Current questions concerning the theory of highly excited vibrational states

V B Pavlov-Verevkin
Lomonosov State University, Moscow

ABSTRACT. Certain current questions concerning the theory of highly excited vibrational states have been examined. The change in the form and the objectives of the theory as a function of increased energy of the system has been analysed. Much attention has focused on the role of classical concepts in regard to both the definition of the objectives and the formation of concepts and models used to interpret experimental data in the field of high-energy states. The concept of localised quantum states has been introduced. This concept plays a key role in the interpretation of many processes in which highly excited vibrational states are involved. The experimental consequences of the formation of localised quantum states in different physical situations are discussed. Examples examined include rearrangements of vibrational polyads, the appearance of periodic orbits in wave functions and in low resolution spectra, and bound states in continua.

The bibliography contains 208 references.

VI. Conclusion 11

There has been much interest in the properties of polyatomic molecules in highly excited vibrational states as a result of the progress made in fields such as high-resolution spectroscopy, multiquantum processes, intramolecular dynamics, and laser chemistry. The appearance of new experimental data has provided a great impetus for the development of new strategies and methods associated with the highly excited vibrational states theory, and the appearance of new theoretical concepts and ideas.

The vibrational spectra of polyatomic molecules rapidly become complex with increase in energy. This leads to a change in the method used to interpret the experimental material. Certain traditional questions lose their significance and are replaced by new questions which are of a qualitatively different type. In the present review some of these new questions will be examined, and most attention will be paid to the role of classical ideas and concepts of the local quantum states.

I. Characteristics of the theory of highly excited vibrational states in different regions of the spectrum

1. The low energy range. The vibrational spectra in this energy range consist of separate clearly resolved lines. They are individual for each molecule and are used often to identify molecules or functional groups. The objectives of the theory for this energy range are traditional and involve a study of the individual states and the transitions between them. The construction of appropriate dynamic models is the main strategy for their resolution. There is currently a large selection of such models. Models of normal[1] and local[2,3] vibrations are most popular for the description of vibrational states at lower energy. In addition to the traditional models there are so-called algebraic models in which a Hamiltonian is constructed directly from generators of a dynamic group of the symmetry postulated for the system studied. In recent years such models have been widely used in the study of vibrational spectra and intramolecular dynamics of small polyatomic molecules (see Refs. 4–14, and the references cited in these reports).

Using several different models an equally satisfactory quantitative description of a limited section of the spectrum may be obtained. The simultaneous use of these models is of profound physical significance, since each model generates its own specific language, its set of quantum numbers by means of which lines in the experimental spectra may be assigned and the selection rules for different transitions may be determined, etc. In this case the states which do not have good quantum numbers in one particular model may have them in another model. Thus by using different models a more profound understanding of the quantum states may be acquired.

2. The transitional range. With increase in energy the system enters the transitional range, which separates the low-energy state range from the quasicontinuum. In this range models designed to describe low-lying states begin to lose their efficiency which is reflected as a sharp increase in computing difficulties when they are used and by the appearance of states which do not have good quantum numbers in any of the integrated models. The latter problem is of fundamental importance and is associated with the characteristics of the vibrational dynamics of polyatomic molecules in the classical limit.[15–17]

A description of the vibrational spectra of polyatomic molecules is based on the model of coupled anharmonic oscillators. At low

energies the classical dynamics of such a system is for the most part regular. This implies that under virtually all initial conditions the phase trajectories of the system lie on the surfaces of the N-dimensional tori and in the $2N$-dimensional phase space. During motion along such trajectories the meaning of the N integrals of the motion calculated along specially selected close curves on the torus are preserved. Such regular trajectories may be quantised by one of the variants of the quasiclassical method. In this case states with particular quantum numbers N will correspond to them.

Apart from regular trajectories the system contains chaotic trajectories, which fill a certain $2N$-dimensional region of the phase space. With increase in the energy in the system the relative volume of the phase space filled by chaotic trajectories usually increases. There is currently no sequential method available to quantise such trajectories, while the states corresponding to the trajectories do not have motion integrals distinct from the energy.

The rapid increase in the density of the vibrational states with increase in energy is another difficulty encountered with the theory in the transitional energy range. However in this case the characteristic groups of levels such as the vibrational and rotational polyads are preserved. This leads to the possibility of defining new objectives associated with the investigation of the properties of the separate groups of levels and the change in these properties with change in the different motion integrals.

Initially such objectives were defined in the theory of rotational spectra of highly symmetrical molecules.[18–27] In the theory of vibrational spectra the definition of analogous objectives began with the discovery of local modes, special vibrational states which arise with increase in energy within molecules containing equivalent A–H(D) bonds, where A is a heavy atom (usually O, C or N) characterised by an extremely asymmetrical distribution of vibrational energy between the bonds (see Ref. 2 and 3 and the literature cited in these papers). A distinctive feature of the vibrational spectra of such molecules is the existence of vibrational polyads, independent characteristic groups of levels corresponding to the excitation of the A–H bonds. In this case the states with $\sum n_k = N$ enter the Nth vibrational polyad, where n_K is the number of vibrational quanta in the k-th mode, whereas the number of the vibrational polyad N is expressed as the total number of vibrational quanta and is an approximated motion integral.

The appearance of local modes from normal vibrations on excitation of the molecules is a typical phenomenon caused by the significant linearity of the molecular vibrations.[28–36] It is reflected as a qualitative change in the structure (rearrangement) of vibrational polyads with increase in N and is an example of a broad class of vibrational localisation processes with increase in energy.

The rearrangements of the vibrational polyads do not exhaust all qualitative changes in the relative position of the levels with increase in energy. More complex phenomena are also known in vibrational-rotational spectra such as the redistribution of levels between different groups of states (see Refs. 37, 38 and 39, and the references cited in these papers).

3. The quasicontinuum. A further increase in energy in the system leads to a transition to the quasicontinuum, a region with a discrete spectrum with a very large density of states in which, in contrast to the transitional range, certain isolated groups of states are absent. It has also been relatively recently suggested that quasicontinua are structureless and homogeneous and that the density of the states in the quasicontinua grows systematically with increase in energy, whereas the wavefunctions of the states in the quasicontinuum are delocalised throughout the entire configuration space of the molecule. In such a study the quasicontinua of different molecules are found to be essentially constructed in an identical manner and their only important characteristic is the density of the states and the rate at which this density increases with increase in energy, i.e. in the quasicontinuum range the states of the molecules lose their individuality to a significant extent. Such a concept of the quasicontinuum is consistent with the postulates of the statistical theory of chemical kinetics of the Rice–Ramsperger–Kassel–Marcus theory.[40]

The above model was found to be too simple for many objectives. Thus, it does not explain the presence of regular periodic structures in the low resolution spectra and does not take into consideration the existence of a large number of vibrational states with localised wavefunctions.

Experimental investigations into the quasicontinuum range may be conveniently divided into two major groups, i.e. experiments with high and low spectral resolution. The first group of experiments is characterised by very high resolution and provides information on the individual states. They may be carried out only for relatively simple systems. The spectra obtained in this case have an extremely complex and irregular profile. There is a very large amount of information in these spectra, and a significant change in the method used to interprete the spectra is required. With such a large amount of information it is difficult to study the properties of all states and from a certain standpoint the study would be meaningless. The most important task was to describe and study the properties of the entire combination of states in a complete selected range of energies.

The natural approach to resolve this objective is to study the statistical properties of the selected combination of energy levels and to construct models the statistical properties of which coincide with those of the group of levels studied. A change in the properties of the combination of states with increase in energy usually has regular and irregular components. Thus for example with increase in energy the density of the states in the spectrum increases which leads to a systematic decrease in the distances $\delta_i(E) = E_i - E_{i-1}$ between adjacent levels (the regular component). We are not interested in the $\delta_i(E)$ values themselves but their fluctuations relative to the curve describing the average behaviour of these values with increase in energy (irregular component). A study of the statistical properties of these types of fluctuation in the relative position of the energy levels and in the matrix elements of certain operators (for example transition probabilities) represents the content of the statistical theory of spectra initially developed to describe the spectra of complex nuclei and recently used to analyse spectra of atoms and molecules (see Refs. 41–45 and the literature cited in these reports).

However, when this theory is used, the question arises, with which physical properties of the system are given statistical characteristics of its spectrum associated? The answer to this question proved to be quite unexpected. A profound and nontrivial relationship was found to exist between the statistical properties of the spectrum and the nature of its dynamics in the classical limit. It was thus possible to introduce the concept of regular and chaotic spectra, which differ markedly with respect to their statistical properties, and then with increase in energy a smooth transition for the first to the second is observed. In this case the statistical properties of the chaotic spectrum are described by a Gaussian orthogonal ensemble model consisting of an ensemble of symmetrical actual matrices, the elements of the latter being Gaussian random values.

A lucid and exhaustive account of the statistical theory of spectra and its application to specific physical systems may be found in

review articles.[43,45–50] The review concerning the molecular application should be noted in particular.[45]

The rapid increase in the density of the states with increase in energy of the system leads to the appearance of a new item for study, low resolution spectra obtained either directly as a result of experiments with an insufficiently high resolution or by a corresponding coarsening of high resolution spectra. By studying such spectra it was found that they often possess a structure which cannot be explained by the statistical theory. Clear examples of such a structure are the systematic oscillations of the density of the states and the regular oscillations of intensity associated with them found in the corresponding broadening in the spectra of systems such as the H atom in a magnetic field,[51–54] the molecular ion H_3^+,[55] acetylene molecules,[56] Na_3,[57] O_3,[58] and HCN.[59]

The properties of the separate states are also of interest in studies of the quasicontinuum range. However in this case the theory focuses on the search for and study of a relatively small number of special states which in certain ways are differentiated from the homogeneous background which surrounds them. The most useful and general criterion for the separation of the states from the quasicontinuum is the extent of the localisation of their wavefunctions which could be explained in different ways. It was found that the possible existence of vibrational states with localised wavefunctions and their properties is to a significant extent determined by the structure of the phase space of the system under investigation. This interrelationship is most lucidly expressed by the existence of "scars" of periodic orbits, the localisation of wavefunctions of highly excited states in the vicinity of unstable periodic orbits in configurational or phase spaces.

One more new feature of the theory in the quasicontinuum range is the interest shown towards dynamic objectives arising here quite naturally. In fact as a consequence of the high density of the states in the quasicontinuum, a coherent excitation of a large number of states occurs simultaneously on excitation of the molecule, which leads to the formation of a nonstationary wavepacket. Such wavepackets are usually spread very rapidly. In this case initially the vibrational energy, which is localised in one or in a small number of modes, is redistributed rapidly between all accessible modes. However this situation may alter abruptly, if states with localised wavefunctions which partially stabilise the wavepacket form part of the wavepacket. Thus the localised vibrational states may serve as a basis for special, relatively stable dynamic modes during the intramolecular redistribution of energy.

4. The continuous spectrum. The continuous spectrum range is situated at an even higher energy. In this range the theory ultimately focuses on the study of the dynamics and special states, the resonances of which are typical representatives of localised quantum states. As an example we shall examine below the effect of excitation capture in the continuous spectrum during the decay of a coherently excited group of (quasi)degenerate states.

II. Localised vibrational states

In the high-energy range of the system the special states which in some way can be differentiated from the homogeneous background surrounding them are of greatest interest. In order to understand the nature of such states it is necessary first of all to understand which properties of the vibrational states are typical at high energies. With this objective it was useful to analyse the dynamics of the system studied in the classical limit. In systems of coupled anharmonic oscillators, which are normally used to model the dynamics of nuclei in molecules, a transition from regular to chaotic dynamics with increase in energy is typical. In this regard Percival proposed that such a position is preserved also in the quantum limit in a quasiclassical approximation,[60] i.e. regular and chaotic quantum states with markedly different properties should exist. In this case the chaotic states will be typical by virtue of the principle of congruence.

Three different strategies are currently used to determine the randomness of separate quantum states. These strategies are based on the study of the nature of wavefunction localisation in the phase space, in the configurational space, and in the basis function space. A detailed discussion of these three kinds of localisation in relation to their use to distinguish chaotic and regular quantum states has been published.[49,50,61–65]

1. Localisation in the phase space. The dynamics of an arbitrary quantum system may be described not only in the Hilbert space of quantum mechanics but also in the normal phase space. Let $\mathbf{q}$ and $\mathbf{p}$ be a combination of generalised coordinates and momenta of the system studied respectively. Then the arbitrary wavefunction $\psi(\mathbf{q})$ determined in configuration space can be compared with a certain function $\rho(\mathbf{q}, \mathbf{p})$ determined in phase space and termed the quantum function of the distribution. This may be achieved by different methods.[66–68] The most well known of these methods was proposed by Wigner and leads to the quantum function of the distribution in the form:

$$\rho_W(\mathbf{q}, \mathbf{p}) = h^{-N} \int \ldots \int dx_1 \ldots dx_N \, \Psi^*(\mathbf{q}+\mathbf{x}/2)\, \Psi(\mathbf{q}-\mathbf{x}/2)\, e^{-i\mathbf{p}\mathbf{x}/\hbar}. \quad (1)$$

The description of the quantum states using the Wigner distribution function (1) facilitates significantly a comparison of the properties and dynamics of classical and quantum systems. However, in this case one should bear in mind that the equation of motion for the Wigner function transforms into the equation of motion for the classical distribution function (the Liouville equation) only in the limit $\hbar \to 0$. This permits the isolation of purely quantum effects in the dynamic behaviour of the system.[69]

Moreover the Wigner function does not have definite values at all points of the phase space, i.e. it possesses none of the most important properties of the classical distribution function. This property was found to be quite common for the quantum distribution functions and is associated with the need to satisfy the quantum-mechanical Heisenberg uncertainty principle according to which it is not possible to define simultaneously accurate values of the coordinates and the momenta of particles. Therefore in quantum mechanics the concept of a point in the phase space has no special physical significance and in addition the requirement for a definite value of the distribution function at each point also becomes physically meaningless. The requirement for a definite value of the coarse-grained distribution function obtained on coarsening of the distribution function with respect to the small region of the phase space is more acceptable from the point of view of the physical meaning.

One of the best known examples of such an approximated coarse-grained distribution function is the Husimi distribution function $\rho_H(\mathbf{q}, \mathbf{p})$, [70] which may be calculated as the square of the modulus of the overlap integral of function $\psi(\mathbf{q})$ with the wavefunction of the

specific state $|\alpha(\mathbf{q}, \mathbf{p})>$ parametrised by the coordinates of the phase space. Gaussian functions centred at point $(\mathbf{q}, \mathbf{p})$ are normally used as functions $|\alpha(\mathbf{q}, \mathbf{p})>$. The distribution functions thus formed are apparently positive and finite in the entire phase space.

What is the appearance of the distribution functions of chaotic and regular quantum states? In order to answer this question it would be useful to study the properties of the quantum distribution functions in the classical limit. The classical limit for the Wigner distribution function has been best studied (see discussion and literature cited in Ref. 50). When $\hbar \to 0$ the Wigner coarse-grained function is localised in the regions which fill its corresponding trajectories when $t \to \infty$. This implies that, when $\hbar \to 0$ the Wigner coarse-grained function of the regular state is localised on the surface of the N-dimension torus, whereas the chaotic state tends towards a microcanonical distribution. A similar result is also valid for the Husimi distribution function.[71,72] It would be logical to suggest that such a position is also preserved at small but finite values of $\hbar$.

Thus one might expect that at high energies the typical wavefunctions will be those, which correspond to strongly delocalised and isotropic coarse-grained higher functions more or less constant over the entire accessible volume of the phase space. In this case special states will be characterised by nonisotropic coarse-grained Wigner functions localised in only a small part of the isoenergetic hypersurface, i.e. they will be localised quantum states.

2. Localisation in the configurational space. A second possible approach to the study of the localisation of quantum states would be an investigation into their wavefunctions in the configuration space. The first attempts to use this approach were based on a study of the main surfaces of the wavefunctions. However it was found that in the transition from inseparable integrated systems to nonintegrated systems the topology of the unit surfaces does not undergo a qualitative change and therefore cannot be used to differentiate reliably these two types of states (see discussion in Refs, 49 and 50).

The methods used to isolate the regular quantum states based on the analysis of different statistical properties of their wavefunctions were found to be more valuable. The concept of the wavefunctions of chaotic states and of the random functions of coordinates in which there is no correlation between the values at adjacent points forms the basis of all of these strategies. In this case adjacent points not too close to each other should be selected with the objective of levelling the effects caused by the continuity and normalisation of the wavefunctions.

One should note the following methods, which have been used most widely to study the statistical properties of wavefunctions.[49,50,73–76]

1. Calculation of the normal autocorrelation function

$$F_\delta(\Psi) = \int \ldots \int \Psi^*(\mathbf{q}) \Psi(\mathbf{q}+\delta) \mathrm{d}q_1 \ldots \mathrm{d}q_N, \qquad (2)$$

or its discrete variant

$$F_m(\Psi) = (1/M) \sum_{i=1}^{M} \Psi^*(\mathbf{q}_i) \Psi(\mathbf{q}_{i+m}), \quad m \leqslant M. \qquad (3)$$

In formula (3) the points $\mathbf{q}_i$ are taken as lying on the closed curve in the configuration space and satisfying the condition $\mathbf{q}_{i+M} = \mathbf{q}_i$. In this case the chaotic wavefunctions differ from the regular functions with values close to zero $F_\delta(\psi)$ and $F_m(\psi)$ for all $m \leqslant M$.

2. Calculation of the moments $I_m = \int \ldots \int |\psi(\mathbf{q})|^{2m} \mathrm{d}q_1 \ldots \mathrm{d}q_N$. In the quasiclassical limit $I_m \to \infty$ for regular states and they remain finite for chaotic states.

3. Calculation of informational entropy

$$S = -\int \ldots \int |\Psi(\mathbf{q})|^2 \ln(|\Psi(\mathbf{q})|^2/\rho_{\mathrm{ref}}) \mathrm{d}q_1 \ldots \mathrm{d}q_N, \qquad (4)$$

where ρ_{ref} is the reference density of the probability corresponding completely to an ergodic situation. In this case the value of S for delocalised wavefunctions should be markedly greater than that for the localised wavefunctions.

4. Calculation of the distribution function of the wavefunction values at randomly selected points. In this case the chaotic states should be characterised by a Gaussian distribution.

5. Calculation of the fractal dimensionality D of the density of the probability $|\psi(\mathbf{q})|^2$ determined by the relationship

$$\int \ldots \int |\Psi(\mathbf{q})|^2 |\Psi(\mathbf{q}+\mathbf{q}')|^2 \theta(Y) \mathrm{d}q_1 \ldots \mathrm{d}q_N \sim L^D, \qquad (5)$$

where $Y = L - |\mathbf{q} - \mathbf{q}'|$, and $\theta(Y)$ is the Heavyside function equal to unity when $Y < 0$ or to zero when $Y > 0$.

6. A method based on the study of the surfaces of the level of density probability $[\psi(\mathbf{q})]^2$ has been widely used recently to study wavefunctions in systems with two degrees of freedom. With this method it is possible to determine directly the nature of wavefunction localisation in the configuration space. However one should note that this method becomes significantly less representative in studies of systems where the number of degrees of freedom is greater than two.

When all above analytical methods are used, the concept of random and typical states at high energies is associated with the delocalised state, and with the irregularity and isotropicity of their wavefunctions in the configuration space. It can also be seen that in such an approach the states with localised wavefunctions are separate.

3. Spatial localisation of base functions. The idea of the extent of delocalisation of wavefunctions in space of the decomposition coefficients with respect to eigenfunctions of the integrated models as a criterion of the randomness of quantum states was proposed for the first time by Nordholm and Rice.[77] The main idea of the strategy of these authors is easy to understand, if one remembers that the chaotic trajectory in general has no good integrals of motion apart from energy. One might naturally suggest that this assertion remains true also for chaotic quantum states. However this implies that the wavefunctions of such states cannot have compact decompositions with respect to the eigenfunctions of any integrated model. Let H_0 be the Hamiltonian of one such model. Then it would be natural to associate the degree of randomness of the quantum state with the width of distribution of the decomposition coefficients $\{a_k\}$ of its wavefunction with respect to the eigenfunctions of the operator H_0. In this case the greater the number of coefficients $\{a_k\}$ which are markedly different from zero the more chaotic is the state examined.

The selection of parameters for the quantitative evaluation of the degree of randomness of the quantum state with respect to the set of coefficients $\{a_k\}$ by certain authors remained an open question.[77] It has been suggested that the ratio of the share $p = \sum p_n^2$ or entropy $S = -\sum p_n \ln p_n$, where $p_n = [a_n]^2$ should be used for such an evaluation.[49] In this regard one should note that the values p and S

have been used for a long time to determine the degree of randomness of intramolecular dynamics (see Refs. 78–82 and the references cited in these reports).

A simpler criterion has been studied according to which the quantum state is regular, if an integrated model exists which is such that among the decomposition coefficients of its wavefunction with respect to the basis functions of this model there is a coefficient greater than 0.5.[83–85] By satisfying this criterion it is possible to characterise unambiguously the studied state by a complete set of good quantum numbers and provides convergence of the Brillouin–Wigner theory of perturbations for its wavefunction and energy.[83–85]

The absence of a systematic method for the reassembly of all possible integrated models is a major limitation of the approach examined for the determination of chaotic quantum states. In this regard the earlier suggestion to use a basis of natural orbits for this purpose is of interest.[86] With this approach it should be possible to systemise the search for regular states using a fixed selection of variables. However this possibility has not been exploited on account of the variation in the variables themselves.

In this approach the states localised in the space of the basis functions of a certain integrated model are specific. Although such a determination of localised quantum states is also somewhat arbitrary, since it is dependent on the selection of the basis model, it is found to be very useful when the basis functions have clear physical meaning.

III. Localisation in the vicinity of stable equilibrium positions: a qualitative theory of vibrational polyads and their rearrangements

We shall examine the molecule having M (quasi)degenerate vibrations, the frequencies of which differ markedly from the frequencies of the remaining vibrations. The local vibrations of CH bonds in organic compounds, symmetrical and antisymmetrical normal vibrations in type ABA nonlinear molecules with a heavy central atom, and many others are typical examples. The existence of vibrational polyads is a characteristic feature of the vibrational spectra of such molecules. For simplification we shall discuss the main ideas as an example the vibrational polyads formed by two vibrations. The three types of currently known polyads are illustrated in Fig. 1.

The type *a* so-called normal vibrational polyads correspond to the model of uncoupled harmonic oscillators with slightly different frequencies. The type *c* so-called local vibrational polyads are very satisfactorily described by the model of two identical uncoupled anharmonic oscillators. The type *b* vibrational polyads are mixed, their upper and lower parts corresponding to the model of normal and local vibrations respectively. In certain cases with increase in energy there is a rearrangement of the vibrational polyad-transition from polyad type *a* to polyads types *b* and *c*.

There are at present several approaches for explaining this qualitative phenomenon. One should note the strategies based on the analysis of classical trajectories,[28,29] and also later and accurate methods based on the construction and study of effective algebraic Hamiltonians for separate vibrational polyads.[30–36] We shall use as a basis a strategy developed in previous studies.[30–36] This approach not only provides a simple graphic relationship between the rearrangements of the vibrational polyads and the characteristics of the dynamics of the system under investigation in the classical limit but also permits the description of all possible simplest types of polyad and their rearrangements.

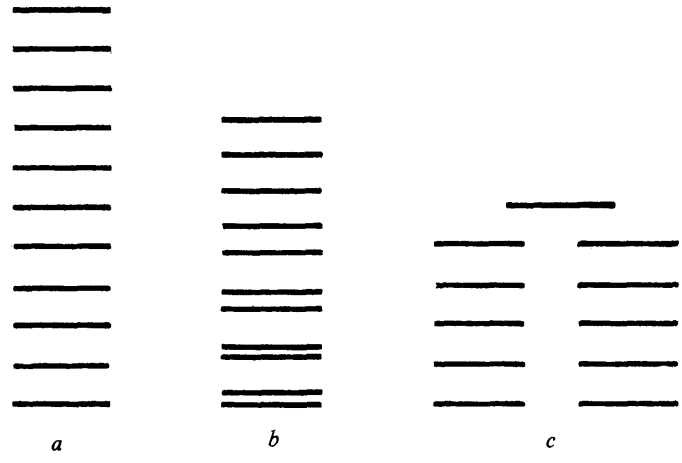

Figure 1. Types of vibrational polyads formed by two vibrations: *a*, normal; *b*, mixed; *c*, local.

We shall assume that the different vibrational polyads interact weakly with each other (N is an approximate integral of motion) and that the structure of the vibrational polyads is not perturbed by the resonance interaction with other molecular vibrations. With these assumptions the relative position of the energy levels in the N-th vibrational polyad may be described by an effective vibrational Hamiltonian $H_{\text{eff}}(N)$ parametrically dependent on N. Further analysis rests on the close relationship between the properties of the quantum system and its behaviour in the classical limit. We shall use this relationship to find a classical analogue of the quantum phenomenon studied here. This may be obtained schematically as a result of the following sequence of steps:

1) construction of the algebraic effective vibrational Hamiltonian $H_{\text{eff}}(N)$ describing the relative position of the energy levels in the N-th vibrational polyad,

2) transition to the classical limit; construction of the corresponding phase space and the Hamiltonian function H_{kl},

3) a study of the system of stationary points of the H_{kl} function and its rearrangements with increase in N.

As a simple example we shall examine the spectrum of stretching vibrations of the ABA molecule which in the formalism of the local vibrations is described approximately by the Hamiltonian

$$H/\hbar\omega = 0.5(P_1^2+Q_1^2+P_2^2+Q_2^2)+AP_1P_2+BQ_1Q_2+C(Q_1^3+Q_2^3)+ +DQ_1Q_2(Q_1+Q_2)+E(Q_1^4+Q_2^4)+FQ_1Q_2(Q_1^2+Q_2^2)+CQ_1^2Q_2^2, \quad (6)$$

where Q_k and P_k are normal dimensionless coordinates and momenta and the constants $A-G$ are dimensionless parameters of the model. If all constants $A-G$ are much less than unity, the energy levels of operator H_{eff} will be grouped into polyads. We shall now apply the above described analytical scheme to the Hamiltonian (6).

1. Construction of an effective vibrational Hamiltonian. We shall rewrite the vibrational Hamiltonian (6) using the creation-destruction vibrational operators a_k and a_k^+, where $a_k = (Q_k + iP_k)/2^{1/2}$, ($k$ = 1, 2) and we shall use the standard technique of canonical transformations for reducing it to an even form.[87]

Being limited for simplicity only by the first non-disappearing contributions from all terms introduced into the Hamiltonian (6) we obtain:[32,33]

$$H_{\text{eff}}/\hbar\omega = H_0 + [\alpha_1 + \alpha_2(J+0.5)]J_x + \gamma J_x^2 + \delta J_z^2, \quad (7)$$

where J_x and J_z are the pseudomomentum operators determined using the creation-destruction vibrational operators as

$$J_x = (a_1^+ a_2 + a_2^+ a_1)/2, \quad J_z = (a_1^+ a_1 - a_2^+ a_2)/2, \quad (8)$$

while parameters α_1, α_2, γ and δ are expressed by the known method through the constants $A-G$. All terms which are constant within the vibrational polyad are introduced into H_0. The operator J = 0.5 $(a_1^+ a_1 + a_2^+ a_2)$ is associated with the number of the vibrational polyad with a ratio of $N = 2J$ and is the motion integral.

The method described for constructing an effective vibrational Hamiltonian is far from being the only method. Moreover it is often more expedient to regard the Hamiltonian (7) as purely phenomenological and to determine the parameters contained in it from the experiment as in the case of algebraic models.

2. The classical limit. The construction of the classical limit for the quantum system is generally quite a complex operation resting on the theory of generalised coherent states.[88,89] In our case this operation is markedly simplified and amounts to a trivial replacement of the pseudomomentum operators by their quasi-classical expressions

$$J_x = L\cos\varphi\sin\vartheta, \quad J_z = L\cos\vartheta, \quad L = J + 1/2, \quad (9)$$

where L is the length of the pseudomomentum vector. Since the value l is conserved during motion, the phase space is a normal two-dimensional sphere. By omitting the term H_0 which is insignificant in our case we finally obtain the following expression for the function H_{kl}:

$$H_{kl} = (\alpha_1 + \alpha_2 L)L\cos\varphi\sin\vartheta + \gamma L^2\cos^2\varphi\sin^2\vartheta + \delta L^2\cos^2\vartheta. \quad (10)$$

3. Qualitative analysis. We shall study the behaviour of stationary points of function H_{kl} on change in N. They are important because closed closely localised trajectories are associated with the stationary points of the minimum or maximum type. Under certain conditions regular sequences of localised quantum states correspond to these trajectories. Thus from a study of the stationary points of the function H_{kl} it is possible to study the possible types of localised quantum states and their change on excitation.

We shall restrict ourselves to an examination of only Hamiltonians of a common form, when no additional limitations apart from those caused by the symmetry of the system were applied to the parameters. The stationary points of the Hamiltonian function (10) and their corresponding total energy values are presented in Table 1, and their behaviour with increase in L is schematically illustrated in Fig. 2. It is apparent from Table 1 and Fig. 2 that at low L values corresponding to the real excitation of the system the function H_{kl} has only two nondegenerate stationary points a and b, one of which is the maximum, the other being the minimum. With increase in energy such a position is preserved whilst L does not exceed a certain critical value $L\P$. When $L > L\P$, the dynamics of the model studied undergo a qualitative change, which is reflected as a change in the number and nature of the stationary points of function H_{kl}. The values of parameter L at which this occurs are called bifurcational, and the process itself is a bifurcation. The diagrams similar to that shown in Fig. 2 in which changes in the system of stationary points of the function are depicted on change in its parameters are called bifurcational diagrams and provide a convenient method for describing systems in which certain qualitative changes may arise when the parameters are continuously changing.

Table 1. Coordinates, energies and conditions for the existence of stationary points (SP) of the function H_{kl}.[33]

SP	φ	ϑ	Energy	Conditions for the existence
a	0	$\pi/2$	$E_a = \alpha L + \gamma L^2$	at all L
b	π	$\pi/2$	$E_b = -\alpha L + \gamma L^2$	at all L
$c_{1,2}$	$\pi[1-\text{sgn}(r_1)]/2$	$\pm\arcsin\lvert r_1\rvert$	$E_{c_1} = E_{c_2} = \delta L^2 + \alpha^2/4(\delta-\gamma)$	$\lvert r_1\rvert < 1$
$d_{1,2}$	$\pm\arccos\lvert r_2\rvert$	$\pi/2$	$E_{d_1} = E_{d_2} = -\alpha^2/4\gamma$	$\lvert r_2\rvert < 1$

Notations: $\alpha = \alpha_1 + \alpha_2 L$, $r_1 = (\alpha_1 + \alpha_2 L)/2L(\delta-\gamma)$, $r_2 = -(\alpha_1 + \alpha_2 L)/2L\gamma$.

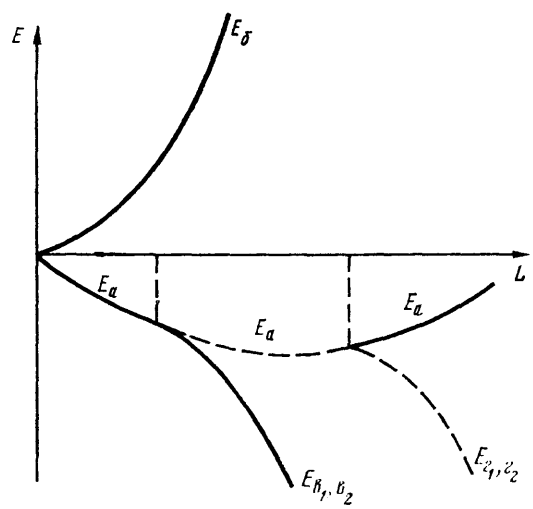

Figure 2. Bifurcational diagram describing the changes with increase in energy of the system of stationary points of the Hamiltonian function (10) for the case of the H_2O molecule.[30]

The system of two harmonic oscillators associated with quadratic potential and kinetic interactions is the simplest system described by the Hamiltonian (6). This system is described by a Hamilton function (10) with $\gamma = \delta = 0$ and is equivalent to two non-interacting harmonic oscillators with slightly different wavenumbers.

Its spectrum is a polyad structure with polyads of a purely normal type, and their structure does not alter with increase in energy. It is apparent from Table 1 that in the case examined with function H_{kl} there are only two non-degenerate stationary points *a* and *b* for all values of *L*. This implies that in the above model the upper and lower parts of the vibrational polyads are constructed from regular sequences of the non-degenerate energy levels which is in total agreement with the results of accurate quantum-mechanics calculations.

We shall now consider the anharmonicity of oscillators which corresponds to the selection of a nontrivial value of coefficient δ. Analysis of the stationary points shows that when $L = L\P = [\alpha_1/2\delta]$ bifurcation occurs in the system. When $L < L\P$ the function H_{kl} has two non-degenerate stationary points *a* and *b*. As in the previous example the vibrational polyads are of the normal type. When $L > L\P$ one of the stationary points is split into two degenerate stationary points of the same type as the point of their origin, and one saddle point. The appearance of two degenerate stable stationary points leads to the formation of a regular sequence of double degenerate energy levels in the vibrational polyads. In this case that end of the vibrational polyads at which the double degenerate energy levels appeared will be better described by a local vibration model, whereas the other end of the polyad will continue to correspond to the normal vibration model.

We shall examine the question of what is the physical nature of the double degenerate localised quantum states arising as a result of the bifurcation. With increase in energy let the distances between the adjacent energy levels of the initial oscillators decrease systematically, which is a typical situation in molecular problems. In this case the double degenerate localised quantum states are formed in the lower part of the vibrational polyads, and the states themselves correspond to vibrations with an extremely asymmetrical energy distribution between the oscillators, i.e. they are well studied local modes.[2,3]

Thus the qualitative analysis of the function H_{kl} gives a simple and clear picture of the formation of local modes from normal vibrations on excitation. It shows that the formation of local modes with increase in energy is a typical phenomenon and is not dependent on the specific values of the Hamiltonian parameters. However one should note that the experimental observation of rearrangements associated with this process in the specific molecules may be made difficult by too great or small values of $L\P$.

Within the framework of the approach examined there are no significant differences between normal and local vibrations. Both are examples of localised quantum states with wavefunctions localised close to the stable stationary points of function H_{kl}. Thus the states described above are a natural generalisation of local and normal vibrations.

Two new effects appear when all coefficients of the effective vibrational Hamiltonian differ from zero: 1) a new type of localised quantum states corresponding to stationary points *d* may arise, and 2) localised quantum states existing only in a limited energy range may appear.

The results obtained from the use of a qualitative approach to the analysis of experimental spectra of stretching vibrations in H_2O, SO_2, and O_3 molecules and vibrations of the CH and CD bonds in C_2H_2 and C_2D_2 molecules taken from literature data are presented in Table 2.[33]

The small values of $L\P$ for C_2H_2 and H_2O molecules are in good agreement with the fact that the vibrational polyads in these molecules have a clearly expressed local nature beginning from the lowest part itself. The vibrational polyads in the C_2D_2 and SO_2 molecules belong to the normal type, which is also in good agreement with the $L\P$ values for these molecules. The ozone molecule spectrum is of greatest interest. Using this as an example it is possible to follow the transition from vibrational polyads of a normal type at low *N* values to the mixed type of vibrational polyads when $N \geqslant 3$. It should be emphasised that the accuracy of the results obtained from the qualitative analysis increases with increase in *N*. At low *N* values one can expect that they agree only qualitatively with the experimental data. In this case the vibrational polyad rearrangements predictable by the theory are more sharply manifested the greater is the value of *N*. Taking into account the comments made the results obtained from analysis of the experimental spectrum presented in Table 2 should be recognised as being unexpectedly good.

Table 2. Analysis of the bifurcations of effective vibrational Hamiltonians of certain molecules.[33]

Molecule	Region of existence of stationary points	
	c	d
H_2O	$L>0.4$	$5.9<L<36.5$
SO_2	$L>6.5$	$L>13.7$
O_3	$L>0.6$	$L>10.8$
C_2H_2	$L>0.4$	Absent
C_2D_2	$L>3.2$	$L>22.8$

The transition from the normal to the mixed polyads in the model spectrum of molecule C_2D_2 may serve as a classical example of the rearrangement of vibrational polyads. A sufficiently large value of $L\P$ corresponding to $N = 6$ leads to a clearly pronounced sharp transition.

Thus we have achieved the objective set at the beginning of this chapter and have found a classical analogue of the quantum rearrangement. We have shown that bifurcations of the Hamilton function, expressed as a change in the number and nature of its extremal points, correspond to rearrangements of the vibrational polyads.

Qualitative changes in the Hamilton function with increase in energy lead to qualitative changes in the phase picture of the system studied and hence to a change in possible forms of its dynamic behaviour. Of great interest in this regard are earlier studies in which a strategy is developed which in the case of two vibrations allows phase pictures of vibrational polyads to be constructed from experimental spectra.[90–94]

In concluding the discussion of the qualitative theory of vibrational polyads and their rearrangements one should note the work in which all kinds of typical elementary rearrangements of vibrational polyads are found in a system of two associated anharmonic oscillators,[33] and a study in which a generalisation of the theory to the case of an arbitrary number of vibrations is presented.[95]

IV. Localisation in the vicinity of isolated periodic orbits: "Scars" of the periodic orbits in the wavefunctions and low resolution spectra

In the systems of interest to us a transition from regular to chaotic dynamics is typical with increase in energy. In this case the volume of the phase space filled by regular trajectories approaches zero. However even in the region of totally chaotic dynamics in the phase space a large number of isolated and unstable periodic orbits is preserved. Since the extent of the volume of the phase space occupied by them is equal to zero, it would appear that they should not appear as quantum properties. In fact the unstable periodic orbits are not only markedly reflected in the quantum properties but also determine them to a significant extent especially at high energies.

The first theory associating the properties of isolated periodic orbits with the quantum characteristics of the system was developed mainly in the work by Gutzwiller, Balian, and Bloch. A good review of this theory and a comparatively comprehensive list of early studies may be found in the literature.[96] The central result of this theory is the formula:

$$n(E)=\bar{n}(E)+\sum_r\sum_j a_{rj}(E)\cos\{j[S_r(E)-\mu_r]\}, \qquad (11)$$

linking the quasiclassical density of states $n(E)$ with the characteristics of isolated periodic orbits. Here $\bar{n}(E)$ is the average density of the Thomas–Fermi states which can be determined by the volume of the phase space enclosed within the isoenergetic surface with energy E, the index r denotes different primitive periodic orbits, the sum with respect to j takes into account the contribution from a multiple inversion at the primitive periodic orbits, while S_r and μ_r represent the action and the index of Maslov for the r-th primitive periodic orbit. It is important to understand that formula (11) establishes the conformity not between individual periodic orbits and quantum states but between the entire spectrum of the system and the combination of all of its periodic orbits in the classical limit.

In recent years attempts have been made to use the formula (11) to calculate quasiclassical spectra of a number of simple model systems both in the regular and chaotic regions. Of the more successful applications one should note that it has been used to resolve the problem described by Kepler[97] regarding the quantisation of free particle motion on a pseudosphere,[98] and in different billiards,[99,100] and the calculation of the H atom spectrum in a magnetic field.[101–105] The generalisation of this formula by introducing into it the contributions from classically forbidden complex periodic orbits, which enable the tunnel distributions to be calculated,[106–109] is of significant interest.

A more general application of the formula (11) for calculating the spectra encounters certain difficulties. The most serious of these problems is the absence of sufficiently general and effective methods to search for all periodic orbits in a chosen energy region, the exponential growth in the number of isolated periodic orbits with increase in their period and the very slow convergence of the series (11). Nevertheless the method based on its use is at present the only sequential approach to the quasiclassical calculation of the spectrum in the field of chaotic dynamics.

In formula (11) contributions remain only from the periodic orbits with periods less than the somewhat fixed time T, although it gives a value $n(E)$ obtained in experiments with a fixed resolution $\Delta E = h/T$ with respect to energy. An interesting consequence of such a rough approximation assuming experimental verification is the confirmation that the quasiclassical density of the states is a multiperiodic energy function and that its oscillation periods are determined by periods of motion with respect to the periodic orbits. Such oscillations of the state densities were in fact observed in spectra of a number of simple systems.[51–59] One should note that the existence of the narrow resolution of different structures in the spectrum indicates that at high energies in the system studied regions of quasiregular motion occur against a background of largely chaotic dynamics.

Low resolution spectra: the dynamic theory. If unstable isolated periodic orbits play such an important role in the formation of chaotic spectra, the question arises as to whether it is possible to obtain information on dynamically existing periodic orbits directly from the spectra, and if so, how? The natural answer to this question is provided by the dynamic theory of spectra,[110,111] which we shall illustrate by the example of the electronic emission spectra.

The process of electron excitation of molecules is often regarded as an instantaneous Franck-Condon transfer of the wave function Φ of the principal vibrational level of the original electronic state into a certain ultimate electronic state in which Φ is already a wave packet describing a nonstationary state. The emission spectrum from this nonstationary state contains information on the dynamics of energy redistribution between different degrees of freedom of the molecule.

The principal idea of the dynamic theory of the spectra resides in the transfer of information within the spectrum from the energy language to the temporal language by calculation of the correlation function $C(t) = <\Phi|\Phi(t)>$. In our case the link between $C(t)$ and the spectrum of infinitely high resolution has the form:

$$S(E)=(1/2\pi)\lim_{T\to\infty}\int_{-T}^{T} C(t)\exp(iEt/\hbar)\,dt, \qquad (12)$$

from where it follows that the information provided by the spectrum of infinitely high resolution is equivalent to that provided by the dynamics of the system studied over an infinitely long period. At high energies it is usually impossible to obtain spectra in which all lines have been totally resolved. Instead spectra with broad spectral contours with a more or less clearly pronounced vibrational structure are obtained. From the dynamic standpoint this implies that such spectra contain information on the dynamics of the system only over a certain final time interval, T. The corresponding spectral contour $S_T(E)$ is given by the formula:

$$S_T(E)=(1/2\pi)\int_{-T}^{T} C(t)\exp(iEt/\hbar)\,dt. \qquad (13)$$

We shall examine the excitation process in which the centre of the Gaussian wave packet, which corresponds to the wave function of the principal vibrational level of the lower electronic state, encounters one of the periodic orbits. The dynamics of the Gaussian wave packets in smooth potentials have been studied in considerable detail.[112] In our case the centre of the packet will move along the periodic orbit, while the packet itself will gradually spread more rapidly the more stable is the periodic orbit. In this case the function $|C(t)|$ will have the characteristics of damped vibrations. Its maxima are associated with the reversions of the wave packet to the starting point, whereas the systematic decrease in their height was caused by the spreading of the packet. Thus each dynamically significant periodic orbit generates in the correlation function a series

of equidistant maxima, their separations being equal to the transformation period along this periodic orbit.

The analysis shows that, in contrast to the high resolution spectra, the low resolution spectra in the chaotic region contain information not on individual states of the quantum system but on the dynamically significant isolated periodic orbits. Therefore it is possible to use the low resolution spectra to study the intramolecular redistribution of vibrational energy in the quasicontinuum.

Another approach to explain the appearance of isolated unstable periodic orbits in the low resolution spectra which is close in principle to the Feshbaich theory of resonances has been developed by other authors.[113–115]

The above-mentioned analytical scheme for the low resolution spectra based on the extraction of information on periodic orbits which they contain has been successfully used to interpret the spectra of the H atom in a magnetic field,[52–54,101–105,113–118] the molecular ion H_3^+,[115–121] Na_3,[116,122,123] O_3,[124,125] CO_2,[126] and HCN[127–129] molecules.

Another interesting manifestation of unstable periodic orbits in the properties of quantum systems was found by Heller in a study of wavefunctions of highly excited states of the quantum billiard "Stadium" consisting of two hemispheres connected by segments of straight lines.[130–132] The classical limit "Stadium" is an example of a totally chaotic system at all levels. Therefore one would expect that in accordance with the quasiclassical analysis and the principle of concordance its wavefunctions will be strongly delocalised. The real position was found to be much more interesting. Analysis of the surfaces of the level of the function $[\Psi_k]^2$ showed that the wavefunctions of many excited states clearly have a tendency to be localised close to the periodic orbits. Heller named this effect as the scars of the periodic orbits in the wavefunctions. Such scars were subsequently found also in other systems including those with smooth potentials.[133] The theoretical basis of this effect from different standpoints may be found in earlier reports.[131,134–137] However the scars of the periodic orbits in the configurational space have not been widely studied. Study of the scars in the phase space with the aid of the quantum cross sections by Poincare for the distribution functions of Wigner[138] or Husimi[139] was found to be markedly more fruitful. Both of these approaches have been compared,[137,140] and it was concluded that the use of the Husimi distribution function was preferable.

Thus the unstable periodic orbitals separate certain special states in the chaotic region which are typical representatives of localised quantum states with the wavefunctions localised in the vicinities of these orbits. From the extent of the localisation of wavefunctions of such states it is possible to develop effective methods for their calculation. As an example one should note the variation method as the basis of Gaussian wavefunctions with the adjacent centres and in the corresponding periodic orbit[113–115,119,141,142] analogous to the stabilisation method used in the calculation of the positions of the resonances and which allows information to be obtained on the class of localised quantum states of interest to us without calculating all lower-lying states.

Another effective approach to the study of localised quantum states under discussion is the use of the adiabatic approximation for separating slow motion along a periodic orbital and rapid vibrations perpendicular to the orbit.[117,133] Such a separation operates more efficiently the less unstable is the corresponding periodic orbit, i.e. the longer the trajectory which will stay in the vicinity of its origin. It was found that only adiabatically stable, attracting periodic orbitals, which possess the same property, lead to scars, and that any trajectory having started in the vicinity of such an orbit, before vacating it will certainly intersect the projection of the periodic orbit on to the configurational space.[133,143] One should note that adiabatically stable periodic orbits may be totally unstable in the Lyapunov sense.

One should also note the method of calculation based on the quasiclassical quantisation of unstable periodic orbits[144,145] which is successfully used to explain the low resolution spectra of the H_3^+ ion.[121]

Nonlinear normal vibrations at which all generalised coordinates at any time period are proportional to one of them and which in the small energy limit is reduced to the usual normal vibrations[146–149] are the most simple periodic motions in nonlinear mechanical systems permitting systematic study. The number of nonlinear normal vibrations is dependent not only on the number of degrees of freedom in the system studied but also on its symmetry. Thus with the CH_4 molecule the number of linear and nonlinear normal vibrations is equal to 9 and 63 respectively.[147]

From a sequential study of the evolution and bifurcation of the system of nonlinear normal vibrations with increase in energy, it is possible to find all periodic orbits of the system originating from the normal linear vibrations. Such periodic orbits and the quantum states localised near them are termed regular orbits.[150] In addition to them irregular periodic orbits may exist in the system which are genetically unassociated with any of the linear normal vibrations. Irregular periodic orbits are of significant interest, since the localised quantum states, the properties of which cardinally differ from those of the localised quantum states associated with the regular periodic orbits, correspond to them.

In recent years it has become more evident that "scars" of periodic orbits in the wavefunctions are only the most simple example of a broad class of effects, which could have been determined as the manifestation of different elements of the phase picture of the system (the structure of the phase space) in its quantum properties. Apart from the above-mentioned, scars from such elements of the phase picture as families of unstable periodic orbits,[115–121,151–153] resistant and nonresistant invariant varieties of periodic orbits,[152,153,160] invariant tori, the dimensionality of which is less than the number of corresponding degrees of freedom,[122–123] homo- and heterocyclic structures,[154,155] and separatrix varieties (see Refs. 152, 155–157, 140 and literature cited in these articles) and cantori (see Refs. 158, 159, 140 and the literature cited in these articles) have so far been observed in the wavefunctions. In particular one should note the manifestations of the cantori, the noteable "bottlenecks" playing an important role in the intramolecular redistribution of energy.

V. Spatial localisation of the basis functions: bound states in a continuous spectrum

As a clear example illustrating the effectiveness of studying the localisation of quantum states in the space of the basis functions we shall discuss the effect of excitation capture in the continuous spectrum caused by the existence of quasibound states in a continuum. In its mathematical form this effect is analogous to such widely known quantum-optical effects as superradiant radiation in a system of identical double-level systems (the Dikke model)[161] and the coherent capture of the occupancies in the N-level systems containing metastable states or interacting with a certain continuum in the presence of intense multimodal laser radiation (see Refs. 162–187

and the literature cited in these articles). In contrast to quantum optics the effect of excitation capture in the theory of nonradiative intramolecular transitions has been studied in considerably less detail,[201,202] although the basic principle that bound states exist in a continuum was substantiated quite a long time ago.[188–191] Such a position is associated with the fact that in the objectives of intramolecular dynamics there are no natural controlling parameters analogous to the intensity of irradiation and to the frequency difference of the resonance in quantum optics, which could have been changed as desired and continuously in order to satisfy the conditions essential for the expression of the effect under discussion.

(Quasi)stationary states in the continuous spectrum may also arise during the decay of quantum systems in stable outer fields.[192–196] In this case the outer field strength plays the role of the continuous controlling parameter. A good example of such an effect is the narrowing of the autoionisation widths of the Rydberg states in the regions of their quasi-intersections which arises as a result of the destructive interference between different decay channels (see Refs. 194–196 and the references cited in these papers).

In a recent series of studies the possibility that (quasi)bound states of a purely intramolecular nature could exist in a continuum was demonstrated. Such states naturally arise during the decay of a coherently excited group of discrete (quasi)degenerate levels interacting with one or several continua. An analogous effect may also arise during the interaction of several continua.[203,204] In a discussion of the theory of this effect we will not give a concrete definition of the physical nature of the discrete states and the continuum; this enables us to obtain results applicable to a very broad range of processes.

We shall examine N degenerate discrete states interacting with a single continuum by means of potential V. We shall assume that the wavefunctions of the discrete states $\{\varphi_k,\ k = 1, \ldots, N\}$ and the continuum φ_E were selected as actual, whereas the interaction V has matrix elements differing from zero only between the states of the discrete and continuous spectra ($V_{kn} = V_{EE'} = 0$, $V_{ke} = 0$) and the matrix elements are not dependent on E. Such assumptions are normal in the theory of nonradiative transitions.[205]

In a description of the decays it is convenient from the start to exclude from examination the states of the continuous spectrum. One of the simplest ways of achieving this is to construct an effective Hamiltonian acting in the subspace of discrete states and implicitly taking into account their interaction with the states of the continuum. Such an effective Hamiltonian may usually be reduced to the form:

$$H=H_0-i\alpha W, \tag{14}$$

where H_0 is the unperturbed Hamiltonian describing the discrete states in the absence of a continuum, W is the effective potential describing their interaction with each other by means of the continuum, while $\alpha > 0$ is a certain parameter characterising the intensity of this interaction. In our case the operators H_0 and W are actual symmetrical matrices with a dimensionality of $N \times N$, and the matrix W was positively determined.

We shall examine the decay of the N-fold degenerate level within the generalised Weisskopf–Wigner formalism.[206,207] Let only the discrete states be coherently excited at the initial moment of time,

$$\Phi(0)=\sum a_k(0)\varphi_k, \tag{15}$$

which corresponds to the situation realised in different physical experiments. The variation in the amplitude vector $\mathbf{a}(t)$ as a function of time is determined by the equation

$$i\dot{\mathbf{a}}(t)=\mathrm{H}\mathbf{a}(t), \tag{16}$$

where the matrix elements of the effective Hamiltonian have the form

$$H_{kn}=-i\alpha\gamma_{kn},\quad \gamma_{kn}=(\gamma_k\gamma_n)^{1/2},\quad \gamma_k=\pi V_{kE}V_{Ek}>0. \tag{17}$$

Here we have used the atomic system of units ($\hbar = 1$) and have set the energy of the degenerate level = 2 and introduced the designation γk for the initial halfwidth characterising the decay rate of the k-th state in the absence of other states. The dynamics of our system is most simply described on the basis of the wavefunctions of the effective states, which are eigenfunctions of operator H. The eigenvalues $\lambda_n = E_n - iG_n$ correspond to them, where E_n determines the position, and G_n determines the halfwidth of the n-th effective state. In our case the spectrum of the matrix h has a very simple form:

$$\lambda_1=\mathrm{Tr}(H)=-i\alpha\sum\gamma_k,\qquad \lambda_2=\ldots=\lambda_N=0. \tag{18}$$

A number of important physical corollaries result from formula (18).

1. The interaction between the degenerate states via the continuum does not reduce their degeneracy.

2. As a result of such an interaction the $N-1$ bound state and only one unbound state with halfwidth G_1 and wavefunction Ψ_1 which were predetermined by the expressions are formed:

$$\Gamma_1=|\mathrm{Tr}(H)|=\alpha\sum\gamma_k,\qquad \Psi_1=\sum(\alpha\gamma_k/\Gamma_1)^{1/2}\varphi_k. \tag{19}$$

Thus we arrive at a very surprising result, i.e. interference between different decay pathways of a coherently excited system of degenerate states each of which in the absence of the other states would have decayed at its own particular rate determined by the halfwidth leads to a situation in which only one rapid channel of decay remains. All remaining decay routes are found to be closed. the effect under discussion is universal and is not dependent either on the number of states in the group or on the magnitude of the halfwidth γk.

3. The probability that the system examined will remain coupled up to the time moment t is given by the equation

$$P(t)=A\exp(-2\Gamma_1 t)+B, \tag{20}$$

where

$$A=\left[\sum(\alpha\gamma_k/\Gamma_1)^{1/2}a_k(0)\right]^2,\qquad B=1-A. \tag{21}$$

From (20) and (21) it follows that relaxation in the process of excitation of the effective states Ψ_k with $k = 1$ leads to the capture of excitation in the continuous spectrum. Thus initial relaxation is significantly dependent on the nature of the physical process (polarised irradiation, short and ultrashort laser pulses, nonradiative transitions, etc.) used for its creation, and the effect under discussion may be used to control both the rate and the direction of the chemical process by localisation of the excitation in a given group of states. It could have been used in particular for the local heating of individual fragments of molecules such as various functional groups and ligands.[208]

4. We shall discuss how the effect examined alters in the case of the disorganisation of the group of quasidegenerate levels. It has already been shown that the interaction between the group of

quasidegenerate states and the continuum leads to two interesting effects which can be seen in Fig. 3 and Fig. 4,[198] in which the dependence of the effective states of two model systems with an initial equidistant arrangement of the energy levels (normal vibrational polyads) and with equal zero halfwidths ($\gamma_1 = \ldots = \gamma_N = \gamma$) on the α axis and the halfwidths are schematically represented. It can be seen that interaction with the continuum leads to the contraction of the group of interacting states and to the redistribution of the widths in favour of a single effective state. In this case instead of the bound states in the continuous spectrum long-lived resonance states are formed with lifetimes which contrary to expectations increase with increase in the intensity of the interaction between the original states φ_k and the continuum.

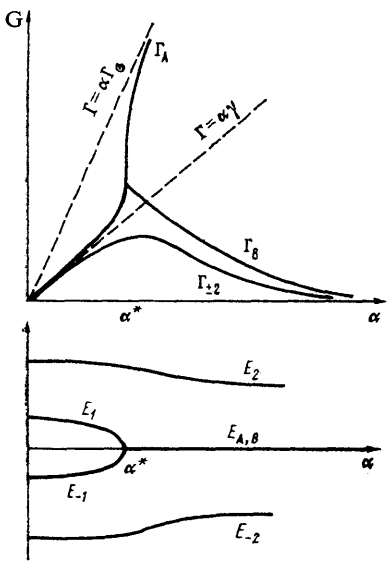

Figure 3. Changes in the positions $\{E_k\}$ and halfwidths $\{G_k\}$ of resonance states in the equidistant N-level system with increase in parameter α, characterising the intensity of the interaction of the coupled states with the continuum. All levels have identical zero halfwidths equal to $\alpha\gamma$, $G_\sigma = N\gamma$. Case $N = 4$.[198]

In general the interaction of N discrete states with the continuum leads to the formation of two different types of resonance state. Firstly the A-resonances the widths of which increase with increase in the interaction between discrete states and the continuum, which lead to their diffusion in the continuous spectrum in the limit $\alpha\to\infty$, and secondly the B-resonances, which in the same limit are transformed into exceptionally long-lived quasistationary states. It is possible to show that the number of A-resonances coincides with the rank of matrix W, which in turn is determined by the number of different decay channels of the system.[198–200] In the Weisskopf–Wigner model the rank of matrix W is equal to unity, which explains the formation of only one A-resonance during the decay. The results obtained have been generalised for the case of the decay of the system in certain of the interacting continua.[199]

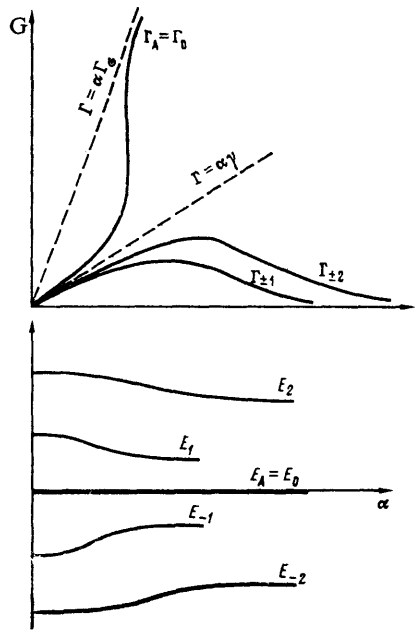

Figure 4. As for Fig. 3, but for case $N = 5$.[198]

VI. Conclusion

The examples considered in this review show that classical concepts play an extremely important role in the theory of highly excited quantum states.

Firstly they serve as the basis for the construction of effective numerical methods of calculation, the most well-known examples being the numerous variants of the quasiclassical method. Moreover information on the characteristics of classical dynamics may be successfully used to increase the efficiency of the standard quantum-mechanical methods of calculation such as the variation method (the selection of the optimum basis) and the adiabatic approximation (the selection of optimum variables).

Secondly the classical concepts serve as a source of both ideas for the design of particular experimental studies and concepts used to interpret the experimental data in the high energy range of the system.

Another important conclusion from the above analysis is the perception of that role played by the concept of localised quantum states by means of which it is possible to examine a set of the most diverse phenomena from common positions.

Thus many rearrangements of vibrational polyads with increase in energy in the transitional range of the spectrum are associated with a change in the nature of the localisation of vibrations on excitation. By studying localised quantum states in the quasicontinuum range it is possible to find and study systematically special relatively stable dynamic regimes and also to observe how they change with increase in energy. Localisation in the continuous spectrum leads to the formation of long-lived resonances and bound states.

A study of the localised vibrational states is of significant interest also because it provides a means of exploring a route to perform selective chemical reactions. From general considerations it is clear that the possibility of controlling a chemical reaction should apparently be closely associated with the possibility of preparing a

molecule in certain special states which have different probabilities for the various reaction pathways. Currently the localised vibrational states are the most practicable candidates for this role.

The dynamic effects of the solvent in electron transfer reactions

L D Zusman
Institute of Inorganic Chemistry, Siberian Division of the Russian Academy of Sciences, Novosibirsk

ABSTRACT. The theories of electron transfer reactions in polar solvents, which describe the dynamic effects of the solvent manifested in these reactions, are examined. The theoretical and the available experimental literature data for these effects are compared.

The bibliography includes 85 references.

I. Introduction

The mechanism of the elementary step in an electron transfer reaction in the liquid phases is as follows. There are two electronic states corresponding to the location of the electron on the electron donor or acceptor. The energies of these electronic states depend on the polarisation of the solvent and the intramolecular degrees of freedom of the donor and the acceptor. The thermal fluctuations in the polarisation of the medium and in the intramolecular degrees of freedom of the reactants lead to the modulation of the energies of the electronic states and sometimes the energy levels intersect. At this instant the electron tunnels from the donor to the acceptor, after which the polarisation of the medium and the intramolecular degrees of freedom of reactants relax to the new equilibrium position.

The theory of the elementary step in electron transfer reactions originated from the classical study by Marcus,[1] who was able to obtain an expression for the free energy of activation for the reaction. This energy is equal to the free energy which the medium and the intramolecular degrees of freedom of the donor and the acceptor must receive in order to attain the point of intersection of the energy levels of the electron. However, Marcus[1] was unable to calculate the pre-exponential factor in the expression for the reaction rate constant. The first calculation of this factor was achieved[2,3] on the basis of the quantum-mechanical perturbation theory using Fermi's famous "golden rule".[4] Within the framework of this theory, the pre-exponential factor in the expression for the rate constant proved to be proportional to the square of the resonance integral characterising the degree of overlap of the donor and acceptor orbitals. If the resonance integral is sufficiently large or the dynamics of the medium sufficiently slow, the perturbation theory ceases to be applicable and it is necessary to set up a theory going beyond the framework of this approximation.

Such a transition to the region of strong interaction was achieved in studies[5–10] where it was shown that, for a sufficiently large resonance integral, the rate of reaction is controlled by the dynamics of the polarisation of the solvent and, in the case of Debye solvents, is proportional to the frequency of the longitudinal relaxation of the solvent polarisation ν_L. This effect of the proportionality of the reaction rate constant to the frequency ν_L has been called the "dynamic effect of the solvent". It was first confirmed experimentally in studies[11–24] where a linear correlation was demonstrated between ν_L in a series of Debye solvents and the rate constant for electron transfer between the reactants dissolved in these solvents. Arguments have been adduced[25] in support of the fact that the dynamic effect of the solvent is manifested in the electron exchange reaction between benzonitrile and its radical-anion in a series of Debye solvents.[26] A similar conclusion has been reached[27] concerning the electron transfer reaction between anthracene and its radical-anion in a mixture of two Debye solvents with different proportions of the latter.[28] The inverse proportionality of the rate constant for electron transfer to the solvent viscosity, predicted by the theory,[5–10] has been confirmed.[29,30]

The dynamic effects of the solvent are observed not only in Debye solvents, having one Debye relaxation time of the polarisation of the medium, but also in solvents of the type of alcohols, which have two and more polarisation relaxation times.[15,17,20,21,31–35] The theories of electron transfer in such solvents will be examined in the present review together with those of the dynamic effect of the solvent in simpler solvents of the Debye type.

A large group of solvents of the type of glycerol have a continuous distribution of relaxation times of the Cole–Davidson type. The dynamic effects of the solvent in such media have a number of characteristic features distinguishing them from the effects in Debye solvents and also in alcohols. The theories of electron transfer in solvents of the glycerol type will also be examined in the present review.

The dynamic effects of the solvent are not limited to the influence of the reorientation relaxation of the solvent, many effects being associated with the translational motion of the solvent dipoles. These questions will be likewise examined in the present review.

II. Theories of electron transfer reactions based on the structureless dielectric approximation

The electron transfer reactions in a polar medium can be described as transitions between two electronic states at the instant when the energy levels of these states intersect under the influence of thermal fluctuations of the medium. It has been shown[39] that the difference between the energies of these states is

$$-\delta H(t)=H_2(t)-H_1(t)=E_0-E(t), \quad (1)$$

where $H_1(t)$ and $H_2(t)$ are the energies of the first and second electronic states fluctuating in a period t,

$$E(t)=-\int \Delta\mathbf{D}(\mathbf{r})\delta\mathbf{P}(\mathbf{r},t)d\mathbf{r}, \quad (2)$$

where $\Delta\mathbf{D}(\mathbf{r}) = \mathbf{D}_2(\mathbf{r}) - \mathbf{D}_1(\mathbf{r})$ is the difference between the electrostatic inductions of the first and second states, and

$$\delta\mathbf{P}(\mathbf{r},\ t)=\mathbf{P}(\mathbf{r},\ t)-\mathbf{P}_1(\mathbf{r}), \quad (3)$$

where $\mathbf{P}(\mathbf{r},\ t)$ is the polarisation of the solvent and $\mathbf{P}_1(\mathbf{r})$ the equilibrium polarisation of the solvent in the first electronic state;

$$E_0=J_2-J_1+E_r, \quad (4)$$

where J_1 and J_2 are the free energies of the first and second states and E_r is the solvent reorganisation energy:

$$E_r=\frac{c_0}{8\pi}\int \Delta\mathbf{D}(\mathbf{r})^2 d\mathbf{r}. \quad (5)$$

Here c_0 is the familiar Pekarov multiplier:

$$c_0=\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_S},$$

and ε_∞ and ε_S are the high-frequency and static dielectric constants respectively.

It has also been shown[39] that $E(t)$ fluctuates in conformity with a Gaussian random process. All the properties of Gaussian processes are known to be expressed in terms of a binary correlation function of a random variable. By virtue of the fluctuation-dissipative theorem, in the given case this correlation function is expressed as follows in terms of the complex dielectric constant of the solvents $\varepsilon(\mathbf{q}, \omega)$ at a frequency ω and for a wave vector $\mathbf{q}$:

$$K(\tau)=\langle E(\tau)E(0)\rangle=\frac{kT}{32\pi^5}\int |\Delta\mathbf{D}_q|^2\frac{\varepsilon''(\mathbf{q},\omega)}{\omega|\varepsilon(\mathbf{q},\omega)|^2}$$

$$\exp(-i\omega\tau)d\mathbf{q}\,d\omega, \quad (6)$$

where k is the Boltzmann constant and T the absolute temperature. The angular brackets in Eqn. (6) denote averaging with respect to the random fluctuations in the polarisation of the medium and

$$\Delta\mathbf{D}_q=\int \Delta\mathbf{D}(\mathbf{r})\exp(-\mathbf{qr})d\mathbf{r} \quad (7)$$

is the spatial Fourier transform of the difference between the inductions $\Delta\mathbf{D}(\mathbf{r})$.

Eqns. (1) and (6) are the initial expressions for the construction of the theory of electron transfer in a polar solvent.

1. Theories of electron transfer reactions in solvents with one Debye relaxation time of the polarisation of the medium

We shall consider the simplest case where the solvent in which the reaction takes place is of the Debye type, i.e. its complex dielectric constant assumes the form

$$\varepsilon(\omega)=\varepsilon_\infty+\frac{\varepsilon_S-\varepsilon_\infty}{1-i\omega\tau_D}. \quad (8)$$

On substituting Eqn. (8) in Eqn. (6), we find that the correlation function of the fluctuations of the electronic energy levels assumes the simplest form

$$K(\tau) = 2kTE_r\exp(-\nu_L|\tau|), \quad (9)$$

where $\nu_L = (E_S/E_\infty)(1/\tau_D)$ is the frequency of the longitudinal relaxation of the solvent polarisation, describing the relaxation of the medium under the conditions of a constant charge polarising it.

It has been shown[5,6] that, when the correlation function of the fluctuations of the energy levels of the electron has the form of Eqn. (9), then motion along the coordinate $E(t)$, which in the given instance is the reaction coordinate, has the character of diffusion with two parabolic terms $U_1(E)$ and $U_2(E)$ corresponding to the first and second electronic states:

$$U_1(E) = J_1 + \frac{E^2}{4E_r}, \quad U_2(E) = J_2 + \frac{(E-2E_r)^2}{4E_r}. \quad (10)$$

The transitions between these electronic terms are described by the following system of kinetic equations for the partial populations $\rho_1(E, t)$ and $\rho_2(E, t)$:[5,6]

$$\dot{\rho}_1(E,t)=-\frac{2\pi V^2}{\hbar}\delta(E-E_0)[\rho_1(E,t)-\rho_2(E,t)]+$$
$$+\nu_L\left[1+E\frac{\partial}{\partial E}+\Delta^2\frac{\partial^2}{\partial E^2}\right]\rho_1(E,t), \quad (11)$$
$$\rho_2(E,t)=\frac{2\pi V^2}{\hbar}\delta(E-E_0)[\rho_1(E,t)-\rho_2(E,t)]+$$
$$+\nu_L\left[1+(E-2E_r)\frac{\partial}{\partial(E-2E_r)}+\Delta^2\frac{\partial^2}{\partial(E-2E_r)^2}\right]\rho_2,$$

where $\Delta^2 = 2kTE_r$.

The partial populations $\rho_1(E, t)$ and $\rho_2(E, t)$ have the physical significance of the probabilities of finding an electron in the first or second electronic state respectively when the reaction coordinate assumes a value E. The first term on the right-hand sides of the equations describes the tunnelling of the electron from the donor to the acceptor at the point of intersection of the electronic terms E_0. The rate of such tunnelling is

$$K(E)=\frac{2\pi V^2}{\hbar}\delta(E-E_0), \quad (12)$$

where V is the resonance integral between the electron donor and acceptor, $\delta(E - E_0)$ the Dirac delta-function, and $\hbar$ the Planck constant. The second terms on the right-hand sides of Eqns. (11) describe diffusion in terms of the potentials $U_1(E)$ and $U_2(E)$ for the diffusion coefficient $\Delta^2\nu_L$.

A general solution of Eqns. (11) has been found[5,6] by the method of Green's functions and it has been shown that, in the limit of high activation energies for the reaction, $E_{a1}/kT \gg 1$ and $E_{a2}/kT \gg 1$ and that, for sufficiently long solvation times $t \gg \nu_L^{-1}$, the kinetics of the transitions are exponential as a function of time. It is possible to introduce the rates of the forward (W_{12}) and reverse (W_{21}) transitions respectively, for which the following expressions have been obtained:[5,6]

$$W_{12}=\frac{W_{12}^{NA}}{1+W_{12}^{NA}/W_{12}^{D}}$$

$$W_{21}=\frac{W_{21}^{NA}}{1+W_{12}^{NA}/W_{12}^{D}}, \quad (13)$$

where W_{12}^{NA} is the rate of the forward non-adiabatic electron transfer reaction, W_{21}^{NA} the rate of the reverse non-adiabatic electron transfer reaction, and W_{12}^{D} the rate of the forward reaction determined by diffusion along the electronic term consisting of two portions of diabatic terms (Fig. 1). W_{12}^{D} is identical with the familiar solution of the Kramers problem[40] concerning the diffusional overcoming of a sharp barrier, for which the following expression has been obtained:[5,6]

$$W_{12}^{D} = \nu_L \frac{|E_0||E_0 - 2E_r|}{|E_0| + |E_0 - 2E_r|} \frac{1}{(2\pi\Delta^2)^{1/2}} \exp\left(-\frac{E_0^2}{4E_r kT}\right). \qquad (14)$$

W_{12}^{NA} and W_{21}^{NA} are defined by the usual expressions of the Levich–Dogonadze–Kuznetsov theory:[2,3]

$$W_{12}^{NA} = \frac{\sqrt{2\pi}}{\hbar\Delta} V^2 \exp\left(-\frac{E_0^2}{4E_r kT}\right),$$
$$W_{12}^{NA} = \frac{\sqrt{2\pi}}{\hbar\Delta} V^2 \exp\left[-\frac{E_0 - 2E_r)^2}{4E_r kT}\right]. \qquad (15)$$

It is seen from Eqn. (13) that, if the rate of the non-adiabatic reaction is sufficiently low ($W_{12}^{NA} \ll W_{12}^{D}$), then the electron tunnelling stage is rate-limiting and

$$W_{12} = W_{12}^{NA},$$
$$W_{21} = W_{21}^{NA}. \qquad (16)$$

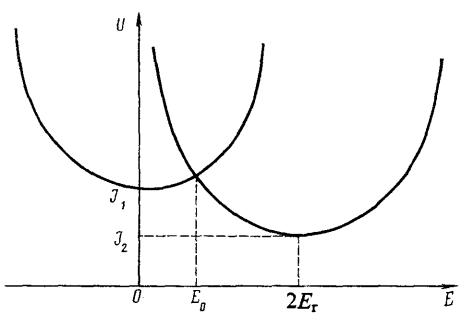

Figure 1. Electronic terms: J_1 = free energy of the first electronic state; J_2 = free energy of the second electronic state; E_0 = point of intersection of the electronic terms; E_r = energy of the reorganisation of the solvent.

On the other hand, if the tunnelling stage is rapid, i.e. $W_{12}^{NA} \gg W_{12}^{D}$, then diffusion along the electronic term is rate-limiting and

$$W_{12} = W_{12}^{D},$$
$$W_{21} = \frac{W_{21}^{NA}}{W_{12}^{NA}} W_{12}^{D} = \exp\left(\frac{J_2 - J_1}{kT}\right) W_{12}^{D}. \qquad (17)$$

As can be seen from Eqn. (14), in this case the rate of reaction is proportional to the frequency of the longitudinal relaxation of the solvent polarisation ν_L. This prediction of the theory has been confirmed experimentally in a number of studies.[11–24]

Eqn. (14) has been revised by the present author,[7] who obtained a somewhat different expression for W_{12}^{D}:

$$W_{12}^{D} = \frac{\nu_L}{\pi} \sqrt{\frac{E_r}{\pi kT}} \sin\left(\frac{\pi E_0}{2E_r}\right) \exp\left(-\frac{E_0^2}{4E_r kT}\right). \qquad (18)$$

If the reaction proceeds in the inverted regime $\Delta J > E_r$, where $\Delta J = J_2 - J_1$ is the driving force of the reaction, then, as shown by Gennett et al.,[41] not only the rate of the diffusional overcoming of the barrier W_{12}^{D} but also the rates of the non-adiabatic reactions W_{12}^{NA} and W_{21}^{NA} depend on ν_L for not very low values of the latter. In this case Eqns. (15) for W_{12}^{NA} and W_{21}^{NA} cease to be applicable and more complex expressions must be used for them.[41] However, with decrease in ν_L, even in the inverted regime, the validity of Eqns. (15) is restored starting from a certain instant and the rate of reaction depends on the solvent dynamics only in the limit where diffusion along the electronic term is rate-limiting.

Eqns. (13) are applicable for not unduly high values of the resonance integral V. The inequalities

$$V \ll kT, \qquad (19)$$

$$\frac{2\pi V^2}{kT\hbar\omega_L}\left(\frac{\pi kT}{E_p}\right)^{1/2} \ll 1, \qquad (20)$$

where ω_L is the frequency characterising the rate of movement of the electron-medium system along the reaction coordinate E over the length of the free path, serve as a criterion of their applicability. The following relation has been obtained[42] for ω_L:

$$\omega_L^2 = \left(\frac{2\varepsilon_S + \varepsilon_\infty}{3\varepsilon_\infty g}\right)\omega_f^2, \qquad (21)$$

where ω_f is the average thermal rate of free rotation of the solvent dipoles[43] and g is the Kirkwood factor.[43]

On the other hand, if the inequality (20) breaks down and the Landau–Zener adiabaticity parameter

$$k_{el} = \frac{\pi V^2}{kT\hbar\omega_L}\left(\frac{\pi kT}{E_r}\right)^{1/2}$$

becomes sufficiently large, i.e. $k_{el} \gg 1$, then instead of Eqn. (13) it is necessary to employ the following formulae:[42]

$$W_{12} = \frac{W_{12}^{WA}}{1 + W_{12}^{WA}/W_{12}^{D}},$$
$$W_{21} = \frac{W_{21}^{WA}}{1 + W_{12}^{WA}/W_{12}^{D}}, \qquad (22)$$

where

$$W_{12}^{WA} = \frac{\omega_L}{2\pi}\exp(-E_0^2/4E_r kT),$$
$$W_{12}^{WA} = \frac{\omega_L}{2\pi}\exp\left[\left(-\frac{(E_0 - 2E_r)^2}{4E_r kT}\right]\right. \qquad (23)$$

Eqns. (23) express none other than the rates of reaction within the framework of the transition state theory. Thus Eqns. (22) imply that the reaction proceeds in two stages. Initially the system reaches the top of the barrier by diffusion and then moves dynamically in the immediate vicinity of the top of the barrier at a certain thermal velocity proportional to the frequency ω_L. Throughout this time, the system is on the lower adiabatic electronic term, which is constructed in the usual way from the diabatic terms defined by Eqn. (10).

Using the method of molecular dynamics, the electron transfer reaction has been modelled numerically in a model solvent which is typical of a series of polar aprotic solvents being investigated experimentally at the present time. It was shown that Eqns. (22) agree better than Eqn. (13) with the results of numerical modelling. This apparently means that the inequality (20) breaks down in the model systems. Indeed, substitution of the parameters used in the above study[44] shows that the Landau–Zener parameter k_{el} is large in these systems.

Formulae (13) and (22) were obtained for condition (19). This condition means that the barrier, which the system overcomes by moving along the reaction coordinate, is nearly triangular. If the inequality (19) is reversed, i.e.

$$V \gg kT, \tag{24}$$

then the barrier overcome becomes nearly parabolic and the expression for the rates of reaction assume the following form:[6]

$$W_{12} \frac{\nu_L}{4\pi} \left(\frac{2E_r}{V}\right)^{1/2} \left(\frac{|E_0||E_o - 2E_r|}{E_r^2}\right)^{3/4} \exp\left\{ -\left[\frac{(E_0)^2}{4E_r} - V\left(\frac{|E_0||E_o - 2E_r|}{E_r^2}\right)^{1/2}\right] \frac{1}{kT} \right\},$$
$$W_{21} = W_{12} \exp \frac{\Delta J}{kT}. \tag{25}$$

It also follows from Eqn. (25) that the rates of the forward and reverse reactions must be proportional to ν_L, i.e. in this limit too the theory[6] predicts the dynamic effect of the solvent. We may draw attention to the fact that, subject to condition (24), the free energy of activation for the reaction is not equal to the Marcus value $E_{a1} = E_0^2/4E_r$ but is smaller than the latter by the amount $V(|E_0||E_0 - 2E_r|/E_r^2)^{1/2}$. This quantity is exactly equal to the splitting of the adiabatic electronic terms at the point of intersection of the diabatic terms E_0.

Eqns. (13), (22), and (25) were derived on the assumption of high activation energies. The non-activated ($E_{a1} = 0$, $E_{a2} = 0$) or low-barrier ($E_{a1}/kT \ll 1$, $E_{a2}/kT \ll 1$) electron transfer reactions are also of considerable interest. The solutions of Eqns. (11) for such processes are non-exponential as a function of time. Strictly speaking, it is therefore impossible to introduce time-independent rates of reaction. Nevertheless, numerical analysis of the solution of Eqns. (11) carried out by Rips and Jortner[45] shows that in the range $\nu_L t < 4$, the kinetics of the transitions are nearly exponential and one can introduce the rates of the forward and reverse reactions W_{12} and W_{21} as an approximation.

It has been shown[46] that in both the normal ($\Delta J < E_r$) and the inverted ($\Delta J > E_r$) regimes the rate of reaction can be controlled by the solvent dynamics, whereupon it is proportional to ν_L. This agrees well qualitatively with the results of experiments[31–35] in which a linear correlation was found for non-activated intramolecular electron transfer reactions between the rate of reaction and the lowest solvent relaxation frequency. However, it is noteworthy that the experiments[31–35] were carried out in alcohols, which are not Debye solvents. On the other hand, the prediction[46] that the rate of reaction is proportional to the lowest solvent relaxation frequency was based on an erroneous study[47] in which an attempt was made to extend the present author's results[5,6] to non-Debye solvents. The conclusion[46,48] that the theory and experiment[31–35] agree is therefore controversial. We shall return to the discussion of these experiments below.

The theories examined above were based on the approximation of a linear medium first introduced by Ovchinnikov and Ovchinnikova.[49] The present author[10] was able to extend the treatment outside the framework of this approximation having shown that in the more general situation the rate of reaction may be proportional to ν_L.

All the theories of electron transfer examined hitherto fail to take into account the reorganisation of the intramolecular degrees of freedom of the reactants and reaction products. The first attempt to take into account the reorganisation of the intramolecular degrees of freedom of reactants and products and to estimate its influence on the dynamic effect of the solvent in the rate of reaction was undertaken by Ovchinnikova.[50] As a result of the allowance for the reorganisation of the intramolecular degrees of freedom, electronic transitions are seen to occur not only at the point of intersection of the electronic terms E_0 but also over the entire range of values of the reaction coordinate E. Eqns. (11) were extended by Ovchinnikova[50] as follows:

$$\dot{\rho}_1(E,t) = -K_{12}(E)\rho_1(E,t) + K_{21}(E)\rho_2(E,t) + \nu_L\left[1 + E\frac{\partial}{\partial E} + \Delta^2\frac{\partial^2}{\partial E^2}\right]\rho_1(E,t),$$
$$\dot{\rho}_2(E,t) = -K_{21}(E)\rho_2(E,t) + K_{12}(E)\rho_1(E,t) + \nu_L\left[1 + (E-2E_r)\frac{\partial}{\partial(E-2E_r)} + \Delta^2\frac{\partial^2}{\partial(E-2E_r)^2}\right]\rho_2, \tag{26}$$

where the following expressions were used for $K_{12}(E)$ and $K_{21}(E)$:

$$K_{12}(E) = \frac{\omega_Q}{2\pi}\exp\left[-\frac{(E_0 - E + E_i)^2}{4E_i kT}\right],$$
$$K_{21}(E) = \frac{\omega_Q}{2\pi}\exp\left[-\frac{(E_0 - E - E_i)^2}{4E_i kT}\right]. \tag{27}$$

Here $K_{12}(E)$ is the characteristic frequency of intramolecular vibrations and E_i is the energy of the reorganisation of the intramolecular degrees of freedom. Eqns. (27) were obtained on the assumption that the intramolecular vibrations are classical, i.e. subject to the condition $kT \gg h\omega_Q$. However, Ovchinnikova[50] was not able to solve Eqn. (26). This was done later.[7] Nevertheless, Ovchinnikova[50] reached the generally correct conclusion that intramolecular vibrations hinder the observation of the dynamic effect of the solvent in the rate of electron transfer.

The influence of intramolecular degrees of freedom of the reactants on the rate of electron transfer has also been considered.[51,52] In the theory of Marcus and co-workers,[51,52] the intramolecular vibrations were assumed to be classical ($kT \gg \hbar\omega_Q$) and the theory was based, as in Ovchinnikova's study,[50] on

Eqn. (28), where, however, no account was taken of the reverse reaction. The authors used Eqn. (27) for $K_{12}(E)$ and assumed that the partial rate of the reverse reaction $K_{21}(E)$ was identically equal to zero. They postulated that the reverse reaction may be disregarded for $\Delta J \gg kT$. Generally speaking, this is correct for the reaction as a whole, but the condition $K_{21}(E) \equiv 0$ constitutes a much stronger limitation than $\Delta J \gg kT$. It implies that the reverse reaction is neglected for any value of the coordinate of the medium E.

On the other hand, analysis of the simpler Eqns. (11) shows that $K_{21}(E) \neq 0$ contributes not only to the rate of the reverse reaction W_{21} but also to that of the forward reaction W_{12}. This contribution is fully comparable to the contribution of the forward partial reactions specified by the rate $K_{12}(E)$. This contribution to W_{12} does not vanish in the limit where $\Delta J \gg kT$. Therefore the hypothesis that $K_{21}(E) \equiv 0$ makes the treatment inconsistent with the physics of the process and the formulae presented by Sumi and Marcus[51] for the case where $E_{a1} \gg kT$ hardly describe the reaction adequately or even approximately. As regards the non-activated reaction with $E_{a1} \ll kT$, the conclusion[51,52] that on reorganisation of the intramolecular degrees of freedom and in the limit $\nu_L \to 0$ the reaction kinetics become highly non-exponential while the average reaction time τ_a may be much shorter than ν_L^{-1} and in the limit $\nu_L \to 0$ may cease to depend on ν_L is believeable. Indeed, subject to the condition $E_{a1} \ll kT$, the analysis of Eqns. (11) carried out by Rips and Jortner[46] shows that the hypothesis that $K_{21}(E) \equiv 0$ in the limit where $\Delta J/kT \gg 1$ becomes more acceptable. The prediction[52] that, when account is taken of the intramolecular degrees of freedom of the reactants, the rate of reaction at $\nu_L \to 0$ should be proportional to ν_L^{α}, where α may depend on the ratio E_i/E_r and varies in the range $0 < \alpha < 1$, is also of interest.

The intramolecular electron transfer in dimethylaminobenzonitrile and in diethylaminobenzonitrile has been investigated[53] in a series of solvents. In conformity with the authors' predictions,[51,52] it was observed that the kinetics of the reactions involving these compounds are markedly non-exponential. It has also been shown[53] that the average reaction time τ_α is shorter for these compounds than the longitudinal relaxation time of the solvent ν_L^{-1}. These data confirm the theory developed by Marcus and co-workers.[51,52]

The conclusion that, when account is taken of the intramolecular degrees of freedom of the reactants the rate of reaction as $\nu_L \to 0$ should be proportional to ν_L^{α} was invoked[52] to account for the observed[54] proportionality between the rate of reaction and ν_L^{β}. However, the reactions investigated by McGuire and McLendon[54] were carried in glycerol—a solvent of the non-Debye type. It is therefore not clear at present what lies behind the proportionality of the rate of reaction to ν_L^{β}—the presence of intramolecular degrees of freedom of the reactants or the nature of the solvent (its not being a Debye solvent). Below, we shall return to the discussion of the results of McGuire and McLendon.[54]

The theories considered above describe the reorganisation of the intramolecular degrees of freedom on the assumption that $kT \gg \hbar\omega_Q$. A theory has been developed[55] for electron transfer where account is taken of the reorganisation of the intramolecular degrees of freedom, but, in contrast to Marcus and co-workers,[50–52] it is assumed that the intramolecular vibrations are quantised, i.e. subject to the conditions $kT \ll \hbar\omega_Q$. The author[55] began his treatment with the kinetic equations (26) where, in contrast to Eqn. (27), the following expressions were used for $K_{12}(E)$ and $K_{21}(E)$:

$$K_{12}(E) = \frac{2\pi V^2}{\hbar} \sum_{n=-\infty}^{\infty} \lambda_n \delta(E_0 + n\hbar\omega_Q - E),$$
$$K_{21}(E) = \frac{2\pi V^2}{\hbar} \sum_{n=-\infty}^{\infty} \lambda_n \delta(E_0 - n\hbar\omega_Q - E), \qquad (28)$$

where λ_n is the Franck–Condon factor for the intramolecular oscillator.[56] Eqns. (28) imply that the transitions do not occur solely at the point of intersection of the E_0 terms but also at the points $E_0 + n\hbar\omega_Q$ and $E_0 - n\hbar\omega_Q$ and are accompanied by the emission or absorption of n quanta.

With the aid of a method analogous to that used by the present author,[5,6] Helman[55] found a solution to Eqn. (26) with the coefficients defined by Eqn. (28) and obtained expressions for the reaction rates W_{12} and W_{21}, generalising Eqns. (13). Thus in the limit corresponding to high activation energies, $E_{a1}/kT \gg 1$ and $E_{a2}/kT \gg 1$, Helman[55] obtained expressions for W_{12} and W_{21} identical with Eqns. (13), where

$$W_{12}^{NA} = \frac{\sqrt{2\pi}}{\hbar\Delta} V^2 \lambda_0 \exp\left(-\frac{E_0^2}{4E_r kT}\right),$$
$$W_{21}^{NA} = \frac{\sqrt{2\pi}}{\hbar\Delta} V^2 \lambda_0 \exp\left[-\frac{(E_0 - 2E_r)^2}{4E_r kT}\right]. \qquad (29)$$

It is seen from Eqns. (13) and (29) that, for the observation of the dynamic effect of the solvent, the following criterion must be satisfied:

$$\frac{2\pi V^2}{\hbar}\lambda_0 \gg \lambda_L \frac{|E_0|\,|E_0 - 2E_r|}{|E_0| + |E_0 - 2E_r|}. \qquad (30)$$

Since $\lambda_0 < 1$, the observation of the dynamic effect of the solvent in the presence of intramolecular degrees of freedom of the reactants requires larger values of the resonance integral V than in the case where the degree of reorganisation of these degrees of freedom is small or is altogether absent. The result of Helman's study[55] was reproduced by Onuchic et al.[57] Results similar to Helman's[55] were also obtained subsequently in later studies.[58,59] The solution found by Helman[55] was refined by the present author.[7]

All the theories examined hitherto describe reactions occurring under homogeneous conditions. The theories of reactions occurring on the electrode are constructed similarly. The present author[60] began with Eqn. (26), where, in contrast to Eqn. (27), the partial rates $K_{12}(E)$ and $K_{21}(E)$ are defined by the following expressions:

$$K_{12}(E) \int \frac{\rho(\varepsilon)}{n_e} f(\varepsilon) K_{12}(\varepsilon, E)\, d\varepsilon,$$
$$K_{21}(E) = \int \frac{\rho(\varepsilon)}{n_e} [1 - f(\varepsilon)] K_{21}(\varepsilon, E)\, d\varepsilon. \qquad (31)$$

Here $f(\varepsilon)$ is the Fermi distribution of electrons in the electrode, $K_{12}(\varepsilon, E)$ and $K_{21}(\varepsilon, E)$ are the partial rate of the forward and reverse electron transfer from the energy level ε in the electrode to the energy level in the reactant, and $\rho(\varepsilon)$ is the density of electronic

states in the electrode. The general expressions quoted by the present author[7,61] are valid for the rates $K_{12}(\varepsilon, E)$ and $K_{21}(\varepsilon, E)$. In view of the very cumbersome nature of these formulae, we do not quote them here.

The kinetic equations (26), with the partial rates $K_{12}(E)$ and $K_{21}(E)$ expressed in the form of Eqns. (31), were solved[60] with the aid of the method used previously;[7] the following formulae were obtained for the rates of reaction W_{12} and W_{21}:

$$W_{12} = \frac{\overline{K}_{12}}{1 + \overline{K}_{12}/W_{12}^{eD}}, \qquad W_{21} = \frac{\overline{K}_{21}}{1 + \overline{K}_{12}/W_{12}^{eD}}, \tag{32}$$

where

$$\overline{K}_{12} = \frac{1}{\sqrt{2\pi}\Delta}\int K_{12}(E)\exp\left(-\frac{E^2}{2\Delta^2}\right)dE, \qquad \overline{K}_{12} = \frac{1}{\sqrt{2\pi}\Delta}\int K_{21}(E)\exp\left(-\frac{E^2}{2\Delta^2}\right)dE, \tag{33}$$

$$W_{12}^{eD} = \frac{\nu_L}{\pi}\left(\frac{E_r}{\pi kT}\right)^{1/2}\sin\left(\frac{\pi E_0'}{2E_r}\right)\exp\left[-\frac{(E_0')^2}{4E_r kT}\right], \tag{34}$$

$$E_0' = e\xi - kT\ln(c_{z-1}/c_z) + E_r. \tag{35}$$

Here e is the electronic charge, Z and $Z-1$ are the charges on the reactant and the reaction product respectively, c_Z and c_{Z-1} are their concentrations, and ξ is the electrode overpotential. Eqns. (32) are analogous to Eqns. (13) describing homogeneous reactions.

Knowing Eqns. (32) for the reaction rates, it is possible to find the transient current of the reaction:[60]

$$i = i_0\left[1 - \exp\left(\frac{e\xi}{kT}\right)\right], \tag{36}$$

where

$$i_o = -\frac{ec_z}{2\kappa}\frac{\nu_L}{\pi}\left(\frac{E_r}{\pi kT}\right)^{1/2}\sin\left(\frac{\pi E_0'}{2E_r}\right)\exp\left[-\frac{(E_0')^2}{4E_r kT}\right]\times$$

$$\times\ln\left\{1 + \pi\left(\frac{\pi kT}{E_r}\right)^{1/2}\frac{\overline{K}_{12}^0}{\nu_L}\frac{\exp[(E_0')/4E_r kT]}{\sin(\pi E_0'/2E_r)}\right\}. \tag{37}$$

In deriving Eqn. (37), it was assumed that

$$\overline{K}_{12} = \exp(-2\kappa r)\,\overline{K}_{12}^0, \tag{38}$$

where the parameter κ^{-1} characterises the scale of the decay of the electronic resonance integral between the reactant and the electrode with distance from the electrode. Eqn. (38) is usually a satisfactory approximation.

It is evident from Eqns. (36) and (37) that, when the resonance integral is fairly small and the inequality

$$\overline{K}_{12}^0 \ll \frac{\nu_L}{\pi}\left(\frac{E_r}{\pi kT}\right)^{1/2}\sin\left(\frac{\pi E_0'}{2E_r}\right)\exp\left[-\frac{(E_0')^2}{4E_r kT}\right], \tag{39}$$

holds, then the second term in the logarithmic expression is small. Expanding the logarithm in series in terms of this small parameter, one can obtain

$$i_0 = -\frac{ec_z}{2\kappa}\overline{K}_{12}^0. \tag{40}$$

This agrees exactly with the results of the non-adiabatic Dogonadze–Kuznetsov theory.[62] On the other hand, if the resonance integral is fairly large or the solvent exhibits a fairly slow polarisation relaxation, i.e. the inequality

$$\overline{K}_{12}^0 \gg \frac{\nu_L}{\pi}\left(\frac{E_r}{\pi kT}\right)^{1/2}\sin\left(\frac{\pi E_0'}{2E_r}\right)\exp\left[-\frac{(E_0')2}{4E_r kT}\right], \tag{41}$$

which is the opposite of the inequality (39), holds, then the following result can be readily obtained from Eqn. (37):

$$i_o = -\frac{ec_z}{2\kappa}\frac{\nu_L}{\pi}\left(\frac{E_r}{\pi kT}\right)^{1/2}\sin\left(\frac{\pi E_0'}{2E_r}\right)\exp\left[-\frac{(E_0')^2}{4E_r kT}\right]\times$$

$$\times\ln\left\{\pi\left(\frac{\pi kT}{E_r}\right)^{1/2}\frac{\overline{K}_{12}^0}{\nu_L}\frac{\exp[(E_0')/4E_r kT]}{\sin(\pi E_0'/2E_r)}\right\}. \tag{42}$$

It follows from Eqn. (42) that, similarly to the processes occurring under homogeneous conditions, the reaction at the electrode subject to condition (41) is controlled by the solvent dynamics and its rate as well as the current are proportional to ν_L in this limit. This theoretical prediction has been confirmed experimentally.[13–15,18–23]

Eqns. (32)–(42) describe the kinetics of the reaction occurring in the region of the normal overpotentials ξ, i.e. subject to the condition $|e\xi| \ll E_r$. For the non-activated region, where $e\xi > -E_r$, and also in the region of anomalous overpotentials, where $e\xi \simeq -E_r$, an approach different from that used previously[7] is required.

Such an approach to the problem of electron transfer from the reactants to the electrode has been developed.[63] The authors began with Eqns. (26), where $K_{12}(E)$ was specified by Eqn. (31) and $K_{21}(E)$ was assumed to be identically equal to zero. They used the variational principle, with the aid of which they found expressions for the rate of reaction on the electrode in both normal and non-activated regions and also in the anomalous range of overpotentials. However, as already mentioned in discussing the studies of Marcus and co-workers,[51,52] the approximation $K_{21}(E) \equiv 0$ is incorrect in the normal region and the formulae of Morgan and Wolynes[63] therefore describe the reaction incorrectly in this case. For normal overpotentials, Eqns. (32)–(42) should be used. As mentioned in the discussion of homogeneous reactions, in the non-activated and anomalous regions, the approximation $K_{21}(E) \equiv 0$ becomes reasonable and the formulae obtained by the above workers[63] for these situations are more believable. The theory of Morgan and Wolynes[63] predicts that, in solvents with a fairly slow relaxation of the polarisation of the medium in the anomalous and non-activated ranges of overpotentials and also in the normal region, the reaction is controlled by the solvent dynamics and its rate is proportional to ν_L. The formulae of the above workers[63] supplement the present author's theory,[60] because they describe the reaction in other ranges of overpotentials.

Thus in both homogeneous and heterogeneous electron transfer reactions in Debye solvents with a fairly slow relaxation of the medium, the reaction begins to be controlled by the solvent

dynamics and the rate of reaction is proportional in this limit to ν_L. This conclusion is qualitatively consistent with the available experimental data.

2. Theories of electron transfer reactions in solvents with two (or more) relaxation times of the polarisation of the medium

The dielectric properties of many solvents of the type of alcohols, where the molecules are linked by a network of hydrogen bonds, are not described by the simple equation (8). The following relation is applicable to such solvents:[64]

$$\varepsilon(\omega)=\varepsilon_\infty+(\varepsilon_S-\varepsilon_\infty)\sum_{i=1}^{N} f_i(1-i\omega\tau_i)^{-1}, \tag{43}$$

where τ_i are quantities differing greatly in magnitude.

If Eqn. (43) is now substituted in Eqn. (6), the correlation function for the fluctuations of the electronic energy levels becomes

$$K(\tau) = 2kTE_\tau\left[\sum_{i=1}^{N}\delta_i\exp(-\nu_i|\tau|)\right], \tag{44}$$

where the correlation times ν_i^{-1} and the coefficients δ_i are expressed in some way in terms of f_i and τ_i. The coefficients δ_i satisfy the relation

$$\sum_{i=1}^{N}\delta_i=1. \tag{45}$$

A general theory of homogeneous electron transfer reaction, applicable to solvents with an arbitrary dielectric losses spectrum and therefore valid for any correlation function $K(\tau)$, has been constructed.[65] This theory is based on the summation of series in powers of V^2 by Padé's method of approximants. It has been shown that the kinetics of transitions with high reaction activation energies are exponential. The following general expressions have been obtained[65] for the rates W_{12} and W_{21}:

$$W_{12}=\frac{W_{12}^{NA}}{1+W_{12}^{NA}/W_{12}^{S}}, \qquad W_{21}=\frac{W_{21}^{NA}}{1+W_{12}^{NA}/W_{12}^{S}}, \tag{46}$$

where W_{12}^{NA} and W_{21}^{NA} are again defined by Eqns. (15) and it has been found that the rate W_{12}^{S} is given by

$$(W_{12}^{S})^{-1}=\int_0^\infty d\tau\left\{\frac{1}{[1-M^2(\tau)]^{1/2}}\exp\left[\frac{E_0^2}{\Delta^2}\frac{M(\tau)}{1+M(\tau)}\right]-1\right\}+$$
$$+\exp\left(\frac{\Delta J}{kT}\right)\int_0^\infty d\tau\left\{\left(\exp\left[\frac{(E_0-2E_\tau)}{\Delta^2}\frac{M(\tau)}{1+M(\tau)}\right]\right)\Big/\right.$$
$$\left.\Big/(1-M^2(\tau))^{1/2}-1\right\}, \tag{47}$$

where

$$M(\tau)=\frac{K(\tau)}{K(0)}. \tag{48}$$

Eqns. (46) extend Eqns. (13) to reactions occurring in media with an arbitrary dielectric constant $\varepsilon(q, \omega)$ and they are therefore applicable to electron transfer reactions in solvents where the correlation function $K(\tau)$ has an arbitrary form.

Eqns. (46) have also been obtained independently by Hynes[42] with the aid of the theory of stable states and Padá's method of approximants, used, however, in a somehwat different way than in the present author's study,[65] and by Sparpaglione and Mukamel,[66,67] while Fonseca[68] showed that Eqns. (46) are not restricted by the approximation involved in Padá's method of approximants but represent an exact solution for reactions in which correlation functions of type (44) play a significant role.

Eqns. (46) as well as Eqns. (13) are applicable only subject to conditions (19) and (20). On the other hand, if the Landau–Zener adiabaticity parameter k_{el} becomes fairly large, i.e. $k_{el} \gg 1$, then, as shown by Hynes,[42] it is essential to use the following expressions instead of Eqns. (46):

$$W_{12}=\frac{W_{12}^{WA}}{1+W_{12}^{WA}/W_{12}^{S}}, \qquad W_{21}=\frac{W_{21}^{WA}}{1+W_{12}^{WA}/W_{12}^{S}}, \tag{49}$$

where W_{12}^{WA} and W_{21}^{WA} are defined by Eqns. (23).

Eqns. (49) constitute an extension of Eqns. (22) to cases where the reactions take place in media with an arbitrary dielectric constant $\varepsilon(q, \omega)$. If all the correlation times ν_i^{-1} are of the same order of magnitude, only short times $|\tau| \ll \nu_i^{-1}$ contribute to the integral (47). Therefore, having expanded the correlation function in series in terms of the parameter $|\tau|$ and having substituted $K(\tau) = K(0) + K'(0)|\tau|$ in Eqn. (47) and then having evaluated this integral, we obtain finally[42,66]

$$(W_{12}^{S})^{-1}=-\frac{K(0)}{K'(0)}\left[\frac{1}{|E_0|}+\frac{1}{|E_0-2E_\tau|}\right]\sqrt{2\pi}\Delta\exp\left(\frac{E_0^2}{4E_\tau kT}\right). \tag{50}$$

The result represented by Eqn. (50) differs from Eqn. (14) only in the replacement of ν_L by $-K'(0)/K(0)$, i.e. for the case where all the correlation times have the same order of magnitude we can describe the reaction with the aid of an effective frequency of polarisation fluctuations:

$$\nu_{ef}=-\frac{K'(0)}{K(0)}. \tag{51}$$

Having substituted Eqn. (44) in Eqn. (51), we obtain a simple relation:

$$\nu_{ef}=\sum_{i=1}^{N}\nu_i\delta_i. \tag{52}$$

By virtue of the relation between ν_i, δ_i and f_i, τ_i, formula (52) can be rewritten in another form:

$$\nu_{ef}=\frac{\varepsilon_S}{\varepsilon_\infty}\sum_{i=1}^{N}f_i\tau_i^{-1}. \tag{53}$$

Eqn. (53) was first obtained by Hynes[42] for two relaxation times of the medium and was then extended to the case of N relaxation times.[69] Admittedly, in the latter study[69] it was claimed erroneously

that Eqns. (52) and (53) differ, although it can be shown that they are equivalent. Furthermore, one should note that Helman[69] obtained an expression for W_{12}^{S} somewhat different from Eqn. (50), which in our view is associated with two causes. Firstly, Helman[69] adopted initial postulates different from those used by Sparpaglione and Mukamel[66] and Hynes[42] and, secondly, he developed[69] an incorrect approximation for the evaluation of one of the final integrals.

Eqn. (52) for the case of two relaxation times has also been found by another method.[70] The results represented by Eqns. (46) and (49) have been obtained subject to condition (19). If the inequality (19) is reversed, then the rate of reaction assumes a form analogous to that defined by Eqn. (25) with the sole difference that ν_L has now been replaced by ν_{ef}.

As already mentioned, Eqns. (50)–(53) were derived on the assumption that all the correlation times ν_i^{-1} have the same order of magnitude. On the other hand, if one of the times $\nu_1^{-1} \gg \nu_2^{-1}, \ldots, \nu_N^{-1}$, then the situation is less clear. There exists only the theory of electron transfer in solvents with two markedly different relaxation times.[72] Furthermore, electron transfer in the case with several markedly different relaxation times for the solvent has been investigated by the numerical evaluation of integrals (47) in two studies.[73,74] Fonseca[68] also investigated electron transfer by numerical methods.

The theoretical and experimental data for electron exchange between metallocenes in a number of alcohols have been compared[73] on the basis of Eqns. (49) and (47). It was shown that these formulae account for a large part of the rate of electron transfer between metallocenes in alcohols.

As already mentioned, the present author[72] developed a theory of electron transfer in solvents with two markedly different relaxation times of the medium. The linear correlation observed[31–35] between the rate of reaction and the lowest relaxation frequency of the solvent was explained by this theory. This explanation of the experimental data[31–35] differs from that quoted for the same data in another study,[46] which was based on Helman's erroneous investigation.[47]

Eqns. (46) were derived on the assumption that the reaction proceeds under homogeneous conditions. Reactions occurring at an electrode in solvents of the type of alcohols have been studied in only one investigation,[75] where the relaxation of the solvent was modelled by two relaxation times. These results[75] are analogous to those of the present author.[72] The theory developed in the latter investigation[72] explained qualitatively the experimental data.[15,20,21]

3. Theories of electron transfer reactions in solvents with a continuous distribution of relaxation times of the polarisation of the medium

In many solvents of the type of glycerol, the dielectric properties cannot be described by either the simple Debye model [Eqn. (8)] or by the more complex Eqn. (43). In such solvents, there is a continuous distribution of the relaxation times of the polarisation and the Cole–Davidson equation is applicable to them:

$$\varepsilon(\omega) = \varepsilon_\infty + \frac{(\varepsilon_S - \varepsilon_\infty)}{(1 - i\omega\tau_0)^\beta}, \tag{54}$$

where τ_0 is the characteristic relaxation time and β is the Cole–Davidson parameter, which satisfies the inequality $0 < \beta \leqslant 1$.

