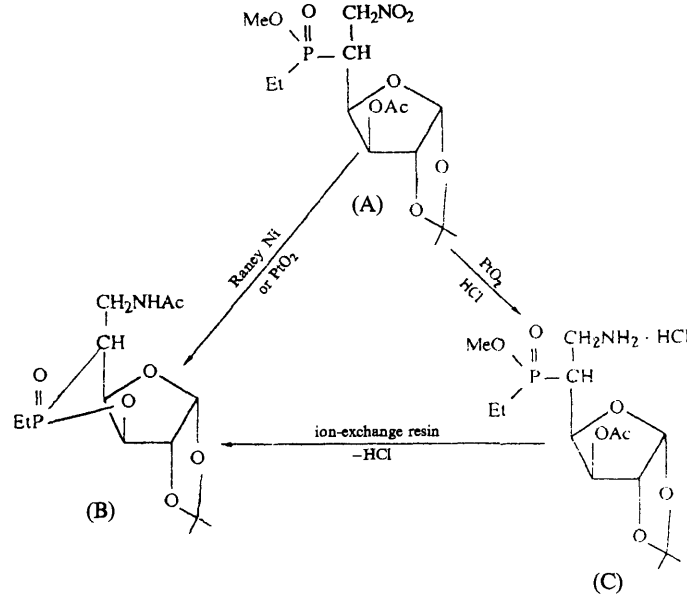


R, R^1 = Alk, Ph; X = OAlk, OH, Ph.

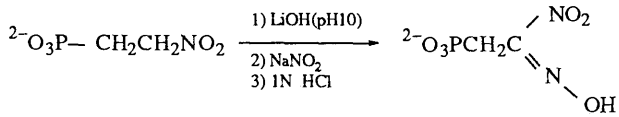
Lithium tetrahydroaluminate reduces 2-nitro-1-phenylethyl(diphenyl)phosphine to the corresponding amine.[51]



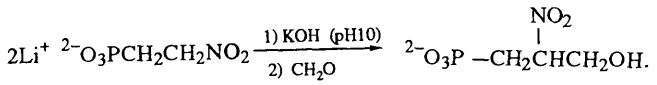
However, in the reduction of nitrosugars—for example, 3-*O*-acetyl-5,6-dideoxy-5-*C*-[ethyl(methoxy)phosphinyl]-1,2-*O*-isopropylidene-6-*C*-nitro-α-D-glucofuranose (A)—with lithium tetrahydroaluminate or with sodium dihydrobis(2-methoxyethoxy)aluminate (SDMA), the sugar derivatives are decomposed. The reduction of compound (A) with hydrogen in the presence of Raney nickel affords a 69% yield of crystalline 6-acetamido-5-(3-*O*-cyclophosphinato)-5,6-dideoxy-1,2-*O*-isopropylidene-α-*D*-glucofuranose (B). In order to rule out cyclisation and the transfer of the acetyl group, compound (A) is reduced in the presence of hydrochloric acid in methanol using platinum oxide as the catalyst. The latter reaction leads to the formation of the unstable hydrochloride of 3-*O*-acetyl-6-amino-5,6-dideoxy-5-*C*-[ethyl(methoxy)phosphinyl]-1,2-*O*-isopropylidene-α-D-glucofuranose (C) in 80% yield. When compound (C) is treated with an ion-exchange resin in methanol, it is converted into compound (B).[61]



2-Phosphonoethylnitronic acid can be obtained by Mayer's method—by treating 2-nitroethylphosphonic acid with sodium nitrite at pH 10 (lithium hydroxide) on ice with subsequent slow acidification with 1 M solution of hydrochloric acid.[80]

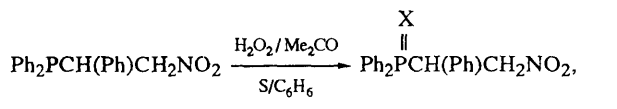


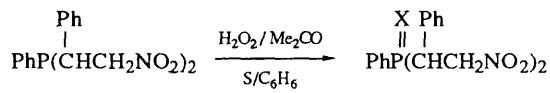
The lithium salt of 2-nitroethylphosphonic acid combines with two equivalents of formaldehyde at pH 10, affording 3-hydroxy-2-nitropropylphosphonic acid.[80]