The microscopic mechanism underlaying Eqn. (54) is at present obscure. There are two hypotheses concerning the nature of this relation. According to the first, the solvent is microscopically homogeneous and Eqn. (54) holds at each point in it. According to the second hypothesis, the solvent is microscopically inhomogeneous and Debye's model [Eqn. (8)] holds at each point in it but with a Debye time τ which varies randomly from point to point. Under these conditions, Eqn. (54) is applicable only on the macroscopic scale and is obtained by averaging Eqn. (8) over the distribution of the Debye times $g(\tau)$, which has the following form according to Bötcher and Bordewijk:[76]

$$g(\tau) = \begin{cases} \dfrac{\sin(\pi,\beta)}{\pi\tau}\left(\dfrac{\tau}{\tau_0 - \tau}\right)^\beta & (\tau < \tau_0), \\ 0 & (\tau > \tau_0). \end{cases} \tag{55}$$

The theory of electron transfer in glycerol type solvents has been constructed in accordance with two hypotheses concerning the nature of the relaxation of the polarisation of the medium. If the first hypothesis concerning the nature of Eqn. (54) is adopted as a basis, then electron transfer can be described within the framework of the formalism of Sparpaglione and Mukamel[66] and the reaction rates are defined by Eqns. (46), where $M(\tau)$ is found with the aid of Eqns. (48), (6), and (54). The integrals (47) have been evaluated with the aid of Eqn. (54) in a study[74] where the expression

$$W_{12}^{S} = \frac{\sqrt{2}\beta[8kTE_r]^{1/2-1/\beta}}{\Gamma(1/\beta - 1/2)\,[4\Gamma(\beta+1)\,\varepsilon_\infty/\varepsilon_S]^{1/\beta}} \times \\ \times [|E_0|^{1-2/\beta} + |E_0 - 2E_r|^{1-2/\beta}]^{-1}\tau_0^{-1}\exp\left(-\frac{E_0^2}{4E_r kT}\right), \tag{56}$$

where $\Gamma(x)$ is a gamma-function,[77] was obtained in the limit corresponding to high activation energies for the reaction.

The theory employing the second hypothesis concerning the nature of Eqn. (54) as a basis has been developed by Rips and Jortner.[78,79] They showed that the reaction kinetics are described by the following formula:

$$n_1(t) = \int_0^\infty \exp[-W_{12}(\tau)]\,g(\tau)\,d\tau, \tag{57}$$

where $n_1(t)$ is the population of the first electronic state and $W_{12}(\tau)$ is defined by Eqn. (13). In the derivation of Eqn. (57), it was assumed that the reverse reaction may be neglected.

On the basis of Eqn. (57), Rips and Jortner[78,79] predicted that, in the reaction regime controlled by the solvent dynamics, the rate of reaction is given by

$$W^{DC} = W_{12}^{NA}\left(\frac{\varepsilon_S}{\varepsilon_\infty}\frac{\hbar E_r}{4\pi V^2\tau_0}\right)^\beta. \tag{58}$$

Two conclusions follow from Eqn. (58). Firstly, the rate of reaction depends on the characteristic relaxation time of the medium τ_0 less than in the case of Debye solvents. Secondly, the rate of reaction in this limit is proportional to $V^{2(1-\beta)}$ when account is taken of Eqn. (15).

The available experimental data on intramolecular electron transfer[80] support the theory of Rips and Jortner[78,79] rather than that of Sparpaglione and Mukamel.[74] Indeed, the observed[80] dependence of the rate of reaction on τ_0 is described satisfactorily by

Eqn. (58) when τ_0 is varied within the limits of two orders of magnitude. The dependence of the rate of reaction on V, described by Eqn. (58), also agrees well with experiment.

As already mentioned, McGuire and McLendon[54] likewise observed the proportionality of the rate of reaction to $\tau_0^{-\beta}$. The reaction which they investigated[54] occurred in glycerol—a solvent of the Cole–Davidson type. Rips and Jortner[78,79] therefore explained this proportionality by Eqn. (58). However, since the proportionality of the rate of reaction to $\tau_0^{-\beta}$ was deduced[54] on the basis of indirect considerations, the reliability of the interpretation of these results[54] within the framework of the theory of Rips and Jortner[78,79] is at present unclear.

4. The dynamic effect of the diffusion polarisation of the solvent in the rate of electron transfer

The theories of electron transfer reactions examined above took into account only the reorientation relaxation of the polarisation of the solvent. On the other hand, in certain solvents the rate of relaxation of the polarisation via the self-diffusion of the dipoles of the medium may be comparable to the rate of relaxation of the polarisation associated with the reorientation of the solvent molecules. The theory of electron transfer taking into account both pathways to the relaxation of the solvent polarisation has been developed.[81] It was shown that the rate of reaction is expressed by the formula

$$W_{12} = \frac{W_{12}^{NA}}{1+W_{12}^{NA}/W_{12}^{DII}}, \tag{59}$$

where

$$W^{DII} = \tilde{\nu}_{ef}\frac{|E_0||E_0-2E_r|}{|E_0|+|E_0-2E_r|}\frac{1}{(2\pi\Delta^2)^{1/2}}\exp\left(-\frac{E_0^2}{4E_rkT}\right), \tag{60}$$

and

$$\tilde{\nu}_{ef} = \nu_L + \frac{\epsilon_S}{\epsilon_\infty}D\frac{c_0}{64\pi^4E_r}\int|\Delta D_q|^2q^2dq. \tag{61}$$

In Eqn. (61), D is the self-diffusion coefficient of the solvent molecules and ΔD_q is defined by Eqn. (7).

Eqn. (59) is applicable only for $V \ll kT$. Subject to the condition $V \gg kT$, a formula has been obtained[81] for the rate of reaction differing from Eqn. (25) only in the replacement of ν_L by $\tilde{\nu}_{ef}$. A formula for $\tilde{\nu}_{ef}$, convenient for making estimates, was also obtained in the above study:[81]

$$\tilde{\nu}_{ef} = \nu_L + \frac{\varepsilon_S}{\varepsilon_\infty}D\frac{2.048(R_2^3+R_1^3)R}{R(R_2+R_1)R_1^2R_2^2-2R_1^3R_2^3}. \tag{62}$$

It is valid for $R \geqslant R_1 + R_2$, where R_1 and R_2 are the radii of the reactants and R is the distance between them.

The estimates made in the above study[81] by Eqn. (62) show that in solvents such as methanol and nitrobenzene, where the diffusion coefficients of the solvent molecules are fairly large and the values of ν_L are fairly small, the contribution of the diffusion-dependent solvent polarisation to $\tilde{\nu}_{ef}$ may become dominant.

III. Conclusion

The dynamic effects of the solvent examined in this review have been described within the framework of the continuous model of a structureless dielectric. At the same time, if the dimensions of the reactants are comparable to those of the solvent molecules, the structureless dielectric approximation becomes poor and it is necessary to construct a theory of electron transfer on a basis which takes into account the molecular structure of the solvent models.

There exist at the present time two approaches to allowance for the molecular structure of the solvent in devising a theory of electron transfer. The first of these (phenomenological) is based on the fact that the relaxation time of the centre of gravity of the fluorescence spectrum of a polar molecule dissolved in the given solvent coincides with ν_S^{-1}, where ν_S^{-1} is the effective frequency of the fluctuations in the polarisation of the medium, which enters into the preexponential factor for the reaction rate constant. This approach has been developed in a number of studies.[36–38]

The second approach to allowing for the molecular structure of the solvent in the electron transfer theory is based on different approximations of the theory of the liquid state. In particular, it is represented by a study,[82] where it was shown that, in a continuous description of the solvent, it is possible to overestimate the activation energy for the reaction. However, in the same investigation an important conclusion was reached: if the energy of the reorganisation of the solvent is regarded not as a theoretically calculated parameter but as an adjustable parameter derived from experimental data, then the expressions for the reaction rate constants obtained within the framework of the continuous approximation can provide an excellent description of the reaction kinetics.

Finally, we may note that the dynamic effect of the solvent may be manifested not only in electron transfer reactions but also in the more general charge transfer reactions,[83–85] but a detailed discussion is outside the scope of the present review.

The photochemistry of phenyl azide

M F Budyka, M M Kantor, M V Alfimov
Institute of Chemical Physics, Russian Academy of Sciences, Chernogolovka

ABSTRACT. The literature data on the photochemical reactions of phenyl azide under different conditions are reviewed. Its photoinitiated autocatalytic chain decomposition reaction is examined in detail. Questions relating to the structure and properties of intermediates formed during photolysis of aryl azides and the mechanism of formation of azo compounds are discussed. The existing information on photoinitiated chain reactions of alkyl and aryl azides is briefly considered.

The bibliography includes 93 references.

I. Introduction

In the present review the photochemical reactions of phenyl azide (PhA)—the simplest compound from amongst the fairly extensive class of aromatic azides—are discussed. The photochemistry of aromatic azides has been widely studied in connection with the use of these compounds in photoresists and vesicular light-sensitive materials and as photoaffinity labels in biology.

By analysing the photochemical reactions of PhA it is possible to derive some idea of the typical properties of this whole class of aromatic azides. Moreover, Waddell, et al. recently published a series of articles[1–8] in which photoinitiated autocatalytic chain decomposition (PACD) was described. As a result of detailed studies the mechanism of reaction and structure of the intermediate products were proposed, and the maximum apparent quantum yield of photodissociation of PhA (Φ_{-PhA}) was 15 300.[7]

The high quantum yield of dissociation and also their kinetic analysis led the authors to claim "a molecular explosion observed for the first time in solution".[7] Information about the PACD reaction is given in a number of reviews[9,10] but so far it has not been possible to confirm that this reaction takes place, despite the fact that direct attempts have been made to do this.

Processes with a quantum yield $\Phi > 1$ are of interest both for the theoretical and practical points of view; so information about the PACD reaction of aromatic azides is examined in this review. Since the basis of this reaction is assumed to be the interaction of triplet phenylnitrene (PhN) with PhA and the final product is azobenzene, it is logical to start this review with the findings on the properties of PhN in the mechanism for formation of azobenzene. The synthetic and applied aspects of the chemistry of azides have been discussed in a recent review.[11]

II. Triplet nitrene and the formation of azo compounds

Triplet PhN was first detected by Wasserman, et al.[12] in 1962 during the photolysis of vitrified solutions of PhA and other azides in poly(chlorotrifluoroethylene) at 77 K using EPR. The parameter D which was calculated from the spectrum and which characterises the magnitude of the interaction between the unpaired spins was determined as 0.99 cm^{-1}, less than $D = 1.625$ cm^{-1} for t-butylnitrene, which suggested that there is considerable delocalisation of one unpaired electron around the aromatic ring of PhN.[13] The parameter E, which characterises the difference in the distribution of spins about the molecular axes, was close to zero for both nitrenes ($E < 0.002$ cm^{-1}).

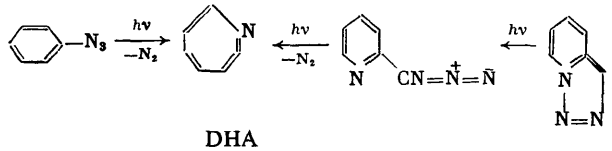
The hyperfine structure of the spectra of nitrenes generated in crystals of the corresponding azides,[14] the effect of substituents in PhN on the spectrum, and quantum-chemical calculations[15] confirmed the structure proposed for triplet PhN. A pair of electrons is situated in an *sp* orbital along the C–N axis, one unpaired electron occupies a molecular orbital enveloping the aromatic π-system, and the second electron is localised on an orthogonal *p* orbital of the nitrogen atom.

On the basis of EPR data Reiser, et al.[16] attributed the electronic absorption spectra obtained in 1965 under similar conditions of photolysis (77 K, organic matrix) to triplet nitrenes. Confirmation of this assignment was obtained from the following evidence:[17] the spectrum did not depend on the type of matrix (vitreous hydrocarbons, ether, ethanol, and their mixtures); the spectrum belonged to a single compound, since an isobestic point occurred on the spectrosocpic curves; quantum yields of photodissociation of about 0.5 were obtained for all the azides studied; the spectrum disappeared on heating the matrix to its softening point (90 K); the spectra had characteristic features relating to the occurrence of an "aromatic system with an open shell", for example, the spectrum of phenylnitrene (λ_{max} 314 and 402 nm) was similar to the spectrum of the aniline radical (λ_{max} 309 and 400 nm).

Subsequently similar spectra were obtained at 77 K by other authors,[18,19] and in all cases they were attributed to triplet PhN. Quantum-chemical calculations of the transition energies and oscillator strength corresponded satisfactorily to the experimental spectra of PhN.[18]

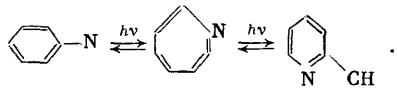
However, in 1978 Chapman, et al.[20] in studying the photolysis of phenyl azide in an argon matrix or in thin films at 8 K using IR spectroscopy demonstrated that the photolysis product under these conditions is dehydroazepine (DHA), which was detected from the

characteristic intense absorption due to the heterocumulated bonds in the IR region at 1895 cm^{-1} (close to the absorption of the spectroscopic model $-C_6H_5-\overline{C}=\overset{+}{N}=CH_2$ with ν_{CNC} = 1930 cm^{-1}). Its spectrum was also demonstrated by counter-synthesis from triazolopyridine:



DHA

At the same time an analysis of the photolysis products of PhA obtained under similar conditions (12 K) using EPR showed that triplet PhN was also present in the mixture,[21] and on subsequent irradiation it was converted to triplet 2-pyridylcarbene. Photolysis in the direction triazolopyridine→pyridylcarbene→phenylnitrene suggested that the nitrene and carbene were interconverted via dehydroazepine:[22]



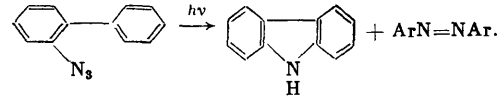
Hence the electronic absorption spectrum that was recorded in four studies[16–19] may belong not only to triplet PhN but also to a mixture of products. However, this assertion is contradicted by studies on the T_1-T_0 luminescence of PhN and its derivatives,[19,23] in which it was shown that the luminescence spectrum of triplet PhN is a mirror reflection of the absorption spectrum of the photolysis products of PhA and the latter coincides with the spectrum of luminescence excitation. Hence it was concluded that the absorption spectrum belongs to a single compound, namely, triplet PhN.

Thus, low-temperature studies have provided an ambiguous answer to the question as to what are the primary photodissociation products of PhA. It would appear that the inconsistency in the results may be due in part to the different conditions of the studies: 4–8 K in an argon matrix[20–22] or 77 K in an organic matrix.[16–19,23] Moreover, taking into account the revealed ability of PhN and DHA to undergo photochemical interconversion, the final result may depend to a significant extent on the intensity, duration, and spectroscopic range of incident light (see below).

The possibility that a number of intermediates are formed was also suggested by the results from a preparative study of the photochemical reactions of PhA and other azides and from flash photolysis of azides at room temperature.

In 1966 Doering and Odum[24] established that the final photolysis product of PhA in the presence of amines was a substituted 2-amino-3*H*-azepine. Subsequently Splitter and Calvin[25] concluded that the azepine was formed from singlet PhN on the basis of the evidence that in triplet sensitisation with *p*-dimethylaminobenzaldehyde the yield of 2-diethylamino-3*H*-azepine, for example, decreased from 34 to 2% while the yield of aniline increased from 70–80%.

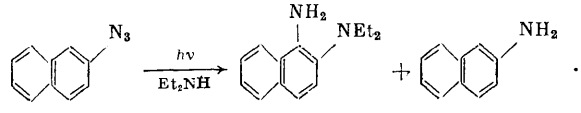
For singlet 2-biphenylnitrene the main reaction is cyclisation to carbazole, the yield of which amounted to 74% in the direct photolysis of azide, while at the same time about 12% azo compound was isolated:[26]



Quenchers of triplet excitation increased the yield of carbazole, reducing the yield of azo compound at the same time, while triplet sensitisers had the reverse effect. It followed from this that triplet nitrene is formed from triplet azide rather than singlet nitrene.

A study of the photolysis of 10^{-2} M solutions of PhA in alcoholic and hydrocarbon solvents showed that a polymer and product derived from insertion of solvent into the molecule are formed from singlet PhN, while aniline and azobenzene are formed from triplet PhN.[27] From the effect of the chemical nature of the solvent, the composition of the solvent mixture, and the added amounts of triplet sensitisers on the molar ratio of the reaction products it was estimated that in the photolysis of PhA only 12–13% PhN is directly generated in the ground triplet state.

A further type of reaction of singlet nitrene—formation of aromatic diamines with migration of the nitrogen atom of the azide group to the neighbouring position of the aromatic ring—occurred during photolysis of 2-azidonaphthalene in diethylamine. 2-Aminonaphthalene, which is probably formed in parallel from triplet nitrene, is also isolated:[28]



The method of flash photolysis at room temperature was first applied in 1966 to studies on the reactions of aromatic azides.[29] In the irradiation of a 5 × 10^{-4} M solution of 1-azidoanthracene in ethanol, 4 μs after the flash a spectrum was recorded that had a characteristic absorption at 342 nm, similar to that found previously at 77 K and attributed to triplet nitrene. The lifetime of nitrene was about 5 μs.

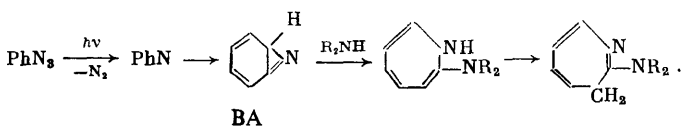
Other aromatic azides have been investigated in detail and the kinetics of certain reactions of nitrenes have been studied.[30] Reiser, et al.[30] maintained that for substituted phenyl azides, 1-azidonaphthalene, and also 1-azidoanthracene, the electronic absorption spectra of the intermediates that were recorded using flash photolysis matched the spectra of the corresponding triplet nitrenes obtained by irradiation of rigid matrices at 77 K, but the actual spectra were not depicted. Unsubstituted PhA was not studied and information on singlet intermediates was also absent.

This information was obtained subsequently by Sundberg, et al.[31] In the flash photolysis of a 10^{-4} M solution of PhA in hexane, an intermediate with an absorption spectrum in the region up to 300 nm was formed. The main reaction product was an unidentified polymeric compound, but the possibility that trace quantities of aniline and azobenzene were formed was not excluded. The presence of oxygen had no effect on the monomolecular kinetics of the increase in the unidentified absorption at a wavelength of 366 nm,

and $\tau_{1/2} \sim 5$ μs (22 °C) was found. It was suggested that the intermediate with this lifetime and spectroscopic properties ($\lambda < 300$ nm) has the stucture of a bicyclic azirine (benzazirine, BA), which is an isomer of singlet PhN.

The structure of BA as an intermediate in the formation of azepines was first proposed for thermal reactions of PhA and then extended to photochemical reactions.[32]

It was shown by Sundberg, et al.[31] that in the flash photolysis of PhA in the presence of dibutylamine, BA reacts with the amine with a rate constant of $k = 9.7 \times 10^5$ M^{-1} s^{-1} (hexane) and 3.5×10^7 M^{-1} s^{-1} (acetonitrile), and the primary product of this reaction—2-dibutylamino-1*H*-azepine—was detected, which then rearranged to the final 3*H*-isomer:

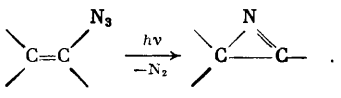


BA

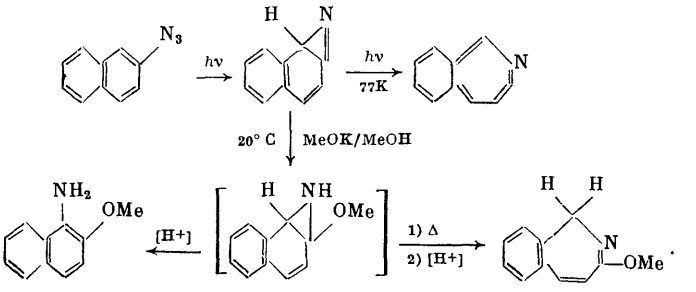
The yield of azepine by flash photolysis (from the increase in absorption) was 85%, and the recorded quantum yield for its formation during stationary photolysis $\Phi = 0.42$. The latter figure is in good agreement with the value of the quantum yield of photodissociation of PhA ($\Phi_{-PhA} = 0.53$),[33] if it is assumed that both flash and stationary photolysis give the same percentage (85%) conversion of azide to azepine. Moreover, this is in agreement with the estimate of Reiser and Leyshon[27] that 12–13% of phenylnitrene is generated in the triplet state, which does not give an azepine.

After dehydroazepine was detected amongst the photolysis products of PhA at 8 K, the reaction scheme involving bicyclic azirine became a subject of criticism.[20] DHA instead of BA was proposed as the isomer of singlet PhN and intermediate in the reactions of PhA. Chapman and Le Roux[20] related the prejudice against DHA to the results of quantum-chemical calculations[34] which showed that the structure of DHA must be less stable than that of BA or even singlet nitrene. However, the low-temperature studies of photolysis of Ph and the isomeric pyridyl diazomethanes provided clear evidence for the existence of such structures.[22]

On the other hand, supporters of the benzazirine structure doubted the validity of making direct use of the results of low-temperature studies to interpret the data obtained at a normal temperature. Moreover, evidence in favour of the BA structure was provided, for example, by the preparative isolation of azirines in the photolysis of vinyl azides:[35]



For naphthyl azides the formation of azirines was demonstrated in photolysis in argon matrices (12 K) from the appearance of bands in the region of 1708–1738 cm^{-1} in the IR spectra, and on further photolysis the azirines were converted to dehydroazepines (bands at 1910–1930 cm^{-1}).[36] At 20 °C photolysis of 2-naphthyl azide (and 2-anthryl azide) in methanol in the presence of potassium methoxide gave different final products depending on the subsequent conditions of treatment. On neutralisation directly after irradiation, 1-amino-2-methoxynaphthalene was formed, while on boiling the irradiated mixture or keeping it at 20 °C for several hours, methoxybenzazepine was isolated.[37] Rigaudy, et al.[37] suggested that a fairly stable intermediate with an aziridine structure is formed by photolysis, since the strongly alkaline medium inhibits its rapid isomerisation. These latter two studies are combined in the following scheme:



Thus, in contrast to phenyl azide, for condensed aryl azides the formation of aziridine structures during photodissociation has been demonstrated experimentally.

Without going further into the experimental details, it may be concluded that, despite the possible variants of the isomeric intermediates and the assertion that the same intermediates are formed at both 77 K and 20 °C,[30] at least for phenyl azide the majority of the results suggest that direct photolysis at room temperature mainly gives singlet PhN while low-temperature photolysis yields mainly triplet PhN.

We shall now turn to an examination of the data on the mechanism of formation of azo compounds in the decomposition of aromatic azides. Frequently the authors have confined themselves solely to an assertion that triplet nitrene takes part in this reaction without specifying the scheme in any detail. Nevertheless, three main reaction routes can be distinguished:[38–40]

dimerisation of nitrene in the triplet state:

$$2Ar-\dot{N}^{\cdot} \rightarrow Ar-N=N-Ar\ ,$$

reaction of triplet nitrene with the initial azide:

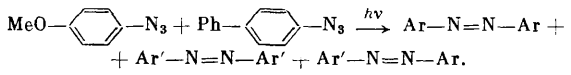
$$Ar-\dot{N}^{\cdot} + ArN_3 \xrightarrow[-N_2]{} Ar-N=N-Ar\ ,$$

dimerisation of aminyl radicals followed by oxidation of diarylhydrazine by nitrene:

$$Ar-\dot{N}^{\cdot} \xrightarrow{[H]} ArNH^{\cdot} \longrightarrow Ar-NH-NH-Ar \xrightarrow{2ArN} \rightarrow Ar-N=N-Ar + 2ArNH\ .$$

In terms of the PACD reaction under consideration, it is definitely the second scheme, in which the formation of an intermediate that decomposes to two nitrenes, namely, propagation (branching) of the chain (see below) is assumed, that is the specific reaction route of the greatest interest (in the first and third schemes chain termination occurs). There are a number of ambiguous results obtained by different authors which can either be used in support of a reaction between triplet nitrene and azide, to refute such a reaction, or included in an explanation of experimental results for a scheme that does not involve nitrenes.

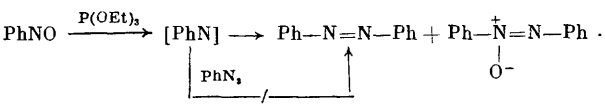
Thus, in the photolysis of a mixture of two azides—azidoanisole and azidodiphenyl—in benzene at 20 °C, almost equal quantities (about 30%) of all three possible azo compounds were formed:[41]



The formation of an asymmetric azo compound in this case may be due to the dimerisation of two different nitrenes that are formed simultaneously during photolysis, but the reaction of a single nitrene with another azide cannot be excluded.

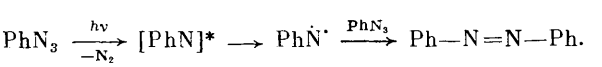
However, later findings on the thermolysis of a mixture of azides—the same *p*-azidoanisole and 1-methyl-3,5-diphenyl-4-azidopyrazole—at 80 °C testify against a reaction between nitrene and azide.[42] The temperature was selected in such a manner that the first azide was stable and only the second azide decomposed. These are the most favourable conditions for proving that a crossed reaction occurs between one nitrene and another azide. Despite the fact that *p*-azidoanisole was present in fivefold excess, the authors did not manage to detect any appreciable quantities of the product of this reaction.

Attempts were made to detect the reaction of nitrene with a suitable azide by generating the nitrene through reaction of a nitroso compound with triethyl phosphite.[43] It was found in this case that when PhA was added to the reaction mixture with nitrosobenzene, PhA did not undergo reaction and the main reaction products were azoxybenzene and tar, azobenzene being formed in trace amounts:

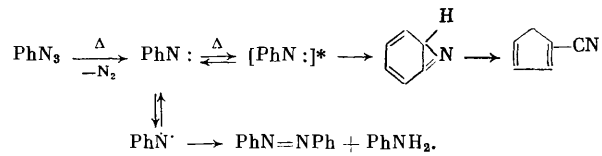


Although it was shown for a number of nitroso compounds that deoxygenation occurs via a nitrene intermediate,[44] in general it may not take place in this manner.[45] Therefore the possibility that it may nevertheless occur for other azides and/or other reaction conditions with nitrene giving an azo compound should not be completely ruled out.

The feasibility of this reaction occurring in the gas phase was demonstrated by Lehman and Berry.[46] The spectrum of PhN was recorded in the region of 340–370 nm on flash photolysis of PhA vapour in the presence of an inert gas—a quencher of excess excitation (rapid isomerisation occurred when the gas was not added). Azobenzene was formed (yield 6%) with a pseudo-monomolecular rate constant of 5×10^4 s^{-1}, from which the rate constant of the bimolecular reaction between PhN and PhA was determined as $k_{II} = 1.3 \times 10^{-12}$ cm^3 s^{-1}. The authors[46] note that because of the very high rate of reaction between PhN and PhA it was not possible to determine the rate of dimerisation of PhN, since higher concentrations of the latter were needed for this.



On the other hand, in an earlier study[47] of the pyrolysis of PhA in the gas phase (300–670 °C) it had been concluded from the dependence of the yield of azobenzene and aniline (and cyanocyclopentadiene) on the rate of admission of PhA into the hot zone (a decrease in yield of the first two with an increase in rate, namely, concentration, of reactant) that azobenzene was formed by the dimerisation of triplet PhN rather than as a result of a reaction with PhA:



It would appear that thermal generation achieved considerably higher concentrations of PhN than by photolysis.

On irradiaiton of a degassed 10^{-4} M solutions of 1-azidonaphthalene in hexane with low-intensity light, a mixture of amines was formed and the azo compound was not detected.[30] However, the latter was obtained as the main product by slow thawing of matrices irradiated at 77 K and by flash photolysis of solutions of this azide in organic solvents. The kinetics of the increase in absorption of azonaphthalene at a wavelength of 400 nm corresponded to second-order, and the rate constant for recombination of triplet nitrene was determined as $k = 5.5 \times 10^8$ M^{-1} s^{-1}. It was shown in the same study that on flash photolysis of a solution of 1-azidoanthracene in ethanol with light of reduced intensity, when only about 5% of the azide was converted to nitrene, the kinetics of the disappearance of nitrene corresponded to first-order with $\tau_{1/2}$ of 5 μs, from which the bimolecular constant for reaction between nitrene and azide was obtained ($k = 5 \times 10^8$ M^{-1} s^{-1}).[30]

At the same time, as was mentioned above, in studying the reactions of PhA using flash photolysis, Sundberg, et al.[31] did not observe the spectrum of triplet PhN at normal temperatures. The primary reaction product (not more than 30 μs after the flash) was benzazirine[31]—an isomer of singlet PhN—or dehydroazepine, as Chapman, et al. maintain.[20]

Thus, an azo compound may be formed by reaction of an azide and nitrene (which does not have to be in the triplet state),[48] but if an alternative exists for the formation of the azo compound, the nitrene reacts in a different manner.

With regard to the labile compound formed as an intermediate in the reaction between nitrene and azide, its structure was first suggested as a tetraazadiene derivative[41] ("tetrazene"), and it was assumed that it decomposes to an azo compound and nitrogen.

Subsequently, in a review Smith[38] extended this idea by the introduction of 1,2- and 1,4-isomers of substituted tetraazadiene, where the possibility of the latter decomposing to two nitrene molecules had already been admitted. Smith[38] noted that at a given ratio of the rate constants of the intermediate reactions dissociation of aryl azide will occur with first-order kinetics and it will not be possible to distinguish the formation of the azo compound by dimerisation of nitrene or by reaction of nitrene with azide. The data published by that time on the thermolysis of aryl azides suggested that the kinetics of the disappearance of azide are always first-order regardless of whether the final product is an azo compound or another product.[38]

III. Photoinitiated autocatalytic chain decomposition of aromatic azides

Let us examine the literature data of Waddell, et al. on the PACD reaction of aryl azides.

The first report on the PACD reaction of phenyl azide appeared in 1982.[1] For the photodissociation of PhA at 77 K in 3-methylpentane a value of $\Phi_{-PhA} = 0.49$ was determined (in good agreement with the results of Reiser and Marley).[33] It transpired, however, that the values of Φ_{-PhA} in solution were markedly dependent on the concentration of PhA, the solvent, and the presence of oxygen. A value of $\Phi_{-PhA} = 300$ was obtained for a 0.03 M solution of PhA in acetonitrile, and the yield decreased sharply on dilution, in the presence of oxygen, or by the addition of 2,3-dimethylbutene or tetracyanoethylene. The quantum yield of considerably greater than unity was also obtained for substituted PhA in degassed solutions: $\Phi = 210$ for *o*-tolyl azide (0.069 M), while $\Phi = 60$ for *p*-tolyl azide (0.066 M).

The authors reported that at the initial stage of photolysis in the spectroscopic curves an isobestic point was maintained at 261 nm, the absorption due to PhN at 250 nm decreased, and the absorption due to azobenzene in the region 270–360 nm increased. The latter was the sole reaction product with short irradiation times and a low conversion of PhA, on further irradiation there was considerable tar formation. It was shown by Reiser and Leyshon[27] that under similar conditions—photolysis of hydrocarbon solutions of PhA to 2% conversion—the main products are azobenzene and tar in equal ratio.

In order to explain the experimental phenomena, the authors took as a basis the possibility suggested by Horner, et al.[41] that nitrene reacts with azide to form an intermediate tetrazene. However, it was assumed that in accordance with Smith,[38] only the 1,2-isomer of the latter decomposes to azobenzene and nitrogen, while 1,4-diphenyltetraazadiene (DPTA) yields a molecule of nitrogen and two PhNs, thus propagating the chain reaction:

$$\mathrm{PhN} + \mathrm{PhN_3} \longrightarrow \mathrm{Ph{-}\overset{+}{N}{=}N{-}Ph} + \mathrm{Ph{-}N{=}N{-}N{=}N{-}Ph},$$
$$\mathrm{N{=}\bar{N}}$$

$$\mathrm{Ph{-}\overset{+}{N}{=}N{-}Ph} \longrightarrow \mathrm{Ph{-}N{=}N{-}Ph} + \mathrm{N_2},$$
$$\mathrm{N{=}\bar{N}}$$

$$\mathrm{Ph{-}N{=}N{-}N{=}N{-}Ph} \rightarrow 2\mathrm{PhN} + \mathrm{N_2}.$$

The formation of two PhNs directly by reaction of PhN with PhA without intermediates was also assumed:

$$\mathrm{PhN} + \mathrm{PhN_3} \rightarrow 2\mathrm{PhN} + \mathrm{N_2}.$$

The authors cited the formation of stable complexes between 1,4-diaryltetraazadiene and transition metal ions[49] as well the mass spectrometric reaction of the PhN anion with PhA to form the DPTA anion[50] as confirmation of the existence of the tetraazadiene structure.

An attempt was made[2] to demonstrate the involvement of DPTA as an intermediate in the decomposition of PhA by nanosecond laser photolysis (excitation wavelength 266 nm, pulse 10 ns) in a continuous-flow cuvette. It transpired that the spectroscopic properties of the intermediate were virtually the same for dilute and concentrated solutions. The spectrum was preserved with virtually no changes throughout the whole of the timescale studied—from 15 ns to 5.45 μs—whether oxygen was present or not.

Feilchenfeld and Waddell[2] conclude on the basis of the lifetimes that were determined that the spectrum observed in the region of 330–500 nm belongs to a single compound, and citing studies already reviewed on the photolysis of azides at 77 K[17] and 20 °C[30] and their own results at 77 K[3] they attribute the spectrum to triplet PhN. We should note that only the spectroscopic region and not the spectrum itself matches the results of Reiser, et al.,[17] while PhA was not investigated at all in the other study.[30] The reasons for the absence of a reaction between PhN and oxygen are not discussed, although reactions of this type usually takes place at a considerable rate.

A parallel study was made of the spectrum of the intermediate derived from phenyl isocyanate, which loses a CO molecule on photolysis and also yields phenyl nitrene:

$$\mathrm{PhNCO} \xrightarrow{h\nu} \mathrm{PhN} + \mathrm{CO}.$$

The spectra of the intermediates from both compounds as well as the lack of dependence of the shape of the spectrum on the concentration of PhA while the quantum yield of photodissociation of PhA changed by a factor of 10 made it possible for Feilchenfeld and Waddell[2] to conclude that there was no spectroscopic evidence for the formation of diphenyltetraazadiene as an intermediate (the spectroscopic region of 250–550 nm and a period of time up to 6 μs after a flash).

This conclusion was supported[3] by a study of the PACD reaction of phenyl isocyanate. A quantum yield of greater than unity was observed for this compound also, but formation of a tetraazadiene-type of structure from it is impossible. An estimate was made of the number of branches (length of chain n) of the autocatalytic chain on the basis of the ratio $2^n = \Phi/\Phi_0$, where Φ_0 is the quantum yield of dissociation at infinite dilution. For phenyl isocyanate $\Phi_0 = 0.057$, which is an order less than the corresponding value for PhA; but similar values of n were obtained at similar concentrations for both compounds.[3] When $[PhN_3] = 0.03$ M, $n = 9.2$; while when [PhNCO] = 0.015 M, $n = 7.35$. Unfortunately, a "crossed" experiment was not carried out. The spectra of PhA and phenyl isocyanate differ sufficiently for a particular reactant to be excited selectively: for PhA $\lambda_{max} = 250$ nm ($\varepsilon = 1 \times 10^4$ M^{-1} cm^{-1}) with a long-wavelength limit of the spectrum at about 292 nm, for phenyl isocyanate $\lambda_{max} = 227$ nm ($\varepsilon = 1 \times 10^4$ M^{-1} cm^{-1}) with a long-wavelength limit at about 280 nm (both spectra in acetonitrile).[2] Involvement of one reactant in the reaction when the other is excited while retaining high quantum yields and the formation of azobenzene would act as a significant argument in support of the reactions detected by Waddell, et al.[1–8] However, there is no information about this in these studies.

Despite the conclusion[3] that the chain reaction occurs through the phenyl nitrene-sensitised decomposition of PhA or phenyl isocyanate to give two PhNs:

$$\mathrm{PhN} + \mathrm{PhN_3} \rightarrow 2\mathrm{PhN} + \mathrm{N_2},$$
$$\mathrm{PhN} + \mathrm{PhNCO} \rightarrow 2\mathrm{PhN} + \mathrm{CO},$$

intermediates such as diphenyltetraazadiene and its isomeric compounds were subsequently introduced again to explain the PACD reaction.[4,5]

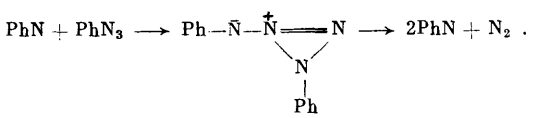
In one of these studies[4] the main focus of attention is a detailed analysis of the reaction products of PhA under different conditions. It is verified that the primary photoproduct in the irradiation of PhA in an inert atmosphere is (*E*)-azobenzene, which is then converted to the (*Z*)-isomer with a quantum yield of $\Phi = 0.14$. The data on the quantum yield of photodissociation of PhA differ somewhat from those reported previously,[1] when $\Phi_{-PhA} = 3$ at [PhA] = 3×10^{-5} M (acetonitrile, atmosphere of N_2) was recorded. In the later study[4] $\Phi_{-PhA} = 0.72$ when [PhA] = $10^{-5}-10^{-4}$ M; the latter figure is in closer agreement with the results of Reiser and Marley,[33] who found $\Phi = 0.53$.

In the presence of oxygen the primary product of the photolysis of PhA was established as nitrobenzene, which on further irradiation is converted to nitrobenzene and azobenzene. Since the value of Φ_{-PhA} in dilute solution did not depend on the presence of oxygen, it was concluded that azobenzene is formed under these conditions, probably by dimerisation of phenylnitrene. In concentrated solution oxygen significantly reduced the quantum yield of photodissociation of PhA, but when [PhA] > 3×10^{-3} M, $\Phi_{-PhA} > 1$ even in a solution saturated with oxygen.

In a later study[5] the range of concentrations of PhA studied was extended from 10^{-5} M to 0.218 M. Spectroscopic studies indicated that an isobestic point was maintained at 271 nm, i.e. in the opinion of Lee Go and Waddell,[5] the two-component nature of the system remained up to 40% conversion of PhA. High-performance liquid chromatography confirmed that the content of azobenzene increased linearly as the concentration of PhA decreased.

The quantum yield was determined up to a conversion of 3%; when [PhA] = 2.3×10^{-5} M, $\Phi_{-PhA} = 0.5$ was reported, while the maximum value of $\Phi_{-PhA} = 4330$ was obtained when [PhA] = 0.137 M. It was shown that the dependence of Φ_{-PhA} on the logarithm of the concentration of PhA is not linear but in fact has an exponential form, whereas the length of the chain n increases linearly with log [PhA].

In order to explain the autocatalytic chain reaction, the schemes already considered were supplemented with the possible intermediate formation of a triaza compound that decomposes to two phenylnitrenes and nitrogen:



The authors carried out an analogous process to this reaction with chain branching reactions during explosions in the gas phase and solid state, such as for metal azides. They note, however, that such reactions have not been recorded in solution. Since it was assumed in calculations of the chain length that the efficiency of the chain propagation stages is equal to unity (i.e., at the intermediate stages PhN is not lost through side reactions), the actual values of n could be even higher.

On repeated study of concentrated solutions of phenyl azide and phenyl isocyanate using pulsed laser photolysis, Feilchenfeld and Waddell[6] recorded a nonexponential decrease and oscillation of the induced optical density over the wavelength range 450–550 nm with a period of about 10 μs. For example, with a PhA concentration of 0.5 M, an increase in D_{450} occurred over a period of about 20 μs after a flash, then on the declining section of the curve there were six cycles of increase and decrease in optical density that were unaffected by the presence of oxygen. With a decrease in [PhA] the time for reaching a maximum value of D_{450} and the number of cycles decreased, and when [PhA] was 5×10^{-4} M the maximum of D was reached after 2–3 μs followed by a monoexponential decrease with a lifetime of 2.8 μs. A similar monoexponential decrease occurred for concentrated solutions in the presence of tetracyanoethylene.

Feilchenfeld and Waddell[6] concluded from these results and also the symbatic relationship between the decrease in the number of cycles on the oscillograms and the length of chain n and the decrease in concentration of PhA that they were detecting an oscillation in the content of triplet PhN in the reaction mixture.

The maximum value obtained—$\Phi_{-PhA} = 15300$ when [PhA] = 0.722 M in degassed acetonitrile and $\Phi_{-PhA} = 2280$ when [PhA] = 0.793 M in a solution saturated with oxygen—was subsequently reported.[7] An attempt was made to represent the PACD reaction of phenyl azide quantitatively. Four reactions form the basis of the kinetic scheme:

$$PhN_3 \xrightarrow{h\nu} PhN + N_2, \quad (1)$$

$$PhN + PhN_3 \xrightarrow{k_2} [Z] \longrightarrow 2PhN + N_2, \quad (2)$$

$$PhN + PhN_3 \xrightarrow{k_3} Ph{-}N{=}N{-}Ph + N_2, \quad (3)$$

$$2PhN \xrightarrow{k_4} Ph{-}N{=}N{-}Ph. \quad (4)$$

The scheme does not distinguish between the direct formation of two phenylnitrenes by reaction of PhN with PhA and the formation of an intermediate Z. On the basis of a quasi-steady-state condition for the PhN concentration with a fixed intensity of incident light I_0 and low conversions of PhA the following ratio was obtained:

$$\alpha = \beta + \lg\left[(k_2+k_3)^2\Phi_1 N_0/2k_4\right],$$

where: $\alpha = \lg\left[(\Phi-\Phi_1)^2/(1+2Q(\Phi-\Phi_1))\right]$,

$$Q = (k_2-k_3)/\left[2\Phi_1(k_2+k_3)\right],$$

$$\beta = \lg\left[[PhN_3]^2 V_0/(I_0(1-10^{-A}))\right],$$

Φ_1 is the quantum yield of reaction (1), $\Phi = \Phi_{-PhA}$, N_0 is the Avogadro number, V_0 is the volume of irradiated solution, and A is the optical density at the wavelength of incident light at an initial moment in time. All of the parameters in α and β were determined experimentally, with the exception of Q, whose value was found by trial and error. For degassed solutions a linear correlation between α and β was obtained with a gradient of unity when $Q = 0.0019$. For the complete series of 56 values of Φ_{-PhA} ranging from 0.3 to 15000 in solutions that were degassed or saturated with air and oxygen over a concentration range of 1.4×10^{-5} to 0.793 M, a linear correlation was also obtained, but with $Q = 0.0004$.

Costantino, et al.[7] consider that the excessively low values of Q indicate that the constants k_2 and k_3 are of virtually the same magnitude, which is not unexpected. The derived equation also accounts for the observed decrease in Φ_{-PhA} as the light intensity increases.

In the last of the series of publications by Waddell, et al.[8] on the PACD reaction, tetraazadiene is again rejected as an intermediate, and the species with the composition PhN is assumed to be the chain

carrier. In order to choose between four possibilities—singlet PhN, triplet PhN, benzazirine, or dehydroazepine—the authors studied the reactions of substituted phenyl azides and investigated triplet sensitisation†.

For all of the azides studied, the values of the quantum yields of photodissociation Φ were greater than 1. For example, at concentrations of 0.1 M, Φ = 81 for 4-bromo-PhA, Φ = 143 for 2,4,6-tribromo-PhA, and Φ = 434 for 4-nitro-PhA (for PhA itself, Φ = 1800 was found under similar conditions).[8] The quantum yields increased exponentially with the concentrations of the azides and at small degrees of conversion the corresponding azo compounds were established as photoproducts.

The following evidence illustrates that triplet nitrene is the intermediate that drives the chain:

for bromo-substituted PhAs, $\Phi \gg 1$, and it has been experimentally demonstrated for these compounds that because of accelerated intersystem crossing (heavy atom effect) they rapidly reach a triplet state;[51]

for nitro-PhA, $\Phi \gg 1$ also, and the formation of triplet nitrene has been demonstrated experimentally for this compound as well;[52]

in triplet-sensitised photodissociation of 4-nitro-PhA, $\Phi \gg 1$ also occurred regardless of the presence of n-butylamine in the mixture, whereas in direct photolysis the quantum yield decreased sharply on addition of the amine (a "singlet trap").

In summarising our review of the series of publications of Waddell, et al. on the photoinitiated autocatalytic chain decomposition (PACD) reaction of phenyl azide, it may be concluded that, despite the ambiguity of certain assumptions such as that concerning the spectrum of the intermediate in the photolysis of PhA at 20 °C, the actual existence of a chain reaction is not doubted by these authors.[1–8]

However, this cannot be said of other research workers, and we shall now turn to a discussion of their results.

IV. Different routes in the photochemical reactions of aryl azides

The first evidence for a lack of dependence of the quantum yield of photodissociation of aryl azides on their concentration was actually obtained much earlier than the first study on the PACD reaction. In 1968 Reiser and Marley[33] reported that over a concentration range from $10^{-5}-10^{-2}$ M the quantum yield of dissociation of 1-naphthyl azide was constant and equal to 1.00 ± 0.02.

† Raising the question in this way seems strange since the evidence cited by Waddell, et al.[1–7] that it is indeed triplet nitrene which is the chain carrier has already been examined above. It may be assumed that the article[8] was published in response to the criticism of Leyva, et al.[51] of the studies on the PACD reaction. Jenkins, et al.[8] refer to the formation, as demonstrated in two studies,[51,52] of triplet nitrenes in the photolysis of tribromo-PhA and 4-nitro-PhA at room temperature, but nothing is said about the lack of confirmation that triplet PhN is formed under similar conditions and hence the impossibility of it fulfilling the intended function. Moreover, it is shown by Liang and Schuster[52] that the azo compound is formed as a result of the dimerisation of 4-nitro-PhN rather than by a reaction with the azide (for further details, see below).

The first studies in which the disagreement with the results of Waddell, et al. is directly indicated were published in 1984. On irradiation of 1-azido-4-naphthylsulphonic acid with light at 310 nm the quantum yield of dissociation (0.66) did not depend on the concentration of azide, the presence of oxygen, or the presence of a second azide—*p*-azidobenzenesulphonic acid, which hardly absorbs at all at 310 nm and whose concentration exceeded that of the naphthyl azide by a factor of up to 100.[53]

We should note again that selective generation of one nitrene, let us say ArN, in the presence of another azide—Ar′N_3—and isolation of an asymmetric ("crossed") azo compound—ArN=NAr′—is a powerful argument in favour of a reaction between nitrene and azide. Geiger, et al.[53] give no information about the photolysis products, but they concluded that the second azide is not involved in a reaction with the nitrene obtained from the first azide.

The absence of a chain reaction could be due to the structural changes in the azides, but these changes should in fact have resulted in an intensification of the expected effect. Thus, acceptor substituents in PhA are known to increase the activity of the nitrene[54] and assist its formation in the triplet state at room temperature.[51,52] Replacement of the benzene ring by a naphthalene ring effects it in the same way.[30,37]

In the same year Shrock and Schuster[55] published the results of a detailed examination of the photochemical properties of PhA using flash photolysis with identification of the reaction products. In contrast to the results of Waddell, the yield of azobenzene depended only slightly on the degree of conversion of PhA and, what is more significant, decreased as the concentration of PhA increased—when [PhA] > 10^{-3} M virtually all of the PhA was converted to polymer. Changing from a stationary source of radiation to a laser also led to a marked reduction in yield, despite the fact that intermediates with concentrations 20 000 times higher were generated at the same time. The spectrum of the intermediate with λ_{max} at about 340 nm (hexane) which was formed less than 20 ns after a flash and with a lifetime of about 100 μs was attributed by the authors, also in contrast to Waddell, to a single intermediate, namely dehydroazepine, since this intermediate was not formed by triplet sensitisation, did not react with oxygen, and did not react with the standard singlet "trap"—diethylamine.

The somewhat contradictory nature of this study[55] should be noted. Shrock and Schuster report that PhA effectively quenched the triplet state of benzophenone with a rate constant of $k = 2 \times 10^9$ M^{-1} s^{-1} (acetonitrile) and considerable quantities of azobenzene were formed at the same time, but subsequently the low efficiency of photodissociation of PhA by triplet sensitisation is indicated—about 20% of the Φ_{-PhA} during direct photolysis—as well as low yields of azobenzene in the sensitised reaction. However, it was found previously[56,57] for concentrated solutions that the quenching constants had values that were lower by a factor of 10^3 and that every second sensitised molecule of PhA dissociates. In order to explain this discrepancy in their results, Shrock and Schuster[55] mention the values of $\Phi_{-PhA} \gg 1$ obtained by Waddell for concentrated solutions, but in calculations $\Phi = 0.5$ is used and the results of their own measurements of the quantum yield are not given. In interpreting the results the authors[55] believe that a reaction of triplet PhN (PhN^3) or its precursor occurs with PhA, and they refer to the studies of Waddell, but in contrast to the latter, they indicate that a polymer is formed as the final product rather than azobenzene:

$$PhN^3 + PhN_3 \xrightarrow[-N_2]{} [\dot{P}hN]_2 \xrightarrow[-nN_2]{nPhN_3} [PhN]_{n+2} .$$

In fact the only point of agreement between Shrock and Schuster[55] and Waddell, et al.[1-4] is that azobenzene is formed from triplet PhN.

The other study by Shrock and Schuster published at that time[58] on the photochemical properties of polynuclear azides did not shed light on this question. Certain arguments were put forward in favour of both the possibility of triplet nitrene reacting with azide and the formation at the same time of an intermediate that subsequently decomposes to the azo compound.

On irradiation of a mixture of two azides—PhA and 1- or 2-naphthyl azide (NA)—with low-intensity light of wavelength 350 nm, both azonaphthalene and the "crossed" asymmetric product, but not azobenzene, were obtained.

$$C_{10}H_7N_3 \xrightarrow[-N_2]{h\nu} C_{10}H_7N \xrightarrow[-N_2]{PhN_3} C_{10}H_7N{=}NC_{10}H_7 + C_{10}H_7N{=}NPh.$$

In contrast to the study of Horner, et al.[41] considered above, in which an asymmetric azo compound was also isolated, Shrock and Schuster[58] had a clearer result since light was absorbed by only one azide (NA). On laser photolysis (337 nm) the same mixture yielded only azonaphthalene, from which it was concluded that the rate of reaction of nitrene with azide is much lower than the rate of dimerisation of nitrene, the rate constant of which was determined as $k = 1 \times 10^9$ M^{-1} s^{-1} for 1-NA (but compare with the reaction of anthrylnitrene with anthryl azide:[30] $k = 5 \times 10^8$ M^{-1} s^{-1} and the reaction of PhN with PhA in the gas phase: $k = 1.3 \times 10^{-12}$ cm^3 s^{-1}).[46]

Interesting observations were made in analysing the products of stationary photolysis after standing in the dark. It transpired that the yields of azo compounds determined directly after photolysis gradually increased over a period of several hours, and in experiments with two azides this applied to both reaction products. Since the content of azides on standing in the dark did not change and the yield of azo compounds from laser photolysis remained constant and equal to that measured directly after irradiation, it was concluded that an additional quantity of azo compound is formed by decomposition of a fairly stable intermediate obtained by reaction between nitrene and azide. Shrock and Schuster,[58] with reference to the study of Waddell, et al.,[1] assumed that the intermediate had the structure of a tetraazadiene (tetraazine)[58] and defined the scheme for formation of the crossed azo compound as

$$ArN + Ar'N_3 \longrightarrow$$

$$\longrightarrow [Ar{-}N{=}N{-}N{=}N{-}Ar'] \xrightarrow[-N_2]{} Ar{-}N{=}N{-}Ar'.$$

There is no spectroscopic or any other form of evidence for a tetraazadiene. Unfortunately, data on the quantum yields for formation of the azo compounds and photodissociation of the azides are also absent. On photolysis of solutions of pure PhA it was noted that the yield of azobenzene did not vary on standing in the dark.[55]

A direct refutation of the results of Waddell on the PACD reaction of aryl azides was made in subsequent studies of Schuster, et al.[59-61]

An investigation of the photochemical properties of 4-nitrophenyl azide showed that on irradiation of degassed acetonitrile or benzene solutions with low-intensity light the main reaction products were the azo compound (75%) and polymer, while the azo compound (>96%) was exclusively formed on laser photolysis[59] (a result that is in direct contradiction to that obtained by the same authors for PhA itself).[55] It followed from this that the azo compound was obtained by dimerisation of nitrophenyl azide; the experimental rate constant of dimerisation was $k = 1 \times 10^9$ M^{-1} s^{-1}. This conclusion was supported by an experiment with two azides. On irradiation of a mixture of PhA and 4-nitro-PhA under conditions where light was absorbed solely by the latter (313 nm), in contrast to the mixture of PhA and naphthyl azide,[58] neither a "crossed" azo compound nor azobenzene were formed, and only dinitroazobenzene—the dimerisation product of nitro-PhN—was isolated:

A quantum yield of $\Phi = 434$ was reported by Waddell, et al.[8] for concentrated (0.1 M) solutions of 4-nitro-PhA. Liang and Schuster[59] undertook a detailed examination of the dependence of Φ_{-N_2} on the concentration of azide. It transpired that over the concentration range 0.001–0.1 M azide, the quantum yield remained constant and equal to 0.7. A similar result was obtained for 3-nitro-PhA. It was therefore concluded[59] that there was no evidence to support the postulated PACD reaction of 4-nitro-PhA.

Another substituted PhA—4-dimethylaminocarbonylphenyl azide—was studied[60] by means of flash photolysis with the IR and electronic absorption spectra being recorded. Like PhA itself, irradiation of this azide in the presence of diethylamine resulted in the formation of a substituted 3*H*-azepine. On laser photolysis an intermediate was detected that was formed 20 ns after a pulse, and the kinetic curve for disappearance of this intermediate had an exponential form with a half-life of 1 μs, the rate of decay increasing in direct proportion to the content of amine. The spectroscopic properties—absorption in the UV region at 350–370 nm and in particular a band at 1887 cm^{-1} in the IR spectrum—provided clear evidence for the dehydroazepine structure of the intermediate. The characteristic band due to an azirine at 1730 cm^{-1} was absent. Since the kinetic and spectroscopic data and the reaction product accorded for dimethylaminocarbonyl-PhA and PhA,[55] Schuster, et al.,[60] by drawing a parallel between the properties of these two azides, concluded that the spectrum of DHA had been incorrectly attributed by Waddell, et al.[2] to triplet PhN and that the data on the "hypothetical molecular explosion in solution" should be carefully checked.

In order to explain the formation of 70% azo compound during stationary photolysis of dimethylaminocarbonyl-PhA in cyclohexane in the absence of an amine (and oxygen), it was suggested[60] that DHA may isomerise "with moderate efficiency" to triplet nitrene, probably via the singlet state.

The method of time-resolved IR spectroscopy was applied to PhA by Li, et al.[61] On laser photolysis of degassed heptane solutions of PhA, an intense band at 1887 cm^{-1} due to the cumulated double bonds of DHA was recorded, which shifted, in accordance with theory, to 1877 cm^{-1} when PhA enriched with ^{15}N isotope on the N(1) atom (joined into the ring) was used. The kinetics of the decrease in absorption of DHA had an exponential character, and the rate of decrease proved to be directly proportional to the concentration of PhA, from which the rate constant for reaction between PhA and DHA was obtained ($k = 7.5 \times 10^4$ M^{-1} s^{-1}). In the opinion of Li, et al.,[61] the reaction of DHA with PhA may, at least partly, account for the formation of tar (polymer) and the quantum yields of $\Phi_{-PhA} > 1$ in the photolysis of concentrated solutions of PhA. The lifetime of DHA (4.8 μs) was obtained by

extrapolation to zero concentration; this characterises the rate of irreversible conversion of DHA to triplet PhN‡.

In addition to PhA, 13 of its derivatives were also studied by Li, et al.[61] The formation of DHA was detected during photolysis at room temperature for all of them, with the exception of 4-dimethylamino-PhA. It had been demonstrated previously for the latter that singlet nitrene which is formed less than 25 ps after absorption of a quantum of light is completely converted to the triplet state over a period of 120 ps.[62] Relatively small quantities of DHA occurred for nitro- and iodo-substituted PhA because of the increase in the rate of intersystem crossing of singlet nitrene to the triplet state.

The possible occurrence of a chain reaction involving triplet PhN was examined.[61] The principal argument in favour of such a reaction was the increase in quantum yield of photodissociation to values of $\Phi \gg 1$ on increasing the concentration of PhA.[1-8] But Li, et al.[61] believed that at a high concentration it was doubtful whether any molecules of PhA would reach the triplet state PhN^3 after elimination of nitrogen. For example, they estimated that even when [PhA] = 0.05 M, less than one in twenty dissociated PhA molecules would be converted to PhN^3. This is also supported by the fact that with an increase in the concentration of PhA, the yield of azobenzene formed from PhN^3 decreases sharply. It was concluded[61] that the results obtained did not completely rule out the feasibility of a possible chain reaction but they limited its potential significance.

Thus, repeated studies of the properties of the intermediate formed during photolysis of PhA at room temperature clearly indicated a dehydroazepine structure rather than triplet phenylnitrene. However, the latter, according to the EPR data, is undoubtedly present in the photolysis products of PhA in rigid matrices at low temperatures. Leyva, et al.[51] proposed that competition between the two routes for conversion of singlet PhN—thermally activated isomerisation to DHA and temperature-independent intersystem crossing to PhN^3—leads to an almost complete change in reaction route on lowering the temperature from 20 °C to 77 K.

A study of the effect of temperature on the ratio of the final products of photolysis as well as the joint application of EPR, absorption and emission spectrosocpy supported this theory. It transpired that both intermediates—DHA obtained by laser photolysis of PhA in acetonitrile solution at 20 °C and PhN^3 obtained by photolysis in an EPA matrix (diethyl ether : isopentane : ethanol = 5 : 5 : 2) at 77 K—absorb in the region of 330–450 nm, which explains the certain amount of confusion in assigning the spectra. Nevertheless, the spectra are sufficiently clear for both intermediates to be distinguished: the spectrum of PhN^3 has distinct maxima at 490, 382, and 303 nm, which are absent in the spectrum of DHA (λ_{max} = 345 nm).

Leyva, et al.[51] demonstrated once again that the spectrum obtained at 77 K is actually that of PhN^3 rather than a mixture of products (in contrast to the previous findings of Reiser, et al.,[17] in which the spectrum of PhN^3 proved to be contaminated with DHA). Firstly, the EPR, absorption, and fluorescence spectra appeared and disappeared (on further photolysis) in the same way; secondly, the O–O bands in the latter two spectra were the same; and thirdly, the fluorescence excitation spectrum corresponded satisfactorily to the absorption spectrum (see the study of Smirnov and Brichkin).[23] The spectrum of DHA at 20 °C was unaffected by a change of solvent (benzene, hexane, acetonitrile), concentration of azide and wavelength of excitation (248 nm at 1×10^{-4} M and 308 nm at 1×10^{-3} M PhA), presence of oxygen.

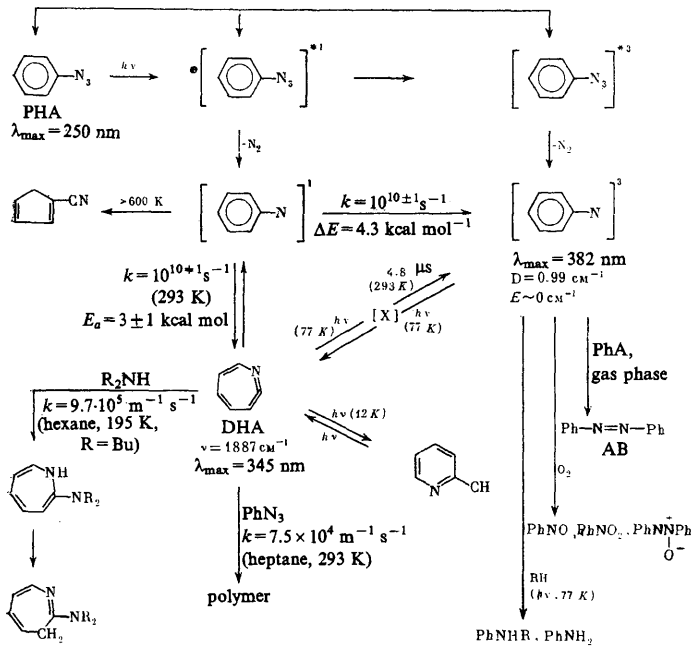
An attempt was made to generate PhN^3 by triplet sensitisation. At 77 K photolysis proved ineffective, while at 20 °C, despite the fact that the triplet states of sensitisers (benzophenone, 2,3-dimethylnaphthoquinone) were quenched by phenyl azide at a diffusion-controlled rate, the presence of PhN^3 could not be deduced from the spectra of the intermediates. This finding is in agreement with the study of Shrock and Schuster,[55] in which it was found that the quantum yield of photodissociation of PhA on triplet sensitisation was $\Phi < 0.1$, and with the study of Reiser, et al.,[30] in which the rate constant of reaction between 1-anthrylnitrene and the initial azide was determined as $k = 5 \times 10^8$ M^{-1} s^{-1}. Consequently, at the high concentrations of PhA necessary for flash photolysis experiments, even when small quantities of PhN^3 are formed the latter may rapidly disappear, so that it cannot be observed. Leyva, et al.[51] stated that these results did not support the mechanism of autocatalytic decomposition of PhA with triplet PhN as an initiator as proposed by Waddell, et al., and that they did not agree with the spectrum obtained by the latter authors[2] at 20 °C being attributed to triplet PhN. No data were given[51] on the quantum yields of dissociation of PhA.

The energy of activation of the isomerisation $PhN^1 \rightarrow$ DHA (E_a = 3 ± 1 kcal mol^{-1}), the rate constant of isomerisation at 20 °C ($k = 1 \times 10^{11\pm1}$ s^{-1}), and the temperature-independent rate constant of intersystem crossing ($k = 1 \times 10^{10\pm1}$ s^{-1}) were estimated[51] from the effect of temperature of the ratio of the photolysis products. The latter value is in good agreement with the recorded time of the singlet–triplet conversion of 4-dimethylamino-PhN ($\tau = 1.2 \times 10^{-10}$ s);[62] for the much more stable 1-pyrenylnitrene this value is substantially higher ($\tau \sim 3 \times 10^{-8}$ s).[63]

The results of the recent most exhaustive studies[51,61] supplemented with the data of earlier studies are combined in Scheme 1, which indicates the possible routes for (inter)conversion of intermediates in the photolysis of phenyl azide under different conditions.

‡Processes with first-order kinetics in the photolysis of solutions of pure PhA had already been observed previously. It would appear that the increase in absorption at a wavelength of 366 nm in the flash photolysis of a solution of PhA in hexane[31] characterises the formation of the product derived by reaction between DHA and PhA. In that case, starting with an apparent constant of about 1.4×10^2 s^{-1} and a PhA concentration of 1×10^{-4} M, the rate constant of the reaction between DHA and PhA can be determined as $k = 1.4 \times 10^6$ M^{-1} s^{-1}, which is somewhat higher than in heptane.[61] If the spectrum observed by Waddell, et al.[6] is that of DHA rather than triplet PhN, from the lifetime of the intermediate of $\tau = 2.8$ μs and a PhA concentration of 5×10^{-4} M, we obtain the rate constant of the reaction between DHA and PhA in acetonitrile ($k = 7 \times 10^8$ M^{-1} s^{-1}). The considerable increase in the rate of reaction between DHA and PhA on changing from hexane to acetonitrile is comparable to the increase in the rate of reaction of DHA with dibutylamine: $k = 9.7 \times 10^5$ M^{-1} s^{-1} (hexane) and 3.5×10^7 M^{-1} s^{-1} (acetonitrile).[31]

Scheme 1



Excitation of PhA leads to excited singlet PhA^{*1} and then to excited triplet PhA^{*3}. Both of the latter can dissociate to a nitrogen molecule and nitrene, and more will be said later about the relative proportion of these two reaction routes at different temperatures. Quantum-chemical calculations showed that in both of the excited states of PhA dissociation starts with movement of the terminal N(3) nitrogen atom out of the plane of the molecule, resulting in a decrease in the N—N—N angle, followed by cleavage of the N(1)—N(2) bond.[64] Since the quantum yield of dissociation $\Phi < 1$, there exists a route for the deactivation of excited singlet and/or excited triplet PhA.

Depending on the reaction conditions, singlet phenylnitrene PhN^1 is converted to the triplet state or isomerises to dehydroazepine DHA, and at high temperatures its isomerisation to cyanocyclopentadiene has been recorded[47,65] (one of the possible isomers is shown in Scheme 1). Singlet PhN (the protonated form) is also likely to be responsible for the formation of substituted aminophenols during photolysis in acetic acid,[24] similar products being formed in the protolytic decomposition of PhA.[66] Moreover, certain substituted phenylnitrenes ArN^1 are capable of reacting with amines R_2NH to give hydrazines $ArNHNR_2$.[59,67]

In the presence of amines DHA can be converted to a susbtituted 3*H*-azepine, form a polymer on reacting with azide[61] or by self-polymerisation,[68] and isomerise photochemically or by a slow thermal process to PhN^3 (for the possible intermediate "X" in this process, see below).

Triplet phenylnitrene PhN^3 on reacting with hydrogen donors can be converted to aniline and/or a substituted aniline or dimerise to azobenzene (AB). In the gas phase AB is also formed by the reaction of PhN^3 with PhA;[46] in solution this process occurs for anthrylnitrene,[30] but it has been demonstrated for substituted phenyl azides that an azo compound is formed by dimerisation of triplet nitrene.[59] In the presence of O_2, PhN^3 gives oxygen-containing photolysis products.[4,11,59]

The structure of diphenyltetraazadiene DPTA as an intermediate is not shown in Scheme 1 since there is no indisputable evidence for its participation in the formation of AB. Two questions should evidently be singled out—is the formation of a diphenyltetraazadiene structure generally feasible; and, if it formed during the photolysis of PhA, is its decomposition to a nitrogen molecule and two phenylnitrenes possible?

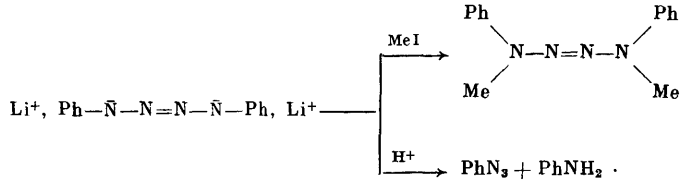
There is a positive answer to the first question. As has already been mentioned, the formation of DPTA and AB radical anions have been detected by mass spectrometry in the reaction between the PhN radical anion and PhA:[50]

$$PhN^{\cdot-} + PhN_3 \longrightarrow [Ph{-}N{=}N{-}N{=}N{-}Ph]^{\cdot-} + [Ph{-}N{=}N{-}Ph]^{\cdot+},$$

and the rate constant of this process ($k = 1 \times 10^{-12}$ cm^3 s^{-1}) proved to be almost equal to the rate constant of the gas-phase reaction for formation of AB in the reaction between PhN and PhA.[46]

Diaryltetraazadiene structures are generated under very mild conditions (20 °C) in exothermic reactions of aryl azides with transition metal complexes and are stabilised through formation of two metal—nitrogen σ-bonds with the N(1) and N(4) atoms. The reaction between a metal nitrene and azide at an intermediate stage has been suggested.[49]

The lithium salt of the DPTA dianion has some interesting properties. On treatment with methyl iodide it gives dimethyldiphenyltetrazine while proton solvents cause it to decompose to PhA and aniline:[69]



It follows from the data of X-ray diffraction analysis[69] that metal complexes with DPTA as the ligand are actually 2-tetrazene derivatives. For example, the following values of the bond lengths were for obtained for a palladium complex: 1.39 Å for N(1)—N(2); 1.26 Å for N(2)—N(3); and 1.37 Å for N(3)—N(4), which corresponds to two single and one double bond.

The formation of a fairly stable intermediate in reactions involving naphthylnitrenes is suggested by the data on the increase in yield in the dark of azo compounds when irradiated solutions are left to stand,[58] but there is no real evidence for a tetraazadiene structure. Hence, the second question—whether DPTA participates in the formation of AB—remains open.

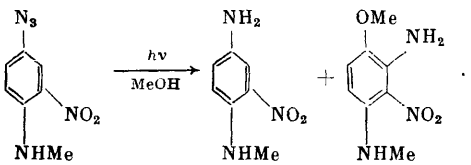
The structure of benzazirine that was widely discussed in earlier studies on the photochemistry of PhA is also not shown on the general scheme (Scheme 1) for interconversion of intermediates. The formation of condensed azirines during low-temperature photolysis of naphthyl azides was experimentally demonstrated from the appearance of bands in the region of 1700—1740 cm^{-1} in the IR

spectrum.[36] In similar studies of monocyclic aryl azides, the IR and UV spectroscopic data indicated the formation of DHA,[22,51,70] while UV and EPR spectroscopic data provided evidence for the formation of PhN^3.[13,17,19,51]

In order to resolve this contradiction, Leyva, et al.[51] suggested that the primary photolysis product is in fact PhN^3 and DHA is formed as a result of secondary photochemical reactions of nitrene. However, a recent examination of the results of low-temperature photolysis of PhA showed that this theory is only partly correct. In fact, on irradiation of PhA with light over a wide spectroscopic range ($\lambda > 210$ nm), including the region of PhN^3 absorption, the latter rapidly undergoes secondary reactions.[71] But photolysis with light at the region of the absorption minimum of PhN^3 (about 330 nm) also gave a mixture of DHA and PhN^3 in the ratio 1:4, whatever the concentration of PhA, matrix, or temperature. It was concluded that DHA, like PhN^3, is a primary photoproduct, namely at 12–45 K the proportion of "singlet" to "triplet" products formed at the same time is almost the inverse of that which occurs at 20 °C (we should recall that at 20 °C this proportion is equal to about 7:1).[27] An accurate knowledge of the composition of the photolysis products made it possible for Hayes and Sheridan[71] to record the IR spectrum of PhN^3 for the first time.

Thus, it is clear from the above that not a single method under any conditions has provided confirmation that benzazirine is formed during the photolysis of phenyl azide.

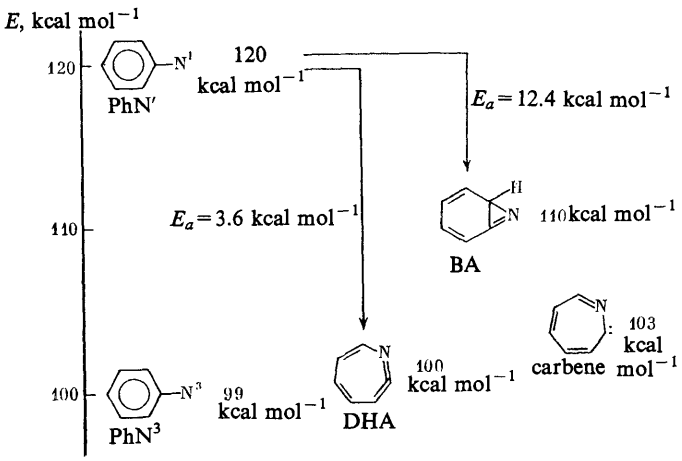
Indirect evidence for the existence of a benzazirine intermediate in the reactions of substituted PhA may possibly be provided by the results of a study by Nielsen and Buchardt,[72] in which during the photolysis of 3-nitro-4-methylamino-PhA migration of the nitrogen atom of the azide group to the *ortho* position of the benzene ring occurred and the corresponding isomeric anilines were isolated:



As was mentioned above, the most probable intermediate in this type of migration in a series of naphthyl azides is naphthazirine.[28,37] It should be noted that some of the findings of Nielsen and Buchardt[72] give rise to doubt. In the flash photolysis of PhA the authors did not succeed in detecting an intermediate with an absorption in the region above 300 nm, at variance with an earlier study[31] and more recent ones.[51,55,61]

Let us consider again the question of the tautomers of singlet PhA. After the unsuccessful attempts to find spectroscopic evidence for the formation of benzazirine, the only argument in favour of the existence of this intermediate was provided by the results of quantum-chemical calculations[34] which placed BA below DHA on the energy scale. Using this MNDO method[61] the potential energy surface for the interconversions of structures with the composition of PhN was calculated (Scheme 2).

Scheme 2



The calculated value of the singlet–triplet splitting (21 kcal mol^{-1}) is higher than the experimentally determined value of 4.3 kcal mol^{-1} for PhN, but Li, et al.[61] note that the MNDO method provides a reliable prediction of relative rather than absolute energy differences.

A more important result is that the calculated heat of formation of BA is 10 kcal mol^{-1} higher than that of DHA. Moreover, the energies of activation of the processes involving conversion of singlet PhN^1 to BA and DHA are equal to 12.4 and 3.6 kcal mol^{-1} respectively. Thus, calculations of both thermodynamic and kinetic criteria indicated the preference for a dehydroazepine structure as an intermediate, in complete agreement with the experimental results.

The reliability of this method was confirmed by calculations of the reaction route for 1-naphthylnitrene, for which it was found that, conversely (compared to PhA), naphthazirine is 10 kcal mol^{-1} more stable than the isomeric benzodehydroazepine and the activation barriers for their formation are equal to 3.1 and 13 kcal mol^{-1} respectively, which is also fully consistent with the experimental results.[36,37]

Li, et al.[61] subsequently considered the question of the possible structure of the intermediate "X" formed during interconversions of PhN^3 and DHA. It is generally assumed that the reaction occurs via PhN^1. In the opinion of the authors,[61] the intermediate conversion of DHA to a triplet carbene rather than PhN^1 is more probable. As an argument, use was made of the results of calculations in which it was found that the energy difference ΔE(carbene–DHA) = 3 kcal mol^{-1} was considerably less than the difference $\Delta E(PhN^1 - DHA)$ = 20 kcal mol^{-1}. The results of these calculations should evidently not be overrated. Starting from the experimentally determined value of the difference $\Delta E(PhN^1 - PhN^3)$ = 4.3 kcal mol^{-1}, $\Delta E(PhN^1 - DHA)$ should be less than 4.3 kcal mol^{-1}, i.e. singlet nitrene as well as triplet carbene could act as "X". We should note that even for the second excited singlet state of PhN the experimental difference $\Delta E(PhN^{*1} - PhN^3)$ = 8.8 kcal mol^{-1},[73] in other words, the calculated value for PhN^1 (21 kcal mol^{-1}) is considerably overestimated.

The quantum yield of dissociation of PhA under different conditions was determined by Budyka, et al.[74] It was shown that over a concentration range of $10^{-4} - 10^{-1}$ M the value of Φ_{-PhA} stays equal to less than one (0.4–0.5), which is in agreement with the study of Reiser and Marley[33] and at variance with the data of

Waddell, et al.[1-8] Also, in contrast to the latter[1-8] but in agreement with the studies of Schuster, et al.,[55,61] the polymer was predominant amongst the photolysis products of concentrated solutions and the yield of AB did not exceed 20%.

Table 1. Effect of conditions of photolysis of phenyl azide on the quantum yield of photodissociation (Φ) and the ratio of reaction products (in an inert medium unless shown otherwise).

Thus, we may summarise our discussion of the photochemical properties of phenyl azide. In Table 1 the available data on the quantum yields of photodissociation of PhA and the ratio of the reaction products under different conditions have been arranged in chronological order (by insertion product is meant both substituted 3*H*-azepines and anilines that are substituted in the benzene ring—both are formed in reactions of isomers of singlet PhN with nucleophiles). It is clear from Table 1 that the total results can be divided into two groups: the first is made up by the results of Waddell, et al., and the results of the remaining research workers are in the second group. Despite the spread and frequent absence of values of the quantum and chemical (preparative) yields, on the whole the results of the second group are consistent with each other and are markedly at variance with the results of the first group. Up to the present time no one apart from Waddell, et al. has succeeded in observing a value of $\Phi > 1$ in the photodissociation of aryl azides and the quantitative formation of azobenzene in the reactions of PhA.

V. Photochemical chain reactions of azides

We shall now consider the available data on other photochemical chain reactions involving organic azides.

In 1963 it was found in a study of the photolysis of methyl azide in the gas phase that the quantum yield for liberation of nitrogen—the main gaseous product—varied from 1.7 to 2.3 on changing the wavelength of incident light from 313 to 254 nm (30 °C, 300 mm Hg), but it did not depend on the light intensity, temperature, or pressure. Radical "traps" inhibited the process and the composition of the condensate corresponded to a polymer with the general formula $(MeN)_n$.[77]

It was suggested that the methylnitrene which is formed at the first stage then reacts with the initial azide:

$$MeN_3 \xrightarrow{h\nu} MeN + N_2,$$
$$MeN + MeN_3 \rightarrow (MeN)_2 + N_2.$$

The resulting compound, presumably azomethane, also reacts with nitrene and at a higher rate than the azide since, firstly, azomethane was not present in the final products and, secondly, the addition of azomethane to the reaction mixture reduced the quantum yield:

$$MeN + (MeN)_2 \rightarrow (MeN)_3.$$

However, these two reactions of nitrene could only explain values of Φ up to 1.5, so the reaction of thermally excited ("hot") nitrene with azide to form two nitrenes was also introduced:

$$MeN^* + MeN_3 \rightarrow 2MeN + N_2.$$

Confirmation of the formation of nitrene in an excited state, in the opinion of Currie and Darwent,[77] was the dependence of Φ on the wavelength of radiation and the considerable excess of energy of the absorbed quantum of light over the energy of dissociation of the N—N bond. A similar explanation—reactions of nitrene in a "hot" state—was introduced to interpret the effect of the wavelength of exciting light on the ratio of the photolysis products of 4-cyanophenyl azide.[67]

A somewhat different interpretation of the values of Φ greater than 1 in the gas-phase photolysis of methyl azide was later put forward.[48] It was suggested that nitrene reacts with azide to form azomethane and also an aminonitrene, which on reacting with azide gives the trimer, etc., subsequently producing the polymer:

$$MeN + MeN_3 \rightarrow MeNHCH_2N + N_2,$$
$$MeNHCH_2N + MeN_3 \rightarrow (MeN)_3 + N_2,$$
$$MeN + (MeN)_3 \rightarrow (MeN)_4 \ldots$$

In contrast to the gas-phase reaction, the quantum yield of photodissociation of methyl azide (and hydrazoic acid) in methanol solution increased with an increase in concentration and reached a maximum value of 2.1 at a concentration above 1 M.[78] The dependence of the molar absorption index of these compounds on concentration suggested that molecules of azides were associating with each other or with molecules of solvent. On the basis of kinetic analysis Koch[78] assumed that the azide does not decompose in a

monomolecular reaction to nitrene, but existing for a sufficient time in an excited state, reacts with another, unexcited molecule of azide, solvent or intermediates. It is interesting to note that the quantum yield for ethyl azide under similar conditions did not depend on the concentration of azide and was equal to unity.[78]

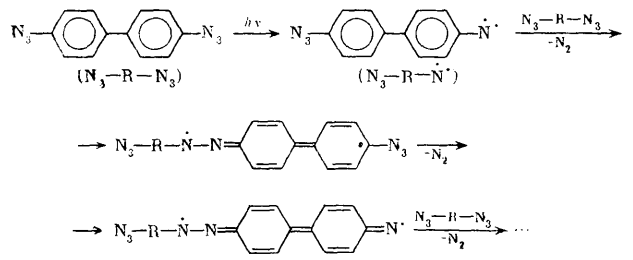
The thermolysis of PhA induced by chloromethyl radicals at 79.8 °C was autocatalytic in nature.[79] The sequence of stages of this reaction is similar to that proposed in the PACD reaction, if the radical nature of triplet PhN is assumed:

$$PhN_3+\dot{C}Cl_3 \rightarrow Ph-\dot{N}-N=N-CCl_3,$$
$$Ph-\dot{N}-N=N-CCl_3 \rightarrow Ph-\dot{N}-CCl_3+N_2.$$

Amongst the large number of nucleophilic substitution reactions known at present that are induced by electron transfer,[80] there are those that involve an azide. Thus, in the preparation of 4-nitrocumyl azide from the corresponding chloride and sodium azide it has been demonstrated that the substitution reaction is considerably accelerated when the reaction mixture is irradiated with light. The maximum quantum yield recorded was $\Phi \sim 6000$.[81] The dependence of Φ on the wavelength of incident light supported the conclusion that the first stage of the reaction is electron phototransfer within a charge-transfer complex between the cumyl chloride and azide ion followed by dissociation of the radical anion of the chloride and reaction with a second azide ion:

$$RCl+N_3^- \rightleftharpoons (RCl\cdot N_3^-),$$
$$(RCl\cdot N_3^-) \xrightarrow{h\nu} (RCl^{\cdot-}, N_3^{\cdot}),$$
$$RCl^{\cdot-} \rightarrow R^{\cdot}+Cl^-,$$
$$R^{\cdot}+N_3^- \rightarrow RN_3^{\cdot-},$$
$$RN_3^{\cdot-}+RCl \rightarrow RN_3+RCl^{\cdot-},$$
$$R=NO_2-C_6H_4-C(CH_3)_2- .$$

A polymer is formed in the photolysis of aromatic diazides in the crystalline stage. It has been suggested that the reaction may occur by a linear (nonbranching) chain mechanism, as, for example, that of diazidobiphenyl:[82]



Zelentsov, et al.[82] suggested that the conditions needed for this mechanism to occur are: firstly, a triplet state of the nitrene, which prevents the recombination of the adduct at the second stage of the reaction to an azo compound; secondly, a conjugation chain for intramolecular transfer of spin to the α-position of the second azide group; and thirdly, proximity of the nitrene to the azide group of the neighbouring molecule, which is determined by the packing of the diazide molecules in the crystal.

Theoretical calculation of the densest packing of the molecules of diazidobiphenyl in the crystal demonstrated the possibility for achieving a favourable molecular configuration. The fact that it is for this diazide (from the series of those studied), in which all three conditions are met, that the maximum yield of polymer occurred was considered to be experimental confirmation of a chain mechanism of decomposition.

In a study of the pyrene-sensitised photodissociation of 4-dimethylaminocarbonylphenyl azide in acetonitrile it was shown that the reaction is initiated by electron transfer from pyrene to azide with subsequent decomposition of the azide radical anion (Pyr = pyrene):[83]

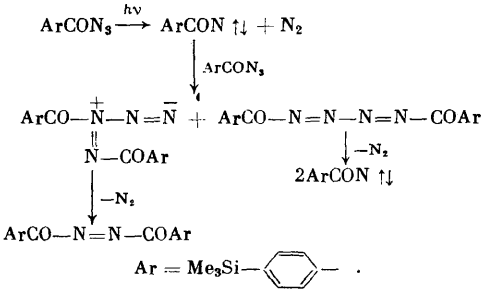
$$ArN_3 \xrightarrow{h\nu/Pyr} ArN_3^{\cdot-} \longrightarrow ArN^{\cdot-} + N_2,$$
$$Ar=Me_2NCO-C_6H_4- .$$

In order to account for the exclusive formation of an azo compound during the sensitised photolysis, Schuster, et al.[83] suggested that, in addition to dimerisation of nitrene, the nitrene radical anion may give rise to a chain reaction of azide decomposition.

A chain process initiated by 4-nitro-PhA radical anions was found in the electrochemical decomposition of this azide in the presence of weak methylene acids such as diethyl malonate.[84,85] Reaction resulted in the transfer of a diazo group from azide to ester to form aniline and diazoalkane, while the passage of not more 0.1 Coulomb mol^{-1} was sufficient for a quantitative yield of products:

$$ArN_3 + \bar{e} \rightleftarrows ArN_3^{\cdot-} \xrightarrow[-N_2]{SH} ArNH^-,$$
$$ArNH^-+H_2C(CO_2Et)_2 \rightleftharpoons ArNH_2+H\bar{C}(CO_2Et)_2,$$
$$ArN_3+H\bar{C}(CO_2Et)_2 \rightleftharpoons ArNH^-+N_2=C(CO_2Et)_2,$$
$$Ar = NO_2-C_6H_4- .$$

In 1989 the PACD reaction of an acyl azide—4-trimethylsilylbenzoyl azide—was reported. Abraham, et al.[86] found that the quantum yield of photodissociation of this azide in cyclohexane reached a value of $\Phi = 3-4$ at azide concentrations of 0.01–0.1 M; in dilute solution, as in the case of unsubstituted benzoyl azide, $\Phi < 1$ was obtained. With reference made to a study of Waddell, et al.,[5] the following reaction scheme was proposed:



In contrast to the earlier study,[5] the chain carrier was assumed to be singlet nitrene, although triplet is postulated as the ground state of nitrene (for a number of aroyl azides it was shown that singlet is the

ground state).[87,88] Isocyanate and cyclohexylamide, which were isolated as reaction products, are obtained from excited singlet azide and singlet nitrene. No products derived from triplet nitrene could be detected.

In support of their proposed reaction scheme, Abraham, et al.[86] refer to a study of Lwowski, et al.[89] in which photolysis of pure liquid ethyl azidoformate results in the isolation of an azo compound. However, it is shown by a special experiment in this study[89] that the reaction between thermally generated nitrene and azide does not result in the formation of an azo compound. It should be noted that in this case as well, there is no need to introduce this reaction in order to explain the values of $\Phi > 1$.

If it is assumed that the initiator of a chain process, if it exists, is triplet nitrene, it is possible that fluorinated PhA derivatives would be suitable substrates for the PACD reaction, since it has been demonstrated for them that singlet nitrene is not isomerised to DHA (or BA) but is quantitatively converted to the triplet state.[90] In studies of the chemical properties of fluorophenyl azides it was found that one of the main reaction products, and the predominant one in some cases, is the corresponding fluoroazobenzene.[91,92] However, there is no information about the quantum yields of photodissociation of these products.

---o0o---

Thus, the literature data on the photoinitiated autocatalytic chain decomposition reaction of azides are contradictory, and it is evidently premature to say for certain that such a reaction may occur.

It can be stated that the main detected primary products of the photolysis of phenyl azide are dehydroazepine and triplet nitrene in the ratio of about 7:1 at 20 °C and about 1:4 below 77 K. Aromatic azo compounds may be formed both by dimerisation of nitrene and from its reaction with azide.

With regard to the reaction routes during photolysis of phenyl azide, it would appear that a complete picture of the possible intermediates and the ways in which they are interconverted has been built up, and the discussion about the photochemical properties of this compound can be brought to a close. However, new questions have arisen with the development and research application of novel physicochemical methods.

Recently high-resolution pulsed laser photolysis was used to study the rotational and spin structure of the electronic transition in the spectrum that was attributed to phenylnitrene,[93] and it was concluded that the data obtained were difficult to correlate with what was expected for phenylnitrene. Although the results of studies in the gas phase cannot be completely transposed to reactions in condensed media, Cullin, et al.[93] consider that with this lack of confirmation of a nitrene structure for the intermediate, it will be necessary to make a careful check of all the previously obtained data.

In our view, the aromatic azide with the simplest structure has proved to be probably the most complex in terms of its properties.

Iodoperfluoroalkanes

L E Deev, T I Nazarenko, K I Pashkevich, V G Ponomarev
Institute of Chemistry of the Bashkir Scientific Centre, Urals Branch of the Russian Academy of Sciences, Sverdlovsk
Perm Branch of the State Institute of Applied Chemistry

ABSTRACT. **In this review the methods for preparing iodoperfluoroalkanes and their chemical properties, namely, radical addition to the carbon–carbon multiple bonds of unsaturated compounds with functional groups, reactions with elements of groups IV–VI and their compounds, cleavage of single bonds by an R_f radical, oxidation of iodoperfluoroalkanes with degradation of the perfluoroalkyl chain or formation of iodonium derivatives, the formation of charge-transfer complexes, and α-halodefluorination reactions are examined. The uses of iodoperfluoroalkanes are described.**

The bibliography includes 285 references.

V. Conclusion 50

I. Introduction

The iodoperfluoroalkanes (IPFAs) CF_3I and C_2F_5I were first prepared at the end of the 1940s for use in the synthesis of organomercury compounds.[1] This marked the beginning of extensive research into perfluoroalkyl derivatives. The use of IPFAs in the syntheses of organic and organoelemental compounds demonstrated their potential as perfluoroalkylating agents[2–6] and reagents for telomerisation.[7] Separate applications for IPFAs in laser,[8–15] electronics,[16] and other fields of engineering[17–19] were progressively established, stimulating further research into preparative methods and a study of their reactivity. At the present time IPFAs are key products in a number of countries for the industrial synthesis of organofluorine compounds and for preparing the initial compounds in the production of drugs and surfactants and the components of artificial blood.[16]

Prominent amongst IPFAs are tertiary iodoperfluoroalkanes,[20,21] which have future potential as working solids for gas lasers.[11]

However, the monographs that are currently available on the chemistry of organofluorine compounds[6,7,16,22–24] do not give a sufficiently clear idea of the methods of synthesis, reactivity, or application of iodoperfluoroalkanes.

In this review an attempt is made to provide a correlated report on the preparative and synthetic methods for obtaining IPFAs and their chemical properties and applications.

With the exception of alkenes with functional groups, reactions of IPFAs with alkenes, which are described in sufficient detail in one monograph,[7] are not covered by the present review. We have made perfluoroalkylation reactions, which are of very considerable synthetic importance and involve extensive literature material, the subject of a separate review.

II. Preparation of iodoperfluoroalkanes

1. Exchange or addition of halogens

Iodoperfluoroalkanes, in particular CF_3I, were first obtained by fluorination of tetraiodomethane.[1] Because of the difficulty in obtaining periodides, this method has more historic significance than preparative value.

$$CI_4 \xrightarrow[20-100^\circ C]{IF_5} CF_3I. \quad 95\%$$

Some considerable time later 2-iodoperfluoro-2-methylpropane was successfully obtained by trifluoromethylation of CI_4 in a glow discharge:[25]

$$CI_4 + CF_3{-}CF_3 \xrightarrow[30\ mm\ Hg]{glow\ discharge} (CF_3)_3CI. \quad 55\%$$

$(CF_3)_3CI$ was synthesised in low yield from 2-bromo-perfluoro-2-methylpropane.[27]

$$(CF_3)_3CBr + NaI \xrightarrow[refluxing]{CH_3CN} (CF_3)_3CI. \quad 5.5\%$$

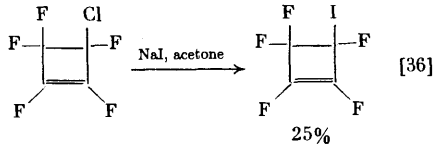
The replacement of iodine in diiodopolyfluoroalkanes is of somewhat greater importance. Usually the reaction consists of the formation of an α,β-diiodoperfluorocarbon by iodination of the corresponding perfluoroalkene followed by replacement of one of the iodine atoms by fluorine. For the substitution reaction use is made of iodine pentafluoride,[1] mixed halofluorides of pentavalent antimony or sulphur tetrafluoride,[28,29] electrochemical fluorination in anhydrous HF,[30,31] and fluorination with hydrogen fluoride in the presence of the catalysts $HF-H_2SO_4$, I_2-HNO_3, $I_2-SO_2Cl_2$ [32] or metal oxides.[33,34]

$$CF_2{=}CF_2 \xrightarrow{I_2} ICF_2CF_2I \longrightarrow \underset{75-100\%}{CF_3CF_2I}.$$

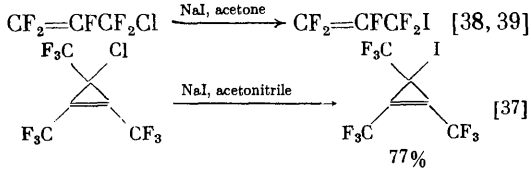
Iodotrifluoromethane labelled with ^{18}F isotope was obtained in 3% yield on treatment of tetrafluoromethane with a mixture of I_2 and $^{18}F_2$:[35]

$$CF_4 \xrightarrow{^{18}F_2+I_2} CF_2{}^{18}FI.$$

Replacement of chlorine at an allylic position by iodine in cyclic and aliphatic chloroperfluoroalkenes is achieved by treatment with sodium iodide in solution at room temperature. Replacement of fluorine on sp^2-hybridised carbon does not occur in this case.[36–39]



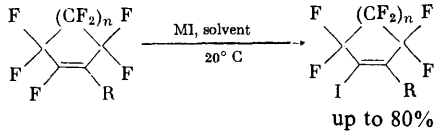
[36]



[38, 39]

[37]

At the same time substitution of a fluorine atom at a vinyl position mainly occurs for perfluorinated cycloalkenes.[40–42] This forms the basis of the preparation of iodoperfluorocycloalkenes by treatment of the respective perfluorocycloalkenes with potassium iodide[40] or sodium iodide[41–43] in a polar solvent. At an elevated temperature the formation of diiodoperfluorocycloalkenes along with the monosubstituted derivative is possible.[43]



,

n = 1, 2; R = CF_3, F; M = Na, K.

At the same time when a fluorine and chlorine atom occur on an sp^2-hybridised carbon it is the chlorine atom which is replaced,[44,56] which corresponds to the order of replacement at an allylic position.

$$(CF_3)_2C{=}CFCl \xrightarrow[\text{refluxing}]{\text{NaI, acetone}} (CF_3)_2C{=}CFI.$$

60%

On treatment of tetraiodoethylene with iodine pentafluoride, addition of fluorine to the double bond takes place together with the replacement of three iodine atoms leading to the formation of iodopentafluoroethane.[1] This method has no preparative value.

$$CI_2{=}CI_2 \xrightarrow[0-130^\circ C]{IF_5} CF_3{-}CF_2I.$$

26%

An interesting case of the formation of iodopentafluoroethane on treatment of iodotrifluoroethylene with an $F_3NO.BF_3$ complex at low temperatures has been reported in a patent.[46]

$$CF_2{=}CFI \xrightarrow[-196^\circ C]{F_3NO\cdot BF_3} CF_3CF_2I.$$

2. Preparation from derivatives of perfluorocarboxylic acids

The slow heating of anhydrous silver perfluoroalkanecarboxylates with a slight excess of iodine (the Borodin–Hunsdiecker reaction) affords the corresponding iodoperfluoroalkanes in high yield.[47,48] The reaction is versatile and can be used to synthesise not only aliphatic[47] but also cyclic[22] and perfluoroalkoxyl iodides[49] as well as diiodoperfluorocarbons (in the case of dibasic acids).[22] This method is important industrially—for the production of CF_3I, for example.

It is assumed[50] that the Borodin–Hunsdiecker reaction occurs via the formation of acyl hypoiodites.

$$R_fCOOAg \xrightarrow{I_2} [R_fCOOI + AgI] \longrightarrow R_fI + AgI + CO_2$$

$R_f{=}C_nF_{2n+1}$ [47], $CF_3OCF_2CF_2$ [49],

$I(CF_2)_n$, cyclo-C_8F_{11} [22].

Iodoperfluoroalkanes can also be obtained from salts of alkali metals[51] or mercury,[52] but in lower yield. The reaction is usually carried out in an aprotic polar solvent. When iodine is replaced by the more polar iodine monochloride in this reaction, the yield of IPFAs does not increase.[53] The two-stage nature of the process and the length of time needed for evaporation and drying of the intermediate salts have impeded the application of this method in industry.

Iodoperfluoroalkanes are also formed by the decomposition of perfluorocarboxylic acid derivatives. Thus, electrolysis of trifluoroacetyl hypoiodite[54] or the decomposition of trifluoroacetyl iodide at room temperature in the presence of hexamethyldistannane[55] gives iodotrifluoromethane in low yield.

$$CF_3COOI \xrightarrow{\text{electrolysis}} CF_3I \xleftarrow{(CH_3)_3Sn-Sn(CH_3)_3} CF_3COI.$$

A method for the synthesis of higher iodoperfluoroalkanes by reaction of the corresponding acids with iodine and benzoyl peroxide has been developed.[56–59] The reaction is radical in nature and takes place in a nonpolar solvent (dibromo- or dichloro-ethane, dibromopropane). The method of preparing IPFAs as described in a patent[56] has industrial value.

$$F(CF_2)_7COOH \xrightarrow[BrCH_2CH_2Br;\ 110^\circ C]{I_2 + (C_4H_9COO)_2} F(CF_2)_7I \quad .$$

60%

3. Preparation from perfluoroalkenes

Because of the ready availability of lower perfluoroalkenes, iodotrifluoromethane, and iodofluorinating agents at the present time, the synthesis of IPFAs from perfluoroalkenes has assumed increasing importance and has been developed in three areas: electrophilic iodofluorination, nucleophilic iodofluorination, and telomerisation of perfluoroalkenes with iodotrifluoromethane and iodopentafluoroethane.

Electrophilic iodofluorination. This was first reported in the case of tetrafluoroethylene (TFE) when a mixture of iodine and iodine pentafluoride was used.[60–62] The reaction takes place via the formation of a carbocation on addition of iodine to the alkene. The reaction is suitable for alkenes with different structures,[63,64] including

perfluoroisobutene[65,66] and perfluoromethylvinyl ether.[67] High yields of the products were obtained (Table 1).

$$R^1R^2C{=}CF_2 + [I{-}F] \xrightarrow{(IF_5+2I_2)} [R^1R^2C\overset{+}{C}F_2] \xrightarrow{F^-} R^1R^2ClCF_3.$$

Iodopentafluoroethane was obtained at 60–80 °C and atmospheric pressure in 90% yield. The conversion of tetrafluoroethylene was 40%.[68] The latter increases on introducing catalysts such as metals[73] or their salts[69–72] into the iodofluorinating mixture. Metal fluorides[69–71] are recognised as the most effective catalysts of the electrophilic iodofluorination of TFE. The methods reported in two Japanese patents[70,71] have been used in the industrial production of iodopentafluoroethane.

Table 1. Yields of products of the iodofluorination of $R^1R^2C{=}CF_2$

R^1	R^2	Yield, %	R^1	R^2	Yield, %
H	F	76*	F	CF_3O	94
Cl	F	95*	F	CF_3	69
F	F	99	F	F	90
F	CF_3	69	F	F	70

*Total yield of isomers is given.

Electrophilic iodofluorination of excess TFE with a mixture of iodine and iodine pentafluoride in the presence of antimony fluorides gives a mixture of telomeric IPFAs[74–77] with a small quantity of C_2F_6:

$$CF_2{=}CF_2 \xrightarrow[[SbF_5;\ SbF_3]]{I_2+IF_5} F(CF_2CF_2)_nI + ICF_2CF_2I + \text{cyclo-}C_4F_8 + C_2F_6,$$

$$n=1-8.$$

Iodoperfluoroalkane polyfluorides have been proposed for the electrophilic iodofluorination of hexafluoropropene (HFP).[78]

The principles of the electrophilic addition of interhalogen compounds have been reviewed.[79]

Nucleophilic iodofluorination. This was first put forward by several authors[80–82] in the 1960s and is achieved in aprotic polar solvents on heating. The reaction is initiated with the addition of a fluoride anion to perfluoroalkene. Thus, for example, 2-iodoperfluoropropane is obtained by reaction of HFP with iodine and potassium fluoride in acetonitrile at 100 °C in an autoclave.[80]

$$CF_3CF{=}CF_2 \xrightarrow[CH_3CN]{KF} CF_3{-}\overline{C}F{-}CF_3 \xrightarrow[CH_3CN]{I_2} \underset{60\%}{CF_3CFICF_3}.$$

Even perfluoro-2-butene,[80] which is extremely stable towards iodofluorination,[63] reacts under such conditions. The nucleophilic iodofluorination of perfluoroisobutene takes place the most readily,[82–84] giving 2-iodoperfluoro-2-methylpropane in high yield. In this case even bound iodine (from an organic compound) adds to the intermediate perfluoro-t-butylcarbanion.[85–87]

$$(CF_3)_2C{=}CF_2 \xrightarrow{CHI_3+KF} \underset{7\%}{(CF_3)_3CI}.$$

Iodoperfluorocyclobutane is formed in a nucleophilic iodofluorination reaction of perfluorocyclobutene.[80] Conjugated nucleophilic addition of (IF) to perfluoro(methyl vinyl ether) only occurs under severe conditions, giving 1-iodoperfluoro-1-methoxyethane in negligible yield.[67] Lur'e, et al.[67] attribute this to destabilisation of the intermediate $CF_3O\overline{C}FCF_3$ by the electron pair of the neighbouring oxygen. An industrial method for the iodofluorination of TFE using hydrogen fluoride and lead(II) oxide has been reported in a French patent.[88]

$$CF_2{=}CF_2 \xrightarrow[200^\circ C]{I_2,\ HF,\ PbO} \underset{90\%}{CF_3CF_2I}.$$

2-Iodoperfluoro-2-butene has been obtained in a similar manner from perfluoro-2-butyne.[89]

$$CF_3C{\equiv}CCF_3 \rightarrow CF_3CF{=}ClCF_3.$$

A modification of this reaction occurs in the preparation of iodoperfluoroalkoxyalkanes with a branched chain[90,91] by reaction of hexafluoroacetone with the respective alkene and I_2 in the presence of excess alkali metal fluoride in a solvent.[90–95]

$$(CF_3)_2C{=}O \xrightarrow{F^-} (CF_3)_2CF{-}O^- \xrightarrow{RCF=CF_2} (CF_3)_2CFOCF_2\bar{C}FR \xrightarrow{I_2} \rightarrow (CF_3)_2CFOCF_2CFIR.$$

R=F (17%), CF_3 (13%) [89].

The nucleophilic iodofluorination of perfluoroalkenes has been studied in greater detail in a review by Joung,[96] and the mechanism of the reaction between alkoxide anion and fluorine-containing alkenes in the presence of iodine is examined in a report by Evans, et al.[97]

Radical iodofluorination. Radical iodofluorination of perfluoroalkenes has not been used very extensively. Only the preparation of 2-iodoperfluoropropane from hexafluoropropane has been reported.[98]

$$CF_3CF{=}CF_2 \xrightarrow{F_2+I_2} \underset{60\%}{CF_3CFICF_3}.$$

With the methods for preparing iodoperfluoroalkanes and iodoperfluoroalkoxyalkanes examined above it is possible to obtain mainly compounds with a short carbon chain containing up to eight carbon atoms.

Radical addition. For the synthesis of higher IPFAs, radical addition of lower iodoperfluoroalkanes and iodoperfluoroalkoxyalkanes to perfluoroalkenes is normally used, frequently with

oligomerisation of the latter occurring at the same time. The process is usually carried out in solution under pressure in the presence of metal salts.[99–102]

Thus, IPFAs with 5–29 carbon atoms in the chain have been obtained by addition of CF_3I to TFE.[102] This method is important industrially. However, on exposure to radiation IPFAs are formed containing not more than 11 carbon atoms in the chain.[103] Higher IPFAs are also obtained by electrophilic iodofluorination of TFE[76] together with C_2F_5I (see above). These methods have future potential for the production of higher perfluorocarboxylic acids from the corresponding IPFAs.[104]

The addition of CF_3I to HFP is not regiospecific and occurs with a low conversion. The formation of specific products depends on the conditions. Thus, Deev, et al,[27] on conducting the reaction in a nickel tube at a temperature of up to 380 °C, succeeded in obtaining about 77% 2-iodoperfluoro-2-methylpropane.

$$CF_3I + CF_3CF{=}CF_2 \xrightarrow{h\nu} CF_3CFIC_2F_5 + (CF_3)_2CFCF_2I \quad [105]$$
$$80\% \qquad 20\%$$
$$CF_3I + CF_3CF{=}CF_2 \xrightarrow[320-380^\circ C]{[Ni]} CF_3CFIC_2F_5 + (CF_3)_2CFCF_2I + (CF_3)_3CI \quad [27]$$
$$9\% \qquad 6\% \qquad 77\%$$

It was possible to obtain trifluoromethyl-substituted IPFAs containing more than 33 carbon atoms from HFP and higher IPFAs by oligomerisation on exposure to radiation.[106] Branched perfluoroalkenes containing more than three carbon atoms on exposure to radiation with iodotrifluoromethane give products derived from the replacement of fluorine at vinyl and allyl positions together with addition products.[107]

$$CF_3I + (CF_3)_2CFCF{=}CF_2 \xrightarrow{h\nu}$$
$$\longrightarrow (CF_3)_2CFCFICF_2CF_3 \quad 22\%$$
$$\longrightarrow (CF_3)_2CFCF(CF_3)CF_2I \quad 5\%$$
$$\longrightarrow (CF_3)_2CFCI{=}CF_2 \quad 16\%$$
$$\longrightarrow (CF_3)_2C{=}CFCF_2I \quad 12\%$$
$$\longrightarrow (CF_3)_2CFCFICF_3 \quad 2\%$$

Oligomerisation of tetrafluoroethylene with C_2F_5I in the presence of antimony pentafluoride or organic peroxides under pressure and at an elevated temperature[108,109] gives IPFAs with an even number of carbon atoms in the chain.

$$C_2F_5I + nCF_2{=}CF_2 \xrightarrow[(CCl_2{=}CClCOO)_2]{65-75\ ^\circ C,\ 7-10\ atm} C_2F_5(CF_2CF_2)_nI \quad n=1-5,\ 95-97\%$$
$$C_2F_5I + nCF_2{=}CF_2 \xrightarrow[(C_6H_5COO)_2]{125^\circ C} C_2F_5(CF_2CF_2)_nI \quad n=5-7,\ 95\%$$

Both of the isomeric iodoperfluoropropanes undergo a similar reaction, forming IPFAs with 21–25 carbon atoms.[110,111] IPFAs with an isomeric structure containing from 5 to 23 carbon atoms are obtained by oligomerisation of $(CF_3)_2CFI$ with TFE in the presence of peroxides.[110,112,113] In the absence of catalysts IPFAs can be obtained under pressure.[114]

The aqueous-emulsion oligomerisation of TFE with $(CF_3)_2CFI$ or C_2F_5I at 15–30 °C in the presence of ammonium persulphate or emulsifying agents has been reported.[115]

$$(CF_3)_2CFI + nCF_2{=}CF_2 \xrightarrow[[NaHSO_4+C_8F_{17}COONH_4]]{[(NH_4)_2S_2O_8]} (CF_3)_2CF(CF_2CF_2)_nI$$
$$n=2-5,\ 63\%.$$

Thus, by varying the initial reactants and their ratio, using different catalysts and solvents, and changing the process conditions it is possible to obtain iodoperfluoroalkanes and iodoperfluoroalkoxyalkanes with quite a long carbon chain. Even though the use of a telomerisation process leads to the formation of a wide range of products that are difficult to separate, the production of iodoperfluoroalkanes with seven or more carbon atoms in the chain is actually based on this process.

4. Other methods for preparing iodoperfluoroalkanes

It was shown by Knunyants, et al.[26] that reaction between nitrosoperfluoroalkanes with iodine in an aprotic polar solvent leads to the formation of IPFAs in high yield.

$$R_fNO + I_2 \xrightarrow{50-70^\circ C} R_fI \quad 80-95\%$$
$$R_f{=}CF_3,\ C_3F_7,\ (CF_3)_3C.$$

Iodotrifluoromethane is formed by prolonged UV irradiation of methyl trifluoromethyl sulphide[116] and bis(trifluoromethyl) sulphide[117] in the presence of sources of iodine radicals.

$$CF_3SCF_3 \xrightarrow[h\nu]{n\text{-}C_3F_7I} CF_3I \xrightarrow[h\nu]{CH_3I} CF_3SCH_3$$
$$64\%\ [117] \qquad 30\%\ [116]$$

On treatment of perfluoropropane-2-sulphinic acid with iodine monochloride, 2-iodoperfluoropropane was formed in 33% yield.[118] The action of an alcoholic solution of iodine on perfluoroalkanesulphonyl chloride at an elevated temperature results in the replacement of the sulphonyl chloride group by iodine.[119]

$$R_fSO_2X \xrightarrow[R_f'=(CF_3)_2CF,\ X=H]{ICl} (CF_3)_2CFI$$
$$R_fSO_2X \xrightarrow[R_f=R_f'OCF_2CF(CF_3)OCF_2,\ X=Cl]{I_2} R_f'OCF_2CF(CF_3)OCF_2I.$$

Oxidation of the triiodomethyl ester of n-perfluoropropanesulphonic acid on exposure to UV radiation gives 1-iodoperfluoropropane through removal of iodine from the triiodomethyl group.[120]

$$n\text{-}C_3F_7SO_3CI_3 \xrightarrow{\text{UV irradiation, } O_2} n\text{-}C_3F_7I.$$

The progress made by different research workers[121,122] in the 1980s in studies on the chemistry of perfluoroalkenyl fluorosulphates led to the development of a preparative method for the synthesis of 1-iodoperfluoro-2-propene and other 1-iodoperfluoro-2-alkenes through replacement of the fluorosulphate group by iodine and made this class of compounds, which was previously little-studied but very promising in terms of synthesis, quite accessible.

$$R_fCF_2OSO_2F \xrightarrow{NaI,\ solvent} R_fCF_2I$$
$$R_f=CF_2=CF,\quad CCl_2=CCl,\quad (CF_3)_2CFCF=CF,\quad (CF_3)_3CCF=CF.$$

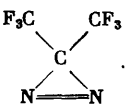
Iodoperfluoroalkanes are also formed by reaction of perfluoroalkyl-containing organoelemental compounds with iodine[123–129] or iodine monochloride.[130] Thus, reaction of iodine with $(CF_3)(CH_3)_2Bi$ or iodine monochloride with $(CF_3)_3Bi$ [123] gives iodotrifluoromethane, while reaction of iodine with bis-(perfluoroisopropyl)mercury gives 2-iodoperfluoropropane.[124] The replacement of halogens in haloperfluorocycloalkenes by iodine in the presence of ethylmagnesium bromide constitutes a variant of this method.[45]

Mixed alkylpolyfluoroalkylsilanes[125] and organolithium compounds behave in a similar manner. The latter are obtained at quite low temperatures.[126,129] It has been shown that the reaction is nucleophilic in nature towards iodine.[126]

$$(R_f)_n - M - R_m + I_2 \xrightarrow[\text{acetonitrile}]{DMF\ or} R_fI.$$

Small quantities of 2-iodoperfluoro-2-methylpropane are obtained from perfluoro-t-butyl chloroformate and potassium iodide or bis(trifluoromethyl)diazirine and iodotrifluoromethane.[26]

$$(CF_3)_3COCOCl \xrightarrow[\text{yield 30\%}]{KI,\ 180-200\ ^\circ C} (CF_3)_3Cl \xleftarrow[\text{yield 10–12\%}]{CF_3I,\ 150-200\ ^\circ C}$$



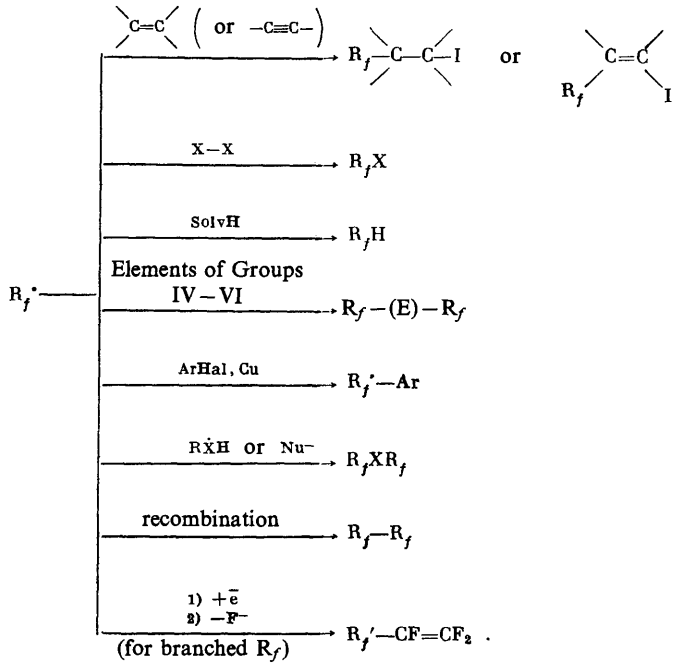
Thus, it is possible to approach the synthesis of IPFAs in different ways, but only some of the methods examined can be used in industry. Amongst these are the reaction of perfluorocarboxylates of Group I metals with iodine, the catalytic electrophilic iodofluorination of perfluoroalkenes, fluorination of diiodoperfluoroalkanes, and the oligomerisation of TFE and HFP with iodotrifluoromethane, iodopentafluoroethane, and iodoperfluoropropanes. The reaction between polyfluoroalkyl fluorosulphates and sodium iodide also appears to have considerable potential.

III. Chemical properties of iodoperfluoroalkanes

The energy of the C–I bond in iodoperfluoroalkanes is low, and they readily undergo homolytic dissociation to form $R_f^{\cdot}$ and $I^{\cdot}$ radicals on thermal or photochemical excitation. They yield an $R_f^{\cdot}$ radical from the action of radical initiators (RIs) or $R_f^{\cdot}$ and I^- on capture of an electron from an electron donor [optical electron detector (OED)] although in far from every case is it possible strictly to distinguish these reactions.

$$R_f^{\cdot} + I^- \leftarrow R_fI^{\cdot-} \xleftarrow{OED} R_fI \xrightarrow{RI} R_f^{\cdot}.$$

The resulting perfluoroalkyl radicals $R_f^{\cdot}$ are highly reactive and are stabilised through addition to carbon–carbon multiple bonds, homolytic cleavage of the bonds of molecules of substrate or solvent, and as a result of perfluoroalkylation of aromatic compounds, nucleophiles, and certain elements, and to a lesser degree by recombination or reduction to a perfluorocarbanion followed by ejection of F^- and formation of an alkene:



On the whole the above scheme almost completely governs the chemical properties and general trend for the synthetic use of IPFAs, which are characterised exclusively by radical or radical anion processes rather than by ionic reactions as proposed in early studies.[22,84,131] Beyond the scope of our review is a small group of reactions, also partly radical in nature, related to the oxidative conversions of iodine itself in an IPFA molecule, the oxidative degradation of $R_f^{\cdot}$, the formation of donor-acceptor complexes, and the halodefluorination of the CF_2I group, which are also examined in the present review.

Through lack of sufficient space we shall not examine the radical addition reactions of IPFAs to multiple bonds, as analysed in a monograph,[7] except for those reactions with unsaturated compounds that contain in addition to the multiple bond other functional groups. Reactions that are initiated by one-electron transfer have also been excluded.

1. Addition to unsaturated functional compounds

Radical reaction of iodoperfluoroalkanes with alkenes containing functional groups occurs exclusively as an addition to the C=C bond without affecting the functional groups[132,133] whereas radical-ion reactions can also occur on the functional groups. As a rule the reactions take place on treatment with conventional radical initiators such as azo compounds,[134,135] and hydrocarbon[136] and fluorinated[137] peroxides. In certain cases initiation is achieved photochemically, with the reaction carried out in a solvent.[132]

Thus, CF_3I adds to methyl vinyl ketone at its C=C bond with an anti-Markownikoff orientation.[138]

$$CF_3I + CH_2{=}CHCOCH_3 \xrightarrow{h\nu} CF_3CH_2CHICOCH_3.$$

The radical reaction of other iodoperfluoroalkanes[133–135,139–153] and iodoperfluoroethers[154,155] with unsaturated alcohols,[133–135,139–144] alkoxy alcohols,[134,147–152] and diols[153] occurs in a similar manner. Most frequently the reactions are carried out in the presence of azobis(isobutyronitrile) (ABN) at its decomposition temperature (70–85 °C),[134,135] while peroxides[136] or UV irradiation with heating[155] are used less often.

$$CH_2{=}CH{-}R{-}CH_2OH + R_fI \xrightarrow{\text{[initiator]}} R_fCH_2CHI{-}R{-}CH_2OH,$$

$R_f = C_3F_7,\ C_4F_9,\ (CF_3)_2CF,\ (CF_3)_2CFO(CF_2)_8;$

$R = -CH_2OCH_2\underset{|}{C}HOH,\ -CH_2OCH_2\underset{|}{C}HCH_3,\ -CH_2OCH_2-,$
$-(CH_2)_9-$ [133–135, 147–154].

Unsaturated carboxylic acids,[137,156–158] their amides,[159] and nitriles and esters[137,138,158,160–164] behave in a similar manner.

$$R_fI + CH_2{=}CH(CH_2)_nC(O)X \xrightarrow[ABN]{70-80^\circ C} R_fCH_2CHI(CH_2)_nC(O)X,$$

X=OH: $R_f = CF_3,\ C_3F_7,\ C_4F_9,\ C_6F_{13},\ C_7F_{15}$,

n=0–4 [137, 156–158];

$X=NH_2$: $R_f = C_7F_{15}$, n=8 [159];

X = OR: $R_f = (CF_3)_2CFO(CF_2)_m$,
where m = 2, 5, 6, n = 8 — 18 [160, 162, 163, 165];

$R_f = (CF_3)_2CF,\ CF_3(CF_2)_m$,

where m = 1 — 7, n = 1, 2 [162, 163].

$$R_fI + CH_2{=}CH(CH_2)_nCN \xrightarrow{\text{[initiator]}} R_fCH_2CHI(CH_2)_nCN,$$
$R_f = CF_3$, n=0 [138]; $R_f = C_3F_7$, n=1, 2 [158, 163].

Carboxylic acids with two or three CH_2 groups between the carboxyl group and the double bond constitute an exception. After addition of R_fI to the double bond these acids undergo lactonisation through intramolecular nucleophilic dehydroiodination. The process is assisted by *gem*-substitution.[137]

$$R_fI + CH_2{=}CHCH_2\underset{CH_3}{\overset{CH_3}{\underset{|}{\overset{|}{C}}}}{-}COOH \xrightarrow{\text{[initiator]}} R_f{-}CH_2{-}CHICH_2\underset{CH_3}{\overset{CH_3}{\underset{|}{\overset{|}{C}}}}{-}COOH \xrightarrow{-HI}$$

$$\longrightarrow R_f{-}CH_2{-}\underset{H_3C\ CH_3}{\overset{O}{\underset{|}{\overset{|}{C}}}}{=}O \quad .$$

With initial esterfication of the carboxyl group it is possible to obtain esters of unsaturated carboxylic acids with perfluoroalkyl substituents from these acids.[137]

$$CH_2{=}CHCH_2\underset{CH_3}{\overset{CH_3}{\underset{|}{\overset{|}{C}}}}{-}COOR \xrightarrow[2)\ -HI]{1)\ C_6F_{13}I,\ [ABN]} C_6F_{13}CH{=}CHCH_2\underset{CH_3}{\overset{CH_3}{\underset{|}{\overset{|}{C}}}}{-}COOR.$$

There is no information available on the addition of IPFAs to unsaturated functional compounds with a trifluorovinyl group.

The products of the addition of IPFAs to unsaturated compounds as listed above have considerable industrial value since they are the starting compounds for the synthesis of organofluorine surfactant and textile-auxiliary materials (see, for example, several studies).[133–136,147–163,166–168]

The radical addition of IPFAs to vinyl and allyl esters of carboxylic acids occurs in a similar manner.[161,166–170] All of the members of the homologous series of iodoperfluoroalkanes up to n = 14 undergo a reaction with vinyl acetate.[166,170] The reaction provides a preparative method for the synthesis of higher homologues of carboxylate esters with a terminal polyfluoroalkyl group and an iodine atom at the β-position relative to the R_f substituent.[168,171]

$$C_3F_7I + CH_2{=}CH(CH_2)_nOCOCH_3 \xrightarrow[70^\circ C]{\text{[ABN]}} C_3F_7CH_2CHI(CH_2)_nOCOCH_3,$$
n=3–9.

The characteristics of the reaction between vinyl and allyl acetates and IPFAs in the presence of peroxides have been reviewed in a monograph.[7] Iodoperfluoro(isopropyl alkyl ethers)[160,162] react with vinyl acetates to form monomers for the synthesis of fluorine-containing polymers with unique properties.

$$(CF_3)_2CFO(CF_2)_{1-20}I + CH_2{=}CH(CH_2)_{0-8}OCOCH_3 \xrightarrow{\text{[initiator]}}$$
$$\longrightarrow (CF_3)_2CFO(CF_2)_{1-20}CH_2CHI(CH_2)_{0-8}OCOCH_3.$$

The addition of nonbranched IPFAs to unsaturated carbocyclic acids occurs stereospecifically (up to 97% *exo* isomer is formed), whereas branched IPFAs form *endo* and *exo* isomers in a ratio of about 1 : 1.[171]

Radical addition of IPFAs to amines containing a double bond in the carbon chain[147] and perfluorovinyl sulphur pentafluoride[172] also results in saturation of the C=C bond.

$$CF_3CF_2CFISF_5 \xleftarrow[R_f = CF_3]{CF_2{=}CFSF_5,\ h\nu} R_fI \longrightarrow$$

$$\xrightarrow[\text{[ABH]};R_f = C_7F_{15}]{CH_2{=}CHCH_2NHC_2H_5} C_7F_{15}CH_2CHICH_2NHC_2H_5.$$

The radical reaction of iodoperfluoroalkanes with acetylenic compounds containing other functional groups,[164] including silicon[173] and germanium[174] atoms, generally occur in a similar manner with these groups remaining unaffected. A characteristic of these reactions is the inability of the resulting perfluoroalkyl-substituted alkenes to react further with IPFAs, apparently because of the inductive effect of R_f, which renders the double bond inert. For example, the addition of 1-iodoperfluoropropane to diethyl propargylmalonate[164] stops when the monoadduct is formed.

$$\underset{|}{\overset{CH_2C{\equiv}CH}{C_2H_5OCOCHCOC_2H_5}} \xrightarrow{C_3F_7I} \underset{|}{\overset{CH_2CI{=}CHC_3F_7}{C_2H_5OCOCHCOC_2H_5}}.$$

Radical addition of IPFAs to functionally substituted olefins and acetylenes is a convenient method of preparing polyfluoroalkyl-substituted compounds.

2. Stabilisation of $R_f^{\cdot}$ radicals by addition to elements of Groups IV–VI and their derivatives

Apart from the addition to unsaturated carbon–carbon bonds, a set of radical reactions with elements of Groups IV–VI (S, Se, P, As) and their compounds, occurring as a result of the unfilled state of the outer electron shells of these elements, is also characteristic of IPFAs. Thus, the reaction of iodoperfluoroalkanes with sulphur at 250 °C gives a mixture of di- and tri-sulphides,[175,176] while at 300 °C a mixture of mono-, di-, and tri-sulphides is formed. The reaction of branched IPFAs with sulphur occurs in a similar manner.[177]

$$R_fI \xrightarrow{250-300^\circ C} R_f^{\cdot} + I^{\cdot},$$
$$R_f^{\cdot} + S \rightarrow R_fS^{\cdot},$$
$$R_fS^{\cdot} + R_fS^{\cdot} \rightarrow R_fSSR_f + R_fSS^{\cdot} + R_f^{\cdot},$$
$$R_fS^{\cdot} + S \rightarrow R_fSS^{\cdot},$$
$$R_fSSR_f + R_fSS^{\cdot} \rightarrow R_fSSSR_f + R_fS^{\cdot},$$
$$R_fSS^{\cdot} + S \rightarrow R_fSSS^{\cdot},$$
$$R_fSSS^{\cdot} + R_fSR_f \rightarrow R_fSSSR_f + R_fS^{\cdot},$$
$$R_fS^{\cdot} + R_f^{\cdot} \rightarrow R_fSR_f.$$

At the same time, when IPFAs were reacted with HgS,[177] only 22% bis(perfluoroisopropyl) disulphide was formed, with 74% conversion of 2-iodoperfluoropropane leading to the formation of 2,3-perfluorodimethylbutane through recombination of perfluoroisopropyl radicals.

Under more severe conditions perfluorinated iodine-containing ethers react with sulphur to give mainly disulphides.[178]

$$2(CF_3)_2CFOCF_2CF_2I \xrightarrow{S;\ 450^\circ C} [(CF_3)_2CFOCF_2CF_2S]_2.$$

Reactions of IPFAs with selenium can be carried out in continuous flow systems,[179] with diselenides mainly being formed in good yield.

$$CF_3I + Se \xrightarrow[40-160\ s]{300-350\ ^\circ C} CF_3—Se—Se—CF_3.$$
79%

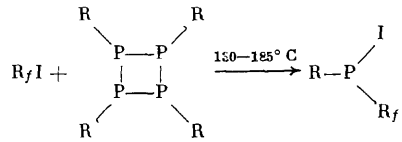
A characteristic of reactions of IPFAs with sulphur and selenium is the participation of the resulting $I^{\cdot}$ radicals solely in chain termination.

In reactions of IPFAs with phosphorus and arsenic[180–185] different types of phosphines and arsines are obtained depending on the structure of the perfluoroalkyl radicals. For the reaction of iodotrifluoromethane the formation of all three possible iodotrifluoromethylphosphines, apparently through the participation of iodine atoms along with $R_f^{\cdot}$ in chain termination, has been detected.[181,182]

$$CF_3I + P \xrightarrow[pressure]{220\ ^\circ C;\ 48\ h} (CF_3)_3P + (CF_3)_2PI + CF_3PI_2.$$

The formation of tris(perfluoroalkyl)phosphines and tris(perfluoroalkyl) arsines does not occur in the case of longer perfluoroalkyl radicals (C_2-C_{10}).[183–185]

Asymmetric iodophosphines have been obtained in reactions of IPFAs with tetrakis(alkyl or perfluoroalkyl)cyclotetraphosphines.[186–188]



$R=CF_3,\ C_3F_7,\ (CF_3)_2CF,\ C_2H_5;\quad R_f=C_2F_5,\ (CF_3)_2CF.$

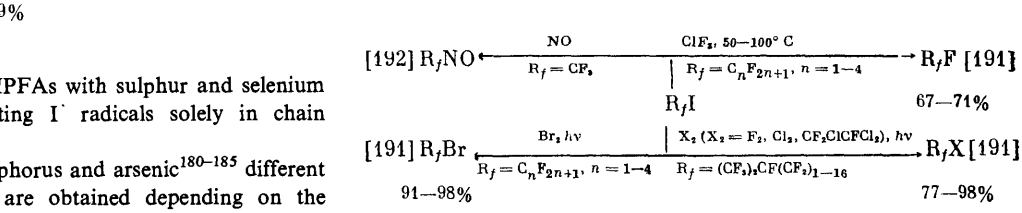
It has been established kinetically that on changing from n-C_3F_7I to $(CF_3)_2CFI$ the rate constant and energy of activation of the reaction are reduced [*sic*. The latter is presumably increased, (Ed. of Translation)], namely, the reactivity of the iodoperfluoroalkanes decreases as the degree of chain branching increases, because of both the increasing electronegativity of the fluoroalkyl group and steric hindrance.

A general reaction of nonbranched iodoperfluoroalkanes is their addition to silicon difluoride.[189]

$$R_fI + SiF_2 \rightarrow R_fSiIF_2,$$
$R_f=CF_3,\ C_2F_5,\ C_3F_7.$

3. Stabilisation of $R_f^{\cdot}$ radicals through cleavage of single bonds

In addition to radical reactions involving the addition to carbon–carbon multiple bonds, IPFAs exhibit a wide range of reactions with stabilisation of $R_f^{\cdot}$ through cleavage of the single bonds of organic and inorganic molecules and the subsequent formation of products that are more stable under the conditions of radical decomposition than the initial IPFAs. During radical initiation the iodine atom of IPFAs is readily replaced by more electronegative halogens or groups,[190–194] resulting in the formation of more stable polyfluoroalkyl-containing compounds. In this case the primary radical source can be a halogen molecule,[192,193] if the energy of its homolytic dissociation is lower than that of the IPFA.



On the other hand, in the radical reaction of IPFAs with cyanogen, in which it is possible to obtain nitriles of the corresponding perfluoroalkylcarboxylic acids in quantitative yield, the IPFAs act as a radical source.[194] The radical nature of the reaction is confirmed by the presence of a small quantity of product derived from the coupling of polyfluoroalkyl radicals:

$$R_fI + (CN)_2 \xrightarrow[pressure]{350^\circ C} R_fCN + R_f—R_f.$$
trace amounts

On reacting with hydrogen, IPFAs are converted to monohydroperfluoroalkanes.[195] The involvement of hydrocarbon iodoalkanes in radical reactions is also possible. Thus, 1,1,1-trifluoroethane and 1,1-difluoroethylene are formed from iodomethane. The latter is formed as a result of stabilisation of the excited state of 1,1,1-trifluoroethane through elimination of HF.[198,199]

$$CF_3I + CH_3I \xrightarrow{h\nu} CF_3CH_3^* + I_2 \xrightarrow[-HF]{} CF_2{=}CH_2.$$

Stabilisation of an $R_f^{\cdot}$ radical may also be achieved by the removal of a proton from a C–H bond of alcohols,[152] alkanes, cycloalkanes,[200–202] and alkylsilanes.[203]

$$CF_3H \xleftarrow[h\nu;\ 100^\circ C]{(CH_3)_3SiSi(CH_3)_3} CF_3I \xrightarrow[C_3H_8 \text{ or cycloalkane}]{h\nu} CF_3H.$$

Reactions of IPFAs by a radical mechanism depend in many respects on the process conditions and are principally governed by initiation (thermal, photochemical, or using initiators). The addition of IPFAs to multiple bonds and elements of Groups IV–VI as well as reactions with cleavage of X–X bonds (X = CN, Hal) occur most frequently by this mechanism. By varying the methods of generating radicals and the length and branching of the hydrocarbon chain of IPFAs it is possible to influence the reaction route, achieving the formation of given products. A characteristic of all these processes is that other functional groups present in the molecule, such as a nitrile group as well as the perfluoroalkyl-substituted double bond formed from alkynes, are stable towards IPFAs during reaction.

A radical mechanism is in doubt for certain cases of these reactions, since in addition to energetic excitation of the molecules there is the theoretical possibility of electron transfer, and this in turn can alter the process mechanism.[204]

4. Oxidation of iodoperfluoroalkanes

The oxidation of IPFAs is one of the few reactions which, depending on the conditions and nature of the oxidising agent, occurs either on the iodine atom or on the perfluoroalkyl group leading to its degradation.

Oxidation of IPFAs on the iodine atom. This gives perfluoroalkyl compounds of polyvalent iodine and takes place with all of the bonds being preserved in the molecule. Of reactions of this type, prominence should be given to oxidative halogenation. This reaction was first carried out using chlorine trifluoride,[205,206] and then subsequently with fluorine diluted with nitrogen[207] and with xenon difluoride.[208] Depending on the reagent, oxidative fluorination occurs with the formation mainly of perfluoro-alkyliodine tetrafluorides and perfluoroalkyliodine difluorides. A similar reaction may be carried out when other oxidising agents such as chlorine nitrate or perchlorate[210–212] and trifluoroperacetic acid[209] are used. The ratio of the iodine oxidation products depends on the reaction conditions.

R_fI —

- $\xrightarrow[T<0^\circ C]{ClF_3}$ $R_fIF_4 + R_fIF_2$ ($R_f = C_nF_{2n+1}$), trace amounts; $n = 2-22$ [205, 206]; (when $R_f = CF_3$ yield of R_fIF_4 100%)
- $\xrightarrow[-78^\circ C]{F_2/N_2,\ CCl_3F}$ R_fIF_2 ($R_f = CF_3$ [207])
- $\xrightarrow[20^\circ C]{XeF_2}$ R_fIF_2 ($R_f = C_3F_7$ (60%) [208])
- $\xrightarrow[\text{pressure}]{ClONO_2}$ $R_fI(NO_2)_2$ ($R_f = CF_3$ [210])
- $\xrightarrow[-78\text{—}-20^\circ C]{ClONO_2,\ CCl_3F}$ $R_fICl(NO_2)$ + $R_fI(NO_2)_2$ ($R_f = CF_3$ [211])
- $\xrightarrow{ClOClO_3}$ $R_fI(OClO_3)_2$ ($R_f = (CF_3)_2CF$ [212])
- $\xrightarrow[(CF_3CO)_2O,\ CF_3COOH]{80\%\ H_2O_2}$ $R_fI(OCOCF_3)_2$ ($R_f = C_3F_7$ (65%) [209]).

The resulting perfluoroalkyliodine difluorides and tetrafluorides are sensitive to hydrolysis. The stability of the tetrafluorides at 20 °C increases in the series

$$CF_3 < (CF_3)_2CF < C_6F_5 \ [206].$$

Perfluoroalkyliodine dinitrates and diperchlorates are obtained in low yield, probably because of their low stability at room temperature compared to the corresponding polyfluorides. The decomposition of perfluoroalkyliodine dinitrates may evidently occur according to the following scheme:[210,211]

$$10CF_3I(NO_3)_2 \rightarrow 5CF_3I + 5COF_2 + 10N_2O_5 + I_2 + IF_5 + I_2O_5.$$

Starting from perfluoroalkyliodine difluorides and acetates, L M Yagupol'skii, et al.[6,209,213] developed a preparative method for the previously inaccessible arylperfluoroalkyliodonium salts, which are convenient reagents for the preparative perfluoroalkylation of

different nucleophiles, which determines the considerable synthetic value of these compounds.

$$R_fIF_2 + BF_3 \longrightarrow R_f\overset{+}{I}FBF_4^- \xrightarrow{C_6H_5CH_3} CH_3C_6H_4\overset{+}{I}R_fBF_4^-;$$
87% (R_f=C_3F_7)
83% (R_f=C_6F_{13})

$$CH_3C_6H_4\overset{+}{I}R_fX^- + MNu \rightarrow R_fNu \quad [6]$$

M=Na, K; Nu=PhS, PhSe, NO_2, SCN, SeCN.

Oxidation with degradation of the perfluoroalkyl chain. Photochemical oxidation of perfluoroalkanes with oxygen occurs quite rapidly and is accompanied by stepwise degradation and the formation of carbonyl fluoride. When the oxidation is carried out in a quartz vessel, silicon tetrafluoride is also found amongst the reaction products. It is thought that decomposition of the perfluoroalkyl residue occurs via the formation of a perfluoroalkoxy radical. The latter, by eliminating COF_2, forms a new perfluoroalkyl radical which contains one less CF_2 group and which undergoes further oxidation.[22,214]

$$C_3F_7I \xrightarrow{h\nu} C_3F_7^{\cdot} + I^{\cdot} \xrightarrow{O_2} C_3F_7OO^{\cdot} \xrightarrow{C_3F_7I} C_3F_7OOI + C_3F_7^{\cdot} \xrightarrow{O_2} \text{etc.}$$

$$C_3F_7OOI + C_3F_7^{\cdot} \xrightarrow{C_3F_7I} C_3F_7O^{\cdot} + IO^{\cdot} \longrightarrow C_2F_5^{\cdot} + COF_2$$

$$C_2F_5^{\cdot} + COF_2 + I^{\cdot} \longleftarrow C_3F_7OI + C_3F_7^{\cdot}$$

$C_2F_5^{\cdot}$ + O_2 → etc.; $C_2F_5^{\cdot}$ + O_2 → etc.

In the presence of water or mixtures of water and chlorine and bromine, which is better, the radicals formed during oxidation undergo side reactions, giving perfluoroalkylcarboxylic acids. Thus, a mixture of acids is obtained on photochemical oxidation of 1-iodoperfluoropropane with oxygen in the presence of moist bromine.[22]

$$C_3F_7I \xrightarrow[h\nu]{O_2,\ Br_2,\ H_2O} \underset{45\%}{C_2F_5COOH} + \underset{23\%}{CF_3COOH}.$$

On treatment with other oxidising agents, such as oleum, degradation of the carbon skeleton does not usually occur, and polyfluorocarboxylic acid fluoride and a small quantity of perfluoroalkyl fluorosulphate are formed. Both products contain one less CF_2 group compared to the initial IPFAs.[215]

$$R_fCF_2I \xrightarrow[130-200\ ^\circ C,\ 1-20\ h]{\text{oleum}} \underset{88\%}{R_fCOF} + \underset{1.8\%}{R_fCOOH} + \underset{2.7\%}{R_fCF_2OSO_2F}.$$

When iodoperfluoroisopropoxyalkanes were oxidised with oleum, the product derived from the replacement of the fluorine atom of the fluorosulphate group in the by-product fluorosulphate by a second fluorosulphate group was identified together with the normal acid fluoride:[216]

$$(CF_3)_2CFO(CF_2)_6I \xrightarrow[140^\circ C]{SO_3} \begin{cases} \longrightarrow (CF_3)_2CFO(CF_2)_5COF \\ \longrightarrow (CF_3)_2CFO(CF_2)_6OSO_2OSO_2F. \end{cases}$$

The temperature of the process can be reduced by the addition of chlorine and zinc sulphates to oleum.[217] A number of methods for the oxidation of IPFAs to perfluorocarboxylic acid fluorides are currently available. It may be assumed that the process for preparing acid fluorides by oxidation of IPFAs (provided that iodine is returned to the process cycle) can compete successfully with the traditional method for preparing them—electrochemical fluorination in anhydrous hydrogen fluoride. Complex equipment design, high energy consumption, and low yields of acid fluorides because of degradation of the carbon skeleton of the initial molecule are characteristic of the latter.[16]

5. Formation of charge-transfer complexes

The polarisation of the C–I bond in IPFAs, which is the reverse of that in CH_3I, gives rise to their ability to form molecular complexes (1 : 1) with electron-donating solvents in which the iodine acts as the acceptor.[218–225] This is supported experimentally by the shift of absorption bands that are characteristic of IPFAs in the UV spectra[218,219] and by changes of the chemical shifts in the ^{19}F NMR spectra.[219]

$$R_f\overset{\curvearrowleft}{I} + :B \longrightarrow R_fI-B$$

R_f=CF_3, C_2F_5, C_3F_7, $(CF_3)_2CF$, $(CF_3)_3C$;
B:=$C_6H_5NR_2$, C_5H_5N, $(CH_3)_3N$, C_2H_5OH, $(C_2H_5)_2O$.

In the complexes the C–I bond in IPFAs changes its nature and becomes similar to the corresponding bond in hydrocarbon iodoalkanes. The reactivity of the complexes differs slightly from that of IPFAs. Thus, $(CF_3)_2CI$ in a solution of diethyl ether reacts with diethylamine to form the corresponding enamine:[84]

$$-\overset{|}{N}: + I-C(CF_3)_3 \longrightarrow \left[-\overset{|}{N}^{\delta+}\cdots I^{\delta-}\cdots C^{\delta-}(CF_3)_3\right] \longrightarrow$$

$$\longrightarrow -\overset{|}{N}^{+}-I + {}^{-}C(CF_3)_3 \xrightarrow[-F^-]{} CF_2=C(CF_3)_2 + \left[-\overset{|}{N}-I\right]^+F^- \xrightarrow[-HF]{(C_2H_5)_2NH}$$

$$\rightarrow (CF_3)_2C=CFN(C_2H_5)_2.$$

It should be noted that the greatest shifts of the absorption bands occur in the UV spectra of a mixture of 2-iodoperfluoro-2-methylpropane with diethyl ether and ethanol.

6. Reaction between iodoperfluoroalkanes and aluminium halides

Iodotrifluoromethane readily reacts with aluminium halides, forming a mixture of substitution products.[226] Eapen, et al.[227] found that its higher homologues and iodoperfluoroalkoxyalkanes also undergo such a reaction in the presence of a 1.5- to 3-fold excess of $AlCl_3$ or $AlBr_3$.

$$R_fCF_2I \xrightarrow[75-120\ ^\circ C,\ 24-74\ h]{AlX_3} \underset{55-56\%}{R_fCX_3}$$

R_f=C_3F_7, C_8F_{17}, $C_{10}F_{21}$; X=Cl, Br.

It follows from the experimental results that the formation of trichloro derivatives occurs via the intermediate formation of R_fCCl_2I. The latter can be isolated at a lower temperature with a

yield of about 15%. In our opinion, cleavage of the stronger C–F bond occurs in this case because the formation of AlF_3 is thermodynamically more favourable compared to AlX_3 (X = Cl, Br). The reaction with branched iodoperfluoroalkoxyalkanes is complicated by dechlorofluorination and more extensive substitution of fluorine atoms, probably because of the close proximity of the electron-donating oxygen atom.

$$(CF_3)_2CFOCF_2CF_2I \xrightarrow[60\ h]{AlCl_3,\ 100-105\ ^\circ C} \begin{cases} \longrightarrow (CF_3)_2CFOCF_2CCl_3 \quad 26\% \\ \longrightarrow (CF_3)_2CFOCF{=}CCl_2 \quad 19\% \\ \longrightarrow (CF_3)_2CFOCCl{=}CCl_2 \quad 19\% \\ \longrightarrow (CF_3)_2CFOCCl_2CCl_3\ . \quad 2\% \end{cases}$$

IV. Use of iodoperfluoroalkanes and perfluorinated iodine-containing ethers

Iodoperfluoroalkanes and perfluorinated iodine-containing ethers have found extensive use in chemical technology and in different areas of science and engineering—in laser technology, etching of dielectrics, separation of carbon isotopes, and as intermediates in the synthesis of surfactants, textile-auxiliary materials, and biologically active compounds.

1. Use of IPFAs in chemical technology and engineering

In 1971 the use of iodopentafluoroethane on a support was proposed as a source of radicals for the initiation of polymerisation processes.[228,229] Highly fluorinated oils were subsequently obtained by polymerisation of tetrafluoroethylene[230] and other perfluoroalkenes[231] in the presence of C_2F_5I. It should be noted that IPFAs can be used in polymerisation processes not only for initiation but also for modification of the polymers obtained.[323]

Long-chain branched IPFAs with the general formula $(CF_3)_2CF(CF_2CF_2)_nI$ (n = 6–16) are used as components of self-lubricating compositions (at a level of 5–30%).[233,234]

Starting in 1979 there has been an increase in the number of publications on the use of IPFAs in photodissociation iodine lasers (FIL). Laser generation from the transition of an excited iodine atom (obtained by pulsed photolysis of CF_3I) to an unexcited state was first achieved in 1964.[8]

For the last 20 years the processes that occur during pulsed photolysis of CF_3I and after it and the parameters of a CF_3I laser have been thoroughly investigated. In order to improve the energetic characteristics of a FIL and to simplify its use, including the ability to use an active medium repeatedly, the use of homologues of iodotrifluoromethane—n-C_3F_7I, n-$C_5F_{11}I$, n-$C_6F_{13}I$ and their isomers and also $C_2F_5CFICF_3$ and $(CF_3)_3CI$—has been proposed.[9–11,235–238] Amongst these compounds there is considerable interest in 2-iodoperfluoro-2-methylpropane because, in contrast to other IPFAs, the $(CF_3)_3C^{\cdot}$ radical formed during its photochemical decomposition mainly gives the initial compound on account of its structural characteristics and high stability in recombination processes, thus preventing the formation of molecular iodine and making it theoretically possible to produce a frequency FIL.[11]

The use of IPFAs in laser technology is not restricted solely to FILs. The use of a mixture of CF_3I with hydrogen-containing components such as iodomethane, hydrogen bromide, and fluorine and hydrogen has been proposed for obtaining an HF-laser emission.[13–15,198] Studies have been conducted on the production of a laser based on molecular iodine by excitation of a mixture of CF_3I and argon with an electron beam.[239]

The coincidence of the absorption spectrum of iodotrifluoromethane containing a small quantity of $^{13}CF_3I$ with the wavelength of a CO_2 laser forms the basis of the use of iodotrifluoromethane in the separation of carbon isotopes by multiphoton dissociation of CF_3I at –80 °C in the field of a CO_2 laser.[17] The efficiency of this method is very high (enrichment coefficient 600); in future it is likely to evolve as the principal method for ^{13}C isotope enrichment.

2. Surfactants based on iodoperfluoroalkanes

At the beginning of the 1960s Brace[156,159] and then Litt and Blöchl[93,240] established that starting from 1-iodo-1,1,2,2-tetrahydroperfluoroalkanes or iodoperfluoroalkoxyalkanes it is possible to obtain compounds that can produce a marked change in the surface tension of solutions and which are considerably superior to known surfactants. Research in this field has been considerably extended.[168,178,195,241–250] Current methods for the synthesis of surfactants based on IPFAs are exhibited in the scheme given in a monograph.[16] This scheme can be supplemented by the following:

$$C_3F_7I \begin{cases} \longrightarrow C_3F_7CH_2CHI(CH_2)_nOCH_2OCOCH_3 \longrightarrow C_3F_7CH_2CHI(CH_2)_nOCH_2OH \\ \qquad\qquad\qquad\

1-iodoperfluoroheptane.[147,252,253] 1-Iodoperfluorooctane is used in the synthesis of antisoiling agents for fabrics.[149–152,156] A more extensive group of iodoperfluoroalkanes R_fI (R_f = C_4-C_{16} perfluoroalkyl) is used in the synthesis of ammonium polyhydroxyalkylselenates and their derivatives, which impart oil and water resistance to textile fibres.[150] Members of the homolytic series of IPFAs with the number of C atoms $\leqslant 4$ are used less frequently for this purpose.[133,135,254–256]

Iodoperfluoroalkoxyalkanes are the starting materials for the preparation[162,163,257] of esters that are used in the synthesis of the corresponding acids and their complexes with chromium hypochlorite. The latter are efficient oil-repellent agents.

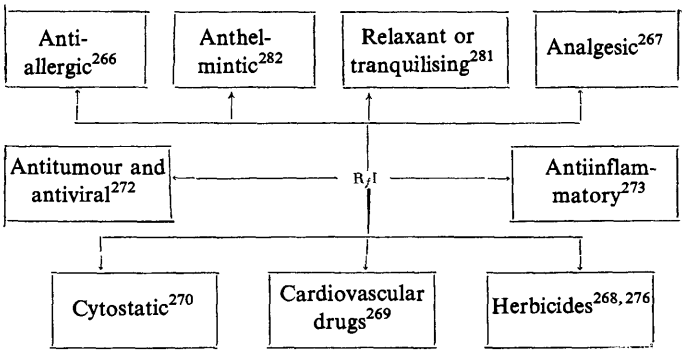
IPFAs and iodoperfluoroalkoxyalkanes have been used to synthesise novel monomers and polymers,[134,153,154,258,259] such as fluorine-containing polyurethanes,[153,260] with dust- and soil-resistant properties. The monomers obtained using IPFAs with the number of carbon atoms ranging from 1 to 10 have proved promising for the synthesis of novel polymer materials having the properties of rubbers,[261] vulcanised rubber,[262] and other vulcanised materials,[263] as well as vulcanising agents.[139]

By using 1-iodoperfluoropropane in the synthesis of fluorine-containing benzoxazoles, the authors of one patent[264] discovered novel anticorrosive lubricant additives.

4. Biologically active compounds

The use of IPFAs in the synthesis of biologically active compounds has assumed a prominent position. Reaction of CF_3I and certain of its homologues with organic substrates gives cyclic, aromatic, and heterocyclic perfluoroalkylated compounds that have diverse forms of biological activity (Scheme 1).[265–282] Iodotrifluoromethane is used most frequently in the syntheses of biologically active compounds because the compounds prepared from it have the greatest activity and also because of the high stability of CF_3I. As a consequence of the latter, the trifluoromethylation reactions, which are usually carried out at a temperature not lower than 110 °C, are not accompanied by side reactions due to the degradation of the perfluoroalkyl substituent. This is a considerable advantage in the synthesis of pharmacological compounds.

Scheme 1. Spectrum of biological effect of perfluoroalkyl-containing compounds obtained by perfluoroalkylation of aromatic and heteroaromatic substrates.



Research into novel alkylating agents for the preparation of biologically active fluorine-containing compounds has recently been undertaken. Halodifluoroacetic acids and their derivatives have been used in particular for this purpose. Thus, Delyagina, et al.[283] pointed out their ability to undergo nucleophilic substitution, while in subsequent syntheses with methyl iododifluoroacetate it was shown that they are characterised by addition and substitution reactions that are normal for IPFAs, including the alkylation of aromatic and heterocyclic compounds.[284] As a result of these studies it was possible to introduce the CH_3OOCCF_2 group into complex organic molecules, considerably extending the synthetic possibilities of the resulting compounds.

5. Other areas of application

In addition to the traditional areas of application, IPFAs and iodoperfluoroalkoxyalkanes are used as intermediates in the synthesis of various materials with useful properties,[16] including the production of dyes.[262] Iodoperfluoroalkanes are used as sources of fluorine for etching glass surfaces in order to improve their stability towards water and aqueous solutions.[18] An assessment of the possibility of using CF_3I in radiation dosimetry has been carried out.[19] In certain cases IPFAs are convenient solvents in IR spectroscopy.[285]

V. Conclusion

The presence of the highly fluorinated R_f residue in IPFAs gives rise to a basic difference between them and their hydrocarbon analogues, involving a withdrawal of electron density for the C–I bond. This almost completely deprives the molecule of the ability to participate in nucleophilic substitution reactions. Radical and radical-ion reactions are typical. Nevertheless, IPFAs, like their nonfluorinated analogues, are convenient alkylating agents, and by using simple methods they enable fluorine-containing substituents to be introduced into complex organic molecules without causing them to degrade, thus establishing their main use in organic synthesis.

The independent practical value of IPFAs results from their use in areas of modern technology such as mechanical engineering, laser technology, isotope separation, etc.

IPFAs (in particular CF_3I and n-C_3F_7I) have disadvantages in terms of their practical application because of their relatively high costs, since at the present time no technologies for synthesising them have been developed that can compete with the Borodin–Hunsdiecker method. Therefore, the development of alternative and oxygen-containing iodoperfluoroalkanes based on available products is a useful and promising trend.

We do not claim that the bibliography presented in this review is comprehensive in its coverage. However, the main directions of research into the preparative methods as well as the reactivity of iodoperfluoroalkanes are fully reflected in it. We hope that the contents of this review will be useful not only to researchers working in the field of the organic chemistry of fluorine but also to a wider circle of synthetic chemists.

Organic dyes for constant memory optical discs

T N Gerasimova, V V Shelkovnikov
Institute of Organic Chemistry, Siberian Branch of the Russian Academy of Sciences, Novosibirsk

ABSTRACT. **Literature data on the use of organic dyes in constant memory optical discs and information recording by semiconductor laser irradiation in the 780–830 nm range are summarised and systematised. Questions on the suitability of the properties of different classes or organic dyes for the main requirements of optical information-recording media have been considered. Future trends in the development of the field of organic dyes for the laser recording of discrete information have been defined.**

Bibliography includes 232 references.

IV. Conclusion 63

I. Introduction

Optical information disc drives have a number of advantages over magnetic discs (higher recording density, possible contact-free reading, storage life of recorded information, etc.) and have been increasingly used abroad over recent years. They are mainly used in the external memories (EM) of computers. The recording of information on an optical disc is achieved by a focused laser beam, which deposits a particular trace on the surface of an active layer. The recorded information can be read by the same laser at lower power by measuring changes in the characteristics of the reflected beam.[1–5]

Memory recordings may be assigned to one of three categories with respect to the type of the recording/reading regime and the properties of the support: 1) permanent external memory devices with single recording and multiple reading (DRAW or WORM) and reversing facilities. The present review is concerned with the use of organic dyes with the DRAW type of optical discs.

The optical disc consists of a profiled support on to which an active layer <1 μm in thickness is deposited. The reaction of the laser beam on the light-sensitive layer may involve different mechanisms. The ablation process has been most extensively used. In this process the energy of the laser pulses with a duration of $\leqslant 1$ μsec is converted into heat energy causing an increase in temperature of up to 1000 °C or more at the point of exposure, leading to melting of the film, and the material is therefore unsuitable since it vapourises or decomposes. As a result of this process pits $\lesssim 1$ μm in diameter are formed. The information is read by a laser beam of energy less than the threshold value by measuring the difference in the reflectivity from the pit and the background surface. A quantitative characteristic of the recording is the signal/noise ratio at the point of recording (CNR, carrier-noise ratio).[6–9]

The recording LWR-(laser write and read) medium of the optical disc may have a mono-, bi- or tri-layer structure. A metal monolayer transferred on to the support by vacuum evaporation as a thin (ca. 30 nm) film is the most extensively used structure. The recording leads to a decrease in the reflection from the surface of the pits relative to the background. In the bi-layer (antireflex) structure the metal film is covered by a layer of organic dye $\leqslant 100$ nm in thickness. This leads to a decrease in the reflection from the surface of the recording layer of up to ca. 5% and to an increase in its sensitivity. In the pits obtained by ablation the reflectivity increases by up to ca. 90%. In the tri-layer structure the absorbing layer is separated from the metallic mirror by a transparent dielectric which leads to an increase in the efficiency with which the laser beam energy is utilised, i.e. to a further increase in the sensitivity of the material.[8,10] An increase in the number of layers of accurately controlled thickness naturally creates complications in the preparation and also leads to an increase in the price of the optical disc. The recording medium is a key component of the optical disc and should provide higher sensitivity to laser irradiation (ca. 10^{-2} J cm^{-2}), high recording resolution ($\geqslant 1000$ lin mm^{-1}), adequate recording contrast (CNR > 50 dB) a real time recording with immediate reading, and also an adequate storage period for the recording ($\geqslant 10$ years).[8–12]

Gas lasers were used in the initial stage of development of the optical discs of computer memories. Since the beginning of the eighties solid body diode lasers were most widespread and had a number of advantages such as low cost, small dimensions, long storage period, in-use stability, and the possibility of rapid change-over. Present-day optical memory systems are based on the use of GaAlAs semiconductor lasers with emission in the 780–850 nm range.[13–15]

II. Optical disc recording layers based on organic compounds

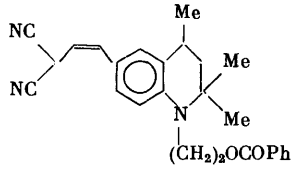
Systematic screening of metals and chalcogenides to identify optimal materials for photothermal recording showed that tellurium and its alloys possess the best characteristics,[5] although it is difficult to produce optical discs based on these materials, since tellurium readily undergoes oxidative degradation in a moist atmosphere.[14] This finding created interest in LWR-media based on organic dyes, since on account of their high stability and low toxicity they are more marketable than Te-containing layers.[11]

Carlson was first to propose the use of organic materials for laser recording in 1969.[16] Recording with a helium-neon laser beam on to a film containing a triarylmethane dye in nitrocellulose was achieved at the expense of the decolourisation of the dye. Two new

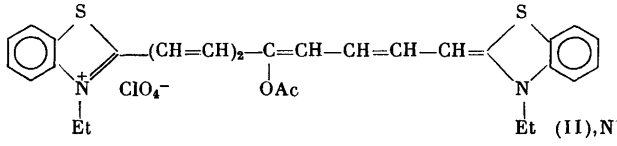
laser recording processes in an organic dye were subsequently proposed. In the first process a bi-layer structure of a polymeric dye was used. In the presence of argon-laser irradiation the dye diffused into the polymeric substrate, thereby causing a change in the spectral characteristics of the layer. 1,4-Diaminoanthraquinone and a series of polymethine dyes (PMD) on a polyethyleneterephthalate film 50 μm in thickness were used as the recording system.[17]

The second process which later became extensively used involved recording with a laser beam through ablation on a film of an organic dye deposited by vacuum evaporation on to a reflecting surface (an aluminium layer 30 nm in thickness on a glass support).[18] With a layer of fluorescein 58 nm in thickness 90% of the incident light was absorbed. The recorded information was ready by means of the difference in the reflectivities from the surface of the pits formed during the recording from the dye layer. This material was superior to the mono-layer structures based on metals in regard to sensitivity and contrasting.[18]

A defect in this system is the possibility of crystallisation of the dye in the sprayed state leading to a decrease in the CNR value.[18] Law et al. were able to surmount this process,[19] by proposing that the dye dissolved in a polymeric matrix should be used as the absorbing layer. A polyvinylacetate film 59 nm in thickness and containing 20% (by mass) of dye (I) when transferred on to a reflecting layer of aluminium provided a higher degree of sensitivity and contrast during recording with a helium-cadmium laser than layers based on tellurium. Similar bi-layer structures based on organic dyes sensitive in the visible range of the spectrum were later described in several reports.[20,21]



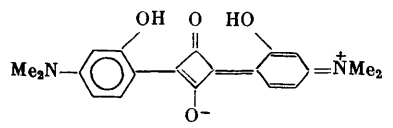
The first report on a DIP-system (dye in polymer) sensitive to irradiation in the near-infrared region of the spectrum appeared in 1981.[13] A film 105 nm in thickness containing 20% PMD (II) in polyvinylacetate transferred on to an aluminiumised glass support exhibited 3.5-fold higher sensitivity than a 15 nm tellurium monolayer during recording with a laser beam with λ_{gen} = 835 nm.



(II), NK-1748

The absorption spectra of dye (II) in the film and in methanol are presented in Fig. 1.

In the same year publications appeared on the use of vanadylphthalocyanine[22] and squarylium dye (III) [23] absorbing in the near-infrared region for laser recording.



In order to use the organic dye as a reflecting type of recording medium in a mono-layer structure, it was essential that the film formulated from the dye had adequately high reflectivity. Data confirming that this was the case were obtained for the first time in 1983.[24] It was shown that a film of a naphthaquinone dye 50 nm in thickness transferred by vacuum deposition on to a polymethylmethacrylate (PMMA) support and absorbing more than 40% of the incident light at a reflectivity of >20% provides adequate sensitivity towards irradiation of the diode laser and good recording characteristics (CNR > 50 dB at a pulse power of ≤5.5 mW).

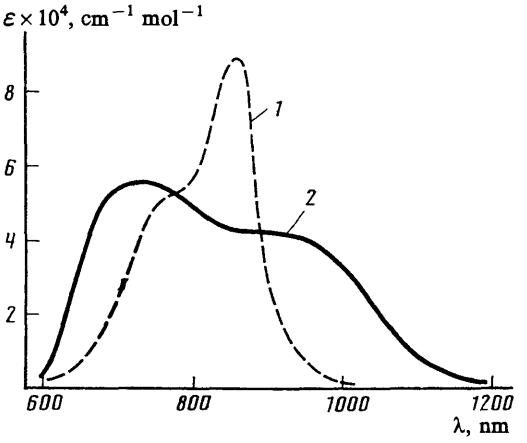


Figure 1. Absorption spectra of dye (II) in methanol (*1*) and in a poly(vinyl acetate) (*2*).

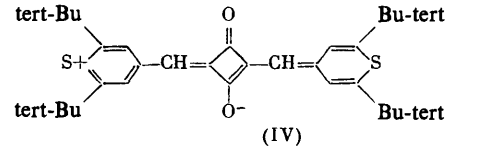
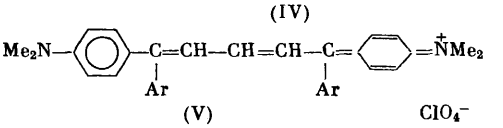
Even higher CNR values were found by certain authors with mono-layer structures obtained by spin-coating of solutions of dyes (IV) and (V) on to profiled PMMA and glass discs.



(IV)



(V) ClO_4^-

As already mentioned above the formation of pits in the LMR type of recording media is largely a photothermal process in which incident light energy is converted into heat more efficiently the more effective is the light absorption and the subsequent oscillatory relaxation of the dye molecules. By studying the mechanism of this process in the DIP-layers as described in earlier reports,[6,23,26,27] and by comparison with layers based on tellurium and other metals, it was possible to determine the optimal characteristics of the recording media and the recordings on them. The laser beam power was 5–10 mW when the diameter of the latter was 1 μm, the threshold energy of the recording was 0.1–0.2 nJ/bit, the energy essential for

the total opening of the pit and to obtain a satisfactory CNR (50–60 dB) was 0.5–1.0 nJ/bit, the optimal thickness of the layer was 60–120 nm, and the recording time was 50–100 nsec. In order to attain these values, the recording material should possess a high extinction coefficient (ca. 10^5 M^{-1} cm^{-1}) at the recording wavelength, low thermal conductivity (5×10^4 cal sec^{-1} deg^{-1}) and thermal capacity, and also a sufficiently low melting point and vaporisation temperature (100–250 °C).

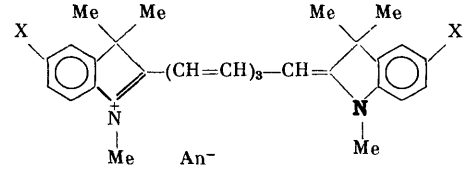
Chemical and photochemical stability under the disc storage conditions and also resistance to the action of the reading beam are important properties determining the suitability of organic dyes as active media in optical memory discs.[15] Testing of the recording layers involves maintenance at an elevated temperature (35–70 °C) in a moist atmosphere (90–95% relative humidity), illumination with visible light at ⩾50000 lux, and continuous reading over a prolonged period.

The characteristics of the DIP-layer are dependent not only on the absorbing dye but also on the properties of the polymer. Determination of the threshold energy of the recording on DIP-layers of dye (I) with different polymers (polyvinylacetate, polyvinylbutyral, PMMA, polycarbonate, etc.) showed that the viscosity and vitrification temperature of the latter do not affect the sensitivity of the recording material.[28] Nevertheless the pit size and hence the quality of the recording is dependent on the viscosity, due to the arisal of a reverse inflow of the pit after the recording.[7] A series of review articles have already been published in which the main criteria determining the selection of components (dyes and polymers) for such materials, their ratios, and the optimal physical and chemical properties of the polymer supports have been formulated.[9,11,15] These questions have been discussed in detail in the review by Pearson.[29] The further advancement in organic recording media for optical memories based on semiconductor lasers is mainly associated with the intensive development of studies of the synthesis of thermally and photochemically stable organic dyes exhibiting intense absorption in the near-infrared spectral range and the testing of these compounds in recording systems. The present state of the art and the potential for advancements in the field of infrared dyes for optical discs are described below.

III. Dyes for optical discs with absorbance in the near-infrared region of the spectrum

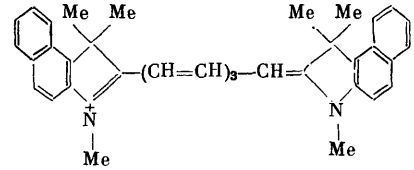
1. Polymethine dyes

Polymethine dyes have been most extensively used in laser recording, since the PMD films possess sufficiently high reflectivity (up to 40%) which provides a high degree of recording contrast.[11,14] Symmetrical polymethine dyes containing indolenine, quinoline, benzthiazole, benzoxazole residues etc. as terminal groups are most often used. Absorption in the region of semiconductor laser generation is achieved in the presence of a chain of seven or more methine groups† in the dye molecule, and therefore 1,1'3,3,3',3-hexamethylindotricarbocyaniniodide [dye NK-125 (VI),[38–41] its perchlorate,[42–44] the 4- and 5-chlorosubstituted dyes (VI) [45,46] including dye NK-2882 (VII),[47–49] 1,1,3,3,3',3-hexamethyl-4,4',5,5'-dibenzo-2,2'-indotricarbocyaninperchlorate (dye NK-2014, VIII)],[38,50–59] and 3,3'-dimethylthiatricarbocyaniniodide[60–63] are most often described in the patent literature as dyes for optical discs.



(VI), NK-125 : X = H, An = I^-

(VII), NK-2883 : X = Cl, An = ClO_4^-



(VIII), NK-2024, $\lambda_{max\ abs}$ = 782 nm

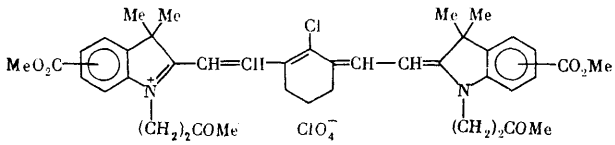
Heterocyclic nitrogen atoms in molecules of such dyes may in addition to the methyl group contain alkyl or substituted alkyl groups (Et, Pr, Bu, C_2H_4OH, etc.),[30–35,37,53,64,65] whereas the aromatic rings contain electron acceptor or electron donor substituents.[31–36] These spectra contain intense absorption bands in the 740–780 nm range. At a given polymethine chain length the benz[c,d]indole derivatives are the most deeply coloured.[66]

The polymethine colour may be deepened by increase in the length of the outer polymethine chain of the dye. In the symmetrical polycyanines an increase in length by one vinylene group leads to the displacement of the absorption maximum by 90–100 nm to longer wavelengths.[67] Thus the first dye in the polymethine series used to record information with the semiconductor laser was tetracarbocyanine(II).[13] However it is known that an increase in the number of vinyl groups to 4 or more leads to a sharp fall in the extinction and to the leveling of the absorption curve as a result of *trans-cis*-isomerisation in the polymethine chain.[68] In this case the thermal and photochemical stability of the dye also falls significantly.[69]

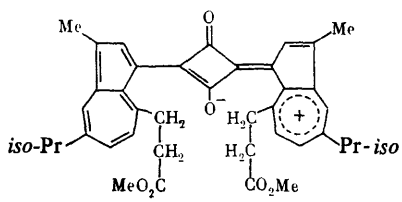
One approach by means of which a bathochromic effect may be obtained and at the same time the stability of the polymethine dye molecule is increased involves the cyclisation of part of the chromophore by bridging groups which rigidly fix the separate units of the polymethine chain.[69] There are a number of patents describing the use in optical discs of indo- and thiatri(penta)carbocyanines containing a di- or trimethylene bridge in the outer polymethine chain.[70–80] Thus a film of dye (IX) 75 nm in thickness transferred by spin-coating on to a glass support has a reflectivity of 37% and provides adequate sensitivity to semiconductor laser irradiation at 830 nm and high CNP values. The recording was stable when maintained at 50 °C in a moist atmosphere (after 150 h the CNP value decreases by 3% or more) and was stable to illumination with a 500 W daylight lamp (after 100 h the decrease in

† The use of dicarbocyanines with a maximum absorption up to 700 nm for recording with the semiconductor laser has been described.[30–37]

CNP was ⩽4% or less).[72] Hydrated aromatic or heteroaromatic rings may serve as the bridge.[11,81,82]



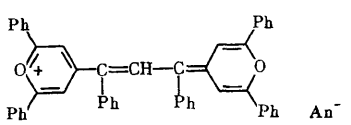
Polymethine dyes containing a squaric acid or a croconic acid fragment between the heterocyclic residues is widely used in laser recording materials.[12,14,26,83–85] Synthetic routes for squarylium dyes with absorbance in the near-infrared range of the spectrum have been described.[86] Their absorption maxima are displaced relative to the spectra of the corresponding symmetrical polymethine dyes with linear polymethine chains by 20–60 nm to longer wavelengths. The largest number of patents describe the type (X) squarylium dyes containing azulene rings[87–89] or their aza-analogues[90] as terminal groups. Active layers based on



(X), $\lambda_{max\ abs}$ = 773 nm

diazulyltri- and diazulylpentamethincyanines, which contain identically or differently substituted azulene rings, have been described.[91,92] Their absorption spectra are similar to those of polymethine dye derivatives of indolysine[93] which are also used in optical discs.[94] Replacement of hydrogen atoms in the azulene rings by alkyl groups leads to a bathochromic shift of the longwave band in the electronic spectrum and to an increase in the solubility in organic media.[89,92]

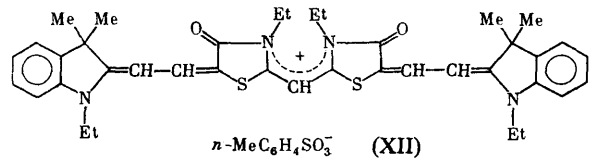
Intense absorption in the near-infrared region of the spectrum when the polymethine chain length is comparatively short may be achieved by replacement of the nitrogenous heterocycles in the polymethine dye molecules by pyrylium or thio- or selenopyrylium residues. Pyrylo- and thiopyrylocyanines containing three or five methine groups exhibit intense absorption in the 680–880 nm range and are suitable for recording information with the laser.[60,95–98] A film of dye (XI) 100 nm in thickness showed high sensitivity and good recording quality at 790 nm (stability to visible light at 54 000 lux for 50 h).[95]



(XI)

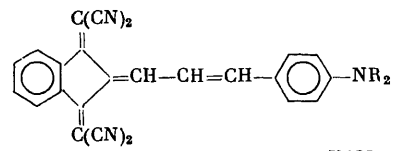
Good results have been obtained with type (IV) squarylium dyes containing pyrylium or thiopyrylium rings.[11,14,26,99] The presence of tert-butyl groups in the dye molecule increases it solubility in organic media and facilitates the formation of active layers by the spin-coating technique.[26]

There are relatively little data on the use of hemi- and mercocyanines for optical recording. Derivatives of indolenine, oxoindolysine, and pyrylium salts and their heteroanalogues,[12,100–107] assymmetrical polymethine dyes containing the azulene ring,[108–110] and also three- and four-nuclear polymethine dyes containing branched or linear chromosphores have been described.[11,112] Thus recording



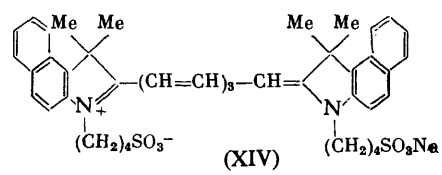
at 790 nm on a film of dye (XII) deposited on to a PMMA support by spin-coating gave a highly contrasted image stable to visible light.[111]

The identification of recording media for optical discs among the deeply coloured neutral polymethine dyes type (XIII), the dicyanomethyleneindan residue or its sulphur analogue serving as the acceptor group would appear to be a promising approach.[12,113,114]



(XIII)

Essentially the only method for the formation of thin polymethine dye films on formatted substrates of the optical discs is the spin-coating of their solutions in organic solvents,‡ dichloroethane and methyl ethyl ketone being most often used. Aqueous or aqueous-alcoholic solutions are used only for type (XIV) dyes, the latter molecules

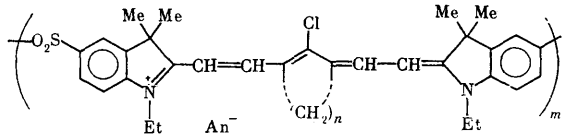


containing alkylsulphonate groups in positions 1 and 1′.[75,115]

The low solubility of polymethine dye salts in organic solvents and their tendency to crystallise are factors which hinder the production of homogeneous amorphous films which are stable and which have a suitable absorption coefficient in the semiconductor laser generation range. The most widely used method providing a means of surmounting this obstacle involves the creation of DIP-films. Nitrocellulose is most frequently used for this purpose,[55,57–59,97,102,104,106] and there are references in the literature on the use of polyvinylbutyral, PMMA and a number of other polymers and copolymers.[39,40,51,56,76,83,88] The preparation of

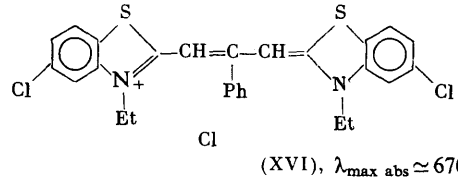
‡ Vacuum deposition may be used only for the squarylium type of polymethine dyes.[12,84]

recording layers based on type (XV) polymeric dyes has been described.[116,117] A positive effect is apparently achieved on deposition of a layer containing a mixture of two dyes.[44,118,119]

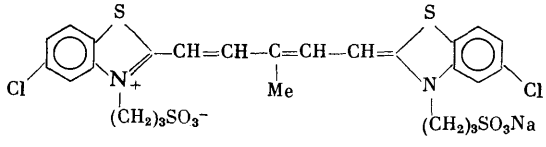


(XV) n=2, 3

Langmuir–Blodgett technology is a novel and extremely promising means of deposition of recording layers on to the reflecting supports.[120] Layers based on *J*-aggregates§ of dyes (XVI) and (XVII) exhibiting absorption in different spectral regions and obtained by this method have been described.[121]



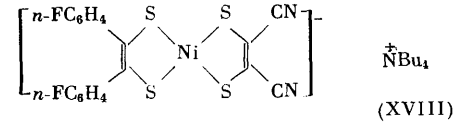
(XVI), $\lambda_{max\ abs} \simeq 670$ nm



(XVII), $\lambda_{max\ abs} \simeq 800$ nm

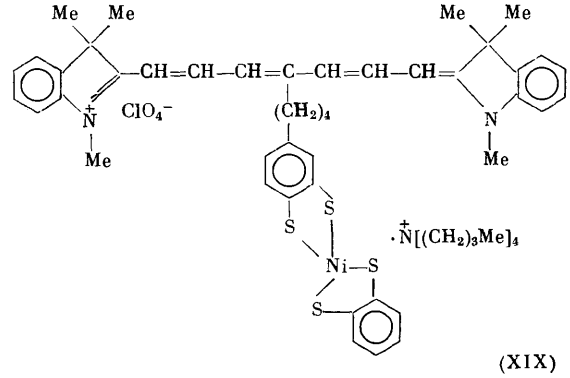
The structure of the layer containing these dyes in the Langmuir–Blodgett films and the change in its spectral characteristics by the action of a diode laser at 780 nm and xenon flash-lamps are presented in Fig. 2. The authors propose that an eight-fold spectral thickening of information is possible in the 400–800 nm range when the layer thickness of each dye is 10 monolayers, and at a total LWR-layer thickness of 250 nm and a *J*-aggregate absorption band width in the order of 50 nm.

Poor light stability is known to be a feature of polymethine dyes. There is relatively little information on the mechanism of discoloration of these dyes, although it has been proposed that an oxidative mechanism is responsible for this process.[122] In this regard recording layers based on polymethine dyes usually include singlet oxygen at a level equivalent to 10–50% of the mass of the dye. Derivatives of aliphatic and aromatic amines,[52,63,85,123] nickel acetylacetonate,[76] or titanium acetylacetonate[65] and also other transition metal complexes are used as stabilisers. Aliphatic or aromatic azomethines,[58,59,124] and derivatives of *o*-phenylenediamine, *o*-oxy- or *o*-aminothiophenol etc.,[49,55,547] may serve as organic ligands in these layers. The most widely used compounds are dithiobenzyl nickel and its substituted analogues,[61] and dithienes (dithiolates) of nickel and other transition metals.[41,42,48,53,54,98,100,125–127] Anionic salts of nickel dithienes possessing high sensitivity to atmospheric oxygen are particularly effective stabilisers.[128] There are patent data indicating that the introduction of 15% quencher (XVIII) into a recording layer based on polymethine dyes reduced the extent of its degradation by 75–80% on exposure to visible light.[125,126]



(XVIII)

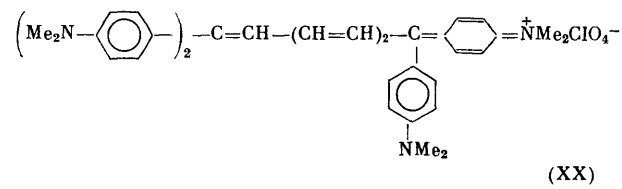
The light stability of the active layer and the repeated information reading may be significantly increased, when nickel salts of polycyanines containing alkylsulphonate or alkylcarboxylate groups at the heterocyclic nitrogen atoms are used in the LWR-layers,[129–131] and also when polymethine dyes containing nickel dithiolate fragments in the molecules are used.[132] Thus degradation of dye (XIX) in the presence of light is five-fold lower and stability to reading is ten-fold higher than those in the case of dye (VI).[132]



(XIX)

2. Dyes in the di(tri)arylmethane and triarylamine series

Triphenylmethane dyes with intense absorption in the visible range were some of the first dyes to be tested in recording layers of optical discs.[16,18] Examples of their use in computer external memories based on semiconductor lasers later appeared.[12,139] Absorption in the infrared range is achieved by introduction of chains of two or more vinylene groups into their molecules,[133–139] and in a number of cases by incorporation into the rings.[12,139] A similar effect is obtained, when the benzene rings are replaced by heteroaromatic residues,[140] and also when a squaric acid residue is introduced into the chain.[141] Type (XX) arylmethane dyes containing dialkylamino groups in *para*-positions of the aromatic rings have been most extensively used.[133–138,141]

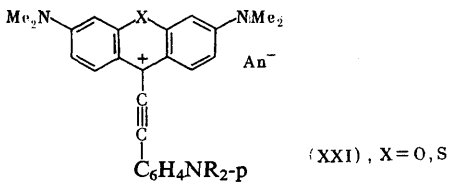


(XX)

It has been shown that the binding of two phenyl rings in the triphenylmethane dye molecule by means of a heteroatom containing unshared electron pairs leads to a deepening of the colour.[122,142]

§ *J*-Aggregation, aggregation of the dye molecules leading to the displacement of absorption to longer wavelengths.

The opposite effect was obtained by Japanese chemists on introduction of an acetylene group between the central carbon atom and the *p*-dialkylaminophenyl residue in the type (XXI) dye molecule.[143] Films of such dyes in polymer supports show adequate stability and are appropriate for laser recording.[144,145]



(XXI), X = O, S

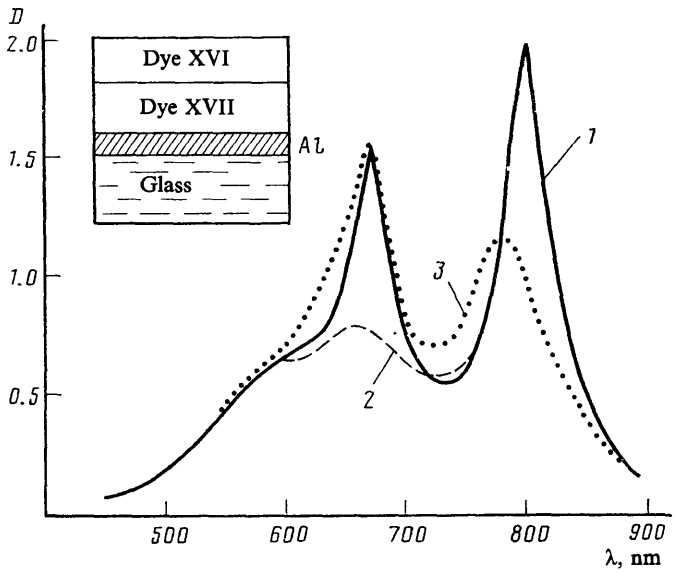


Figure 2. Absorption spectra of a Langmuir–Blodgett film containing layers of dyes (XVI) and (XVII) before irradiation (*1*), after irradiation with a xenon flash-lamp (*2*) and after irradiation with a diode laser at 780 nm (*3*).

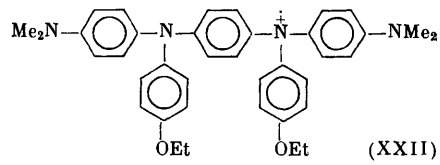
Cationic arylmethane dyes have been tested in both mono-layer and bi-layer structures of LWR-materials. They may be deposited on to profiled supports by spin-coating of solutions in dichloroethane, methyl ethyl ketone, dimethylformamide, or some other organic solvent. Polymer additives (PMMA, nitrocellulose) or crown-ethers are used to form the film.[133,134] By using these additives a wider range of solvents will be suitable for this purpose.[138] Although the triarylmethane dyes share the common property of reduced light fastness,[122] there are patent data which describe the creation of films based on type (XX) dyes which have adequate resistance to the action of visible light[135] and to prolonged heating in a moist atmosphere.[139] The light fastness may be improved by introduction of nickel dithiolates into the recording layer.[137]

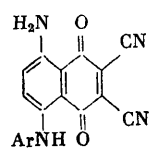
Triarylaminylic salts (the electronic spectra of which contain broad absorption bands in the near-infrared range) have also been proposed as dyes for optical discs.[142,146,147] Despite the cation-radical nature of these compounds and their thermal instability in solution there are patents describing the preparation of dye (XXII) in a film for the laser recording of a contrasted image stable to prolonged irradiation from a daylight lamp.[147] However, this type of dye is most often used in a mixture with a polymethine dye as a singlet oxygen quencher.[37,54,80]



(XXII)

3. Quinone and quinonimine derivatives

Calculation of the electronic absorption spectra of aminosubstituted naphtho- and anthraquinones shows that the longwave absorption band results from the $\pi-\pi^*$-transition involving the transfer of electron density from the benzene to the quinoid ring.[142,148] Consequently this band may be displaced to the near-infrared region as a result of the introduction of donor groups into positions 5 and 8 or acceptor substituents into positions 2 and 3 of the 1,4-naphthoquinone molecule. In accordance with this observation in 1983 it was shown that 2,3-dicyano-5-arylamino-8-amino-1,4-naphthoquinone (XXII) derivatives absorb in the 760–800 nm range and may be used in optical discs as the reflecting type of recording medium in the monolayer structure.[24,149,150] The synthesis of type (XXIII) dyes has been described in detail.[151]

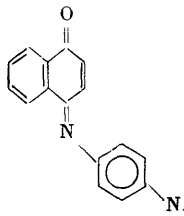


(XXIII)

In later years many patents have appeared on the use in laser recording of type (XXIII) dyes with different substituents (Alk, Hal, OR, NHR, NHAr, etc.) in the aryl residue.[12,14,152–162] The structure of the dye has a specific effect on the absorption range, and on the sensitivity and stability of the active layer. The best results were obtained with *p*-alkoxy-substituted compounds.[14,157,158,160] Other authors have shown that introduction of the methoxy group into the *para*-position of the N-aryl residue increases the stability of the recording from several months to ca. 10 years.[158]

The neutrality of the naphthoquinone dyes confers good solubility in organic media and high stability. Films of such dyes may therefore be formed on the supports by spin-coating and vacuum deposition.[151–162] At a thickness of 60–200 nm they have adequately high reflectivity ($\gtrsim$30%) and it is therefore possible to use them in monolayer structures without a metallic reflecting layer. Recording by GaAlAs-laser irradiation at 830 nm and an impulse strength of 4–10 mW provides a CNR value of more than 50 dB.[152,153,162]

In recent years the search for new naphthoquinone dyes for optical discs has advanced in several directions. One of these directions involves the use of the 1,4-naphthoquinone-4-imine (XXIV) structure containing the *para*-dialkylaminophenyl group in the nitrogen atom.[163]



(XXIV), $\lambda_{max\ abs} \simeq 580$ nm

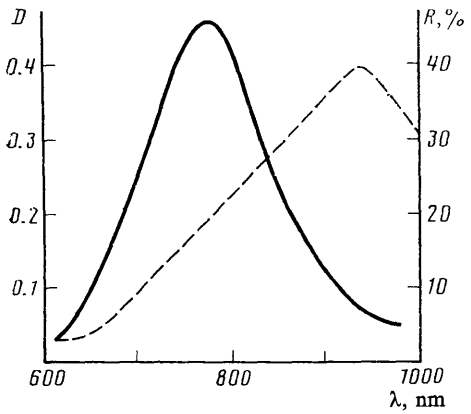


Figure 3. Absorption spectra and the reflection of a layer of dye (XXVI) in PMMA 60 nm in thickness.

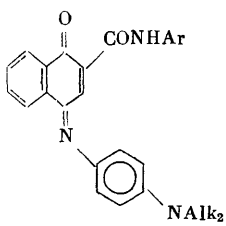
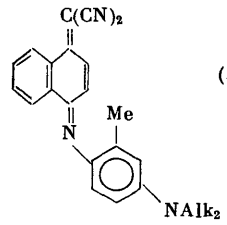
Introduction of acceptor substituents into the quinoid moiety of the type (XXIV) dye molecule leads to the appearance of an intense absorption band with a charge-transfer in the near-infrared range which confers sensitivity to semiconductor laser irradiation.[163] Data in Japanese patents confirm that indoaniline dyes (XXV) may be used in mono- and bi-layer structures for laser recording at 780 nm.[164,165]



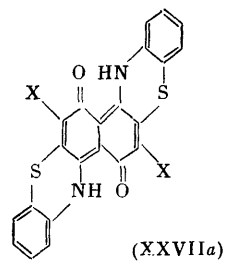
(XXV), $\lambda_{max\ abs} \geqslant 720$ nm

Displacement of the longwave absorption band into the infra-red range may be attained also as a result of the replacement of the oxygen atom in structure (XXIV) by the dicyanomethylene group. Synthesis of type (XXVI) dyes has been described.[166,167] Their films transferred on to a polymeric support have a broad absorption band in the 600–1000 nm range in the electronic spectrum and adequate reflectivity (Fig. 3) which provides excellent recording characteristics at 830 nm at a laser pulse power of 4 mW.[166–168]

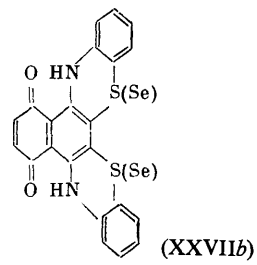


(XXVI), $\lambda_{max\ abs} \approx 760$ nm

Another approach for obtaining the quinoid type of infrared-absorbing dyes is the creation of structures (XXVII*a*, *b*) based on the 1,4- and 1,5-naphthoquinone molecules and containing azine heterocycles.



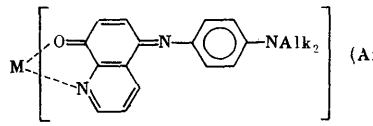
(XXVII*a*)



(XXVII*b*)

Compounds of this type have been obtained by interaction of a 6-X-substituted 2,3-dichloronaphthazarine with a salt of *o*-aminothio(seleno)phenol. Spectral studies showed that they exist in the quinoid form and that the introduction of *peri*-located phenylamino groups into the azine rings leads to a bathochromic shift of the longwave absorption band by 50–100 nm.[148,150,169,170] The 1,5-bis(phenothiazin)quinone (XXVII*a*) absorbs in a region of longer wavelengths in comparsion with 1,4-naphthoquinone (XXVII*b*).[170] An additional bathochromic shift is found for the disulphoxide, compound (XXVII*b*), owing to an increase in the electronegativity of the azine ring.[170] Bis(phenothiazine)quinone films 20–110 nm in thickness transferred to polymeric supports by vacuum deposition have been tested as a recording medium for use at 780 nm in mono-layer structures and were found to exhibit adequate thermostability.[169,171,172]

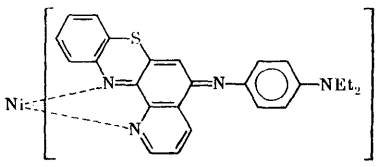
The stability of recording layers based on naphthoquinone dyes may be significantly increased by complex formation with cobalt salts.[158] This observation marked the beginning of a series of studies on the molecular "design" of infrared-absorbing dyes by creating transition metal complexes based on 1,4-naphthoquinone or 1,4-naphthoquinone-4-imine derivatives.[173–176] Complex formation leads to the appearance of an intense band with a charge-transfer in the near-infrared range. Its longwave shift relative to the absorption band attributable to the $\pi-\pi^*$-transition in the ligand molecule is 140–170 nm for type (XXVIII) structures.[175]



M=Ni, Co, Cu

(XXVIII), $\lambda_{max\ abs}$ ca. 770 nm

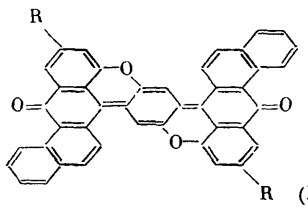
An even greater bathochromic effect is obtained during complex formation of pyrido-[2,3-a]phenothiazine dyes. For example when complex (XXIX) is obtained from the corresponding ligand, the longwave absorption band is displaced by 184 nm, and there is a 4,9-fold increase in the molar coefficient of extinction.[177,178] The complex of physical and chemical properties of type (XXVIII) and (XXIX) dyes determine their potential in the field of optical disc recording.



(XXIX), $\lambda_{max\ abs} = 838$ nm

There are relatively little data on the use of anthraquinone dyes in memories based on diode lasers. The patent and scientific literature describe anthraquinone derivatives containing the amino- and arylamino groups in *peri*-positions,[179,180] including the groups incorporated into azine rings.[150,169,181,182] The spectral properties of lasers based on these derivatives and also the characteristics of laser recording in such layers are similar to the readings obtained for analogous naphthoquinone derivatives.

In recent years patent data have appeared on the LWR-layers based on vat dyes, anthrapyridone derivatives,[183] and the (XXX) type of polycarbocycles.[184] Films from these compounds



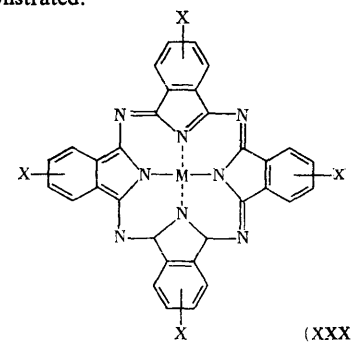
(XXX), $\lambda_{max\ abs} = 770$ nm

may be formed by vacuum deposition and by spin-coating, and they are highly resistant to heating in a moist atmosphere.

4. Phthalocyanines and other metallic complex dyes

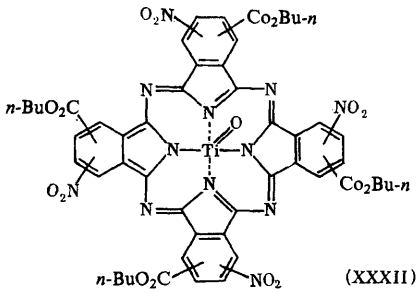
The phthalocyanines or tetrabenzotetraazaporphines are structurally similar to natural pigments based on the porphine-16-centric aromatic system. The spectra of metallised phthalocyanines contain narrow and very intense absorption bands in the 650–750 nm range. This class of dyes typically possesses extremely high thermal- and light-stability,[122,142] resulting in the use of phthalocyanines in optical disc information recording in the early stages in the development of this field.[14]

The use of phthalocyanines (XXXI) of both transition (manganese,[185,186] nickel,[187,188] iron,[188] titanium,[189,190]) and nontransition metals (magnesium,[191] zinc,[188] lead,[187,188,192] aluminium,[193,194] tin,[188,195] and silicon elements[196]) in optical discs has already been patented. The titanium, aluminium, tin, and silicon derivatives contain in the complex forming element an oxygen or halogen atom, Alk, Alko, Alk_3SiO-groups, etc. Materials based on copper[187,188,197–199] and vanadium[187,188,198,200–206] phthalocyanines have been most widely used. The possibility of laser recording on films of metal complexes of phthalocyanine thioanalogues has been demonstrated.[207,208]



(XXXI)

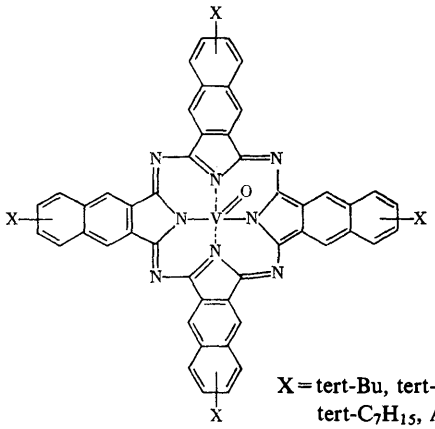
SSP molecular orbital calculations of phthalocyanine dye molecules show that excitation leads to the displacement of electron density from the centre of the molecule to its perimeter and consequently a decrease in the electronegativity of the complex forming group and the introduction of electron acceptor substituents into the benzene rings should lead to a bathochromic displacement of the longwave absorption band.[122] Accordingly in the electronic spectra of films based on titanylphthalocyanines (XXXII) containing strong electron acceptors in the aromatic nuclei



(XXXII), $\lambda_{max\ abs} = 805$ nm

absorption in the infrared range is found which provides high sensitivity to semiconductor laser irradiation and a recording with good contrast (CNR $\geqslant$ 51 dB).[189,190]

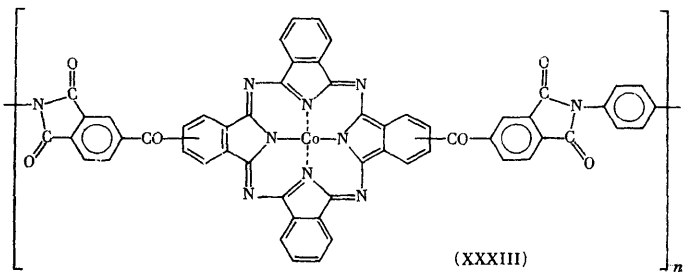
Naphthalocyanine dyes have been widely used in optical disc recording.[209–217] The extension of the conjugated system owing to linear annelation of benzene rings to form 2,3-naphthocyanine causes a bathochromic displacement of the absorbance by 80–100 nm, moving it nearer to the diode laser generation range (ca. 800 nm).[142] The same elements as those in the type (XXXI) phthalocyanines may serve as complex forming groups. Lasers based on vanadyl-naphthocyanine are most widely used.[218,220]



X = tert-Bu, tert-Am tert-C_7H_{15}, AlkS, N = NR and others

On account of their high thermal stability the phthalocyanine dyes may be deposited on supports by vacuum deposition.[185,191,195,208] Nevertheless despite the low solubility of the phthalocyanines in organic media, the spin-coating technology is becoming increasingly used.[186,189,190,194,202,209,214,216] Solubility can be increased by introduction into the dye molecule of alkyl or alkoxy groups containing three or more carbon atoms or silicon-containing residues containing long-chain alkyl groups or several halogen atoms.[186,187,194,202,204,211,214,216–219] Good recording characteristics were obtained on layers containing mixtures of phthalocyanines with polymethine dyes[43,199] and 2,3-dicyano-5-amino-8-arylamino-1,4-naphthoquinones.[221,222]

DIP-layers based on phthalocyanine dyes have been used much less frequently than those based on polymethine dyes. Nitrocellulose and polystyrene, etc. have been used as polymeric supports.[186,211,218] Excellent laser recording readings have been obtained on layers of polymeric dye (XXXIII).[223]

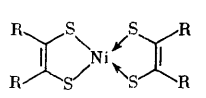


(XXXIII)

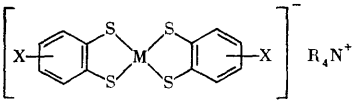
Films of metallic complexes of phthalocyanines possess relatively high reflectance in the near-infrared range and therefore may be used within both bi-layer recording materials incorporating a metallic reflecting layer (Sn,[203] Re,[224] Al[205,215,218]) and monolayer structures.[189,190,202,206] Thus a naphthalocyanine layer containing the complex-forming group $Ge(OSiEt_3)_2$ 90 nm in thickness has a reflectivity of 50% at 825 nm and provides a CNR value equal to 50 dB at a recording beam pulse power of 5.3 mW.[213]

A characteristic feature of the phthalocyanines is their high thermal and light stability.[122] The recording layers based on these compounds do not require the use of stabilisers, although a positive effect has been observed when they are supplemented with triarylaminyl salts[199,214] and titanium acetylacetonate.[200] The high operating features of the LWR-layers based on the phthalocyanine dyes and also on the inexhaustible flow of patent literature indicate that, together with the polymethine and naphthoquinone dyes, they are undoubtedly of interest in regard to the technology of the optical memory discs.

In addition to the phthalocyanines and metal-containing quinone derivatives (see previous section), metal (Ni, Cu, Co, Fe, etc.) complexes with *o*-oxynitrosonaphthalenes, aromatic azomethines, and other organic ligands have been reported as being active media for optical recording.[225,226] The extensive use of dithiolate complexes of metals and recording layers based on polymethine dyes and other dyes as singlet oxygen quenchers has already been described. Their use as supports in photothermal recording has also been described.[227–230] A large amount of data concerns both the neutral (XXXIV) [227–229] and also the anionic (XXXV) type[230,231] of nickel complexes.



(XXXIV)



(XXXV)

The metal dithiolates have low solubility in organic media which is a serious defect of these dyes, since only the spin-coating technique may be used to transfer them on to supports. Solubility may be increased by introducing into the ligand molecule alkyl groups with seven or more carbon atoms, several Me-groups, or halogen atoms[227,228,230,231] and also by creating dye-polymer compositions.[281,231] Since the metal dithiolate films have low reflectivity they may be used only in bi-layer structures with a metal reflecting layer (Al, Au).[227,228,232]

IV. Conclusion

Thus in the past decade a new direction has appeared in the field of non-silver photography, discrete laser recording on organic dyes for use in optical systems with a large capacity memory. A study of organic recording media has revealed a number of advantages over lasers based on tellurium and its alloys, i.e. high resistance to the action of atmospheric oxygen and moisture, lower toxicity, relatively low melting points conferring higher sensitivity, low thermal conductivity with the consequent attainment of a higher recording density, a comparatively inexpensive technology for disc preparation, and the possibility of altering the optical and thermomechanical properties of the recording medium by modification of the structure of the organic dye.

From the experience gained to date from the experimental study of the electronic structure of dyes and with the aid of quantum chemical calculations it is possible to conduct a targetted synthesis of dyes suitable for use in optical discs during recording with semiconductor lasers at a wavelength of 780–830 nm. The polymethine dyes, metallic complexes of phthalocyanines and naphthoquinone dyes are most promising. The growing market abroad in DRAW optical discs and the introduction of the flexible type of carrier for optical recording on organic dyes ("digital paper") are undoubtedly powerful stimulants for the further development of studies in the field of organic dyes and photothermal materials based on these compounds.

The authors wish to thank L V Ektova for assistance in compiling the literature.

Tin–antimony oxide catalysts: preparation conditions and properties

R A Lemberanskii, I B Annenkova, Z A Bakhshieva
Azizbekov Azerbaidzhan Industrial University, Baku

ABSTRACT. The influence of preparation conditions of tin–antimony catalysts on their phase composition and olefin-oxidation activity is analysed. Special attention is paid to the influence of the starting compounds, the preparation method and the calcination temperature on the formation of the catalytic surface. The catalyst properties can be regulated by varying their synthesis conditions. Information about the effect of preparation conditions on the properties of the catalysts is scientifically and practically significant for their designed synthesis.

The bibliography contains 44 references.

I. Introduction

The economy requires highly active and selective catalysts of reactions, including oxidations, of organic compounds in order to produce the necessary chemical commodities.

The development of a process is an important but not the only condition for preparing an effective catalyst. The synthesis itself is an exceedingly complicated and delicate problem. It requires the strictest observance of the ratio of starting compounds, succession of operations and technical process parameters. This is necessary because the specific structure and given physicochemical, mechanical and catalytic properties are formed during the catalyst preparation. Therefore the numerous investigations of heterogeneous catalysts intentionally include careful studies of the synthesis process, the influence of the preparation method, the nature of the starting materials, the medium, the heat-treatment temperature, and other process parameters on the properties of the synthesised catalysts. An analysis of the results obtained is certainly of interest.

In the present review an attempt is made to generalise and analyse literature data for the influence of such factors on the structure and properties of the tin–antimony oxide system, which is known to contain highly active and selective catalysts of oxidation of olefins into unsaturated aldehydes.

II. Influence of preparation method on the catalytic activity of tin and antimony oxides

Tin–antimony catalysts are especially sensitive to the synthesis conditions. This is particularly evident in the contradictory data for the influence of composition on activity in oxidation and oxidative dehydrogenation of low-molecular-weight olefins.

Traditional preparation methods of such catalysts are rather complicated. They are usually prepared from Sn and Sb oxides that are precipitated separately by the action of boiling concentrated HNO_3 on the metals (or their oxides)[1–4] or of ammonia on HCl solutions of Sn^{IV} and Sb^{III} or Sb^{V} chlorides[5–9] followed by drying of the hydroxide mixture at 120 °C and prolonged (up to 16 h) calcination at 500–1000 °C.[1–5] Vartanov, et al.[10] suggest that the active catalyst phase is formed during the early stages of preparation and possibly even at the time of mixing of the hydroxides.

The prepared catalyst is a complicated heterogeneous system consisting of miscible Sn and Sb oxides over a wide range of Sn/Sb ratios. Data on the boundaries of the miscibility of the oxides are contradictory. Thus, the limiting Sb concentration in the SnO_2 lattice, according to the literature,[2,3,5,8,11–15] varies from 3 to 30 at.%. Such a wide range of concentrations can be explained on one hand by the different methods of determining the oxide solubility limits. X-Ray investigations indicate that Sb is dissolved in the catalyst lattice up to 20–30 at.%. The solid-solution region is limited to 7–8 at.% Sb according to electrical conductivity. On the other hand, the solubility of Sb in SnO_2 depends on the duration and temperature of calcination. It increases with increasing temperature up to 900 °C and then decreases at $t > 100$ °C.[5,13,16]

The question of whether the catalyst components undergo a chemical reaction has not been answered. A chemical compound in the Sn–Sb oxide system could not be detected by X-ray diffraction.[2,3,11] However, it could possibly exist in an X-ray amorphous form. This was confirmed by IR spectrosocpic studies that enabled Alkhazov to detect formation of a chemical compound of proposed composition $8SnO_2.Sb_2O_4$.[17]

Precipitation produces rather highly active and selective Sn–Sb catalysts of mild oxidation of olefins such as propylene into acrolein, isobutene into methacrolein, and oxidative dehydrogenation of butene into divinyl.[10,17–19] Thus, the yield of methacrolein and divinyl is 70% with a selectivity of 80–90% at 400 °C and a gas-mixture flow rate of 3600 h^{-1}. Solid solutions of Sb in SnO_2 in the range 10–20 at.% Sb are most active in mild oxidations.

The method for synthesising Sn–Sb catalysts mentioned above also has drawbacks. It includes many steps and involves formation of toxic and corrosively aggressive side products. The method of synthesising Sn–Sb catalysts from the metal oxides consisting of calcining their mixtures is technically simpler and devoid of these shortcomings. There were concerns about whether the components

reacted in this instance and whether it was extensive enough to form the active phases. Vartanov, et al.[10] confirm that oxides of Sn (SnO_2) and Sb do not react during joint calcination. The possibility of a solid-state reaction between SnO_2 and Sb oxides leading to a solid solution based on rutile has been demonstrated in other studies.[5,13,20]

Rather detailed studies of Sn–Sb catalysts prepared by calcining a mechanical mixture of Sn and Sb oxides have been carried out.[19–21] Oxides of $Sn^{II,IV}$ and $Sb^{III,V}$ were used as starting materials. A moist paste of their mixture was dried at 120 °C and calcined in air at 800 °C for 8 h. Thermographic analysis of the resulting oxide mixtures and X-ray phase analysis of the catalysts suggested with certainty that the starting components reacted during catalyst synthesis. This formed two types of solid solutions. One was based on rutile with the limiting solubility of Sb in SnO_2 of ~15 at.%. The other was a solid solution of Sn (15 at.%) in Sb_2O_4. X-Ray diffraction also detected an X-phase different from each of the starting oxides.

Tests of the samples for gas-phase oxidation of isobutene suggested that the products of reaction of Sn and Sb oxides are the active catalysts. The individual oxides do not catalyse formation of methacrolein. The binary compositions are rather active in this reaction.[19,22] Samples synthesised from SnO_2 and Sb oxides are slightly active.

Systems prepared from SnO and Sb oxides are very active for partial oxidation of isobutene. Compositions in the range of oxide solid solutions 80–90 at.% Sn and 70–80 at.% Sb are most active. The sharp reduction in the yield of CO_2 with the addition of even a small amount of antimony to tin oxides likewise confirms the existence of inter-reaction between the original oxides, but it does not explain the results for dilution of SnO_2 with antimony oxides.

In Fig. 1, the activity for isobutene oxidation of catalysts synthesised from Sn and Sb oxides is compared with that of those prepared by coprecipitation from their metallic powders. The ratios Sn/Sb in the starting materials, the heat-treatment conditions and the isobutene oxidation process are in all instances identical. Catalysts prepared from SnO_2 and Sb oxides have greater selectivity than those synthesised by the usual coprecipitation method. However, they give poorer yields of methacrolein. Samples prepared by calcination of a mixture of SnO and Sb oxides are slightly more selective than those prepared from SnO_2 and Sb oxides although the latter are nonetheless sufficiently selective. The activity of the former for methacrolein formation is much greater than that of the latter and comparable to that of catalysts of metallic Sn and Sb.

Therefore, oxides of $Sn^{II,IV}$ and $Sb^{III,V}$ react when their mixture is calcined. Phases that are active in partial olefin oxidation are formed. Differences in the activity of various series of catalysts indicate that the extent of reaction of the catalyst components and the phases formed are apparently different. These properties depend on the oxides chosen as starting materials and more accurately on the valence of the metal forming the oxide, among other factors. The valence of Sn in the starting oxide has a greater effect on catalyst formation than the Sb valence. In fact, it can be seen from Fig. 1 that samples prepared from various Sb oxides differ little in activity for isobutene oxidation whereas catalysts synthesised for SnO are much better (by about two times) than those prepared from SnO_2.

It is possible that Sn^{2+} becomes easier to oxidise after formation of a solid solution of Sb in the lattice of SnO, which is though to be responsible for oxidation of an olefin to a aldehyde.[13,14] Dissolution of Sb in the previously formed SnO_2 is apparently more difficult. This leads to enrichment of the catalyst surface in Sb as dispersed Sb_2O_4. According to the literature[23] this ensures the high selectivity. The role of surface Sb in selective partial olefin oxidation is also evident in a comparison of the catalytic properties and the surface composition of the Sn–Sb–O system. The experimental data obtained previously[19,21,22] show that samples over a wide range of compositions (10–90 at.% Sb) are sufficiently selective in mild oxidation of isobutene into methacrolein. The selectivity is practically independent of the ratio of starting Sn and Sb oxides. Structural studies of these samples by XPS demonstrated that the surface layer was enriched in Sb by at least two times compared with the bulk.

Catalysts of metallic Sn and Sb (*1*), $SnO_2-Sb_2O_3$ (*2*), $SnO_2-Sb_2O_5$ (*3*), $SnO-Sb_2O_3$ (*4*), $SnO-Sb_2O_5$ (*5*).

III. Influence of calcination temperature on catalyst phase composition

One of the most important process parameters in synthesising catalysts is the calcination temperature, which has a substantial effect on their structure and phase composition and eventually determines their catalytic activity.

The need for high-temperature activation of Sn–Sb catalysts in order to achieve high selectivity for mild oxidation products in olefin oxidations has repeatedly been pointed out.[6,14,16,20,24,25] Various explanations of this need for high-temperature calcination have been offered. According to some,[20,24,26] it is required to increase the solubility of Sb in the SnO_2 lattice. This increases the number and stability of free electrons at high temperatures and also the stability of Sb^V to calcination and redox processes. The improved catalytic properties of the mixed oxides may be a result of both of these factors or only one of them.

Godin, et al.[14] view the role of high-temperature treatment as the destruction of microporosity. This increases the crystallinity and the particle size of the rutile.[9]

In the opinion of Roginskaya, et al.,[16] such heat treatment is necessary to effect the conversion of Sb^V into Sb^{III}.

Sala and Trifiro[20] think that the high-temperature calcination has three different types of effect on the mixed Sn–Sb oxides: a) It sharply increases the extent of SnO_2 modification by Sb, exhibited as increased absorption in the visible spectral region and a greater amount of butadiene formed after oxidative dehydrogenation of *n*-butenes. b) It sharply increases the isomerisation ability due to migration of Sb^V into the SnO_2 lattice and subsequent surface dehydrogenation. c) It decreases the irreversible catalyst mass loss in the redox process caused by the reduction of Sb oxide and partial sublimation of the metallic Sb formed.

The conclusions supported by the experimental data that the solubility of Sb in the SnO_2 lattice increases with increasing calcination temperature are still rejected by certain investigators. According to the literature,[8,15] Sn–Sb catalysts calcinated at high temperatures show a reduced tendency to incorporate Sb into the SnO_2 lattice. Thus, as demonstrated previously,[27–30] the catalytic surface is enriched in Sb. Several authors think[8,15,29,30] that a high calcination temperature induces migration of Sb from the bulk of the rutile to the surface. This forms an equilibrium solid solution of Sb in Sb oxide through thermally excited aggregation of SnO_2 octahedra. The Sb oxide readily volatilises at high temperatures. This leaves on the surface a crystalline solid solution of the rutile type that contains 4 at.% Sb in SnO_2 and up to 25% Sb in the catalyst.

Investigations of Sn–Sb catalyst[27] containing 4 at.% Sb, which according to the literature[8,27] corresponds to the limiting solubility of Sb in SnO_2, did not detect a segregated crystalline Sb oxide phase on the surface of the solid solution, as was described previously.[29] This suggested to Berry and Smith[27] that the enrichment of the surface of Sn–Sb catalyst in Sb after high-temperature calcination is due to concentration of Sb, possibly completely surrounded by Sn, on the SnO_2 rutile surface and is not accompanied by formation of a segregated crystalline surface phase of Sb oxide.

Samples with a high Sb content consist, after calcination at 1000 °C, as demonstrated before,[9] of a rutile solid solution, a small amount of a crystalline substance different from rutile, and significant quantities of an amorphous substance containing Sb. Several investigators[9,30] think that the amorphous phase is formed from Sb that did not enter the solid solution and did not act as a nucleus for formation of Sb_2O_4, which is readily volatiled at high temperatures. The crystalline phase different from rutile was not identified.