(b) Reactions of the phosphorus-containing group

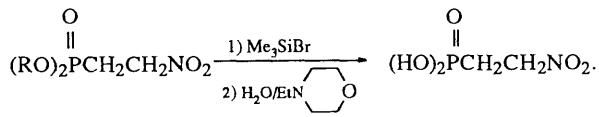
β-Nitro-derivatives of trivalent phosphorus are readily oxidised by a solution of hydrogen peroxide in acetone to *P*-oxides or are converted into *P*-sulphides on treatment with sulphur in benzene.[51]





X = O, S.

Dialkyl 2-nitroalkylphosphonate can be converted into the free acid by treatment with bromotrimethylsilane and subsequent hydrolysis of the resulting bis(trimethylsilyl) 2-nitroethylphosphonate with 0.5 M solution of *N*-ethylmorpholine.[80]



After the neutralisation of the reaction mixture with 1 M HCl solution, 85% of the nitro-groups remain unhydrolysed.

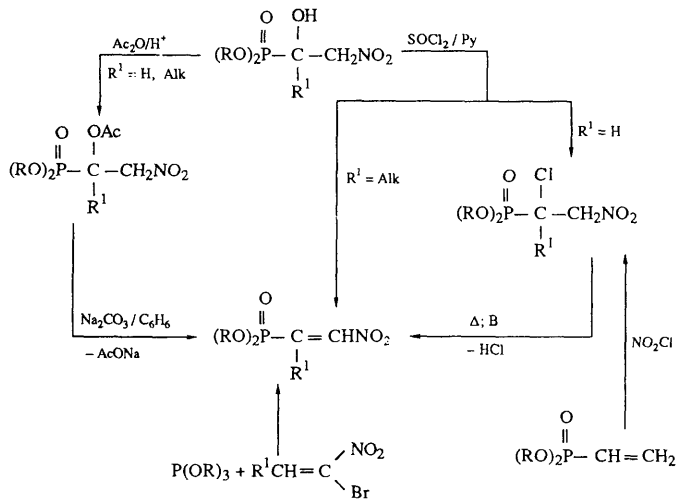
(c) Other reactions

The synthesis and properties of 2-nitrovinylphosphonates. The first representatives of 2-nitrovinylphosphonates were synthesised by deacetylating the acetyl derivatives of organophosphorus nitroalcohols[68] and by dehydrohalogenating 1-chloro-2-nitroalkylphosphonates.[78] Several representatives of 1-alkyl-substituted nitrovinylphosphonates have been obtained by the reaction of trialkyl phosphites with conjugated *gem*-bromonitroalkenes.[36,50]

The present authors investigated in detail the possibilities of the synthesis of 2-nitroalkenylphosphonates from organophosphorus nitroalcohols and nitronitrates.[89]

Direct dehydration of β-nitroalcohols with diphosphorus pentoxide or phthalic anhydride proved to be impossible owing to the low strength of the C–P bond. The acetyl derivatives of β-nitroalcohols are therefore formed initially, their deacetylation occurring readily in inert solvents in the presence of sodium carbonate.[68]

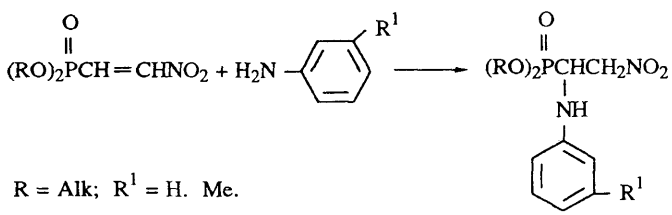
Thionyl chloride reacts with tertiary organophosphorus nitroalcohols in the presence of pyridine, affording satisfactory yields of nitrovinylphosphonates, while its reaction with secondary organophosphorus nitroalchols gives rise to 1-chloro-2-nitroalkylphosphonates which are isolated by column chromatography. On the other hand, chloronitroalkylphosphonates split off hydrogen chloride during distillation and on treatment with organic bases, forming the corresponding nitrovinylphosphonates in a low yield.[89]



It has been shown by ^{1}H and ^{31}P NMR spectroscopy that 2-nitrovinylphosphonates give rise predominatly to the (*E*)-isomers.

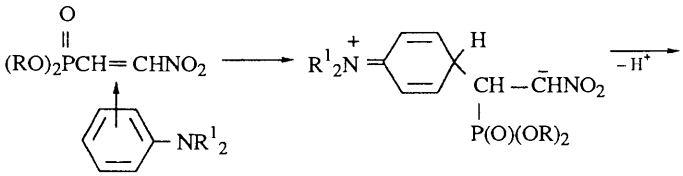
Nucleophilic reactions of 2-nitrovinylphosphonates. Condensation of 2-nitrovinylphosphonates with many nucleophiles and their involvement in the diene synthesis[90] have expanded their synthetic possibilities.

Aromatic amines (aniline, *m*-toluidine) readily add to 2-nitrovinylphosphonate in acetic acid, affording the corresponding products in satisfactory yields.[90]

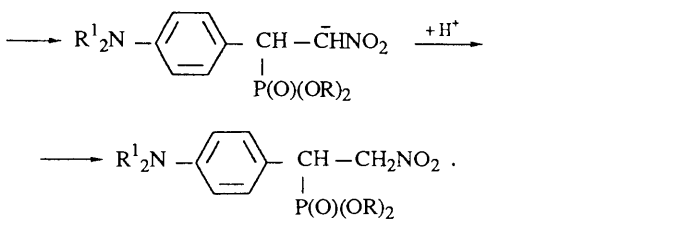


R = Alk; R^1 = H, Me.

It has been observed that 2-nitrovinylphosphonates are arylated by *N,N*-dialkylanilines.[90]

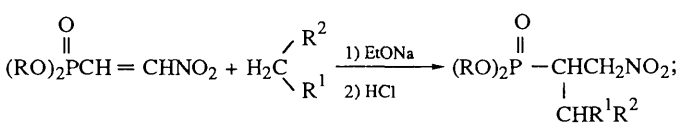


π-complex σ-complex



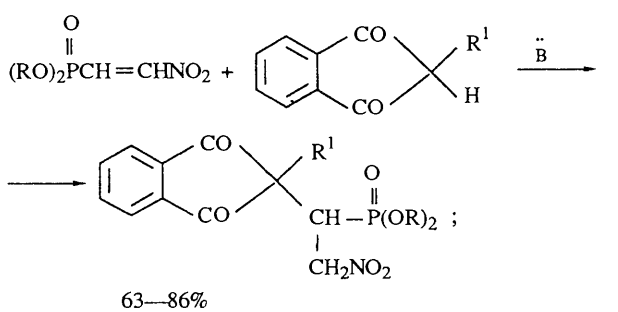
The reaction apparently proceeds via stages involving the formation of π- and σ-complexes.

The general mechanism of the addition of aliphatic CH acids to nitrovinylphosphonates can be represented as follows:[90,91]



R = Alk; R^1. R^2 = H. COOAlk. CN. NO_2. C(O)Me.

The conditions for the addition of β-diketones to 2-nitrovinylphosphonates depend on the structure of the β-diketones.

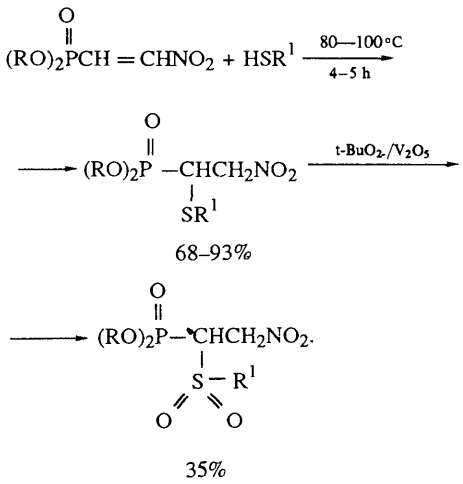


63—86%

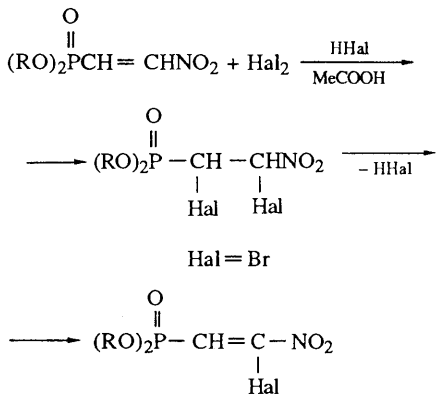
R = Alk; R^1 = H, Ph, *p*-$MeOC_6H_4$, MeCO.