Thus we can see that there are various ideas about the surface phase composition formed during high-temperature calcination of Sn and Sb oxides. The question of which phases are responsible for the selective partial olefin oxidation in this catalytic system remains unanswered. The increase of selectivity for mild oxidation of butene[31,32] and propylene[29] of Sn–Sb catalysts due to their high-temperature calcination and the resulting enrichment of the surface in Sb is connected by some authors[14,24,26,32,33] with a solid solution of Sb in SnO_2 and by others[29,34] to the presence on the surface of a catalyst of this solid solution in combination with an Sb oxide phase or to an Sb_2O_4 phase.[23,35] It is also thought[8] that the bulk crystalline SnO_2 lattice is just as important to the occurrence of the catalytic reactions as the presence on the catalytic surface of Sb and Sn ions in close contact with each other.

The majority of investigations of the Sn–Sb oxide system have been carried out with compositions enriched in Sn. The middle region of compositions are still largely unexplored. In the opinion of Kustova, et al.[5] a compound of Sn and Sb oxides is not formed in samples calcined at 500–950 °C. This agrees with previous results.[14] However, Roginskaya, et al.[16] think that an unidentified phase containing 50–80 at.% Sb in addition to a solid solution of Sn is formed in the Sb_6O_{13} structure at 700 °C or in Sb_2O_4 at 900 °C. Structural relationships are unclear even for the Sb–O system in compositions enriched in Sb.

IV. Dependence of catalyst properties on Sn- and Sb-containing starting materials

The choice of Sn- and Sb-containing reagents is an important factor in catalyst formation during its synthesis. This last condition can often change even the influence of heat treatment on the catalyst properties. An investigation of this problem demonstrated[36,37] that high-temperature treatment can produce, depending on the Sn- and Sb-containing compounds chosen as starting materials for the catalyst synthesis, in one instance, samples differing substantially in phase composition and properties. This occurs regardless of an identical Sn/Sb ratio. In another instance catalysts with very similar properties are produced from components with an identical starting ratio.

Lemberanskii, et al.[36,37] studied catalysts of two extreme compositions in which Sn/Sb = 1/9 and 9. These were prepared from metallic Sn and Sb (series A) and from the metal chlorides (series B).

In the region enriched in Sb, the density of series A samples was approximately constant in the calcination temperature range 300–1000 °C at about 6.5–7.0 g cm^{-3}. The specific surface decreased from 6.4 to 4.0 m^2 g^{-1}. The mass change was insignificant. A stronger temperature effect is observed in series B. The density of this series increases continuously and substantially with increasing heat-treatment temperature. It is three times greater for a sample with a calcination temperature of 1000 °C than for one calcined at 300 °C and 1.5 times greater than that of the series A sample of analogous composition. Series B catalysts are more intensely coloured. A large mass loss is observed during heat treatment of series B samples. A significant amount of sample volatilises at all calcination temperatures.

X-Ray phase analysis of calcined catalysts and the phases that were vapourised and then condensed (Fig. 2) showed that series A samples are solid solutions based on Sb_2O_4 (curve *1*). The series B catalysts after calcination at 300 °C are a complicated mixture consisting apparently largely of various chloride compounds. Bands belonging to the pure Sn and Sb oxides are not observed by X-ray diffraction. Starting at 600 °C bands characteristic of SnO_2 (curve *2*) appear in the diffraction patterns and are observed up to 1000 °C. Lines belonging to other Sn and Sb oxides are practically absent. Thus, even at 600 °C the sample is exclusively SnO_2 (poorly formed). At 1000 °C it is already well crystallised SnO_2. The presence of a solid solution of Sb in SnO_2 is possible. It is thought that a significant part of the Sb volatilises as oxides during the calcination. Strong bands of Sb_2O_4 in addition to lines of the other Sb oxides Sb_2O_3 and Sb_2O_5 (curve *4*) are clearly evident in the diffraction patterns of the sublimed phases.

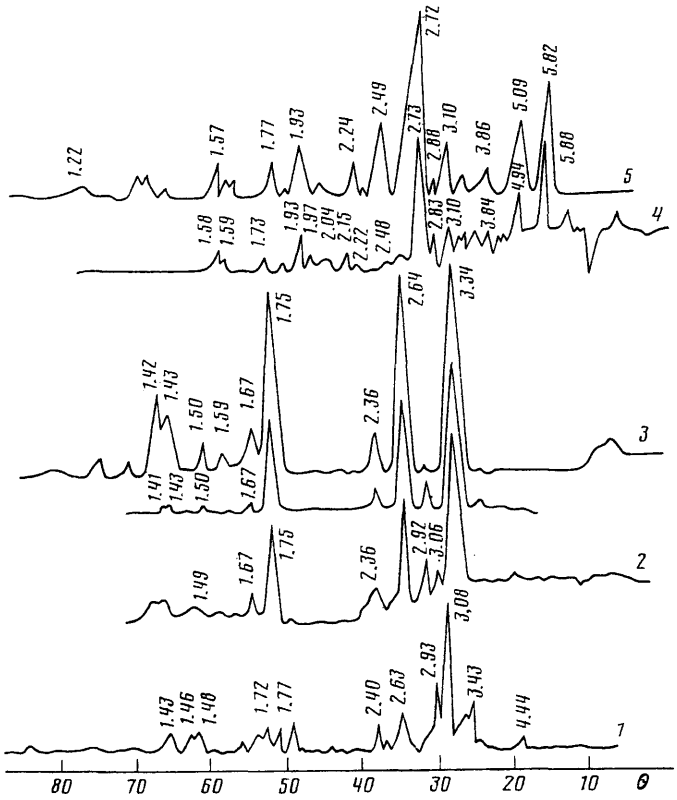

Figure 2. Diffraction patterns of tin–antimony catalysts and sublimed phases: catalysts of metallic Sn and Sb, t_{pr} = 1000 °C, Sn/Sb = 1/9 (*1*); for the curve over the curve *2*, Sn/Sb = 9. Samples of Sn and Sb chlorides, t_{pr} = 1000 °C, Sn/Sb = 1/9 (*2*), 9 (*3*). Sublimed phases of samples of Sn and Sb chlorides, t_{pr} = 600 °C, Sn/Sb = 1/9 (*4*), 9 (*5*).

In the region of compositions enriched in Sn (Sn/Sb = 9), the influence of heat-treatment temperature on catalyst formation depends little on the starting materials and is seen mainly as an intense volatilisation and a large amount of volatilised material. Whereas series A samples lose 5–7% of their mass, series B samples lose 70–80% at 600–1000 °C. The density and bulk mass of samples calcined in the temperature range 600–1000 °C are practically constant. The samples are dark blue, i.e. the catalyst is practically formed even at 600 °C. X-Ray phase analysis of samples with Sn/Sb = 9 demonstrated that the catalyst prepared from the metals is a solid solution of Sb in SnO_2 and that the maximal possible Sb concentration reaches 10–15 at.%.[38] Bands of SnO_2 (curve *3*) are also noted in the diffraction pattern of the sample synthesised from the metal chlorides. Bands characteristic of Sb oxides are not observed and they are not found in the diffraction patterns of the sublimed phases. The amount of sublimed phase is rather large. A comparison of the observed diffraction bands (curve *5*) with previous results[39,40] suggests that this phase contains mainly ammonium chloride and ammonium chlorostannate(IV). Therefore, it seems that all of the Sb is dissolved in the Sn oxide and that the catalyst is a solid solution based on SnO_2, probably in combination with SnO.

Thus, the phase composition of the Sn–Sb catalysts substantially depends on the synthesis conditions. Stucture formation in series A samples, which are prepared from metallic Sn and Sb, is mainly finished up to 600 °C. For series B samples, which are prepared from Sn and Sb chlorides, a longer time and higher temperatures are required and the process is accompanied by a significant loss of catalyst mass. According to thermographic and thermogravimetric analyses, water is lost up to 200 °C. Endotherms are observed in the range 400–500 °C. These are accompanied by large mass losses (65–85%). A Sn compound containing ammonium and chlorine (Sn/Sb = 9) and Sb oxides (Sn/Sb = 1/9) are vapourised. The oxide SnO_2 is more stable.

The high volatility of Sb oxides during heat treatment of series B samples is surely explained by the preparation method. The rate of migration of Sb oxides in series A samples is not so fast and leads only to concentration of Sb on the catalyst surface. Many authors use this to explain the high-temperature activation of Sn–Sb catalysts that is necessary to increase their selectivity for mild oxidation products in olefin oxidation reactions.[6,14,16,20,24,25] therefore, depending on the migration rate of Sb cations, which in turn depends on the starting materials and the catalyst preparation method, the surface of samples in one instance becomes enriched in Sb (series A). In the other instance, even with a high starting Sb content, the surface is depleted of Sb during heat treatment due to volatilisation and becomes enriched in Sn (series B). It is interesting to compare the diffraction patterns of catalysts prepared from Sn and Sb chlorides that have a different ratio of starting materials. In both cases only bands corresponding to SnO_2 are seen (Fig. 2, curves *2* and *3*).

Naturally this cannot affect the catalytic properties of the samples. The test results for isobutene oxidations that are plotted in Fig. 3 confirm this hypothesis.

It can be seen from Fig. 3 that the activity of catalysts of various compositions synthesised from the metals are substantially different. The sample with a high Sn content is significantly more active. Thus, an isobutene conversion of 70 mol% under the chosen oxidation conditions is achieved already at 350 °C whereas it does not exceed 20 mol% at this same temperature on the second sample (Sn/Sb = 1/9). However, the methacrolein yield is much greater at Sn/Sb = 1/9 (60 mol%) than for Sn/Sb = 9, where it does not reach 10 mol%. The sample enriched in Sn in practice catalyses the complete oxidation whereas conversion of olefin into the destructive oxidation products is less than 10 mol% (at 450 °C) on the catalyst

enriched in Sb. This catalyst is selective (up to 90 mol%) for methacrolein formation.

However, a sample of this same composition (Sn/Sb = 1/9) but prepared from metal chlorides is much more active than the series A sample for complete oxidation. It is much less selective for mild oxidation. These samples differ substantially in phase composition. The surface of the series B catalyst is enriched in SnO_2 due to volatilisation of Sb oxides.

In comparing samples with an identical ratio of components that are prepared from different starting materials, it is found that series B samples are always more active than series A samples for oxidation of isobutene to CO_2. The selectivity for methacrolein on them is much lower due to combustion of both isobutene and the methacrolein that is formed (methacrolein is not observed in the reaction products in the studied temperature range on the series B sample with Sn/Sb = 9).

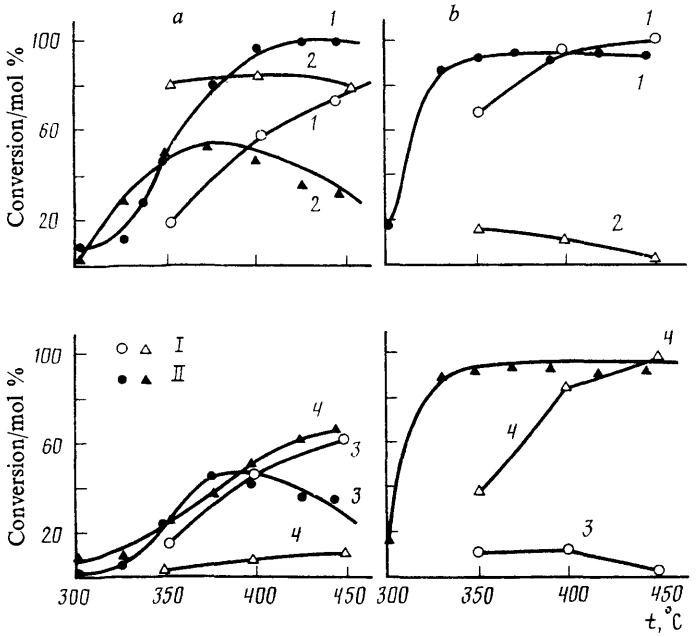

Figure 3. Activity of tin–antimony catalysts [Sn/Sb = 1/9 (*a*) and 9 (*b*)] for oxidation of isobutene (3600 h^{-1}, 5 mol% of *iso*-C_4H_8): series A (from metallic Sn and Sb) (*I*), series B (from Sn and Sb chlorides) (*II*). Total conversion of isobutene (*1*), selectivity for methacrolein (*2*), conversion into methacrolein (*3*), conversion into carbon oxides (*4*).

V. Influence of synthesis conditions on formation of the catalytic surface

The substantial difference in the activity of catalysts prepared by various methods is mainly due to the different nature of the catalytic surface formed under given catalyst synthesis conditions.

High-temperature migration of Sb from the crystal bulk to the catalyst surface has been observed.[8,15,27–30,36,37] The rate of migration and the resulting effects substantially depend on the preparation method of the catalyst. In particular, the starting Sn- and Sb-containing compounds are important. Oxygen necessarily migrates with the Sb and then is redistributed in its various forms on the surface. All of this should change the acid–base characteristics of the catalyst surface and eventually the catalytic properties.

According to Lemberanskii, et al.[36,37] the high oxidising capability of samples prepared from Sn and Sb chlorides, which markedly exceeds that of catalysts from metallic Sn and Sb, is largely controlled by the surface acid–base properties and is explained by their high surface acidity.

This argument is supported by the known fact that the products of complete oxidation are formed at acidic surface centres that depend on surface Sn cations for the Sn–Sb oxide catalysts.[7]

Data for the isomerisation of butene-1 into butene-2 (Fig. 4) confirm this hypothesis.[36,37] The isomerising capability of samples prepared from the chlorides is greater than that for catalysts prepared from the metals. It also appears at lower temperatures. This difference is especially large for the composition with Sn/Sb = 1/9, in which a sharp difference in the phase composition is observed according to X-ray structural analysis.

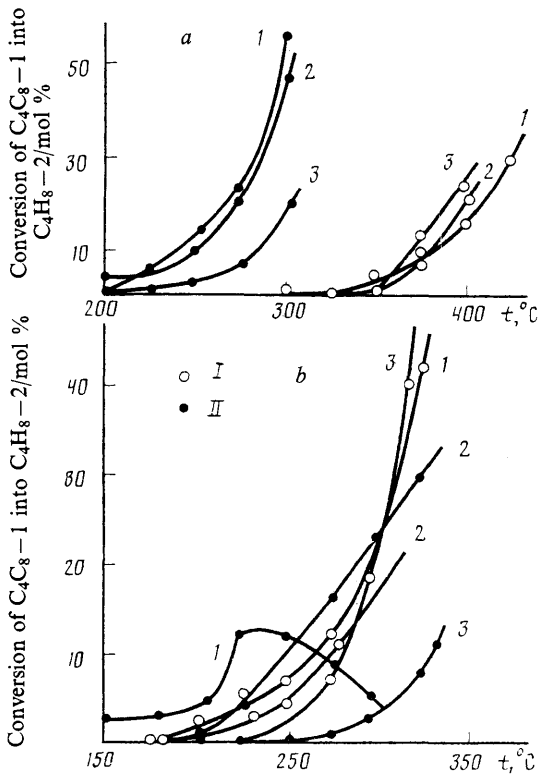

Figure 4. Isomerisation of butene-1 and butene-2 on tin–antimony catalysts (3600 h^{-1}, 5 mol% C_4H_8): Sn/Sb = 1/9 (*a*), Sn/Sb = 9 (*b*). Series A (from metallic Sn and Sb) (*I*), series B (from Sn and Sb chlorides) (*II*); t_{pr}, °C: 600 (*1*), 800 (*2*), 1000 (*3*).

Such results agree with previous studies[20] in which the strong isomerising capability of Sn–Sb catalysts prepared from metal chlorides is explained by the increase in the number of Lewis acid centres formed after dehydration of the surface. This is confirmed

by studies of the isomerisation of butene-1 into butene-2 in an oxidising atmosphere without oxygen in the reaction mixture.[36,41] The experiments were carried out by a response method. An olefin–air mixture was continuously passed at a volume rate of 3600 h^{-1} through a catalyst. After each half minute (analysis time) the reaction products were analysed. After a steady state was attained, the oxygen flow rate was replaced by an equivalent amount of nitrogen to maintain the given volume flow rate. The response of the system to removal of oxygen from the gas phase was followed by continuously analysing the reaction products. After a new steady state was attained, the oxygen flow was started, expelling the nitrogen from the system. The product analyses were stopped after the system again reached a steady state.

Catalysts were prepared by calcining at 800 °C Sn and Sb hydroxides prepared in one instance by the action of concentrated HNO_3 on metallic Sn and Sb and in another by the action of ammonia on the metal chlorides.

It can be seen in Fig. 5*a* that *cis*-butene-1 is formed in greatest yield in an oxidising atmosphere (region *I*) on samples enriched in Sn (curves *1* and *2*). The different activities of the catalysts of the two compositions Sn/Sb = 1/9 and 9 is especially large for samples prepared from the metals (curves *1* and *3*). It is interesting that the isomerisation of butene-1 into *cis*-butene-2 stops on all samples after oxygen is taken out of the gas mixture (region *II*). Subsequent addition of oxygen (region *III*) restores the activity of samples with Sn/Sb = 1/9 to the original value whereas that of samples enriched in Sn (Sn/Sb = 9) does not quite reach the initial value.

Catalysts with a high Sb content are most active in the isomerisation of butene-1 into *trans*-butene-2 (Fig. 5*b*). The yield of *trans*-butane-2 is much less than that of the *cis*-isomer and does not depend on the presence of oxygen in the reaction mixture.

The following conclusions were made by Lemberanskii, et al.[36,41] after analysing their experimental data and results of earlier experiments.

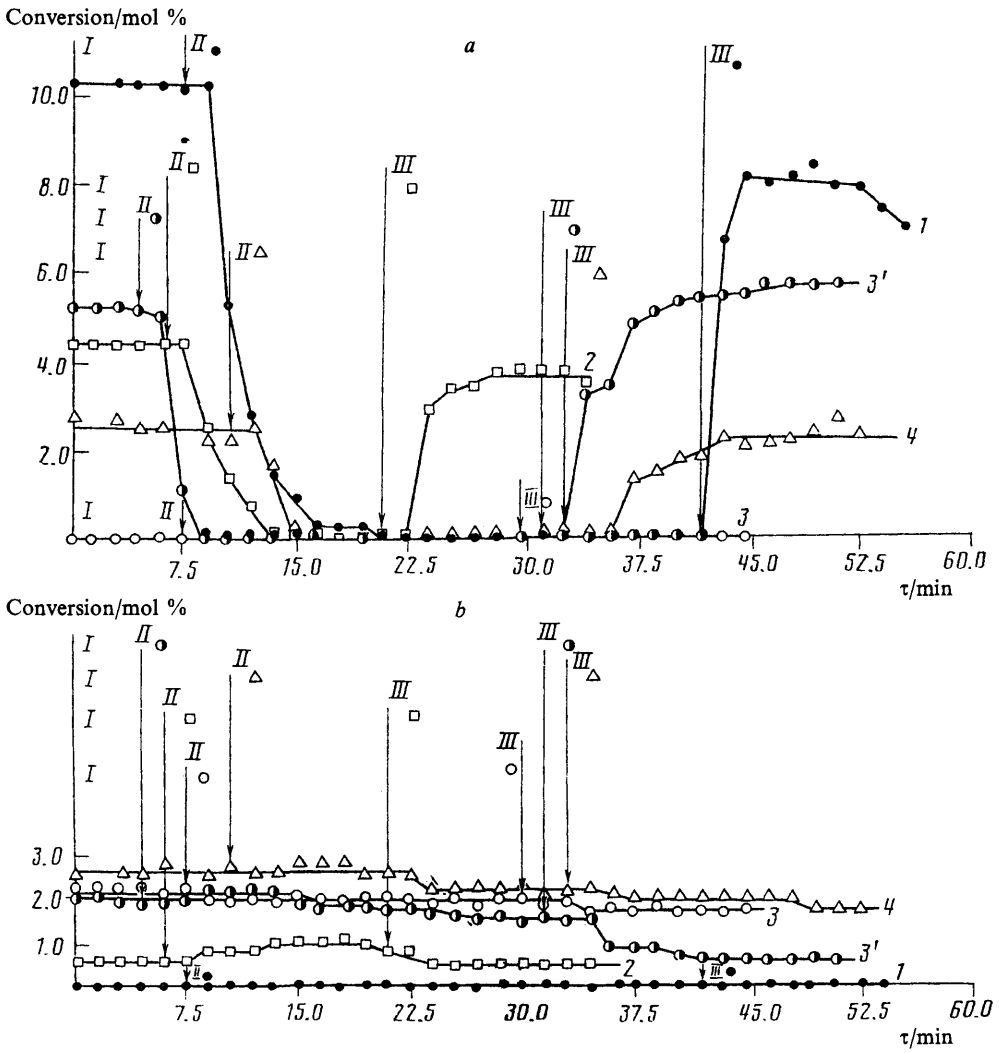

Figure 5. Isomerisation of butene-1 into *cis*-butene-2 (*a*) and *trans*-butene-2 (*b*) on tin–antimony catalysts. Sn/Sb: 9 (*1*, *2*), 1/9 (*3*, *4*). From metallic Sn and Sb (*1*, *3*), from Sn and Sb chlorides (*2*, *4*). O_2 in the gas mixture (*I*, *III*), N_2 in the gas mixture (*II*).

Butene-1 is isomerised into *cis*- and *trans*-butene-2 on Sn–Sb catalysts in an oxidising atmosphere. The yield of *cis*-butene-2 is much greater than that of the *trans*-isomer. Without oxygen in the gas mixture the isomerisation of butene-1 into *trans*-butene-2 continues practically unabated whereas the formation of *cis*-butene-2 is completely inhibited. This certainly indicates that butene-1 is isomerised into *cis*- and *trans*-butene-2 by different mechanisms. In particular, weakly adsorbed molecular oxygen is surely involved in the formation of the *cis*-isomer.

It follows from the experimental data presented that butene-1 is isomerised into *cis*-butene-2 on the catalytic surface enriched in Sn. This is clearly seen by comparing samples prepared from metallic Sn and Sb that differ sharply in composition (Sn/Sb = 1/9 and 9). In the first instance conversion of butene-1 into *cis*-butene-2 is greater; in the second, the *cis*-isomer is not formed under the selected experimental conditions (t = 275 °C). Formation of *cis*-butene-2 is observed on the sample of analogous composition (Sn/Sb = 1/9) that is synthesised from the metal chlorides. However, this does not contradict the preceding observations. It must be considered that according to physicochemical investigations this sample is relatively enriched in Sn due to the fast rate of migration of Sb to the surface and the subsequent volatilisation of Sb, which does not enter the solid solution.[37] The comparison is made with the catalyst of the same nominal composition but prepared from metallic Sn and Sb, where the slower rate of migration of the Sb cations from the bulk limits volatilisation and ensures concentration of Sb on the surface. Therefore, these samples differ in ability to isomerise butene-1 to *cis*-butene-2.

The requisite presence of oxygen in the gas in combination with the catalytic surface enriched in Sn for isomerisation of butene-1 into *cis*-butene-2 indicates that Sn ions are responsible for weakly adsorbed molecular oxygen. This conclusion is confirmed by data for the high activity of SnO_2 and also of Sn–Sb catalysts with surfaces enriched in Sn due to their specific synthesis conditions in complete oxidation reactions requiring the participation of oxygen weakly bound to the catalyst surface.[11,18,22,37,42]

An analysis of previous experimental data[36,37] also suggests that Sb cations are responsible for the conversion of butene-1 into *trans*-butene-2. In fact, butene-1 isomerises into *trans*-butene-2 on the sample enriched in Sb (Sn/Sb = 1/9). No isomerisation is observed on the catalyst with the minimal Sb content (Sn/Sb = 9). This is clearly evident for catalysts prepared from metallic Sn and Sb that are solid solutions of the oxides (Fig. 5*b*, curves *1* and *3*). For samples synthesised from the metal chlorides, formation of the *trans*-isomer becomes noticeable even at Sn/Sb = 9. This is not unexpected if the enrichment of the catalyst surface in Sb as a result of migration from the crystal bulk is considered.

The established fact that Sn and Sb ions are responsible for *cis*- and *trans*-isomerisation, respectively, of butene-1 is of definite interest. It is known that the isomerisation of butene-1 is proposed as a qualitative test for the determination of the total acidity of an oxide catalyst.[43] The study of the acidity of Sn–Sb catalysts by IR spectroscopy of adsorbed ammonia[44] suggested that the Brönsted acidity is caused by Sb ions; the Lewis acidity, by coordinatively unsaturated Sn ions on the surface. Keeping this in mind and recalling the data mentioned above, isomerisation of butene-1 into *cis*- and *trans*-butene-2 can be recommended as a test for Lewis and Brönsted acidity, respectively.

VI. Conclusion

It can be seen from the material presented that the synthesis conditions of Sn–Sb catalysts play such an important role in the formation of their structure and properties that they often dominate over the chemical composition. In fact, the choice of starting Sn- and Sb-containing reagents can affect the rate of high-temperature migration of Sb from the crystal bulk to the surface. This can produce samples with similar or sharply differing catalytic properties depending on the starting ratio of components. In one instance highly selective catalysts of partial oxidation of isobutene into methacrolein are obtained; in the other, active catalysts of complete oxidation.

The optimal synthesis method can be selected on the basis of data for the influence of the method and preparation conditions on the catalyst properties. This method would be fully responsive to economic, technical and ecological demands. For the Sn–Sb oxide system, an analysis of the experimental data indicates that solid-state high-temperature reaction of Sb oxides with SnO should be considered the most rational method of catalyst preparation. This method is technically simple and produces catalysts with sufficiently high activity and selectivity for mild oxidation of olefins that is free of toxic and corrosive starting materials and side products.

Recent trends in research into ionic polymerisation

B L Erusalimskii
Institute of Macromolecular Compounds, USSR Academy of Sciences, St Petersburg

ABSTRACT. The results of original studies on the mechanism of formation of macromolecules in ionic systems are discussed. Amongst these are polmerisation involving living carbocation chains, cationic processes that occur via the activation of a monomer, anionic polymerisation initiated by aluminium and zinc porphyrins, group transfer polymerisation, and polymerisation of olefins using homogeneous Ziegler–Natta catalysts that exhibit high activity.

The bibliography includes 76 references.

IV. Processes initiated by Ziegler–Natta catalysts 83

I. Introduction

During the last ten years the range of agents capable of initiating the ionic polymerisation of various monomers has increased considerably. Many agents have been successfully used to solve important practical problems, such as the preparation of novel polymers, simplifying the conditions for the synthesis of narrowly dispersed macromolecules, and the development of highly effective polymerisation processes. The properties identified in original initating systems have had a marked influence on existing ideas about the mechanism of formation of macromolecules in ionic processes. In the present article particular attention is given to this very question. The desirability of discussing it arises from the fact that the trends in research which will be considered below have so far not been reflected in the Russian review literature.

We should mention that in comparing cationic with anionic polymerisation it was customary to emphasise the marked difference in stability of the active sites. The specific features of polymerisation occurring via active anionic sites are as follows: a linear increase in molecular weight (MW) of the polymers with conversion, and a narrow molecular weight distribution (MWD). These characteristics, which had been established for a number of specific processes, were for a long time considered unattainable for active cationic sites.

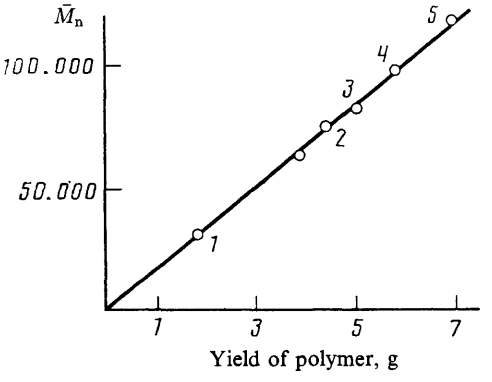

Figure 1. Polymerisation of isobutylene by the system dimethoxy-*p*-dicumyl (DMDC)–$TiCl_4$ in the mixed solvent $CH_3Cl-C_6H_{14}$ (40:60 by volume) at −80 °C.[9] Concentration, mol litre^{-1}: $TiCl_4$ 1×10^{-3}, DMDC 6.4×10^{-5}; total volume 25 ml; conversion 100%; values of $\overline{M}_w/\overline{M}_n$: *1*, 1.11; *2*, 1.10; *3*, 1.17; *4*, 1.10; *5*, 1.09.

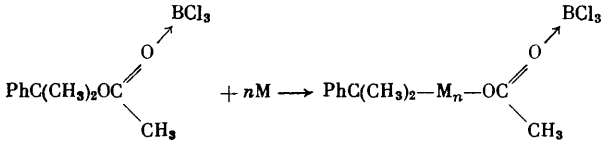
II. Cationic processes

1. Mechanisms of cationic processes

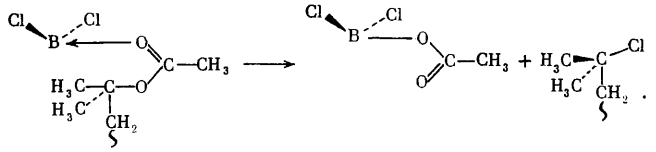
A comparison of the practical significance of the results that characterise cationic and anionic polymerisation has often pointed to the considerable advantage of the latter. This has mainly been connected with the possibility of synthesising various block and multiblock copolymers with a widely controlled range of physicomechanical properties in anionic rather than cationic systems. The development of novel cationic initiators has substantially altered this situation in recent years, and this contrasting position has now lost its original importance.

Studies undertaken in recent years led to a revision of this idea. The basis for this was provided by the studies by Kennedy et al. that developed from previous research by the same authors which focused on the so-called "quasi-living" chains. The results of these studies were examined in a previous review.[1] We shall confine ourselves to the following observation: the distinctive features of polymerisation processes involving quasi-living chains are governed by slow batching of the monomer into the reaction mixture ($3-5 \times 10^{-3}$ mol min^{-1}); this technique results in a marked narrowing of the molecular weight distribution compared to polymerisation under normal conditions. For example, in the case of *p*-t-butylstyrene with the use of boron chloride–cumyl chloride as initiating system in dichloromethane at −50 °C and a conversion of 100%, the $\overline{M}_w/\overline{M}_n$ ratios were 6.53 and 1.38 respectively for introduction of monomer in a single batch and gradually.

The characteristics of the growth of living chains were identified when initiating systems containing Lewis acids in combination with cumyl ethers or esters were used.[2–25] Boron chloride and cumyl acetate (CA) or methyl cumyl ether were used most frequently as components of these systems. For this type of polymerisation the formation of polymers with $\overline{M}_w/\overline{M}_n$ almost equal to 1.1 is typical as is a retention of the linear dependence of $\overline{M}_n$ on the degree of conversion up to 100%. This is shown in Fig. 1 in the case of the polymerisation of isobutylene. The following scheme[4] illustrates the mechanism for polymerisation of this monomer (M) with the system boron chloride–CA

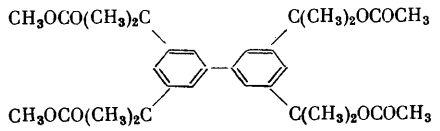


Deactivation of the living polymers, which is caused in particular by an increase in temperature of the reaction mixture, results in the formation of macromolecules with a terminal chlorine atom, which has been interpreted in the following way:[2]



It is worth noting that terminal chlorine atoms have also been found in polymers deactivated by nucleophilic reagents; no details about the mechanism of this effect were given by Faust and Kennedy.[2]

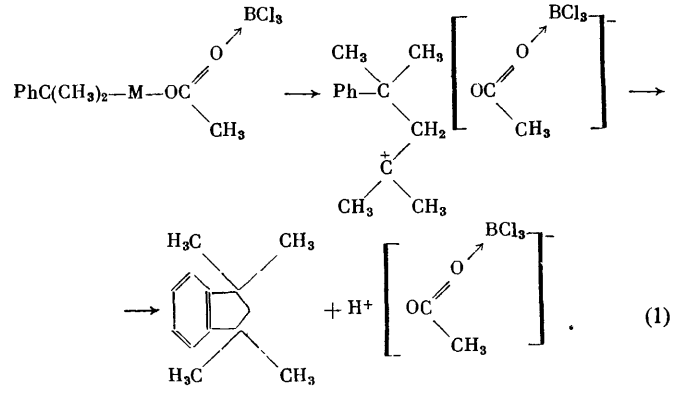
Interesting results are obtained by replacing CA and methyl cumyl ether with the di-, tri- and tetra-functional analogues of these compounds.[4,6–8,11] The last of these has the structure (I):



(I)

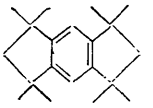
"Tetrablock" macromolecules were obtained from this compound. Polymerisation in the system isobutylene–(I)–BCl_3–CH_2Cl_2 at –80 °C gave this result.[11]

The above processes are accompanied by side reactions that result in the formation of indane rings. This is typical for growing cationic chains containing aromatic rings. Such cases are illustrated by the following scheme:[6]



(1)

For bifunctional initiators the formation of diindane structures is possible:



The relative role of these reactions depends on the temperature and nature of the medium. A reduction in the polarity of the solvent and temperature may lead to their being completely excluded, as depicted in Fig. 2.

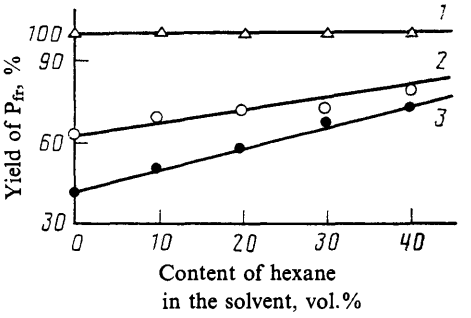


Figure 2. Effect of polarity of the medium and temperature on the formation of polyisobutylene free of indanyl groups (P_{fr}).[6] Initiating system BCl_3–DMDC; temperature, °C: *1*, –70; *2*, –50; *3*, –30.

Let us consider the preferred use of boron chloride compared to other Lewis acids in initiating systems by the authors of these studies. This also refers to the above-mentioned polymerisation processes involving quasi-living chains.[1]

The characteristics of boron chloride are revealed when it is compared with certain aluminium derivatives that form highly active initiating systems with the compounds R_3CCl or HCl. The former do not yield any suitable initiators with BCl_3 while the combination of BCl_3 and HCl constitutes an equilibrium system with a low initiating activity. According to Kennedy and Chen,[12] the reason for this is the low stability of the BCl_4^- counterion, which undergoes reaction (2*c*):

$$HCl \cdot BCl_3 \underset{a}{\rightleftarrows} H^+, BCl_4^- \xrightarrow[b]{(CH_3)_2C=CH_2} (CH_3)_3\overset{+}{C}, BCl_4^- \xrightarrow{c} \longrightarrow (CH_3)_3CCl + BCl_3. \quad (2)$$

The features that are typical of living carbocation chains are also found in the polymerisation of styrene monomers. In this respect the best results have been obtained for 2,4,6-trimethylstyrene,[10] whose structure excludes side reactions of the type (1).

In some studies titanium tetrachloride has been used as a component of the initiating systems. A combination of it and *p*-dimethylcumyl ether (DCE) proved active towards isobutylene

down to −80 °C.[9] The introduction of $TiCl_4$ into a reaction mixture containing all the remaining components achieves good results ($\bar{M}_w/\bar{M}_n$ = 1.1, $\bar{M}_n \sim 10^5$). The use of a previously prepared complex of $TiCl_4$ and DCE gives rise to the formation of indane rings on one or on both ends of the chain. This effect led the authors to make the following assumptions.

When the initial complex is allowed to stand, it gives rise to the formation of the ion pair $\geqslant C^+ [OTiCl_4]^-$, for which an intramolecular conversion to $H^+ [OTiCl_4]^-$ is possible, accompanied by the development of an indane ring at the end of the chain. The contribution of such a conversion must depend on the length of time of storing the initial complex until its introduction into the solution of monomer, which is what actually occurs. With an increase in time for allowing the complex to stand, the content of indane rings in the polymers increases (for example, in one study[9] data is given for times of 30, 75, and 90 s). The relatively slow ionisation of the complex may be attributed to the low polarity of the solvent — a mixture of methyl chloride and n-hexane in the ratio 2:3 was used.

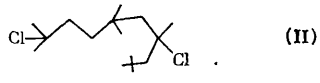
We should mention a further route for the exclusion of side reactions of the type (1) as described by Biswas and Kennedy.[3] In this case the ability of boron chloride to interact with 2,5-dichloro-2,5-dimethylhexane (DDH) was established, leading to the formation of an active initiator for the polymerisation of isobutylene. The absence of a similar effect in the case of monohaloalkanes led the authors to conclude that the bifunctionality of DDH has a special role, making it possible for a cyclic halonium ion to be formed:

$$Cl{-}C(CH_3)_2CH_2CH_2C(CH_3)_2{-}Cl \xrightleftharpoons{BCl_3} (CH_3)_2C\begin{array}{c}CH_2{-}CH_2\\ |\quad\quad |\\ \quad Cl,\ BCl_4^-\end{array}C(CH_3)_2 \quad (3)$$

The propagating chains formed by the action of this sytem undergo spontaneous termination by the normal route (4), but the characteristic signs of reinitiation could not be detected

$$\geqslant C^+,\ BCl_4^- \longrightarrow \geqslant C{-}Cl + BCl_3. \quad (4)$$

The combination of spontaneous termination and lack of reinitiation is indirect confirmation of mechanism (3). Positive evidence for it is also provided by the formation of the dihalide (II) on reaction of 2,2,4-trimethyl-1-pentene (TMP) with DDH and BCl_3 in CH_2Cl_2 at −20 °C, namely, with conditions under which TMP does not polymerise. For the sake of brevity, we shall use the skeletal structural depicted by Biswas and Kennedy,[3]



(II)

It follows from the above that replacement of cumyl chloride as a component of the initiating systems by cumyl ethers gives rise to a change in behaviour of quasi-living and living chains in the majority of cases. Similar qualitative effects were subsequently obtained when another method was used, namely, the addition of a catalytic quantity of a strong electron donor (ED) to binary systems of the type Lewis acid — t-alkyl chloride. The result of such an addition are illustrated by data on the polymerisation of isobutylene in a mixed solvent of n-hexane — methyl chloride (3:2) at −40 °C on treatment with the system 2-chloro-2,4,4-trimethylpentane — $TiCl_4$ in the absence and in the presence of an ED:[5]

Polymerisation conditions	$\bar{M}_w/\bar{M}_n$ of polymer
In the absence of an ED	1.21
In the presence of dimethyl sulphoxide	1.05.

In this case 2,5-di-t-butylpyridine, which acts as a proton trap but which is inert towards carbocations, was also included amongst the components of the reaction mixture. Its presence leads to removal of the proton component of the initiation reaction, which results from an uncontrolled number of proton donors. (For further details, see the review of Erusalimskii).[1] Dimethylacetamide was used as an ED in other systems of a similar type.

These compounds may be regarded as agents stabilising the active cationic sites. The hypothetical structure (III), relating to a system based on boron chloride,[4] has been put forward to explain this theory:

$$\sim\overset{\delta+}{\underset{CH_3}{\overset{CH_3}{C}}}{-}Cl\cdots ED\cdot n\,BCl_3\cdots\overset{\delta-}{BCl_4} \quad (III)$$

Evidence for polymerisation occurring on living chains was found by Kennedy et al. in the case of certain chlorine-substituted styrene monomers.[3,4] In particular, in the system *p*-chlorostyrene — $TiCl_4$ — 2-chloro-2,4,4-trimethylpentane — methyl chloride — cyclohexane — dimethylacetamide — di-t-butylpyridine, polymerisation at −80 °C is characterised by a linear dependence of $\bar{M}_n$ on the degree of conversion.[13] However, $\bar{M}_w/\bar{M}_n$ in this case is not less than 1.26, which may be due to side reactions.

Results of practical significance were obtained by polymerisation of *p*-chlorostyrene via mono-, di-, and tri-functional living polyisobutylene chains.[14] In this way linear and three-arm block copolymers containing comparable proportions of blocks of both types were synthesised with a total value of $\bar{M}_n$ of the order of 5×10^4. Their properties are typical of thermoplastic elastomers — polymers with rubber-like and "glass-like" sequences. They have a considerable advantage over block copolymers based on butadiene and styrene that are similar in general type, but they differ from them by virtue of their increased stability towards atmospheric oxygen and lower combustibility (due to their chlorine content) while having similar physicomechanical parameters.

An assessment of the degree of success obtained from the studies carried out in this area has been given in a general summary by Kennedy,[15] in which considerable attention is given to the applied aspects.

Before the series of studies by Kennedy was published, only the polymerisation of vinyl ethers by the initiating system HI — I_2 could be classed as a cationic process occurring via living chains. The first studies in this area, which were carried out by Higashimura et al., have been discussed in an earlier review.[1] Let us consider more recent studies by these same authors, which extended the range of systems of a similar type and their applicability to other monomers.

A number of novel systems based on HI were obtained when I_2 was replaced by different zinc halides.[16] Their effect in relation to the polymerisation of vinyl isobutyl ether (VIBE) is briefly illustrated

by the results obtained in toluene at 0 °C and with complete conversion of monomer at concentrations (mol litre^{-1}) of: 0.38 (VIBE), 5×10^{-3} (HI), and 1×10^{-4} (ZnX_2):

X	I	Br	Cl
$\bar{M}_w/\bar{M}_n$	1.05	1.04	1.05 .

The introduction of a second equal portion of monomer after polymerisation of the first portion was complete led to the formation of polymers with $\overline{M}_n$ of the order of 1.5×10^4 while preserving a linear dependence of this value on conversion and with only a slight broadening of the molecular weight distribution ($\overline{M}_w/\overline{M}_n$ 1.07–1.08).

The possibility of replacing both the iodine components by others was demonstrated in the case of the polymerisation of VIBE in toluene by the system $(CH_3)_3SiI-ZnI_2$. Effects that were typical of polymerisation via living chains were found at −40 °C.[17] The dependence of the final result on temperature, with complete conversion of monomer and concentrations of VIBE, trimethyliodosilane, and zine iodide equal to 0.38, 0.005, and 0.001 mol litre^{-1} respectively was as follows:

t, °C	−40	0	25
M_n	8200	640	470
$\bar{M}_w/\bar{M}_n$	1.06	1.14	1.26 .

The active sites that are effective in $HI-ZnX_2$ systems have been attributed a structure containing the fragment $(I\cdots I_2)^-$ proposed for the active sites formed by interaction of monomer with a combination of HI ands I_2.[1] Generation of active sites in the last of the above-mentioned systems may be viewed in a similar manner—activation by ZnI_2 of the C–I bond in the adduct between the silane component and monomer.

The polymerisation processes of VIBE initiated by the system $HI-ZnI_2$ have been studied in the greatest detail. Of the other properties, the lifetime of the growing chain in relation to the conditions selected has been determined. We shall list the results obtained with VIBE, HI, and ZnI_2 concentrations of 0.38, 0.01, and 0.0001 mol litre^{-1} respectively:[18]

Solvent	t, °C	half-life* of active sites, min
Dichloromethane	−15	270
Toluene	−15	390
Toluene	0	180
Toluene	25	30

*The period of time over which the concentration of the active sites is halved through deactivation reactions.

The use of different iodine-containing initiating systems for the polymerisation of vinyl ethers with polar substituents [$CH_2=CHO(CH_2)_2Cl$, $CH_2=CHO(CH_2)_2CH(COOC_2H_5)_2$, $CH_2=CHO(CH_2)_2OC_6H_4X$, where X = OCH_3 or Cl] gave narrowly dispersed polymers.[19–21] Some of these were used for the synthesis of block oligomers with a given sequence of monochain residues corresponding to different monomers. An interesting example of this type is the heterotetramer obtained in toluene at −40 °C using the system $HI-ZnI_2$:[22]

$$CH_3CH(O-n\text{-}Bu)-CH_2CH[OCH_2CH_2CH(COOEt)_2]-CH_2CH\cdot$$
$$\cdot(OCH_2CH_2OCOPh)-CH_2CH[OCH_2CH_2OCOC(CH_3)=CH_2]OCH_3.$$

It is formed as a result of the activation of the adduct of vinyl n-butyl ether and hydrogen iodide by zinc iodide and the step-wise introduction of equimolar quantities of the other three monomers into the reaction mixture. By using 2-(vinyloxy)ethyl methacrylate as one of these (the last one in this case) this tetramer may be considered capable of undergoing addition polymerisation.

Table 1. Synthesis of block copolymers through living polymers corresponding to monomer M_1.[23]

M_1	M_2	Properties of block copolymers	
		$\bar{M}_n \times 10^{-3}$	$\bar{M}_w/\bar{M}_n$
VIBE(38)*	*p*-(*t*-Butoxy)styrene, TBS(100)	17.5	1.08
TBS(38)	*p*-Methoxystyrene, MS(38)	12.0	1.05
MS(38)	TBS(100)	19.0	1.04

Note. Process conditions: initiating system $HI-ZnI_2$ (2:1); toluene as solvent: temperature −15 °C; 100% conversion of each monomer.
*The degree of polymerisation of the monomers is given in brackets.

Block copolymers containing alkoxy derivatives of styrene have recently been obtained using the same initiating system (Table 1). The interaction of the active sites corresponding to different $CH_2=CHOR$ monomers (where R is C_2H_5, iso-C_4H_9, or n-$C_{16}H_{33}$) with a small quantity of the bifunctional vinyl ether $(CH_2=CHOCH_2CH_2OC_6H_4)_2C(CH_3)_2$ as a cross-linking agent resulted in the formation of more complex structures such as star-shaped polymers. Polymers that were completely soluble in toluene and THF were thus obtained with the number of branches ranging from 3 to 60, controlled by the ratio of reagents and the total concentration of the living chains.[24] The value of $\overline{M}_w$ of star-shaped polymers synthesised in this manner is in the region of 2×10^4 to 3.8×10^5 with an average degree of polymerisation of the branches ranging from 38 to 114.

It was pointed out by Higashimura et al.[23,24] that the wide range of polymers synthesised provides a sound basis for their use for various practical objectives.

Let us consider two further points concerning the exact nature of the active sites occurring in the processes described in the studies of Kennedy and Higashimura. Their substantially longer lifetime compared to the carbocations formed in normal cationic systems does not make it possible to identify both these agents. The authors of these studies have taken this into account. The view of Plesch,[25,26]

according to which these processes should be classed as pseudocationic, is stated with considerable clarity in this connection. We should mention that the mechanism of pseudocation polymerisation put forward in the 1960s by Gandini and Plesch (for further details, see four studies)[25–28] is based on the concept of the covalent nature of the active sites occurring in such processes.

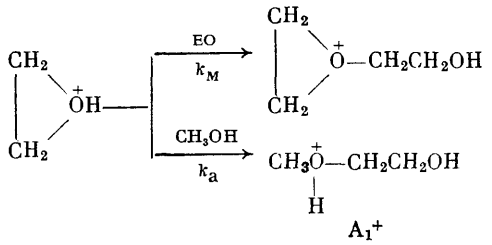
The second point, which is of a more fundamental nature, touches on the question as to whether it is legitimate to define these same active sites as living polymers. This was called into question by Sigwalt in the middle of the 1980s,[29] as was briefly mentioned in an earlier review.[1] In maintaining his point of view subsequently, Sigwalt[30] emphasised that for relatively low values of the degrees of polymerisation (in several of the cited studies they do not exceed 100) the possibility of chain transfer is not excluded, which in cationic polymerisation is usually characterised by C_M constants that do not exceed 10^{-4}. This argument is contradicted by the known facts[15] about the increase of $\overline{M}_n$ with conversion up to values of the order of 10^5 and the possibility of synthesising different block copolymers in these processes with the active sites corresponding to monomer M_1 being completely used up in the formation of products $(M_1)n-(M_2)_m$.[31,32]

Certain deviations from results of this type[1,31] merely attest to the influence of the monomer on the final effect.

2. Mechanism of the cationic polymerisation of oxygen-containing heterocycles

In recent years Penczek et al.[33–37] formulated a new mechanism for the cationic polymerisation of oxygen-containing heterocycles, which the authors called polymerisation via an activated monomer (PAM). This denotes the generation of active sites for propagation via the formation of a protonated monomer (HM^+), which then transfers the proton to a more active acceptor. The protonated acceptor then reacts with a further molecule of monomer. This sequence has been studied in detail in the case of the system $EO-BF_3-CH_3OH$, where EO is ethylene oxide.[33]

For the product HM^+ the following reactions are possible:



(5)

(6)

Route (5), which occurs provided that

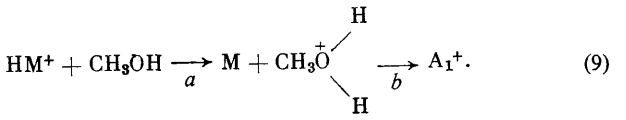
$$k_M[M] > k_a[CH_3OH], \tag{7}$$

leads to active sites of the tert-oxonium ion type, namely, to a trivalent mechanism for cationic polymerisation processes of such monomers. In the presence of a nucleophile with high activity another situation is feasible, namely

$$k_M[M] < k_a[CH_3OH], \tag{8}$$

i.e., the condition under which route (6) occurs.

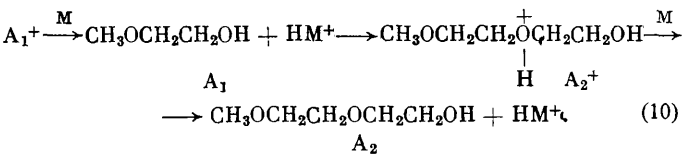
We should note that from the definition by Penczek et al. of route (6) as proton transfer from HM^+ to a nucleophile, this stage may be assumed to occur in two steps



(9)

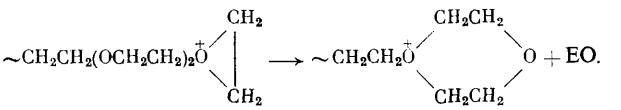
On the basis of the greater nucleophilicity of methanol compared to EO, the authors evidently do not regard stage (9*b*) as probable and assume that there is a concerted single-stage mechanism for formation of a secondary oxonium ion. In the studies cited above this question was not considered.

The subsequent course of this process is given by the scheme



(10)

Its validity is supported by the formation of product A_2. As noted in one study,[33] this compound may also be formed by mechanism (5), but only together with the elimination of a 1,4-dioxan. This possibility arises for active sites of the tert-oxonium ion type which can undergo the following rearrangement:



However, in reaction mixtures obtained by polymerisation in the presence of a sufficient quantity of methanol, only a small amount of dioxan was detected.[33] From this the contribution of the PAM route could be assumed to exceed 98%.[38]

The amount of A_2 in the system, in accordance with condition (8), decreases during the process as a result of its consumption by mechanism (10). The dependence of the contribution of this route to the total process of the methanol content in the system also provides support for mechanism (6). A reduction in its content causes an increase in the role of route (5), which is suggested by the increased yield of dioxan that occurs at the same time (Table 2). The PAM mechanism starts to predominate only when there is a large concentration of methanol. The unfavourable results of these conditions for the molecular-weight characteristics of the polymers can be avoided by operating at a very low concentration of monomer, which is achieved by slow batching of it into the reaction mixture. How this is reflected in a decrease in the role of side reactions and the values of $\overline{M}_n$ of the polymers is indicated by the results of polymerisation of epichlorohydrin by the system boron fluoride–ethylene glycol with complete conversion of monomer[33] (no details were given about the other experimental conditions in this study):

Method of introducing the monomer	Yield of tetramer	$\overline{M}_n$ (calc)	$\overline{M}_n$ (experiment)
Single batch	21	2350	1530
Slow batching	0.01	2100	2100

Results of a similar type were obtained in the polymerisation of propylene oxide (PO) in dichloromethane by $HBF_4 \cdot Et_2O$ in the presence of 1,6-hexanediol. In this case the yield of PO tetramer, which amounts to about 50% when the diol is absent, decreases to 4% when the ratio of monomer to diol is equal to 10.[36] Slow batching of monomer (0.02 ml min^{-1}) reduces the yield of tetramer to 1%. These results relate to room temperature and to a total concentration of monomer of 2.0, initiator of 5×10^{-3}, and diol of 0.2 mol $litre^{-1}$.

Table 2. Effect of methanol on the formation of 1,4-dioxan in the polymerisation of ethylene glycol by $BF_3 \cdot CH_3OH$ in dichloromethane.[33]

[M], mol $litre^{-1}$	$[CH_3OH]/[M]$	Yield of dioxan, %
1.1	2.0	1.1
1.1	3.2	13.4
1.2	6.0	39.5
1.3	17.0	66.5

Note. Process conditions: concentration of initiator 0.03 mol $litre^{-1}$; temperature 25 °C; 100% conversion of monomer.

We should note the effect discovered during polymerisation in the systems $EO-HSbF_6-CH_2Cl_2-CH_3(OCH_2CH_2)_nOH$ at 30 °C. The results presented below represent the total rate constant of polymerisation (k_t, litre mol^{-1} min^{-1}) in the presence of these hydroxyl derivatives (0.5 mol $litre^{-1}$) with a concentration of monomer and initiator of 0.5 and 4×10^{-4} mol $litre^{-1}$ respectively:[36]

n	0	1	2
k_t	8±1	13±2	22±3 .

This result has been interpreted by the authors as the consequence of an increase in the number of processes of type (6) as the oxygen-containing residues in the proton acceptor increase in length.

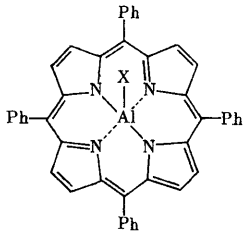
Conditions favouring a PAM mechanism can be used for the synthesis of block copolymers. This has been demonstrated[39] in the polymerisation of cyclic acetals in the presence of poly(ethylene oxide glycol) (PEOG). Thus, in the case of dioxolane and dioxepane on treatment with trifluoromethanesulphonic acid, the formation of products of the general type $HO-M_n-PEOG-M_n-OH$ and their corresponding multiblock copolymers was established.

A general review of the kinetics of PAM processes has recently appeared.[40]

III. Anionic processes

1. Initiating systems based on porphyrin

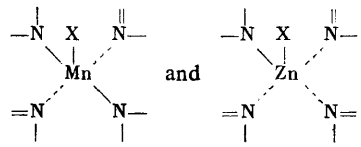
At the beginning of the 1980s the first results were published on the ability of aluminoporphyrin derivatives of the type (IV) to cause the efficient polymerisation of different types of oxygen-containing heterocycles



(IV)

In compounds (IV) the substituent can be a halogen, alkyl, OR or COOR group. These initiators will subsequently be denoted by the symbols TPhPAl–X, with substituent X being specified.

Development of these studies extended the range of initiators of a similar type and their use in the polymerisation of other monomers, including acrylic compounds.[44–48] Subsequently results were published on the initiating activity of certain tetraphenylporphyrin derivatives of manganese[49] and zinc[50,51] towards three-membered heterocycles. These compounds contain central groups that are similar to (IV)



in which X = $OCOCH_3$ in the case of manganese and X = C_2H_5, iso-C_3H_7S, or iso-C_3H_7O in the case of zinc.

Polymerisation of heterocycles. Let us first consider the validity of classifying the mechanism of these processes as anionic. The following circumstance can cast doubts in this respect. Effective polymerisation of the simplest epoxides is achieved when it is carried out in dichloromethane by the action of initiator (IV) with X = Cl. Under these conditions a cationic mechanism for the process could formally be expected. The result obtained in a model system, i.e., with an equimolar ratio of initiator and propylene oxide, would also appear to lend support to this argument. According to the PMR data, this reaction in dichloromethane gives the product $TPhPAl-OCH(CH_3)CH_2Cl$. The insertion of monomer into an Al–N bond would be more natural in anionic polymerisation. On the other hand, the further stages of chain propagation occur through polarisation of the $O^{\delta-}-Al^{\delta+}$ bond. An active $Cl^{\delta-}-Al^{\delta+}$ bond, respectively for initiation, should evidently be regarded in a similar light.

A general characteristic of initiators (IV) with different substituents X is the lack of chain termination in polymerisation caused by them and the formation of narrowly dispersed polymers with $\overline{M}_w/\overline{M}_n$ = 1.05–1.10. This relates, in particular, to epoxides[41] and lactones.[44,45] The individual nature of the initiators is most clearly revealed in the latter case. For example, the compounds

TPhP–AlCl and TPhP–AlCOOR are only active towards β-lactones, and not towards higher lactones. Compounds (IV) with an OR substituent are noted for their initiating activity towards the latter.[48,49]

The polymerisation of δ-valerolactone has been studied in greater detail, and in this case the following noteworthy effect has been identified. The low rate of polymerisation caused by the methoxy derivative of (IV) increases markedly in the presence of TPhPAl–Cl, which by itself is inert under the same conditions towards the same monomer. The scale of this effect is illustrated in Fig. 3.

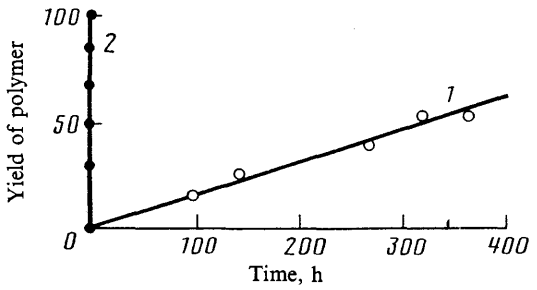


Figure 3. Polymerisation of δ-valerolactone in the absence of a solvent at 30 °C.[48] Initiators: *1*, TPhP–$AlOCH_3$; *2*, TPhP–$AlOCH_3$–TPhP–AlCl. Molar ratios: monomer/TPhP–$AlOCH_3$ = 200:1; TPhP–$AlOCH_3$/TPhP–AlCl = 2:1.

The effect of this chloride has been attributed by Aida et al.[43] to its high complexing activity towards the monomer, as was concluded from the PMR spectroscopic data. The conclusion that this type of complexation has a promoting role is consistent with the order of reaction in the absence and in the presence of this reagent:

$$v = k[\text{TPhPAl}{-}\text{OCH}_3]^2[\text{M}],$$
$$v = k'[\text{TPhPAl}{-}\text{OCH}_3][\text{TPPhAl}{-}\text{Cl}][\text{M}].$$

The effects revealed in a study of the interaction of the active sites corresponding to these initiators with typical deactivators of anionic chains (HCl, ROH, H_2O, etc.) are unusual. In these systems deactivation of the active sites occurs at the same time as regeneration of the initiator, for example

$$\text{TPhAl}{-}\text{M}_n{-}\text{Cl} \overset{\text{HCl}}{\rightleftarrows} \text{TPhPAl}{-}\text{Cl} + \text{H}{-}\text{M}_n{-}\text{Cl}.$$

The high frequency of these exchanges, exceeding the rate of propagation, leads to results that are typical of polymerisation via living chains. This is achieved by the introduction of a mixture of proton donor and monomer into a solution of initiator. Several examples are given in Table 3. A second portion of monomer introduced after complete conversion of the initial portion results in an increase in the molecular weight of the polymer while retaining a narrow molecular weight distribution. This result has been obtained in particular for the system PO–TPhPAl–Cl–CH_2Cl_2–CH_3OH; the final value of $\overline{M}_w/\overline{M}_n$ in this case was 1.09.

Similar results were obtained in the polymerisation of lactones and also with the introduction of a "foreign" monomer into the reaction mixture at the second stage of the process. An EO–PO block copolymer was synthesised in this manner.

Table 3. Polymerisation in R–CH(O)–CH_2–TPhPAl–Cl–CH_3OH systems in the absence of a solvent.[48]

R	Time, h	$\bar{M}_n$	$\bar{M}_w/\bar{M}_n$
H	48	700	1.05
CH_3	48	1300	1.08
CH_3CH_2	96	1200	1.10
CH_2Cl	48	1500	1.04

Note. Process conditions. Molar ratios: monomer/initiator = 200, methanol/initiator = 9; room temperature; 100% conversion of monomer.

On the basis of these characteristics, Inoue et al.[45] introduced the term "immortal polymerisation" for such processes.

Similar effects were recently found in systems incorporating zinc derivatives of tetraphenylporphyrin. This was demonstrated, in particular, for the polymerisation of PO by the system TPhP–$Zn(C_3H_7)S$–CH_3OH. In this case the value of $\overline{M}_w/\overline{M}_n$ corresponding to 100% conversion of monomer was 1.08.

The molecular-weight characteristics suggest that the rate of exchange between active sites and proton donor molecules is much higher than the rate of propagation.

Polymerisation of polar unsaturated monomers. Some of the initiators under discussion have proved active towards methacrylates, but only in the light, according to the original findings.[42] It was subsequently shown to be possible to carry out polymerisation also in the dark provided that initiators (IV) with substituents X = OR or SR were used.[46] An example of this is the polymerisation of methyl methacrylate (MMA) in dichloromethane at 35 °C by TPhP–$AlSC_3H_7$. With a ratio of MMA:(IV) = 200:1 and complete conversion of monomer, a polymer with $\overline{M}_n = 2.2 \times 10^3$ and $\overline{M}_w/\overline{M}_n = 1.12$ was obtained.

Use of initiator (IV) with X = SPh achieves results of a similar type. A linear dependence of $\overline{M}_n$ on the degree of conversion and formation of polymer with $\overline{M}_n = 3 \times 10^4$ and $\overline{M}_w/\overline{M}_n = 1.1$ has been established in this case.

Information on nitrile monomers is currently limited to data on the polymerisation of methacrylonitrile (MAN) by propagating MMA chains. An MMA–MAN block copolymer was obtained in this case.

We should note that the possibility of polymerising these monomers in the dark depends not only on the nature of the initiator but also on the selected reaction temperature. Thus,

polymerisation of PO by TPhPZn–SC_3H_7 occurs in the light at 25 °C but is also achieved in the dark at 70 °C; the $\overline{M}_w/\overline{M}_n$ values in these cases were 1.05 and 1.07 respectively.[51]

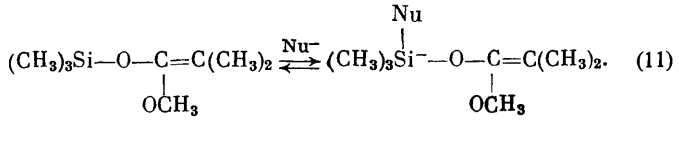
2. Group transfer polymerisation

The first publication of Webster et al.[52] concerning a new method of anionic polymerisation, established under the name of group transfer polymerisation (GTP), appeared in 1983. The mechanism of GTP differs fundamentally from other known polymerisation processes in that each stage of addition of the next monomer molecule to the growing chain combines initiation and propagation, concluding with reproduction of the structure that in principle matches that of the original initiator.

The method is based on the use of mixtures of *O*-silyl ketals of ketenes with nucleophilic or electrophilic compounds. According to the accepted terminology, the first of these components are called initiators and the second are known as catalysts. Nucleophiles such as HF_2K, $FNBu_4$, and certain others or electrophilic compounds of the Lewis acid type such as zinc halides can function as catalysts. Nucleophilic catalysts have proved more convenient for the polymerisation of methacrylates, to which most of the studies on GTP have been devoted.

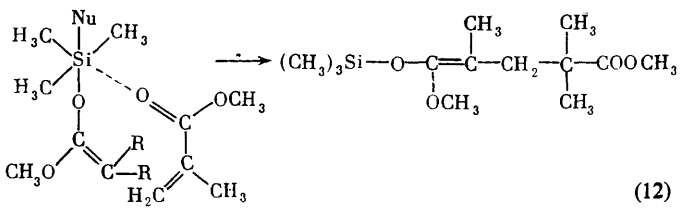
An important advantage of these processes over polymerisation of the same monomers using conventional anionic initiators (organometallic compounds) is that propagation of the living chains is not complicated by side reactions† even at room temperature. This characteristic of GTP considerably simplifies the synthesis of narrowly dispersed polymers—a task of considerable practical significance. Even with the normal technique (simultaneous introduction of the whole portion of monomer into the reaction mixture), $\overline{M}_w/\overline{M}_n$ for the MMA polymers is equal to 1.3, while with slow batching of the monomer, $\overline{M}_w/\overline{M}_n$ = 1.01. This property has substantially simplified the synthesis of block copolymers of different methacrylates, including hybrid macromolecules of the type A–B–C.

The scheme put forward by Webster et al.[54,55] to interpret the mechanism of GTP involves the formation of a pentacoordinate silicon derivative in the reaction between initiator and catalyst, which has been demonstrated for the simplest example of ketene *O*-silyl ketals and a nucleophile (Nu^-), which may be an F^- or HF_2^- ion.



(11)

The product of this reaction interacts with the monomer to form an intermediate hexacoordinate silicon derivative, rearrangement of which completes the propagation step. We can illustrate this in the case of methyl methacrylate (MMA), where R = CH_3:



(12)

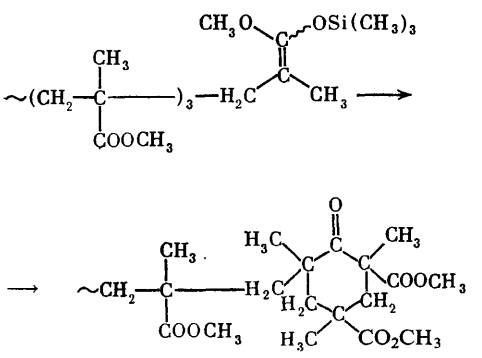
† The mechanism and results of these reactions are examined in detail in another review.[53]

The existence of an intermediate has not been confirmed experimentally, but the results of nonempirical calculations, referred to in a study by Müller,[56] provide evidence for it. However, the conclusion that there is a combination of initiation and propagation steps at each stage of the insertion of monomer into the polymer chain is valid. The final product of reaction (12) interacts with the nucleophile according to scheme (11), thus achieving the further progression of polymerisation.

In practice, tris(dimethylamino)sulphonium difluoride (DSDF) has been used to a relatively greater extent than other nucleophiles. Amongst the reaction products in systems in which it involved, triple block copolymers of MMA with n-butyl and allyl or glycidyl acrylates have been synthesised. Kinetic studies were carried out with DSDF and the simplest of the ketene *O*-silyl ketals. Let us consider the results of Müller et al.[57]

Standard conditions were selected: THF as solvent, temperature 20 °C, concentrations of monomer, initiator, and catalyst equal to 0.18, 1×10^{-3}, and 2×10^{-6} mol litre^{-1} respectively. One of these parameters was varied, keeping the remaining conditions constant. With a concentration of catalyst $\leqslant 3 \times 10^{-6}$ mol litre^{-1}, rapid initiation occurred with a propagation reaction that was first-order with respect to this reagent. With a concentration of catalyst $> 3 \times 10^{-5}$ mol litre^{-1} the initial stage of polymerisation was characterised by an induction period and the rate of reaction then passing through a maximum. However, the decrease in rate of polymerisation due to termination stages did not prevent the complete conversion of monomer. When the concentration of initiator was varied, similar effects—an induction period and a curve with a maximum on the conversion/time coordinates—occurred in the region of higher concentrations of this reagent. The authors assume that in this case these are due to the deactivating effect of excess initiator rather than as a result of termination.

A study by Brittain and Dicker,[58] in which the behaviour of short-chain oligomers of this type was studied under standard conditions, has shed light on the question of the mechanism of termination reactions in GTP processes. MMA–(1-methoxy-2-methyl-1-propenyl)oxytrimethylsilane (P_1^*) was chosen as the initial system, with ratios of MMA/P_1^* equal to 2 and 3. Under the conditions employed (THF, tetrabutylammonium dibenzoate as catalyst, room temperature) oligomerisation of MMA is complete after 2 min. The IR characteristics of deactivated samples of the reaction mixture taken after different intervals of time indicated a gradual decrease in intensity of the absorption band due to the C=C bond (1687 cm^{-1}) together with the appearance and increase in intensity of an absorption band due to a carbonyl group (1716 cm^{-1}). These effects were attributed to intramolecular cyclisation of the active sites:[58]



In a determination of the rate of cyclisation of the oligomers based on the change in intensity of these bands, good agreement was obtained for the results calculated for each of the IR properties: 0.009 and 0.010 mol litre^{-1} s^{-1} for the C=O and C=C groups respectively. The authors emphasised that the role of this reaction is important only in the absence of monomer. According to their results, under real polymerisation conditions the ratio of the rate of propagation to the rate of deactivation by this mechanism is 2600.[58]

Of the other monomers that display an ability to undergo GTP, acrylates, methyl vinyl ketone, acrylonitrile, and pentadiene- and hexadiene-carboxylate esters are mentioned in the literature.

GTP processes are of definite practical value because of the possibility of using such initial reagents that can be used to synthesise polymers with reactive terminal groups. In particular, initiators containing the group $\geqslant C(OSi(CH_3)_3)O(CH_2)_2OSi(CH_3)_3$ are of this type. On hydrolysis of the polymers obtained by GTP involving these initiators, macromolecules with terminal OH groups are formed.

An interesting development for GTP processes was made in a study by Miller et al.,[59] the subject of which was an investigation of the possibility of extending the rate of nucleophiles through the reaction of different crown ethers with alkali metal salts. This was successfully carried out in the case of a system containing $(CH_3)_3Si-O-C=C(CH_3)_2$ (OCH$_3$), dibenzo-18-crown-6, and potassium acetate. When the crown ether was absent, this system was inert towards MMA, whereas by using a three-component system with this composition it was possible to obtain PMMA in 92% yield with $\overline{M}_w/\overline{M}_n$ = 1.9 (acetonitrile as solvent, temperature 50 °C).

A comprehensive description of the experimental details of the synthesis of the initial reagents, the effects on GTP of varying them, and the characteristics of the resulting polymers appear in a study.[55] Replacement of Si initators by their Sn and Ge analogues is included amongst the points mentioned in it.

A detailed comparison of the process characteristics of normal anionic polymerisation of methacrylates and the behaviour of the same monomers in GTP processes has been carried out by Müller.[56,60] The distinct nature of the latter does not prevent them from being classified under the general title of anionic-type reactions.

IV. Processes initated by Ziegler–Natta catalysts

In the Russian literature of recent years that has been devoted to problems of catalytic polymerisation,[61–64] there has been no review of the polymerisation of olefins by homogeneous Ziegler catalysts, which has undergone a particular rapid development during these years.

At the early stage of research into these processes, homogeneous systems were regarded as a convenient subject for studying the mechanism of polymerisation. For a long time they had no practical use, since all of the known systems of this type were considerably inferior to heterogeneous systems of a similar nature, differing from them through having much lower values of the rate constants of propagation and by their inability to form stereoregular polymers.

At the beginning of the 1980s the development of homogeneous Ziegler systems acquired a "second wind" as a result of the production of catalytic complexes of extremely high activity, surpassing the activity of heterogeneous systems of the same type. The replacement of aluminium alkyl and haloalkyl compounds, which were extensively used as components of a large number of Ziegler–Natta catalysts, by aluminoxanes in combination with derivatives of certain transition metals led to this situation.

The first results on highly active soluble catalysts of this type were obtained by Sinn, Kaminsky et al.[65,66] for systems containing aluminoxanes and zirconium or titanium compounds. In particular, in the polymerisation of ethylene by an initiating system based on a cyclic methylaluminoxane containing 10–20 OAl(CH$_3$) groups and the compound $Cp_2Zr(CH_3)_2$, where Cp = cyclopentadienyl, the value of the propagation constant k_p was 10^5 litre mol^{-1} s^{-1} (data for 90 °C).[67] It is approximately 10^4 times higher than those values which are known for conventional homogeneous initiating systems and $10^1-10^{1.5}$ times higher than the kinetic parameters relating to heterogeneous catalysts.[68] The relative activity of certain other systems based on the same type of aluminoxane are briefly indicated by the data in Table 4.

Table 4. Polymerisation of ethylene by soluble complexes of methylaluminoxane with compounds of Group IV metals with a constant pressure of monomer.[67]

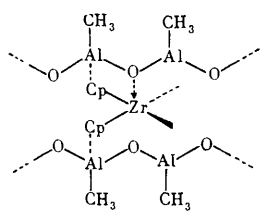
Compound	Concentration, mol litre^{-1}	t, °C	Activity of system, g polymer (g M*)$^{-1}$ h 100 kPa
$Cp_2Ti(CH_3)_2$	$3\cdot10^{-6}$	20	500
$Cp_2Ti(CH_3)Cl$	$3\cdot10^{-6}$	20	50 000
$Cp_2Zr(CH_3)_2$	$1\cdot10^{-7}$	20	9 000
$Cp_2Zr(CH_3)_2$	$1\cdot10^{-7}$	70	700 000
Cp_2ZrCl_2	$3\cdot10^{-8}$	70	1 000 000
$Cp_2Hf(CH_3)_2$	$3\cdot10^{-8}$	70	60 000

Note. process conditions: concentration of aluminoxane based on a single unit 1.5×10^{-2} mol litre^{-1}; monomer pressure 800 kPa.

*Transition metal.

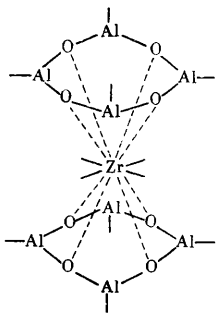
We should note the considerably higher concentration ratio of Al to transition metal in these examples compared to those normally used in Ziegler processes. The above-mentioned high efficiency of the alumino-zirconium system is provided by the very small concentration of the transition metal compound but only with a large excess of aluminoxane (see Table 4). When its concentration is reduced to a value exceeding that of the zirconium component even by a factor of 10^2-10^3, the activity of the system decreases sharply.[66]

On the basis of this phenomenon, Kaminsky et al.[66] attributed to the active agents structure (V), the formation of which requires a large excess of aluminoxane.

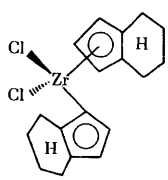


(V)

The kinetics of formation of the catalytic complex, corresponding to first and second order with respect to the zirconium and aluminium components respectively, are consistent with this. We should note, however, that structure (V) has no experimental support, although it seems plausible for linear aluminoxanes. For cyclic aluminoxanes it is necessary to take into account the increase in promoting effect of these compounds together with the increase in the number of >Al−O− residues contained in it.[65] It may be assumed from this that polyligand structures are formed in systems involving cyclic aluminoxanes, as is shown schematically in the case of a four-unit aluminoxane:[69]



Many of the same catalysts have been used for efficient polymerisation of propylene,[67] but it was only possible to improve on the synthesis of atactic polymers when a zirconium bis(indenyl) derivative with ligands rigidly connected by an ethylene bridge was used:[70]



The use of the *l*-enantiomer of this compound in combination with methylaluminoxane resulted in the formation of polypropylene with the following properties (toluene as solvent, temperature 10 °C)

Fraction*	Content of isotactic triads, %	$\bar{M}_n \times 10^{-4}$	$\bar{M}_w \times 10^{-3}$
Soluble in boiling heptane	96.0	1.77	4.96
Insoluble in boiling heptane	98.6	8.90	22.78

*Relative proportions of the fractions not indicated.

The above results contradict the idea that the use of insoluble Ziegler–Natta complexes is obligatory for carrying out the stereospecific polymerisation of olefins.

Recently Kaminsky[71] prepared a number of novel catalysts based on chiral zirconocenes in combination with methylaluminoxane that effected the synthesis of isotactic polyolefins. Some of these catalysts for the first time opened up the possibility of the polymerisation of cyclic olefins (cyclobutene, cyclopentene, etc.) without the complication of ring opening.

The studies of Kaminsky and Sinn[65–67,70,71] do not contain the physicochemical characteristics of the catalysts mentioned. Let us therefore introduce the data of Fink et al.[72,73] that relate to one of the simplest homogeneous aluminotitanium systems, namely, $Cp_2TiEtCl-EtAlCl_2$. They are worthy of attention mainly because they provide the first direct evidence for the insertion of monomer into the bond of the carbon atom of the active site with a transition metal. This follows from a detailed analysis of the ^{13}C NMR spectra of this system in the absence and in the presence of ethylene.[73] Kinetic studies by the same authors, which suggest that there is a two-stage mechanism for formation of the active sites in systems of the general type $Cp_2TiRCl-EtAlCl_2$, where R = alkyl, are of considerable interest.[74–76] This conclusion is based on the lack of initiating activity in the 1:1 complex indicated below as C_1:

$$Cp_2TiRCl + {}^1/_2(EtAlCl_2)_2 \overset{K_1}{\rightleftarrows} C_1. \qquad (13)$$

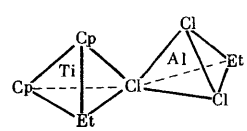
Only when it reacts with an excess of the aluminium component does it give rise to the formation of an active site (C*), which is accompanied by the formation of a dimeric aluminium derivative (Al_2') of an undetermined nature

$$C_1 + (EtAlCl_2)_2 \overset{K_2}{\rightleftarrows} C^* + Al_2'. \qquad (14)$$

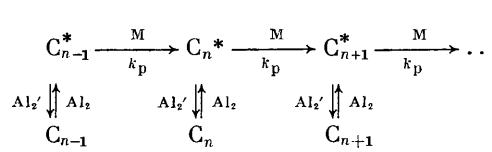
According to Eqns. (13) and (14), an increase in the original ratio of Al to Ti increases the initial rate of polymerisation of ethylene.

From the intensity of the ^{13}C NMR signals due to the $Ti-CH_2$ group, limiting values of $5 \times 10^{-3} \geqslant K_1 \geqslant 5 \times 10^{-4}$ litre mol^{-1} at −33 °C have been calculated for the equilibrium constants of Eqn. (13), while for K_2 a value of the order of 10^{-3} litre mol^{-1} was obtained.

The results that followed from an analysis of the ^{13}C NMR spectra (reduction in electron density on the titanium atom, absence of bridging methylene groups) led the authors to conclude that the C_1 complex probably exists in the form of the structure



The results of studies by Fink et al.[74–76] were used for mathematical simulation of the processes studied, which by neglecting chain termination and chain transfer made it possible to determine the rate constants of the successive propagation steps corresponding to the scheme



According to the calculations carried out, the value of k_p depends on the size of R up to R = C_5H_{11} in the component Cp_2TiRCl (data for ethylene at 283 K):[76]

Reaction	$C_2 \xrightarrow{M} C_4$	$C_3 \xrightarrow{M} C_5$	$C_4 \xrightarrow{M} C_6$	$C_5 \xrightarrow{M} C_7$	$C_6 \xrightarrow{M} C_8$
k_p, litre mol^{-1} s^{-1}	120—140	96	62	48	47.

By using a flow method with a rate of flow 2 m s^{-1} that made it possible to control the kinetics of oligomerisation and starting with a reaction time equal to 0.095 s, it was possible to characterise the dependence of the rate of the process on the concentration of monomer while retaining homogeneity of the reaction mixture. As a result the reaction was established as first-order with respect to monomer.[76]

* * *

Each of the trends in research examined here has developed rapidly, considerably strengthening ideas about the mechanism of the formation of macromolecules in ionic systems. Of no less importance are the studies reviewed here on the synthesis of polymers with practical value. This relates in particular to the preparation of various block and multiblock copolymers based on the use of different types of novel initiating systems.

Heterocyclic bifunctional monomers in the synthesis of polymers

R D Katsarava, D P Kharadze
Institute of Molecular Biology and Biological Physics, Georgia Academy of Sciences, Tbilisi

ABSTRACT. One of the variations of activated polycondensation, the "active ring" method is reviewed. The method consists essentially of the reaction of *bis*- and polyfunctional nucleophiles with monomers containing various heterocycles (three-, four-, five- and six-membered rings) as the electrophilic functional groups. Polyaddition reactions in which the heterocycle is opened are examined. It is demonstrated that many of the discussed reactions are promising for the synthesis of functionalised polymers that are often unattainable using traditional polycondensation methods.

The bibliography includes 139 references.

I. Introduction

Heterochain polymers traditionally are synthesised using high-temperature or low-temperature polycondensations. The latter is based on the use of activated monomers such as dichloroanhydrides, *bis*-chloroformates and *bis*-carbamoylchlorides, diisocyanates, etc.[1–5]

Recently new polycondensation methods based on novel methods of activating monomers and arbitrarily called "activated polycondensation" have become widespread. Five principal directions have been defined.[6] Two of the methods of activated polycondensation, "direct polycondensation"[7,8] and the "leaving group" method,[6] have been analysed in the cited references.

The present review treats a third type of activated polycondensation, the "active ring" method.

The method consists essentially of the polycondensation of heterocyclic compounds of increased reactivity due to intramolecular electronic effects or strain in the ring with nucleophiles. During the reaction the ring opens†, often under mild conditions. The resulting polymers are difficult to produce using other polycondensation methods. This is especially true of functionalised polymers. The review does not include reactions involving dianhydrides of tetracarboxylic acids, upon which the synthesis of thermally resistant polyimides is based. These have been thoroughly discussed in numerous monographs and reviews (for example, see Refs. 9–11). Reactions occurring without opening of the heterocycle, for example, copolymerisation (also a polyaddition process) or polycondensation involving the heterocycle, also are not included. These have been reviewed before.[12]

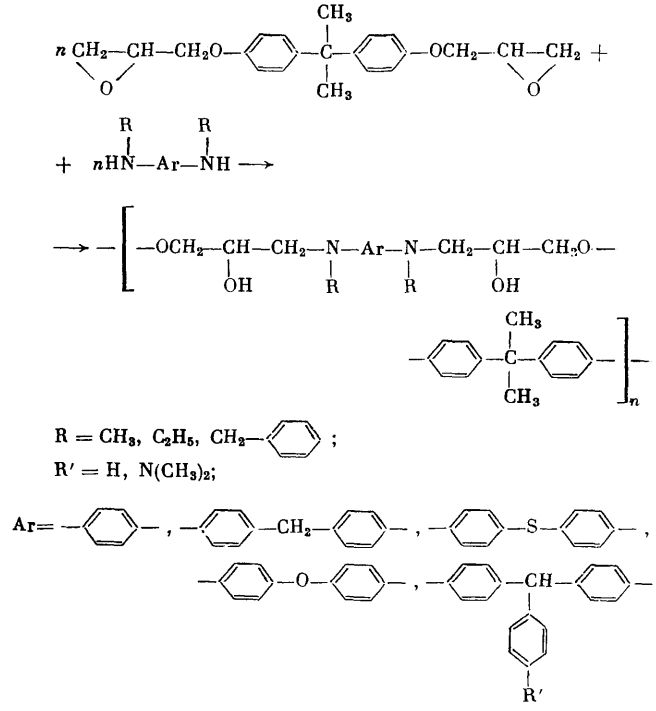
In the present review, we attempted to correlate examples of the use of various bifunctional heterocyclic monomers in polyaddition reactions with ring opening[12] and to describe some of the properties of the polymers formed.

Three-, four-, five- and six-membered heterocycles containing O, N, or O (more rarely S) and N together are discussed separately.

II. Three-membered heterocycles

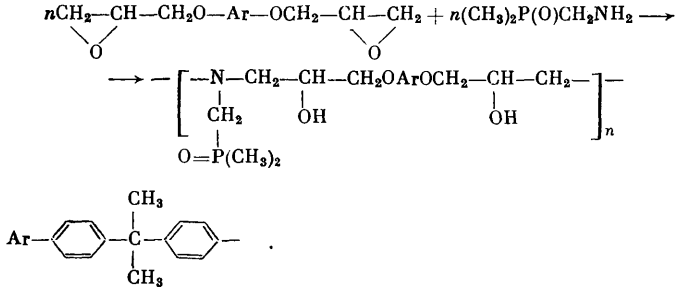
1. *bis*-Epoxides. The role of epoxides in the chemistry of high-molecular-weight polymers is well known. The present review is not concerned with the widespread processes that use epoxide resins. Only certain comparatively new polymer-synthesis reactions involving monomers containing oxirane rings are discussed.

It is known that diepoxides react with diamines by forming crosslinked polymers.[13,14] Hoerhold, et al.[15,16] successfully synthesised linear polymers ($M_n = 8-18 \times 10^3$) of polyamines with hydroxyl side groups by reacting *bis*-glycidyl ethers of *bis*-phenol-A with *N,N'*-alkyl-substituted aromatic diamines:

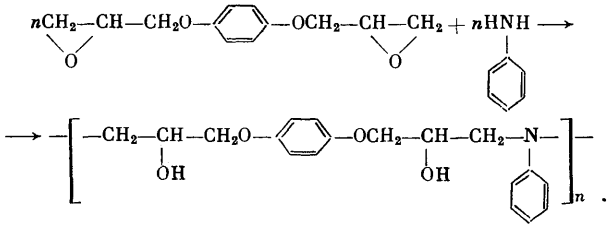


†Such polymerisation processes can be categorised as "multiple addition reactions with ring opening".

Using a phosphorus-containing primary monoamine as the monomer, linear polyaminohydroxy-ethers (M_n = 12.2 × 10^3) with increased fire-resistant properties are produced:[17]



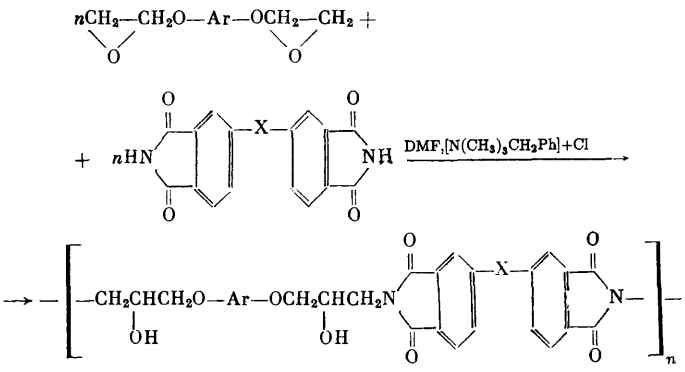
Iwakura, et al.[18] effected an essentially similar reaction by using aniline as the nucleophilic monomer:



This resulted in linear polyhydroxyaminoethers capable of forming fibres.

An interesting feature of the above reactions is that the primary amines exhibit a practical functionality (Φ_{pr}) of two.[19]

The reaction of bisimides with diepoxides[20] produces linear polyhydroxyalkylimides that are soluble in polar aprotic solvents (η_{inh} = 0.10–0.19 dl g^{-1}):



Ar =  ;

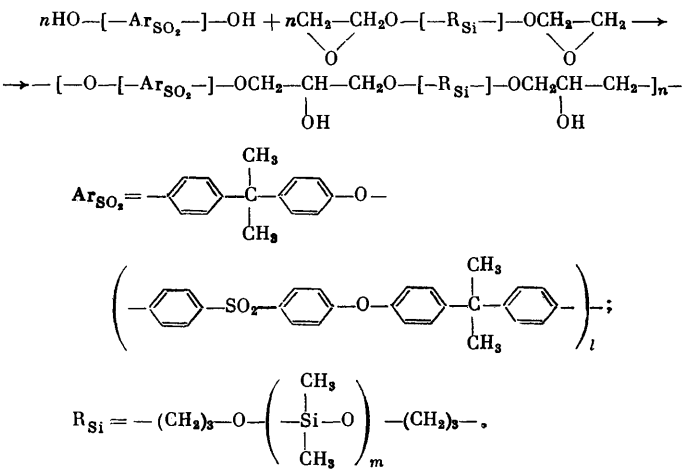
X = CO, COOROCO, CONHR'NHCO;

R = —$(CH_2)_2$—, —$(CH_2)_6$—, —$(CH_2)_{10}$—, , ,

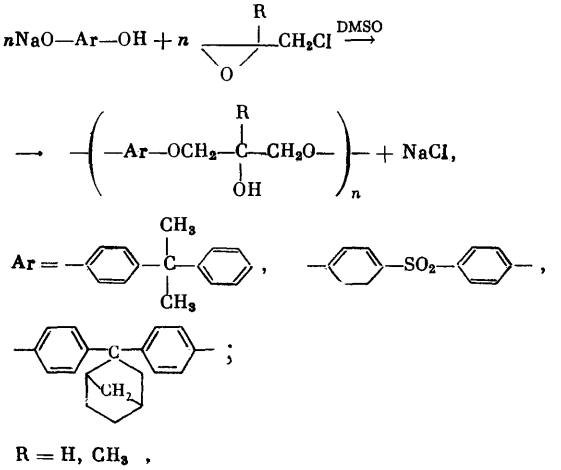
 ;

R' = —$(CH_2)_6$—, —$(CH_2)_{12}$—,  ,  .

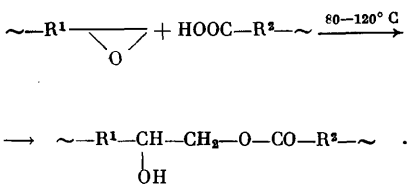
Having investigated in detail the model reaction between phenol and the epoxide ring in a melt,[21] Marechal, et al.[22] successfully used it to synthesise simple polyethers containing hydroxyls, in particular, block polyethers, through the reaction of α,ω-diphenyloligosulphones with α,ω-diepoxyoligosiloxanes:



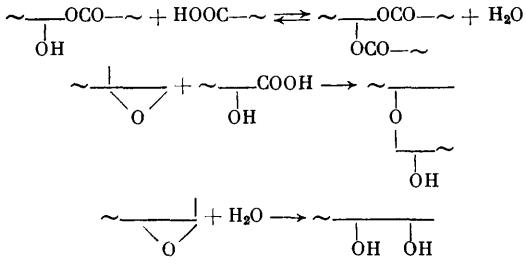
Rokicki and Kuran[23] prepared simple polyethers containing hydroxyls in one step without preliminary synthesis of the *bis*-glycidyl ethers:



Based on a detailed study of the reaction of epoxides with carboxylic acids, linear polyesters could be synthesised according to the scheme:[24–26]



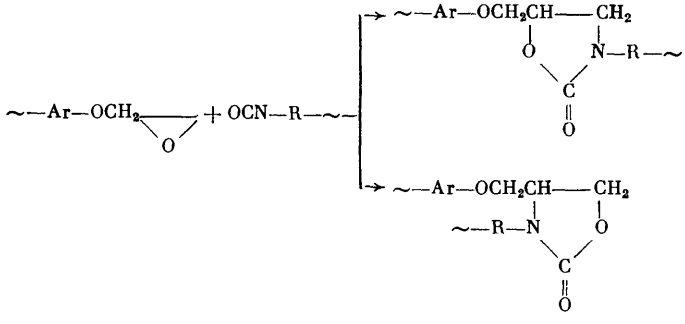
It was found that side reactions including those involving side hydroxyl groups that lead to crosslinked polymers occur only at higher temperatures.



Use of Cr^{III} diisopropylsalicylate instead of tertiary amines as catalyst helps to suppress these undesired reactions.

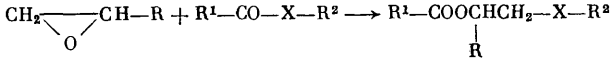
The prepared polyesters with side hydroxyl groups are capable of further polymeric conversions and can have practical application, for example, as biodegradable carriers of bioactive substances etc.

Frisch, et al.[27,28] established that the reaction of *bis*-glycidyl ethers with diisocyanates can be used to synthesise polyoxazolidones. Two isomeric rings are formed, the ratio of which depends on the reaction temperature:



The synthesis of polyoxazolidones through reaction of epoxides with isocyanates are examined in greater detail in a review.[29]

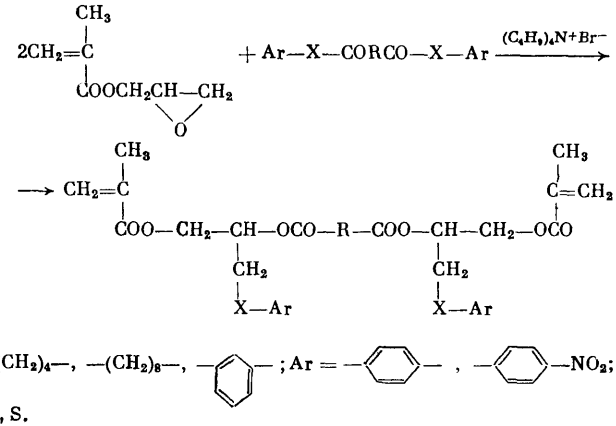
Korshak, et al.[29–32] discovered an interesting insertion reaction of oxirane rings into the bond to the heteroatom (esters and amides):



X = O, NH.

These reactions were used to modify the properties of polyesters and polyamides by reacting them with epoxide resins.

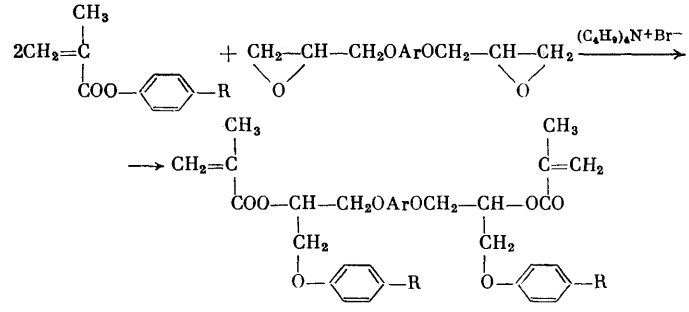
Nishikubo, et al.[33,34] also found that glycidyl ethers react with activated diesters of dicarboxylic acids according to the insertion scheme mentioned above. The reaction occurs under conditions enabling the readily polymerising double bonds to be preserved:

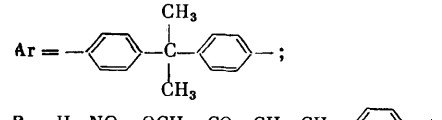


R = $-(CH_2)_4-$, $-(CH_2)_8-$, ; Ar =

X = O, S.

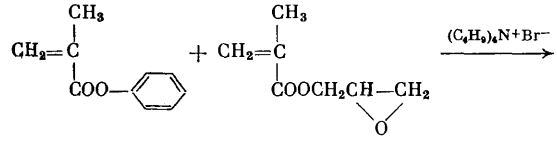
Bifunctional unsaturated monomers were also obtained by an alternative scheme:

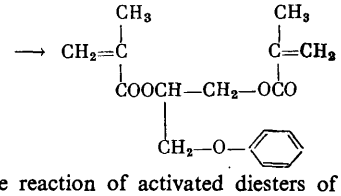




R = H, NO_2, OCH_3, CO—CH=CH— etc.

or

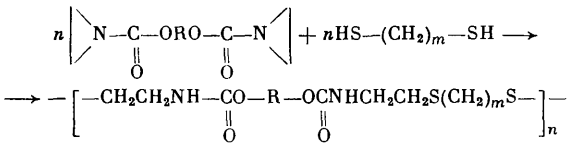




The reaction of activated diesters of dicarboxylic acids with the oxirane ring that occurs at elevated temperatures was also used to harden epoxide resins.[34]

The insertion reactions described above can apparently be used to synthesise linear polymers, converting them into bifunctional compounds. Such processes would be promising for preparation of functionalised polymers.

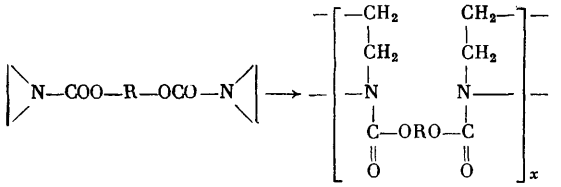
2. Aziridine derivatives. Iwakura, et al.[18,35] already at the start of the 1960s proposed an original synthesis of high-molecular-weight ([η] ≤ 1.4 dl g^{-1}) polyurethane sulphides. The method consists essentially of alkylation of dimercaptans with polymethylene-*bis*-(*N,N*-ethyleneurethanes) in DMF at 75–120 °C in the presence of triethylamine:



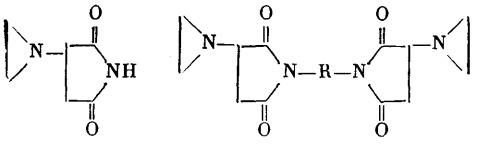
where R = $-(CH_2)_{4-6}$, *trans*-1,4-cyclohexyl, and *trans*-hexahydro-1,4-xylenyl.

It was found that the polyurethanesulphides prepared by this polyaddition scheme are slightly more heat resistant than analogous polymers synthesised by interphase polycondensation of the corresponding *bis*-chloroformates with polymethylene-*bis*-(β-aminoethylthioethers). The other characteristics of the polymers are completely identical.[35]

At elevated temperatures (in the absence of the dimercaptan), *bis*-(*N,N*-ethyleneurethanes) polymerise with ring opening to form polymers that are insoluble in organic solvents:



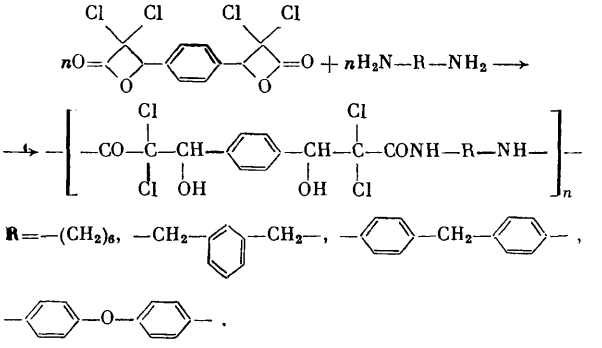
The molecules 3-(1-aziridinyl)succinimide and *N,N'*-alkylene-*bis*-(1-aziridinyl)succinimides were also suggested as monomers.[36]



These compounds polymerise at 125 °C in the melt with opening of the imide and imine rings to form crosslinked polymers. Under the appropriate conditions they can be used in linear polycondensation.

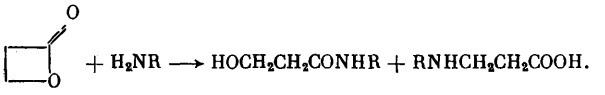
III. Four-membered heterocycles

***bis*-β-Lactones.** It is known that β-lactones are highly reactive toward nucleophiles due to strain in the four-membered ring.[37] This feature was successfully used by Ueda, et al.[38] to synthesise high-molecular-weight polyamides containing hydroxyls ($\eta_{inh} \leqslant$ 1.12 dl g^{-1}) through reaction of 3,3'-*p*-phenylene-*bis*-(2,2-dichloro-β-propiolactone) with diamines:



It is noteworthy that the high-molecular-weight polyamides are formed even with aromatic diamines under mild conditions (20 °C in nonpolar dioxane, although the reaction does indeed take 12 days).

It was found that aminolysis of this *bis*-β-lactone occurs exclusively with cleavage of the O-acyl bond whereas the O-alkyl bond also breaks in the unsubstituted propiolactone to form the *N*-substituted β-aminoacid:

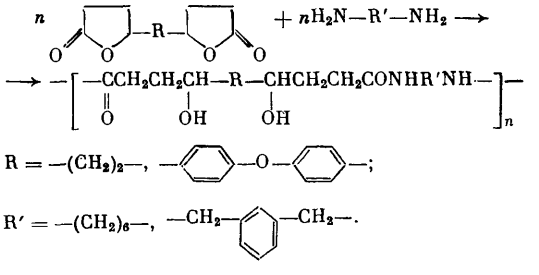


Apparently the two Cl atoms affect the *bis*-lactone and additionally activate the carboyl group.

IV. Five-membered heterocycles

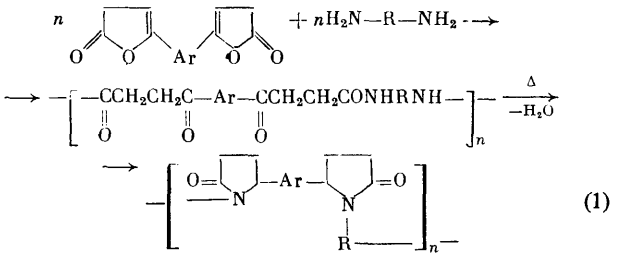
1. *bis*-γ-Lactones

Unsaturated γ-lactones are much less reactive than β-lactones. However, they are more reactive than the corresponding linear analogues, alkyl esters of carboxylic acids, which are exceptionally unreactive toward aminolysis.[39–43] Reaction of a *bis*-γ-lactone with aliphatic diamines (65–80 °C, 20 days, in alcohols and diethyleneglycol) produces hydrophilic polyamides containing hydroxyl groups with $\eta_{inh} \leqslant 0.53$ dl g^{-1}.[44,45]

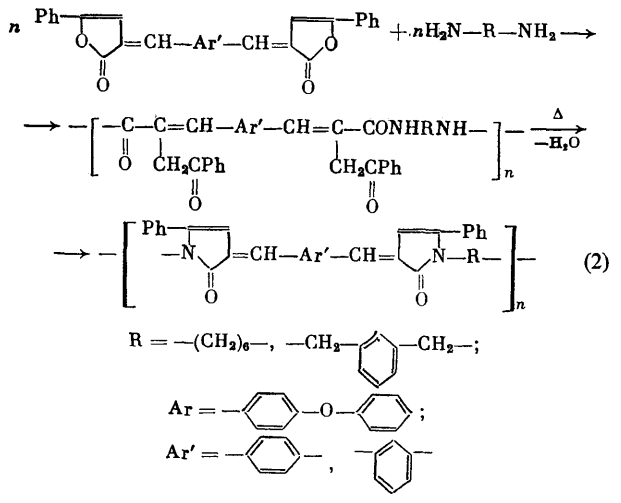


Unsaturated *bis*-γ-lactones are more reactive toward aminolysis. They react with aliphatic diamines to produce polyamides with $\eta_{inh} \leqslant 0.8$ dl g^{-1}.[45,47] In this instance the effect of ring strain is apparently not "innocent" since the unsaturated lactones are cyclic

analogues of vinyl esters, which are more reactive toward aminolysis than their saturated analogues.[39] This is due to the greater electronegativity of a vinyl group compared with an alkyl group. An additional driving force for starting with an unsaturated alcohol is the ease of isomerisation into a stable ketone. Here we note that whereas the reaction of diamines with unsaturated *bis*-lactones forms polyamides containing hydroxyl groups, reaction with unsaturated *bis*-lactones produces polyketoamides containing keto groups in the main [Reaction (1)][47] or side [Reaction (2)] chain:[46]

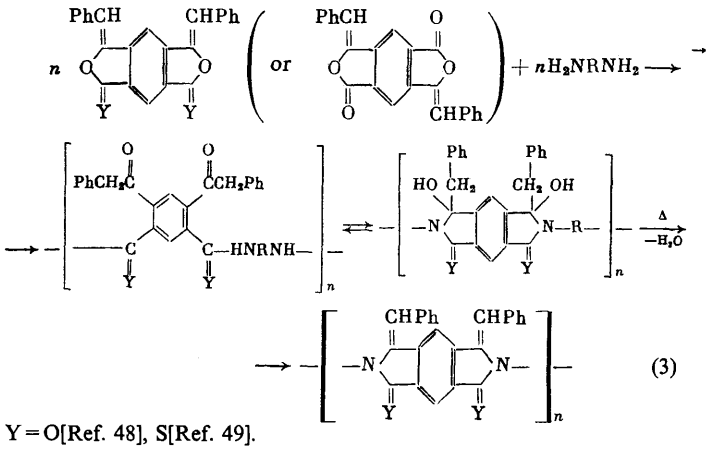


(1)



(2)

The *bis*-benzylidene derivatives of pyromellitic[48] and pyromellitdithioic[49] anhydrides (pyromellitides) react analogously with diamines:



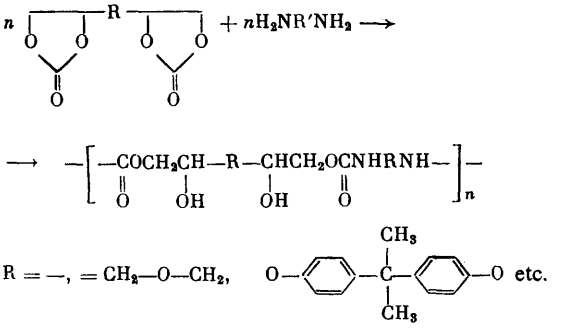
(3)

Y = O[Ref. 48], S[Ref. 49].

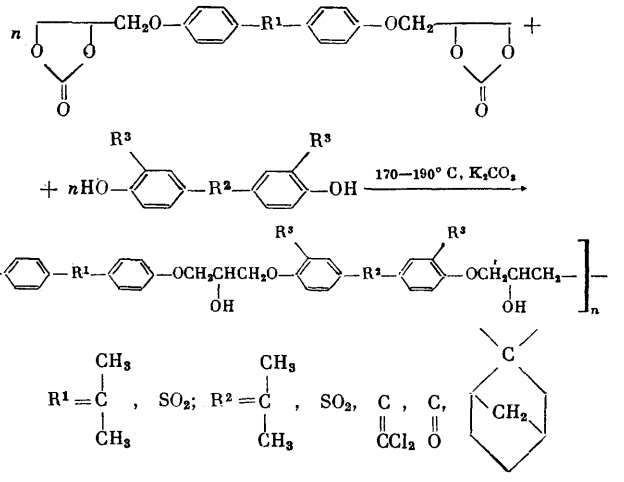
Other 3,5- and 3,7-disubstituted pyromellitides (for example, see Ref. 49 and references cited above) have also been synthesised. It has been demonstrated that benzylidene-substituted pyromellitides are more reactive toward diamines than phenyl-substituted ones and that those containing S are more reactive than the analogues containing O. Polyimidines with good heat resistance and solubility in organic solvents are obtained by cyclodehydration of the intermediate polyketoamides [or the cyclic hydroxy forms, see Reaction (3)]. It is noteworthy that the polyketoamides mentioned above [see Reactions (1) and (2)] also undergo cyclodehydration to the corresponding polymeric heterocyclic compounds.