It has been established[90,92] that β-diketones which do not enolise in their usual state (indan-1,3-dione, 2-phenylindan-1,3-dione, 2-anisylindan-1,3-dione, and 2-acetylindan-1,3-dione) react with 2-nitrovinylphosphonate in aprotic solvents (benzene) in the presence of triethylamine, i.e. under conditions suppressing enolisation according to Mayer's inverse rule,[93] whereas enolisable β-diketones (dimedone, barbituric acid) react in the presence of sodium ethoxide in ethanol, i.e. under conditions promoting enolisation in conformity with Mayer's inverse rule.

Alkanethiols interact with organophosphorus nitroalkenes on heating in a sealed tube.[90,94] The reaction apparently proceeds via a radical mechanism. The organophosphorus nitrosulphides formed as a result are oxidised to the corresponding sulphones by t-butyl peroxide in the presence of divanadium pentoxide.



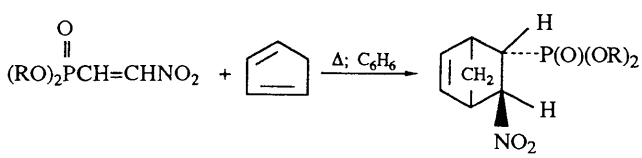
The increased nucleophilicity of the double bond in 2-nitrovinylphosphonates permits their halogenation only under the conditions of nucleophilic addition, namely in acetic acid in the presence of a hydrogen halide as the catalyst.[90]



Hal = Cl. Br.

In the bromination of an organophosphorus nitroalkene, it is possible to obtain in the first stage an adduct, which after isolation and during storage is gradually converted into a bromonitroalkenylphosphonate. However, on chlorination of the nitroalkene, the intermediate could not be isolated.

The reaction with cyclopentadiene takes place stereospecifically for 2-nitrovinylphosphonate with retention of the(*E*)-configuration.[91]



IV. Organophosphorus γ-nitro-compounds

Organophosphorus γ-nitro-compounds are interesting as precursors of phosphonic analogues of γ-aminobutyric acid, which exhibit a broad spectrum of biological activity.[95]

1. Synthesis of organophosphorus γ-nitro-compounds

The addition of nitryl chloride to diethyl allenylphosphonate and subsequent dehydrochlorination of the adduct with triethylamine lead to nitroallenylphosphonate.[78]

$$(EtO)_2P(O)CH_2CH{=}CH_2 + NO_2Cl \longrightarrow (EtO)_2P(O)CH_2CHClCH_2NO_2 \xrightarrow{Et_3N} (EtO)_2P(O)CH_2CH{=}CHNO_2$$

53.8%

Nitromethane adds to vinylphosphonates under the conditions of the Michael reaction with formation of mono-, di-, and tri-adducts. The monoadduct was obtained by the reaction of nitromethane with diethylvinylphosphonate.[96,97] However, di-(2-chloroethyl) vinylphosphonate reacts with nitromethane to form predominantly di- and tri-adducts, which were isolated by column chromatography.[90]

$$(RO)_2P(O)-CH{=}CH_2 + MeNO_2 \xrightarrow{\ddot{B}} \left[(RO)_2P(O)CH_2CH_2\right]_n CH_{(3-n)}NO_2$$

R = Et. n = 1 (37%); R = CH_2CH_2Cl. n = 2 (70%); n = 3 (9%).

Diethyl 1-cyanovinylphosphonate also combines actively with nitroalkanes under the conditions of the Michael reaction.[98]

$$(EtO)_2P(O)-C(CN){=}CH_2 + RR^1CHNO_2 \longrightarrow (EtO)_2P(O)-CH(CN)-CR^1(NO_2)-R;$$

R, R^1 = H, Me.

Trinitromethane reacts with diethyl vinylphosphonate in ether without a catalyst at room temperature.[99]

$$(EtO)_2P(O)-CH{=}CH_2 + HC(NO_2)_3 \longrightarrow (EtO)_2P(O)CH_2CH_2C(NO_2)_3.$$

Nitroacetic ester reacts with vinyl phosphonates under the conditions of the Michael reaction, affording either mono- and di-adducts or dihydroisoxazole depending on the nature of the aklkoxy-substituents at the phosphoryl and carbonyl groups.[90]

$$(RO)_2P(O)CH{=}CH_2 + CH_2(NO_2)COOR^1 \xrightarrow{\ddot{B},\ -H_2O} [(RO)_2P(O)CH_2CH_2]_n CH_{(2-n)}(NO_2)COOR^1;$$

$$(RO)_2P(O)-CH(CH_2)-C(=N)-COOR^1;$$

n = 1. 2;

R = R^1 = Et.

Triethyl phosphonacetate adds to 1-nitroalkenes in the presence of bases to form organophosphorus γ-nitro-compounds.[58,59]

$$(EtO)_2P(O)CH_2COOEt + RCH{=}CHNO_2 \xrightarrow{\ddot{B}} (EtO)_2P(O)CH(R)-CHCH_2NO_2-COOEt;$$

R = Me, iso-Pr.

The interaction of triethyl phosphonacetate with *p*-di(β-nitrovinyl)-benzene leads to a crystalline diadduct.[100]

$$O_2NCH{=}CHC_6H_4CH{=}CHNO_2 + (EtO)_2P(O)CH_2COOEt \xrightarrow{\ddot{B}}$$

$$\longrightarrow O_2NCH_2-CH(EtOOC-CH(P(O)(OEt)_2))-C_6H_4-CH(CH-COOEt)-CH_2NO_2$$

As a weak CH acid, dimethyl methylphosphonate reacts with nitroalkenes only in the presence of a superbase—lithium diisopropylamide.[101]

$$(MeO)_2P(O)-Me \xrightarrow[2)\ ClC_6H_4-CH{=}CHNO_2]{1)\ LDA/THF/\ -78\ ^\circ C} (MeO)_2P(O)CH_2CH(C_6H_4Cl)CH_2NO_2$$

71%

Methoxycarbonylmethylenetriphenylphosphorane (a CH acid) reacts with conjugated nitroalkenes at 90 °C to form ylides—methoxycarbonylalkylidenetriphenylphosphoranes.[102,103]

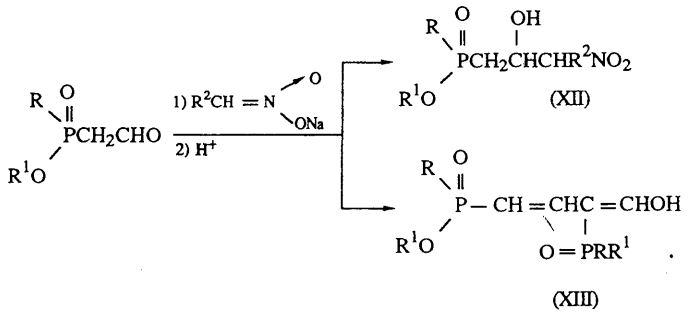
$$Ph_3P{=}CHCO_2Me + R(H)C{=}C(NO_2)R^1 \longrightarrow$$

$$\longrightarrow Ph_3P{=}C(CO_2Me)-CH(R)-CH(R^1)NO_2 \underset{Na_2CO_3}{\overset{Br_2}{\rightleftharpoons}}$$

$$\rightleftharpoons Ph_3P^+-C(Br^-)(Br)-CH_2-CH(NO_2)-CH_3(CO_2Me).$$

The preferential formation of ylides rather than a phosphonium salt in this reaction has been demonstrated by bromination.