2. Cyclic *bis*-carbonates

Cyclic *bis*-carbonates also readily react by ring opening and polycondensation with aliphatic diamines. Thus, hydrophilic polyurethanes ($[\eta] \leqslant 1.0$ dl g^{-1}) containing hydroxyl groups are formed:[50–53]



It was found[54] that cyclic *bis*-carbonates in the melt or in a polar aprotic solvent (DMSO, sulpholane) at 170–190 °C in the presence of K_2CO_3 alkylate *bis*-phenols, forming simple polyethers‡ containing hydroxyl groups ($[\eta]$ = 0.3–0.7 dl g^{-1}):



R^3 = H, CH_3.

The synthesis of polymers through reaction of anhydrides of unsaturated dicarboxylic acids (maleic, itaconic, cyclohexen-1,2-dicarboxylic, etc.) with cyclic carbonates (ethylene- and

‡ Polymers of this class are also obtained through reaction of *bis*-phenols with diepoxides or epichlorohydrin (cf. Part II).

propylenecarbonate) has been reported. Depending on the reaction conditions, either crosslinked or linear polymers with $\eta_{inh} \leqslant 0.21$ dl g^{-1} are formed.[55] This reaction apparently can be extended to cyclic *bis*-carbonates.

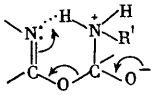
Syntheses involving cyclic *bis*-carbonates are rather attractive since, on one hand, monomers are obtained through reaction of diepoxides (of independent interest as starting monomers, cf. Part II) with CO_2 and, on the other, polymers, in particular, polyurethanes, are obtained by a scheme avoiding use of highly toxic phosgene.

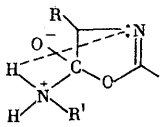
3. *bis*-Azlactones

a) Saturated *bis*-azlactones

Some of the first representatives of cyclic bifunctional monomers of this class were saturated azlactones, 2,2′-*p*-phenylene (or polymethylene)-*bis*-(oxazoline-5-one). These were first synthesised by cyclisation of *N,N′*-diacyl-*bis*-α-aminoacids§ and used to synthesise polymers by Cleaver and Pratt in 1955.[56,57]

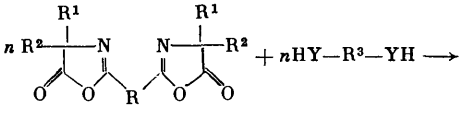
It is noteworthy that azlactones contain the isoimide structural moiety $-N=C-O-CO-$, which is distinguished by a great propensity to react with nucleophiles.[58–60] Adducts of carbodiimides and carboxylic acids containing analogous structural elements also are exceptionally reactive toward nucleophiles.[61,62] This feature along with the ring strain apparently is responsible for the high acylating potential of azlactones. However, it must be mentioned that aminolysis in linear isoimides can be accelerated owing to the freedom of intramolecular rotation taking into account anchimeric assistance from the isoimide N atom in the transition complex. This should be hindered in the cyclic analogues (azlactones) although the existence of a similar effect in the latter instance also cannot be completely ruled out:



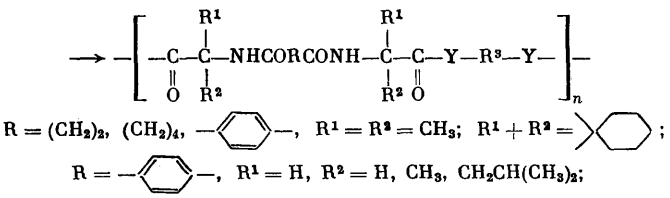


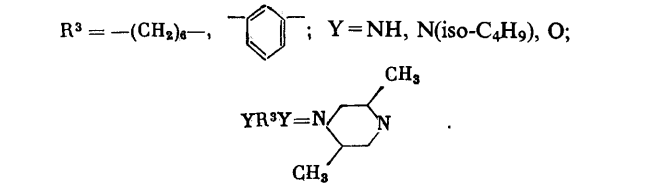
A study of the kinetics of anilinolysis of 4,4′-R-substituted 2,2′-*p*-phenylene-*bis*-(oxazoline-5-ones) demonstrated[63] that they are comparable in reactivity to *p*-nitrophenyl esters of aliphatic carboxylic acids.[64,65] Thus, it was also demonstrated that 2,2′-*p*-phenylene-*bis*-(oxazoline-5-ones) are monomers with an independent reactivity of functional groups and that the radical R in the 4-position of the azlactone ring has comparatively little effect on their reactivity.

Cleaver and Pratt[57] used various 2,2′-*p*-phenylene-*bis*-(oxazoline-5-ones) to synthesise regularly alternating polymers, mainly polyamides, containing α-aminoacid moieties in the principal macromolecular chains:



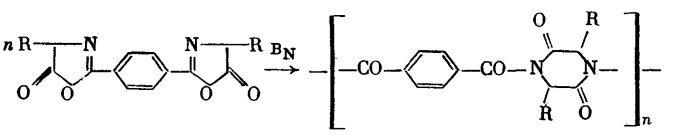
§Obtained through reaction of the dichloroanhydrides of dicarboxylic acids with α-aminoacids.[56]





High-molecular-weight polyamides were prepared based on aliphatic diamines. An aromatic diamine and aliphatic diol were used to synthesise low-molecular-weight polymers.

It was found[57] that 2,2′-*p*-phenylene-*bis*-oxazolinones in the presence of a tertiary amine (B_N) undergo homopolymerisation to form poly(*N,N′*-terephthaloyl-diketopiperazine):



These compounds are polymeric acyllactams (activated amides) and are very reactive toward nucleophiles.[6] In analogy with polyanhydrides,[66] they can be used as quickly decomposing materials for medical and biological applications.

Other investigators[67–70] subsequently also prepared various 2,2′-*p*-phenylene-*bis*-(oxazoline-5-ones) and used them to synthesise ordinary polyamides. A slightly different path to *N,N′*-diacyl-*bis*-α-aminoacids, reaction of dinitriles with an α-hydroxyacid (benzylic) according to Ritter, has been proposed.[68]

The variety of α-aminoacids used to synthesise 2,2′-*p*-phenylene-*bis*-(oxazoline-5-ones) has been significantly expanded.[71] As a result, polyamides and copolyamides that contain enzyme-specific side groups in the macromolecules and are susceptible to biodegradation have been prepared.[72] These polyamides exhibit good biocompatibility and are promising as surgical materials.[73,74] The rapid rate of reaction of 2,2′-*p*-phenylene-*bis*-(oxazoline-5-ones) with aliphatic diamines[71] determined the ability to prepare block-copolymers based on telechelic oligopeptides containing terminal amino groups. Such block-copolymers undergo biodestruction at an incresed rate[72,75] and are promising as drug delivery systems.

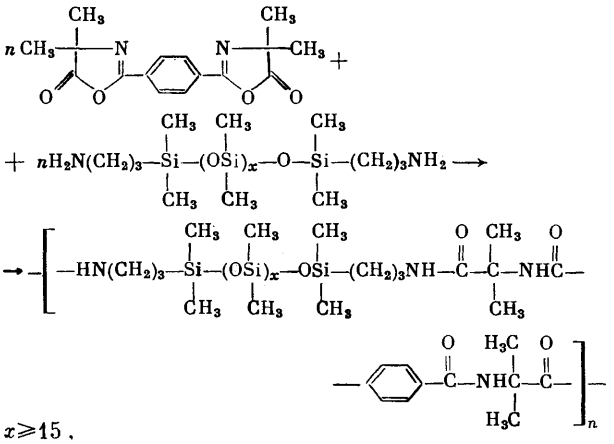
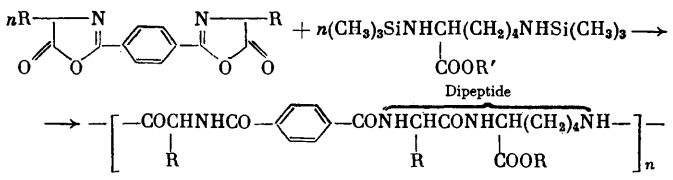
An alternating block-copolymer was also prepared on the basis of telechelic oligosiloxanes:[76]



$x \geqslant 15$.

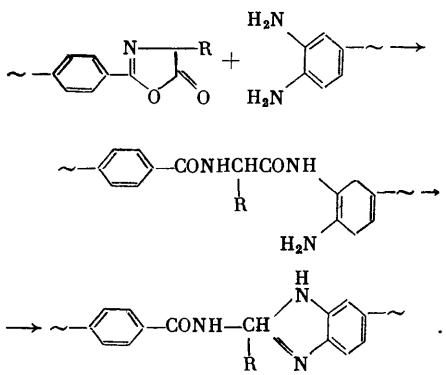
It has been demonstrated that *bis*-(oxazoline-5-ones) react with *N,N'*-trimethylsilylated diamines to form high-molecular-weight polyamides ($[\eta] \leqslant 0.68$ dl g^{-1}).[75]

This reaction was successfully used to prepare polyamides with dipeptide fragments using alkyl esters of N^{α},N^{β}-*bis*-trimethylsilyl-L-lysine as the diamine:[75,77]



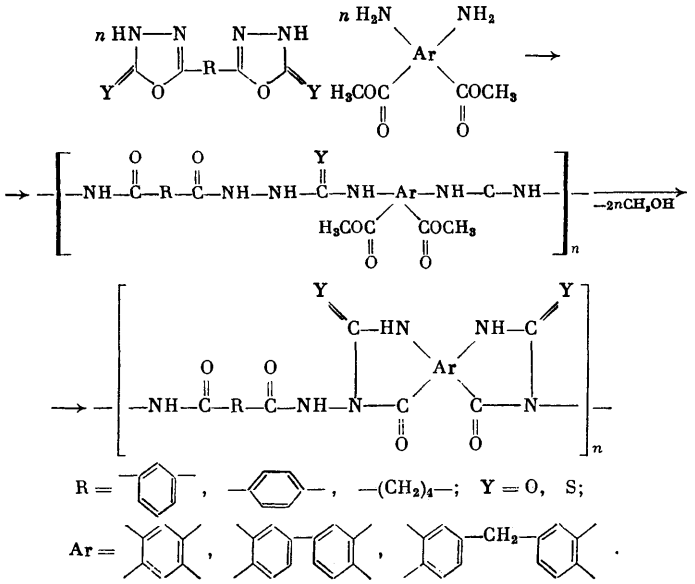
R′ = CH_3, C_2H_5.

Polyamidobenzimidazoles have been prepared through reaction of 2,2′-*p*-phenylene-*bis*-(oxazoline-5-ones) with tetraamines:[78,79]



The saturated five-membered *bis*-azlactones used to synthesise polymers are presented in Table 1.

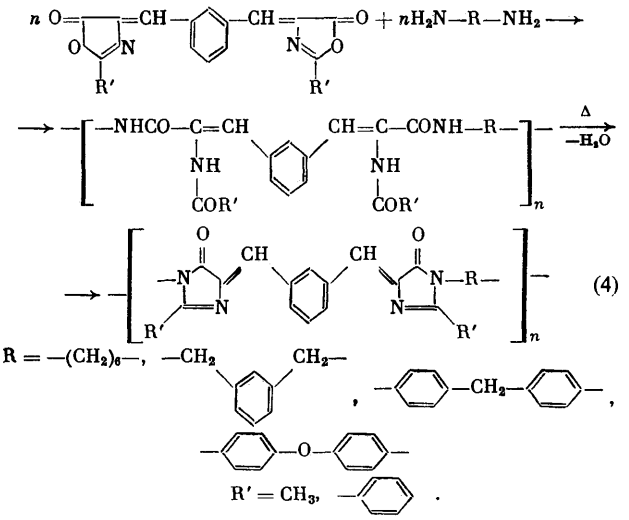
Iwakura, et al.[80,81] used five-membered azlactones with two N atoms in the ring, 2,2′-arylene (or alkylene)-*bis*-(1,3,4-oxadiazoline-5-ones) and 2,2′-arylene (or alkylene)-*bis*-(1,3,4-oxadiazoline-5-ones), as bifunctional cyclic monomers in polycondensation with *bis*-*o*-aminoesters:



The reaction was carried out in *m*-cresol at 180 °C (Y = O;[80] [η] of the obtained polyamidequinazolinediones is 0.09–0.27 dl g^{-1}) or at 150–160 °C (Y = S;[81] [η] of the obtained polyamidequinazoline-4-one-2-thiones is 0.07–0.31 dl g^{-1}). The comparatively mild reaction conditions in the latter instance may be related to the greater reactivity of the analogue containing S.

b) Unsaturated azlactones

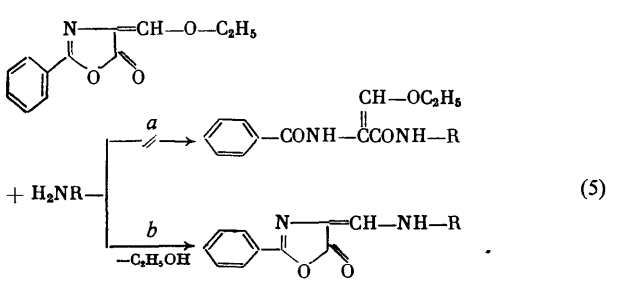
Ueda, et al., who have greatly contributed to the development of the active-ring method, synthesised unsaturated *bis*-azlactones[82] and investigated their polycondensation with diamines:



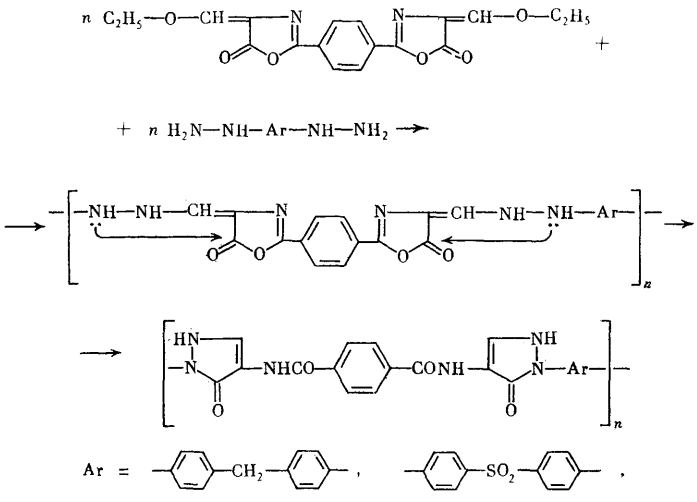
It was found that unsaturated *bis*-azlactones are sufficiently reactive to synthesise polymers (η_{inh} = 0.17–0.51 dl g^{-1}). However, as should have been expected,[83] they are inferior to the saturated analogues. In all probability the reason for the poorer reactivity of the unsaturated azlactones should be sought both in the conjugation of the heterocyclic carboxylic group with the C–C double bond, which decreases its electrophilicity, and in the ring conjugation of the electrons that stabilises the azlactone ring in general.

It was suggested that the unsaturated polyamide that was formed with pendant amide groups undergoes cyclodehydration with formation of the corresponding polyimidazolone [Reaction (4)] near 200 °C for R = $(CH_2)_6$ and R′ = CH_3.

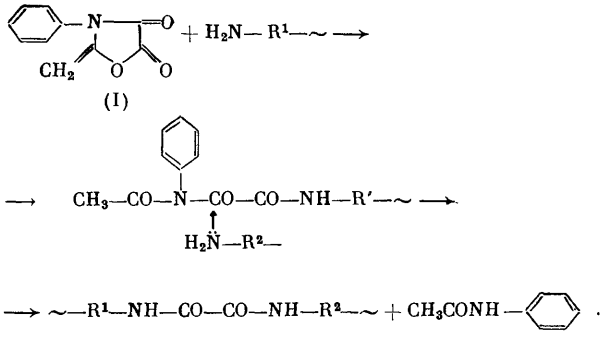
It is interesting that the ring is stabilised so much if the 2,2′-*p*-phenylene-*bis*-azlactone contains an ethoxymethylene group as the substituent in the 4,4′-positions that it is not opened by amines. Instead of acylation [Reaction (5*a*)], nucleophilic substitution occurs [Reaction (5*b*)]:



This fact was established by Imai, et al.,[84–87] who prepared high-molecular-weight polyenamines containing azlactone rings in the principal chains of the macromolecules instead of the expected polyamides through reaction of the corresponding *bis*-azlactone with diamines. The polycondensation of a *bis*-azlactone with aromatic dihydrazines occurs analogously in the first step. However, in this instance the reaction proceeds further with involvement of a second N atom of the hydrazine and is accompanied by opening of the azlactone ring and intramolecular rearrangement.[86] As a result, high-molecular-weight (η_{inh} = 0.5–1.23 dl g^{-1}) polyamide-pyrazolines are formed:



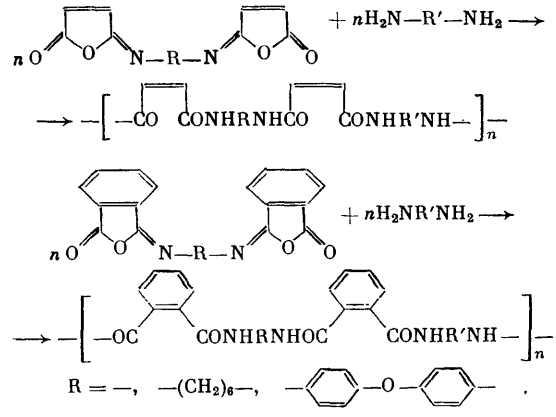
An original method of synthesising polyoxamides is based on use of an unsaturated monoazlactone, 2-methylene-3-phenyloxazolidine-4,5-dione (I), exhibiting Φ_{pr} = 2. The ring opens in the first step of the reaction of this compound with diamines. In the second, aminolysis occurs with loss of acetanilide and the polyoxamide forms ($\eta_{inh} \leqslant$ 0.35 dl g^{-1}):[88]



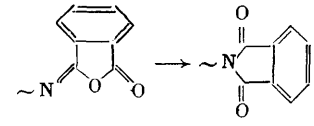
This process is a unique combination of two methods of activated polycondensation. These are the active-ring method and the leaving-group (active-amide) method.[6]

4. Cyclic *bis*-isoimides and *bis*-imides

The synthesis of various *bis*-isoimides has been reported.[89–91] These are structural isomers of the *bis*-azlactones examined above. As was expected, the isoimides react readily with aliphatic diamines in aprotic polar solvents at room temperature to give the corresponding polyamides:

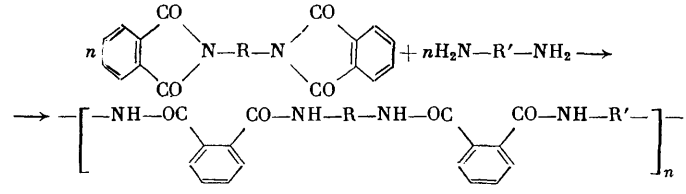


The *bis*-maleic isoimides were more reactive. Reaction of these with *m*-xylylenediamine in *N*-methylpyrrolidone is complete after 1 h.[89] They react with aromatic 4,4′-diaminodiphenyloxide much more slowly. The reaction is complete only after three days. Polyamides based on *bis*-maleic isoimides had higher viscosities ($\eta_{inh} \leqslant$ 0.7 dl g^{-1}) than those based on *bis*-isophthalimides ($\eta_{inh} \leqslant$ 0.26 dl g^{-1}). This and the slow rate of the principal reaction are related to the ease of isomerisation of the latter to the corresponding phthalimides. This inhibits chain propagation:[90]



For this reason the use of high temperature to accelerate the reaction of *bis*-isophthalimides with diamines is undesirable.

However, it was demonstrated that under certain conditions (in dry organic solvents, e.g. toluene at 20–95 °C) the ring opens during reaction of polymethylene-*bis*-phthalimides with aliphatic diamines. This leads to polyphthalimides ([η] $\leqslant$ 0.32 dl g^{-1}):[92,93]



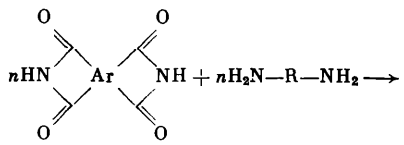
(6)

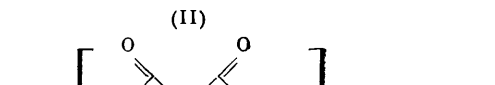
where R = $-(CH_2)_2-$, $-(CH_2)_4-$, $-(CH_2)_6-$, and $-(CH_2)_{10}-$.

It is noteworthy that Reaction (6) does not occur in the presence of water. Furthermore, other *bis*-imides (see above) react better with diamines in aqueous medium.

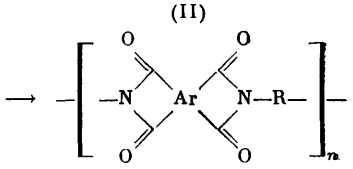
For example, Zhubanov, et al.,[94,95] synthesised the polyamido-amides (II) through reaction of imides of aromatic tetracarboxylic acids with aliphatic diamines in aqueous suspension at room

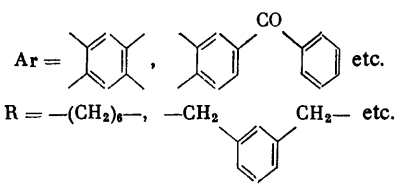
temperature. Alkylaromatic polyimides were prepared by cyclisation of these at 200–250 °C:



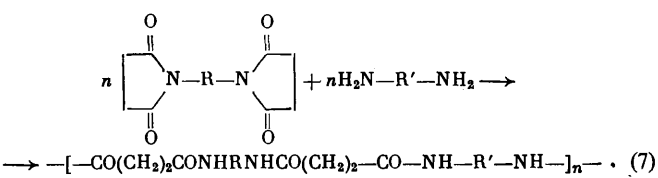


(II)





In contrast with aromatic phthalimides (the imide ring is stabilised by conjugation with the benzene ring), the ring of aliphatic imides, in particular, *N,N'*-alkylene-*bis*-succinimides, tends to open during reaction with aliphatic diamines. This forms the corresponding polysuccinamides:

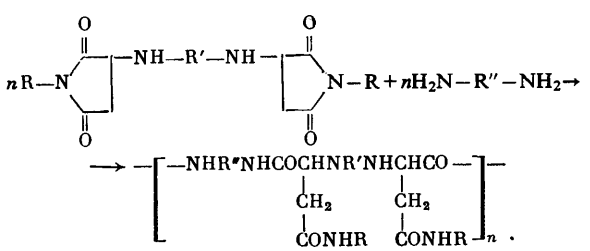


(7)

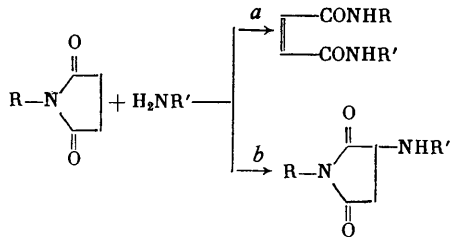
Kagiya, et al.[96] carried out this reaction in the melt at 200 °C and produced polyamides with $[\eta] = 0.2-0.5$ dl g^{-1}.

It has been found[97] that this reaction occurs better (under mild conditions of 0–20 °C) in aqueous ethanol to produce polysuccinamides with a relative molecular mass up to 20×10^3. It is interesting that Reaction (7), in contrast with Reaction (6), practically does not occur in dry and in polar aprotic solvents.

Diimides of *bis*-aspartic acid have also been used as starting monomers in reactions analogous to Reaction (7):[98]

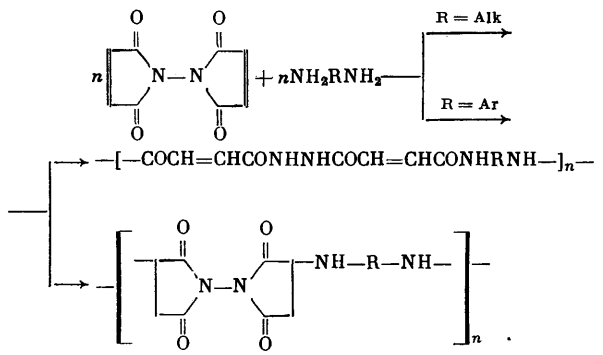


Cycloimides based on unsaturated acids, e.g. maleic and citraconic,[99] are also capable of being opened by amines. This reaction also occurs in aqueous medium [Reaction (8*a*)]. The amine adds to the double bond in anhydrous organic solvents [Reaction (8*b*)]:[100]



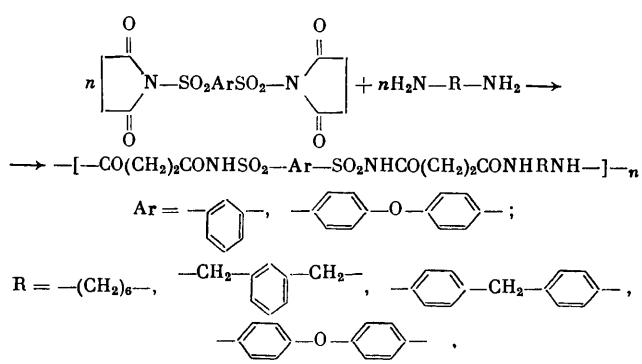
(8)

The direction of the reaction depends on the nature of the amine.[100] For example, *N,N'-bis*-maleimide in *m*-cresol at 65 °C with aliphatic diamines forms polyamides ($\eta_{inh} \leqslant 0.98$ dl g^{-1}) whereas addition to the double bond occurs for aromatic diamines to form polysuccinimides ($\eta_{inh} \leqslant 0.56$ dl g^{-1}):

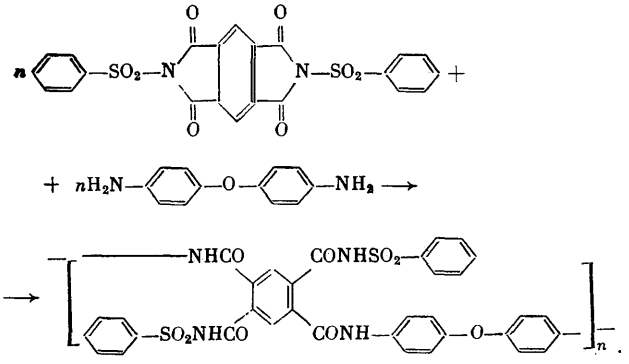


It is noteworthy that polyamides based on 1,2-dicarboxylic acids are promising as self-destructive polymers since the neighbouring amide groups facilitate hydrolytic decomposition of each other.[101]

Activated imides containing electron acceptor groups on the N atom were more reactive toward amines. For example, it was found that *N,N'*-arylenedisulphonyl-*bis*-succinimides react with diamines in *N*-methylpyrrolidone at 10–20 °C to form polyamides with $\eta_{inh} \leqslant 0.4$ dl g^{-1}.[102]

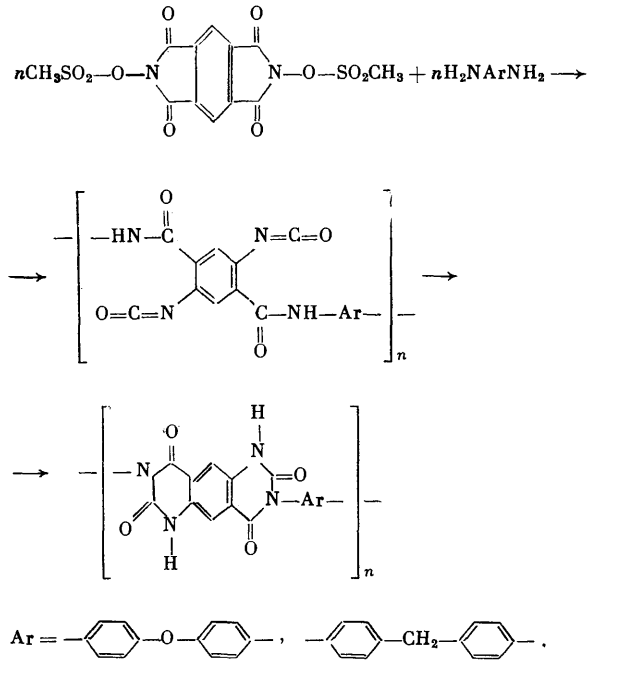


The reaction of *N,N'-bis*-(phenylsulphonyl)pyromellitimide with an aromatic diamine (η_{inh} of the polyamide formed = 0.74 dl g^{-1}) occurs analogously at room temperature:[103]

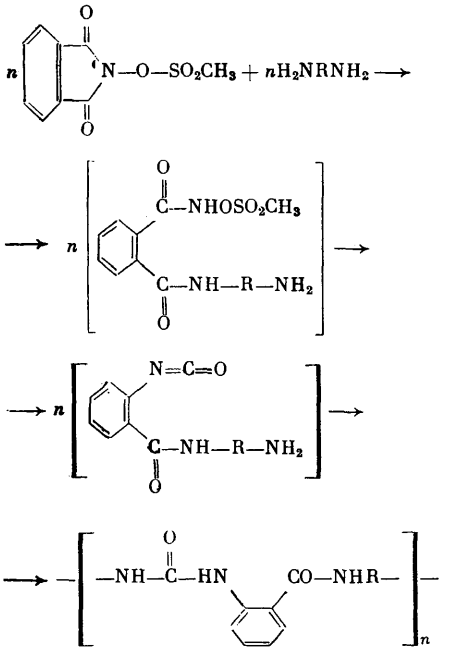


It is noteworthy that the reaction of *N*-arylsulphonylimides and diamines occurs with ring opening and without cleavage of the $=N-SO_2-$ bond whereas the exocyclic $=N-CO-$ bond primarily cleaves during aminolysis of *N*-acylimides with loss of the corresponding imide.[6]

The mesyloxy group also substantially activates the imide ring. In this instance the mesylhydroxamic acid formed undergoes the Lossen rearrangement. Polyquinazolinediones ($\eta_{inh} \leqslant 0.25$ dl g^{-1}) are formed as a result:[104]

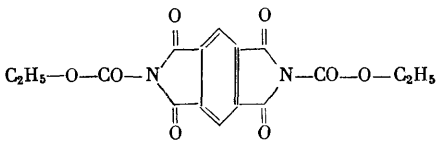


Thanks to the rearrangement mentioned above the *N*-mesylphthalimide exhibits $\Phi_{pr} = 2$ with diamines (at a 1 : 1 mole ratio). This leads to formation of polybenzamidoureas:[105]



The synthesised polymers have low viscosities (η_{inh} = 0.12–0.34 dl g^{-1}). Apparently this is due to chain breaking as a result of cyclisation of the intermediate isocyanate to the corresponding quinazolinedione.

An ethoxycarbonyl group also activates the phthalimide ring towards reaction with amines.[106] For example, *N,N'-bis*-(ethoxycarbonyl)pyromellitimide



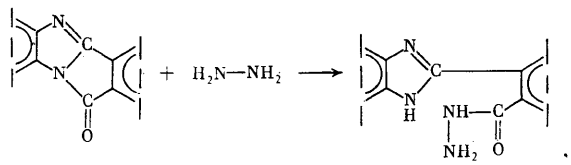
is significantly more reactive than the unsubstituted pyromellitimide; however, it is less so than the *N,N'-bis*-phenylsulphonyl derivative examined above. The latter in turn is less active than pyromellitic dianhydride. The *N*-substituted pyromellitimides, like pyromellitic dithioanhydride, were polymerised[107] during a search for better methods of synthesising pyromellitimides. An important advantage of these compounds is the ease of cyclisation of the prepolymers prepared from them compared with the polyamido acid synthesised through pyromellitic dianhydride.

The polymerisation involving cycloimides (both with opening and without opening of the imide ring) are discussed in more detail in a review.[12]

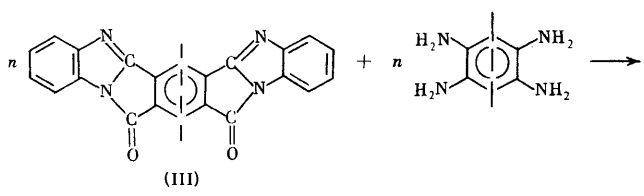
5. Cyclic *bis*-amides

Korshak, et al.[108] found in 1969 that benzoylenebenzimidazoles (benzimidazopyrrolones) are intramolecularly activated amides (their acyclic analogues have since been widely used to synthesise

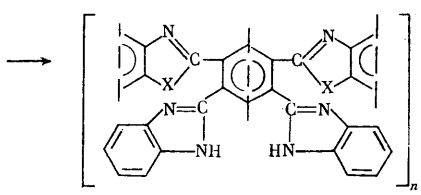
polyamides[6]) and readily react with a highly basic nucleophile (hydrazine) under mild conditions:



Then *bis*-benzoylenebenzimidazoles (III, IV) were successfully used as monomers both for the synthesis of various polybenzazoles with *o*-benzimidazole substituents in the principal chains of the macromolecules:[109–111]

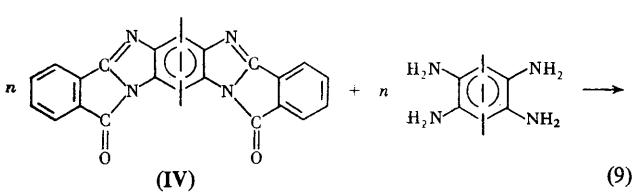


(III)

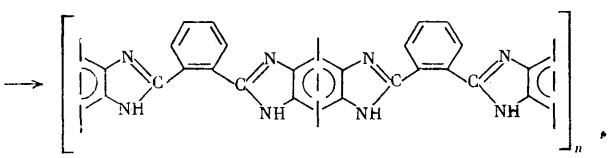


X = O, S, NH.

and for the synthesis of copolymers of polybenzimidazoles[112] with a regular alternation of two tetraamine residues.

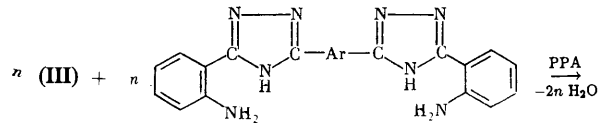


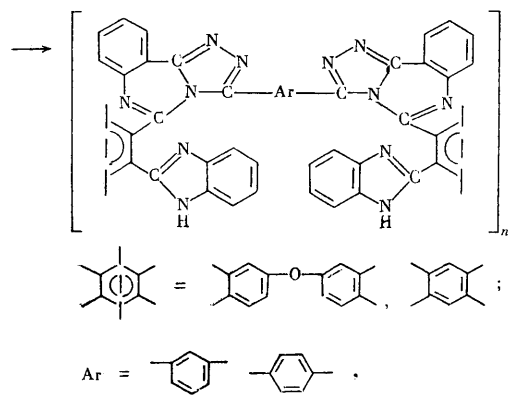
(IV) (9)



These reactions were carried out in polyphosphoric acid (PPA) at 180–200 °C. The prepared polymers are soluble in organic solvents and are capable of forming layers.

In analogous reactions in PPA, *bis*-[5-(*o*-aminophenyl)-*s*-triazolyl-3]phenylenes were used with III as tetrafunctional nucleophiles.[113] This resulted in block-ladder soluble polytriazoloquinazolines with *o*-benzimidazole side groups:





In contrast with the five-membered benzoyleneimidazoles, six-membered naphthoylenebenzimidazoles containing the structural element

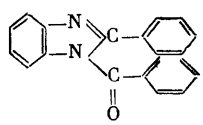


exhibit high chemical resistance[114] and do not undergo analogous reactions.

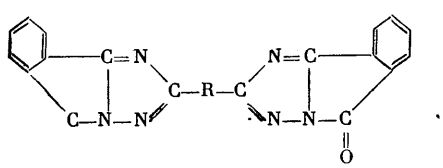
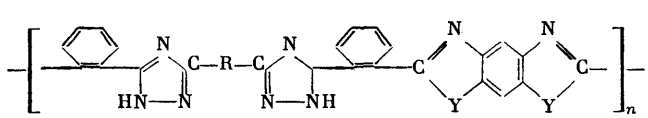
It has been demonstrated[115] that *bis*-benzoylenetriazoles of the general formula below can be used as bifunctional cyclic activated amines to synthesise polyheteroarylene through Reaction (9):

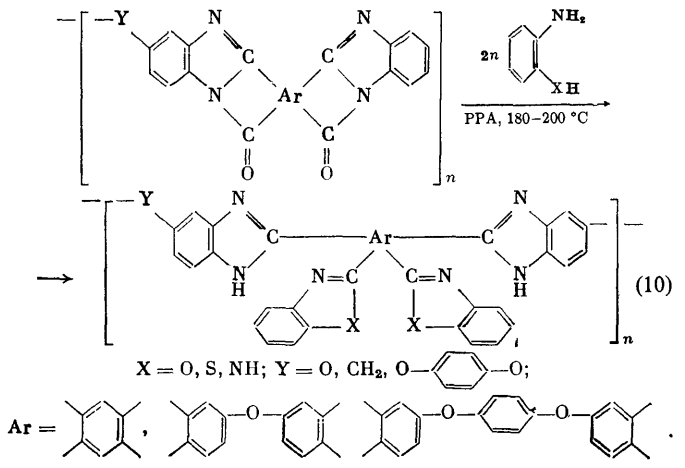


Copolymers with a regular alternation of benzazole and triazole rings in the principal chains of the macromolecules are produced:

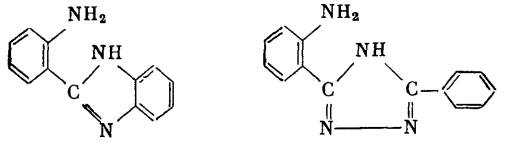


Y = O, S, NH.

Reactions similar to those given above have also been used for polymer-like conversions of polybenzoylenebenzimidazoles in order to prepare modified polybenzimidazoles:[116]

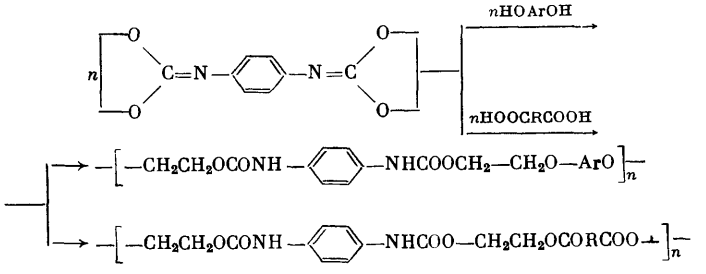


In order to increase the heat resistance and solubility of the polymers, 2-(*o*-aminophenyl)-benzimidazoles and 3-phenyl-5-(*o*-aminophenyl)-1,2,4-triazoles have been employed as the *o*-substituted anilines in Reaction (10):[117]

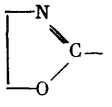


6. Cyclic *bis*-iminoesters and their analogues

An interesting method of synthesising polyesterurethanes consisting of the reaction of a bifunctional cyclic iminocarbonate with *bis*-phenols[118] and dicarboxylic acids[119] has been proposed by Mukayama, et al.

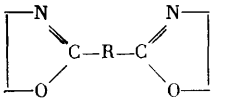


Bifunctional oxazolines containing the structural element



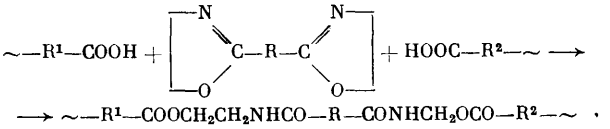
were used to synthesise hetero-chain polymers by various authors. These can be viewed as cyclic iminoesters.

bis-Oxazolines of general formula



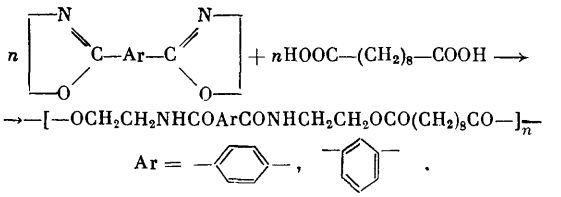
R = —[Ref. 120],  —[Ref. 121];

have been used[120,121] as chain extenders of polyesters with terminal carboxylic groups:

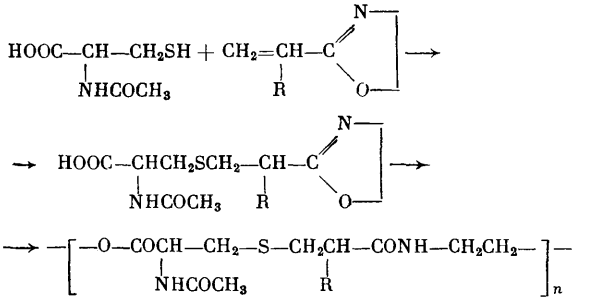


It is noteworthy that the reaction was carried out at elevated temperatures (200—280 °C) in the polyester melt. Under these conditions the stable *bis*-oxazolines are more suitable chain extenders than their more thermally resistant analogues, the *bis*-oxazolinones examined in part 4.

The reaction of oxazolines with carboxylic acids was investigated in detail and used successfully by Sano[122] to synthesise high-molecular-weight polyesteramides ($[\eta] \lesssim 1.21$ dl g^{-1}) in the mass at 185—240 °C:

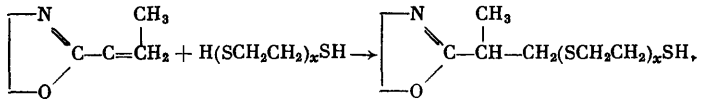


An original synthesis route to polyesteramides employing unsaturated 2-alkylene-2-oxazoline has been proposed.[123] An AB-type monomer is first prepared by its reaction with *N*-acetyl-L-cysteine:

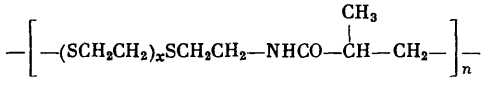


where R = H and CH_3. This is then polymerised with the terminal carboxylic and oxazoline group (analogously to the reactions mentioned above). The mechanism involves polyaddition in DMF at 50—100 °C and produces an optically active polymer with a relative molecular mass up to 13.8×10^3.

An essentially similar process has been carried out.[124] Reaction of 2-isopropenyl-2-oxazolines with H_2S or a dithiol was used to synthesise AB-monomers with SH- and oxazoline groups:

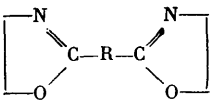


where $x = 0$ and 1. The latter was polymerised in the melt or DMF at 100–200 °C. Polyamidethioethers were prepared with the structure:



with $M_n \leqslant 4300$ depending on the reaction conditions.

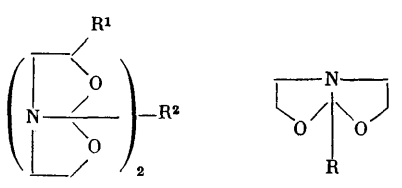
The nucleophilic substitution reaction on which the processes described above are based was also used to prepare polyamides containing simple ether bonds through reaction of *bis*-oxazolines of general formula



where R = alkylene C_{1-20} and arylene C_{6-20}, with polyphenols at 170 °C using $Ph_3(C^+X^-$ (X = BF_4, PF_6, SbF_6, AsF_6, BPh_4, or ClO_4) as catalysts.[125] High-melting thermally reactive polyamidoethers with a 5% mass loss at 390 °C (TGA) were obtained.

The *bis*-oxazolines also react with aromatic diamines to form prepolymers that undergo intermolecular crosslinking in the presence of strong acids as catalysts.[126] These systems are useful for preparing thermally reactive formed compositions with good strength indicators.

Bicyclic amidacetals of the general formula shown below with structures similar to the iminoethers were also used as cyclic monomers to prepare polymers:



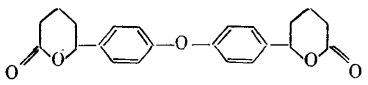
Reaction of these with alkanolamines produces oligomeric polyols that are used to synthesise polyurethanes.[127]

Polyurethanes are also synthesised through reaction of bicyclic amidacetals with polyols and diisocyanates[128] or directly with diisocyanates.[129]

V. Six-membered heterocycles

1. *bis*-δ-Lactones

Six-membered *bis*-δ-lactones are unreactive in aminolysis reactions, like their five-membered analogues (see Part IV). The *bis*-δ-valerolactone shown below has been synthesised:[130]



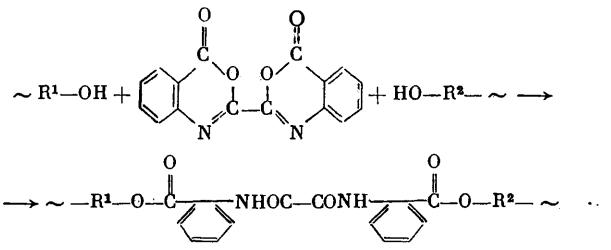
It was found that a polyamide containing hydroxyl groups with $\eta_{inh} \leqslant 0.26$ dl g^{-1} is formed through its reaction with hexamethylenediamine (65–80 °C, 10 days, in methanol, *m*-cresol or *N*-methylpyrrolidone).

2. *bis*-Benzoxazinones

Ueda and Imai[131] synthesised various *bis*-(3,1-benzoxazine-4-ones) (Table 2, compounds Nos. 1–6) from *bis*-anthranilic acids. These are six-membered analogues of isoimide azlactones (Part IV). During a study of model reactions it was established that these compounds at room temperature comparatively easily react with aliphatic amines (butylamine, benzylamine). More forcing conditions are required with an aromatic amine (aniline). This is probably due to both the decrease of electrophilic reactivity of the isoimide fragment (its carbonyl group) and the significant stabilisation of the heterocycle owing to conjugation with the condensed benzene ring. It was found that 2-methyl-substituted benzoxazines are more active than the 2-phenyl-substituted analogues. This may also indicate the importance of conjugation in determining the acylating potential of a given heterocyclic system.

High-molecular-weight layer-forming polyamides with $\eta_{inh} \leqslant 0.6$ dl g^{-1} are produced through reaction of *bis*-benzoxazinones with hexamethylenediamine and *m*-xylylenediamine in polar aprotic solvents (DMF, hexametapol, DMSO, etc.).[131]

Inata and Matsumura[132] also synthesised the novel isoimide benzoxazinone 2,2′-*bis*-(4H-3,1-benzoxazine-4-one) and used it as a chain extender of polyethyleneterephthalate:



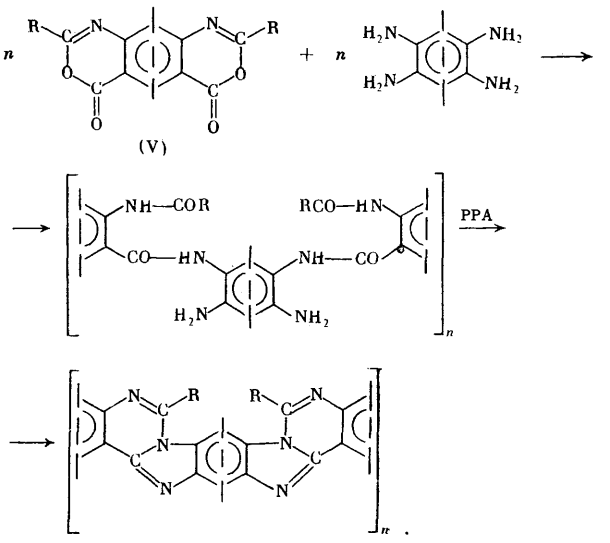
The reaction was carried out in the melt at 280 °C. A linear polymer with an elevated molecular mass was prepared. It is appropriate to mention here that *bis*-oxazinones, as was expected, react with OH groups with more difficulty than five-membered azlactones.

Table 2. *bis*-Oxazinones used to synthesise polyamides.

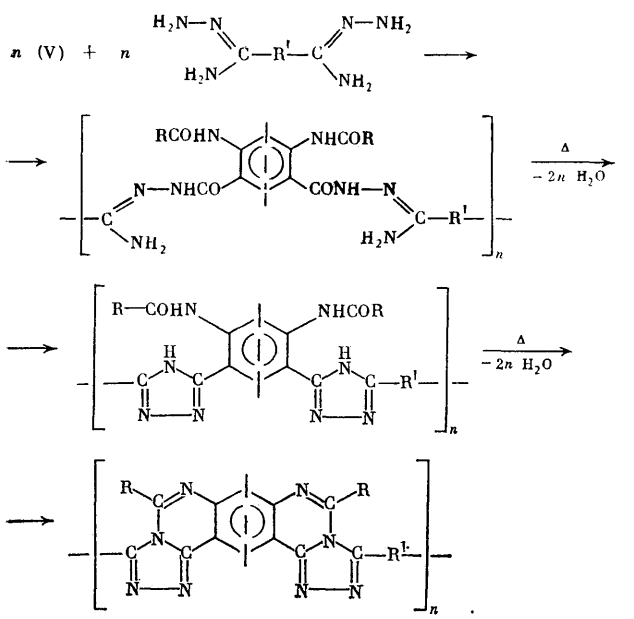
Sample No.	*bis*-Oxazinone	Reference
1		[131]
2		[131]
3		[131]
4		[131]
5		[131, 133]
6		[131]
7		[132]
8		[137]
9		[137]

Quinazoloneimide¶[133] copolymers with an initial decomposition temperature of 380–396 °C are obtained through reaction of 6,6′-methylene-*bis*-(2-methyl-3,1-benzoxazine-4-one) (Table 2, compound No. 5) with 4,4′-diaminodiphenyloxide and 3,3′,4,4′-benzophenonetetracarboxylic acid in *m*-cresol in the temperature range 130–180 °C.

The reaction of isoimide *bis*-benzoxazinones with *bis*-*o*-phenylenediamines (aromatic tetraamines) was used to synthesise full or partial ladder polymers, polybenzimidazolequinazolines:[134,135]



Korshak, et al.[136] used *bis*-amidrazones as tetrafunctional nucleophiles in the reaction with *bis*-benzoxazinones to synthesise partial ladder (block–ladder) polytriazoloquinazolines:

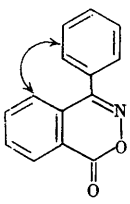


The isomeric *bis*-oxazinones *bis*-4-phenyl-2,3-benzoxazine-1-ones (Table 2, compounds Nos. 8 and 9) were also synthesised.[137] In contrast with the benzoxazinones examined above that contain isoimide moieties, the reactive structural elements of the

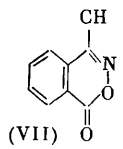
¶Adducts of *bis*-benzoxazione and diamines undergo thermal cyclodehydration to form polyquinazolones.

benzoxazinones that are isomeric with them are O-acyloxime fragments $-CO-O-N=C\diagup\diagdown$, which are distinguished by a comparatively low acylating potential.[138,139]

A study of model reactions demonstrated that the 4-phenyl-substituted 1H-2,3-benzoxazine-1-one (VI) readily reacts with aliphatic amines (*n*-butylamine and benzylamine) at 20 °C to form the corresponding adducts in quantitative yields regardless of the solvent nature (ethanol, THF, *N*-methylpyrrolidone). This azlactone does not react with aniline even under more forcing conditions (at 80 °C). In contrast with VI, its 4-methyl-substituted analogue (VII) is stable and does not react even with aliphatic amines at 80 °C.

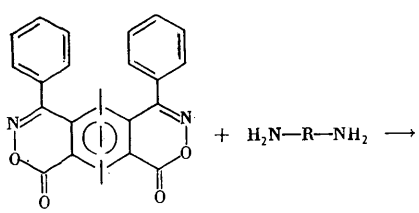


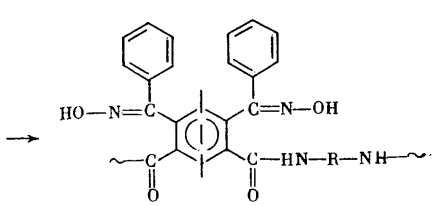
(VI)



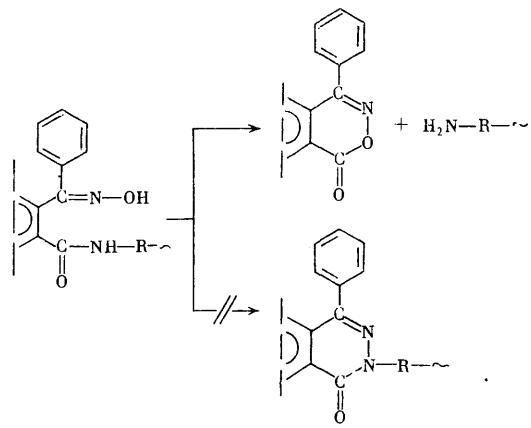
(VII)

Therefore, acyloxime benzoxazinones are much less reactive than the isoimide analogues. The higher reactivity of VI compared with its linear analogues[138,139] may be due to both strain in the ring and steric interaction between the benzene rings (shown by an arrow), which is relieved after opening of the heterocycle by aminolysis. Polycondensation of 4-phenyl-substituted benzoxazinones (Table 2, compounds Nos. 8 and 9) with aliphatic diamines in aprotic polar solvents at 20 °C is complete after 2–3 days. Polyamides are formed in quantitative yields. However, they have comparatively low viscosities (η_{inh} = 0.12–0.38 dl g^{-1}).





This and the low reactivity of the heterocycle may be due to the equilibrium nature of the reaction. This view is consistent with the ease of depolymerising the polyamide at elevated temperature (220 °C):



- - -o0o- - -

The polymer syntheses examined in the present review are stepwise polyaddition processes that obey the rules of polycondensation. A number of the reactions, for example, those involving saturated *bis*-azlactones, *bis*-isoimides and *bis*-imides, in addition to certain unsaturated *bis*-azlactones, are polyaddition processes in the pure sense. In the remaining instances, some groups or others (hydroxyls, ketones, etc.) are lost that formally can be viewed as low-molecular-weight side products. However, these do not abandon the macromolecular chains and remain bonded to them by a covalent bond. Such reactions are promising for the synthesis of various functionalised polymers including those for biomedical applications.

Quinone methides in the chemistry of wood

S M Shevchenko, A G Apushkinskii
St Petersburg Forestry Academy

ABSTRACT. Modern ideas about the stereoelectronic structure of quinone methides and their reactivity and role as intermediates in the lignification and delignification of wood are treated systematically. A special section is devoted to the method of synthesis of model quinone methides in lignin.

The bibliography includes 249 references.

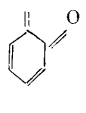
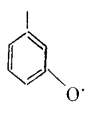
I. Introduction

The model quinone methods (QM) of lignin are unsaturated cyclic conjugated ketones—derivatives of alkylidenecyclohexadienones; the starting materials for their synthesis are aromatic compounds modelling various structural units of lignin. The involvement of QM in key lignification and delignification reactions is assumed to be generally recognised and this is reflected both in a special review[1] and in familiar monographs.[2–4] Stable QM which are not model compounds of lignin will be mentioned only when needed for comparisons, because the properties of these compounds have already been the subject of a recent review.[5] Endeavouring to achieve a logical description of the data, we shall begin with the properties of the simplest models and shall only then proceed directly to the chemistry of lignin. In conformity with the data accumulated in the literature at the present time, most attention will be devoted to *p*-QM (I); the less stable *o*-QM (II) have been much less investigated. Like the corresponding *m*-quinodimethanes,[6] *m*-QM (III) can apparently exist only as a biradical intermediate with negligible lifetimes. Hitherto their involvement in any kind of reactions of lignin has not been discussed.

(I)



(II)



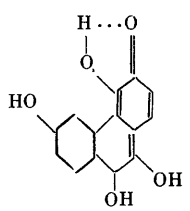
(III)

II. Methods of synthesis

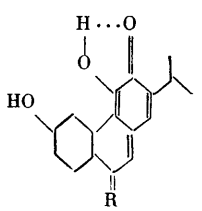
Reliable methods of synthesis of model QM of lignin, which are convenient objects for the study of the mechanisms of lignification and delignification and are synthons for model compounds of lignin, have now been developed.

In contrast to the stable sterically hindered QM,[5,7,8] the model *p*-QM of lignin cannot be isolated in a pure form because of their low stability. They can be characterised only in solutions. The sterically hindered QM and QM fused with a benzene ring have no direct bearing on the chemistry of lignin. However, one should note that 10-methyleneanthrone has been isolated from the liquors in the anthraquinone (AQ) pulping of wood, while bianthrone has been detected among the products of the decomposition of the adduct of anthrone and model QM of lignin.[9]

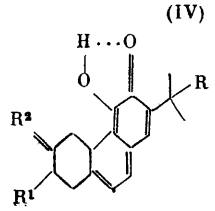
It appears useful to quote examples of stable QM isolated from plants:[10–16]



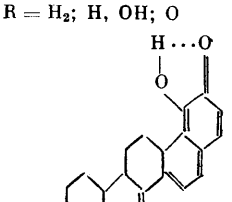
(IV)



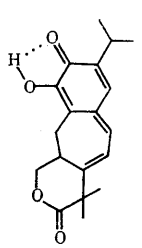
R = H_2; H, OH; O



R = H, OH; R^1 = H; R^2 = H_2
R = H, R^1 = OH; R^2 = O

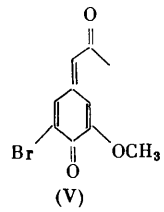


R = H_2, O



In these compounds, the QM system is stabilised both as a result of the lengthening of the conjugation chain and by the intramolecular hydrogen bond. Compound (IV), whose enolic form (a QM) is apparently more stable than the α-keto-isomer, is noteworthy.

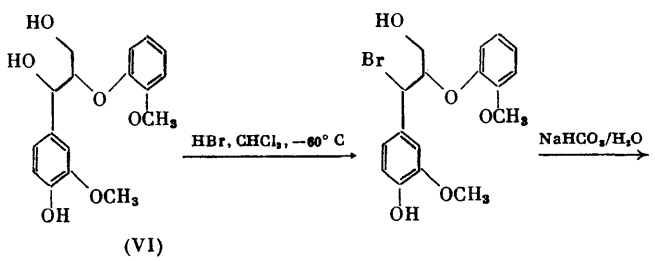
Compound (V) is a rare example of a compound close to the model QM of lignin which has been isolated in a crystalline form; however, its synthesis is poorly reproducible.[17]



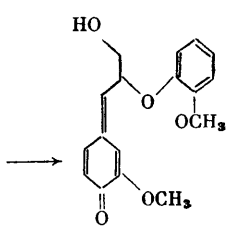
(V)

We shall emphasise two factors. Firstly, there have been numerous studies in which the formation of QM in the course of the processes investigated was postulated. Such publications must be distinguished form the few investigations whose authors dealt with QM directly and the structure of the latter was reliably demonstrated. Secondly, one should treat with caution studies where QM have been identified solely on the basis of electronic absorption spectra. The products of the degradation of these compounds are frequently coloured, which can readily lead to confusion. Thus our experience suggests that Pospisek et al.[18] and Adler and Stenemur[19] could not have obtained all the compounds which they list.

There exist two convenient routes to the synthesis of model QM of lignin: dehydrohalogenation of the corresponding *p*-hydroxybenzyl halide and oxidation of alkylphenols. For example, the method of Johansson and Miksche,[20] whereby fairly complex QM with β-aryloxide substituents have been obtained,[21] leads to success.

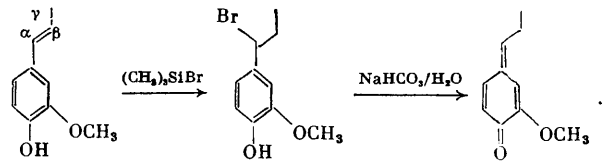


(VI)



(VII)

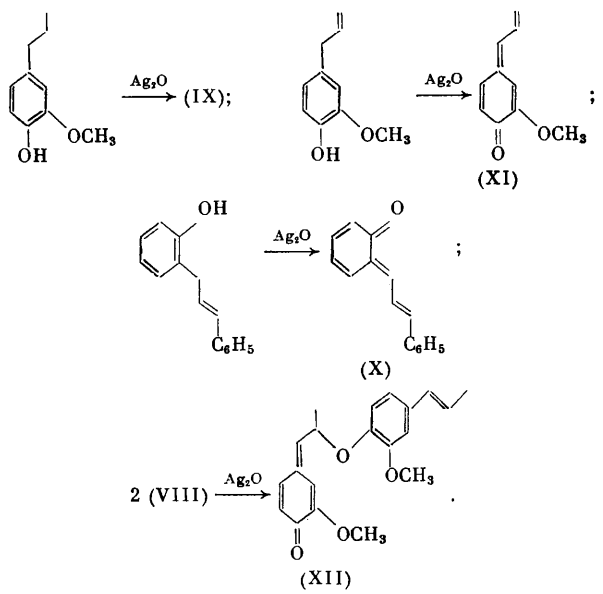
In recent years, this method has lost its importance. Its disadvantage is the use of low temperatures and a reactant such as dry hydrogen bromide, which can give rise to side reactions. In a certain sense, the method of synthesis of QM using bromotrimethylsilane (BTMS) (for its synthesis, see Andrianov[22]) proved to be ideal—this is a "test tube reaction" proceeding at room temperature with total conversion of the initial compound and as a rule an insignificant formation of side products.[23] It involves the formation of the same intermediate bromide as in the case where dry HBr is used.[248] Using bromotrimethylsilane, it is possible to obtain QM not only from *p*-hydroxybenzyl alcohols but also from α-alkenylphenols, for example isoeugenol (VIII):[147]



(VIII) (IX)

QM of the guaiacyl and syringyl series can be readily synthesised by this method; among derivatives of the *p*-hydroxyphenyl series, it has so far been possible to obtain only QM with a β-aryloxide substituent,[24,25] which apparently exerts a "through space" stabilising effect on the mechanism. There is so far no reliable evidence that QM without substituents in the α-position have been obtained.

Another common method of synthesis of QM is oxidation of alkyl- and alkenylphenols by silver oxide:[26–30]



(XII)

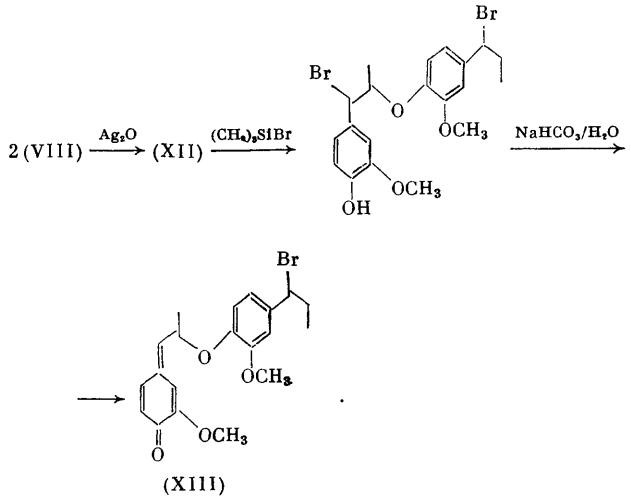
It is assumed that the mechanism of the oxidative conversion of phenols into QM includes either the disproportionation of the corresponding radicals or the formation of an intermediate quinol ether[31] (QM are probable intermediates in the rearrangement of quinol ethers to benzyl ethers[32]).

The formation of QM in the oxidation of phenols is not a "general" reaction; the result of the process depends on the type of oxidant, substrate, and conditions. Thus, contrary to expectations, homovanillic acid affords a product of a completely different type on oxidation with lead tetraacetate.[33] On the other hand, judging from the composition of the secondary products, a QM is formed on oxidation of guaiacylacetone with 2,3-dichloro-5,6-dicyanobenzoquinone.[17] In many cases, oxidation yields a broad spectrum of products.[34–36] We may note that the formation of QM in the oxidation of phenols is regarded as one of the stages of the enzymic degradation of model compounds of lignin and apparently of lignin itself.[37] It is seen from the examples presented above that, depending on the substrate, the reactions of the phenoxyl radicals generated initially may be of different kinds: in one case, they

involve the dehydrogenation of one molecule and in another dimerisation takes place. Thus each method opens up routes of QM of different types.

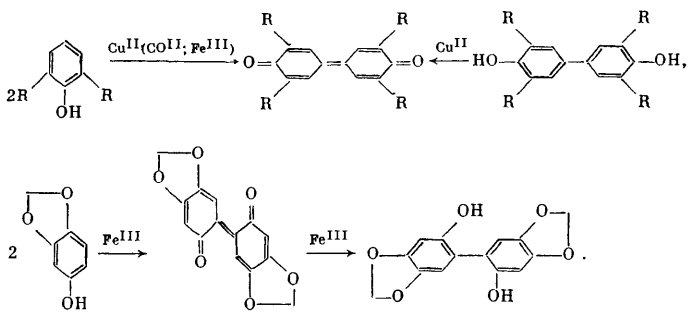
An important feature of the dimerisation reaction of the phenoxyl radicals derived from α-alkenylphenols is the retention of the steric orientation of the alkenyl substituent in the aryloxide group of the β-aryl ether type QM formed. Previously this reaction was deduced from the analysis of the secondary products formed during processes simulating the initial stages of lignification;[35] this reaction has been recently established directly for the transformation (VIII)→(XII).[38] Thus one can claim confidently that during their lifetime the alkenylphenoxyl radicals do not undergo changes in configuration. Consequently the steric structure of the unsaturated side fragments of lignin must correspond to the stereoisomeric composition of the monomeric alkenylphenols. This conclusion has definite importance for the understanding of the lignification process.

The combination of both methods of synthesis of QM opens a route to the preparation of interesting QM of the type (XIII), which contain a halogen atom in the side chain:[38]



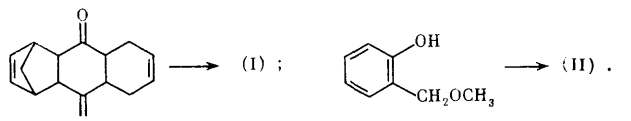
The fact that bromotrimethylsilane does not leave unaffected the multiple bonds of the molecule conjugated with the aromatic ring is used here. The same fact also precludes the employment of bromotrimethylsilane for the synthesis of QM vinylogues from compounds of the type of coniferyl alcohol (we may draw attention to an erroneous study[19] where the opposite was claimed).

The oxidative dimerisation of phenols serves as a familiar preparative method for the synthesis of substituted diphenoquinones—compounds related to QM and differing from the latter by a greater stability:[39–41]



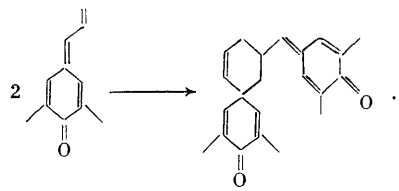
Attention should be drawn to the possibility of the formation of similar structures in lignin, for example, from fragments of the biaryl type.[42]

Individual highly reactive QM, the first members of the *p*-QM (I) [43] and *o*-QM (II) [44,45] homologous series, have been obtained by flash thermolysis:

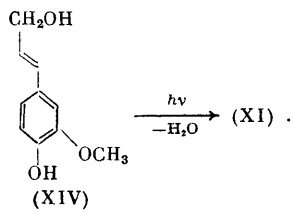


Compounds (I) and (II) remained unchanged in the solid state at a low temperature, but underwent rapid reaction on heating to room temperature or on adding nucleophiles. Flash thermolysis can hardly be used as a general preparative method. We may note that the formation of the unstable QM (II) in the gas phase was detected by photoelectron spectroscopy.[46]

In the series of sterically hindered QM, there is a method for the synthesis of stilbenenquinones by the dimerisation of QM with subsequent disproportionation.[5] In contrast to this, unhindered QM with the α-vinyl substituent are capable of dimerisation of a different type, affording an even more complex QM:[47]



Studies[48,49] in which it was possible to detect the formation of QM vinylogues [of types (XI)] in both aprotic and protic solvents (including water) in the flash photolysis of the corresponding alcohols merit mention:



In hydroxylated media, the QM obtained rapidly undergo nucleophilic addition reactions. The presence of QM was detected in this case only from electronic spectra but, together with the published results mentioned above,[48,49] the detection is convincing. It is striking that only α-vinyl-substituted QM, whose reactivity is reduced compared with the simplest representatives of the series, can be obtained by this method.

The convenient preparative methods described above lead to the formation of typical model QM of lignin in dilute solutions, but the presence of impurities is then inevitable. The target product can be purified by liquid chromatography.[28,50] Hitherto the isolation of model QM of lignin in a pure state under normal conditions has not been reported, although it is possible to concentrate a solution of a QM of the β-aryl type without degradation of the target product.[21,50]

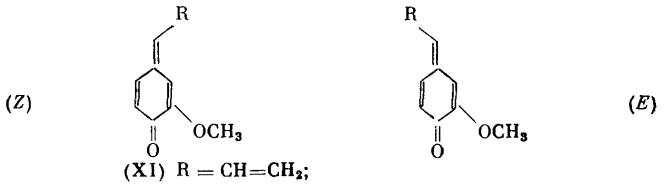
III. Stereoelectronic structure

Hitherto no data have been published on the structure of the quinone methide fragments of the polymeric lignin, but certain significant conclusions can be arrived at by investigating low-molecular-weight objects. Experimental methods, such as X-ray diffraction analysis, which yield detailed information about the molecular geometry, have been applied to certain stable crystalline QM. The introduction of aryl substituents in the α-position in the QM [compounds (XV) [51] and (XVI) [52]] or of t-butyl groups in the ring [we may draw attention to the stability of galvinoxyl (XVII) — a free radical containing a QM fragment[53]] as well as fusion with benzene rings [compound (XVIII) [54]] are methods for the stabilisation of the quinone methide system. We may note that the QM are not themselves in any way exotic compounds. It is sufficient to mention that this class includes fluoresceine and alkaline forms of phthaleine dyes.[55] On the other hand, the majority of such systems have no bearing on wood and can be in no sense regarded as model compounds of lignin. An exception is QM with an elongated conjugation chain isolated from plant raw material (see above); one of such substances [compound (XIX)] has been subjected to X-ray diffraction analysis.[11]

A detailed knowledge of the geometry of the skeletons of the simplest QM is important for the understanding of the physicochemical properties of compounds of this class. QM are quinone derivatives occupying in terms of many properties an intermediate position between benzoquinone (XX) and quinodimethane (XXI). The *para*-substituted compounds (I), (XX), (XXI), etc. belong to the D_{2h} symmetry group, while the corresponding *ortho*- and *meta*-substituted compounds belong to the C_{2v} group. In conformity with this, a classification of the atomic orbitals (AO) constituting the basis of the π-electron system has been put forward.[56] It is significant that, as a consequence of the different symmetries, the orbitals of the lone pairs of the oxygen atom do not mix with the π-system.

An important source of structural information is provided by calculations with optimisation of the geometry. The first attempt of this kind was apparently undertaken[57] using the MINDO/3 method for calculations relating to the simplest molecule of compound (I). In contrast to the semiempirical quantum-chemical methods, *ab initio* calculations and calculations by the empirical method of atom–atom potentials (AAP) provide more reliable predictions of the geometry. Calculations of both types have been carried out by the present authors[58] for the simplest models (XI) and (XXII). As regards molecular geometry, there is good agreement between the two methods. The distinct alternation of bonds leaves no doubt as to the quinonoid structure of QM.

An extremely interesting feature of asymmetric QM is the predominance of the (*Z*)-isomer in the vast majority of reaction mixtures obtained in the synthesis of these compounds. The (*Z*):(*E*) ratio is usually 2:1 [24,25,59,80] regardless of the mechanism of the synthesis: heterolytic cleavage of bromides or homolytic oxidation of phenol-alcohols. Calculation by the AAP methods, which are known to provide an adequate treatment of non-valence interactions, does not indicate the predominance of either the (*Z*)- or the (*E*)-isomer.[58,60,61] The same result was obtained by the semiempirical calculation using the AM1 method. On the other hand, the *ab initio* calculation in terms of the 3-21G basis set yielded a quantitative estimate of the ratio (*Z*):(*E*) which agreed fully with the experimental ratio.[58] Hence one may conclude that the stereochemistry in the series of QM is regulated not by steric but by electronic factors whose nature has not been elucidated hitherto. In combination, these data suggest that the stereoisomeric composition of QM is usually determined by thermodynamics, i.e. the corresponding synthetic reactions are subject to thermodynamic control. An exception is the case where QM is formed via the recombination of aryloxyl radicals. Such reactions lead to equal amounts of the (*Z*)- and (*E*)-isomers, maintenance of the reaction mixture at room temperature leading to a change in the ratio in the expected direction:[28,38]



(XI) R = CH=CH$_2$;

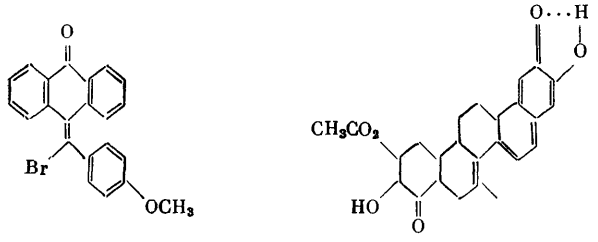
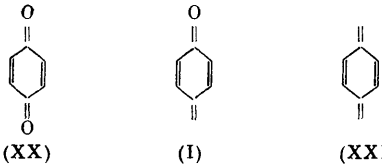
(XV) (XVI) (XVII), R = C(CH$_3$)$_3$



(XVIII) (XIX)



(XX) (I) (XXI)

A detailed conformational analysis of the model QM of lignin has been carried out.[58,60–63] It was established by the AAP and AMI methods that the planar conformer of compound (XI) is preferred subject to the stipulation that a second conformer with the ethenyl group displaced from the plane by ~60° should also be present in an appreciable amount.[58] On the other hand, as was to be expected, only the non-planar orientation can be achieved for the α-phenyl

substituent with the same angle of rotation.[63] The β-aryl ether QM (XXIII) have more interesting conformational features especially in connection with the elucidation of the nature of the structural reorganisation of lignin in pulping processes. Clearly, the chemically reversible transformations of the structural units (for example, the conversion of benzyl alcohol units into quinone methide units and conversely) can lead to irreversible changes in the steric structure of the polymer.

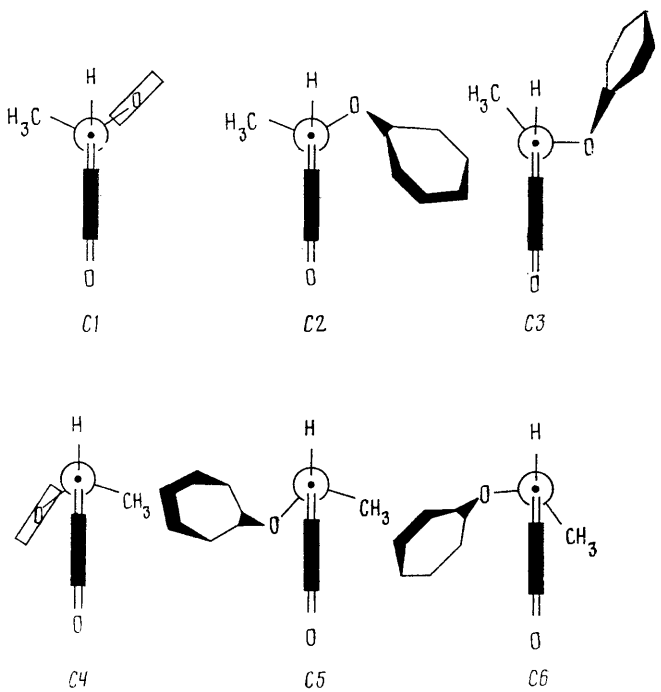


Figure 1. Conformers of the *p*-quinone methide (XXIII, $R^1 = CH_3$): the same conformers occur for other representatives of the series.[62]

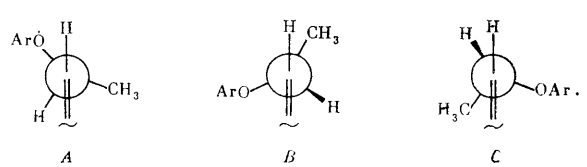
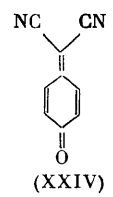
Calculations by the AAP method[60–62] for compounds (XXIII) made it possible to identify the set of the possible conformers *C*1–*C*6 (Fig. 1) and to conclude that the conformational lability of the corresponding lignin units is high. The preference for the most favourable conformers *C*2 and *C*5 increases with increase in the steric hindrance of the molecule. Quantitative estimates of the relative energies of the conformers must be treated with caution, bearing in mind the data of Raos and Shevchenko.[64] However, there is no doubt that the ideas concerning the conformational composition of β-aryl ether QM developed previously[24] require revision. It was assumed[24] that three stable conformations are possible for QM (XXIII) ($R^1 = CH_3$, $R^2 = R^3 = OCH_3$): *A*, *B*, and *C*, the conformation *C* being clearly unfavourable owing to steric hindrance:



Using NMR spectroscopy combined with the nuclear Overhauser effect, the authors[24] demonstrated that the H(2) proton of the (*Z*)-isomer is close to the β-methyl group (R^1) and the H^β proton, which constitutes unambiguous demonstration of the existence in solution of the conformer *A*. Nevertheless, the conformation *A* cannot correspond to a potential energy minimum and the same experimental result would have been obtained if the given QM existed as a mixture of the conformers *C*2 (or *C*1) and *C*5 (or *C*4).[62]

The electronic structure of QM and its relation with the reactivity and chromophoric properties of these compounds have attracted attention a fairly long time ago. This was initiated by the simplest calculations using the HMO method.[65,66] Calculations within the framework of better approximations (PPP,[67] CNDO/S [8,28,68–72]) made it possible to reproduce with a high degree of accuracy the electronic absorption spectra of mononuclear QM and to assess the nature of the structural influences. The electronic spectra have long been used for the analysis of QM and large sets of data have been accumulated (for example, see Pospisek and co-workers[18,67] for special studies). However, their main importance at the present time is to serve as a control for quantum-chemical calculations[8,28] and in connection with photochemical problems.[73] The hitherto few attempts at an experimental estimation of the characteristics associated with reactivity have aroused much interest. Thus the first ionisation potentials of QM (II) and (XV), 8.80 eV [46] and 7.72 eV [70] respectively, have been determined by photoelectron spectroscopy. The proton affinity of the simplest QM (I) was found by the method of ion cyclotron resonance as 915 kJ mol^{-1}.[57] An electron affinity of 2.36 eV has been determined for the QM (XXIV) on the basis of not unduly reliable data concerning the position of the band associated with the charge transfer between the QM and hexamethylbenzene.[74] However, we were unable to detect the charge-transfer band for the QM (XI) even in a mixture with donors giving rise to characteristic bands in the presence of benzoquinone.[249] Such behaviour is consistent also with the results of quantum-chemical calculations.[72,75]



(XXIV)

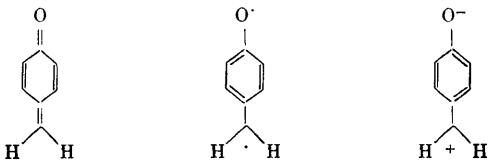
Simplest calculations by the HMO and PPP methods made it possible to establish important features of the electronic structure of QM [5,66,67,76–79] and their protonated forms.[4] The structure of QM and the associated problems of reactivity have now been analysed in fair detail on the basis of a considerable number of semiempirical (CNDO/2, CNDO/S and CNDO/S3, MNDO) [8,28,71–73,75,80–88] and non-empirical[58] calculations.

According to the results of calculations by the CNDO/S3 method,[84] the calcualted energies of the singlet–triplet excitation are too high for the corresponding structures to be regarded as the biradicals (XXV) in the ground state. Only certain excited states can have the biradical character. For planar QM, the energies of such states are unobtainable under the conditions of thermal reactions. The achievement of the biradical state is assisted by the "rotation" of the methylene group out of the plane, but such "rotation" itself requires large energies and the resulting conformation does not correspond to minima on the potential energy surface for the ground state. Thus the biradical forms of the QM (XXV) may play an

appreciable role, in our view, only in photochemical reactions (cf. Burlakov et al.[73]). The non-involvement of the QM biradicals in thermal reactions has also been confirmed by the high regioselectivity of the latter. Mentions concerning the possibility of the existence of QM in a biradical form under normal conditions, which are sometimes encountered, are based on an erroneous interpretation of EPR data during the years when the method only just began to be applied in organic chemistry. In fact solutions of pure QM are diamagnetic.[28]

As regards the zwitter-ionic structures (XXVI),[89] analysis of the bond and atomic valence indices permits the conclusion that such structures (incidentally they have a much higher energy compared with the quinonoid structures) do not correspond to a minimum on the potential energy surface for the ground state.[72,75,84] It is sufficient to say that, after the equalisation of the bond lengths in the ring (with the corresponding lengthening of the C–O and C–C$^{\alpha}$ bonds), the bond alternation does not vanish and there is no significant change in the charge on the C$^{\alpha}$ atom. The electronic[28,71] and ^{13}C NMR spectra[87,90] actually agree well with the quinonoid structures.

Like the biradical structure (XXV), the zwitter-ionic structure (XXVI) can appear only in the vicinity of the saddle point, located an extremely high energy, corresponding to the rotation of the alkylidene group. Therefore, in contrast to Zarubin and Kiryushina,[89] we do not attribute the reactivity of QM for the possibility of their existence in the zwitter-ionic form.



(I) (XXV) (XXVI)

As early as 1983,[72,81] we demonstrated that, as a consequence of the isolated nature of the energy level of the lowest unoccupied molecular orbital (LUMO), the reactions of QM with nucleophiles are usually orbital-controlled. This postulate, which is of key importance for the understanding of the reactivity of QM and which has since been justified by a whole series of empirical and non-empirical calculations,[28,58,71,75,82–87] makes it possible to account for the regioselectivity and the chemoselectivity of numerous reactions involving nucleophilic addition to QM, including those which determine the nature of the pulping processes. The regioselectivity of the orbitally controlled reactions is determined by the contributions of the atomic orbitals to the frontier molecular orbital. For all the QM examined hitherto, the atomic orbital of the C$^{\alpha}$ atom makes the dominant contribution to the LUMO. Only in the case of the QM vinylogue (XI) does another reaction centre, the C$^{\gamma}$ atom, appear with a comparable contribution of its atomic orbitals to the LUMO;[28,58] experimental kinetic data are in full agreement with this assignment.[27]

Many structural influences on the energy of the LUMO of QM have now been elucidated[8,28,71,72,75,81,83] and experimental electrochemical reduction potentials have been obtained for a series of QM in good agreement with calculated data.[28,71,79] Nucleophiles can be in their turn classified in terms of their affinity for QM in conformity with the energies of the highest occupied molecular orbitals.[81,82,89] Such classifications make it possible to estimate reliably the chemoselectivity of nucleophilic addition reactions involving QM. It must be emphasised that there is a small negative charge on the C$^{\alpha}$ reaction centre and the behaviour of QM cannot therefore be explained within the framework of charge control (only the quinonoid tautomers of α-carbonyl-containing phenols are perhaps an exception[83]).

Calculations have now been carried out by the MNDO [87] and CNDO/S3 [71] methods for fairly complex QM of the β-aryl ether type and in the latter case the effect of the conformational isomerism on the electronic structure of the molecules of (*Z*)-(XXIII) ($R^1 = CH_3$, $R^2 = R^3 = OCH_3$) has been determined. This effect is fairly weak, as is, incidentally, also the effect of the appearance of the β-aryloxide substituent itself (which verifies the applicability to lignin of the conclusions obtained from calculations for simplest models). The low-intensity band for the transition involving an intramolecular charge transfer is distinguished by a high conformational sensitivity; the energy of this transition is minimal in the *C*2 and *C*5 conformers, where the two fragments are close to one another.

A similar and more complex and perhaps more important problem is that of a theoretical assessment of the interaction of QM with phenols in neutral and ionised forms. In principle, this reaction is a typical example of the donor–acceptor interaction of a π-acid (QM) and a π-base (phenol) leading to the formation of a covalent chemical bond. Clearly, its mechanism is of interest because interactions of precisely this type determine the nature of many processes leading to the cross-linking and degradation of lignin (see below). It is important to determine whether this reaction proceeds as a classical heterolytic process or whether pre-reaction electron transfer is possible. The point is that the ways in which the heterolytic and radical-ion reactions are influenced are different. A reliable answer to this question can be obtained only by examining the "macroconformations" of the reacting system with variation of the mutual orientation of the reactants and of the distance between them, because the electronic characteristics of the electrophile and the nucleophile change as they approach one another.

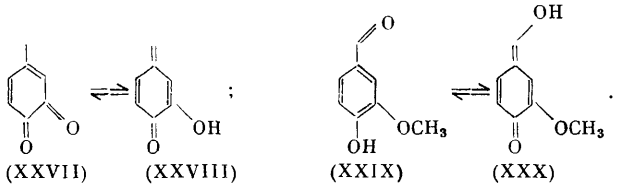
It has been shown[85,86] that the energy of the charge transfer transition in the QM–phenol and QM–phenoxide ion systems is too large for the thermal electron transfer. The addition of phenols to QM is therefore a classical polar reaction regardless of the pH. Another point is that the neighbouring location of the donor and acceptor fragments of the polymer in space makes the polymer sensitive to UV radiation, which is capable of effecting the transition of the system to the chemically excited state with charge separation. On the other hand, in the QM–9,10-anthrahydroquinone dianion (AHQ^{2-}) system the charge transfer energy is low, which indicates a high probability of electron transfer as the first stage of the dark chemical reaction. This difference between the usual phenols and 9,10-anthrahydroquinone makes it possible to explain the significant difference between the influences of the former and the latter on the pulping of wood.[86] We may note that the principal effect of the mutual approach of the reactants is an increase in the energy levels of the LUMO of the QM and that on the whole calculation for the reacting systems confirms the conclusions reached for isolated molecules.

Over short distances, electron transfer can be only a radical-ion stage of the addition reaction (it is important that the barriers to such polar reactions vary in parallel with the charge transfer energies). At the same time, one can imagine also the direct degradation of lignin by electron transfer from AHQ^{2-} or the radical-anion AHQ^{-} to the QM.[92,93] As a result of such a process, a new species is generated from the QM—the *p*-hydroxybenzyl radical-anion, which has the properties of a nucleophile and a base,

dimerising rapidly with formation of the $C^{\alpha}-C^{\alpha\prime}$ bond in the case of sterically hindered QM.[5,94] The possibility of dimerisation is explained by the fact that the negative charge in this structurally benzenoid system is located on the oxygen atom, while the spin density is concentrated on the C^{α} atom, which has a negligible charge, as in the case of the QM itself.[75] Contrary to the hypothesis of Dimmel and Shepard,[92] the direct two-electron reduction of the QM (or the one-electron reduction of the radical-anion) with formation of the corresponding dianion is virtually ruled out because of the inability of the latter to exist independently.[75]

It has been shown experimentally that the electrochemical reduction of model lignin QM of the β-aryl ether type leads to the reductive cleavage of the β-aryl ether bond.[95] The radical-anion obtained from such a QM is unstable and the principal route to its degradation is in fact the cleavage of the β-aryl ether bond. In the presence of 9,10-anthraquinone (AQ), the phenomenon of electrocatalysis is observed, i.e. electron transfer from AHQ^{-} to the QM.[95] This phenomenon is characteristic only of QM whose radical-anions are capable of rapid decomposition via the cleavage of the β-aryl ether bond: other model QM are also reduced irreversibly, but electrocatalysis in the presence of 9,10-anthraquinone does not occur.[91] An attempt has been made[88] to assess theoretically the energetics of electron transfer to QM from both reduced forms of 9,10-anthraquinone—AHQ^{2-} and AHQ^{-}. It was found that the reaction should be highly exotheric for the dianion, while for the radical-anion the difference between the energies of the initial compounds and products is low. This, however, did not enable the authors to reach a definite conclusion whether the first or second process was preferred; we may note that the very attempt at a calculation for the energetics of reactions with participation of ions without taking into account solvation is incorrect.

In conclusion we may mention that the prototropic (phenol—quinonoid) tautomerism of QM has been the subject of a theoretical study in recent years. In connection with the problem of the physiological activity of dopamine, a non-empirical calculation (STO-3G) has been carried out with complete optimisation of the geometry of the tautomers (XXVII) and (XXVIII):[96]



(XXVII) (XXVIII) (XXIX) (XXX)

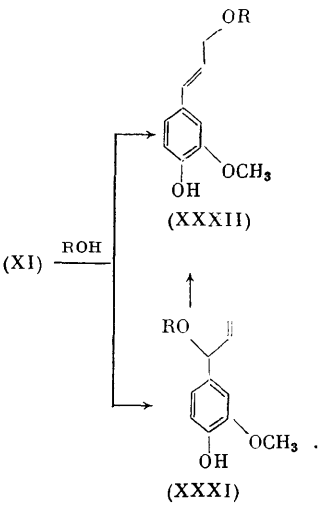
The appreciable energy difference in favour of the *o*-quinone (XXVII) and the large dipole moment of the latter, ensuring stabilisaiton in solution, led the authors to the conclusion that the fraction of the QM (XXVIII) is negligible. The situation is the same also as regards the tautomerism of *p*-hydroxycarbonyl compounds, for example (XXIX)⇌(XXX): for typical model compounds of lignin, the equilibrium is always displaced towards the phenol.[83] Nevertheless the possibility of tautomerism must be taken into account in estimating the reactivity of model compounds of lignin in conformity with the Curtin—Hammett principle.

IV. Chemical reactions

There is no doubt that in the chemistry of wood nucleophilic addition, in which these compounds play the role of substrates, is of greatest importance among the reactions of QM. The addition of water, alcohols, and phenols to QM is of interest in connection with the analysis of the lignification process and hence also of the primary structure of lignin. Another (hitherto completely undeveloped) applied aspect of this reaction is that of the chemistry of organic solvent pulping of wood in alcohols and water—alcohol mixtures.

The kinetics of the addition of hydroxylated compounds to QM have been investigated[49,97—101] using a fairly wide set of reagents but for an extremely limited number of QM. The interpretation of the results and the conclusions about the mechanism of the addition reaction reached in some of the publications[49,98,99] must be treated with caution, since the products were not identified. On the other hand, the quantitative data concerning the stability of QM in various media (in particular as a function of pH) are of undoubted interest. In aqueous solutions, the rate of reaction of the QM (XI) increases with both decrease and increase in pH, the nature of the kinetic curves agreeing with the expected change in mechanism (the primary step is the addition of a proton at low pH and the addition of a hydroxide anion at high pH; in neutral media, one can postulate a concerted nucleophilic and electrophilic attack by water molecules).[49]

Compared with the data of Hemmingson and Leary,[49] the conclusion that the reactivity of QM is low in relation to the SH^{-} and OH^{-} ions, based on the fact that solutions of QM in solvents immiscible with water are stable in contact with aqueous NaOH and Na_2S solutions, appears paradoxical.[102] In fact Ralph's interpretation[102] is erroneous; the observed behaviour apparently arises simply from the heterophase nature of the systems considered.



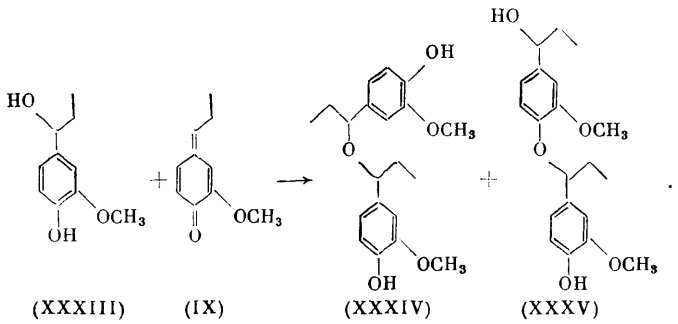
(XXXII) (XI) ROH (XXXI)

The fact that the mechanisms of the addition reactions in neutral and alkaline media are different explains also the characteristic "contradiction" between the theory and experiment in the treatment of structural influences on the reactivity of QM. It is not difficult to understand why the appearance of methoxy-groups in the ring lowers the rate of addition;[49] the reason lies in the electron-donating effect of the substituent. On the other hand, an increase in the length of the conjugation chain lowers the energy level of the LUMO, which should entail an increase in the reactivity in one-electron reduction and orbital-controlled nucleophilic addition reactions.[28] Electrochemical data have shown that such is entirely the case in the reduction reaction. As regards addition, one can confidently assume that this also applies under pulping conditions, where highly nucleophilic ions behave as active agents. On the other hand, in a neutral medium the rate of addition of hydroxylated compounds

falls sharply on passing from QM to their vinylogues.[29,100] Hence it follows that in a neutral medium the reaction mechanism involves the protonation of the carbonyl group as the first stage and not attack on the C^{α} atom. In general, one may conclude that the reactivity of QM in a neutral medium varies in opposition to their stability (an increase in stability may be achieved both by introducing electron-donating substituents and by increasing the conjugation chain length).

Analysis of the orders of the reactions of QM with various hydroxylated compounds in a neutral medium leads to the conclusion that a complex, possibly concerted addition mechanism operates,[99] but kinetic data alone are insufficient for any reliable conclusion. According to Leary et al.,[99] acids add faster than alcohols and only in the former case can one trace the parallel variation of the rate of reaction and the pK_a. In the latter case, a distinct dependence of the rate of addition on steric factors is observed (see also Apushkinskii et al.[100]). Water adds to QM fairly slowly; a sharp acceleration of the process is achieved by adding an acid catalyst.[101] The introduction of type (XI) QM vinylogues into the reaction usually leads to a mixture of 1,6- and 1,8-adducts.[27,49,97] Kinetic control of the addition reactions of both neutral hydroxy-compounds and their ionised forms (OH, OCH_3^-) leads to the preferential formation of the thermodynamically less stable product (XXXI); in an acid medium, equilibrium is readily established and the fraction of the product (XXXII) increases.[27,97] We may note that reduction by lithium tetrahydroaluminate, which in terms of its mechanism is also a nucleophilic addition reaction, affords similarly a mixture of the 1,6- and 1,8-hydrogenation products with the former predominating.[29]

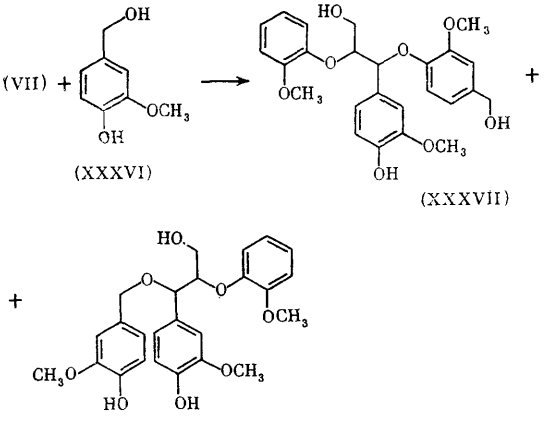
An important factor determining the results of the competitive addition of hydroxy-compounds to QM is the stability of the product. For example, under lignification conditions, the rate of hydrolysis of β-aryl ethers can exceed by a factor of 400 the rate of hydrolysis of β-alkyl ethers.[103] This is an additional factor (together with the higher rate of addition of alcohols to QM compared with phenols), which explains why the reactions of the model lignin QM with vanillyl[104] and dihydroconiferyl[103] alcohols afford dialkyl and not alkyl aryl ethers. The addition of phenols to QM in an anhydrous medium makes it possible to obtain α-aryl ethers,[100,101,105] but in aqueous solution containing an alcohol and a phenol, the alcohol addition product is formed exclusively according to Hemmingson and Leary.[104] We may note, incidentally, that the main factor is undoubtedly kinetic: according to our data, the rate of addition of alcohols to QM is much higher than that of phenols.[100] We have established by ^1H NMR spectrscopy that in an anhydrous medium guaiacylpropanol (XXXIII) adds to the corresponding QM (IX) with the preferential formation of the product (XXXIV).



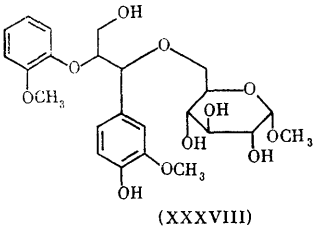
(XXXIII) (IX) (XXXIV) (XXXV)

The alternative product (XXXV) is formed in an insignificant amount, corresponding to the ratio of the rates of reaction of phenol and isopropyl alcohol with the QM (IX). Taken together, these data show that the fraction of benzyl ether linkages of the type $C^{\alpha}-O-C^{\alpha}$ and $C^{\alpha}-O-C^{\gamma}$ in native lignin must be much higher than the fraction of the α-aryl *p*-hydroxybenzyl ether fragments.[1,103]

On the other hand, according to Brunow et al.,[101] the product of the addition of vanillyl alcohol (XXXVI) to the β-aryl ether type QM (VII) is predominantly the *erythro*-benzyl aryl ether (XXXVII) in both non-aqueous and neutral aqueous organic media. Incidentally this conclusion is based on the composition of the products isolated from the reaction mixture by column chromatography in a fairly low yield.



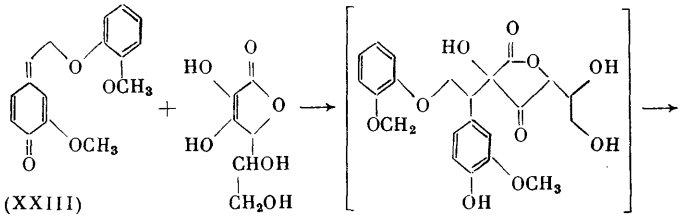
The addition of sugars and related compounds to QM has been investigated in connection with the problem of the formation of lignocarbohydrate linkages. It was shown that D-glucose, methyl α-D-glucoside, and D-glucuronic acid react with β-aryl ether type QM via the C^{α} atom with formation of the corresponding ethers and esters, for example, (XXXVIII).[106–109] It is significant that the nucleophile competing with sugars *in vivo* (water) suppresses to an appreciable extent the interaction of QM with glucose but not with glucuronic acid.



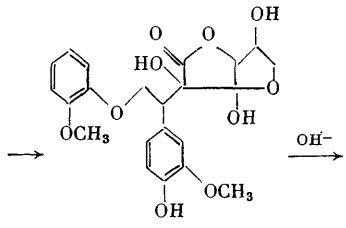
(XXXVIII)

Yet another interesting aspect of reactions of this type is associated with the delignification of wood. It has been found that reducing sugars and their derivatives are capable of cleaving β-aryl ether linkages in phenolic model compounds of lignin under the conditions of alkaline pulping.[110–112] The stability of the methylated models supports the view that this reaction proceeds via a QM intermediate, while the high reactivity of ascorbic acid and at the same time the inactivity of non-reducing sugars are evidence for the involvement of the enediol form of the cleaving agent. Indeed, under neutral conditions, the reaction of the QM (XXIII) with ascorbic acid afforded the adduct (XXXIX), which on heating in

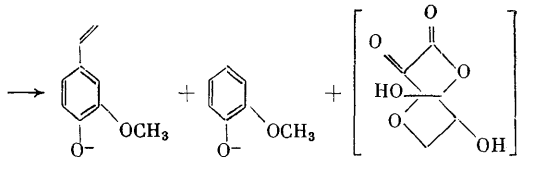
aqueous alkali gave rise to the products of the cleavage of the β-aryl ether — guaiacol and vinylguaiacol:[110]



(XXIII)

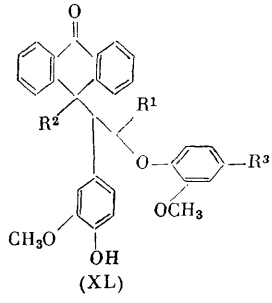


(XXXIX)



It is easy to note the close analogy between the mechanism of this reaction and the heterolytic mechanism of the action of anthrahydroquinone.[9] The difference between the structures of the adducts (XXXVIII) and (XXXIX) is noteworthy: the $C^{\alpha}(QM)-O-C$ linkage is formed in the former case and the $C^{\alpha}(QM)-C$ linkage is formed in the latter. The NMR spectra published in the literature[108,110] give rise to no doubts about the assignment of the structures, but we believe that the interpretation from a single standpoint of the mechanism of the interaction of QM with carbohydrates and related compounds requires further accumulation of experimental data. At any rate, it can now be postulated that, together with ether and ester linkages between components of the lignocarbohydrate complex (LCC), there are also carbon–carbon bonds which are readily hydrolysable in alkaline solutions.

In recent years studies on nucleophilic addition to QM received a fresh stimulus in connection with the investigation of the mechanism of the anthraquinone pulping of wood. In connection with this problem, the range of nucleophiles has expanded, which led to new fundamentally important results. The adducts (XL) of anthrahydroquinone and related compounds with model lignin QM[9,113–124] and lignin itself (under the conditions of the formation of QM *in situ* [113,125]) were obtained under mild conditions.



(XL)

$R^1 = H, CH_3, CH_2OH$; $R^2 = H, OH, CH_3\ C_6H_5$; $R^3 = H$, lignin.

Such compounds (R^2 = OH) readily undergo the Grob heterolytic fragmentation in aqueous alkali, which results in the cleavage of the β-aryl ether bond and the regeneration of anthraquinone.[9] The high regio- and stereo-selectivities of the addition are striking: in the case of model compounds, a single adduct is formed as the *threo*-isomer (R^2 = H, OH),[114,118] while for lignin the formation of the *threo*-isomer is preferred.[113] Sterically hindered derivatives of anthrone give rise to a mixture of the *threo*- and *erythro*-adducts (XL, $R^2 = CH_3, C_6H_5$), under the conditions of kinetic control the *threo*-isomer being formed preferentially; an increase in the reaction time in an aqueous alkaline solution leads to an increase in the fraction of the *erythro*-isomer, which, however, rarely reaches one half.[119,122] Such behaviour indicates the reversibility of the addition and the ease of the dissociation of the adducts in aqueous alkali. This is also indicated by other data.[126,127]

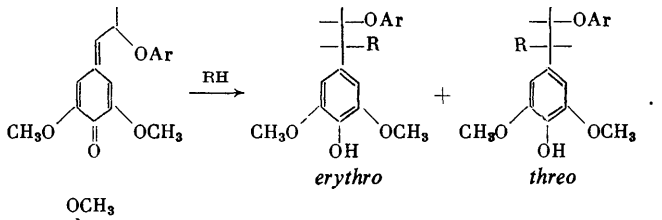
α-Aryl ethers are known to be readily converted into QM in aqueous alkali even at room temperature.[128] Therefore the introduction of dehydrodiisoeugenol and related compounds into the reaction with anthrone and anthrahydroquinone under these conditions leads to the formation of the corresponding adducts, but in the given instance with a distinct preference for the *erythro*-isomer.[115] We may note incidentally that in the case of β-aryl models containing the hydroxymethyl group the splitting off of formaldehyde is so fast that the formation of the corresponding product (stilbene) predominates over the formation of the adduct.[115]

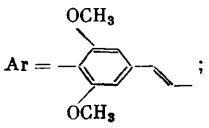
Other nucleophiles, such as amines[23] and water (in dioxane),[129] afford *threo*-adducts preferentially. Such stereoselectivity is actually the property of the QM themselves: in an acid medium, where the reaction probably proceeds via a carbonium ion, selectivity falls sharply.[23,114,129] The regioselectivity of the addition to QM can be logically accounted for within the framework of ideas about orbital control (see above) but as regards stereoselectivity the situation is more complex. In principle, in this case one might begin with modern ideas about the hindrance of reaction centres[130] and the conformational composition of the QM attributed to them by Ralph and Adams.[24] The trouble is that the ideas of Ralph and Adams (see also Chum et al.[50]) are most probably erroneous (see above). The stereochemistry of the formation of the adducts therefore still awaits its elucidation. It has been shown that the action of *erythro*-phenol-alcohols with bromotrimethylsilane[23] gives rise exclusively to the *threo*-bromo-derivative, which is converted into a 1 : 1 mixture of *erythro*- and *threo*-derivatives in 0.5 h.[102] On this basis, the author[102] put forward the hypothesis that S_N2 substitution takes place in this case. It is much more likely that the reaction proceeds via a carbonium ion.[248] The related reaction of acetyl halides with *p*-hydroxybenzyl alcohols, affording *p*-acetoxy-α-halo-derivatives in a quantitative yield under mild conditions, is known.[131] We may note that the latter derivatives are convenient synthons for the generation of QM *in situ* in an alkaline medium.[123,124,132]

General rules which would make it possible to predict the stereochemistry of the product of the addition to QM do not exist. Nevertheless, this question is important if only because of its relation with the stereoisomeric composition of the lignin chains, since the lignification process proceeds with participation of QM as intermediates. It is therefore significant that, according to Nakatusbo and Sato[21] and Dyall and Winstein,[29] the addition of water to the QM (VII) gives rise to the ratio *threo* : *erythro* = 7 : 3 in dixoane and 1 : 1 on catalysis by HCl. At the same time, carboxylic acids afford predominantly the *erythro*-diastereoisomers in their reactions with QM.[21,26,129] Kinetic data[99] make it possible to postulate a trimolecular reaction in the latter case and to relate the

anomalous stereoselectivity to the specific formation of intermolecular hydrogen bonds in a pre-reaction complex;[23,133] incidentally, such explanations have not been supported by serious evidence. The involvement of hydrogen bonds in the transition state has been discussed also in an attempt to account for the preferential formation of the *threo*-isomer in the reaction of QM with water.[21]

We may draw attention to the fact that the conclusion that one of the stereoisomers is slightly preferred is frequently reached by comparing their final yields (see, for example, Zanarotti[26]). Naturally, such results are unreliable: the correct procedure involves the analysis of spectroscopic data for the reaction mixtures. In this connection, it is not clear whether a slightly greater amount of the *erythro*-isomer is really formed in the addition of water in the presence of HCl to the β-aryl ether QM in the case of the syringyl derivatives while for guaiacyl QM the isomers are present in equal proportions.[26] The conclusion that the *erythro*-adducts of a whole series of nucleophiles are preferred under the conditions of acid and base catalysis[26] appears reliable, since the preference is fairly distinct:

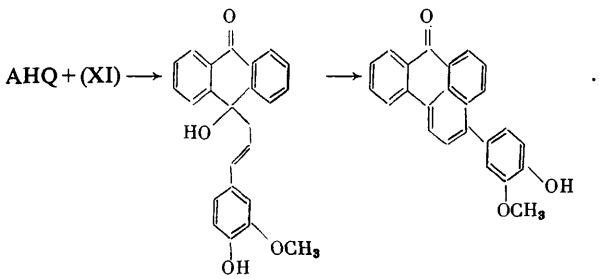




R=OCH_3, CH_3COO, C_6H_5O, $(CH_3CO_2)_2CH$, 2,4,6-$(CH_3O)_3C_6H_2$.