Organophosphorus β-aldehydes react with nitroalkanes in the presence of bases to form β-hydroxy-γ-nitro-derivatives (XII), which were isolated by molecular distillation.[104] The reaction is accompanied by aldol self-condensation to compound (XIII).



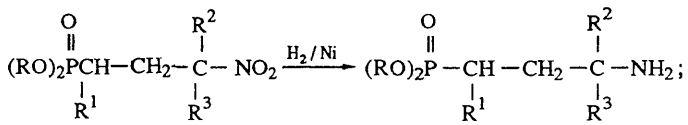
(XIII)

Organophosphorus γ-nitroalcohols (XII) form associated species characterised in the IR spectra by an OH absorption band in the range 3229–3267 cm^{-1}. On dilution with non-polar solvents and also on raising the temperature, the associated species decompose into monomers with intramolecular OH...O=P [ν(OH) = 3320–3400 cm^{-1}] and OH...O_2N [ν(OH) = 3488–3550 cm^{-1}] hydrogen bonds.

2. Chemical reactions of organophosphorus γ-nitro-compounds

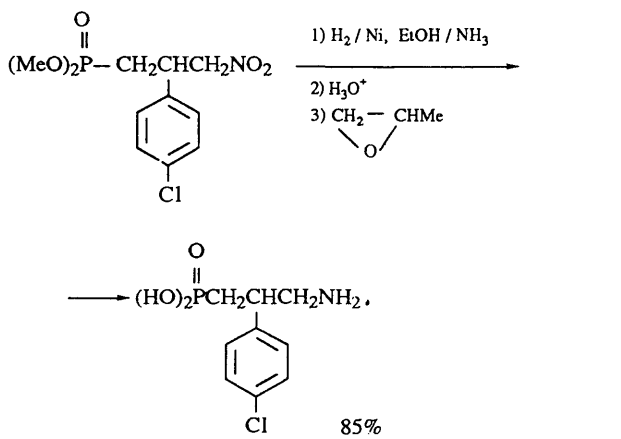
The chemical reactions of organophosphorus γ-nitro-compounds are predominantly reduction reactions.

Amino-derivatives are obtained by hydrogenating nitro-compounds in the presence of Raney nickel. In most cases they were isolated as the picrates.[83]



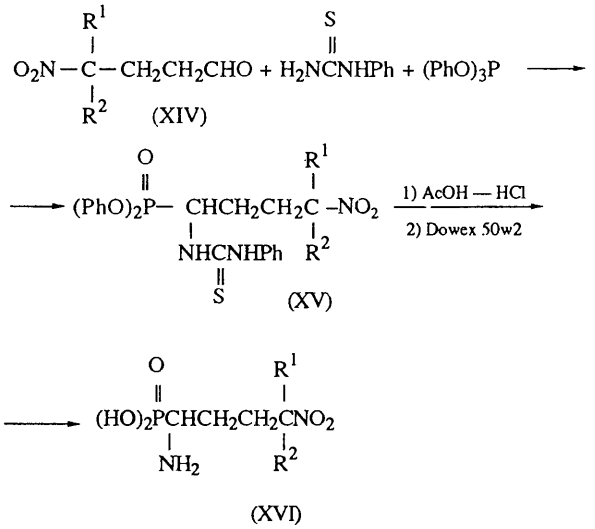
R = Et; R^1 = H, CN; R^2 = H, Me; R^3 = H, Me.

3-Aminopropylphosphonic acid was synthesised by condensing nitromethane with diethyl vinylphosphonate and subsequent reduction and hydrolysis.[97] (±)-3Amino-2-(4-chlorophenyl)propylphosphonic acid (phaclofen)—an antagonist of γ-aminobutyricacid (GABA)—is obtained similarly from the adduct resulting from the addition of dimethylmethylphosphonate to β-nitrostyrene.[101]



V. Organophosphorus δ-nitro-compounds

The condensation of nitroaldehydes (XIV) with triphenyl phosphite and phenylthiourea followed by decomposition of complexes (XV) by acid hydrolysis leads to α-amino-δ-nitroalkylphosphonic acids (XVI).[105]

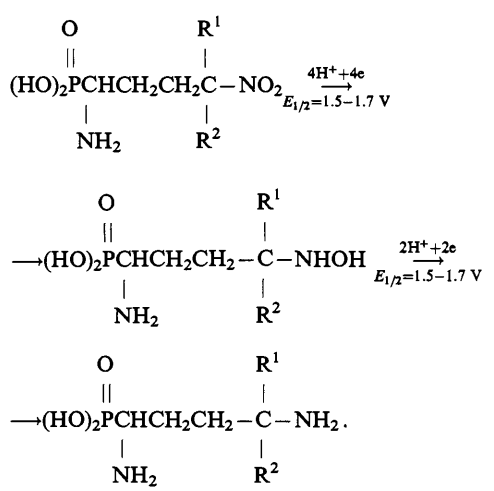


(XVI)

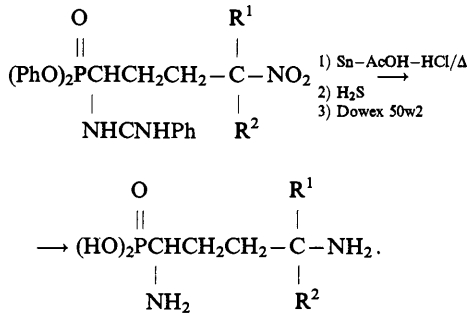
Compound	R^1	R^2	Yield of (XV), %	Yield of (XVI), %
a	H	H	72	10
b	Me	H	75	10
c	Me	Me	70	60

The acid hydrolysis of the nitro-compound (XVc), which contains no hydrogen atoms in the *gem*-positions relative to the nitro-group, takes place more successfully (60%). The hydrolysis of other nitro-derivatives is apparently accompanied by the Nef reaction.

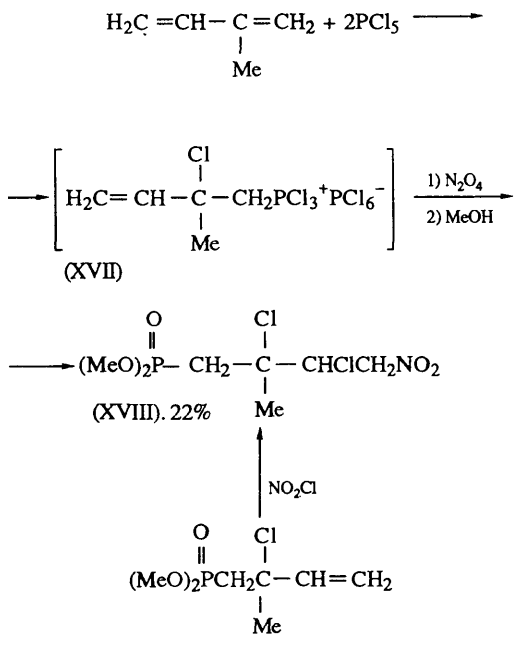
Compound (XVI) is reduced electrochemically initially to α-amino-δ-hydroxyamino-derivatives and then to α, δ-diaminoalkylphosphonic acids.[105]



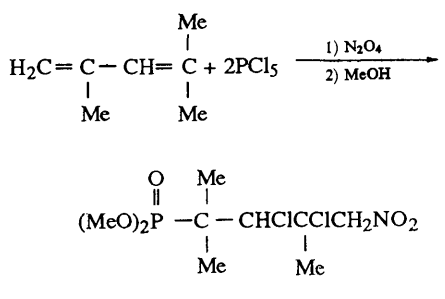
The reduction of diphenyl phosphonates (XV) with tin in the presence of acetic and hydrochloric acids affords in one stage α, δ-diaminoalkylphosphonic acids.[105]



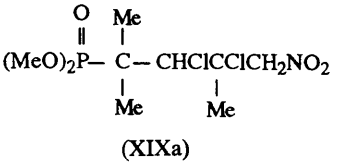
The decomposition with dinitrogen tetroxide of the complex between phosphorus pentachloride and isoprene (XVII) at 0 °C in an inert solvent with subsequent esterification is completed by the synthesis of dimethyl 2,3-dichloro-2-methyl-4-nitrobutylphosphonate (XVIII).[106–108] The structure of the product (XVIII) was confirmed by unambiguous synthesis.