It may be that the discrepancy between data for the stereoisomeric composition of the products of the nucleophilic addition to QM depends on whether thermodynamic or kinetic control operates in the course of the reaction (this depends on the reactants and to a greater extent on the conditions).

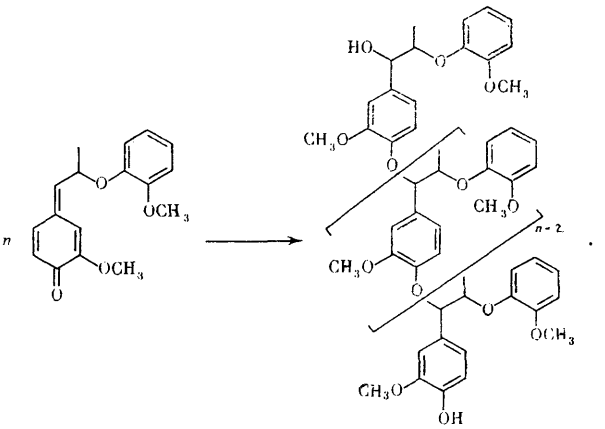
The addition of anthrone and anthrahydroquinone to QM vinylogues takes place with formation of the C(10)–C^{γ}(QM) bond;[116,125] under pulping conditions, such products are irreversibly converted into condensed systems:[9]



We may note further that in the reaction of anthrahydroquinone with QM there is a possibility of the formation also of a small amount of the product of hydroxyalkaltion in the β-position in the aromatic ring; such substances have been found also in the anthraquinone pulping liquors.[9,123]

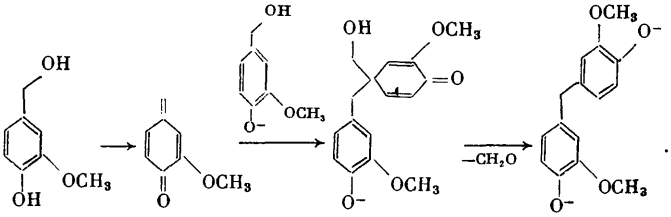
It has been recently shown in relation to the addition of primary amines that the reactivities of (*E*)- and (*Z*)-QM are different: for the (*Z*)-isomer, the addition is 1.4 times faster.[59] This observation throws new light on the significance of the studies on the stereochemistry of QM described above.

It is well known that a convenient method of modelling lignin as a polymer involves the use of a dehydropolymer, in the formation of which QM intermediates apparently play a role (see below). A different type of a model regular polymer can be obtained directly from QM by polymerisation initiated by a base or electrochemically:[50,102]



In terms of its mechanism, such polymerisation also represents nucleophilic addition. In the presence of alkali metal cations, the addition reaction is controlled kinetically and the *threo*-isomer is formed preferentially; in the presence of bulky tetraalkylammonium cations, thermodynamic control operates and preferential formation of the more stable *erthro*-product is observed (the possible explanation of this reaction is provided by the difference between the degrees of chelation of the cations).[50] A polymer, in all probability with a different structure, is formed on oxidation of guaiacylacetone derived from the corresponding QM.[17]

Under the conditions of alkaline pulping, *p*-hydroxybenzyl alcohols, which are capable of forming QM, readily undergo self-condensation with formation of oligomeric products.[104,126,134] This process, which simulates one of the possible pathways leading to the cross-linking of lignin, apparently also takes place as nucleophilic addition to QM *in situ*, for example:



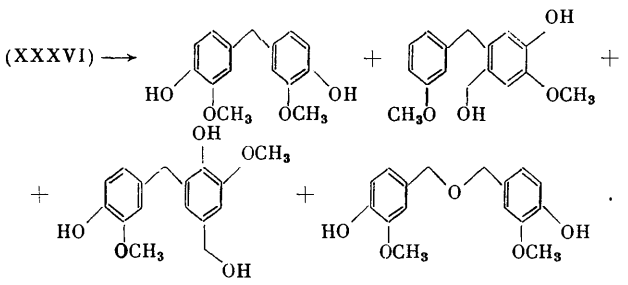
(XXXVI)

Similar reactions may be observed also in the generation of QM in another way, for example from sulphones.[135]

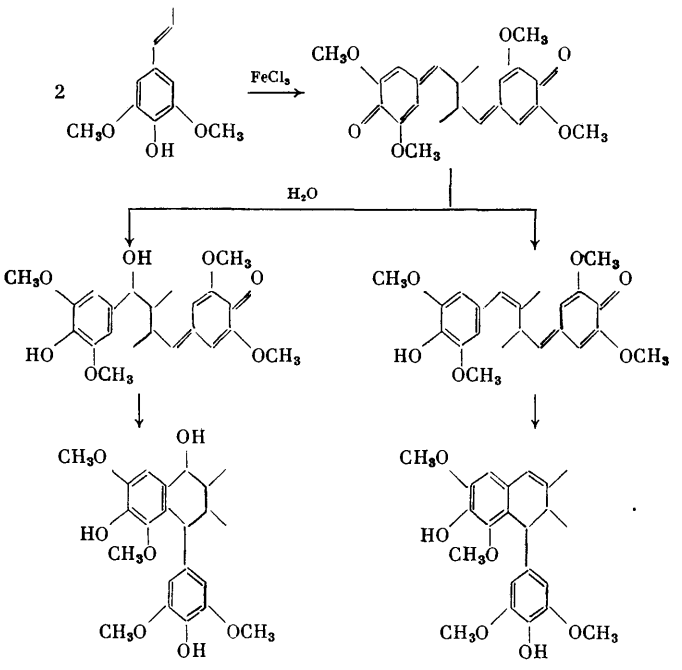
In the presence of anthrahydroquinone, this reaction is suppressed[136] and the formation of bibenzyl derivatives is observed—these may be the products of the "head to head" dimerisation of the radical-anions formed from the QM.[126]

We may draw attention to the fact that processes similar to alkaline oligomerisation take place also in neutral aqueous or

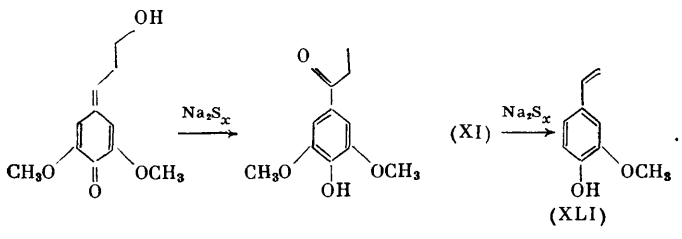
aqueous alcoholic media[104] as well as in the solid phase on silica gel[137] (simulation of the heterogeneous medium in plants), constituting therefore one of the possible lignification pathways:



An interesting example of intramolecular cross-linking has been described[34] (the reaction mechanism has not been reliably demonstrated by the hypotheses put forward are well founded):

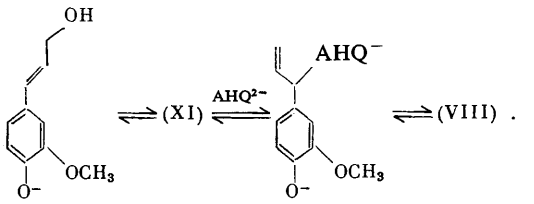


Depending on the nucleophile, the addition may be the first stage of a more complex process. Whereas sodium sulphide affords the corresponding thiol in the reaction with QM, the reaction of QM with sodium polysulphide in aqueous solution affords oxidation products even at room temperature; in the latter case the additon is merely the first undetected stage:[138]

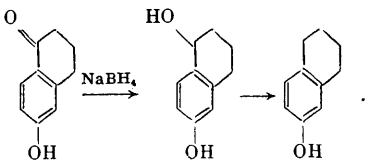


Dimethyl sulphoxide reacts similarly with QM.[132]

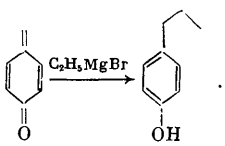
The QM reduction reactions have also been frequently discussed. On the basis of the dynamics of the accumulation of coniferyl alcohol (XIV) and isoeugenol (VIII) during anthraquinone pulping, it has been suggested that compound (VIII) is actually obtained in the pulping process from compound (XIV) by direct reduction of the latter to a QM:[139]



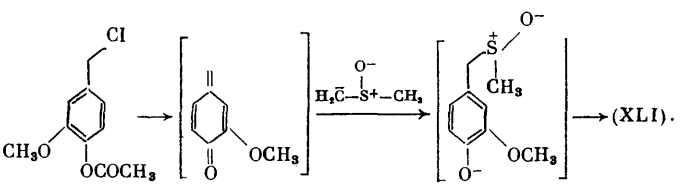
The increase of the fraction of isoeugenol among the coniferyl alcohol reaction products in aqueous alkali after the addition of anthrahydroquinone agrees in principle with this hypothesis.[140,141] However, the interaction of vanillyl alcohol (XXXVI) and apocynol (XLII) with anthrahydroquinone on heating in aqueous alkali leads not to the reduction of the corresponding QM [142] but to the formation, as shown in the first example, of adducts.[136] Apparently the hydride transfer reactions are nevertheless not characteristic of anthrahydroquinone. Reagents such as lithium tetrahydroaluminate and sodium tetrahydroborate can naturally reduce the QM directly.[26,27,29] This apparently constitutes the mechanism of the familiar reaction of alkyl hydroxyphenyl ketones with sodium tetrahydroborate:[142,143]



The use of organometallic compounds as nucleophiles makes it possible to obtain alkylphenols with a lengthened chain via QM:[43]

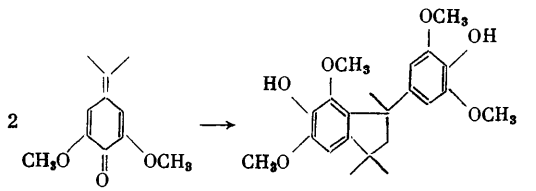


An increase in the length of the chain can be achieved also by the nucleophilic addition of the dimsyl anion (generated from dimethyl sulphoxide and sodium hydride) to QM:[132]

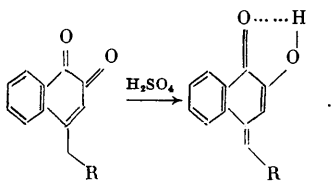


We may note that the difficulty of experiments with unstable compounds such as QM sometimes gives rise to doubts about the reliability of the results. This applies to many reports of the formation of "head to head" QM dimerisation products, for example that of Leray and Thomas.[144] The mechanism of the QM dimerisation reactions, similar to the reaction on treatment with

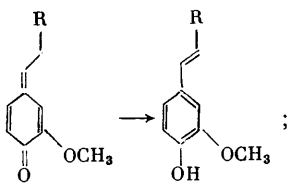
triethylammonium acetate presented below, is frequently osbscure and hardly represents the direct coupling of two QM molecules:[145]



Tautomeric transformations constitute a special type of reactions of QM. We mentioned above that the phenol–quinonoid tautomerism is usually manifested only in the case of sterically hindered compounds; for typical model compounds of lignin, aromatisation is the driving force of the rearrangement and the QM are usually transformed irreversibly into related phenols but not conversely. Condensed systems are an exception. Thus on treatment with a catalyst, 4-benzyl- and 4-alkyl-1,2-naphthoquinones are converted into QM:[146]

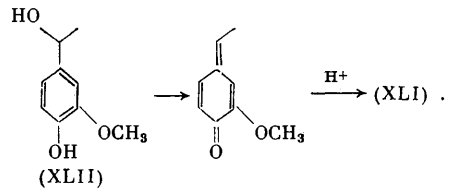


A typical rearrangement of QM is their irreversible stereoselective conversion into (*E*)-α-alkenylphenols, for example:[100,147]

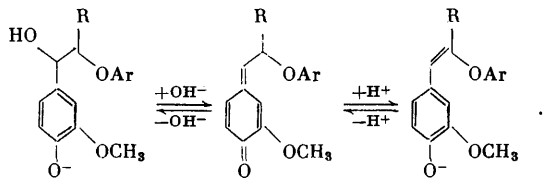


R = H, CH_3, C_6H_5, CH_2Br.

This reaction was observed previously only under the conditions of acid–base catalysis (the involvement of water was postulated at the neutral pH).[145,148,149] Thus, whereas primary and secondary amines add readily, like ammonia, to QM, treatment with tertiary amines actually leads to isomerisation.[148] Incidently, it has been found that this isomerisation also proceeds in a neutral solvent at a rate comparable to the rates of addition of alcohols and phenols (in equimolar amounts).[100,147] It is of interest to note that conversion into alkenylphenols is in essence the only pathway to the degradation of the simplest model lignin QM in the absence of other reagents.[147] Such a reaction provides a method of synthesis of stereoisomerically pure alkenylphenols, which can be in their turn quantitatively converted into the initial QM (see above). QM can isomerise also under pupling conditions. According to kinetic data, *p*-hydroxybenzyl alcohols with β-aryl ether substituents are in fact converted in this way into enol ethers.[150,151] An example of the simplest model experiment is provided by the heating of an equimolar mixture of apocynol (XLII) with anthrahydroquinone-monosulphonate in aqueous 1 M NaOH (137 °C, 1 h).[142] The expected products ethylguaiacyl (the QM reduction product) and vinylguaiacyl (XLI) (the QM isomerisation product) were isolated:



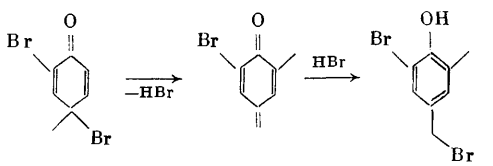
The authors[142,152] postulate the following equilibrium under pulping conditions:



This is supported by the similarity of the cleavage products in the anthraquinone pulping of phenol-alcohols and the corresponding enol ethers and also the (*E*,*Z*)-isomerisation of the latter under these conditions.

It is of interest to note that the conversion of many model compounds of lignin into isoeugenol (VIII) via a QM intermediate is achieved with formation of precisely the (*E*)-isomer;[138] the cleavage of the β-aryl ether linkage with participation of anthrahydroquinone[122] or anthrone[120] also belongs to reactions of this class. The factors which determine the stereochemistry of the product have no bearing on the stereochemistry of the intermediate adduct despite the views of the author.[122]

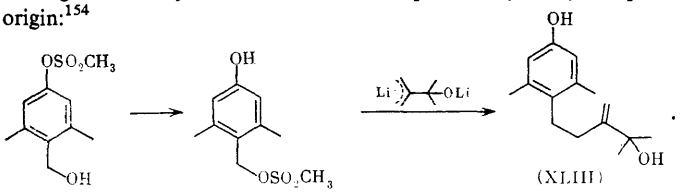
QM are capable of acting as isomerisation intermediates but this time of a completely different kind[153] (cf. Brunow and Sumelius[32]):



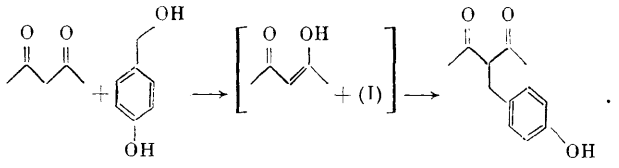
In recent years, there has been a growth of interest in organic chemistry in QM as promising synthons.[5,26,27,132,154–158] We should like to draw attention to studies unrelated to the chemistry of wood; the use of their results may lead to the discovery of new procedures for the specific transformation of lignin.

The high electron affinity of QM is responsible for the possibility of their copolymerisation with electron-donating monomers. Thus the 1,6-addition of styrene to α,α-dicyanoquinone methide takes place readily with formation of a linear regular copolymer.[74] The characteristic addition reactions make it possible to use QM in the synthesis of lignans and neolignans[26,27,159–161] and numerous compounds with *p*-hydroxybenzyl groups. It is most convenient to use QM *in situ*, whereupon *p*-hydroxybenzyl alcohols or, what is much more convenient, their derivatives, which are capable of readily affording QM under the reaction conditions, enter into the reaction directly. Such derivative may be esters,[27,162] halides,[23,123,126,132,163] methanesulphonates,[154] benzenesulphonates,[164] aminophenols,[163,165] etc.[52,166]

As an exotic example, we may quote the following reaction leading to the synthesis of a natural product (XLIII) of plant origin:[154]

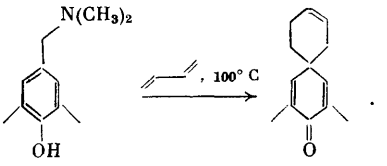


The possibility of the formation of a QM as an intermediate has been used also in the development of a method for the removal of a protecting group in the series of benzyl ethers.[131] *p*-Hydroxybenzylation of the readily enolisable 1,3-diketones takes place on heating in water (it is striking that benzyl alcohol, which is incapable of being converted into a QM, does not enter into this reaction):[155]



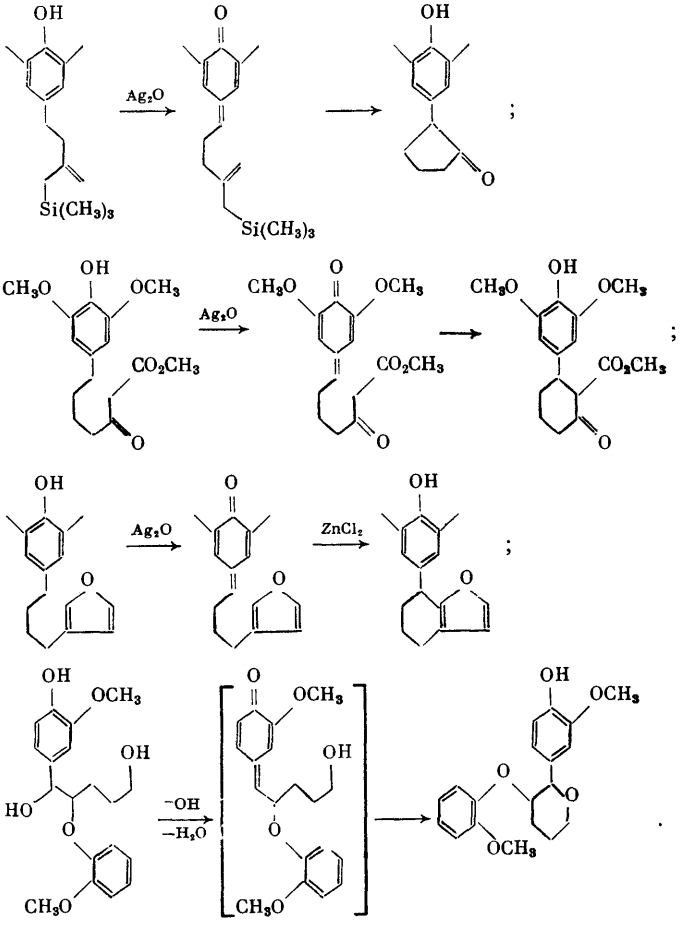
In the case of QM vinylogues, similar reactions with acetylacetone and nitroethane afford mixtures of regioisomers.[27] There is a reaction, involving intramolecular addition to the C^{α} atom, which leads to various carbocycles and heterocycles[111,167,168] (examples are given in Scheme 1).

QM can also enter into cycloaddition reactions as dienophiles and dienes. Attention should be drawn to the fact that the Diels–Alder reaction makes it possible to use specific trapping agents for QM and gives rise to prospects of obtaining unusual lignin derivatives. The following reaction may serve as an example of the use of butadiene as a trapping agent for *p*-QM formed *in situ*:[165]

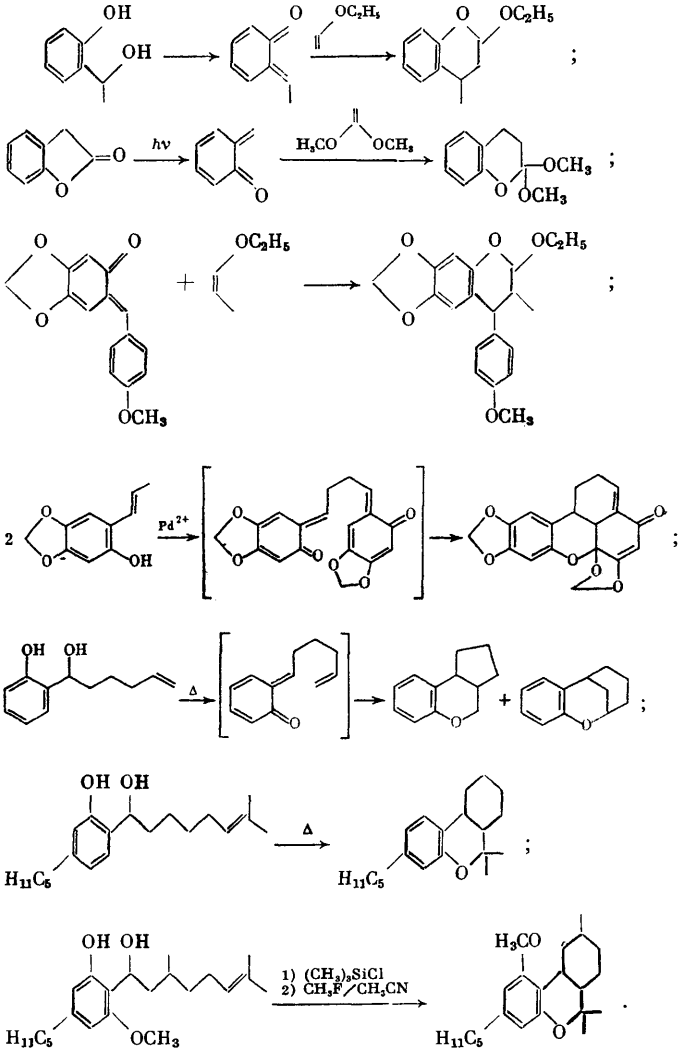


Addition to the exocyclic double bond of the QM takes place according to the idea of the orbital control of the reaction. Examples of reactions with participation of *o*-QM, also preferentially *in situ*,[30,52,166,169–175] are given in Scheme 2.

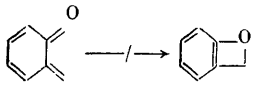
Scheme 1



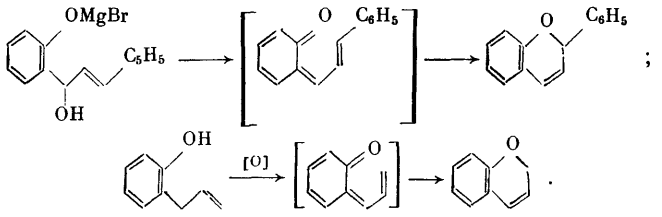
Scheme 2



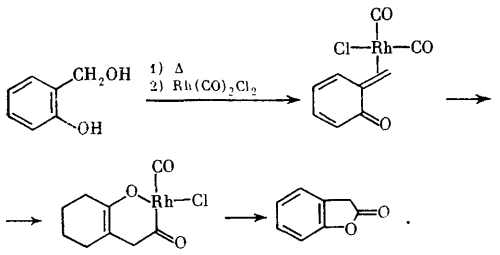
These examples refer to intramolecular cycloaddition. We may note that direct cyclisation with formation of oxetans is not characteristic of *o*-QM, in contrast to, for example, *o*-quinodimethanes:[56]



On the other hand, examples of the formation of a six-membered ring are known:[30,176]



An intermolecular cycloaddition reaction, leading to trimers, has also been noted for the simplest *o*-QM.[44,45,173,175,177] An interesting example of a reaction of QM, proceeding via an organometallic complex, which was not isolated, has been described:[178]



The properties of *o*-QM as dienes are such that the [4 + 2]-cycloaddition reaction with dienophiles having an enhanced electron density at the multiple bond, such as keten acetals and vinyl ethers, is preferred; the reactions with alkenes having weak electron-donating let alone electron-accepting substituents, do not take place quite so readily.[172]

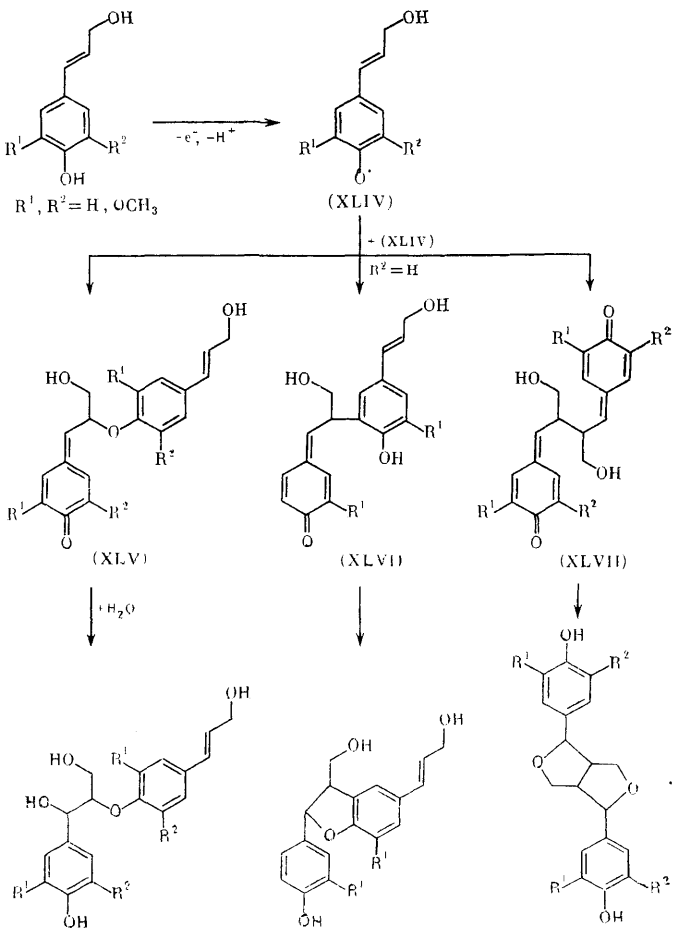
V. Quinone methides and the structure of lignin

The biosynthesis of lignin is traditionally represented as a dehydrogenation polymerisation process, during which QM, playing the role of intermediates, are formed. These views arose as a result of a considerable number of early studies and have been reflected in familiar monographs.[2,3,179] In the 1950's–1960's, it was sometimes reported that the formation of QM had been detected directly in processes modelling lignification;[1] these reports appear doubtful nowadays. The idea that QM intermediates participate in lignification processes is based mainly on the analysis of oligomeric products of model experiments on the oxidative polymerisation of compounds considered as lignin precursors.

According to Freudenberg and Neish,[179] lignin is formed via the stage involving the dehydrogenation of low-molecular-weight precursors with formation of the corresponding radicals whose dimerisation actually constitutes the first stage of the polymerisation. The rules governing the recombination of aryloxyl radicals are well known. This process leads to the formation of QM dimers, whose structure is determined by the selectivity of the dimerisation reaction. *p*-Hydroxyphenylallyl alcohols have been considered as the main lignin precursors. This agrees well not only with the available information about the structure of native lignin but also with the latest data on the ionisation potentials of the possible precursors:[180] indeed, phenols with an α-unsaturated side chain should in fact exhibit the highest reactivity in oxidation in neutral and weakly acid media; this preference is very pronounced. The regioselectivity of the dimerisation is consistent with the familiar distribution of spin density in the radicals (XLIV),[181,182] which is manifested by the formation of the dimers (VIII) and (XLV)–(XLVII) (in the form of racemic mixtures).[34,183] We should warn, incidentally, against attempts to relate directly the spin density to the fraction of particular structures in the polymer. The latter is to a large extent determined by steric factors and the relative stabilities of the products.[181]

The QM (XLV)–(XLVII) are converted into phenolic dilignols as a result of a nucleophilic addition reaction (the reaction with water affords β-aryl ether structures; an intramolecular reaction gives rise to cyclic systems). Examples of the possible processes are given in Scheme 3.[1,184,185]

Scheme 3



Subsequent growth of the macromolecule involves the oxidation of the dilignols to the corresponding radicals and the reactions of the latter with one another and with other radicals. This can also result in the formation of QM.[183] According to Forss and Fremer,[184] the

macromolecule is formed from the dilignols via the following stages (only the stages with participation of QM are listed):

dehydrogenation of oligolignols, which subsequently react with one another and with monolignols, affording biaryl derivatives, diaryl ethers, and QM;

the addition of phenols to QM, in which oligomeric lignols participate without losing a hydrogen atom;

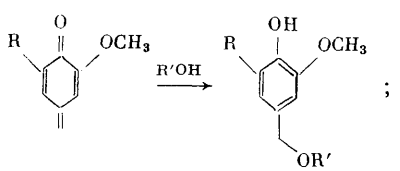
addition of carbohydrates to QM, which results in the formation of lignocarbohydrate linkages;

polymerisation of QM leading to linear aryl benzyl ethers.

Two mutually complementing models of lignification exist—bulk and endwise models; the true process can be only of a mixed kind.[184]

We emphasise that the existing ideas about lignification should be regarded merely as a hypothesis but a hypothesis which is fairly logical and which works well. Within its framework, QM play an unusually great role as intermediates. Thus about 70% of the interunit bonds in conifer lignin are formed as a result of β-coupling[185] and any radical reaction involving the β-position yields an intermediate QM which is subsequently converted into a more stable system. Among the characteristics of the reactions of QM, nucleophilic addition to the C^{α} atom is the most important reaction (if not the only one) for lignification.[1] Plant tissues contain simultaneously a multiplicity of compounds capable of acting as nucleophiles (water, carbohydrates, uronic acids, and alcoholic and phenolic groups of the lignin being formed). Nucleophilic addition ensures the formation of typical lignin structures: *p*-hydroxybenzyl alcohols, ethers, and esters. Therefore studies on the kinetics and mechanisms of the above reaction are of primary importance for the understanding of the structure of wood: thus whatever nucleophile adds preferentially to the QM, it determines the frequency of various types of benzyl structures in the final polymer.

The situation as regards the relative nucleophilicities of the solution components in the wood cell is fairly complex. We have already mentioned the mixed order of the addition reaction, indicating its complex mechanism. The dependence of the rate of reaction on the pK_a of the hydroxy-compound[179] seemingly shows that the addition of acids should proceed more readily and hence that one should expect a higher content of ester linkages in the lignocarbohydrate complex compared with ether linkages.[2] At the same time, it has been noted[186] that without a catalyst coumaric and ferulic acids react fairly slowly with QM (in the presence of tetrabutylammonium hydroxide, esters are formed instantaneously and quantitatively). The experiments on the competitive addition of nucleophiles such as ethanol, water, and acetic acid[98] showed that the reaction of a model QM with their isoequimolar mixture afford predominantly benzyl ethyl ether:

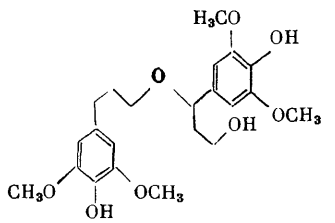


;

R = $C(CH_3)_3$, R′ = H, C_2H_5, CH_3CO.

At a higher pH (4–6), the concentration of the more nucleophilic CH_3COO^- ion increases and benzyl acetate becomes the main product, although benzyl ethyl ether is formed in appreciable amounts. In an alkaline medium, the presence of the strong nucleophiles HO^- and $C_2H_5O^-$ again leads to a low yield of the ester. One may conclude that in the neutral or weakly acid medium, characteristic of plant tissues, ester type lignocarbohydrate linkages are formed most readily, although a considerable proportion of ether linkages should be present together with the latter. It is significant that, by virtue of its weaker nucleophilic properties, water does not interfere with the formation of the lignocarbohydrate complex. However, an excess of water in the presence of a deficiency of other nucleophiles makes the formation of linear chains with α-alcoholic groups the main reaction pathway of primary QM; we may note that similar structures arise also in the hydrolysis of benzyl ether linkages, which takes place readily.[179]

The nucleophilic addition of lignin fragments to QM with participation of alcoholic, phenolic, and carboxylic acid groups of the former should be regarded as one of the important routes to the formation of lignin.[1,101,183] Unfortunately, the instability of the $C^{\alpha}-O-C^{\gamma}$ and $C^{\alpha}-O-C(4)$ bonds formed gives rise to serious difficulties in securing evidence for their presence in the native polymer; early studies devoted to the formation of such bonds require additional tests. However, the isolation of the dimer (XLVIII) from the products of the hydrogenolysis of lignin[1] appears to constitute convincing evidence for this; the presence of bonds of this kind agrees also with the familiar results of computer simulation of the biosynthesis lignin.[187]

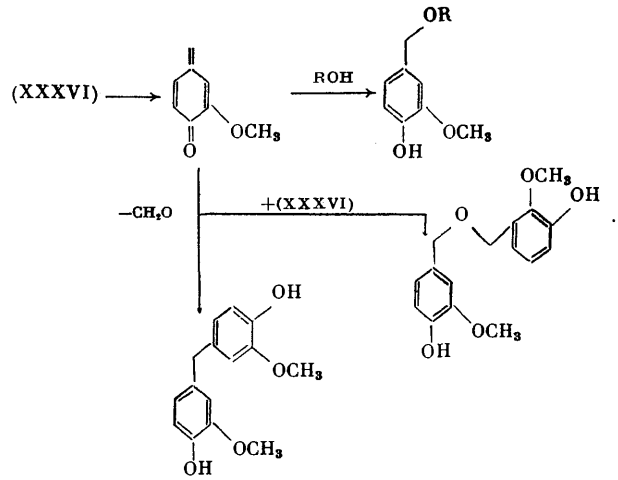


(XLVIII)

Model QM combine with glucuronic acid[107] and glucose[107,183] (see above). This reaction proceeds also in the presence of water. Such processes can be regarded as simulation of the formation of the lignocarbohydrate complex. However, bearing in mind the competition by water and other nucleophiles, the formation of an appreciable amount of the lignocarbohydrate linkages in this way requires a fairly high concentration of carbohydrates near the QM at the instant of their formation or the fixation of the quinone methide structure in the vicinity of the carbohydrates of the cell wall. The latter is fairly probable since it is believed that the dehydrogenation polymerisation of monolignols takes place in the outer cell membrane in the vicinity of the carbohydrates of the cell wall, which contains in addition a relatively small amount of free water.[183]

The view that the reactions of QM during lignification are irreversible and that the structure of native lignin is therefore directly determined by the nature of the reactions of the primary QM was widely held previously.[2,179,185] Hence follows, for example, the misunderstanding arising on comparing the frequency of the lignocarbohydrate linkages and the number of carbon fragments capable of reacting with QM. It was found later that not only under severe pulping conditions but also directly in plant tissues there is a possibility of the formation of "secondary" QM.[188,189] If this is so, then the autodegradation and secondary structure formation processes can lead in the course of time to appreciable changes in the frequency with which interunit bonds of different types are encountered (we have in mind both the ways in which the lignin subunits are joined together and the lignocarbohydrate linkages).

This possibility is supported by convincing experiments on model compounds. Thus in neutral and weakly acid aqueous media, vanillyl alcohol (XXXVI) forms α-ether linkages with aliphatic alcohols and glucose (the half-reaction time for 10% ethanol is 2.7 years).[188] The involvement of QM in this process is confirmed if only by the fact that veratryl alcohol is converted into an ether much more slowly under the same conditions. The self-condensation of vanillyl alcohol can serve as the simplest model of the secondary cross-linking of lignin. Under lignification conditions, this process also takes place[1] with the exclusive formation of dibenzyl and not aryl benzyl ether. Further self-condensation of lignin over a period of time with formation of diarylmethane structures is also possible.



Model studies together with the analysis of the composition of the lignins and dehydropolymers isolated suggests the important role of QM both in the initial stage of lignification and in the course of the wood ageing processes.[1] In the early stage, the competition by the nucleophile for the "primary" QM determines the ratio of the structural units with a free and etherified α-hydroxyls. It has been suggested that, owing to the presence of a large amount of water during lignification, the "primary" lignin contains many benzyl alcohol groups and resembles Feudenberg's dehydropolymers.[1] After a time, re-etherification and the formation of stable *p*-hydroxybenzyl ether structures (the lignocarbohydrate linkages and the $C^{\alpha}-O-C^{\gamma}$ linkage) take place. Such development of the lignification process agrees with the model[187] proposed as a result of computer simulation using data for the compositions of the lignins isolated.

The question of the relation between the colour of lignins and the presence of quinone methide structures in them is interesting and hitherto has been little elucidated. Its practical importance is evident, since a correct answer to it may lead to novel procedures for combating the yellowing of cellulose.

It is believed that, together with qinonoid structures, stilbenequinones, conjugated bis-*p*-quinone methides, and hydroxyaryl-substituted QM are included among the chromophoric systems of the residual lignin.[190−192] It must be emphasised that these are only hypotheses based on the results of model experiments and not on the analysis of the lignins themselves after chemical processing of wood (the assignment of the structures in the latter case is not unambiguous). The formation of stable QM structures in the self-condensation and subsequent oxidation in air of a number of model compounds of lignins has been postulated[193−195] on the basis of the spectroscopic characteristics of the products. Even these data, obtained on simple models, do not appear to be reliable. On the other hand, the presence of such systems both in the bulk of cellulose and in treated liquors is fairly likely. The conjugated and shielded QM are stable and are usually brightly coloured—both as a result of conjugation and as a consequence of the possibility of intramolecular charge transfer in systems of this kind.[63,68,196] The latter effect should be manifested particularly strikingly in the presence of alkali when the electron-donating phenolic groups are ionised.

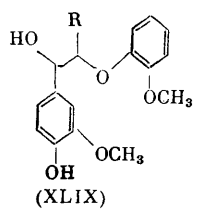
VI. Quinone methides as intermediates in the delignification of wood

Although it has not so far been possible to detect the presence of quinone methide structures under the conditions of the pulping of wood, nevertheless this does not by itself justify a sceptical attitude to the proposed mechanisms of the pulping reactions with participation of QM. In principle, such a situation arises for the majority of intermediates: if they are indeed highly reactive, then their stationary concentration is low; the study of intermediates always requires special methods and conditions different from those which obtain when the relevant reactions are carried out.

It is remarkable that QM give rise to identical problems in the chemistry of wood and in bioorganic chemistry. Thus hypotheses that many biological processes take place with participation of these intermediates and that one is dealing with compounds very similar to model QM of lignin have long been put forward.[17,197−204] It has been suggested that the formation of QM can explain the reactivity of many flavonoids.[205]

The conclusion that many key pulping reactions take place via QM is based on numerous experiments performed on model compounds. As early as the beginning of the 1960's, the results of kinetic studies on the hydrosulphide and hydrosulphite treatment of vanillyl alcohol (XXXVI) suggested that these processes proceed via a QM intermediate whose formation is the rate-limiting stage; this has received additional confirmation from the marked retardation of the reaction in alkaline and neutral media on alkylation of the phenolic hydroxyl.[206,207] It was also established that the formation of QM determines the rate of degradation of the benzyl ether linkages[208] (the blocking of the phenolic hydroxyl stabilises such linkages, in particular the lignocarbohydrate linkages[106]).

Subsequently these views were confirmed by kinetic experiments on more complex models[111,209−212] and it is at present regarded as established for example, that the stage determining the rate of the alkaline degradation of β-aryl ethers (XLIX) is the formation of QM. The situation is similar also as regards the corresponding syringyl analogues but with the difference that the presence of two electron-donating methoxy-groups (incidentally such groups stabilise the QM) promotes a faster elimination of the α-hydroxy-group.[212]



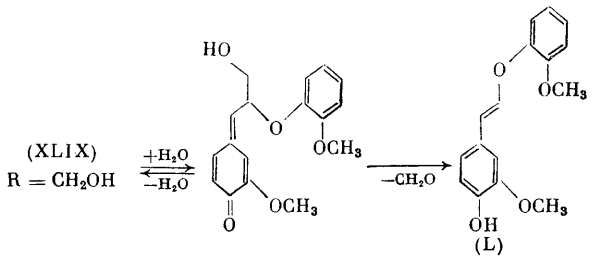
(XLIX)

R = H, CH_3, CH_2OH.

In experiments on model compounds, it was shown that the conversion of the initial *p*-hydroxybenzyl alcohol into a QM is the rate-limiting stage both in the cleavage of β-aryl ethers under the conditions of sulphate pulping and in condensation processes.[210,213] This is why the given reaction is of first order with respect to the initial alcohol and its rate is independent of the concentration of the OH^- and SH^- ions (at pH ⩾ 12 when the phenolic groups are fully ionised and at a SH^- concentration sufficient to capture all the QM intermediates). These data are part of the experimental evidence for the quinone methide mechanism of the cleavage of β-aryl ether linkages. An additional confirmation of this mechanism comes from the fact that β-aryl ethers without a free phenolic hydroxyl are cleaved more slowly.[214–216] However, the mechanism of degradation in the case of models containing two syringyl nuclei has not been ultimately elucidated and is apparently more complex than in the case of the guaiacyl–guaiacyl and syringyl–guaiacyl models; it is sufficient to say that the transition from the β-guaiacoxide to the β-syringoxide substituent accelerates the cleavage[212] (cf. Miksche[209]).

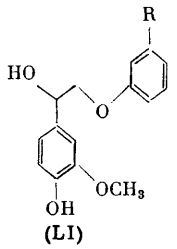
The most important experiment demonstrating the formation of QM during pulping was carried out by Miksche and co-workers.[20,213] They kept the stereoisomerically pure model (XLIX, R = CH_3) in 0.1 M aqueous NaOH at 100–120 °C for several hours. A considerble proportion of the initial compound was then recovered from the reaction without change in its chemical structure but in the form of a 1 : 1 mixture of the *threo*- and *erythro*-stereoisomers. Only the reversible formation of a planar intermediate could lead to such a result. Bearing in mind that the reaction proceeds in alkali and the formation of a carbonium ion is therefore ruled out, one can assume that under the conditions specified *p*-hydroxybenzyl alcohol give rise to QM at an appreciable rate and the latter combine in their turn with a OH^- anion to reform the initial compound; thus a stationary concentration of QM exists in the solution.[128]

These data have been confirmed in principle also in another study,[102] where the behaviour of the more representative model (XLIX, R = CH_2OH) was investgiated and 79% of the initial compound in the form of an *erthro*:*threo* = 3:1 mixture was recovered from the pure *erythro*-isomer. It was found that, under similar conditions (125 °C, 1.5 h), both in the presence of pure NaOH and in the presence of Na_2S the starting material is recovered to the extent of 50–60% having isomerised to the extent of 5–10%; the vinyl ether (L) is then formed as a reaction product in an appreciable amount (15–30%). Hence follows the following reactivity sequence: (HO^- > HS^-) ≃ retroaldol condensation (i.e. the elimination of formaldehyde).[102]



In our view, the results of these experiments (if they are confirmed) indicate something else, namely that, under the conditions of alkaline pulping, the conversion of the β-aryl ether structures of the type considered into vinyl ether structures is the main reaction pathway. However, one should refrain in this case from making assessments of the reactivity of the kind which refer in principle to chemical reaction kinetics: it is extremely likely that the process is thermodynamically controlled. A strikingly low degree of isomerisation has been quoted by Ralph:[102] it can be either a result of the virtually complete conversion of the QM formed into a vinyl ether or can be eividence of a low degree of conversion of the initial β-aryl ether into the QM. Overall, these results conflict with modern ideas and clearly require additional tests.

Whereas the hypothesis that the pulping reactions of *p*-hydroxybenzyl alcohol groups proceed via QM itself belongs to the class of generally accepted ideas, makes it possible to explain the entire set of experimental data, and is hardly criticised, the answer to the question of the rate-limiting stage in the cleavage of β-aryl ether structures is far from being unambiguous. In the study of the cleavage of the model (LI) under the conditions of alkaline pulping, a distinct dependence of the rate of the process on the substituent R was obtained.[217] This is possible only when the slow stage in the overall mechanism is the direct decomposition of the β-aryl ether linkage. On the other hand, in the formation of vinyl ethers from similar models the rate-limiting stage is in fact the formation of the QM.[217]



(LI)

The rapid and slow stages can apparently change depending on the models and the types of pulping. Thus under the conditions of sulphate and anthraquinone pulping of wood, the influence of the substituent R is no longer felt but a distinct dependence of the rate of cleavage on the substituent in the phenolic ring (QM precursor) is observed.[218] Here the slow stage is clearly the formation of the QM; the reason for the change in the rate-limiting stage is clear from Fig. 2.

Yet another question is important: how many QM precursor structures are present in native lignin and is their number sufficient for QM to play the appreciable role attributed to them? A large proportion of the phenolic hydroxyls in structures of the arylglycerol–β-aryl ether type have been converted into ether groups.[138,185] The fraction of *p*-hydroxybenzyl alcohol groups in the lignin of ground pine wood is estimated as 0.06 per methoxy-group[3] (p. 167, see also Veeramani[219]), but it is difficult to estimate the reliability of these data. However, we may note that *p*-hydroxybenzyl ethers, which can be readily converted into QM, may also serve as QM precursors[138,150] and the rupture of only a small number of weak bonds may be sufficient for the degradation of the polymer, facilitating its dissolution. Furthermore, the fraction of QM precursor structures increases during pulping as the α- and β-aryl ether linkages are cleaved and phenolic hydoxyls are thereby liberated. The new phenolic units are capable in their turn of being cleaved via the quinone methide mechanism and such cleavage of units can proceed until a subunit of a different type is encountered (lignin piling[216]). Gierer[220] noted that the delignification in the course of traditional pulping of wood proceeds exclusively via nucleophilic reactions, while in the bleaching of bulk cellulose electrophilic reactions take place initially and may then be

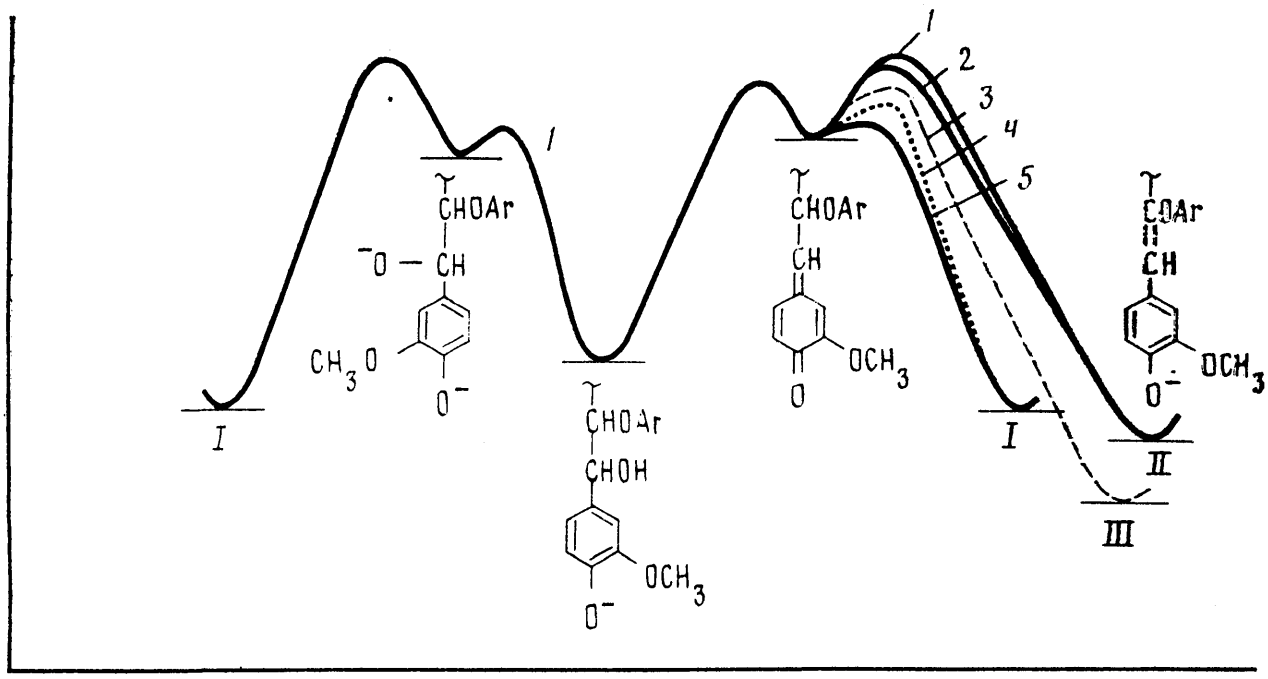


Figure 2. Proposed energy diagram for the reaction of terminal phenolic units of lignin:[218] (I) fragments (dissociation of the β-ether linkage); (II) vinyl ether; (III) condensation products; (*1*) OH^-; (*2*) terminal CH_2OH group, elimination of CH_2O; (*3*) ArO^-; (*4*) SH^-; (*5*) AHQ^{2-}.

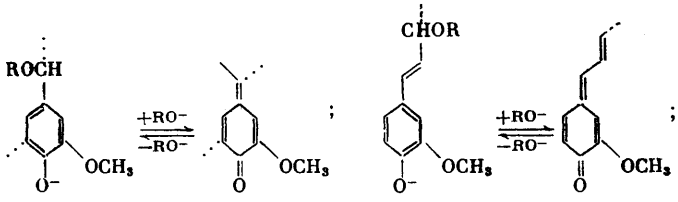
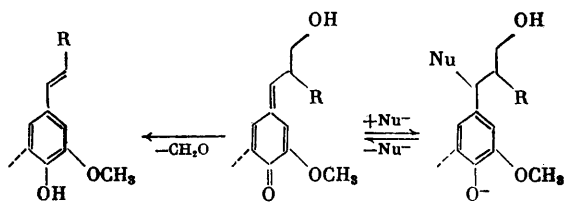
followed by nucleophilic processes. The active agent in pulping consists of nucleophiles (SO_2 and OH^-, SH^-, HSO_3^-, SO_3^{2-}, AHQ^{2-}, and AHQ^-). According to current ideas, these agents do not destructure lignin via direct substitution reactions. In the first stage, they react with electrophilic substrates, which also include QM. The latter are known to be formed via the elimination of an α-substituent or, in the case of conjugated systems, a γ-substituent. This process may proceed at any pH. A reaction of this kind at high pH is illustrated by the following scheme:



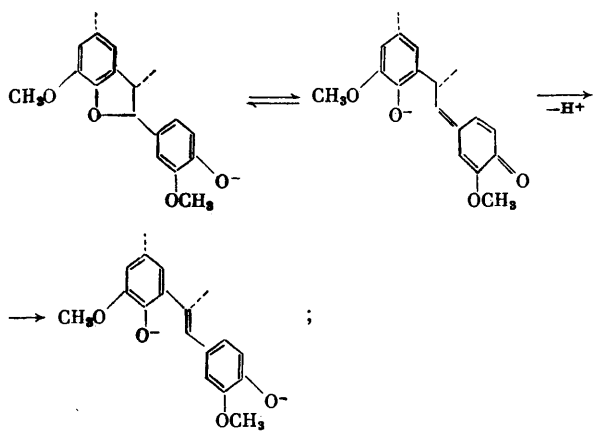
R = H, Alk, Ar.

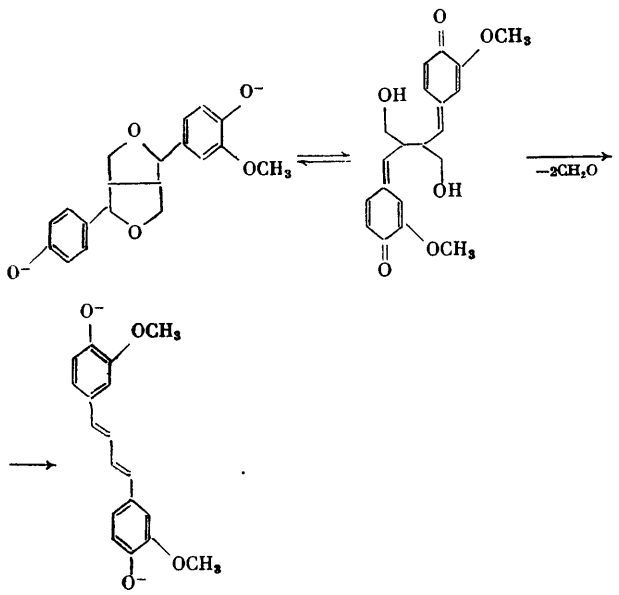
In a familiar review,[220] similar schemes refer also to the reactions of lignin in acid media; this is erroneous, since in the latter case one should refer to the formation of the corresponding α-carbonium ions.

When several nucleophiles are present in solution, they compete with one another, attacking the substrate, and the nature of the reaction of lignin in different types of pulping is determined to a large extent by the relative nucleophilicities of the components of the liquor, their concentration, and also the properties of the corresponding α-substituents as leaving groups (we recall that the formation of the QM is reversible). Another competing reaction leading to aromatisation is the elimination of formaldehyde with formation of the more stable styryl structures.[111,141,221,222]



The stilbene and diarylbutadiene structures are formed from coumaran and pinoresinol lignin fragments:

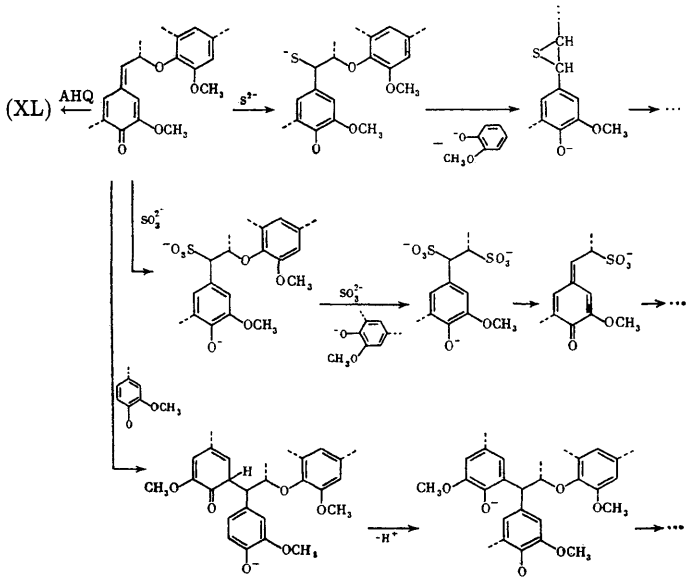




Since similar processes are inhibited on blocking the phenolic hydroxyl, one may conclude that the formation of the QM intermediate is essential for the reaction of the given type;[223,224] it is probably in fact the rate-limiting stage in the formation of vinyl ethers.[111]

According to existing ideas, the pulping reagents are strong nucleophiles which effectively capture the QM with formation of adducts, which rapidly and irreversibly decompose with the dissociation of β-aryl ether linkages. Such cleavage represents in essence a redox process. In broad outline, the mechanism of the heterolytic addition–cleavage is the same for sulphate,[140,216,225] sulphite,[226–228] and anthraquinone[9,229] pulping as well as the pulping in the presence of low-molecular-weight phenols[230,231] (Scheme 4).

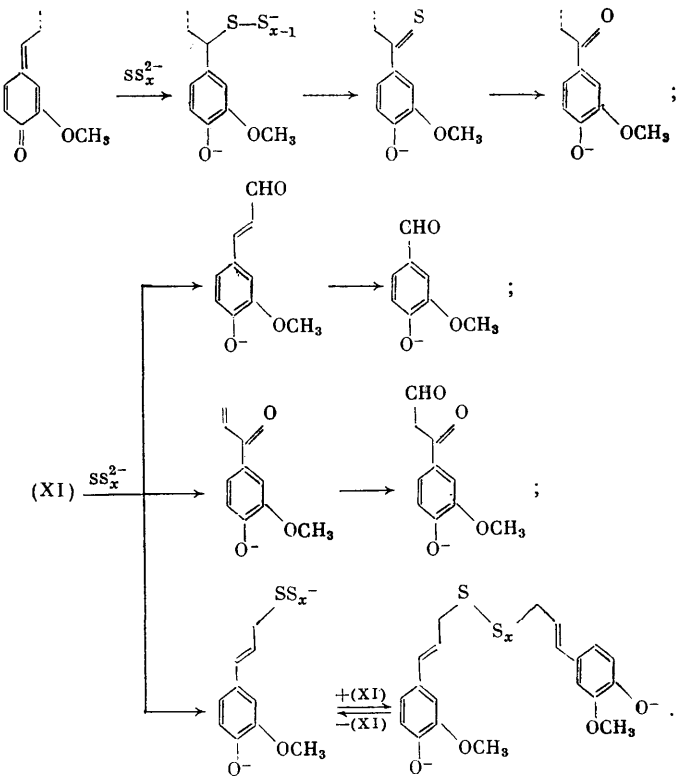
Scheme 4



We may note that similar products of the addition to *o*-QM under pulping conditions are formed also from *o*-hydroxybenzyl alcohol structures.[232] The cleavage of the β-aryl ethers via intramolecular attack on the ionised α-substituent is in principle possible both in the case of α-alcohols and α-thiols. However, the p*K* values for the ionisation of benzyl alcohols are much higher than for thiols. Therefore it appears that the fragmentation of the phenol-alcohol units is more effective in the sulphate pulping than in the soda pulping.[121]

Other complex processes also take place at the same time. Thus the formation of a number of products from model compounds of lignin under the conditions of sulphate pulping has been explained by the mechanisms presented in Scheme 5, which apparently operate in the course of the reactions of wood itself.[138,141]

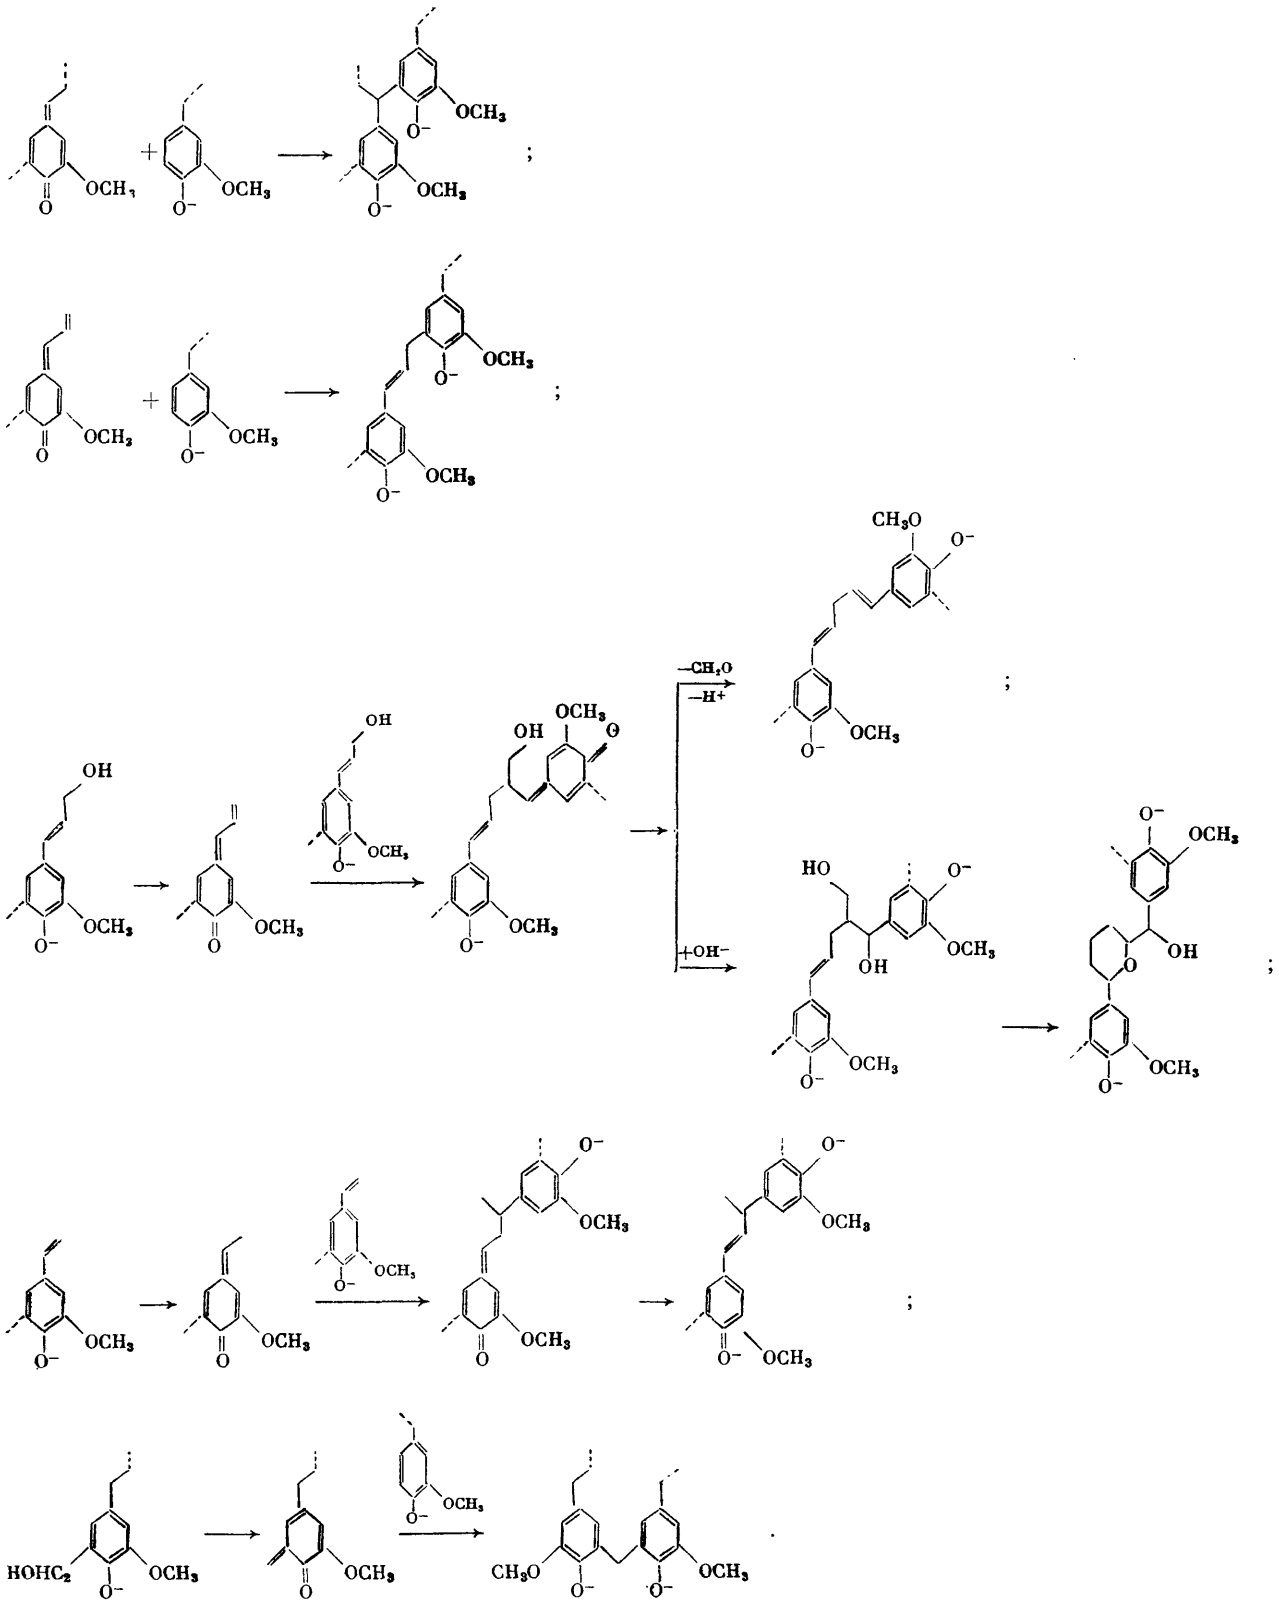
Scheme 5



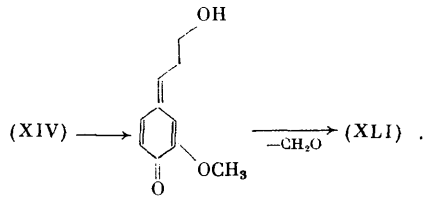
These reactions constitute polysulphide oxidation and in the case of the QM (XI) the initial stage is 1,6- or 1,8-addition. Clearly in polysulphide pulping their role should increase.

In the absence of strong nucleophiles (soda pulping), the elimination of terminal hydroxymethyl groups with conversion of the native β-aryl ether structures into the β-aryloxystyryl structures (more stable in alkali) predominates.[216] This reaction naturally does not belong to the class of fragmentation reactions. On the contrary, it produces formaldehyde, which is in principle capable of cross-linking phenols. The elimination of formaldehyde from various fragments of lignin represents generally speaking a process which can be fairly readily achieved and the formation of QM as intermediates

Scheme 6



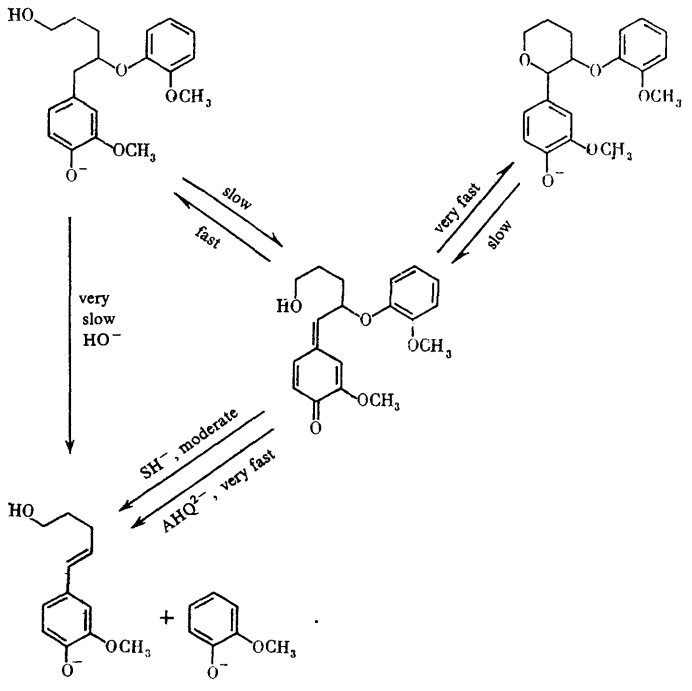
actually facilitates it. Thus the following mechanism has been postulated for the simple coniferyl alcohol (XIV) model:[141,233]



The relative importance of various routes to the rearomatisation of the QM is determined by the basicity and nucleophilicity of the reagents. Competitive experiments made it possible to establish the following series based on the rates of the reactions considered: the formation of QM $\ll$ elimination of CH_2O < addition of carbanions to QM < addition of SH^- to QM.[210]

When the structure of the lignin fragment does not lead to the chain degradation pathway, the addition of a low-molecular-weight nucleophile nevertheless assists the delignification process, retarding (although not blocking completely) the condensation of lignin and preventing the formation of stable styrene structures.[216,234] One of the important routes to such condensation involves the addition of phenolic fragments of lignin to QM, which takes place readily in an alkaline medium[104,138,141,216,220,232,233,235,236] (Scheme 6).

A remarkable example of a model system of competing pulping reactions has been described:[111]



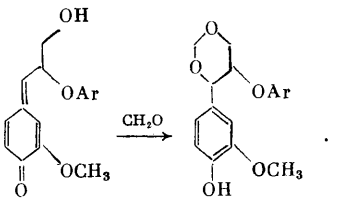
In the case represented, the nucleophilic addition of pulping agents competes with intramolecular addition and the efficiency of the suppression of the latter by the introduction of anthrahydroquinone demonstrates the unique properties of this nucleophile. Striking examples of the suppression of the self-condensation of *p*-hydroxybenzyl alcohols and dioxane-lignin by this reagent as well as other strong nucleophiles as reductants are also known.[126,135,237]

We may note that the corresponding bibenzyls have been detected among the products of the self-condensation of model alcohols in the presence of anthrahydroquinone.[126] In principle, these compounds can be the products of the dimerisation of the radical-anions produced by electron transfer to the QM,[238] but an unambiguous conclusion concerning their origin is so far impossible. Bearing in mind the theoretical considerations described above, the hypothesis[238,239] of the possibility of electron transfer to the QM from arylate anions or carbohydrates under the pulping conditions appears unconvincing.

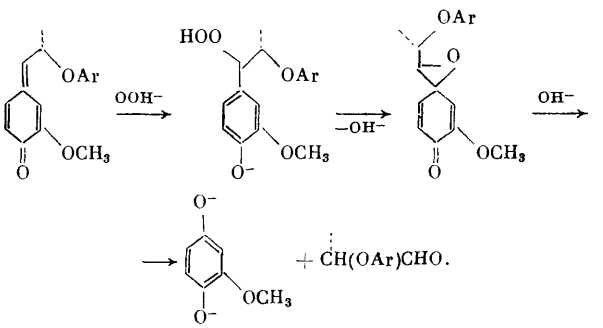
It is of interest to note that heating of *p*-hydroxybenzyl alcohols in aqueous alcoholic mixtures affords, together with their self-condensation products, also etherification products which are most probably produced via QM.[104,188] It appears that such processes can occur in the course of organic solvent pulping.

Evidently the influence of phenols on the pulping process should depend on their molecular weight: the interaction of lignin QM with low-molecular-weight phenols leads to cross-linking accompanied by the rupture of the chain (the overall effect is positive), while the addition of high-molecular-weight fragments of lignin prevents the delignification process. Low-molecular-weight phenols, for example coniferyl alcohol (XIV), which can themselves be readily converted into QM condensing with lignin under pulping conditions, are an exception. As already mentioned, the presence of powerful nucleophiles (for example, SH^- and AHQ^{2-}) in the pulping liquor hinders condensation processes of different types.[136,237,240] We emphasise that the final result of the "fight for QM" depends not only on the nucleophilicity of the reagents but also on the rates of the subsequent irreversible reactions—cleavage or condensation.

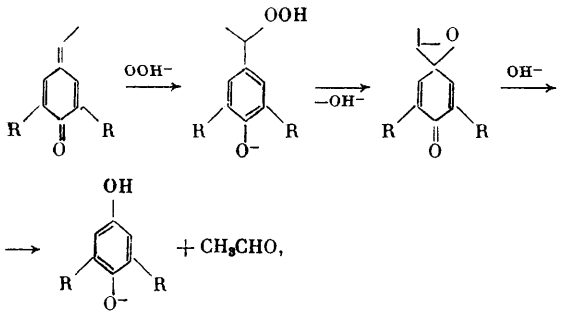
We may also note the following reaction as an interesting example of condensation with participation of QM and low-molecular-weight lignin degradation products:[241]



Unusual reactions with participation of QM may occur in oxidative delignification, where both electrophiles (for example, O_2) and nucleophiles (for example, OOH^-) function as active agents. The addition of the peroxide ion can lead to the rupture of the lignin chain:[233,241]

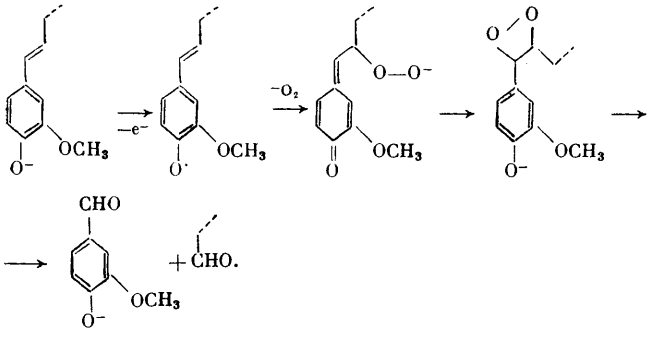


The following reactions were observed in a model experiment:[241,242]



R = C(CH$_3$).

The oxidation of conjugated phenols leads to the dissociation of the $C^{\alpha}-C^{\beta}$ bond, the intramolecular nucleophilic addition to QM being an important stage of the process:[233,241–243]

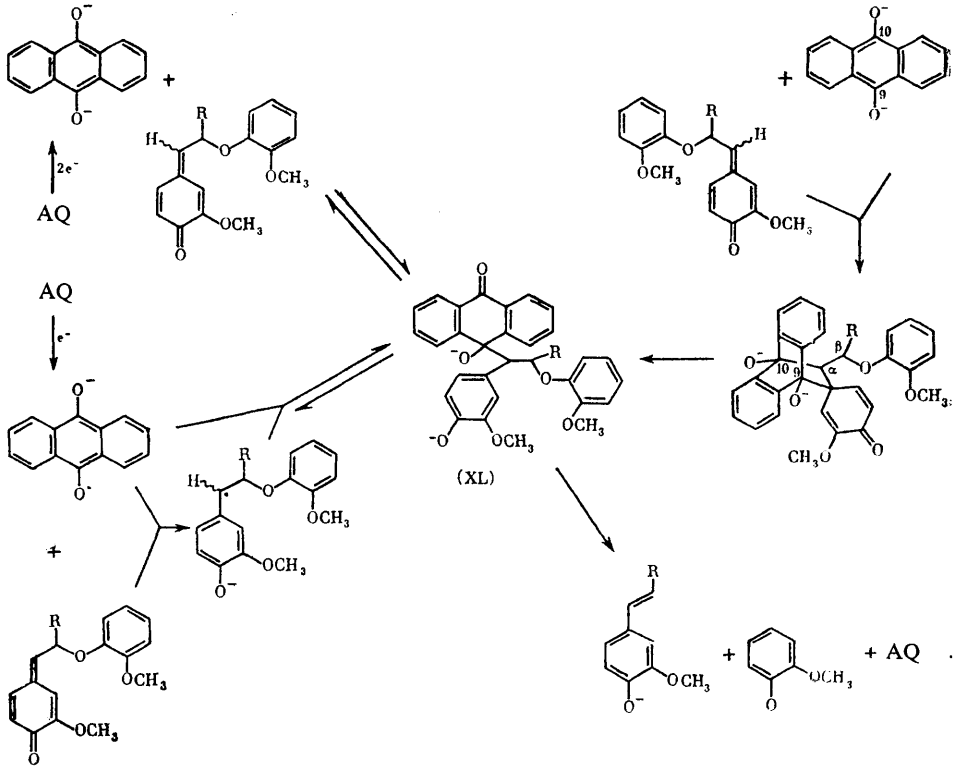


We have already noted that there is a close similarlity between the mechanisms of pulping involving strong nucleophiles (the fact that the addition of anthraquinone exerts a greater effect on the soda pulping of wood than on the sulphate pulping has in fact been explained by the competition between the related reagents[9]). The results of studies of the anthraquinone pulping carried out in recent years are therefore of special interest. Together with the observation of the characteristic features of the process involving anthraquinone as such, they made it possible to re-examine the properties of lignin and its reactivities in various technological processes.[9]

Above we discussed in detail various aspects of the reactions of model lignin QM with derivatives of anthracene such as anthrahydroquinone and anthrone. The "classical" mechanism of the cleavage of phenolic β-aryl ether subunits of lignin in the course of pulping involves the formation of the adduct (XL), which then undergoes Grob fragmentation. Such ideas are based on the isolation of the adduct under mild conditions; the adduct decomposes via the postulated mechanism on heating in aqueous alkali. However, this does not yet rule out the possibility of other reaction pathways.

Anthranol and anthrahydroquinone may be regarded as effective trapping agents for QM. The reasons for their high affinity for QM and the associated ability of these compounds to cleave the β-aryl ether linkages of lignin have been interpreted within the framework of different theories. The interaction of the above reagents with QM can be quite logically explained within the framework of the theory of hard and soft acids and bases:[9,89] in this approach, the anions behave as nucleophiles attacking the electrophilic substrate and the key stage of the process is the formation of an adduct of the type (XL) (Scheme 7).

Scheme 7



It has been suggested[142] that the oxidation-reduction interaction of anthrahydroquinone with QM can proceed via the formation of a charge-transfer π-complex and that the anthraquinone–AHQ^{2-} system as it were "creeps" along the surface of the gel-like lignin polymers and hemicelluloses supplying or abstracting electrons. Dimmel and co-workers[92,93,95,111,238,239,244] proposed a likely one-electron transfer theory in which the key stage ensuring cleavage is electron transfer to QM.

Finally, Ralph[102] recently put forward the hypothesis (with a reference to a private communication by Suckling) that the primary stage of the reaction of the reduced form of the catalyst with the lignin QM may be the Diels–Alder reaction. This hypothesis is least well founded. However, it is significant that all three mechanisms can involve the formation of the "key" adduct (XL), admittedly via different pathways, so that it is so far not clear whether we are justified in regarding all the above pathways as alternative pathways. On the other hand, it is useful to formulate a fundamental question the answer to which would make it possible to understand whether there is any point in considering a charge-transfer mechanism as an alternative to the "classical" mechanisms. This question refers precisely to the properties of QM and can be written as follows: what is faster under the pulping conditions—the decomposition of the corresponding radical-anion or the coupling of the latter to anthrahydroquinone? Only in the former case can the specific features of the one-electron reactions be manifested significantly (although, as we have already mentioned, in the latter case also the demonstration of the existence of a one-electron stage might affect the choice of procedures for intensifying the catalytic process).

Dimmel et al.[95] drew attention to the fact that the reductive cleavage of β-aryl ether QM with participation of the reduced forms of anthraquinone, but without the formation of an adduct, is observed in electrochemical experiments. However, it is not clear how likely in general the formation of an adduct is under the conditions of the electrochemical carried out by Dimmel et al.[95] Furthermore, as a consequence of the dependence of the rates of formation of the adduct and of the electron transfer on the temperature and the solvent, the legitimacy of the extrapolation of the results of Dimmel et al.[95] to the pulping process is not evident. We may note that experiments do not provide an answer to the following question either: is the dianion AHQ^{2-} or the radical-anion $AHQ^{\cdot-}$ more likely as the electron donor? The rapid disproportionation of $AHQ^{\cdot-}$ usually leads to the simultaneous formation of AHQ^{2-} and Dimmel et al.[95] dealt with a mixture of reduced forms of anthraquinone at least in preparative experiments (cf. Shevchenko et al.[127]).

In our view, the mechanism of electron transfer catalysis is quite likely, but it is very difficult to demonstrate it reliably and so far there is no such evidence. This is a fairly common situation; electron transfer processes do not constitute any kind of exception but the assignment of any reactions to the given class is based on a set of indirect evidence and is frequently liable to be controversial. Apparently in the given case one should use photostimulation, but so far such experiments have not been carried out. The hypothesis is supported by the catalytic activity of bulky organometallic complexes.[245]

One should not imagine that the situation is one where the operation of an electron transfer mechanism necessarily implies that the reduced form of the catalyst is able to "bombard" lignin readily with electrons from a large distance. Outer-sphere electron transfer is known to constitute the least favourable pathway in the reaction between two compounds: the two reagents should react regardless of any advantages which the electronic interaction between them could afford. Polar and inner-sphere processes are in most cases preferable as regards energy.[246] The phenomenon of autocatalysis observed by Dimmel et al.[95] does not in any way conflict with this: it nevertheless implies that the electron transfer to QM in solution takes place more readily than from the electrode surface. This does not imply that the mutual approach of the reactants is not necessary for the process to occur. Naturaly tunnelling over a large distance is possible,[247] but, for reasons already stated, its probability must be much lower than the probability of more complex mechanisms involving, for example, the formation of pre-reaction charge-transfer complexes. Such mechanisms with chemical stages are characteristic of electron transfer reactions.[246]

Specific characteristics of catalysis by polymer-immobilised complexes†

A D Pomogailo
Institute of Chemical Physics, Russian Academy of Sciences, Chernogolovka

ABSTRACT. The most important factors which affect to different extents the activity and selectivity of immobilised complexes in numerous processes have been examined. Attention has focussed particularly on a discussion of the factors responsible for the increase in cooperative stabilisation of active centres in such systems in comparison with homogeneous systems. The basic facts about polyfunctional catalysis based on immobilised complexes are presented. Certain questions and the potential for further advancement in this direction are discussed.

I. Introduction

A simple and promising idea, based on the knowledge of the chemical or physical forces which bind metallo-complexes (MX_n) with an organic or inorganic microligand, has promoted the development of many catalytic processes and has become the main factor for subsequent convergence of homogeneous and heterogeneous catalysis. The relevance of the concept itself and the intensity of the investigations have led to the creation of an essentially new avenue of catalysis with its own constructive principles and techniques.

There are two main objectives in the immobilisation of metallo-complexes. The first is the creation of stable catalysts with high activity, selectivity and reproducibility (as in homogeneous systems) and moreover readily separable from the reaction products and recoverable (as in heterogeneous contacts). Thus it was suggested initially that from the practical standpoint such systems should combine the advantages and eliminate the disadvantages of traditional catalysts.

In scientific terms the second objective is no less important, i.e. to construct catalysts possessing a high concentration of active centres with known structures which are also suitable for the analysis of their evolutionary transformations during the catalysed reaction. By resolving this question it would be possible to move towards a scientifically founded selection of catalysts and to predict their catalytic action.

It is necessary immediately to make the proviso that, despite significant advances in this field, it has been found much more difficult than anticipated to resolve the tasks set. Firstly, it was found that it is not easy to obtain isostructural metallo-complexes which can be firmly retained on the surface under the conditions of a catalysis. Secondly, along this route a multitude of specific difficulties arise which are associated with the behaviour of immobilised complexes in heterostructural catalytic reactions. The causes of the increase in rate of certain processes concomitantly may be the causes of the decrease in rate of other processes. Thirdly the nature of such systems which is determined by many factors hinders the prediction of the behaviour of system MX_n, the polymeric support during the catalytic reaction, and the preliminary assessment of the effect of the conditions under which this reaction takes place on all possible transformations of the components. Macromolecular effects including the effect of the microenvironment (local polarity, the neighbour effect, the effect of the size of the polymeric globule, the degree of substitution of the functional groups L, etc.) the electrostatic properties of the ionic groups bound with the polymeric chain (polyelectrolyte catalysis), isolation of active centres (dilution effect), local concentration effects (functional groups during the spherical binding of the chains on one side and the substrate close to the polymeric globule on the other), and the effect of polydentaticity, etc. play a particularly important role. When insoluble polymers are used as supports, it is necessary to take into account the biographic heterogeneity of the surface, and the swelling and migration of the attached complexes in the course of the reaction, etc. The situation becomes much more complicated if the attached complex undergoes partial dissociation during the reaction and if catalysis is achieved simultaneously with mobile and immobile particles.

The author considers that the present review summarises the most important features of catalysis by immobilised complexes, the synthesis and structures of the latter having been the subject of a large number of reviews and monographs.[1–5]

† The first five articles are a continuation of No. 12 in 1990 concerning problems of catalysis.

II. Ligand exchange in metallo-polymeric systems

Almost all studies have shown that immobilised systems have higher stability than normal catalysts even under conditions which are comparatively severe for metallo-complex catalysts (increase in temperature and pressure, highly polar solvents, active substrates). Since the metallo-polymers are formed in an enclosed microvolume in which quite a large number of macromolecules, functional groups, and different types of particles (MX_n, electrons, protons, radicals, oligomers, etc.) is involved, on the whole the state of the metallo-polymeric system is characterised by a combination of concentrations of free functional groups, and also complexes, which may contain different numbers of ligands of each type which may occupy various positions in the macromolecule.

The two main reasons leading to a decrease in the cooperative stabilisation and even to the disruption of the immobilised complexes during catalysis are their instability:

$$\widetilde{L}\text{—}MX_n \overset{K'}{\rightleftharpoons} \widetilde{L} + MX_n, \quad \widetilde{L}\text{—}MX_n + S \overset{K''}{\rightleftharpoons} \widetilde{L} + MX_nS$$

(S is the solvent, substrate, co-catalyst, or specially introduced additive). The overall contribution of these processes is reflected in the decrease in content of the metal on the support or in the concentration of the metal passing into solution. The specific contribution of the chemical instability of macrocomplexes is usually higher than thermodynamic instability. In systems which are used to polymerise olefines,

$$MX_n \cdot D \overset{K'}{\rightleftharpoons} MX_n + D$$

$$MX_n \cdot D + AlR_xCl_{3-x} \overset{K}{\rightleftharpoons} MX_n + D \cdot AlR_xCl_{3-x}$$

when $MX_n = VCl_4$, D = MMA or $AlR_xCl_{3-x} = AlEt_3$ in benzene at 293 K, $K' = 1.8 \times 10^{-3}$ mol l^{-1}, while $K = 8.7 \times 10^2$.[6] Replacement of the ligand environment by the polymeric environment leads to an increase in both the thermodynamic and chemical stability of the complexes. Thus by using the stopped-flow technique the kinetics of the pseudo-first order exchange reaction (pH 9.3–11.0; 298 K; excess of EDTA) was studied,[7]

$$Cu(2+)\text{-PVC} + EDTA \rightarrow Cu(2+)\text{-EDTA} + PVC$$

the kinetic equation of which has the following form:

$$-\frac{d[Cu(2+) - PVC]}{dt} = k_1 \frac{[Cu(2+) - PVC]}{[PVC]} = k_2 \frac{[Cu(2+) - H - PVC]}{[PVC]},$$

and $k_1 = 3.62 \times 10^{-3}$ mol sec^{-1}, $k_2 = 3.68 \times 10^4$ mol sec^{-1}. The ligand exchange occurs by two mechanisms, either by H^+ attack (from EDTA) with the formation of the intermediate complex Cu(2+)-H-PVC and its subsequent dissociation, or by solvolysis involving water.

One of the characteristic examples of exchange reactions involving low- and macromolecular ligands is the exchange of the axial ligand in benzylcobaloxime and in cobaloxime $Co(DH)_2$ covalently linked with chloromethylated polystyrene (PS):[8]

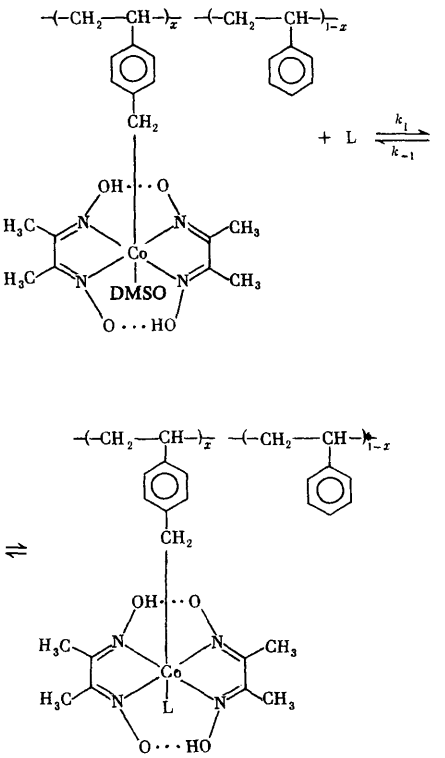

Table 1. Rate constants of ligand exchange in $RCo(DH)_2DMSO$.[8]

R	L	k_1, $l\,mol^{-1}\,sec^{-1}$	k_{-1}, $l\,mol^{-1}\,sec^{-1}$	$K \cdot 10^{-2}$
Polymer	SCN^-	$1 \cdot 10^3$	4.8	2.1
Benzyl	SCN^-	$1.2 \cdot 10^3$	15	0.8
Polymer	Py	23.6	$2 \cdot 10^{-3}$	118
Benzyl	Py	16.5	$1.7 \cdot 10^{-2}$	9.8

Although the Co(3+) complexes are comparatively resistant to substitution, the presence of the macromolecular ligand promotes a more rapid substitution of the axial ligand in the *trans*-position (solvent was DMSO or DMSO + benzene). It is apparent from Table 1 that the rate constants of the forward reaction in the systems compared are similar, although the constants of the reverse reaction for the dissociation of the complex which contains the low molecular weight *trans*-ligand is approximately 3 ($L = SCN^-$) and 9 (L = Py) times higher.

Thus the higher values of the equilibrium constants of ligand exchange in the metallo-polymer systems in comparison with the low molecular weight benzyl complexes may be attributed to the smaller

values of the rate constants for the reverse reactions. This may be associated both with the higher local concentration of cobaloxime in the polymer matrix in comparison with its concentration in the volume of the DMSO solvent and also with steric hindrances which create a macrochain, hampering ligand transport from the polymeric "cells" and promoting its recombination. In the DMSO-benzene mixed solvent with increase in the latter the polymeric globule expands, as a result of which the effect of these factors decreases. Increase in this characteristic viscosity is accompanied by a decrease in the rate constant of the forward reaction and an increase in the rate constant of the reverse reaction (Fig. 1). The higher rate constant of the ligand exchange (L = Py) in polymer-bound cobaloxime (in DMSO) was due to great changes in entropy.

R	ΔF, k J mol^{-1}	ΔH, k J mol^{-1}	ΔS, a.u.
Polymer	−17.6	−38.6	−16
Benzyl	−16.4	−67.2	−40

Similar results have been obtained in studies of other systems. One should note that the calculation of the standard potentials and observed rate constants of outer-sphere exchange involving Co(2+) and Fe(3+) ions taking into account the change in structural parameters of the macrocomplexes indicates that the systems examined are in many ways similar to metallo-protein complex systems.[9]

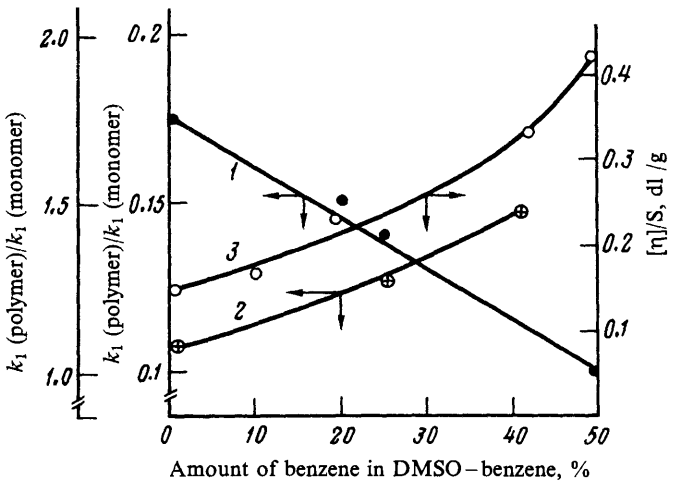

Figure 1. Variation in the relative rate constants of the coordination of pyridine with cobaloxime k_1 (*1*) and k_{-1} (*2*) and the characteristic viscosity of the macrocomplex (3) as a function of the composition of the DMSO-benzene mixture.[8]

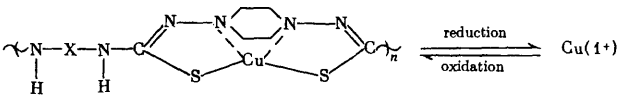
Hence the replacement of a low molecular weight ligand environment by a polymeric environment hinders the entry of the reagents into the coordination sphere of the transition metal and causes its additional polarisation in the heterogeneous electrostatic field of the ligands, which also confers increased stability upon the macrocomplex. The ability of the coordinatively saturated metal atom in the macrocomplex to form coordination vacancies should have significant value for ligand exchange. They may arise at the immobilisation stage owing to the prevention of dimerisation of the metallo-complexes or on account of the easy disruption of M–M bonds, as a result of the reduction of the transition metal, the effective adsorption of excess of ligand by the matrix, etc.

III. Characteristics of electron transfer reactions in metallo-polymeric systems

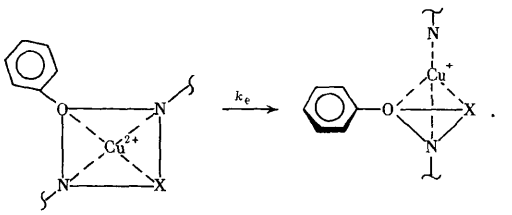
Electron transport in metallo-polymeric systems determines the rate of many processes, and is almost always the slowest stage of the catalytic act. Such an intramolecular process is very sensitive to the active centre environment, i.e. the nature of the ligand, the solvent, the ionic strength, pH, etc. It is accompanied by a rearrangement of the complex and by conformational changes in the polymer.

The primary structure of the support, the distribution of the redox-centres, the charge density, and the polarity of the polymer domains have a strong effect on electron transport in macromolecular formations. The most frequent redox transformations occur in the immobilised systems Fe(2+) ⇄ Fe(3+), Cu(1+) ⇄ Cu(2+), Co(2+) ⇄ Co(3+), and Mo(5+) ⇄ Mo(6+) and certain others. The redox processes sometimes occur even at the metallo-complex immobilisation stage,[5] and they most often occur in oxidation reactions. Thus the chelate complexes of Cu(2+) catalyse the oxidation of aldehydes to acids or cyclohexanol to cyclohexanone. In this case Cu(2+) is reduced to Cu(1+).[10]



In turn the Cu(1+) ion in the polymeric complex is oxidised to Cu(2+) in the reduction reactions of nitrobenzene to azoxybenzene, nitrocyclohexane to cyclohexanoxime, 1,4-benzoquinone to hydroquinone, and $KMnO_4$ and MnO_2. Such a conjugated process is named the "ping-pong" mechanism.

To determine the specific characteristics of the polymeric environment, the oxidation of Cu(1+) complexes with polyvinylimidazoles (PVI) by molecular oxygen was compared with their imidazole analogue.[11] The study was conducted using the stopped-flow technique in buffer systems (Table 2). A higher enthalpy and a lower entropic factor is typical of the oxidation of polymer complexes. The differences in the kinetic and activation parameters are associated with conformational transformations of the macroligand in the course of the redox reaction which lead to a change in bond lengths and the angles between them in the Cu(1+) and Cu(2+) complexes:



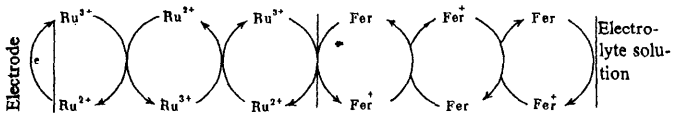
The occurrence of conformational transformations during the oxidation were demonstrated by viscosimetric measurements.

Similar patterns are also found in the redox cycles Co(3+) ⇄ Co(2+). For example the outer-sphere reactions of Co(3+) macrocomplexes with poly-4-vinylpyridine (P4VP), polyethylenimine (PEI), polyvinylimidazole (PVI) and Fe(2+) complexes with electron transport occur at lower rates than the reactions of Co(3+) complexes with low molecular weight ligand-analogues.[12,13] The opposite situation is found, when hydrophobic interactions occur between the polymer ligand and Fe(2+). This is associated with an increase in the local concentration of the reducing agent in the macrocomplex (see Chapter V). Thus addition of styrene sulphonate increases the rate of reduction of Co(3+) in the P4VP-complex 10–30-fold in comparison with the pyridine complex.

Table 2. Kinetic and activation parameters of the oxidation of Cu(1+) complexes at 298 K.[11]

Ligand	pH	$k_{eff} \times 10^2$, l mol^{-1} sec^{-1}	$\Delta F^{\neq}$, kJ mol^{-1}	$\Delta H^{\neq}$, kJ mol^{-1}	$\Delta S^{\neq}$, J mol^{-1}, deg^{-1}
Poly-1-vinylimidazole	4.7	2.7	61.3	48.3	−44.1
	4.3	14.0	57.1	29.4	−92.4
Poly-4(5)-vinylimidazole	6.0	0.10	66.0	61.8	−14.4
	4.7	0.26	64.7	57.5	−24.0
Imidazole	8.0	4.9	60.5	13.4	−154.6

Metallo-complexes bonded to the polymers are quite extensively used in electrocatalytic redox processes. With this objective, by immobilising metallo-polymers on electrodes, chemically modified electrodes and also bilayer polymeric electrodes incorporating two types of electroactive films are obtained. In such composites the outer layer is subjected to the action of the substrate, while the inner layer is in direct contact with the surface of the electrode. The scheme for such a bilayer electrode is shown below:[14]



At a particular electrode potential the outer film of poly-[Ru(Dipy)$_3^{2+}$-vinylpyridine] participates in the redox reaction with polyvinylferrocene (PVFer):

$$\text{Poly[Ru(Dipy)}_3]^{2+} + \text{PVFer} \rightarrow \text{poly[Ru(Dipy)}_3]^{+} + \text{PVFer}^{+}.$$

At high potentials the reduction of the outer and oxidation of the inner films occur.

It will be shown below (see Section VI) that the extent of chain loading (the extent of coordination of functional groups f) is found to have a significant effect on the specific catalytic activity (SCA) of the macrocomplexes. The extent of chain loading also affects the activation parameters of the electron transfer reaction (Table 3). With increase in f the values of $\Delta F^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ decrease, which may be associated with the state of the polymer chain, and particularly with its elongation (as indicated by the increase in the characteristic viscosity) and hence with a change in the charge density on the polymer chain.[13] The reverse oxidation reaction Co(2+) → Co(3+) may be both more rapid and also slower than with the low molecular weight reagents.

Table 3. Activation parameters of the electron transfer reaction and the change in viscosity in the Co(3+).PVI–Fe(EDTA)$^{2-}$ system at pH 5 and 303 K.[13]

f	[η], dl mmol^{-1}	$\Delta F^{\neq}$, kJ mol^{-1}	$\Delta H^{\neq}$, kJ mol^{-1}	$\Delta S^{\neq}$, e. e.

0.12	2.33	50.4	136.1	67.4
0.15	2.86	49.1	106.3	45.0
0.25	3.25	46.6	97.4	39.3
0.32	3.34	45.3	94.5	30.3
N-vinyl-2-methylimidazole	–	52.0	31.9	15.6

Of the other comparatively numerous examples confirming the concepts being developed, redox-reactions involving molybdenum macrocomplexes should be mentioned, i.e. cyclic redox-processes of peptide Mo(5+) complexes immobilised as a chloromethylated copolymer of styrene with divinylbenzene (CSDVB) (a reductase or oxidase analogue),[15] and also redox reactions of cystein thiolato dioxomolybdenum(6+) centres attached to polyethyleneglycol (molybdo-oxidase model).[16]

It is important that repetition of electron transport acts does not cause changes in the multinuclear state of Cu, Co, and Mo complexes, etc., whereas the macroligand reorganisation relates to certain of the most important factors influencing the reaction with electron transfer in the polymer matrices.[17]

IV. Protective functions of the macroligand

One of the protective functions of the macroligand is the creation of diffusion barriers, which impede the deactivation of the active centres or interaction of the substrates with reactive reagents or microadditives in the reaction medium (for example H_2O, O_2, etc.). Thus to protect high-spin Fe(2+)-porphyrin complexes, which are oxidised in solution to low-spin Fe(3+)-complexes and which thereby bind O_2, their combinations with polymeric ligands in aqueous solution are used (polymers and copolymers based on 1-vinylimidazole, 1-vinyl-2-methylimidazole, 1-vinylpyrrolidone, water-soluble copolymers based on quaternised 4-vinylpyridine, etc.).[18] Such an approach is more effective than the creation of steric hindrances around the active centres, and the use of low temperature, etc.

There have been successful attempts to construct on this basis synthetic O_2 carriers for reverse oxidation in water and other proton media. With this objective the metalloporphyrins are bonded to the hydrophobic regions of water-soluble polymers (oxygen protection).

The spatial stabilisation of active centres also plays an important role. The presence of a hydrophobic environment around them reduces or even excludes the possibility that oxodimers are formed in the presence of O_2 and in the subsequent irreversible oxidation of M^{n+}.[19]

The protective function of the macroligand which is realised for example in the oxidation of phenols by molecular O_2 ensures the protection of the catalytically active binuclear Cu(2+) complex.[20,21] A similar stabilising effect is directed against the so-called substrate inhibition. The mechanism of the reaction incorporating the transfer of two electrons from the substrate to oxygen in the molecular orbital system of the metal is more easily achieved in immobilised binuclear Cu(2+) complexes.

We shall examine certain other variants in which the protective function of the macroligand is exerted. A major defect of traditional heterogeneous catalysts for the isotopic exchange of hydrogen in the liquid phase is their extreme instability caused by the capillary condensation of water and by blocking of the catalyst. To prevent such phenomena different variants of its hydrophobisation have been elaborated, including the use of polymers. Such an approach may be regarded as the microencapsulation of the catalyst in the polymer. Thus, the T−H-exchange catalyst was obtained by immobilising MX_n on CSDVB, and polytetrafluoroethylene (PTFE) is most often used for this purpose.[22] Regeneration involves heating the catalyst to remove water droplets from the pores. The polymer matrix plays such a role by ensuring the protection of diazo-complexes from the action of moisture thereby increasing their life-time even at room temperature.[23]

An unusual hydrophobic protection was used in relation to unstable Mo(5+) complexes. Being immobilised on chloromethylated CSDVB modified with peptide groups, they become stable within several days in the presence of H_2O and O_2.

Another mechanism of the protective action of water and even of the increase in rate of catalytic processes for the water is realised when the water is bound by hydrophilic polymers.[24] For example, on account of the solvate effect observed in the presence of polymers (polyethyleneimine propionate, poly-4-vinyl-N-ethylpyridinium bromide, etc.) there is a 10^5-fold increase in the rate of polyelectrolytic catalytic hydration of *tris*-(oxalato)cobalt in binary mixtures of water with DMSO or DMF. This is associated with the selective adsorption of H_2O from a mixture of solvents. The preferred hydration of the complex close to the polymer on the one hand leads to the localisation of anionic reagents around this polymer, and on the other hand leads to repulsion of H_3O^+.

Hydrophobic protection plays a major role in reactions catalysed by metallo-organic compounds (or by organometal intermediates formed). Polar media are also used for these purposes. This is possible because in many reactions the globules of the functionalised macromolecules with attached catalytic centres surrounded by solvents fulfil the function of isolated microreactors.[25,26]

V. Local concentration effects in metallo-polymeric catalysis

The increased activity of immobilised catalysts may be caused both by an increase in the local concentration of substrate and active forms in such microreactors, despite possible steric hindrances as the reagent approaches the catalyst and during the transport of the reaction products. The super-equilibrium substrate concentration in domains situated adjacent to the active centres is achieved by electrostatic, donor-acceptor, and π-interactions involving active regions and functional groups (L) of the polymers. There are numerous examples of such effects. Thus on hydrogenation of styrene in the presence of Pd(0) bonded to functionalised CSDVB (4−6% DVB) the rate of the reaction increases, if the L group promoted the formation of π-complexes with the substrate.[27] The activity of allylacrylate correlated with the π-acceptor and polar properties of L. The $-NO_2$ and $-OMe$ groups promote the formation of molecular associates with the substrates, while $-OH$, $-NH_2$, $-NR_3$, and $-CH_2OCH_2$ groups react with the substrate owing to polar effects. Polymers with a hydrophobic surface retard the rate of hydrogenation of nonpolar substrates. The introduction of 2,4-dinitrophenyl groups even at a level of 7% causes a marked reduction in the rate of hydrogenation of 4-vinylcyclohexane. The high activity of Rh(1+) on phosphinated CSDVB in hydrogenation reactions of polynuclear heteroatomic compounds is associated with an increased substrate concentration close to the metallo-centre.[28]

Differences in the polarity of the polymer and solvent lead to an increase in substrate concentration in the polymer in comparison with the reaction volume. When a more polar solvent is used, the nonpolar substrate is able to penetrate more readily into the polymer phase owing to the polarity gradient. Transport of the polar substrate into the nonpolar sphere is made difficult, which is reflected in the decrease in rate of the reaction. The form of the catalyst particles (granules, powder, film, fibre) also has an influence.