The complex of 2,4-dimethylpenta-1,3-diene and phosphorus pentachloride reacts with dinitrogen tetroxide under analogous conditions to form dimethyl 3,4-dichloro-2,4-dimethyl-5-nitropentylphosphonate (XIXa).[107]

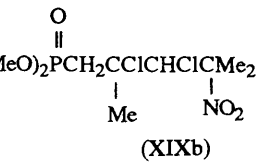


The δ_P = 16 p.p.m. signal in the ^{31}P NMR spectrum of the product (XIXa) confirms the postulated structure. On the other hand, nitrochlorination with nitryl chloride of the ester obtained form 2,4-dimethylpenta-1,3-diene and PCl_5 affords a mixture of the isomers (XIXa) and (XIXb) according to ^{31}P NMR data.



(XIXa)

δp = 16 p.p.m.

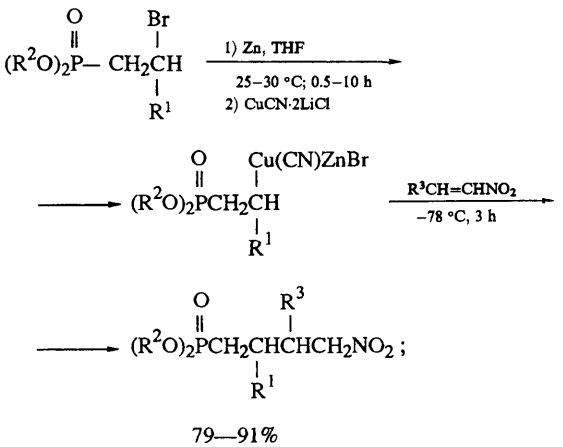


(XIXb)

δp = 26 p.p.m.

The formation of one isomer in the first case can be explained by the greater stability of compound (XIXa), containing a tertiary phosphonate group, in the stage involving the decomposition of the complex with dinitrogen tetroxide.

Certain zinc- and copper-containing β-metal-substituted alkylphosphonates also give rise to organophosphorus δ-nitro-compounds on reaction with nitroalkenes.[109]



79—91%

R^2 = H, Me, Et, Pr; R^1 = Me, Et; R^3 = Pr, Ph.

VI. Conclusion

Analysis of data on aliphatic organophosphorus nitro-compounds shows that the relative positions of the phosphoryl and nitro-groups influence significantly the choice of reactions for the synthesis of such compounds and also determine their chemical properties. Thus organophosphorus α-nitro-compounds are obtained by nitrating the corresponding alkoxyvinylphosphonates with acetyl nitrate, while organophosphorus β-nitro-compounds are obtained by nitrating vinylphosphonates with dinitrogen tetroxide or pentoxide.

It has been established that trivalent phosphorus (P^{III}) compounds can scarcely be used for the synthesis of organophosphorus α-nitro-compounds, whereas the reactions of dialkyl and trialkyl phosphites with conjugated nitroalkenes have been used successfully to synthesise organophosphorus β-nitro-compounds. Reactions involving addition to 2-nitrovinylphosphonates are of special interest for the synthesis of various organophosphorus β-nitro-compounds containing functional-group substituents. The high electrophilicity of 2-nitrovinylphosphonates is manifested by their ability to alkylate *N,N*-dialkylanilines in the *para*-position in the aromatic ring.

Organophosphorus γ-nitro-compounds are obtained as a rule by the nucleophilic addition of nitroalkanes to vinylphosphonate or of phosphorus-containing CH acids to nitroalkenes. Only specific reactions are used for the synthesis of organophosphorus δ-nitro-compounds, for example, the reaction of nitroaldehydes with triphenyl phosphite and phenylthiourea.

Among all types of organophosphorus nitro-compounds, only α,α-disubstituted α-nitroalkylphosphonates readily withstand acid hydrolysis and conversion into acid chloride on treatment with phosphorus pentachloride. The capacity of aliphatic organophosphorus nitro-compounds for reduction opens a new way to the synthesis of aminoalkylphosphonic acids with functional-group substituents which are difficult to obtain otherwise but are of interest as biologically active compounds.