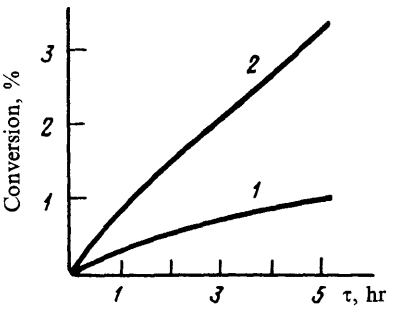

Figure 2. Kinetic curves of the oxidation of ethylbenzene in the presence of macrocomplexes not built (*1*) and built (*2*) on ethylbenzene.[30]

The functional groups may be involved not only in the binding of MX_n but also in the catalytic process itself by protecting the active centre from microadditives and catalyst poisons or by promoting secondary reactions. In principle the interaction of L with the substrate may be accompanied by more profound transformations such as protonation, ionisation, and alkylation, and sometimes also by quaternisation and oxidation in reduction reactions. Such processes apparently play a particularly significant role with metallo-complexes immobilised on strongly cross-linked polymers in which the proportion of the vacant L is comparatively high. However they may occur also in reactions in which grafted macroligands are involved. Thus from a kinetic study of the oxidation of cyclohexene by molecular O_2 in the presence of Co(2+), bonded to PE-grafted-poly(acrylic acid) (PE-pr-PAA) it was concluded that a high

concentration of the peroxide being formed is created close to the surface of the heterogeneous catalyst, and that peroxide decomposition provides the major contribution to the initiation of chains in the developing process. Close to the catalytic centres, the cobalt ions on the polymer, there are vacant carboxylic groups which, owing to the formation of hydrogen bonds, are able to adsorb ROOH molecules, thereby creating their high local concentration. Apparently by regulating the concentration of the vacant L, it is possible to control the course of the reaction, i.e. in the immobilised systems one more control level appears which has no analogues in homogeneous or heterogeneous catalysis.

A new phenomenon of structural adjustment of the active centres on the substrate has been observed in the liquid-phase oxidation of ethylbenzene and xylols by molecular oxygen.[30,31] This process involves the formation of soluble Co(2+) complexes, for example with the copolymer of the diethyl ester of vinylphosphonic acid and AK in the presence of the substrate (ethylbenzene) or α-phenylethylhydroperoxide. The specific structural adjustment for the reacting substances is then fixed by intermolecular cross-linking of the polymer support by *N,N'*-methylene bis-acrylamide with subsequent removal of the template substrates from the cross-linked formations. Such an adjustment markedly increases the activity and selectivity of the catalyst (Fig. 2).

Cases are known in which a "hyperequilibrium" concentration of the product forming in metallo-polymeric particles is attained. Thus on polymerisation of ethylene by gel-immobilised systems,[32] after contact with monomer the catalyst particles swollen in the solvent undergo further swelling and PE accumulates within each particle. The "hyperequilibrium" swelling of cross-linked catalyst particles is caused by the accumulation of polymer within the previously created three-dimensional network of the polymeric support. The energy of extending such particles by the value ΔV (additional increase in volume owing to the "hyperequilibrium" swelling of the three-dimensional structure of the original gel) is equal to

$$A = \int_{V_p}^{V_{ст}} P(V)\mathrm{d}V,$$

where P is the swelling pressure, V_{st} is the particle volume in the stationary working state, V_p is the volume of the particle stably swollen in the pure solvent, and $\Delta V = V_{st} - V_p$. This work is accomplished owing to the free energy of ethylene polymerisation and causes additional stress to the elastic network of the support. Apparently in such systems a specific mechanism also operates to limit material chains. The swelling pressure acting on the growing macromolecules strives to "force" it out on the catalyst granule† (mechanical activation of the elementary act).

Thus the nature of the macrocomplexes is such that they behave as a special phase in which the concentration of reagents is higher than in the volume of the solution (or in the gas phase in the case of gas phase processes).

† It is assumed that a certain prolonged stress arises also at the "growing point" of the macromolcule, i.e. at the metal–carbon bond. It may be the source of the increase in probability of chain restriction.

VI. Problems of homogeneity and evolution of active centres in immobilised systems

The frequently higher specific catalytic activity of the immobilised complexes may be attributed to structural defects in the coordination centres and to unsaturation, which promotes coordination of the substrate, and also to cooperative effects. Many of these factors may be taken into account during the construction of the immobilised catalysts. For example the composition of bonded complexes may be controlled to a certain extent by selecting the L:M ratio. In most reactions between the macroligand and MX_n the equilibrium is established almost immediately after the components are mixed, but sometimes a prolonged period is required for this to be attained, particularly if the macroligand is polyfunctional. In certain cases the total rearrangement of the complex occurs more slowly than the catalysed reaction. Since the structural homogeneity of the complex is important for ensuring high and stable activity, it becomes essential to take into account the rate of such a rearrangement.

The formation of the required structure determined by the electronic configuration of the transition metal ion is also dependent on the conformational exchange in the macroligand which leads to the creation of the appropriate orientation. Such an exchange is associated with energy losses which are greater the more the chain conformation differs from the required conformation. In this sense the "pliability" of the macromolecule is important, and therefore the macroligand cannot be regarded as a certain set of independent functional groups.

Furthermore the polymeric matrix may bind and stabilise coordinatively unsaturated metallo-complexes.[33] The rate of rearrangement (relaxation) of the active centre is low because of the large size of such formations, especially in the case of strongly cross-linked matrices. These processes become complicated in the transition from homogeneous to heterogeneous and especially to enzyme-mediated catalysis.[34] Therefore in a catalysable reaction a nonequilibrium configuration of active centres (and their hyperequilibrium concentration) becomes possible. In heterogeneous catalysis in this case nonequilibrium phases may arise.

During catalysis by immobilised complexes not only the total content (concentration) of the attached MX_n but also its distribution profile in the polymeric matrix (topography) is of great importance. Numerous observations indicate the static distribution of the transition metal on the support. Analysis and calculation of the topography of immobilised complexes opens one of the avenues for increasing the efficiency of the catalysts. Optimisation is achieved by moving the active centres on to the surface (or on to the thin layer adjacent to the surface layer) of the polymeric support.[35] When such catalysts are constructed their main role is attributed to the topography of the functional groups of the macroligand and its accessibility. The latter is determined by the contribution of the polymer chain during a change in the microenvironment of functional groups, viscosity and density of the cross-linkages in gel and microgel particles and by the thermodynamic compatibility of the polymer matrix and reaction medium and by the polymeric support pore structure and their size distribution (including in the swollen state). On account of a certain mobility of the polymeric chains on the surface and at the boundary of the section of the polymer-medium phases, reorientation and rearrangement of the macromolecular fragments occur,[36] as a result of which the polar groups are found to be turned to the side of the polar phases or vice versa. Moreover the nature of the distribution may also affect even

the properties of the functional groups. For example the surface sulpho-groups possess lower acidity than groups situated within the polymer mass.[37] The interaction between adjacent dicarboxylic groups (a copolymer of maleic acid and methylvinyl ether) leads to the emergence of alternating singly and doubly charged dicarboxylic groups, etc.[38]

When coordinatively unsaturated Rh(3+) complexes situated within the polymeric globules are reduced, they form multinuclear associates, which are active centres for photoinduced catalytic evolution of H_2 from H_2O (the rate of the process reaches 640 mol H_2/g-atom PRh. h^{-1}) and there is no reduction in activity after 6000 cycles).[39]

The nature and topography of the functional groups have a significant effect on the migration processes. We shall follow this process using two examples.[40] Active centres of ethylene dimerisation with homogeneous "nickel" systems are formed from Ni(2+) compounds via a series of transformations:

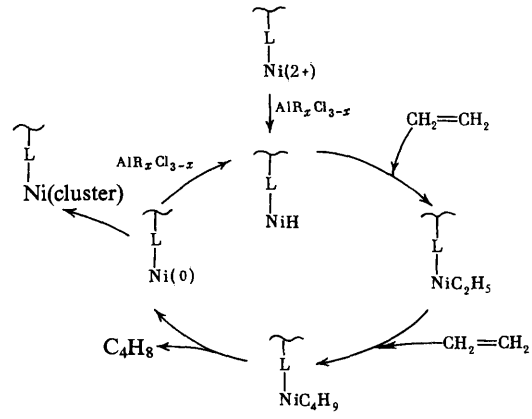
$$\begin{array}{c} Ni(2+)+AlR_xCl_{3-x}\rightarrow Ni(1+)+Ni(0)\rightarrow(\text{colloidal}) \\ \downarrow {\scriptstyle AlR_xCl_{3-x}} \\ Ni(2+)+Ni(0)\ \text{etc.} \end{array} \qquad (1)$$

The average productivity of the active complex ("chain length") is $(2-3)\times 10^3$ moles of monomer per mole of σ-alkyl (or hydride) Ni(2+) complex. It is important that regeneration of the active centres is ensured through the presence of Ni(0) complexes into the redox ring (1). However in homogeneous systems even at 333–343 K the system is essentially totally deactivated within only 1–2 h. The role of the polymeric support in the Ni-immobilised catalysts is reduced to the stabilisation of active centres and to the prevention of the association of Ni(0) in the course of the reaction.[41] In fact the magnetic susceptibility of the isolated products is dependent on the intensity of the magnetic field apparently because of the presence in them of ferromagnetic nickel in addition to the paramagnetic ions.

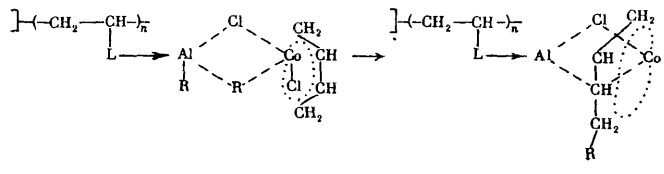
Table 4. Content of ferromagnetic nickel (%) in products of the interaction of $Ni(CH_3COO)_2$ with PE-pr-PAK (A) and Ni(naphthenate)$_2$ (B) with $Al(C_2H_5)_xXCl_{3-x}$.[41]

System	Measurement temperature, K		
	293	80	4.2
(A)+$Al(C_2H_5)_3$	0.34	0.56	2.4
(A)+$Al(C_2H_5)_3$+C_2H_4	0.48	0.50	1.4
(Б)+$Al(C_2H_5)_3$	1.2	2.1	
(A)+$Al(C_2H_5)_2Cl$	0.55	1.2	6.3
(Б)+$Al(C_2H_5)_2Cl$	27	34	37.5
(Б)+$Al(C_2H_5)_2Cl$+C_2H_4	34	53	
(A)+$Al(C_2H_5)Cl_2$	0.34	0.31	
(Б)+$Al(C_2H_5)Cl_2$	31.2	31.6	51.4
(Б)+$Al(C_2H_5)Cl_2$+C_2H_4	14.5	17.6	43.8

The proportion of the latter increases significantly with decrease in the temperature of the measurement, which can be attributed to the presence of finely dispersed superparamagnetic particles of smaller size (10–100 Å)[42] among the products of the reduction in addition to the large ferromagnetic particles (> 100 Å). On dimerisation of the ethylene by homogeneous systems (B) within only 0.5 h ca. 30% of the Ni(2+) ions are converted into finely dispersed metallic nickel, which is unable to undergo reoxidation (Table 4).[41] Under these conditions the content of metallic nickel in immobilised system (A) is only a fraction of a percentage. In the attached complexes constituting a magnetically diluted system, aggregations of Ni(0) particles should precede their migration over the surface of the support. The functional surface coat apparently prevents such a migration as a result of which during the formation of active centres isolated Ni(0) complexes are formed which have the ability to become involved once more in the redox-cycle even in the absence of substrate (ethylene):



When this is absent in the PE-pr-P4VP.$CoCl_2$–$Al(C_2H_5)_2Cl$ system, the presence of the substrate (on polymerisation of butadiene or isoprene) significantly affects the formation of ferromagnetic cobalt.[43] A quantitative calculation of the cobalt content in the different magnetic states, ferro-[Co(0)]-, dia[Co(1+)], and the Co(2+)-paramagnetic states showed that the fraction of ferromagnetic cobalt is equal to ca. 50%, the same level as in diamagnetic cobalt.[43] The interaction between components of the "cobalt" systems in the absence of monomer leads to the reduction of a significant part (up to 50%) of Co(2+) to the metallic state. At least 90% of the total ferromagnetic cobalt is concentrated in relatively large (> 100 Å) particles. The formation of such associates is the main reason for the fall in activity of "cobalt" systems on ageing in the absence of monomer. When the catalysed reaction takes place, only 6–8% ferromagnetic cobalt is found in the transformation products, and most is present in the diamagnetic state, Co(1+). This is probably attributable to its stabilisation *in statu nascendi* by the monomer as a result of the formation of the π-complex active in the polymerisation:



A similar transformation was observed also in immobilised systems based on Mo(5+),[44] V(4+),[45] etc. complexes.

VII. The effect of surface density of immobilised metallo-complexes on their catalytic activity

The well-known effect of "chain loading" or surface density (ρ_s) on the specific catalytic activity of heterogeneous immobilised systems may be linked with the association of the metal on the support.

Catalysts, the active particles of which are accessible to the substrate, usually possess maximum specific catalytic activity. For example if the Kramer complex $Rh_2Cl_4(C_2H_4)_4$ on phosphinated CSDVB containing different quantities of cross-linking agent (2–60%) are obtained under conditions which essentially exclude polymer matrix swelling (and penetration of the metallo-complex into it), its activity in the hydrogenation of hexene-1 is found to be 1.5–4-fold greater than that in analogues synthesised under conditions in which the polymer becomes greatly swollen (Table 5).[46] Aggregation efficiency is also dependent on the nature of the functional groups. Amino groups usually hinder aggregation more markedly than phosphine groups.[47]

Table 5. Hydrogenation of hexene-1 in the presence of the immobilised Kramer complex.[46]

Divinylbenzene (DVB) content, %	P/Rh in the catalyst		Activity *, sec^{-1}	
	Non-swollen	Swollen	Non-swollen	Swollen
2	25	6.5	2.35	0.49

* Product yield in moles per mole of Rh.

The dependence of the specific catalytic activity on ρ_s is usually a complex relationship. Most often with increase in ρ_s the specific catalytic activity increases, reaches a maximum value, and then decreases. Experiments have shown that such patterns exist for the hydrogenation (Fig. 3),[48,49] oxidation,[50] dimerisation,[51] and polymerisation of ethylene, etc.[52] Maximum specific activity of the PE-pr-P4VP.VCl_4–$AlEt_2Cl$ system during ethylene polymerisation is attained for example at a bonded vanadium content of 0.6 mass% (18 atoms/100 Å^2).

Such patterns are undoubtedly the consequence of the distribution characteristics of the active component. It has been quite reliably established that metal ions are distributed on the support both as isolated complexes and as cluster formations with a high local concentration of attached complexes.[5] With change in ρ_s the ratio between them also changes. There is a general tendency that with decrease in phosphorus content of the phosphinated macroligand and also with decrease in P/Rh the Rh particle size increases and gradually approaches the particle size in the polymer containing no functional groups.[53] An increase in the phosphorus content decreases the rate of decomposition of rhodium complexes to the metal. When P/Rh = 40, crystallites are not found even after heating to 398 K for several days.

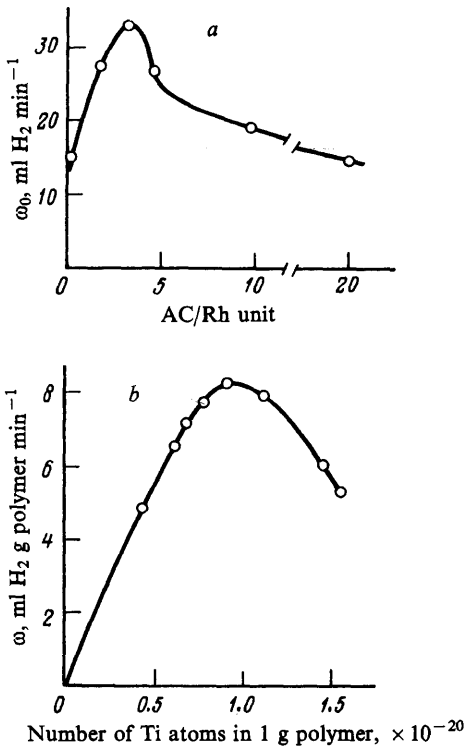

Figure 3. The variation in reaction rate as a function of the quantity of bonded metal in the macrocomplex: *a*, hydrogenation of furfurol in the presence of Rh on PAA;[49] *b*, hydrogenation of hexene-1 in the presence of titanocene bonded to CSDVB modified with cyclopentadienyl groups.[48]

However one cannot associate the observed nature of the dependence of the specific catalytic activity on ρ_s with either the concentration of isolated ions or with the concentration of associates. At the same time it is evident that, on increase in ρ_s, the concentration of associates consisting of a small number of particles, for example dimers or trimers, should pass through a maximum. The suggestion that active particles in the immobilised systems are formed from isolated transition metal ions stabilised by cluster formations is justified. Their content should also be markedly dependent on the surface density. In fact an analysis of the magnetic susceptibility of different spin states of "nickel" systems confirms that with increase in the surface density of Ni(2+) during the formation of active centres the dimensions of the clusters increase and the relative content of the boundary nickel atoms stabilised by the electron system of the entire cluster passes through a maximum.[41] In other words the dome-shaped plot representing the dependence of the specific catalytic activity on ρ_s correlates with the distribution function of the clusters with respect to size. One should note that in certain systems the dependences of the specific catalytic activity on ρ_s are different. For example the rate of H_2O_2 decomposition in the presence of Cu(2+) complexes with a polyampholite (copolymer of 2-methyl-5-vinylpyridine and AK)‡ is

‡ (Owing to the strong dependence on pH this reaction closely resembles enzyme-mediated processes.)

determined by the formation of complexes with different compositions.[54] A correlation is found between the catalytic activity and the content of diamagnetic Cu(2+) complexes, when the latter may include binuclear complexes§ (similar to the active centres of haemocyanin) with a strong antiferromagnetic interaction.

The presence of the ascending branch of the dependence of the specific catalytic activity on ρ_s may be attributed to the collective interaction of immobilised vanadium atoms.[56] A decrease in the activity of the attached $TiCl_4$ complexes during the polymerisation of ethylene continues until each active centre becomes adequately separated from the other.[57]

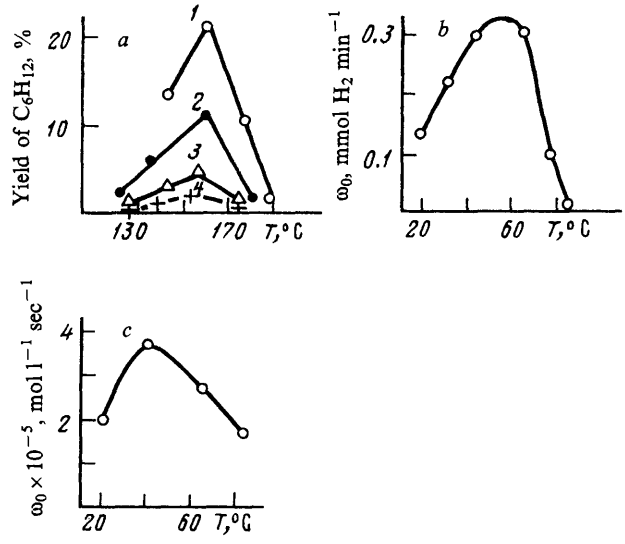

Figure 4. The effect of temperature on the rate of hydrogenation in the presence of the immobilised complexes. *a*, Hydrogenation of benzene with the use of Pt–nylon-66 (*1*), Rh–nylon-66 (*2*), Ir–nylon-66 (*3*) and Pd–nylon-66 (*4*) systems;[59] *b*, hydrogenation amination of 2-methylpropanol in the presence of Pd on polytrimethylolmelamine;[61] *c*, hydrogenation of allylbenzene on the $Ni(acac)_2$–copolymer of butylacrylate, acrylonitrile, acrylic acid and methylolacrylamide–$Al(C_2H_5)_2Cl$.[60]

Thus one of the principal transformations of the immobilised complexes may be associated with the evolutionary transformations accompanied by an increase (more rarely a decrease) in nuclearity. The following sequence of such transformations is observed: immobilised monomer complex → formation of small (bi-, tri- etc.) particles (clusters) → formation of multinuclear associates (diameter 10–20 Å or more) → appearance of metal phase. Small sized particles interact very intensively with the polymer matrices. sized particles interact very intensively with the polymer matrices. Usually as a result of an electronic transition at the metal atoms a positive charge arises promoting coordination of substrate molecules which also affects the activity of the catalyst. The deep interaction of such particles with the support facilitates the conservation in them of a developed π-electron system.[58] The situation becomes complicated because the systems examined are dynamic formations. The concentration and structure of the metallo-complexes may be altered in the course of the catalytic reaction as a consequence of cluster formation, aggregation, crystallisation, and displacement of the metal on to the surface from the body of the matrix, which are especially intensive at the stage of activtion of the attached complex.

VIII. Characteristics of the effects of temperature on the catalytic properties of immobilised complexes

When the catalytic systems under the examination are used one should remember that the temperature usually affects the rate of the reaction in a complicated manner. Since the MX_n-macroligand system itself undergoes certain transformations, the dependence of the reaction rate on temperature often has a bell-shaped relationship. Such dependences are found particularly during the hydrogenation of benzene in the presence of the platinic group of metals on nylon-66 (Fig. 4),[59] hydrogenation of allylbenzene by gel-immobilised nickel complexes,[60] hydrogenised amination of 2-methylpropane by nitrobenzene on Pd-polytrimethylolmelamine,[61] and oxidation of ethylbenzene on Co(2+) macrocomplexes (Fig. 5), etc.[50]

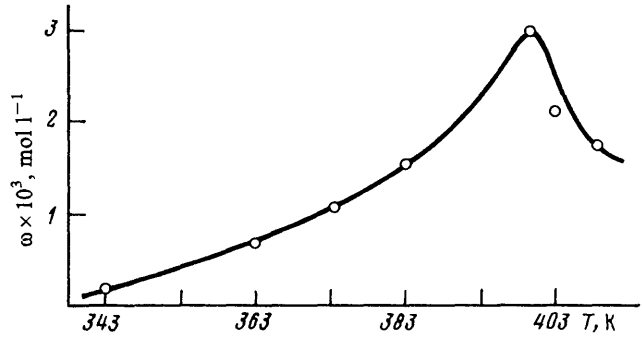

Figure 5. The effect of temperature on the rate of oxidation of ethylbenzene by Co(2+) macrocomplexes.[50]

There may be several reasons for such unusual temperature behaviour. One reason is the occurrence of destructive process initiated in the polymer matrix by the metallo-complexes especially at elevated temperatures. The appearance of descending branches of the curves may also be a consequence of the aggregation of metallo-complexes, occurring vigorously on increase in temperature.

However the most probable reason is the effect of temperature on the phase transformations in the metallo-complex matrices on heating. With increase in temperature the reaction rates at first increase in accordance with the Arrhenius law, and then after the

§ Binuclear complexes cannot be formed, while only one Cu(2+) ion occurs in each polymer globule at high dilution (< 0.05 mass% of the polymer). In this case infinite dilution conditions are modelled.[55]

second-order transition temperature (T_c) is reached or after softening of the polymeric support the rates of the reactions fall. Thus in the temperature range in which the chain segments possess adequate mobility and in which the relaxation processes associated with the reorientation of the entire macromolecular support become controlling, there is a change in the structure of the active centres (a change in the coordination unsaturated state of the transition metal, aggregation of the active centres, reduction of the metal, etc.).

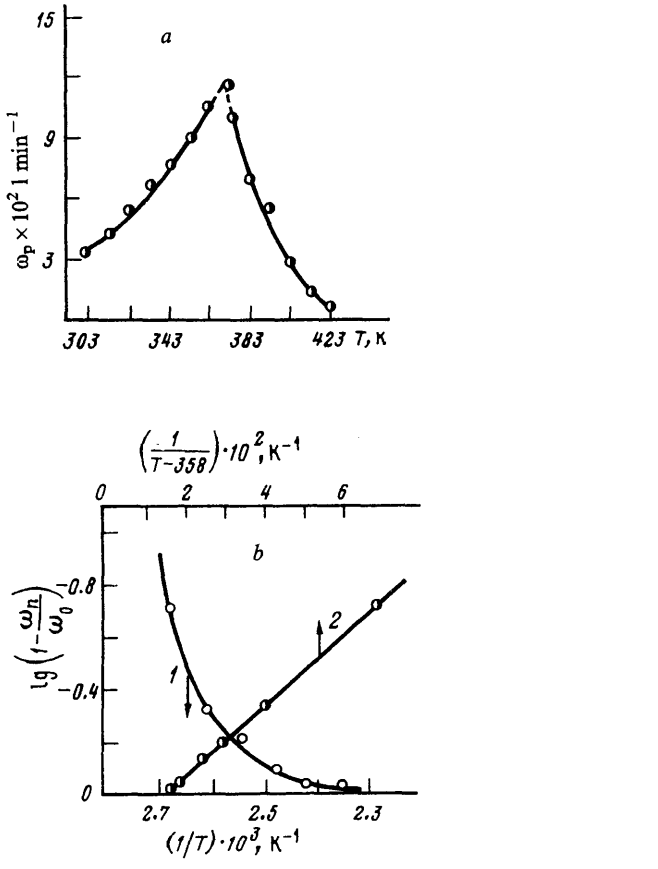

Figure 6. The variation in the rate of ethylene polymerisation in the gas phase as a function of temperature (*a*) (catalytic system, P4VP.VCl_3–$Al(C_2H_5)_2Cl$; the calculated rate is indicated by the dotted line) and the temperature dependence $\lg(1-\omega_p/\omega_0)$ (*b*) on $1/T$ (*1*) and $1/(T-358)$ (*2*).

In particular the rate of gas phase polymerisation of ethylene (P4VP.VCl_4 – $AlEt_2Cl$ system) is dependent on the mobility restoration temperature (the rate of the relaxation process).[62] In the Arrhenius region the process is reversible (Fig. 6) and E_a has a normal anionic-coordination polymerisation value (16 kJ mol^{-1}). In the T_{mp} range and higher the polymerisation temperature coefficient becomes negative (−130 kJ mol^{-1}). If one assumes that the decrease in polymerisation rate (ω_{II}) on the descending branch of the curve is caused by the exceptionally irreversible deactivation of active centres (n_p) caused by the movement of segments of the polymer chain, then

$$\omega_{II} = kn_p\left(1-\frac{\Delta n}{n_p}\right) = kn_p(1-\omega_D\Delta t),$$

where ω_D is the specific decay rate of the active centres according to any of the possible mechanisms. From here

$$\omega_D\Delta t = 1-\omega_{II}/\omega_0$$

(ω_0 is the polymerisation rate in the absence of deactivation). The form of the curve in Fig. 6*b* resembles the normal observed dependence for the relaxation time of segmental movement. The apparent activation energy increases sharply as the mobility defrosting temperature is approached. As usual in such cases the temperature dependence of the rate of the relaxation process is linearised in the coordinates $\lg\omega_D \sim (\Delta T)^{-1}$, i.e. it has the form

$$\omega_D = A\exp\left(-\frac{B}{T-T_0}\right).$$

The value B is associated with T_c and the free volume fractions (α_c) by the relationship:[62]

$$B = (T_c-T_0)/2.3\alpha_c.$$

In this specific case T_c = 360 K (α_c = 0.025) and this is the temperature at which the mobility of the P4VP segments is restored and at which a marked fall in the rate of polymerisation commences. Hence the increase in the progressive diffusion n_p is one of the important factors for the deactivation of immobilised metallo-complex catalysts for the polymerisation of olefins.

The temperature dependences of the rate of polymerisation by gel-immobilised systems also pass through a maximum (in the T_{mp} range of polyethylene). They are totally temperature-reversible, i.e. the decrease in rate in the elevated temperature range was not due to thermal deactivation n_p. An important feature of gel-immobilised systems is their structural and conformation adaptation,[63] i.e. at elevated temperatures microsyneresis of the polyhydrocarbon gel occurs in the aromatic solvent medium, leading to a decrease in the concentration of the monomer in the vicinity of the active centres present in this type of gel. Therefore in the case of local overheating in a particular region of a granule of the immobilised catalyst, temporary retardation of the exothermic reaction occurs. Other authors have suggested that such an inverse relationship ensures the "self-defence" of the catalyst from irreversible thermal deactivation.[63] This is yet another basic similarity between the immobilised catalysts and biomembranes into which enzymes have been incorporated.

At the same time restoration of the mobility may ensure that different sized aggregates of the particles are formed from the zero-valent metals, and the activity of such aggregates is possibly higher than the activity of isolated atoms. Such a local convergence of the metallo-complexes is found to have a favourable influence on hydrogenation and other processes. This phenomenon was studied in greatest detail in the case of gaseous phase hydrogenation of ethylene by Rh complexes attached to triple copolymers consisting of styrene and diphenyl-*p*-styrylphosphine (DRSP) (5–10%) cross-linked with divinylbenzene (2%).[64,65] The temperature dependence is readily reproducible over a broad range. At T_c a discontinuity in

the Arrhenius curve is found (Fig. 7). The activation barrier of the reactions at $T > T_c$ remains essentially the same, i.e. all changes in the rate constant are associated with the entropic factor. This phenomenon arises as a result of the restoration of the mobility of the polymeric segments and the creation of the most suitable configuration of the active centre for the catalytic act. One also cannot rule out the effect of other factors. When $T > T_c$, relaxation of the micro-Brownian movement promotes diffusion and an increase in the probability that the substrate collides with the active centres. Furthermore movement of the adjacent groups and ligands may increase steric hindrances for the coordination of ethylene and may reduce the stability of the bond of the coordinated substrate.[65] Finally a change in the nature of the movement in the polymer leads also to structural transformations of the active centre, since in this case there are changes in the coordinating capacity of the functional groups, their configuration, and the coordination non-saturation of the transition metal, etc. Furthermore the anomalous nature of the temperature dependence cannot be associated either with an increase in ethylene diffusion into the small pores of the catalyst (which would become limiting close to the T_c) or with the fact that at a certain temperature the overall rate of the process begins to be determined by another stage (since the slope of the Arrhenius plot remains virtually constant).

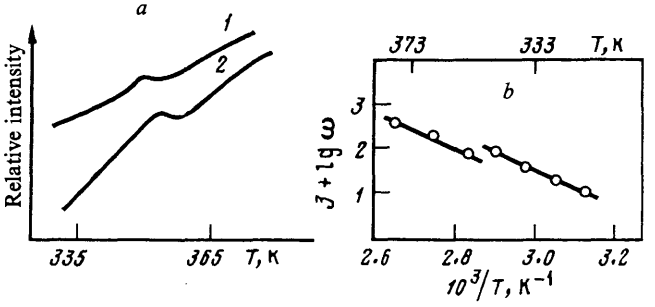

Figure 7. Differential scanning calorimetry curves (*a*) (*1*, T_c = 349; *2*, T_c = 354 K) and the Arrhenius dependence of the rate of ethylene hydrogenation in the gas phase on the rhodium macrocomplex (*b*).

The reversible discontinuity in the Arrhenius dependence may be explained, if one assumes the existence of two different coordination states differing in catalytic activity in the T_c region. The somewhat nonuniform slope of the curve at different sides from the T_c (33 kJ mol^{-1} at higher and 35 kJ mol^{-1} at lower temperatures) may probably be attributed to the fact that the enthalpy or entropy of ethylene coordinated at various Rh-centres differs somewhat on account of the movement of the polymer network.

It is interesting that similar effects are also found in soluble metallo-polymeric catalysts. Thus the effective rate constant (k_{eff}) for the oxidation of cholesterol by molecular O_2 in the presence of soluble porphyrin-containing metallo-polymers temperature-dependent,[66] and there were no analogies in normal homogeneous catalysis. The nonmonotonous nature of the dependence $k_{ef}(T)$ (Fig. 8) indicates that conformational transitions possibly occur in such systems. One such transition may be caused by the disruption of the ordering of polymeric fragments associated with hydrogen bonds, coordinate bonds, and other bonds during their concomitant rupture. In this temperature range the temperature dependence of the characteristic viscosity has the form $\eta = \eta_0 \exp(-E/RT)$, as in any activation process which is also associated with conformational transitions in metalloporphyrin-containing macromolecules. In the transition region a significant fluctuation of the conformations of the chains in the solutions is found, and each conformation corresponds to its reaction rate constant value, because of the difference in the pre-exponential multiple, which reflects steric factors, or because of the mutual effect of the active centres. Since there is a set of different rate constants corresponding to metastable conformational states in the transition region, the dependence $k_{eff}(T)$ also has a non-Arrhenius extremal nature.

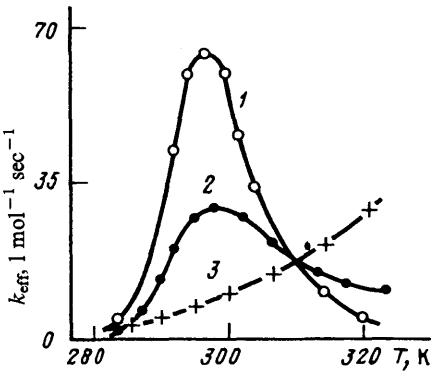

Figure 8. The dependence of the k_{eff} of cholesterol oxidation in the presence of $NaBH_4$ and copolymers of N-Mn-porphyrinate acrylamide with methacrylate (*1*) and butylacrylate (*2*) on the temperature (*3*, the analogous dependence for the low molecular weight analogue, magnesium tetraaminophenylporphyrinate).[66]

In principle such effects may influence not only the activity but also the selectivity of the immobilised catalysts. Only one example will be presented, viz. a reduction in temperature during the synthesis of cyclopropane ethers leads to an increase in the proportion of the *cis*-isomer, probably as a consequence of the limitation in the mobility of the macromolecular chain.[67]

Finally one should also mention such an important phenomenon as the total thermo-reversibility of the binding of MX_n by certain ligands, which form the basis of the construction of "thermo-regulatable" immobilised catalysts. The line diagram of this phenomenon may be represented in the following form:

$$\left|\text{—L—MX}_n\right| \xrightarrow{\text{catalysis}} \left|\text{—L} + \text{MX}_n\right| \xrightarrow{\text{Isolation of the catalyst}} \left|\text{—L—MX}_n\right|$$

Low temperature (Immobilised catalyst)	High temperature (homogenous catalyst)	Low temperature (Immobilised catalyst)

Complexes of $ClRh(PPh_3)_3$ with phosphinated ethylene oligomers are an example of thermo-regulatable catalysts.[68] At 373 K the macrocomplexes dissolved in xylol operate as hydrogenation catalysts, but when the reaction medium is cooled to 298 K, the catalyst is quantitatively (losses of Rh do not exceed 0.1% per cycle) bound to the support. This method is especially effective when the so-called "undeposited" homogeneous catalysts are used.

The question of the thermostability of the immobilised complexes warrants special examination. Binding of MX_n is usually accompanied by a change in the structural organisation of the system and leads to an increase in its thermostability. The best known example is the binding of first transition series metal ions with nucleic acids into a stable complex, which ensures the resistance of the complex to elevated temperatures and its conservation in the denaturation area.

IX. The contribution of energy of non-equilibrium configurations of the chain to catalysis

Not only the nature of the polymeric support and its functional groups but also the distribution profile of L with respect to the copolymer chain (statistical, modular, alternant), and the stereoregular, conformational and configurational structure of the macroligand affect the composition, structure and stability of the macrocomplexes during their formation. There is only a limited amount of information on these questions. Thus, during the oxidative coupling of 2,6-xylenol the activity of the Co(2+) chelates attached to atactic and isotactic polyacrylamidoximes (PAAO) significantly differ.[69] The kinetics of the reactions in both cases obey the Michaelis–Menten equation, although the k_2 value (constant for the second stage determining the rate of the process) is higher for the isotactic ligand (at 303 K, k_2 = 0.304 and 0.284 min^{-1} respectively), whereas the Michaelis constants have similar values (0.274 and 0.282 mmol l^{-1}). These phenomena are caused primarily by an increase in entropy. Since the chain of the isotactic macroligand has a spiral ordered form, it has a lower $\Delta S^{\neq}$ value (Table 6).

Table 6. Thermodynamic and activation parameters of the oxidative combination of 2,6-xylenone at 303 K.[69]

Catalyst PAAO–Co(2+)	ΔG, kJ mol^{-1}	ΔH, kJ mol^{-1}	ΔS, J mol^{-1} deg^{-1}	$\Delta G^{\neq}$, kJ mol^{-1}	$\Delta H^{\neq}$, kJ mol^{-1}	$\Delta S^{\neq}$, J mol^{-1} deg^{-1}
Isotactic	20.6	58.4	260.4	88.2	35.7	−172.2
Atactic	20.7	45.4	218.4	89.0	40.0	−163.6

The Rh and Ru complexes attached to isotactic or atactic phosphorylated polystyrene exhibit different activities in oxidation, hydrolysis and isomerisation, etc. reactions,[26] although it is difficult to make clear conclusions on the causes of this phenomenon.

The activity is dependent on the form of the macromolecules containing attached MX_n. For example Rh and Ru attached to alternating copolymers of maleic acid and vinyl esters and occurring in the reaction medium in the more compact configuration (in *n*-octane) express lower activity in the hydrogenation reaction.[70] In many cases the nature of the solvent is also important. At 343 K modified polystyrene in *n*-hexadecane is present in the glassy state, but occurs in the gum-like state in aromatic solvents. Furthermore, when the chain is compressed, the principal fragment of the metal is localised within the polymer and is not involved in the catalysis. However on oxidation of the hydroquinone by Cu(2+) with a partially quaternised P4VP, an increase in pH, temperature, and the degree of quaternisation of the macroligand on introduction of the electrolytes leads to a decrease in viscosity of the system, to the compression of the polymer chain, and to the creation of conditions required to form intramolecular chelates, which promotes a charge transfer between the neutral hydroquinone or semihydroquinone anion and the Cu(2+) ion of the polymer complex.[71] This causes an increase in catalytic activity, whereas the reverse factors promoting the extension of the polymer chain and hindering the formation of the chelate reduce the catalytic activity.

The rate of oxidation of di-substituted phenols in the presence of Cu(2+) on the copolymer formed from styrene and 4-VP or dimethylaminostyrene increases with increase in the proportion of aminogroups ([N]) to 0.4.[72] This is associated with a change in the activation parameters caused by an increase in the conformational mobility of the intermediates during the deformation of the intermediate catalyst-substrate complex, the formation of which precedes the electron transfer from the substrate to Cu(2+) (limiting stage of the process). In addition at small [N] values in the copolymer there are steric hindrances, which hamper the formation of the binuclear triple complex. At least six intermediate styrene units are required to form the bridging binuclear complexes.[73]

A feature of the soluble macrocomplexes is that not only the structure and conformation of the chain but also chain length has a significant effect on their activity and selectivity. Thus the rate of oxidation of tetralin increases ten-fold with increase in the length of PEG containing attached MCl_2 (M = Co, Mn, Cu) (Table 7).[74,75]

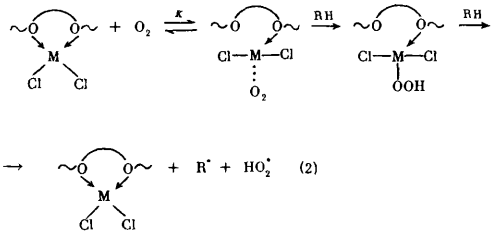
Table 7. Variation in the decomposition of rates (ω_i) of hydroperoxide and the oxidation (ω_0) of tetralin as a function of the relative molecular mass of PEG (355 K, $[ROOH]_0$ = 0.4 mol l^{-1}, O_2).[75]

Relative molecular mass of PEG	ω_0, mol O_2/(g-ion Co min^{-1})	ω_i, mol ROOH/ /(g-ion Co min^{-1})	ω_s/ω_i
4 000	180	35	5
20 000	900	40	22.5
40 000	1800	33	54.5

Macrocomplexes function as initiators and the PEG chain length affects the rate of the initiation stage. In contrast to the oxidation rate the rate of decomposition of ROOH is essentially not dependent on the molecular mass of the polymer. Since E_a is also not

dependent on the molecular mass of PEG, differences in activity are associated with a change in the pre-exponential factor in the reaction rate equation, i.e. with entropy factors. This is an example of a new effect in catalysis, an increase in rate of the process owing to the energies of non-equilibrium configurations of the polymer chains arising in the course of the reaction. The energy increases with increase in chain length, and under certain conditions (for example when the rate of the catalytic act is greater than the rate of relaxation of the polymer nonequilibrium) may be transmitted to the reacting components, thereby increasing the rate at which they undergo transformation.

We shall analyse the mechanism of this phenomenon with a specific example. Macrocomplexes PEG.MCl_2 in tetralin occur as globules, the dimensions of the latter being less than those of the corresponding globules of the original PEG. However activation of O_2 at the metal ion may be accompanied by the temporary rupture of one of the M–O–PEG bonds (according to the type of substitution of ligands in the macrocomplexes described in Section II). This leads to the appearance of the nonequilibrium configuration of the macromolecule striving to unfold. Such an irreversible process is characterised by a constant K, the magnitude of which is determined by a change in the free energy of macrocomplex formation, $RT \ln K = \Delta G$.



(2)

In turn ΔG may be provisionally divided into two components. One component (ΔG_x) is determined by the rupture of old and the formation of new chemical bonds with the metal ion, while the other component (ΔG_{ts}) is determined by the operating of chain stretching which was "stored away" during macrocomplex formation. The entropy component ($T\Delta S_{ts}$ is precisely the function of the molecular mass of PEG and increases with increase in molecular mass) makes the principal contribution to the equation $\Delta G_{ts} = \Delta H_{ts} - T\Delta S_{ts}$. Then $\Delta G = \Delta G_x + \Delta G_{ts}$. From the expression

$$K = \exp(\Delta S/RT) \exp(\Delta S_{ts}/R) \exp(-\Delta H/RT) = K_0 \exp(-\Delta H/RT)$$

it follows that the K values for the polymer complexes and their low molecular weight analogues differ in magnitude ($\Delta S_{ts}/R$) which is part of the pre-exponential factor in the overall reaction rate equation and is dependent on the molecular mass of the macroligand.

Thus one condition for the appearance of the effect examined in the catalysis is an increase in the rate of the catalytic reaction over the rate of relaxation of nonequilibrium conformations of the macroligand.

Apparently this is a common effect and occurs in processes catalysed by soluble immobilised complexes.¶ This effect is similar to the energy recuperation effect in enzymic catalysis in which the protein molecule assumes the role of an energy reservoir. The energy released in the course of the reaction is not dissipated as heat but is utilised to activate the reagents. During the enzymic reaction the protein macromolecule may be transformed from the equilibrium into the nonequilibrium state. The energy of this transition is utilised to overcome the substrate transformation activation barrier, whereas the energy released as a result of the reaction is utilised to return the protein molecule to the original equilibrium state.[77]

Other hypotheses suggest that the small height of the activation barrier of the enzymic reactions may be attributed to the fact that even before the enzyme-substrate complex is formed in the active centre of the enzyme a functional group with high potential energy is present {the hypothesis of the eptatic [entatic? (Ed. of Translation)] state of the active centre of the enzyme}.[78] For example the zinc ion within carboxypeptidase or carbonic anhydrase is much more reactive than zinc occurring in the normal ionic form or in a complex with a low molecular weight ligand. The reason is that in the active centre the zinc atom is only partially associated with protein ligands (as in M in Scheme 2), forming the stressed configuration of the deformed tetrahedron. Such formations are a specific feature of protein macromolcules with secondary and tertiary structures.

X. Cooperative stabilisation of active centres in the immobilised systems

A significant number of segments in the polymer chain is usually involved in the binding of MX_n (and active centres based on these structures). The rupture of one of the bonds between the metal ion and the macroligand unit requires the expenditure of approximtely the same amount of energy as for the rupture of the bond in the complex with the low molecular weight ligand analogue. However these losses in the first case are not compensated by the appearance of new progressive degrees of freedom (i.e. they are not accompanied by an increase in configurational entropy). Thus the probability that the active centre in the immobilised systems is disrupted under stable equal conditions sharply declines, whereas the stability of the intermediate forms may be increased owing to the rapid spontaneous conformational transformations in adjacent units in the chain, fluctuations in its structure, etc. Cooperative interactions of this type increase the stability and activity of immobilised catalysts. Thus in polymers based on Rh(1+)-bis-(4,4'-diisocyanodiphenyl)chloride (the catalyst for the hydrogenation of olefins)[79] in which the Rh is arranged regularly in a tetragonal or

¶ The value of the Michaelis constant (K_m) and the activation parameters for the oxidation of 2-mercaptoethanol by molecular O_2 in the presence of complexes of sodium Co(2+)-phthalocyaninetetrasulphonate with polyvinylamine (PVAm) are dependent on the degree of polymerisation of the latter,[76] which are associated with conformational transformations of the globule. The $\overline{M}_n$ of the 2,4-ionene type of quaternised polyammonium resin is found to have an effect on the charge density of the polymer chains. On increase in $\overline{M}_n$ from 1740 to 6600 the constant K changes from 11.3 to 6.8 mol l^{-1}, whereas the turnover number alters from 3700 to 3300 sec^{-1} (for polyvinylamine with $\overline{M}_n = 3 \times 10^4$ these values are 90 mol l^{-1} and 2800 sec^{-1} respectively).

hexagonal environment where each rhodium atom is associated with 2 or 4 isocyanate ligands, there are three types of active centres (Fig. 9). The first of these (a) incorporates Rh at the end of chain, the second (b) incorporates Rh is the macroligand chain, and the third (c) incorporates Rh on the outer side (001) of the material. The number of centres active in catalysis does not exceed 1% of the number of Rh atoms, but cooperative interactions are observed between the centres (a) arranged at close distances from each other, which increase the activity of the catalyst in the isomerisation of the substrate, whereas the cooperative effect created by the interaction between centres (b) and (c) or adjacent centres (b) is the reason for the increase in activity in the hydrogenation reactions (in this case the Rh–Rh interactions have the characteristics of a metal bond). The relationship between the different centres is dependent on the previous history and the method of preparation of the catalyst, its topography, ρ_s value, temperature, and other factors.

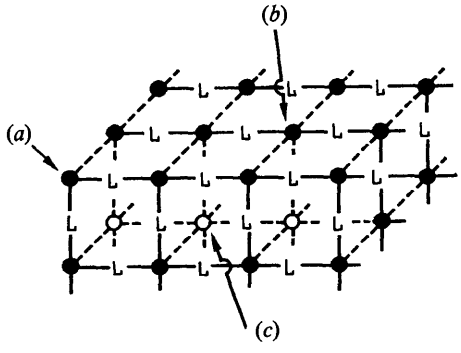


Figure 9. Types of active centres in Rh(1+)-bis-(4,4′-diisocyanodiphenyl)chloride polymers.[79]

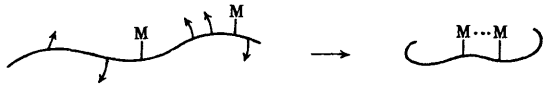
In those cases in which matrix isolation of the active centres is an important condition for the completion of the reaction, cooperative interactions of the segments in the chains may lead to their deactivation.



In order to establish the reason for the stability of attached catalysts for ethylene polymerisation, the decomposition of individual organometallic Ti(4+) compounds (which form the basis of active centres of homogeneous catalysts and catalysts heterogenised by polymeric supports of the catalysts)[80] was studied. Decomposition of $RTiCl_3$ type compounds is known to occur mainly as a result of the completion of processes within the coordination sphere of the transition metal, including β-elimination or disproportionation reactions. The activation energies of these stages are lower than metal–carbon bond energy, and therefore to increase the stability of organometallic compounds it is essential to exclude completely the possibility of the occurrence of inner sphere reactions of the alkyl group. For example CH_3TiCl_3 complexes with 4-substituted derivatives of pyridine decompose in the homogeneous system even below room temperature with the splitting of the $Ti-CH_3$ bond and with the formation of methane according to a coordinated mechanism in the coordination sphere of titanium, and in the course of these reactions Ti(4+) is not reduced. The macrocomplex PE-pr-P4VP.CH_3TiCl_3 is more stable. The Ti–C bond is gradually decomposed only at 298 K with the formation of methane, ethane, and C_4 hydrocarbons. Above 353 K there is an increase in the proportion of homolytic decomposition of the Ti–C bond with the formation of CH_3 radicals, and this is accompanied by the reduction of Ti(4+) to Ti(3+) (Table 8).

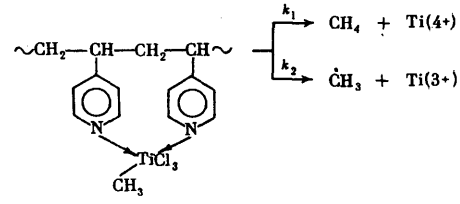


Table 8. Ratio between the rate constants k_1 and k_2 and the quantities of Ti(3+) and Ti(4+) during the decomposition of the complex CH_3TiCl_3.PE-pr-P4VP.[80]

T, K	$k_1 \cdot 10^4$, c^{-1}	$k_2 \cdot 10^4$, c^{-1}	k_2/k_1	Ti(3+)/Ti(4+)
303	0,59	–	–	0
313	0,77	–	–	0
323	1.0	0.7	0,7	0,6
333	1,3	2,1	1,7	1,5
348	1,6	8,0	5,0	2,3

The rate constant value for the coordinated decomposition reaction (k_1) of the macrocomplex examined is two orders of magnitude lower than that for the decomposition of the CH_3TiCl_3 complex with the monomeric ligand. This may be attributed to the extremely low value of the pre-exponential factor ($10^{-2}-10^{-3}$ sec^{-1} against 10^3-10^5 sec^{-1} for the homogeneous system) since the "fine tuning" (deformation) of the polymeric ligand essential for the coordinated reactions to take place, requires significant changes in entropy in the transition state in comparison with the monomeric analogue. It is important that the rate of homolysis of the $Ti-CH_3$ bond occurring with the formation of free radicals (the rate constant of this reaction k_2) in the heterogenised and homogeneous systems are identical.

Thus the thermodynamic stability of the Ti–C bond (and hence the active centres) in the systems compared remains essentially unchanged (similar bond energies). Therefore the stability and high activity of the immobilised systems for example during the polymerisation of ethylene (Fig. 10) are mainly caused by the sharp fall in rate of the coordinated processes in the coordination sphere of the transition metal.

One more important situation should be noted. Apparently reactions leading to the deactivation of active centres require significantly more rearrangement of the ligand environment of titanium than reactions in which the polymerisable ethylene is introduced at the Ti–C bond,[81] which is indicated by the closeness of the rate constants of the chain elongation reactions in the systems compared.[52] An extremely interesting phenomenon is the "fine tuning' of the polymer matrix to create the most favourable configuration of the catalytic centre. Thus on heterogenisation of the bulky $Ti(OC_4H_9)_4$ on the polymer the structure of the active centre is probably such that the energy barrier of the introduction reaction is small, and the effective activation energy for ethylene polymerisation is significantly (up to 11 kJ mol^{-1}) lower than that in the homogeneous system (58 kJ mol^{-1}). However in this case K_p essentially does not change. It therefore follows that there is a sharp decrease in the pre-exponential multiple of the reaction rate constant. The compensation effect indicates that in reactions in which these active centres are involved many closely lying fragments of the polymeric ligands are affected, and hence there is a fall in entropy.

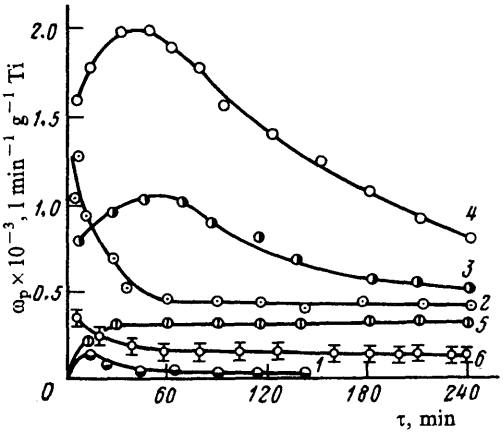

Figure 10. Variation in the rate of ethylene polymerisation by heterogenised systems based on $Ti(OC_4H_9)_4/Al(C_2H_5)_2Cl$ as a function of the reaction time. Polymeric supports: *1*, without support (homogeneous system); *2*, PE-pr-poly(diallylamine); *3*, PE-pr-poly-(allylamine); *4*, PE-pr-poly(allyl alcohol); *5*, PE-pr-PAA; *6*, hydrolysed copolymer of styrene with vinylacetate.

However other patterns are also observed. Thus the rate constants of the homolytic splitting of the Co–R bond in monomeric (R = benzyl) and polymer-associated (R = chloromethylated CSDVB) cobaloximes (L = Py or DMSO)

$$RCo(DH)_2L \overset{h\nu}{\rightleftarrows} R^{\cdot} + Co(2+)(DH)_2L$$

in DMSO have similar values (1×10^{-2} sec^{-1}).[8] In benzene $k_{mono}/k_{poly} = 4.2$. This is associated with the promoting action of the polymer chain on photodecomposition and may be attributed to energy migration along the polymer chain containing aromatic rings, which have the ability to absorb photoenergy. This may be attributed to the fact that the polymer-associated cobaloxime is partially decomposed also on irradiation with light at a wavelength below 350 nm, whereas with benzyl cobaloxime this process occurs only on irradiation with light at a $\lambda_{max} = 450-550$ nm.

Their interaction with the microligand surface caused by the presence of functional groups and surface imperfections and also by physical causes creates yet another possibility for the cooperative stabilisation of the active centres. This has been analysed in greatest detail in the case of the hydroperoxide (tert-butyl hydroperoxide, TBHP) epoxidation of cyclohexane (CH) by Mo(6+) complexes attached to cellulose phosphate (Mo):[82]

$$Mo + TBHP \overset{K_r}{\rightleftharpoons} Mo \cdot TBHP,$$

$$Mo + CH \overset{K_D}{\rightleftharpoons} Mo \cdot CH,$$

$$Mo \cdot TBHP \cdot CH \xrightarrow{k} Mo + CHO + TBA,$$

where CHO is cyclohexane oxide, TBA is tert-butyl alcohol, k is the rate constant of the inherent catalytic act which is achieved in the triple bi-substrate complex, catalyst–hydroperoxide–olefin.

Table 9. Activation parameters of the principal stages in the epoxidation of cyclohexene by heterogenised and homogeneous molybdenum systems.[82]

Rate constant of the reaction	ΔH ($\Delta H^{\neq}$), kJ mol^{-1}	ΔS ($\Delta S^{\neq}$), J mol^{-1} deg^{-1}	E_a, kJ mol^{-1}
K_r	−72	−220	
K_D	−36	−130	
k	133	290	136
K_r'	−24	−92	
k'		166	72

Enthalpy values for the formation of intermediate complexes of the catalyst with reagents (i.e. enthalpies of their chemosorption at the active centres containing Mo) and the activation energies of the decomposition stage of the triple complex into the reaction products are presented in Table 9. For comparison the corresponding parameters of the homogeneous reaction of the direct oxidation of cyclohexene by the molybdenum diperoxocomplex with hexamethylphosphortriamide are presented.[83] The enthalpy and entropy changes during complex formation of diperoxomolybdate with cyclohexene (the rate constant of this reaction, K_r') and also the activation energies and entropies of the transformation of the triple complex (rate constant k') are indicated. The comparative analysis shows that a similar stage of the decomposition of the triple bisubstrate complex Mo.TBHP.CH on the support surface is distinguished by a significantly higher activation energy and by a simultaneously higher positive activation energy. This difference is apparently caused by the heterogeneous nature of the catalyst. The triple complex immobilised on the support matrix is apparently stabilised on account of the addition interaction with the surface and it occurs in a highly ordered, and as a frozen, state. Therefore it

requires a higher activation energy, whereas the release of the products formed into solution is accompanied by a more abrupt disordering of the system. This effect is apparently quite often encountered in catalysis by immobilised complexes.†

A change in the bond energy of the substrate with the support area by 5–10 kJ mol^{-1} may significantly affect the mechanism and selectivity of the reaction. Thus the rate of styrene hydrogenation in the presence of Pd(0) on functionalised CSDVB sharply increases when supports are used containing functional groups which have the ability to form π-complexes with styrene and thereby to increase the lifetime of the adsorbed complexes of the substrate.[27]

XI. The selectivity of immobilised catalysts

Usually immobilised metallo-complexes not only increase the rate of the overall process but also improve its selectivity. Examples are known of the inversion of the selective action of MX_n when they are attached to the support.

In contrast to the homogeneous catalysts the immobilised catalysts are mainly more sensitive to the steric effects of the substituents in the substrate. This is confirmed by the distinct dependence of the reaction rate on geometric sizes of the molecules. Geometrical or matrix selectivity is one of the important features of the processes in immobilised catalysts. For example the rate of hydrogenation decreases on transition from an acrylic to a cyclic olefin. This applies to both individual compounds and components of different fractions or mixtures. The activity of polymer-bound $PdCl_2$ during hydrogenation of substrates forms the following series:[58] dienes > allyl alcohol > alkene-1 > alkene-2 > methyl-alkene-2. The stability of such contacts reaches 1000 or more cycles.

A particularly high order of selectivity is attained on reduction of aromatic and heteroaromatic substrates, including those containing functional groups. Catalysts obtained in this way are suitable for the preparation of cyclohexanol from phenol, and polyols from sugars, and for converting inner alkenes into α-alkenes.[85] The regio-selectivity is especially pronounced in olefin hydroformulation reactions (the ratio of alehydes with the normal structure and the isostructure), and hydrosilylation (α- and β-addition) and oxidation (the predominant formation of a particular product) reactions, and in the formation of an enantiomeric excess (enantioselectivity).

Essentially the same factors which affect the activity of the catalysts also affect selectivity, i.e. the nature and topography of the bonded complex, the nature of the matrix and ligand, the L:M ratio, and also the reaction conditions. For example since the selectivity is associated with the specific adsorption of one of the reagents or the product on the surface, the selectivity of the reaction is dependent on whether the catalyst is swollen or not swollen. The selectivity decreases, also as a consequence of the side reactions including those in which vacant functional groups are involved (hydrolysis, esterification, re-esterification, amination, etc.) and in which the solvent in addition to the substrate is involved. Furthermore, owing to the dissociation of a certain portion of the ligands, the pH of the medium may be altered, which also affects the selectivity. Such effects are extremely varied. For example the ratio between the quantities of ammonia and hydrazine formed in the presence of the titanocene polymers is markedly dependent on the rigidity of the polymeric chain, which regulates the formation of mono- and binuclear diazo complexes of Ti.[86]

During the dimerisation of ethylene by "nickel" immobilised systems the isomeric butenes are primary products, whereas the ratio between *cis*- and *trans*-isomers is regulated at the stage of the transition state in which the ethylene molecules occur at the time of dimerisation.[51] Double bond migration processes and also the geometric isomerisation mainly occur prior to the release of the butylene molecule from the "cell", and the secondary isomerisation reaction arising after its displacement by ethylene is reduced to a minimum. This confers "isomerisation passivity" upon the immobilised complexes in numerous reactions and increases their selectivity. Attention has already focussed on the ratio of isomerisation and hydration active centres (see Fig. 9).[79]

The conformation of the macroligand has a controlling effect on the catalytic properties and selectivity. There are many examples of this effect, which especially concerns polymers possessing the α-helical structure with accurately fixed distances between the ions of the bonded metals. This phenomenon is typical of enantioselective catalysis, where an increase in the stereospecificity is accomplished by limitation of conformational diversity, for example on oxidation of *L*(+)-ascorbic acid catalysed by *trans*-$[Fe(2,2',2'',2'''\text{-}Py_4).(OH)_2]^+$ bonded by Na-poly-(*L*- or *D*-glutamate).[87] When the complex is fixed on a peptide chain it becomes "renaturated" which is associated with the emergence of conformational asymmetry in the metallo-polymeric chains, and asymmetric induction proportional to the content of α-helices in the polymer (stereospecificity factor K_{FeD}/K_{FeL}) is observed. This is associated with a change in the standard free energy of the diastereomer transition states G_{LL} and G_{DL}. The diastereomer *DL* undergoes less steric hindrance than diastereomer *LL*. Consequently electron transport occurs more efficiently because of the more preferable changes in the activation parameters ($G^{\neq}_{LL} - G^{\neq}_{DL}$ = 1.25–3.4 kJ mol^{-1}, Fe_{FeD}/K_{FeL} = 1.5–4.0 on increase in chain load, f = 0.01–0.20) and an increase in relative conformational mobility of intermediate formations of segments in the chain.

Thus the effect of the conformation on asymmetric induction may be associated on the one hand with the formation of a suitable chain structure and on the other hand with a difference in affinity (stability of intermediate complexes) of enantiomers of the substrate and the catalyst. Such a substrate complex should probably contain at least two bonded Cu(2+) ions (on oxidation of 3,4-dihydroxyphenyl-alanine) so that stereoselection is achieved in the catalytic act (Fig. 11).[88] Like enzymic catalysis such a method ensures the generation of large quantities of the enantiomeric product from catalytic quantities of chiral materials.

In principle the selectivity of immobilised complexes may be increased by introduction of a second (supplementary) metal.

XII. The problem of polyfunctional catalysis

Systems consisting of several transition metal compounds (including those bound by a uniting ligand) may be used in different variants in catalysis. They may act either in parallel in one or several unbound rings or independently in sequential stages or in reactions or coordinatively in one reaction.[89] Polyfunctional catalysts, by means of which it is possible to react with successive stages of one multi-stage reaction, are extensively used in the chemical industry.[90] The attachment of two metals within one

† However converse examples are also known. Grafting of peroxides increases the rate of their decomposition, which is associated with their destabilisation as a result of the interaction of the peroxy group with functional groups on the surface.[84]

reaction centre, or statistically in one catalyst grain, often causes a synergistic effect of increasing activity and selectivity.

The role of the additionally introduced metal (M_1) in catalytic hydrogenisation, oxidation, (co)polymerisation and other reactions may be very diverse. On the one hand M_1 (usually nontransitional) may serve as a "trap" for active centres, binding them more firmly with the support and preventing migration and aggregation. On the other hand these effects may be achieved as a result of the insertion of the introduced metal ion between the attached complexes (the $-M-M_1-M-$ type), which promote their matrix isolation. In addition the chemical interactions (formation of weak $M-M_1$ bonds, co-crystallisation, formation of intermetallic compounds, and alloys, etc. on the support) may promote an increase in catalyst yield (as a result of an increase in activity or an increase in concentration of single centres) and its selectivity. For example immobilised bimetallic chloride complexes $AlCl_3-TiCl_4$ on CSDBV,[89] $AlCl_3-SnCl_4$ on polystyrene,[90] and $AlCl_3-FeCl_3$ and especially $AlCl_3-CuCl$ on polystyrene ($CuAlCl_4$/polystyrene)[91] etc. are the strongest solid superacids. Immobilisation of such "dibasic" acids not only increases the acidity but also prevents their irreversible deactivation in a moist atmosphere.

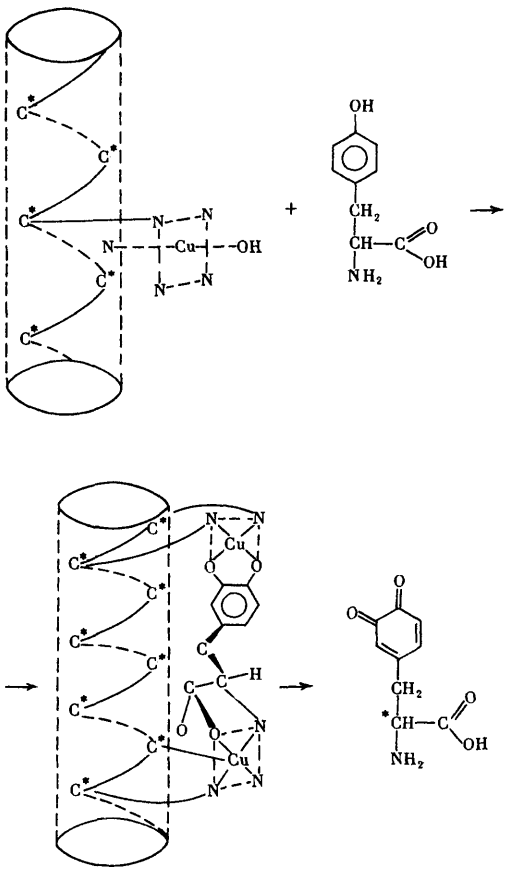

Figure 11. Model of the bifunctional coordination and oxidation of 3,4-dihydroxyphenylalanine on Cu(2+)–poly(L-lysine).[88]

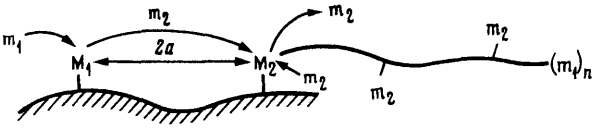
However, those cases in which each of the bonded complexes achieve (according to the coordinated mechanism in the optimal variant) its own stage in the multi-stage process are of more interest. Only one of the most typical examples in the author's opinion will be presented. The case in point is the relay (coordinated) copolymerisation in the presence of immobilised complexes in which two types of active centre (dimerising and copolymerising) are bonded on to one support.[92,93] The line diagram of the process examined may be presented as follows:



The original monomer (in this case ethylene) at the active centre M_1 [for example Ni(2+)] is converted into monomer m_2 as a result of a simple reaction of di-, tri- and oligomerisation, etc. (in particular as a result of the dimerisation of ethylene into butene). In situ copolymerisation of m_1 with m_2 occurs at the active centre M_2 [for example Ti(4+), V(4+), etc.]. The size of the microcell containing different types of active centres is a, which comprises half of the average distance between the centres of pairs of the bifunctional catalyst. The distance between M_1 and M_2 is required during the construction of such catalysts.

The stationary mass-transfer in an individual microcell of this type is determined by the equation:[94]

$$D_i \frac{d^2C_i}{dx^2} = 0 \qquad (i = 1, 2),$$

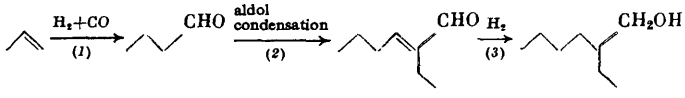
where C_i and D_i is the concentration and effective diffusion coefficient of monomer m_i in microcell respectively. The composition of the copolymer formed (in this case a copolymer of ethylene with butene, so-called branched polyethylene or linear low-density polyethylene) is characterised by the ratio of effective reaction rates of co- and homopolymerisation. In addition to other factors the regulation of the degree of branching is also attained by varying the average distance between different types of centres and has an extremal nature.

The effect of the cell in the immobilised bifunctional centre in principle may lead to an increase in the factor of the first encounters and also to an increase in the contact time of the reacting molecules (to an increase in the number of repeating encounters with the active centre). The metaphor used by the authors is that the operation of the bimetallic centre is "like the action of a conveyer on which each participant operates with great skill and speed".[95] This is promoted by the possibility of more precise control of the synthesis of active centres in the immobilised systems. However, as on a real conveyer, fragments are also found during the operation of such a centre. The complex composition of the gas mixture and the incompletely understood dependence of the behaviour of the centre on the reaction conditions hinder the control of "relay" copolymerisation and even its quantitative description.

The macroligand essentially possesses unlimited combination possibilities within the single matrix of active centres differing widely in nature, so that diffusional limitations should be less than when the corresponding number of monofunctional catalysts are used if a multi-stage reaction is performed on such a catalyst. The magnitude

of the areas of the monofunctional action of the active centres has been estimated to be 12 Å.[96] Both types of active centres should react on the substrate molecule, so that the coordinated mechanism is realised. It has already been mentioned that the most complicated task in the construction of polyfunctional systems is the coordination of the action of the diverse centres and the prevention of their autonomous operation. The main approach to resolve this problem is the control of the spatial arrangement of the active centres, which determines the extension of the transfer pathways of reagents between them, regulates diffusional limitations, and promotes the existence of the bifunctional catalysis itself.[94]

This may be shown in the case of the three-stage synthesis of 2-ethylhexanol from propylene and synthesis gas.[97] The process includes the formation of butyric aldehyde (stage 1), its aldol condensation (stage 2), and hydrogenation (stage 3).



It may be achieved by the use of both two monofunctional catalysts (hydroformylation and hydrogenation) and also one bifunctional catalyst [chloromethylated CSDVB, modified by secondary amino groups with grafted $RhCl(PPh_3)_2(CO)$] (Fig. 12). The rate of the first, second, and third stage on the bifunctional catalyst is 5-, 15- and 30-fold higher respectively than that on two monofunctional immobilised catalysts.

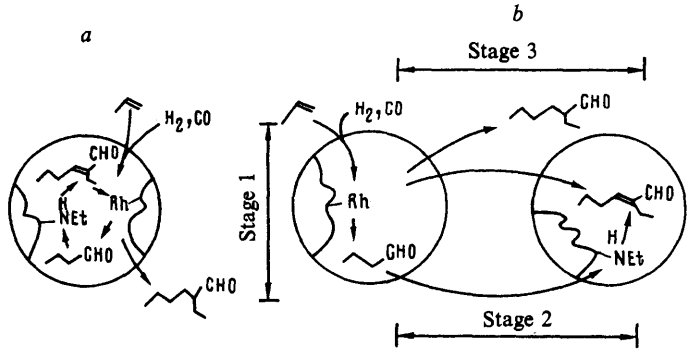


Figure 12. Comparison of diffusional inhibition in reactions catalysed by one bifunctional (*a*) and two monofunctional (*b*) catalysts in the case of the three-stage synthesis of 2-ethylhexanol.[97]

Yet another typical example relates to the reduction of O_2 to H_2O_2. Although the electroreduction of O_2 to H_2O_2 occurs readily on electrodes coated with immobilised metallo complexes, the catalysts used for the reduction of H_2O_2 to H_2O exhibit low efficiency in the O_2 reduction reaction. However it has been found basically possible to bond more than one type of metallo complex on to one graphite electrode.[98] The method involving the modification of the electrode surface by a single bifunctional catalyst for the total 4-electron reduction of O_2 was based on this principle. Ru(3+) and Cu(2+) on a chlorinated copolymer of methacrylic acid and methyl methacrylate are used as such a catalyst.[99]

The range of such examples has been extended significantly in recent years. We shall refer only to the oligomerisation of butadiene with the hydroformylation of vinyl cyclohexene on Ni–Rh-complexes bonded to phosphorylated CSDVB and the preparation of 4-methyl-2-pentanone on composites of polymers consisting of polyamines and polycarboxylic acids impregnated with PVC and incorporating two transitional metals.[100]

All examples mentioned above relate to immobilised heterometallic clusters, which have higher stability than that of the monometallic clusters under the conditions of the catalysed reactions. A search for methods to construct such systems is a promising direction for metallocomplex catalysis.[101]

The action of polyfunctional immobilised complexes is the most adequate model of catalysis by enzymes (an example is the attachment of Mo(6+)–Fe(3+) within a single elementary unit of phosphorus-containing ampholytes, the nitrogenase mode).[102] Such analogies are extremely deep-rooted and they can be extended also to polynuclear metalloenzymes. In the latter the role of multifunctionality consists of the creation of favourable energy and probability factors owing to the optimal use of the respective active centres at each stage of the reaction. In other words in the catalyst-substrate complex there is a restriction of the number of inefficient diffusional movements from the standpoint of the catalytic reaction which do not lead to the formation of products.[103]

An important condition for the realisation of catalytic synchronous processes is the possibility of the dynamic adaptation of the form of the catalytic matrix to the structure of the substrate and the active centres changing in the course of the reaction (fine-tuning). Rapid and reversible conformational transitions both in enzymes and in macroligands and also fluctuations in the matrix structure ensure the necessary structural adaptation. The specific characteristics of the enzyme systems reside in the presence of secondary and tertiary structures, which limit the spatial orientation of metal ions and the possibility of side reactions occurring. By using synthetic metalloproteins it has still not been possible to create a model which under similar conditions (pH, temperature, catalyst, and substrate concentrations) would approach enzyme systems in activity and selectivity. However, the extent to which such a condition can be approached is quite high, for example the efficiency of the binding of O_2 by metallopolymeric complexes is equivalent to the level of efficiency of haemoglobin and myoglobin.[104]

XIII. Conclusion

The author considers that by analysing the fundamental problems considered in this review it is possible to explain the growing scientific interest in catalysis by immobilised complexes and the characteristics of their operation. During the study of immobilised systems new patterns and phenomena have been revealed which are of fundamental importance (it is sufficient to mention those studies in which chelatogenic macroligands,[105] polymerisation and transformation products of metallomonomers,[106] and the use of the lanthanides and transuranium elements etc. have been investigated).

The macroligand stabilises the mononuclear complexes incorporated into unidimensional chains, two-dimensional networks, and three-dimensional frameworks. This increases the thermodynamic and kinetic stability of such systems. The polymeric structure of the ligand environment hampers ligand exchange and

introduces specific properties to the electron transfer reactions and redox processes. Nonvalent interactions affect reactivity, especially the geometry of the transition state. The differences in the kinetic and activation parameters of the reactions of polymeric and monomeric complexes are associated with conformational changes in the macroligands. The systems examined are multi-parameter systems, and it is necessary to take into account the effect of many factors, in order to optimise their activity and selectivity. Total optimisation with respect to all variables would be an incredibly complicated experimental objective. Theoretically founded economically-viable methods for its resolution in immobilised systems are only beginning to be developed.

Catalysis by immobilised complexes is accompanied by a whole series of macromolecular effects, i. e. an increased local concentration of active centres and substrate in the macromolecular globules or in domains close to the active centres, the effect of the spatial structure and polymer chain length, etc. Evolutionary transformations of multinuclear complexes into associates in the immobilised systems occur to a lesser extent than in homogeneous systems.

The realisation of the potentials of these interesting systems (for example in membrane catalysis, when by regulation of the rate at which a substrate passes through a metallopolymeric membrane it is possible to increase the selectivity of the process) will help to explain in detail both homogeneous and heterogeneous catalysis, whereas the information obtained will help to explain the basis of the catalytic action.

Finally the methodological approaches developed during the construction, study and use of immobilised complexes will be extremely useful in a new field of science, chemical biomimetics, in the physicochemical modelling of processes occurring in living nature. Thus the cooperative actions of the macroligand and Zn(2+) or Co(2+) ions as biomimetic catalysts have been found in the study of the hydrolysis of *p*-nitrophenylpicolinate.[107]

Photocatalysis by transition metal complexes

O V Gerasimov, V N Parmon
Institute of Catalysis, Siberian Division of the Russian Academy of Sciences, Novosibirsk

ABSTRACT. The principal tendencies in the development of homogeneous photocatalysis by transition metal complexes are examined. Attention is concentrated on the photocatalytic reactions of organic substrates.

The bibliography includes 164 references.

I. Introduction

Transition metal complexes are well known as excellent highly active catalysts of many homogeneous processes, capable of ensuring not only a high selectivity of the chemical reactions but also the possibility of studying their detailed mechanisms. This makes it possible to act specifically on such reactions by modifying the structure or composition of the catalytic complexes.[1–7] Photochemists have found in their turn that model complexes are objects whose structure and properties can be described quite satisfactorily by modern theories and have used photochemical reactions with participation of transition metal complexes as, on the one hand, an instrument for further improvement of these theories and, on the other, as a means of achieving new chemical reactions which are frequently not merely of academic interest.[8–13] At the junctions of these two fields—homogeneous coordination catalysis and transition metal photochemistry—a new field of physical chemistry, namely photocatalysis by transition metal complexes, has been established and has developed quite vigorously.

Unfortunately the available Russian language monograph and review literature provides an inadequate description of these studies, because it deals mainly with the extremely specific problem of the application of photocatalysis by metal complexes to the direct transformation of solar energy into the energy of chemical fuels (see, for example, Refs. 14–21). The monograph of Kryukov and Kuchmii[13] provides a description of a series of photocatalytic processes on the basis of the photochemical reactions of titanium and iron complexes in aqueous and aqueous organic media. Shul'pin's monograph,[7] devoted to metal complex catalysis as a whole, presents many examples of organometallic photocatalysis, but these are disjointed and are discussed in the context of the problem of the usual thermal catalysis. The only review in Russian devoted directly to the problem of photocatalysis by transition metal complexes is that of Lyashenko.[22]

In the present article, an attempt is made to survey and deal systematically with studies in homogeneous photocatalysis by transition metal complexes in order to acquaint Russian speaking readers with the development and prospects of such research.

In connection with this aspect of the review, the latter is hardly concerned with questions related to the nature of the primary photophysical and photochemical stages of the processes discussed below. Nevertheless, before describing the main material of the review, mention should be made of certain principal characteristics of the nature of the photochemical activity of transition metal complexes.[8]

The following electronic transitions capable of initiating primary photochemical processes take place under the influence of light in transition metal complexes.

Ligand field transitions (LF transitions) or $d-d$ transitions ($f-f$ transitions) occur between orbitals referring to the central ion and are usually observed in the visible region. They are symmetry forbidden for octahedral complexes and the corresponding extinction coefficients are therefore usually small (10^1-10^2 litre mol^{-1} cm^{-1}).

Charge-transfer transitions (CT transitions) are characterised by the transfer of an electron localised predominantly on the central atom to the unoccupied orbitals of the ligand [transition with charge transfer from the metal to the ligand (CTML)] or conversely [transition with charge transfer from the ligand to the metal CTLM)]. Charge-transfer transitions are recorded in the UV region and in the blue part of the visible spectrum. The corresponding extinction coefficients are fairly large—of the order of 10^4 litre mol^{-1} cm^{-1}. A related variety of the transition is phototransfer of an electron from the central metal ion to a solvent molecule or conversely.

Electronic transitions of the above types are responsible for the vast majority of photocatalytic reactions with participation of transition metal complexes. Nevertheless, in many cases other primary photophysical processes, listed below, also play a definite role.

Intraligand transitions (IL transitions), which are frequently called $\pi-\pi$ transitions (because intraligand transitions with participation of σ orbitals lie as a rule in the far UV region and are not manifested in the usual sphere of the complexes), are located in the UV region (with rare exceptions) and are characterised by extinction coefficients up to 10^5 litre mol^{-1} cm^{-1}.

Mention should also be made of charge-transfer transitions which can occur in ion pairs. In dinuclear and polynuclear complexes, there is a possibility of transitions with charge transfer from one metal ion to another (the so called intervalent transitions usually manifested in the presence of a bridging ligand) and also (in the presence of metal–metal bonds) transitions between molecular orbitals) localised on two or more metal ions.

As a result of the absorption of a light quantum, a molecule of the complex receives a large dose of energy: a quantum energy of 2–3 eV corresponds to the visible light and one up to 6 eV corresponds to UV light, while the quantity kT amounts to 0.025 eV at room temperature and the activation energies for the usual thermal ("dark") reactions rarely exceed 1 eV (about 100 kJ mol^{-1}). However, the absorption of a light quantum cannot be regarded as selective 'heating' of an individual molecule. Not the magnitude of the adsorbed energy but a completely definite rearrangement of the electronic structure of the complex is important for the initiation of the photochemical reaction.

For example, as a result of a LF transition, an electron is transferred from a bonding orbital to a non-bonding or antibonding orbital (or from a non-bonding to an antibonding orbital) which entails a weakening of the bond between the central ion and the ligand. Therefore the preferred model of reactions with participation of excited LF states is dissociation or isomerisation of the complexes.

As a result of charge-transfer transitions

$$ML + h\nu \xrightarrow{CTML} M^+L^-$$

$$ML + h\nu \xrightarrow{CTLM} M^-L^+$$

(here and henceforth M and L are understood as the initial states of the metal ion and of one of the ligands of the complex respectively), species differing sharply from non-excited states in their oxidation-reduction properties are formed. Depending on the oxidation-reduction properties of the ligand and the central ion, the nature of the solvent, and the presence in the solution of other compounds, etc., reactions of the excited state of the complex with participation of both $M^+(M^-)$ and $L^-(L^+)$ can take place under these conditions.

Overall, the probability of the occurrence of the primary photochemical reaction in a particular direction can depend on the wavelength of the exciting light, the nature of the excited state, its lifetime, the nature of the solvent, the presence of other substances in solution, etc. Thus the lifetime of the excited state is a parameter which is particularly critical for bimolecular reactions. Indeed, for excitation lifetimes less than 10^{-10} s and reasonable concentrations of the reactants in a homogeneous solution or in the gas phase, the attempts to carry out a bimolecular reaction with participation of such an excited state are virtually hopeless. However, unimolecular reactions (including those with coordinated molecules of substrates) are entirely feasible even for such short times. By altering the wavelength of the exciting light, it is possible to generate more or less selectively various excited states of the same complex or to excite particular compounds among those present in the reaction system and influence thereby the mode of reaction.

Photocatalytic processes are more complex than "simple" photochemical reactions, because they usually include at least two stages. Therefore, before considering specific examples, it is useful to deal with questions of the terminology and classification of the phenomena in the field of photocatalysis.

II. What is understood by the term "photocatalysis"

The term "photocatalysis" and the concepts of "photocatalytic reaction" and "photocatalyst" associated with it are extremely widely encountered in the literature. A whole series of recent books and reviews are fully or partly devoted to photocatalysis.[14–36] At the same time there is as yet no rigorous and generally accepted definition of this concept, which has been noted by almost everyone who has attempted to deal systematically with the terms used in this branch of knowledge.[7,26,28–30,37–39] One of the common approaches consists in the widest possible treatment of the concept of "photocatalysis", which has been firmly expressed by the definition recommended by the IUPAC Commission:[40] "photocatalysis is catalytic reaction involving the absorption of light by the catalyst or the substrate". The reactions included in this definition can be described by the generalising equations

$$S \xrightarrow[K]{h\nu} P \text{ or } S + R \xrightarrow[K]{h\nu} P + Q.$$

Here and henceforth the symbols S and R denote the substrate and reactant molecules, the symbol K represents the initial form of the catalyst or the photocatalyst, and P and Q are reaction products. It is significant that this formulation embraces processes of most varied types. A more rigorous systematic treatment of the process under consideration is therefore proposed below (see also Parmon[39]).

1. Photogenerated (photoinduced photoinitiated) catalysis. The reaction proceeds in accordance with the scheme

$$\begin{aligned} K &\xrightarrow{h\nu} K', \\ S &\xrightarrow{K'} P. \end{aligned} \qquad (I)$$

Here light is used to generate the active form of the catalyst K′, which ensures the occurrence of the usual "dark" catalytic reaction. In principle, if this active form is not deactivated, the rate of the photoinitiated reaction should remain unchanged also after light has been switched off.

2. Catalysis of a photochemical reaction. The scheme

$$\begin{aligned} S &\xrightarrow{h\nu} {}^*S, \\ {}^*S &\xrightarrow{K} P. \end{aligned} \qquad (II)$$

or

$$\begin{aligned} S &\xrightarrow{h\nu} P', \\ P' &\xrightarrow{K} P. \end{aligned} \qquad (IIa)$$

corresponds to this case. After the absorption of light by the substrate S, its excited state *S or the primary photoproduct P′ undergo a catalytic reaction with formation of the final product P.

3. Photosensitised reaction. Reactions involving the transfer of energy from the photosensitiser K to the substrate S are usually referred to this type:

$$\begin{aligned} K &\xrightarrow{h\nu} K^*, \\ S + {}^*K &\rightarrow {}^*S + K, \\ {}^*S &\rightarrow P. \end{aligned} \qquad (III)$$

It is not noteworthy that the term "photosensitisation" is treated, like the term "photocatalysis", very broadly.[38] Thus reactions

involving the phototransfer of an electron, for example in accordance with the scheme

$$\begin{aligned} &K \xrightarrow{h\nu} {}^*K, \\ &{}^*K + S \rightarrow K^+ + S^-, \\ &S^- \rightarrow P, \\ &R + K^+ \rightarrow R^+ + K, \\ &R^+ \rightarrow Q. \end{aligned} \qquad \text{(IIIa)}$$

are frequently classified as photosensitised.

Such extended treatment is apparently not entirely legitimate because electron transfer is a chemical reaction, albeit of the simplest kind, in contrast to the transfer of excitation energy. A reaction in accordance with mechanism (IIIa) should therefore be referred to photocatalysis (type 4).

4. Photocatalysis proper. In the English language literature, reactions of this type are frequently designated as "photoassisted catalysis", i.e. "catalysis with the assistance of light". The simplest cases of photocatalysis are described, together with scheme (IIIa), also by the schemes

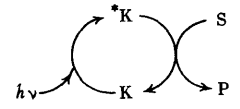
$$\begin{aligned} &K \xrightarrow{h\nu} {}^*K, \\ &S + {}^*K \rightarrow P + K. \end{aligned} \qquad \text{(IV)}$$

[the difference from scheme (III) consists in the absence of the transfer of electronic excitation to the substrate] or

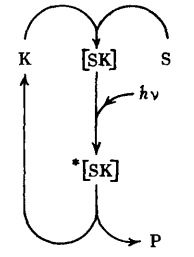
$$\begin{aligned} &S + K \rightarrow [SK], \\ &[SK] \xrightarrow{h\nu} {}^*[SK], \\ &{}^*[SK] \rightarrow P + K. \end{aligned} \qquad \text{(IVa)}$$

In this case, the catalyst participates directly both in the light absorption step, {either in the form of an individual compound of K via scheme (IV) or as a complex with the substrate [SK] via scheme (IVa)}, and in the step involving the catalytic conversion of S into P. Thus a photochemically active catalyst, i.e. the *photocatalyst* proper, is present in the system. In our view, this last factor justifies the naming of reactions of this particular type as truly photocatalytic.

Returning to the extended definition of photocatalysis proposed by IUPAC, we note that it does of course have the right to exist. This is because, for example, the real mechanisms of catalytic reactions occurring under the influence of light are frequently unknown, at any rate in the initial stages of the investigation. Therefore, if it has only been established that the reaction is catalytic and that light influences its rate or pathway, it is reasonable to refer to such reactions as photocatalytic *in a broad sense*. On the other hand, if it is found on closer examination that the reaction is in fact of the dark "thermal" type, as in scheme (I), or the catalyst is not involved in the absorption of light [i.e. is not a photocatalyst, as in scheme (II)], or the reaction is not catalytic at all [i.e. there is no chemical interaction between the light-absorbing compound and the substrate, as in scheme (III)], then in such cases one should avoid using the term "photocatalysis" and apply it only to designate processes illustrated by schemes (IIIa), (IV), and (IVa). This approach to the term "photocatalysis", which we have followed consistently during the last ten years,[15] is based on the definition of the concept of "catalysis" given by Boreskov.[41] The corresponding formulation is as follows: "photocatalysis is the change in the rate or excitation of chemical reactions under the influence of light in the presence of substances (photocatalysts) which, as a result of the absorption of light quanta by them, are capable of inducing chemical reactions of the reactants by entering into intermediate chemical interactions with the latter and regenerating their own chemical composition after each cycle of such interactions". Within the framework of this definition, two situations, illustrated by Schemes (IV) and (IVa), are possible, which can be represented, for greater clarity, by the following cyclic schemes respectively:



,



.

These cyclic schemes differ in the sequence in which light is absorbed and the photocatalyst reacts chemically with the substate. However, in both cases the photocatalyst participates in the two stages indicated.

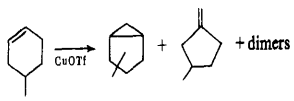
III. Photocatalytic reactions with participation of transition metal complexes as photocatalysts

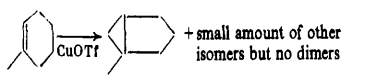
To facilitate the subsequent analysis, photocatalytic reactions with participation of transition metal complexes can be divided into two groups: (1) "inner sphere" reactions in which bonds are dissociated and/or formed in the inner sphere of the metal complex; (2) "outer sphere" reactions in which the main transformations of the substrate molecules occur outside the inner sphere of the complex. Reactions of the first type are in fact characteristic of transition metals with their unique ability to form a wide variety of coordinate bonds. Reactions of the second group are in our view not so specific to coordination compounds, because their first stage is always electron phototransfer—a process characteristic of a wide range of compounds, especially organic ones. Nevertheless, certain characteristic features of metals complexes enable them to occupy a special place also among photocatalytic reactions of the second type. The most characteristic features of reactions of both types are considered below in succession.

1. Inner sphere photocatalytic reactions

Among reactions of this type one can distinguish, in their turn, two subgroups: (1) reactions with participation of transition metal complexes with organic ligands; (2) reactions with participation of simple inorganic metal complexes. The difference as regards the type of ligands is extremely arbitrary because in reactions of the first subgroup compounds of the type CuCl frequently occur as initial photocatalytically active substances, while the substrates in reactions of the second group are usually organic compounds which are, in principle, capable of forming coordinate bonds with the ions of the photocatalytically active complex in some stage of the process. However, a significant difference between these subgroups nevertheless exists and is manifested by the nature of the initiated reactions.

Table 1. Inner-sphere photocatalytic reactions with participation of organometallic and other related complexes.

Type of reaction	Examples	Mechanism	Comments	References
Geometrical isomerisation of alkenes		PC	The non-catalytic reaction takes place only under the influence of UV light, while in the presence of $ClRe(CO)_5$ it occurs under the influence of light with $\lambda = 436$ nm	[43]
	Ditto in the presence of $W(CO)_6$	PG+PC		[23, 44]
Skeletal isomerisation of alkenes		PC		[45]
				
				




Allyl shift		PG		[46]
		PC	An anomalous allyl shift involving an increase in free energy takes place under the influence of light	[26]
		PG	Flash photolysis showed that the substrate is coordinated to the catalyst via the double bond and not the nitrogen atom	[47]
		PG	Reactions of this type usually occur on heterogeneous catalysts of the type KNH_2/Al_2O_3, but the first reaction does not occur on them at all while the second affords only the *cis*-product	[48]
		PG	φ reaches 400; the Ru_3 trimer is active in the visible region	[49]
		PG	The photogenerated catalyst exhibits a very high activity compared with the traditional "dark catalyst"	[50]
Metathesis		PG		[51]
	Ditto in the presence of $W(CO)_5L+ZrCl_4$ in *n*-heptane	PG	The reaction proceeds at room temperature with a high selectivity	[52]

Table 1 (cont'd).

Type of reaction	Examples	Mechanism	Comments	References
Cycloaddition of alkenes		PC	The turnover number of the photocatalyst reaches almost 400; $\varphi = 0.34$ and is independent of the substrate concentration; the formation of a complex between the photocatalyst and the substrate in the ground state is confirmed by UV spectra	[53]
		PC		[54]
		PC	In contrast to the examples presented previously, not only hydrocarbons but also an oxygen-containing compound participates in the reaction	[55]
		PC		[56]
Hydrogenation		PG	The reaction continues for several hours after switching off the light	[57]
		PG	$Fe(CO)_5$ catalyses the reaction also in the absence of illumination but at $T > 150$ °C, while in the presence of light with $\lambda > 366$ nm the reaction takes place at room temperature or even at $T < 0$ °C	[58]
Carbonylation		PG	Flash photolysis showed that CO and not phosphine is split off under the influence of light	[59]
		PG		[60]
		PG		[61]
Hydroformylation		PG	$\lambda = 366$ nm; the photocatalytic reaction takes place at 85 °C but there is no thermal catalysis under these conditions	[62]
Addition to $\rangle C{=}C\langle$ bond		PG		[63, 64]
		PC		[65]
Dehydrogenation		PC		[66, 67]
		PC		[68]
		PC		[69]

Table 1 (cont'd).

Type of reaction	Examples	Mechanism	Comments	References
Dehydrogenation with transfer of hydrogen		PC		[69]
Reduction of CO_2	$CO_2 + N(CH_2CH_2OH)_3 \xrightarrow[Re(bipy)(CO)_3Cl]{} CO + TEA$ oxidation products	PC	See also Table 3	[70]
Water gas shift reaction	$CO + H_2O \xrightarrow[Co(CO)_4]{} CO_2 + H_2$	PG		[71]
	Ditto in the presence of Ir $[(\eta^5-Me_5C_5)Ir(bipy)X]^+$, where X=$Cl^-$ or H^-	PC		[72]
	Ditto in the presence of $HFe(CO)_4^-$	PC		[73]
Polymerisation	Polymerisation of methyl methacrylate, styrene, and other olefins in the presence of $Ti(CH_2Ph)_4$ or $Zr(CH_2Ph)_4$	PG		[74–76]

Note. PC = "true" photocatalysis; PG = photogenerated catalysis; φ = quantum yield.

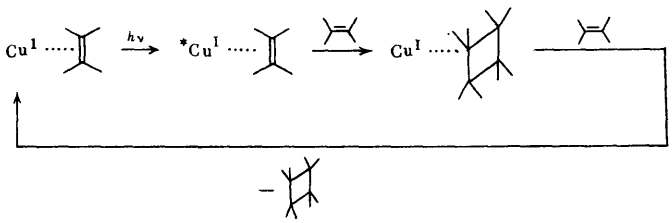
(a) Photocatalysis with participation of complexes containing organic ligands

Photocatalysis with participation of complexes containing organic ligands, in particular "organometallic photocatalysis", is a dynamically developing research field (see, for example, the relevant reviews[23,25,26,29,30,38,42]). The wide variety of chemical reactions which have been achieved in systems of this type is noteworthy. Examples are presented in Table 1, which includes only the most typical and interesting reactions. Those wishing to do so, may find an extensive compilation of reactions of this type in another review[26] and also in recent publications.[38,42]

As can be seen from Table 1, this group includes alkene isomerisation reactions (geometrical and skeletal isomerisation, the allyl shift), metathesis, alkene cycloaddition reactions, hydrogenation, carbonylation, and other processes, i.e. reactions which are, in principle, usual for traditional homogeneous catalysis. Furthermore, the majority of the photocatalytically active compounds are at the same time also traditional (thermal) homogeneous catalysts [$M(CO)_n$, $M(CO)_nL_m$, $M(CO)_n(PPh_3)_mL_k$, CuOTf, $Co(OAc)_2$, etc., where M = Rh, Ir, Fe, Ru, etc. and OTf = trifluoromethanesulphonate]. This gives rise to an especially convenient possibility of comparing reactions occurring in photocatalytic and dark (thermal) catalytic regimes and to discover the characteristic features occurring in photocatalytic and dark (thermal) catalytic regimes and to discover the characteristic features of the photocatalytic method of effecting a number of organic reactions. Comparison shows that, firstly, photocatalytic reactions can occur under much milder conditions than the analogous dark reactions. The hydrogenation of olefins in the presence of $Fe(CO)_5$ can serve as an example: when the system is acted upon by light ($\lambda > 366$ nm), the reaction takes place at a temperature lower by ~150 °C than under dark conditions.[58] This feature may be fundamentally important in syntheses with participation of thermolabile reactants or products and the photocatalytic procedure is in such cases the only one possible. Secondly, the catalyst, formed as a result of its photochemical generation, is not usually inferior as regards its activity, and sometimes is actually superior, to the catalysts obtained under similar conditions by the thermal method.[50] This means that the generation of the catalyst under the influence of light can, in principle, compete with the usual thermal activation of the catalyst, ensuring under identical conditions a higher rate of reactions. Thirdly, direct thermal catalysis of reactions accompanied by a significant increase in free energy is as a rule altogether impossible. In such cases, the photocatalytic (or at least photochemical) method of effecting the reaction via the given pathway, capable of "pumping" energy into the system, is the only one possible. Examples of photocatalytic reactions accompanied by an increase in free energy are certain cycloaddition reactions[53] and the anomalous allyl shift[26] (see also Table 1). Fourthly, photocatalysis can promote the occurrence of photochemical non-catalytic reactions, which is manifested, for example, by spectral sensitisation. Thus direct photochemical *trans–cis* isomerisation of 4-styrylpyridine takes place only under the influence of UV light, whereas in the presence of the $ReCl(CO)_5$ photocatalyst it becomes possible under the influence of visible light with $\lambda = 436$ nm.[43] Similarly, the cycloaddition reactions of olefins in the presence of photocatalysts, for example, copper(I) salts, require milder UV light.[53]

The photocatalytic processes under discussion can proceed via one of two dominant mechanisms. The first is true photocatalysis, which can always be described in terms of a sequence of reactions [scheme (IVa)]. This mechanism has been demonstrated quite satisfactorily, for example, for the olefin cycloaddition reaction in the presence of copper(I) salts.[26] Trifluoromethanesulphonate (triflate, OTf^-) is frequently used as the negatively charged ligand, although the reactions take place also when copper(I) is present in the system as

halide salts (chlorides and bromides). In an olefin solution, the central copper(I) ion coordinates the olefin via its double bond. The presence of such coordination is confirmed by UV spectra—a charge-transfer band, more intense than the bands of the initial compounds, arises. This results, firstly, in an increase in the ability of the system to absorb light, which is actually of intrinsic importance because there exists also a purely photochemical reaction pathway. Secondly, the excitation of the copper(I)–olefin complex by light corresponding to the CTML absorption band leads to a redistribution of electron density among the π orbitals of the olefin, so that the cycloaddition reaction in conformity with the Woodward–Hoffmann rule is promoted. Thirdly, and finally, copper(I) can function as a common coordinating site for the two reacting molecules similarly to what happens in the usual coordination catalysis:[26]

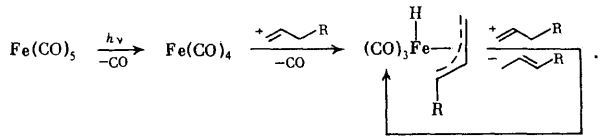


The interaction of the excited complex *Cu... with another olefin molecule (or the intramolecular transformation of the complex ) results in the formation of a saturated cyclobutane ring, which interacts with copper(I) much more weakly than the C=C bond and is therefore rapidly substituted by a new olefin molecule. The catalytic cycle is thus closed.

The second mechanism operating in the group of reactions considered is photogenerated catalysis [see scheme (I)]. The catalyst is photogenerated as a rule as a consequence of an increase in the lability of complexes in the *d–d* excited state. As already mentioned, the rate of reaction proceeding via the photogenerated catalytic mechanism should ideally remain unaltered after light has been switched off. In certain cases, the observed reactions do indeed continue for a long time after light has been switched off, as happens, for example, in the hydrogenation of 2-methylbuta-1,3-diene in the presence of $Cr(CO)_6$.[57] However, the deactivation of the active form of the photogenerated catalyst is frequently extremely rapid, i.e. the reaction actually takes place only in the light and is outwardly manifested as a true photocatalytic process. Thus the isomerisation of pent-1-ene to a mixture of *cis-trans*-pent-2-enes in the presence of iron carbonyls ceases after light has been switched off less than 5 s.[50] The activation of the photogenerated catalyst usually takes place as a result of the occurrence of processes which are the reverse of those which take place during its generation. For example, the active form of iron pentacarbonyl is the coordinatively unsaturated compound $Fe(CO)_4$:

$$Fe(CO)_5 \underset{\text{generation}}{\xrightarrow{h\nu}} Fe(CO)_4 + CO \underset{\text{deactivation}}{\longrightarrow} Fe(CO)_5.$$

If the rate of coordination of $Fe(CO)_4$ to the substrate does not exceed appreciably the rate of the reverse addition of CO, then the turnover number of such a species in the catalytic process from the instant of generation to the instant of deactivation will be relatively small, which actually happens in the pent-1-ene isomerisation reaction. The catalytic reaction proper proceeds via the mechanism usual for processes of this type:



The quantum yield of this reaction can reach several tens, which permits its entirely definite assignment to photogenerated catalytic processes.

(b) Photocatalysis with participation of metal complexes containing simple inorganic ligands

Typical photocatalysts of this group are $TiCl_4$, $FeCl_4^-$, CuCl, $CuCl_2$, VCl_3, $SnCl_4$, oxo-compounds of molybdenum and tungsten, and certain others. However, as in the case examined above, a common factor here is not only and not so much the nature and structure of the photocatalysts themselves as the reactions achieved with their aid. Examples of reactions of this group are compiled in Table 2. These are in the main reactions involving addition to the double bond (C=C and C=X) as well as a wide variety of oxidation reactions. Among the latter, those in which the oxidant employed is not oxygen (or any kind of other traditional oxidant, for example, hydrogen peroxide) but protons (hydronium cations), present in water or in mixed aqueous organic media, have attracted special attention. Simultaneously with the oxidation of organic compounds, such processes involve the reduction of water or other proton-containing compounds to molecular hydrogen. A reaction of this kind frequently represents stoichiometrically the dehydrogenation of organic compounds. For example, in the very first study of this topic,[90] the process

$$C_2H_5OH \xrightarrow[VCl_3]{h\nu} CH_3CHO + H_2, \qquad (1)$$

which is equivalent to the dehydrogenation of alcohol to acetaldehyde, was described. Unfortunately the occurrence of processes with photocatalysts of the type indicated requires as a rule UV light, the proportion of which in the solar spectrum is very small. The photocatalytic generation of hydrogen with the aid of such complexes from water and other readily available hydrogen-containing and/or electron-donating compounds, which is attractive from the standpoint of the utilisation of solar energy, is hardly promising for practical application.

The difference between the mechanisms of the reactions under discussion is significant. Thus in the reactions of the first group, described in the previous Section, the primary photochemical processes are as a rule either intramolecular transformations of substrates coordinated to the photocatalyst or photodissociation with formation of a coordinatively unsaturated species responsible for the catalytic activity. On the other hand, the primary chemical step in reactions of the second group is electron phototransfer from the metal ion or to the metal ion. Here the second reactant may be the ligand of the initial complex or directly the substrate present in the first or second coordination sphere. The detailed mechanism of primary photoprocesses of this kind has been investigated in detail[102–112] in relation to iron(III) and copper(II) chloride complexes. In the presence of an organic substrate, whose concentration is sufficient to ensure the presence of substrate

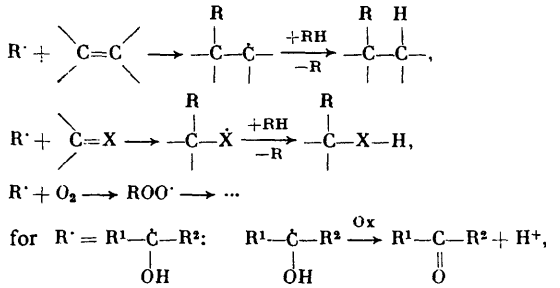
molecules in the second coordination sphere, the following processes take place in the system:

$$MCl_n \xrightarrow[CTLM]{h\nu} {}^*MCl_n$$

$${}^*MCl_n + RH \rightarrow M^-Cl_n \ldots R^{\cdot} + H^+,$$

$$M^-Cl_n \ldots R^{\cdot} \rightarrow M^-Cl_n + R^{\cdot}.$$

The organic radical $R^{\cdot}$ can enter into a wide variety of reactions which depend on the structure of the radical itself and on the presence in solution of other organic compounds, for example:[26]



for $R^{\cdot} = R^1-\dot{C}(OH)-R^2$: $R^1-\dot{C}(OH)-R^2 \xrightarrow{Ox} R^1-C(=O)-R^2 + H^+$,

for $R^{\cdot} = R^1COO^{\cdot}$: $R^1COO^{\cdot} \rightarrow (R^1)^{\cdot} + CO_2$.

The completion of the photocatalytic cycle requires the return of the metal ion to the initial oxidation state. In the example presented, this can be achieved either by the "dark" (thermal) oxidation of the reduced metal ion by a sufficiently strong oxidant, for example:

$$M^-Cl_n + O_2 \rightarrow MCl_n + O_2^-,$$

or photochemically. In the latter case, it is possible to use extremely weak or kinetically inert oxidants:

$$M^-Cl_n + RH \xrightarrow{h\nu} MCl_n + R^- + H^{\cdot}.$$

Thus the most important common feature of photocatalytic reactions of the second group is their free-radical mechanism.

In conclusion, we shall attempt to make a prediction of the development of studies in the given field of photocatalysis. Firstly, this will undoubtedly be the search for new types of reactions capable of being effected under photocatalytic conditions. It is extremely likely that such search will lead to the creation of commercially interesting photocatalytic syntheses. Secondly, one may expect a general increase in the quality of the photochemical aspect of the research into photocatalytic processes, for which an urgent need exists. The point is that, among the large total number of publications on the field under discussion, the proportion of studies carried out at a satisfactory photochemical level is relatively small. This is apparently due to the fact that the majority of studies have been performed by specialists in the field of traditional catalysis and not by photochemists. In many of the published investigations, the experiment consisted merely in the irradiation of the catalytic system by light for a fixed time with subsequent analysis of the final products. By no means all the investigations involve the measurement of the quantum yields of the products. So far the only examples remain those where the reaction mechanisms were investigated by the technique of flash photolysis, which makes it possible to identify the intermediates in photochemical reactions (among these studies, mention should be made of Refs. 47, 50, 59, 113, 114). Thus further progress in this field of photocatalysis requires the joint efforts of specialists in catalysis and photochemists.

2. Outer-sphere photocatalytic reactions

The reactions proceeding via Scheme (3a) or via analogous schemes in which the primary step in the outer-sphere biomolecular stage of the electron transfer are described in this Section. At first sight, these reactions have no specific features which would distinguish them from processes initiated by non-metal complex compounds (for example, organic dyes). However, the transition metal complexes widely used in such reactions [the most popular among them is $Ru(bipy)_3^{2+}$, where bipy = 2,2′-bipyridyl] exhibit an important difference from the organic dyes mentioned above despite the similarity of their photophysical, photochemical, and electrochemical characteristics. The point is that the catalytic cycle in Scheme (IIIa) includes the products of the one-electron oxidation (reduction) of the photocatalyst. In the case of organic dyes, such products are organic radical-cations or radical-anions, which are known to enter extremely readily into fact disproportionation, nucleophilic or electrophilic addition or substitution, etc. reactions.[115] This greatly restricts the range of reactions (and their conditions) in which the K^+ and K^- species can participate. On the other hand, in transition metal complexes, usually the metal ion itself undergoes oxidation-reduction. As a result of this, many transition metal complexes can exist in two, three, or even more forms differing in the oxidation state. The transitions between these forms are usually characterised by a high degree of reversibility.

As mentioned above, the initiation of oxidation-reduction reactions by photocatalysts becomes possible by virtue of the significant difference between the oxidation-reduction properties of the complex in the excited state and its properties in the initial state. In principle, these differences arise not only in a charge transfer transition but also in any other types of excitation (intraligand transitions, $d-d$ transitions, etc.). The predominant involvement of precisely the CT-excited states in oxidation-reduction reactions is mainly due to kinetic factors which are favoured by the corresponding redistribution of electron density on excitation of the complex. The formal oxidation-reduction potentials (ORP) of the excited state of the photocatalytic complex can be estimated knowing the formal oxidation-reduction potential of its ground state and the electronic excitation energy. For example, the electrochemical oxidation and reduction potentials of the complex $Ru(bipy)_3^{2+}$ are -1.28 and $+1.26$ V relative to the normal hydrogen electrode (NHE) respectively.[116] The energy of the longest-lived and chemically most reactive excited state of this complex, determined from the position of the luminescence band, is 2.12 eV.[116] Consequently the formal electrochemical oxidation and reduction potentials of ${}^*Ru(bipy)_3^{2+}$ are $-1.28 + 2.12 = 0.84$ V and $+1.26 - 2.12 = -0.86$ V respectively. Thus the complex, which is extremely inert in the ground state, becomes a powerful oxidant and reductant simultaneously as a result of excitation.

It is also important to emphasise that the photocatalytic oxidation-reduction reactions via the outer-sphere mechanism are frequently induced, in contrast to the processes described above, under the influence of visible and not UV light. This permits the employment of sunlight, which increases the interest in processes of this kind.

(a) Photochemical decomposition of water

Among the outer-sphere oxidation-reduction photocatalytic reactions, the reaction involving the decomposition of water into hydrogen and oxygen has undoubtedly attracted most attention:

$$2H_2O \xrightarrow{h\nu\ K} 2H_2 + O_2.$$

Numerous review articles (see, for example, Refs. 14–21 and the literature quoted therein) have been devoted to the discussion of this process. The photocatalytic decomposition of water can be described by Scheme (IIIa), where the role of the substrates S and R is assumed by the same substance (H_2O). The decomposition of water under the influence of light is a functional analogue of the natural photosynthesis in green plants with the sole difference that the place of the extremely complex process involving the reduction of CO_2 to carbohydrates is taken in this instance by the simpler reaction in which water is reduced to hydrogen. The effective occurrence of this reaction under the influence of visible light (sunlight) would be of enormous practical importance, because it would make it possible to obtain an inexhaustible source of hydrogen—an ecologically clean fuel with a high heat generating capacity. This is why the vast majority of studies on outer-sphere photocatalysis have been devoted to the decomposition of water.

The idea of creating an artificial analogue of plant photosynthesis apparently arose at the very beginning of the study of its mechanism. However, practical applications appeared only in the first half of the 1970s.[117,118] In particular, during this period the trisbipyridylruthenium(II) complex $Ru(bipy)_3^{2+}$ became the first candidate for the role of the photocatalyst of the decomposition of water.[119–121] The most important advantage of this complex is its photochemical activity when the system is acted upon by visible (green and blue) light, the reduction potential of the complex $*Ru(bipy)_3^{2+}$ in the excited state (−0.86 V) being sufficient to reduce water to hydrogen over the entire pH range, while the potential of the oxidised form $Ru(bipy)_3^{3+}$ (+1.26 V) is sufficient for the oxidation of water to oxygen, also over the entire pH range. The achievement of the following photocatalytic cycle is therefore extremely attractive:

$$Ru(bipy)_3^{2+} \xrightarrow{h\nu} *Ru(bipy)_3^{2+}, \quad (2)$$

$$*Ru(bipy)_3^{2+} + H_2O \rightarrow Ru(bipy)_3^{3+} + {}^1/_2H_2 + OH^-, \quad (3)$$

$$Ru(bipy)_3^{3+} + {}^1/_2H_2O \rightarrow Ru(bipy)_3^{2+} + {}^1/_4O_2 + H^+. \quad (4)$$

However, the operation of this scheme requires the preliminary solution of a number of serious problems. In the first place, the oxidation-reduction reactions with direct participation of $Ru(bipy)_3^{2+}$ are one-electron processes, whereas the water reduction and oxidation reactions are respectively two- and four-electron processes. Therefore the formation of the molecular water decomposition products requires the use of additional catalysts. Furthermore, the chemically reactive excited state $*Ru(bipy)_3^{2+}$ is short-lived (620 ns in water at 298 K) and is evidently incapable of participating directly in the catalytic reaction (3). As a consequence of this, the use of an intermediate electron acceptor and the inclusion in the photocatalytic cycle of "auxiliary" reactions with an intermediate electron acceptor A, instead of reaction (3), is inevitable:

$$*Ru(bipy)_3^{2+} + A \rightarrow Ru(bipy)_3^{3+} + A^-, \quad (5)$$

$$A^- + H_2O \rightarrow A + {}^1/_2H_2 + OH^-. \quad (6)$$

An alternative version involves the use of an intermediate electron donor D:

$$*Ru(bipy)_3^{2+} + D \rightarrow Ru(bipy)_3^{+} + D^+, \quad (7)$$

and the introduction of the stages

$$D^+ + H_2O \rightarrow D + {}^1/_4O_2 + H^+, \quad (8)$$

instead of reaction (4). The inclusion of the additional stages (5)–(8) leads to energy losses, which in practice means a narrowing of the pH range in which the reduction (or oxidation) of water is possible. Finally, the main problem consists in the high probability of the recombination of powerful reductants [$*Ru(bipy)_3^{2+}$, A^-, etc.] and powerful oxidants [$Ru(bipy)_3^{3+}$, D^+, etc.], formed as a result of the absorption of light and the occurrence of primary photochemical reactions. In order to solve these problems, studies on the individual stages of the above hypothetical scheme (2)–(8) and their optimisation have been prosecuted since the second half of the 1970s (Table 3).

Photocatalytic reduction of water to hydrogen at the expense of the oxidation of an irreversibly consumed electron donor (usually an organic compound) which is "sacrificed". The communication describing reaction (1) under the influence of UV light[90] was followed by the appearance of a publication[122] by the same authors in which organic dyes sensitive to visible light were used as photocatalysts. After this, systems based on $Ru(bipy)_3^{2+}$ were proposed in a whole series of communications.[123–129] The use of other metal complexes as photocatalysts is also known, among which the most interesting are structural analogues of chlorophyll—metalloporphyrins.[145]

Photocatalytic oxidation of water to oxygen at the expense of the reduction of an irreversibly consumed electron acceptor, which is "sacrificed". This reaction was achieved for the first time in systems, which were in fact based on $Ru(bipy)_3^{2+}$,[130–133] although examples of its occurrence with participation of metalloporphyrins are also known.[146,147]

Processes involving the separation in space and stabilisation of strong one-electron reductants and oxidants, generated under the influence of light, in microheterogeneous stucturally organised systems. The occurrence of such processes makes it possible to prevent the recombination of the primary photogenerated species by direct collisions. Among systems used to carry out processes of this group, the most promising are believed to be lipid vesicles.[148–151] The first advances were achieved using natural and synthetic porphyrins.[152–155] Subsequently much more effective systems based on $Ru(bipy)_3^{2+}$ and its derivatives were proposed.[156–160]

The coupling of all three fragments of the water photochemical decomposition mechanism, which follows logically from studies carried out the first stage of the research, proved extremely difficult. Although examples of the simultaneous photocatalytic generation of both hydrogen and oxygen in suspensions of lipid vesicles are known,[161] there are as yet no experimental data indicating the complete coupling of all three stages. The results of studies of the possibility of the coupling of the processes involving the reduction of water to hydrogen with photochemical charge separation processes in microheterogeneous systems via the phototransfer of an electron through the bilayer membranes of lipid vesicles are hopeful.[162,163] On the other hand, the attempts to couple the water oxidation reaction to the transmembrane charge separation in such systems have encountered appreciable difficulties.[164] Thus the complete water photodecomposition cycle has so far unfortunately not been achieved owing to the existence of a whole series of serious unsolved problems. The present state and prospects of studies in this field are discussed in a monograph.[21]

(b) Photochemical reduction of CO_2

Another problem solved mainly within the framework of outer-sphere catalysis and also associated with the modelling of photosynthesis is that of the photochemical reduction of carbon dioxide. Hitherto, it has been possible to create chemical analogues of bacterial photosynthesis having achieved the reduction of CO_2 at the expense of the oxidation of irreversibly consumed organic compounds (electron donors). The reaction usually proceeds via the mechanisms

$$*Ru(bipy)_3^{2+} + D \rightarrow Ru(bipy)_3^{+} + D^{+}.$$

$$2Ru(bipy)_3^{+} + CO_2 + H_2O \xrightarrow[cat.]{} 2Ru(bipy)_3^{2+} + HCOO^{-} + OH^{-}$$

(or other CO_2 reduction products, for example CO, CH_4, etc.)

$$D + \rightarrow \text{oxidation products};$$

or

$$*Ru(bipy)_3^{2+} + A \rightarrow Ru(bipy)_3^{3+} + A^{-},$$

$$2A^{-} + CO_2 + H_2O \xrightarrow[cat.]{} 2A + HCOO^{-} + OH^{-},$$

$$*Ru(bipy)_3^{3+} + D \rightarrow Ru(bipy)_3^{2+} + D^{+}.$$

$$D^{+} \rightarrow \text{oxidation products}.$$

Evidently, the photocatalytic CO_2 reduction cycle is virtually identical with the corresponding mechanisms of the evolution of hydrogen from water in "sacrificial" systems. Therefore, in proton-containing media, the usual obstacle to the successful occurrence of the dark stage of the reduction of CO_2 is the occurrence of the competing water reduction reaction. Nevertheless, by selecting the reaction conditions, the CO_2 reduction catalysts, and intermediate electron transferring agents, it has been possible to solve the problem successfully in many instances (Table 3).

(c) Other reactions

In principle, many other chemical reactions requiring the involvement of one-electron oxidants or reductants can proceed via Scheme (IIIa). Thus a system has been proposed in which the hydrogenation and hydroformylation of ethylene and acetylene take place in the presence of $Ru(bipy)_3^{2+}$ and a water-soluble analogue of Wilkinson's complex.[140] A number of photocatalytic reactions described have some kind of bearing on biology. For example, certain enzymic processes (the synthesis of aminoacids and other organic acids by amination or insertion of CO_2), occurring under the influence of NADPH (reduced nicotinamide-adenine dinucleotide phosphate) as the reductant, have been achieved, the reductant being regenerated in the photocatalytic cycle with participation of $Ru(bipy)_3^{2+}$.[141–143] Studies on these lines are apparently promising as regards the development of photocatalytic small-scale syntheses of valuable organic products, biologically active substances, medicinal drugs, etc. Such syntheses may become an alternative to biotechnological industrial processes, particularly if it should become possible to find stable, relatively non-toxic, and relatively cheap compounds to replace enzymes and other substances of biological origin.

IV. Conclusion

The brief survey of the principal types of photocatalytic reactions with participation of transition metal complexes indicates the considerable undiscovered possibilities of this field of science which has arisen at the junction between photochemistry and catalysis. The reactions considered may be of interest for the creation on their basis not only of the fairly widely discussed processes involving the transformation of solar energy but also organic synthetic processes. Speaking of the possibility and usefulness of the practical application of photocatalysis for the purpose of synthesis, one should, however, bear in mind the inevitability of using in this case artificial light sources. Since artificial light is much more expensive as a variety of energy than heat, it is necessary to have, first, an idea about the economic desirability of a particular process being carried out under photocatalytic conditions. Nevertheless, a number of advantages of photocatalytic organic synthesis may serve as a stimulus to the development of studies in the field of photocatalysis with participation of metal complexes. Thus photocatalytic reactions can occur under milder conditions than the analogous dark processes. The activity of photogenerated catalysts is not inferior and is sometimes actually superior to that of catalysts obtained by the thermal method under analogous conditions. If the reaction proceeds with an increase in free energy, then the photocatalytic procedure proves to be the only possible way of achieving it (or of increasing significantly the yield of the product). Photocatalysis can facilitate the occurrence of photochemical non-catalytic reactions. Mention should also be made of the great variety of reactions which may be achieved by the photocatalytic method and also of the advantages of light as one of the reactants (the possibility of varying its properties—intensity and wavelength—widely and smoothly). Finally, the action of light on catalytic systems, which is a convenient means of obtaining intermediate reactive species, may become an important instrument in the study of the usual thermal catalysis.

Modern approaches to the preparation of "palladium on charcoal" catalysts

V A Semikolenov
Institute of Catalysis, Russian Academy of Sciences, Novosibirsk

ABSTRACT. **The methods of preparation of deposited palladium catalysts on carbon carriers are discussed. The characteristics of the structures of porous carbon materials, the methods for the regulation of their structural and physicochemical characteristics, the methods for the deposition of palladium on a carbon carrier, and individual stages of a catalyst preparation process are examined.**

The bibliography includes 74 references.

I. Introduction

The vigorous development of the industrial manufacture of products of organic synthesis, including monomers, dyes, medicinal preparations, biologically active substances, and various valuable semi-finished products has aroused during the last decade considerable interest among investigators in the creation of highly selective catalysts for fine organic synthesis. Pd/C catalysts have found extensive applications in the processes involved in fine organic synthesis. Such applications are based on the catalytic chemistry of palladium with its rich content, including virtually the entire range of hydrogenation, isomerisation, dehydrogenation, and hydrogenolysis processes,[1–3] as well as the wide assortment of activated charcoals with extensive porous structures and their ready availability.

The composition of these catalysts is very simple. They include only two components—metallic palladium and the carbon carrier. However, by varying the structural characteristics of the palladium (dispersity, particle shape, distribution within the carrier grain) and of the carbon carrier (grain size, porosity, specific surface), it is possible to create a large set of catalysts for a wide range of processes.[4]

Numerous patents describing the methods of preparation of Pd/C catalysts do not answer the question which physicochemical processes occur at each stage of their preparation and how these processes can be controlled.

Although the available reviews[5,6] and fundamental studies published recently[7–15] throw some light on the structure of the Pd/C catalysts, nevertheless there are as yet no reliable methods for their purposeful construction.

The development of the scientific principles governing the preparation of catalysts should help to elucidate the factors determining their properties and to devise procedures for controlling these factors. The most important characteristics of the Pd/C catalyst are as follows:

the texture of the carbon carrier;

the size and structure of the deposited palladium particles;

distribution of the palladium particles on the carrier surface.

The present review is devoted to the consideration of modern methods for the preparation of Pd/C catalysts and the analysis of processes occurring in individual stages of their preparation.

II. The structure of carbon carriers

The structure of carbon carriers and the principal procedures for their preparation have been described in monographs and reviews.[16–21] Porous carbon materials usually employed as catalyst carriers belong to the class of carbon-graphite materials consisting predominantly of sp^2-hybridised carbon atoms with a definite ordered arrangement in space (extended networks or microcrystallites).

The structure of carbon carriers is illustrated in Fig. 1. The dimensions of the graphite microcrystallites can vary in the range L_a = 0.7–10.0 nm and L_c = 0.9–6.0 nm depending on the nature of the raw material employed and the conditions in their carbonisation.[17,18] High-temperature heat treatment of carbon materials makes it possible to increase the degree of crystallinity of the carbon, i.e. to increase the parameters L_a and L_c and to diminish the interplanar spacing d_{002} to a value close to that for graphite (0.3354 nm).[18]

In the majority of carbon carriers, the carbon microcrystallites are oriented at random on the surface (Fig. 2*a*). At the same time, there exist procedures for the deliberate orientation of basal faces or end faces of microcrystallites. In particular, the deposition of pyrolytic carbon on a solid support promotes the preferential emergence onto the surface of the basal faces of the graphite microcrystallites[22–24] (Fiog. 2*b*). Pyrolysis of hydrocarbons on catalyst particles (Ni, Fe) leads to the formation of carbon fibres and in this case the end faces emerge preferentially onto the surface[25] (Fig. 2*c*).

The chemical nature of the surface groups exerts a considerable influence on the adsorption interaction of the active component with the carbon carrier. Surface oxygen groups are of greatest interest for the preparation of deposited catalysts.

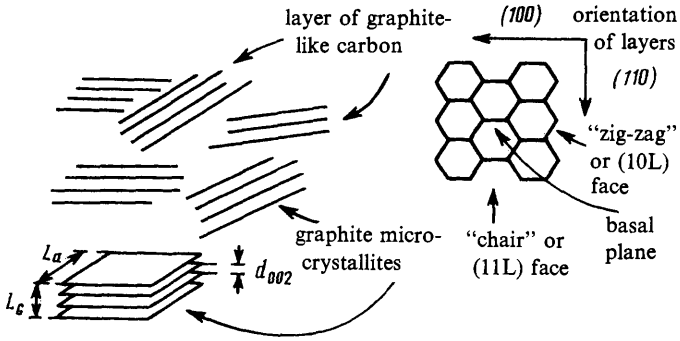

Figure 1. Schematic representation of the microstructures of carbon carriers (according to the data in Walker's book[17]).

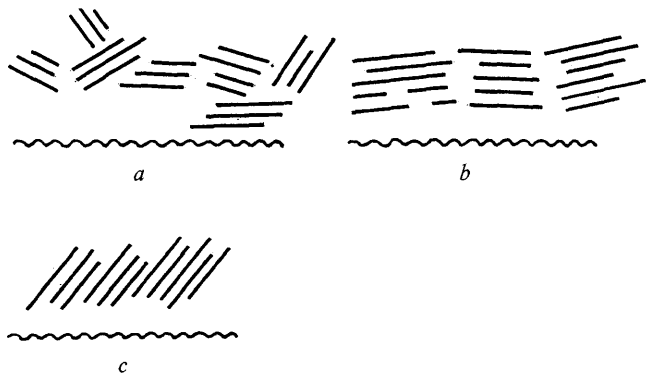

Figure 2. Orientation of graphite microcrystallites on the surfaces of carbon carriers obtained by carbonising cellulose (*a*), by the high-temperature gas-phase pyrolysis of hydrocarbons (*b*), and by the catalytic pyrolysis of hydrocarbons on transition metals (*c*),

Numerous data concerning the identification and study of the properties of such groups are available.[16,26–31] According to a classification,[28] mainly oxygen groups of four types, differing in acidity, are present on the surfaces of carbon carriers (Fig. 3).

The overall concentration of surface oxygen groups can be increased (or reduced) by heating the carbon carrier in an oxidising (or inert) atmosphere.[32] The proportions of groups of different types can be altered by selecting appropriate conditions for the treatment of the carrier and the nature of the oxidising agent.[19,33]

Basic surface oxygen groups can be formed as a result of the low-temperature chemisorption of oxygen on a carbon carrier subjected to a preliminary vacuum heat treatment.[28]

The porous structure of carbon carriers plays an important role in the transport processes involving the molecules of the reactants and reaction products.[31] According to the classification adopted by IUPAC, pores are divided into four types in terms of their dimensions:[34,35] micropores (r_{eq} < 0.6–0.7 nm); supermicropores (0.6–0.7 nm < r_{eq} < 1.5–1.6 nm); mesopores (1.5–1.6 nm < r_{eq} > 50–200 nm), and macropores (r_{eq} > 50–200 nm).

The traditional technological procedures for the preparation of porous carbon materials[18] involve the carbonisation of the initial raw materials and the activation of the carbon material. Pore-forming agents in the form of mineral additives or carbonised polymeric foam materials are used to increase the volume of the macropores.

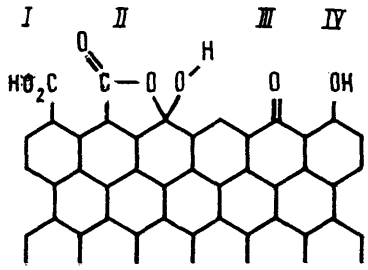

Figure 3. Types of surface oxygen groups: (I) carboxy-groups; (II) lactone groups; (III) carbonyl groups; (IV) phenolic groups.[28]

By using different kinds of carbonised raw material and by varying the parameters of its activation, it is possible to obtain a wide range of carbon carriers with an extensive system of micropores.[21,36]

Mesoporous carbon carriers, in which pores whose size is 2–10 nm predominate, can be obtained by carbonising mixtures of carbon black with a polymeric binder, for example, phenol–formaldehyde resin or furfuryl alcohol.[37]

A new class of porous materials called Sibunit has been developed for the preparation of deposited catalysts with a specified porous structure.[38,39] Sibunit is obtained by depositing a layer of pyrolytic carbon on the surface of technical carbon (Fig. 4). This results in the formation of a carbon–carbon composite material, in which the volume and size of the mesopores and macropores can be regulated by varying the dimensions of the primary globules of the technical carbon, their relative disposition, and the technical carbon/pyrolytic carbon ratio.[40,41] Activation of the composite carbon material with steam and oxygen makes it possible to increase the volume of the micropores and fine mesopores without altering significantly the size of the large pores.[42,43]

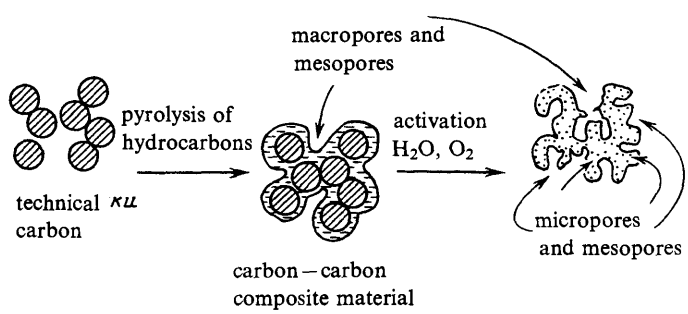

Figure 4. Schematic illustration of the formation of the porous structure of carbon carriers of the Sibunit type.

Thus there is a possibility of creating carbon carriers with specified structural and physicochemical characteristics.

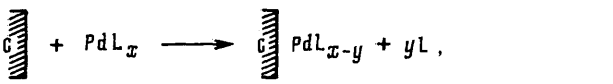
III. Methods for the deposition of palladium on a carbon carrier

In the general case, the preparation of Pd/C catalysts includes two stages—the deposition of the active component and reduction, leading to the formation of metallic palladium on the surface.

It is possible to differentiate three main procedures for the deposition of the active component.

1. Deposition of palladium compounds in the molecularly disperse state

In the general form, this method can be described schematically as follows:



where the surface of the carbon carrier is shown shaded.

Palladium compounds are fixed on the surface of the carbon carrier under these conditions by means of adsorption or chemical interaction.

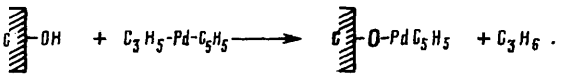
The complex PdL_x can be adsorbed as a result of the interaction of a palladium ion with the structural elements of the carrier surface. It has been shown in a number of studies[43–46] that palladium is adsorbed from solutions of its chloride complexes on the surface of the carbon carrier predominantly in the form of $PdCl_2$. On the surface of the carbon carrier, there are three types of adsorption centres: A_1, A_2, and A_3 which represent a set of surface structures containing unsaturated carbon–carbon bonds and differing in the strength of their interaction with $PdCl_2$. The centres for weak (A_1) and moderate (A_2) adsorption are located on the surfaces of mesopores and macropores, while the centres for strong adsorption (A_3) are in the micropores. The oxidation of the carrier surface by oxygen at 300 °C does not alter its adsorption properties, whilst the liquid-phase oxidation by powerful oxidants (H_2O_2, $KMnO_4$) diminishes appreciably the concentration of the above adsorption centres.[44]

The reduction with gaseous hydrogen of adsorbed palladium chloride complexes leads to the formation on the surface of the carbon carrier of metallic palladium particles, whose size ranges from 1–2 to 3.4–3.7 nm.[12] The reduced palladium particle size does not depend significantly on the volume of the micropores in the carbon carrier, but diminishes sharply after the treatment of the carrier with nitric acid,[15] which results in the formation of oxygen groups on the surface;[19,47,48] this should in turn tend to increase the palladium particle size by reducing the number of adsorption centres for palladium chloride.[44]

The increase in the dispersity of the metallic palladium as a result of the oxidation of the surface is apparently caused not by the adsorption of the chloride complexes but by the stabilisation of the metallic particles on the oxidised sections on reduction of the adsorbed compounds.

The adsorption of the palladium complexes PdL_x can proceed via the interaction of the ligands L with the surface of the carbon carrier. For example, the zerovalent palladium complex Pd_2DBA_3.DBA (where DBA = dibenzoylacetone) is adsorbed on the carbon carrier from a benzene solution. The thermal decomposition of the adsorbed complexes followed by reduction with hydrogen affords a catalyst in which the dominant metallic palladium particle size is approximately 2 nm.[49]

The chemical interaction of the active component with the carrier surface is widely used to obtain complexes fixed on the surface of oxide carriers in a molecularly disperse state.[50] This method has also been used in relation to carbon carriers.[51,52] Its essential feature is the interaction of the organopalladium compound with surface functional groups on the carrier, for example:

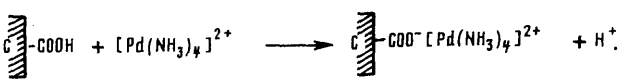


The subsequent reduction of the specimen in a stream of hydrogen leads to the formation of metallic particles on the surface having a particle size of 1–3 nm predominantly.

The chemical interaction of palladium compounds with a carbon carrier can also proceed as an oxidation-reduction process with participation of palladium(II) ions and surface groups having reducing properties (unsaturated carbon–carbon bonds, alcoholic groups, etc.).[53] This process has negative consequences, because palladium is deposited on the carrier surface in an uncontrolled fashion, giving rise to a bright film of metallic palladium. To prevent this process, palladium is deposited in the presence of oxidants: H_2O_2 [53] or Cl_2.[54]

Ion exchange on carbon carriers can also be used to prepare catalysts. The mechanism of the ion-exchange interaction between transition metal compounds and carbon adsorbents has been examined.[19,55] In the simplest case, such interaction takes place via the exchange of the acetate ligands in $Pd(OAc)_2$ for surface carboxylate groups:[56]

The reduction of surface compounds by hydrogen leads to the formation of highly disperse deposited palladium particles with an average size of ~2 nm. When this method is used, the surface concentration of carboxy-groups is important. A five-fold increase in the concentration of surface carboxy-groups after the oxidation of the initial carbon carriers with potassium permanganate diminishes the metallic palladium particle size to 1 nm. On the other hand, decarboxylation of the surface by vacuum heat treatment at 500 °C promotes the formation of large particles up to 10 nm.[56] The ion exchange method has been used most widely for the deposition of amminepalladium complexes:[12,15]

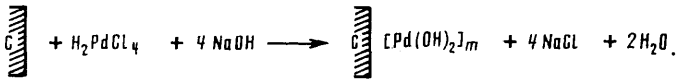


The subsequent reduction of the surface complexes in a stream of hydrogen leads to the formation of deposited palladium particles with an average size of 2.1–2.4 nm.[12] When this method is used, one should recall the significant role played by the texture and chemical composition of the carbon carrier. Thus, when palladium

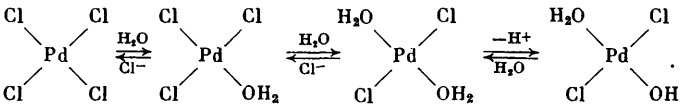
is deposited on the NORIT SXI GA 3/33 carbon carrier, the average particle size, determined from the adsorption of CO, is 48.3 nm. The activation of the initial carrier in a CO_2 atmosphere at 1200 K, involving the burning away of up to 23% of carbon which results in a decrease in the concentration of surface carboxy-groups, increases the palladium particle size to 120 nm.[14] The oxidation of the carrier surface with nitric acid (i.e. the formation of surface carboxy-groups) promotes a sharp decrease in the palladium particle size to 3 nm.[15]

2. Deposition of sparingly soluble palladium compounds

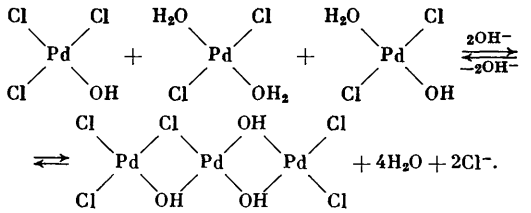
A traditional procedure for the preparation of a wide range of industrial catalysts involves the deposition of palladium hydroxide on the surface of a carbon carrier:



This method is based on the conversion of palladium chloride complexes in several stages. The first of these is the hydrolysis of H_2PdCl_4:

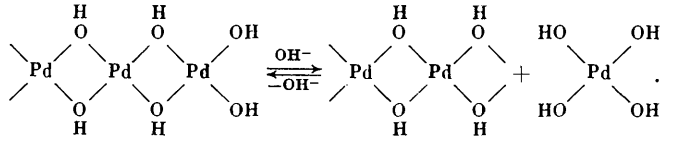


This stage is promoted by diluting the solution, by increasing the pH from 1 to 3, and by reducing the Cl^- concentration.[57-59] This is followed by the formation of a polymer:



The growth of the polymer is favoured by an increase in the concentration of palladium complexes, by an increase in pH from 3 to 8, and by a decrease in the Cl^- concentration.[59]

The polymer is degraded in a highly alkaline medium at pH > 12:



The size of the polymer molecules formed (a polynuclear hydroxo-palladium complex) can be regulated by selecting the pH, the Cl^- concentration, the temperature, and the duration of the "ageing" process.

Alkali metal hydroxides, carbonates, and bicarbonates are used for the deposition of polynuclear hydroxopalladium complexes on a carbon carrier. The Pd/C systems obtained using alkali metal carbonates and bicarbonates as the alkaline agent are the most active. Evidently this is due to the fact that pH 3–8, which is optimal for the formation of polynuclear hydroxo-complexes, is thereby established in the given instance.

When palladium is deposited on a carbon carrier, the order of the addition of the reactants can be various. When sodium carbonate is added to a suspension of activated charcoal in a chloropalladic acid solution,[60] a proportion of the palladium chloride complexes, corresponding to the adsorption capacity of the carbon carrier, is fixed on its surface via an adsorption mechanism, while the remaining palladium is deposited on the surface in the form of hydroxide particles (polynuclear hydroxo-complexes). This results in a multimodal size distribution of the palladium particles with a maximum at 2.0 nm and a plateau in the range from 6 to 16 nm.[47] When a solution of chloropalladic acid is added to a suspension of activated charcoal in a sodium bicarbonate solution,[61] the deposition takes place in a weakly alkaline buffer medium generated by sodium carbonate and the sodium form of the surface carboxylate groups of the carbon carrier.

When solutions of chloropalladic acid and the alkaline agent are added simultaneously to a suspension of the carbon carrier,[62] the deposition takes place at a constant pH 7.5–11.0, which ensures a more uniform size distribution of the palladium particles. Finally, preliminary mixing of solutions of chloropalladic acid and of the alkaline agent with subsequent deposition of the polynuclear hydroxopalladium complexes formed on the carbon carrier[15,63] makes it possible to attain a high dispersity of the palladium (2.0–3.0 nm) with a narrow size distribution of the particle.[63]

According to the mechanism of the hydrolysis of palladium chloride complexes,[59] an increase in the Cl^- concentration prevents an increase in the size of the particles of the polynuclear hydroxopalladium complexes. This may result in an increase in the dispersity of the palladium, which entails an increase in its activity. Indeed, an increase in the concentration of Cl^- during the deposition of palladium hydroxide on a carbon carrier makes it possible to increase by a factor of 1.5 the activity of the Pd/C catalyst in the hydrogenation of dinitrotoluene.[64]

3. Deposition of palladium in the form of colloidal particle sols

This method consists of two stages:

(1) the preparation of the colloidal solution (sol) of the palladium-containing compound $[Pd_c]L_x$, where L_x are ligands stabilising the colloidal palladium Pd_c particle in solution;

(2) deposition of the sol on the carbon carrier, which makes it possible to obtain catalysts with a uniform size distribution of the palladium particles and to regulate the particle size by selecting the conditions in the preparation of the colloidal solution and the palladium-containing compound:

Questions concerning the preparation of colloidal palladium solutions and the study of their properties have been surveyed in reviews.[65-68] It is possible to differentiate two main approaches to the preparation of these solutions. In one case, palladium vapour is

condensed in an inert solvent matrix. For this purpose, palladium is heated in a vacuum chamber and introduced to a stream of the inert solvent. The metal vapour formed is condensed together with the solvent on the walls of a trap cooled with liquid nitrogen. After heating the trap to the melting point of the solvent, a colloidal solution of palladium is obtained.

When methylcyclohexane is used as the solvent, the colloidal palladium solution thus obtained has an average particle size of 2.05 ± 0.5 nm and can be used to prepare deposited palladium catalysts.[65]

Another approach presupposes the reduction of palladium complexes in solution:

$$H_2PdCl_4 + xL \xrightarrow[-HCl]{Red} [Pd_c]L_x,$$

where Red is hydrogen, formaldehyde, sodium citrate, carbon monoxide, hydrazine, sodium formate, acrolein, titanium chloride, etc.[67]

The average size of the colloidal palladium particles formed in the chloropalladic acid–sodium formate–sodium hydroxide system can be regulated in the range from 47.0 to 12.5 nm by varying the pH in the range 2.1–11.2 and the duration of the reduction reaction from 1 to 180 h.

The use of sodium citrate as the reductant permits a decrease in the average palladium size to 7.5 nm.[67] Monodisperse palladium sols with an average metallic particle size from 0.9 to 7.5 nm have been obtained by reducing palladium chloride complexes with sodium citrate under an inert atmosphere at a controlled pH.[69] Pd/C catalysts in which the average metallic particle size is between 3.0 and 7.5 nm according to electron microscope data were prepared by this procedure.[70]

Table 1. The dispersity of palladium in the Pd/C catalysts prepared by different methods.

Method of deposition	Palladium compound	Average particle size, nm		References
		deposited	reduced	
Adsorption	H_2PdCl_4	Molecularly disperse state	3.4	[12]
			0.81–1.91	[15]
			1.0–2.0	[48]
	$Pd_2(DBA)_3.DBA$	Ditto	~2.0	[48]
Chemical interaction	C_5H_5–Pd–C_5H_5	»	1.0–3.0	[51]
Ion exchange	$Pd(OAc)_2$	»	~2.0	[56]
	$Pd(NH_3)_4^{2+}$	»	2.1–2.4	[12]
	$Pd(NH_3)_4^{2+}$	»	2.1–120	[15]
Deposition of sparingly soluble compounds	$Pd(OH)_2$	2.2	2.5	[71]
Deposition of palladium sol	Pd	2.5	3.0	[70]

When palladium is deposited both in the molecularly disperse state and in the form of the hydroxide or a sol, after the reduction of the catalyst the average particle size of the metallic palladium is in the range 1–3 nm (Table 1), which means that the process involving the migration of palladium during the reduction of the catalyst plays an important role in the formation of the deposited particles.

Indeed, the study of the characteristics of the reduction of deposited palladium compounds by hydrogen showed that the size and shape of the metallic particles formed depend on the concentration of palladium ions in the liquid phase.[71] The equilibrium concentration of Pd^{2+} ions in the solution over the palladium hydroxide deposited on the carbon carrier at pH ~ 7 is negligible and after reduction the size of the metallic particles corresponds to the size of the initial palladium hydroxide particles. In an acid or alkaline medium, the equilibrium Pd^{2+} concentration in the solution increases sharply by virtue of the formation of the $PdCl_4^{2-}$ or $Pd(OH)_4^{2-}$ complex. The reduction of the catalyst under these conditions leads to the formation of large palladium crystallites.[71]

The palladium reduction process can be represented in a general form by the scheme illustrated in Fig. 5, which makes it possible to explain the causes of the formation on the surface of the carbon carrier of particles of different size and with a wide variety of geometrical shapes. Thus the use of the procedures listed above leads to the possibility of the purposeful regulation of the dispersity of the deposited palladium particles.

The distribution of palladium with respect to the grain radii is one of the most important parameters determining the efficiency of granulated catalysts.[4] The traditional procedure for regulating the concentration profile of the active component are based on the diffusion of the deposited compound into the bulk of the carrier grain and its adsorption on the surface.[72,73]

The procedures for the regulation of the pore structure and chemical composition of the carbon carrier surface examined above can be used also for the selection of the optimum contributions of the processes involving the diffusion and adsorption of the deposited palladium compounds.

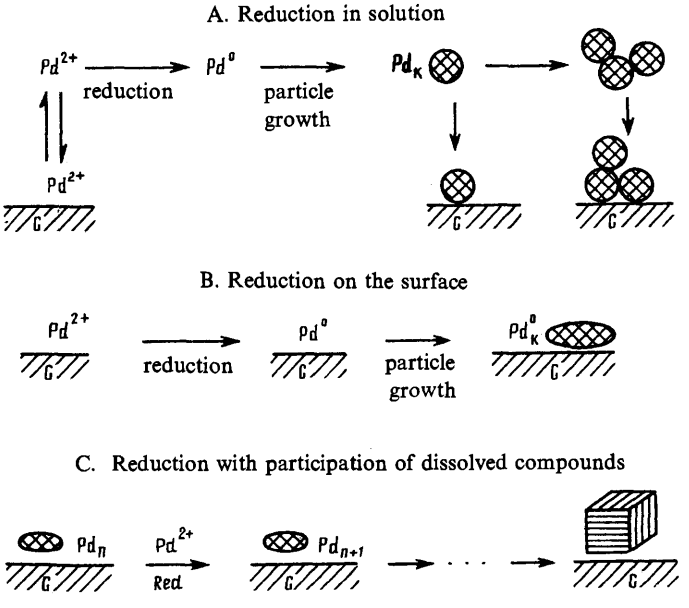


Figure 5. The formation of deposited metallic palladium particles during the reduction of the catalyst.

The preferential distribution of palladium in the outer layer of the catalyst grain can be achieved by the chemical reaction of the deposited component with the carbon carrier surface, for example, as a result of the reduction of palladium nitrate by the surface groups on the carbon carrier in an organic solvent.[74] A highly selective catalyst for the hydropurification of terephthalic acid was obtained in this way. It contained palladium particles, whose size was less than 3.5 nm and which were distributed in an outer layer of the grain up to 500 μm thick.

The deposition of palladium from colloidal solutions makes it possible to obtain crust type catalysts with a thickness of the active layer of ~50 μm.[63] Crust type catalysts can be prepared on carbon carriers with different microcrystalline structures, with pore volumes from 0.2 to 1.6 $cm^3\ g^{-1}$, mesopore and macropore sizes from 15 to 1000 nm, and specific surfaces from 10 to 1000 $m^2\ g^{-1}$.

Mechanism of the hydrogenolysis of thiophene on bimetallic sulphide catalysts

A N Startsev
Institute of Catalysis, Siberian Division of the Russian Academy of Sciences, Novosibirsk

ABSTRACT. The structure of the sulphide bimetallic species (SBMS), which is the active component of hydrodesulphurisation catalysts, is examined. The main principles of the hydrogenolysis of thiophene on well-characterised sulphide catalysts have been analysed. A synchronous mechanism for the reaction of thiophene with hydrogen in the coordination sphere is considered and substantiated.

The bibliography contains 143 references.

I. Introduction

The hydrogenolysis of the C–S bond of organosulphur compounds is one of the key reactions occurring in the hydropurification of petroleum fractions. From the volume of sulphur being refined, hydropurification processes occupy a leading place and their output is growing more rapidly than those of other petroleum refining processes at the present time. The great practical value of the hydrorefining processes for petroleum fractions explains the enhanced interest of investigators in the study of the active component of hydropurification catalysts and their mechanism of action.[1–25]

To clarify the mechanism of a catalytic reaction in a heterogeneous system is more complex than in a homogeneous system. In spite of the many possibilities which the recently developed physical methods for investigating the surfaces of solid catalysts have created, the obtaining of detailed information on the structure of active centres is hindered by the non-uniform chemical composition of the surface compounds in real heterogeneous catalysts. Some of these compounds may be generally inactive in catalysis and surface formations which differ in structure may catalyse a given chemical conversion by various routes and mechanisms. The effect of the reaction medium on the catalyst is important. One type of surface compound may be transformed into another under the conditions of a catalytic reaction at high temperatures and pressures; this may cause a change in the mechanism of the reaction being studied. The problem also arises of synthesising highly active catalysts containing surface formations of one predominant type which are responsible for carrying out just the catalytic reaction in question. A further problem is the checking of the state of the catalyst surface under reaction conditions.

As is known, all hydrorefining processes for petroleum fractions are effected on one type of catalytic system, based on a composition of Mo (or W) with Ni (or Co) as sulphides. The results of numerous original studies on the synthesis and properties of sulphide hydrodesulphurisation (HDS) catalysts, the structure of their active component and the mechanism of the catalytic action have been correlated in several reviews and monographs.[1–25] In each of the reviews, reflecting some aspects of the action of HDS catalysts, the authors form and assert their own point of view on the mechanism of action bringing in further arguments from neighbouring areas of chemistry. Nevertheless these studies are based on two main hypotheses. 1) The active component is Mo(W) and Ni(Co) plays the role of promoter. 2) The HDS reaction takes place with the participation of anionic vacant sites on the $MoS_2(WS_2)$ by an oxidation–reduction mechanism.

An attempt is made in the present review to analyse critically these hypotheses and a new mechanism is proposed for the action of HDS catalysts. This is based on studies carried out in the Institute of Catalysis, Siberian Division of the Russian Academy of Sciences, where highly active sulphide HDS catalysts have been synthesised and characterised. The catalysts were made by attaching metal complexes of Mo, W, Ni and Co to the surface of various carriers (Al_2O_3, SiO_2, and the new carbon material 'Sibunit') with subsequent decomposition of the surface compounds by H_2S.

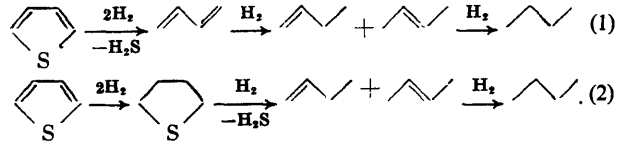
II. General principles for the hydrogenolysis of thiophene on sulphide catalysts

The hydrogenolysis reactions of thiophene and its derivatives are the slowest among the numerous reactions occurring during the hydrodesulphurisation of petroleum fractions, since the aromatic character of the thiophene ring hinders the elimination of sulphur from the molecule. Consequently the hydrogenolysis of thiophene and its derivatives is a generally accepted test for the properties of an HDS catalyst. From a scientific point of view the unsubstituted thiophene molecule is the most suitable for studying the mechanism of hydrogenolysis of the C–S bond, since substituents in the thiophene ring may have an appreciable effect on the coordination of the molecule to an active centre.

The hydropurification of crude petroleum is carried out at temperatures of 300–400 °C and H_2 pressures of 2–10 MPa.[1] The catalyst is in the sulphide state under the conditions of the

process. The inter-regeneration time of a catalyst is from several months to several years depending on the type of crude being refined and the specific consumption of a catalyst varies within the limits 15–60 g m^{-3} of crude.[26] These data indicate the high resistance of the catalysts to poisoning and becoming clogged with coke and the high thermal stability of the active component under process conditions.

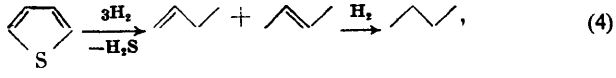
At the present time predominantly two possible routes for converting thiophene on sulphide catalysts are considered in the literature.[16]



In these cases the intermediate products are butadiene and tetrahydrothiophene (THT) respectively which are desorbed from the catalyst surface and may be detected in the gas phase. The possibility of the reaction proceeding by the following scheme may be considered as a variant of scheme (2).

$$T \rightarrow THT \rightarrow C_4H_6 + H_2S \rightarrow \text{products}, \quad (3)$$

where T is thiophene.[6] However a third route exists for the hydrogenolysis of thiophene,[27]



in which saturation of the thiophene ring and hydrogenolysis of the C–S bonds are effected at one active centre without loss of intermediates to the gas phase. This situation is effected on mono- and bimetallic sulphide catalysts both in bulk[28] and attached by various methods to SiO_2,[29] Al_2O_3 [30] and the carbon Sibunit carrier.[31] Catalysts are treated in H_2S at 400 °C before use to provide a steady level for their activity.[27–31] It was shown by special experiments[32] that the reaction route is not the consequence of the specific conditions of carrying out the process. The absence of butadiene and THT as intermediates in the hydrogenolysis of thiophene has also been recorded in other studies (see for example[33,34]), where the stationary activity of the catalysts was studied. We will return to the problem of possible routes for the conversion of thiophene after considering the reaction mechanism.

As already mentioned it is impossible to establish the mechanism of action of solid catalysts without knowing the structure of the active component. Traditional methods of preparing HDS catalysts are based on impregnating a preformed carrier with solutions of salts of the appropriate metals with subsequent drying, calcining and sulphurisation. This method does not allow a purpose-directed fixing of the composition of the active component or its immediate precursor.[35] The main reason for this is seemingly the complexity of the physicochemical conversions of the transition metals applied, including the processes of mass transfer and high temperature chemical interactions of the solid–solid type which are difficult to control.

The approach developed by Ermakov and collaborators[36,37] proved to be extremely productive when preparing catalysts with a fairly uniform content of active compounds on the surface. This comprises attachment of metal complexes of definite composition to a carrier surface and subsequently decomposing them under controlled conditions. This approach was also used for preparing highly dispersed sulphide catalysts.[29,30,38,39]

Catalysts are prepared in several stages. Initially organometallic or complex compounds of Mo or W are attached to the carrier (SiO_2 [29,38,39] or γ-Al_2O_3 [30]) and then, after appropriate treatment, Ni or Co are also applied to the Mo- or W-containing carrier in the form of organometallic or complex compounds. In several cases[30] the application of Ni(Co) was effected under conditions causing their adsorption to the Mo surface compounds. After drying, the catalysts were sulphurised in H_2S at 400 °C to provide a stationary level for their activity in the thiophene hydrogenolysis reaction.

Standard catalysts, prepared by the traditional impregnation method (ST), were studied in addition to the catalysts of metal complex (MC) origin. Among the former the greatest activity was possessed by catalysts obtained by a single impregnation (depending on the water content) of the carrier with an aqueous solution of the salts of the two metals with subsequent drying under an IR lamp, calcining in air at 500 °C and sulphurisation in H_2S at 400 °C. However the activity of standard catalysts prepared under optimum conditions was always less than the activity of samples of complex metal origin.[35]

Table 1. Specific (SCA) and atomic (ACA) activity of bimetallic sulphide catalysts in the hydrogenolysis of thiophene at 300 °C and the binding energy (E_b) of electrons at the Ni $2p_{3/2}$ level.[27–31,38–41]

**E_b Ni $2p_{3/2}$ in α-NiS was 853.0 eV, and in $(NH_4)_2[Ni(WS_4)_2]$ was 853.8 eV.[38–41]

***Here SCA is in mole C_4H_4S m^{-2} s^{-1} × 10^8.

The specific activity of bimetallic sulphide MC catalysts applied to SiO_2 and Al_2O_3 was significantly greater than that of ST catalysts of closely similar composition (Table 1). In all cases the greatest

synergistic effect was observed at an atomic ratio Ni(Co):Mo(W) = 1:2 which corresponds with the majority of the known data.[8–14,21] The activity was reduced in the series (Ni, W) > (Ni, Mo) > (Co, Mo) > (Co, W).

Samples of similar chemical composition applied onto SiO_2 and Al_2O_3 by similar methods have approximately the same specific catalytic activity (SCA), however the SCA of catalysts applied to Sibunit is significantly greater. Possible reasons for this phenomenon will be examined in the following section.

The most characteristic feature of the reaction on all the bimetallic catalysts studied is the reduction in activation energy from 117 ± 8 kJ mol^{-1} in the temperature range 225–300 °C to 59 ± 8 kJ mol^{-1} in the range 300–400 °C (Fig. 1). Such a reduction in E_a is not a consequence of transition of the reaction into the diffusion region since it is characteristic of all catalysts independent of their pore structure and grain size, including the solid porous catalysts Ni/WS_2, Ni/MoS_2 and Co/MoS_2 which possess low specific activity.[29] Seemingly the reason must be sought in the change in the limiting stage of the reaction.

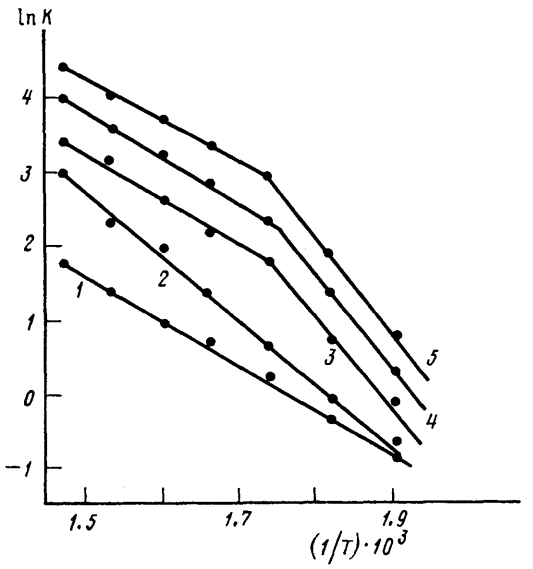

Figure 1. Temperature dependence of the reaction rate for the hydrogenolysis of thiophene on sulphide catalysts: *1*, Ni/Al_2O_3; *2*, Mo/Al_2O_3; *3*, Ni/MoS_2; *4*, $(Co-Mo)/Al_2O_3$; *5*, $(Ni-Mo)/Al_2O_3$.[29,30]

The products of the hydrogenolysis of thiophene on both mono- and bimetallic sulphide catalysts, prepared by various methods and on different carriers, contain only butene and butane in addition to H_2S.[27–31] Tetrahydrothiophene and butadiene are not present in the reaction products at the stationary level of activity of the catalysts. Trace quantities of butadiene were detected only on the most active (Ni–W) catalysts at a temperature of 400 °C and a degree of conversion of thiophene of 100%. The absence of possible intermediates from the reaction products is not a consequence of carrying it out with a large excess of hydrogen, since it was shown by special experiments[32] that a fairly high yield of THT may be obtained under the very same conditions on the very same Ni/SiO_2 and Mo/SiO_2 catalysts if, after sulphurisation, the catalysts are first reduced in H_2 at 400 °C. Significant quantities of butadiene (together with THT) were obtained under the same conditions on reduced zeolite NiY and MoY catalysts.[32]

The same principles for changing their activity in the hydrogenolysis of thiophene are characteristic of the sulphide catalysts (Ni, W), (Ni, Mo), (Co, Mo), and to a lesser extent (Co, W), applied by various methods onto Al_2O_3, SiO_2 and Sibunit. This indicates that the nature of the active component does not depend on the carrier type and method of preparation which affects only the level of activity of the catalysts. This inference does not pretend to be original, analysis of the vast scientific data on this problem leads readily to an analogous conclusion.

III. Structure of the active component of hydrodesulphurisation catalysts

The emergence at the beginning of the seventies of new methods of investigating the surface of a solid catalyst permitted an intensive study of the structure of the active component of HDS catalysts. According to the current classification,[20] 12 different models of the structure of the active component have appeared in the literature as ideas on the mechanism of action of the HDS catalysts have developed. The "Co–Mo–S phase" model is seemingly the most widespread[17,19,42–46] and was initially based on the results of an investigation of catalysts by Mössbauer emission spectroscopy and was then confirmed by the EXAFS method.

According to the "Co–Mo–S phase" model the active component is crystallised in the structural type of MoS_2, on a side face of a single patch of which Co atoms are localised. Other authors have subsequently arrived at a similar conclusion.[47–51] Though the similarity of the "Co–Mo–S phase" and MoS_2 structures is not in doubt there is no single opinion regarding the place of localisation of Co.

Substantially similar results on the structure of the active component of HDS catalysts were obtained in the Institute of Catalysis when studying the properties of highly active catalysts with a fairly uniform composition of surface compounds. A model for the structure of the active component was developed on the basis of the data obtained and was given the name sulphide bimetallic species (SBMS). The characteristic traits of this model will be examined.

1. Morphology of the surface of applied sulphide catalysts

The extended development of high resolution transmission electron microscopy (HRTEM) has enabled the limit of resolving ability of the electron microscope to be reached.[52] This method is used widely for studying the surface of applied catalysts containing ultradisperse particles of size less then 10 Å. On investigating HDS sulphide catalysts by the HRTEM method different authors obtained good agreement between their results.[31,53–58] When using various carriers (Al_2O_3, SiO_2, Sibunit, carbon) to obtain the catalysts, structures morphologically of a single type were detected on their surface irrespective of the method of preparation, the particle surface structure being characteristic of bulk MoS_2 and WS_2. The linear dimensions of the particles may vary within wide limits depending on the type of carrier and the method of preparing the catalyst. In the most disperse catalysts particles of size no greater then 20–25 Å

predominate,[56] but both finer (less than 10 Å) and more coarse (40–50 Å) particles may also be found on the surface.

In the majority of cases the active component is represented as single patches of $MoS_2(WS_2)$ the stabilisation of which is effected by abutting either the basal surface or the side face of the carrier. Well regulated structures which might be ascribed to Ni or Co sulphides were not detected in highly active catalysts. The reasons for the stabilisation of the highly disperse particles on the carrier surface will be examined.

Table 2. Structural characteristics of the carriers used for preparing sulphide HDS catalysts.[31,59,60]

Carrier	SiO_2	Sibunit	γ-Al_2O_3 *
Structure	Amorphous, chains of SiO_4 tetrahedra	Amorphous, flaky hexagonal	Cubic densely packed
Crystalline analogue	Tridymite, crystabolite	Graphite	Spinel $MgAl_2O_4$
Interatomic distances, Å	Si(1)–O(1)=1.6; Si(1)–Si(2)= =O(1)–O(2)=3.2; O(1)–O(1)=2.7; Si(1)–O(2)=4.0	d_{002}=3.356 C–C=1.42	Al_O–Al_O=O–O=2.79 Al_O–O=1.98; Al_T–O=1.71; Al_T–Al_T=3.42; Al_T–Al_O=3.29; O–O=3.95, 4.83

*Al_O and Al_T are aluminium atoms in spinel which occupy octahedral and tetrahedral positions respectively.

Table 3. Structural characteristics of Mo, W and Ni sulphides.[61]

Sulphide	MoS_2	WS_2	NiS
Structure	Flaky hexagonal	Flaky hexagonal	Very dense hexagonal
Structural type	Molybdenite MoS_2	Molybdenite MoS_2	Arsenide NiAs
Unit cell parameters, Å	a=3.16; c=12.395	a=3.187; c=12.52	a=3.427; c=5.31
Interatomic distances, Å	Mo–Mo=S–S=3.16; Mo–S=2.35; S–S=2.96 (patch thickness)	W–W=S–S=3.187; W–S=2.48; S–S=3.33 (patch thickness)	Ni–Ni=S–S=2.65; Ni–S=2.38

The structural characteristics shown in Tables 2 and 3 for sulphides and carriers indicate the closeness of the structures of $MoS_2(WS_2)$ and Sibunit. They belong to the same space group and crystallise in laminated hexagonal structures, the interplanar distances in Sibunit are close to the thickness of a single patch of $MoS_2(WS_2)$. Such a close similarity of structural types and interatomic distances assumes a possible epitaxial interaction of both the basal plane and the side faces. This picture was also observed in the electron microscopic prints. Single patches of the active component are disposed along the edges of the carbon carrier repeating its profile.[31] Evidently the oriented accretion of the active component on the Sibunit surface provides a limiting dispersity for the catalysts even when preparing them by the impregnation method and, as a result, a high activity in the thiophene hydrogenolysis reaction (see Table 1).

A closely similar picture is observed in the case of sulphide catalysts applied to SiO_2 using metal-complex precursors. In amorphous SiO_2 the SiO_4 tetrahedra are joined to one another by the apices in continuous chains which, interlinking with one another, form predominantly 6-membered units.[60] The interatomic O–O distances in the space lattice formed in this way are close to the S–S distance in the $MoS_2(WS_2)$ structure. Consequently on decomposing the surface metal complex in an atmosphere of H_2S the structure of an $MoS_2(WS_2)$ packet may be formed without fission of the Si–O–M chemical bond formed at the stage of applying the metal complexes. In this case also an epitaxial reaction of carrier and active component is therefore possible.

A different picture is seen for catalysts applied to γ-Al_2O_3. In spite of the absence of a geometric correspondence between the carrier structure and the structure of $MoS_2(WS_2)$, it is nevertheless possible to obtain highly dispersed sulphide particles which are thermally very stable and do not cake under the conditions of the catalytic process. Evidently for stabilisation of the highly disperse state it is sufficient either to interact the basal planes of the active component with the surface by Van der Waals forces or to form a relatively small number of bonds of the Al–S–M type between the side face of the active component and the surface of the Al_2O_3.[56]

Comparison of the particle sizes of the active component on the surface of SiO_2 and Al_2O_3 in catalysts prepared by various methods enabled the following conclusions to be drawn. The mean particle size in catalysts obtained on SiO_2 by impregnation was significantly greater than in MC catalysts which, together with the non-uniform composition of the surface compounds, may be one of the reasons for their comparatively low activity. On the other hand, sulphide particles in ST and MC catalysts applied to Al_2O_3 have approximately the same size,[56] consequently the lower activity of the impregnated samples may be explained either by the non-uniform composition of the sulphide particles or by the possibility of forming surface compounds during preparation which are not catalytically active. Evidently the most favourable situation arises on applying the active phase to Sibunit when highly active catalysts are successfully obtained by simple methods. In this case the geometric similarity of the structures of the carrier and the active component provide extreme dispersity for the latter and the carbon nature of the carrier enables phases inactive in catalysis to be avoided.

2. The electronic state of metals forming the active component

One of the main methods of studying the electronic state of metals in applied catalysts is X-ray photoelectron (XP) spectroscopy. The investigation of inorganic and coordination compounds of transition metals showed that the binding energy E_b of electrons in the inner levels of the central atom is a complex function of the oxidation level of the metal and the structure of its first coordination sphere.[62]

A large number of papers (see for example[55,58,63–66]) has been devoted to the study of sulphide catalysts by XP spectrometry. Most frequently the electronic state of Mo(W) in bimetal catalysts corresponds to their state in bulk $MoS_2(WS_2)$. The state of Co(Ni)

has not been assessed so unequivocally. The fact is that after sulphurisation of the impregnated catalysts the lines for Ni 2*p* and Co 2*p* in the XP spectra were markedly broadened, which is most probably linked with the presence of a certain quantity of Ni(Co) ions in the oxygen environment.[55,58,63,64,66] Consequently no changes of E_b were detected, compared to binary sulphide catalysts, for Ni $2p_{3/2}$ and Co $2p_{3/2}$ in bimetallic sulphide catalysts. At the same time a significant increase in E_b was noted for electrons of these levels in some studies,[31,40,64,65] while lines for Ni 2*p* and Co 2*p* in the spectra of MC catalysts were fairly sharp with a symmetrical maximum (Fig. 2), which indicates a similar environment for Co and Ni. The presence of an additional peak in the spectra of impregnated catalysts at a larger E_b shows that a certain quantity of Ni(Co) ions are in an oxygen environment.

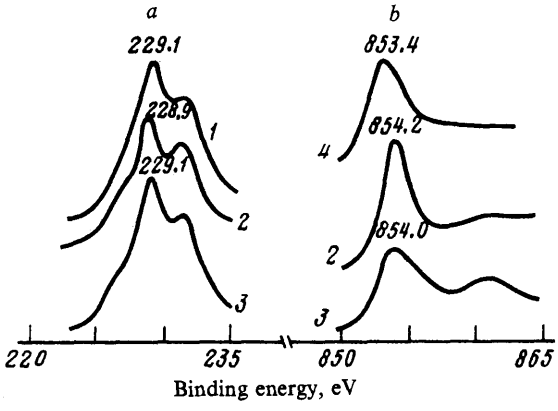

Figure 2. Profile of the *a*, Mo 3*d* and *b*, Ni 2*p* lines in the XP spectra of sulphide catalysts;[41] *1*, 4.5 Mo/Al_2O_3 (CM); *2*, (1.5 Ni, 4.5 Mo)/Al_2O_3 (CM); *3*, (1.2 Ni, 6.0 Mo)/Al_2O_3 (TC); *4*, 1.7 Ni/Al_2O_3 (CM).

The significant increase in E_b for Ni 2*p* and Co 2*p* in bimetallic catalysts in comparison with solid binary and applied sulphides (Table 1) was interpreted by us as a reduction in electron density on the Ni or Co atoms as a result of forming a new chemical compound, a SBMS, in which the Ni(Co) atoms are localised in the side face of $MoS_2(WS_2)$.[27,31,40] From the principles governing the change in E_b it is possible to assign a formal charge of +4 to this Ni(Co) atom. Closely similar values of E_b for Ni $2p_{3/2}$ are obtained for the $[Ni(WS_4)_2]^{2-}$ anion,[40,65] in which the Ni is in the centre of a square plane of S atoms.

3. Structure of dispersed particles of $MoS_2(WS_2)$ and the principle of the electrical neutrality of the molecule

As already mentioned above, the necessary structural unit on which the hydrogenolysis of thiophene can occur is a single patch of $MoS_2(WS_2)$ the linear size of which may vary from a few to several tens of angstroms. We now examine the structure of these highly disperse particles form the viewpoint of the principle of the electrical neutrality of the molecule. In the $(MoS_2)_x$ macromolecule all the valence bonds must be saturated when preserving the MoS_2 stoichiometry without changing the level of oxidation of Mo^{4+} and S^{2-}. In other words, in a macromolecule of any size the quantity of positive charges on the molybdenum atoms must be equal to the quantity of negative charges on the sulphur atoms. The excess (+) or (–) charges arising as a result of breaking valence bonds on the side face of a MoS_2 packet must be compensated by a corresponding quantity of charges opposite in sign. The problem of compensating the excess (–) charge on the terminal sulphur atoms was examined for the first time in 1980.[13]

The minimum structural unit determining the structure of a single MoS_2 patch is a trigonal prism made up of six S atoms in the centre of which is a Mo atom (Fig. 3). The formal excess charge of this cluster is 8 e^-, i.e. its chemical formula may be represented as $[MoS_6]^{2-}$. The macromolecule $(MoS_2)_x$ is formed by joining individual prisms along an edge, consequently a 'sandwich' is formed on joining three prisms, represented in projection from above as a regular hexagon. On the side face $(30\bar{3}0)$ of this hexagon there are two Mo atoms ($m = 2$) and on the $(0\bar{3}30)$ face one Mo atom ($n = m - 1 = 1$).

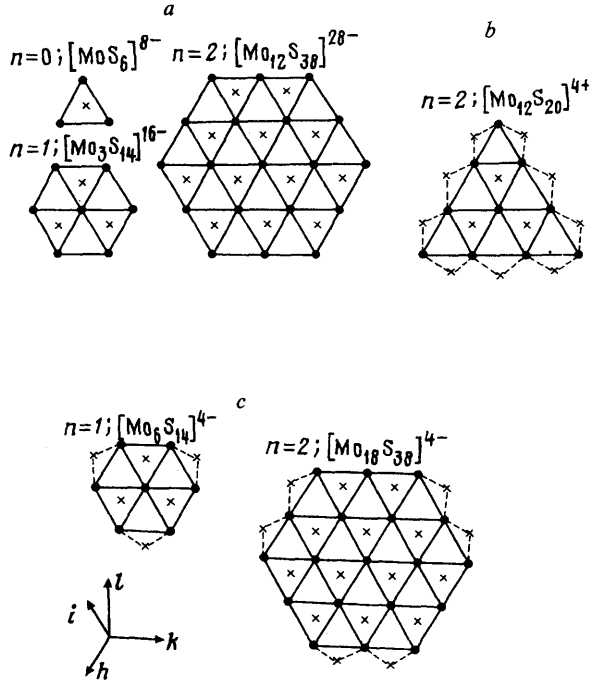

Figure 3. Formation of electrically neutral macromolecules of MoS_2 on putting into effect variants 1 (*a*), 2 (*b*) and 3 (*c*) (see text).

In the hexagon formed by three prisms there are 3 Mo and 14 S atoms which makes an excess charge of 16 e^-, i.e. the formula of the cluster is $[Mo_3S_{14}]^{16-}$. On increasing the length of the rib by one more Mo atom ($m = 3$, $n = 2$) the formula for the cluster will be

$[Mo_{12}S_{38}]^{28-}$. It is easy to show that in the general case a regular hexagon is described by the formula $[Mo_{(3n^2)}S_{2(3n^2+3n+1)}]^{(12n+4)-}$. With an increase in length of the rib the ratio of the sum of (–) charges on the S atoms to the sum of (+) charges on the Mo atoms in an infinitely large molecule $(MoS_2)_x$ will therefore be

$$\lim_{n\to\infty}\frac{4(3n^2+3n+1)}{12n^2}=1,$$

i.e. an infinitely large molecule is electrically neutral.

A significant excess of (–) charges will always exist in the case of a macromolecule of size $\leqslant 25$ Å ($n \leqslant 6$). An electrically neutral macromolecule may be formed by three different routes: 1) by adding protons to form S–H groups, 2) by removing excess S atoms with the formation of anionic vacant sites, 3) by adding additional Mo^{4+} atoms or other cations (Ni, Co, etc.).

We will examine these cases in more detail.

Variant 1. The adsorption of H_2 by bulk MoS_2 is well established experimentally and the presence of S–H groups has been confirmed spectroscopically.[67,68] The possibility of homolytic and heterolytic dissociation of dihydrogen on a MoS_2 surface has been shown by theoretical calculations.[69]

In the present case, $(12n + 4)$ protons are necessary to compensate the excess charge on the cluster the rib of which consists of n atoms of Mo which corresponds to the formula $H_{(12n+4)}Mo_{(3n^2)}S_{2(3n^2+3n+1)}$. This formula may be rewritten in the form $3n^2(MoS_2).2(3n + 1)H_2S$ from which it follows that the atomic ratio S:Mo is always greater than 2. Since this result contradicts numerous data according to which the ratio S:Mo < 2 and also the experimental data[67,68] on the quantity of H_2 adsorbed by MoS_2, it may be concluded that compensation of the (–) charge is probably not solely by addition of protons.

Variant 2. The possibility of removing peripheral S atoms with the formation of anionic vacant sites has been considered in many studies where the formation of adsorption centres and the activation of the reagents were examined (see, for example[70,71]). If the principle of the electrical neutrality of the macromolecule is followed then it is easy to show that to compensate for the (–) charge on a cluster the rib of which consists of n Mo atoms, it is necessary to remove all the S atoms on the side face $(10\bar{1}0)$ (Fig. 3, *b*). In this case the molecule is bordered by molybdenum atoms in the $(30\bar{3}0)$ plane and the quantity of S atoms remaining in the molecule is $(6n^2 - 4)$. Consequently the hexagon may be described by the formula $Mo_{(3n^2)}S_{(6n^2-4)}$, which in an infinitely large molecule

$\lim_{n\to\infty}\frac{6n^2-4}{3n^2}=2,$ corresponds to the formula MoS_2. A small excess of (+) charge is characteristic of clusters of a smaller size.

Variant 3. Extra cations, particularly Mo^{4+} may be added to the terminal S atoms on the $(10\bar{1}0)$ plane and occupy the regular positions of the MoS_2 lattice prescribed for Mo^{4+} ions during the growing process of the macromolecule (Fig. 3, *c*). In this case the formula of the macromolecule has the form $Mo_{(3n^2+3n)}S_{2(3n^2+3n+1)}$ which means that an infinitely large molecule is also described by the formula MoS_2. A small excess of (–) charges is observed in clusters of smaller size. Comparison of Figs. 3, *b* and 3, *c* show that variant 3 is a derivative of variant 2 with removal of angular Mo atoms and the corresponding quantity of S atoms.

The additional Mo^{4+} cations belonging to the side face $(30\bar{3}0)$ are coordinationally unsaturated. Following the principle of minimum free energy at the phase separation border, it may be proposed that the cations in question are able to shift from their regular positions towards the centre of the hexagon (Fig. 4), which may lead to the appearance of additional (+) charge on the peripheral $Mo^{(4+\delta)+}$ atoms. In our opinion this enables the small excess of (–) charge on small clusters to be compensated. It may also be proposed that these $Mo^{(4+\delta)+}$ cations are centres for adsorption and activation of donor molecules, i.e. they act as catalytically active centres.

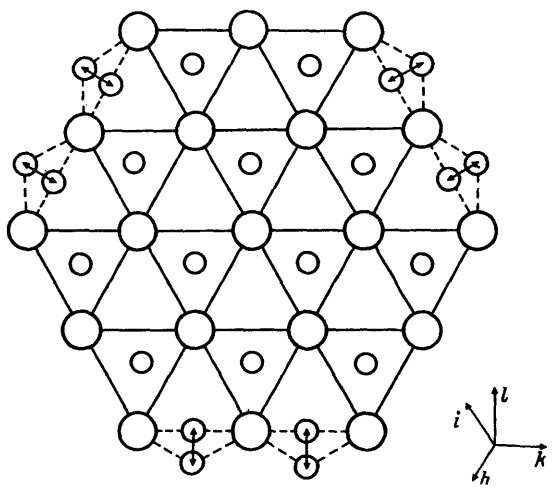

Figure 4. Displacement of cations from the regular positions of the lattice on the periphery of a MoS_2 patch.

In many respects a similar situation arises in the compensation of (–) charge on the terminal S atoms in the plane $(10\bar{1}0)$ after their coordination with Ni^{2+} or Co^{2+} cations. However since square-planar coordination[73–78] is characteristic for compounds of these metals with chelated sulphur-containing ligands then it is most probable that these cations occupy the centre of a square of S atoms in a plane $(10\bar{1}0)$ on the periphery of a $MoS_2(WS_2)$ patch (Fig. 4). With such coordination additional (+) charges on the Ni(Co) ions, corresponding to the formal oxidation level of 4+, are necessary to form electrically neutral fragments. A similar increase in charge was recorded by XP spectroscopy (see above). It is known[78] that reversible electron transfer reactions with the formation of stable products readily occur in square-planar complexes with S-containing ligands.

Evidently the compensation of the excess charge on the terminal S atoms by the addition to them of transition metal cations has a more general character. Thus after applying copper ions to a WS_2 surface a significant reduction was also detected in the electron density at the Cu atoms compared with the binary sulphide.[79] Even more, after applying Ni to the surface of both bulk and applied NbS_2 and ReS_2 (both these sulphides crystallise in the molybdenite

MoS_2 structure[80,81]) a reduction in the electron density on the Ni atoms compared with NiS was also recorded.[79] These observations serve as grounds for proposing that the coordinationally unsaturated electron-deficient atoms of Ni(Co) may act as centres for adsorption and activation of donor molecules.

4. The structure of the sulphide bimetallic species

In the previous section we came close to examining the structure of the active component of HDS catalysts known as the sulphide bimetallic species (SBMS).[27,72,82–86] The structural data forming the basis of this model were obtained by EXAFS [82] and by the X-ray method for the radial distribution of atoms (RDA).[60] According to this model the active component of the HDS catalyst is a uniform patch of $MoS_2(WS_2)$ on the side face $(10\bar{1}0)$ of which the Ni(Co) atoms are located (Fig. 5). In the SBMS the Mo(W) atoms are in the centre of trigonal prisms and are surrounded by six S atoms, the distances being Mo–S = 2.41 Å and W–S = 2.46 Å. The prisms are joined along an edge forming a 'sandwich' in which the distance Mo–Mo = 3.17 Å and W–W = 3.24 Å. All the values given for the interatomic distances are typical of bulk MoS_2 and WS_2.

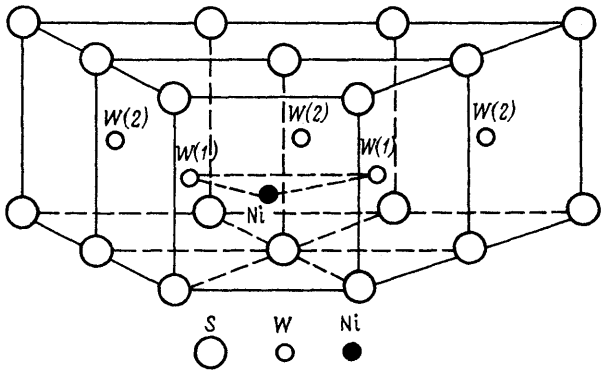

Figure 5. Stucture of the sulphide bimetallic species (SBMS), the active component of HDS catalysts.

When the Ni(Co) is located in the centre of a square of sulphur atoms in the plane $(10\bar{1}0)$, the distance Ni–S = 2.2 Å and Ni–W = 2.4 Å. Precisely the same values were found by EXAFS.[82] It must be emphasised that the distance Ni–S = 2.15–2.20 Å is typical for square-planar complexes with chelated S-containing ligands.[73–76] The short Ni–W distance = 2.4 Å suggests the formation of a direct metal–metal bond between the dissimilar atoms.

The closely similar values of the interatomic distances, particularly Co–S and Ni–S = 2.2 Å, were also found in other studies, however the Mo–Mo distance proved to be longer ~2.8 Å.[87,89] It was confirmed by XANES that the square-planar environment of the Ni atoms was transformed into trigonal-pyramidal after adsorption of a S-containing molecule.[88] It may be suggested that the increase in the Ni(Co)–Mo distance to 2.8 Å is explained by the fact that after adsorption of the donor molecule (H_2S in particular) onto Ni(Co) atoms forming part of the SBMS these atoms emerge from the plane $(10\bar{1}0)$ (Fig. 6). Such a situation is typical of pentacoordinated metal complexes. When the donor molecule occupies a pentacoordinate position in a square-planar complex a compound is formed in which the metal is in a square-pyramidal environment.[90]

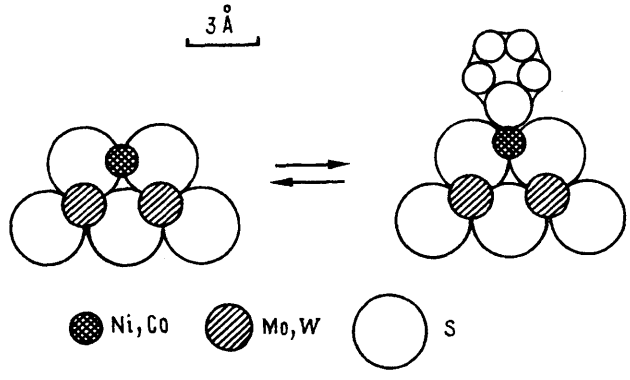

Figure 6. Adsorption of the thiophene molecule on SBMS.

IV. Reaction mechanism of the hydrogenolysis of thiophene

All the reaction mechanisms considered in the literature on the hydrogenolysis of the C–S bond are based on two main hypotheses.

1. The reaction is considered as a multistage oxidation–reduction process with the participation of anionic vacant sites of MoS_2 or Co–Mo–S phases.[8–19] Apparently one of the first mentions of the participation of anionic vacant sites of sulphide catalysts in the catalytic cycle appeared in 1969.[91] It may be suggested that this hypothesis arose from ideas on reaction mechanisms on oxide catalysts. Up to the present, fairly persuasive confirmation has been obtained of the participation of surface oxygen atoms of solid catalysts in the catalytic cycle.[92,93]

2. The active component of the catalyst is considered to be MoS_2, on the anionic vacant sites of which adsorption and activation of the S-containing molecule occurs. The Ni(Co) atoms are assigned the role of promoters. Various authors assess the role of promoters in a different way leading either to activation of hydrogen,[20] or to increase the number of anionic vacant sites,[22] or to the creation of qualitatively new types of vacant sites,[17,19,22] etc. The hypothesis on the distribution of roles between the active components and promoter is based, seemingly, on the following considerations. In the first place it is well known that addition of even small quantities of Ni(Co) to Mo(W) in the sulphide form leads to a sudden non-additive growth in activity, while addition of small quantities of Mo(W) to Ni(Co) sulphide causes only an insignificant increase in it. Secondly, modern methods, particularly electron microscopy, have shown the presence of $MoS_2(WS_2)$ particles in the catalysts (see part 1 of section III), while structures typical of Ni(Co) sulphides have not been detected.

The participation of anionic vacant sites in the catalytic cycle was also assumed on the basis of theoretical calculations on the reaction of thiophene with an MoS_2 surface.[94,95] The possibility of coordinating thiophene to an anionic vacant site through the S atom (η^1-coordination) and through the plane of the ring of the molecule (η^5-coordination) was examined in this way.

Table 4. Comparison of the amount of sulphur removed on TPR, the rate of exchange with $H_2{}^{35}S$ and the activity of sulphide catalysts in the hydrogenolysis of thiophene.[27,107]

Catalyst	Amount of sulphur removed on TPR in the range 25–500 °C, as % S content of the initial catalyst	Initial rate of isotopic hetero-exchange with $H_2^{35}S$ at 300 °C, g. at S/[g.at (Ni+M).s] × 10^3	Activity on thiophene hydrogenolysis at 300 °C, mole C_4H_4S/[g.at(Ni+M).s] × 10^4
Ni/SiO_2	100	–	2
Mo/SiO_2	35	42	5
$(Ni, Mo)/SiO_2$	41	36	60
W/SiO_2	26	–	3
$(Ni, W)/SiO_2$	31	25	123

However both of these suggestions are no more than hypotheses since there is no direct experimental confirmation and the indirect correlations are extremely inconsistent. We shall examine these hypotheses in more detail.

1. Participation of anionic vacant sites of $MoS_2(WS_2)$ in the catalytic cycle

Anionic vacant sites on the surface of sulphide particles may arise by the reaction of surface sulphur atoms with H_2 at elevated temperature and their removal as H_2S. The number of anionic vacant sites may be determined from the quantity of H_2S evolved in a temperature-programmed reduction (TPR) of the sulphide catalyst,[96,97] and also from the quantity of donor molecules adsorbed on the surface of sulphide catalysts after reducing them in H_2 at a particular temperature.[98–103] Both these procedures were used to construct correlation relationships. In some cases a correlation with catalyst activity in the hydrogenolysis of the C–S bond was detected[96–100] and in others it was absent or was not clearly displayed.[101–103]

To assess the mobility of oxygen in oxide catalysts and to study its role in catalysis, the method of hetero-exchange with oxygen in the gas phase has been widely used.[92,93] In the case of sulphide catalysts H_2S, labelled with the radioactive ^{35}S isotope, may serve as the appropriate test molecule.[104–106]

Correlations between catalytic activity and the mobility of surface S atoms were not detected by TPR or by $H_2{}^{35}S$ exchange methods on highly active sulphide catalysts.[27,107] After the addition of Ni to Mo(W) catalyst the rate of $H_2{}^{35}S$ exchange with the surface was reduced but the quantity of sulphur removed in the TPR process was practically unchanged and the activity of the catalyst was increased many times (Table 4).

A calculation of the enthalpy of the reaction of H_2 and sulphur atoms belonging to different faces of a single $MoS_2(WS_2)$ patch has been made by the interacting bond (IAB) method.[72] It turned out that to remove sulphur atoms from the basal plane $(000\bar{1})$ and from the side face $(0\bar{1}10)$ it was necessary to expend 335–398 and 92 kJ mol^{-1} respectively while the reaction of H_2 with S atoms in the plane $(10\bar{1}0)$ was characterised by a negative value of ΔH = 21–42 kJ mol^{-1}. This indicates that the removal of peripheral S atoms from plane $(10\bar{1}0)$ is energetically advantageous and consequently may occur even on forming a single $MoS_2(WS_2)$ patch.

As a result of forming an electrically neutral macromolecule (Fig. 3, *b*, *c*) the sulphur atoms which may be removed as H_2S are found in plane $(0\bar{1}10)$ and are coordinated with two Mo(W) atoms, i.e. for their removal ~92 kJ mol^{-1} is required. However the addition of S atoms to the vacant site formed is accompanied by a significant energy advantage. The enthalpy of this reaction is ΔH = –239 kJ mol^{-1}.[72] This indicates that under the conditions of the catalytic reaction the electrically neutral molecule must be thermodynamically stable since the reaction equilibrium is shifted strongly to the left.

$$S+H_2 \rightleftharpoons \square+H_2S.$$

A similar situation also arises in the case of the bimetallic catalysts. Calculations within the framework of IAB show[72] that it is necessary to expend 50–63 kJ mol^{-1} to remove sulphur atoms coordinating Ni(Co) atoms in the SBMS, while their addition to the vacancies formed is accompanied by an energy advantage of ~209 kJ mol^{-1}. Consequently in this case also the electrically neutral SBMS is a thermodynamically stable unit.

An important conclusion emerges from comparison of the enthalpy of the addition of S and removal of S from sulphide catalysts of various composition.[72] Since, according to Temkin's rule,[108] the rate of the two-stage catalytic process is maximal if the Gibbs' energies of both stages are approximately the same, the structure-forming sulphur atoms, i.e. those atoms which form the structure of the electrically neutral SBMS, may not participate in the catalytic cycle. Only those S atoms which have just one chemical bond with a metal atom may be catalytically active. This rule is better satisfied by the coordination of sulphur to the Ni or Co atoms than to Mo or W.

Examination of the thermodynamics of forming vacant sites on the surface of an electrically neutral SBMS places doubt on the possibility of their participation in the catalytic cycle. The absence of a correlation between the catalytic activity and the mobility of the surface sulphur atoms is inconsistent with this hypothesis.

2. The role of Ni(Co) and Mo(W) atoms in the activation of reacting molecules

The reductive desulphurisation of thiophene became apparent more than half a century ago[109] when it was discovered that benzene or toluene may be completely purified from thiophene contamination with Raney nickel. Subsequently the method of reductive desulphurisation of thiophene compounds was widely used in preparative organic chemistry both to establish the structure of thiophene derivatives and also for the synthesis of various saturated systems.[110–114] Raney cobalt is less suitable for these purposes.

The reductive desulphurisation of thiophene and its derivatives occurs on Raney nickel under very mild conditions. As a rule it takes place at room or elevated temperature (60–80 °C) using fairly inert solvents such as diethyl ether, ethanol, toluene, etc.[109–114] A necessary condition for high yield is the presence of hydrogen dissolved in the Raney nickel which is formed in the process of leaching out the Ni–Al alloy and is retained for a long time in large quantities in the bulk of the Raney nickel.[115] Usually the reaction is carried out in the absence of hydrogen in the gas phase and with an excess of Raney nickel. The reaction takes place fairly smoothly. Sulphur from the substrate molecule is irreversibly adsorbed onto the surface, deactivating it. The olefinic bonds are reduced with the evolution of aliphatic molecules into the gas phase. This reaction must be considered to be stoichiometric rather than catalytic[110,111] since it is necessary to remove the bound sulphur to complete a catalytic cycle. Seemingly this is impossible to accomplish under the conditions of the reaction since Ni sulphides are only reduced at a higher temperature.

Numerous experimental data convincingly point to a radical mechanism for the hydrogenolysis of a C–S bond on Raney nickel.[110,112] Fission of the C–S bond occurs after adsorption of the S-containing molecule with the formation of firmly bound sulphur and free radicals. The latter are saturated by the dissolved hydrogen and when this is absent the saturation of the free valencies occurs by dimerisation or disproportionation.[110]

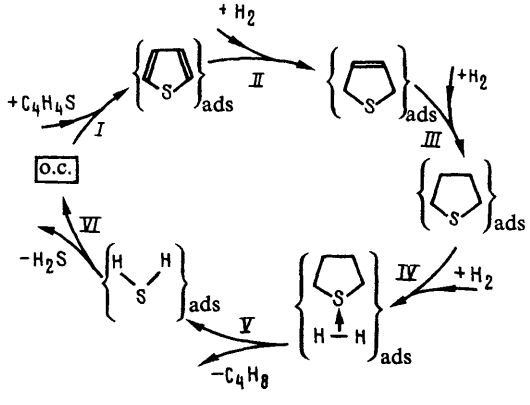
The desulphurisation reaction of dibenzothiophene (DBT) and its derivatives on Ni complexes, which also occurs under very mild conditions, is very representative.[116] The reaction of (2,2′-bipyridyl)-(1,5-cyclooctadiene)nickel(0) with DBT at ~60 °C is accompanied by the formation of only small quantities of diphenyl and its derivatives with nickel.[117] However if this complex of Ni(0) is first treated with $LiAlH_4$ in a molar ratio of 1:2 then the resulting complex will carry out the desulphurisation of DBT in quantitative yield.[116,118] These results indicate that nickel is extremely active in the fission of a C–S bond, however an excess of activated hydrogen is required to bring about the process.

A detailed study of the catalytic properties of Ni sulphides has shown[70] that they are inactive in H_2-D_2 exchange, in deuterium–hydrogen exchange reactions with olefins and in the hydrogenation of olefins at low temperatures. These catalysts begin to display activity only after reduction in H_2 at elevated temperatures. In addition the stoichiometric sulphides CoS, CoS_2, Co_9S_8 and Ni_3S_2 proved to be inactive in the hydrogenation of dienes.[119,120] However CoS in the absence of hydrogen accelerated the reaction of buta-1,3-diene with cyclohexa-1,3- and 1,4-dienes and also the disproportionation reaction of cyclohexadiene.[120] These data indicate the difficult activation of hydrogen on Ni and Co sulphides.

In contrast, MoS_2 is active in the hydrogenation of olefins and dienes at low temperature[118] and carries out the H_2-D_2 exchange reaction even at −40 °C.[121,122] Hydrogen is adsorbed in the dissociated form on MoS_2 and WS_2 with the formation of S–H groups.[67,68,123] From this it may be concluded that the activation of H_2 on $MoS_2(WS_2)$ occurs fairly readily.

The activation of hydrogen under mild conditions (25–75 °C, H_2 pressure 2 atm) is also effected on molybdenum complexes with S-containing ligands.[124–127] The resulting S–H groups readily hydrogenate olefinic and acetylenic hydrocarbons.[127]

On the other hand the heats of formation of MoS_2 (272 kJ mol^{-1}) and WS_2 (259 kJ mol^{-1}) are far greater than the heat of formation of NiS (71 kJ mol^{-1}).[128] Nickel sulphides readily lose sulphur in an atmosphere of H_2 and are reduced to the metal even at 300–400 °C while Mo and W disulphides are fairly stable at these temperatures.[27] In other words, the strength of the M–S bond in Mo or W sulphides is greater than in Ni sulphides.



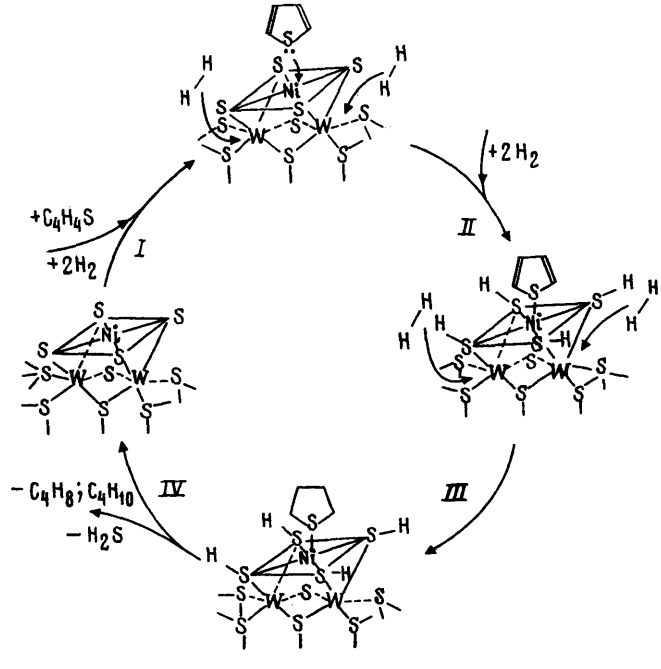
A catalytic cycle is shown for the hydrogenolysis of thiophene in six sequential stages, in each of which adsorption and activation of the reactants or desorption of the products occurs. The separation of the overall reaction into these stages is arbitrary since their number and sequence may be different. It is only important that the possible intermediates are strongly adsorbed on the catalyst and are not evolved into the gas phase during the entire catalytic cycle.[27,86] In spite of its arbitrary nature such a scheme for the conversion is convenient for examining the problem of the limiting stage of the reaction.

In the light of the arguments mentioned above one of the stages *II–IV*, in which activation of molecular hydrogen occurs, may be considered to be probably limiting for reaction on Ni(Co) sulphide catalysts. The stage for fission of the Ni–S(Co–S) bond and the desorption of H_2S into the gas phase (*VI*) seems to be rapid. On the other hand, stages *II–IV* are probably rapid on $MoS_2(WS_2)$ and the stage determining the rate of the whole process may, for example, be the removal of sulphur from the active centre (stage *VI*).

The clearly defined non-additive increase of the activity of bimetallic sulphide catalysts may be explained by the fact that those stages which determine the overall reaction rate on monometallic catalysts remain rapid. However for this it is necessary to assume that the adsorption of thiophene on Ni(Co) atoms occurs with the formation of a labile M–S bond and the ease of activation of H_2 on $MoS_2(WS_2)$ provides rapid hydrogenation of the thiophene ring. Then a different stage may become limiting, for example stage *V* in which fission of the C–S bond occurs.

3. Synchronous mechanism for the hydrogenolysis of thiophene in the coordination sphere of the SBMS

Analysis of the arguments mentioned above and the experimental data enable the following mechanism to be proposed for the hydrogenolysis of thiophene on a SBMS.



According to this mechanism the thiophene molecule is adsorbed on coordinationally unsaturated Ni(Co) atoms existing in a square-planar environment of S atoms. The deficiency of electron density on the Ni(Co) atoms enables coordination to them of an S atom, which in the thiophene molecule has an unshared electron pair. Simultaneously with the adsorption of thiophene on Ni(Co), activation of H_2 may occur in parallel and independently on Mo(W). The activated hydrogen may be passed on to the thiophene molecule, for example, via the S atoms coordinating the Ni(Co). However, other possible transfers of activated hydrogen are not excluded if the short metal–metal distance between the dissimilar atoms is taken into account, assuming the formation of a direct chemical bond. Seemingly the activation of hydrogen occurs continuously with its consumption in the hydrogenation of the thiophene ring. We propose that stages *I–III* for the activation of hydrogen and thiophene occur rapidly and stage *IV*, the fission of the C–S bond may be limiting after which the reaction products (H_2S, butenes, butane) are rapidly desorbed into the gas phase. The high rate for the process is provided by the synchronous interaction of reactants in the coordination sphere of the SBMS. A significant portion of the energy consumption on activating the reactants is compensated by the heat of adsorption and the hydrogenation energy of the thiophene ring, indicated by the low value of the activation energy $E_a = (59 \pm 8)$ kJ mol^{-1} (see Fig. 1).

Direct experimental confirmation of the proposed reaction mechanism has been obtained recently. It was shown by EXAFS *in situ* that the chemosorption of the selenophene molecule (the structural analogue of thiophene) on sulphide catalysts (Ni, Mo)/Al_2O_3 (MC) occurs only on the Ni and not the Mo atoms forming part of the SBMS.[129] Similar conclusions were reached previously.[88]

In order to answer the question of why thiophene is adsorbed by SBMS and H_2S is desorbed but the possible intermediate THF is not desorbed, the heats of adsorption of these molecules on SBMS of various composition were calculated within the framework of the IAB method.[130] The calculated heat of adsorption of H_2S was 48–52, of thiophene 88–94 and of THT 146–155 kJ mol^{-1}. The low value of the heat of adsorption of H_2S indicates the reversible nature of its adsorption under the reaction conditions and the possibility of displacing adsorbed hydrogen sulphide by thiophene. The significantly greater heat of adsorption of THT indicates that it is adsorbed practically irreversibly and the only possible variant of the catalytic cycle is hydrogenolysis of a C–S bond with desorption of hydrogen sulphide and hydrocarbons into the gas phase. Seemingly the main reason for the strength of the binding of THT to the active centre is the basicity of this S atom which is higher than that of thiophene and is caused by a reduction in the π-resonance energy on hydrogenating the aromatic thiophene molecule.

An additional argument in favour of the axial coordination of thiophene to the Ni(Co) atom (see Fig. 6) may be the existence of well-studied square-planar metal complexes with chelated macroligands.[131] The ability of square-planar complexes to undergo a reversible electron transfer reaction with the formation of stable products and the high electron-accepting ability of these complexes in relation to an organic donor have been well studied.[78,132]

The coordination of the thiophene molecule to a Ni(Co) atom in an SBMS is accompanied by a change in its coordination state. The adsorbed molecule adds on to the environment of the Ni(Co) to make a square pyramid which seemingly leads to a displacement of the Ni(Co) atoms from the centre of the square formed by the S atoms in the $(10\bar{1}0)$ plane of the SBMS (see Fig. 6). Such a displacement of atoms is very characteristic of square-planar metal complexes when they are transformed into pentacoordinated complexes after coordination of the donor ligands.[90] It is evident that the shift of Ni(Co) atoms is accompanied by a lengthening of the Ni(Co)–Mo distance. This effect has been observed in other studies.[87–89]

4. Other routes for converting thiophene

The synchronous mechanism for the hydrogenolysis of thiophene on SBMC enables the absence of the possible intermediates THT and butadiene from the gas phase to be explained. However they were recorded nevertheless in several cases when carrying out the reaction on one type of catalytic system. One of the most probable explanations for this discrepancy is the presence on the catalyst surface of other active centres, different from the SBMS, which may catalyse this reaction by a different route.

For some time past much attention has been paid to the study of the hydrogenolysis of the C–S bond on various faces of Mo, W and Ni single crystals.[24,25] The first stage of the hydrogenolysis of thiophene on Mo face (100) is fission of the C–S bond with evolution of butadiene into the gas phase.[133] The limiting stage of the reaction is the hydrogenation of sulphur adsorbed on the surface of the monocrystal.[134] At the same time propylene is the main product of THT hydrogenolysis and therefore THT cannot be an intermediate in the hydrogenolysis of thiophene.[133]

The desulphurisation of thiophene proceeds in a different way on a W surface (211).[135] The main product of the temperature-programmed desorption is propylene which indicates fission of a C–C bond at the α-carbon atom of the thiophene molecule. On the other hand with a Ni (111) surface, hydrocarbons C_{5+} are desorbed which implies dimerisation and possibly disproportionation of the reaction products.[136] However since the reaction took place in the absence of hydrogen,[135,136] one should speak of cracking and not hydrogenolysis in these cases.

Nevertheless the data on the reaction of thiophene with the surface of single crystals shows that the first stage of the process is fission of a C–S bond with subsequent saturation of the free valencies of radicals by reaction with H_2 or by recombination.

One way of clarifying the action mechanisms of solid catalysts is the study of the coordination of substrate molecules to the metal complex stabilised with different ligands. Although a large number of stable metal complexes of thiophene with various transition metals exist,[23,25] only a few of them include metals forming part of HDS catalysts.[137,138] A thiophene molecule coordinated to a metal through the S atom may be readily replaced by a weak ligand.

The preparation of THT by the catalytic hydrogenation of thiophene is not a simple problem. From a preparative point of view the ionic and electrochemical hydrogenation of thiophene are the most acceptable methods.[139] The hydrogenation of thiophene with molecular hydrogen is complicated by the rapid poisoning of the catalysts and by side reactions of hydrogenolysis of the C–S bond. Seemingly the most effective catalysts are based on noble metals and also rhenium sulphide.[140]

The appearance of THT among the hydrogenolysis products of thiophene on sulphide HDS catalysts may be linked with the formation of qualitatively new active centres. As has been shown[27,32,86] at a given level of activity of mono- and bimetallic sulphide catalysts based on Ni, Co, Mo and W prepared by various methods using various carriers, the hydrogenolysis of thiophene leads to the evolution only of H_2S, butenes and butane. The appearance of significant quantities of THT in the gas phase was observed under

the same conditions and on the same monometallic sulphide catalysts if, before carrying out the reaction, the catalysts are reduced in H_2 at 400 °C after sulphurisation in H_2S.[32] It was concluded from this that the responsible metal ions were in a low oxidation state after the reaction of hydrogenation of thiophene to THT. They may arise as a result of reduction of the catalyst surface either on carrying out the reaction in a non-stationary mode (for example, using pulse equipment in a H_2 stream), or with a deficient sulphur content in the raw material (for reoxidation of the catalyst surface), or in the presence in the catalyst of active centres different from the active centres of the HDS sulphide catalysts and not forming sulphides under the reaction conditions. It is more probable that the thiophene molecule is coordinated to that type of active centre not through the sulphur atom but by π-binding of the ring of the molecule.

V. Conclusion

Analysis of the principles for carrying out the hydrogenolysis of thiophene on highly active sulphide catalysts has enabled a new reaction mechanism to be proposed. The characteristic features of the proposed mechanism are as follows.

1. The hydrogenolysis of thiophene occurs within the coordination sphere of a sulphide bimetallic species without the participation of structure-forming sulphur atoms in the catalysis.

2. The adsorption and activation of the thiophene molecule is effected on Ni (or Co) atoms in the composition of the SBMS and the activation of H_2 occurs with the participation of Mo (or W) atoms.

3. The reaction occurs by a synchronous mechanism when the high rate of chemical conversion is provided by the synchronous interaction of reagents in the coordination sphere of the SBMS. In this way a high degree of compensation for the energy consumed on activating the reagents is achieved by the energy evolved on adsorption and hydrogenation of the thiophene ring.

The proposed mechanism for the hydrogenolysis of thiophene explains the occurrence of a synergistic effect. The clearly defined, non-additive increase in the chemical reaction rate on bimetallic in comparison with monometallic sulphide catalysts is explained by the formation of a new chemical compound, an SBMS, which combines the qualities of monometallic catalysts in relation to the activation of the reactants, viz. the activation of H_2 on $MoS_2(WS_2)$, the lability of the Ni(Co)–S bond and the transfer of the activated hydrogen to the adsorbed thiophene molecule by direct metal–metal reaction between the dissimilar atoms.

A synchronous mechanism for the interaction of reactants in the coordination sphere of a metal has been discovered most frequently in heterogeneous catalysis.[92] Thus, for example, partially and completely oxidised traditional molybdenum oxide catalysts, prepared through the synthesis of surface metal complexes, conduct the oxidation of H_2 and CO [141,142] and propylene[143] by a synchronous mechanism. Their activity and selectivity is appreciably higher than for the analogous catalysts prepared by the impregnation method. It may be suggested that the synchronous mechanism is more widespread in heterogeneous catalysis than has been considered until now. The main difficulty in detecting it is seemingly the non-uniformity of the chemical composition of the surface of solid catalysts, since in several cases the appearance of particular intermediates may be caused by an alternative reaction route having no direct relation to the mechanism being examined.

X-Ray diffraction study of carriers and deposited metallic catalysts

E M Moroz
Institute of Catalysis, Siberian Division of the Russian Academy of Sciences

ABSTRACT. The possibilities of applying some X-ray diffraction methods in the study of multicomponent highly disperse systems are examined. Such methods include the method based on the radial distribution of atoms (RDA), full-profile X-ray diffraction analysis (FPA), and the method involving the determination of substructural characteristics (MDSC). Examples of the determination of the structural and substructural characteristics of the most important catalyst carriers as well as deposited and non-deposited metallic catalysts are presented.

The bibliography includes 129 references.

I. Introduction

Despite the widescale use of X-ray diffraction methods in materials science, the application to the study of catalysts is mainly limited to qualitative and quantitative phase analyses of well crystallised coarsely disperse (crystallite size in the range 50–1000 Å) systems. In his concluding remarks in a well known monograph devoted to methods for the study of catalysts, Lambert[1] indicates eight criteria in terms of which the effectiveness of the method should be estimated: (1) the need to use centralised or local laboratory equipment; (2) speed of analysis; (3) the possibility of studying catalysts in the course of their operation or after use; (4) destructiveness or non-destructiveness of the method; (5) the universality of the method (sensitivity in relation to various chemical elements, suitability for the study of deposited and non-deposited catalysts); (6) the possibility of obtaining useful information in the presence of a large amount of contaminants formed during the operation of the catalyst; (7) cost; (8) thickness of the layer of the specimen investigated.

Evidently, from this standpoint, X-ray diffraction methods are entirely effective, but, since it is assumed that they yield information mainly about the structural and substructural characteristics of the bulk phase of the specimen, inadequate attention has been devoted to them. The authors of monographs in which the structural features of catalysts are discussed, for example, Lambert[1] and Anderson,[2] as a rule do not dwell on the X-ray diffraction methods for their investigation. At the Ist European Conference on Powder Diffraction held in March 1991 in Munich, a small number of experimental studies on highly disperse materials were presented,[3–9] only three of which[7–9] were devoted to the study of catalysts. Nevertheless, X-ray diffraction methods occupy a place among the series of physical methods for the study of catalysts, especially deposited catalysts, because they make it possible to obtain information simultaneously about the dispersity and phase composition of the active component and the carrier and about their structural characteristics and the degree of their interaction.

Examination of the usual parameters of the diffraction patterns of well crystallised substances, such as the positions, intensities, and form of the diffraction maxima, for the investigation of highly disperse multicomponent catalytic systems yields little information. Special X-ray diffraction methods for the investigation of highly disperse materials, based on the integral analysis of the curve for the X-ray scattering intensity, namely the method based on the radial distribution of atoms (RDA), the methods based on the determination of substructural characteristics (MDSC), and full-profile X-ray analysis (FPA), are being developed at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences. This review deals with the fundamental possibilities of the methods developed and presents the results of their use in order to obtain structural and substructural characteristics of the principal catalysts carriers (aluminium oxides and carbon materials) as well as deposited and non-deposited metallic catalysts having different chemical compositions.

II. The possibilities of X-ray diffraction methods in the study of multicomponent highy disperse systems

1. Methods based on the radial distribution of atoms

Mainly liquids (solutions and liquid metals) and amorphous and vitreous materials have been studied experimentally by the RDA method (see, for example, Refs. 10–13). Procedures for the interpretation of data and for the analysis of errors of different kinds have been examined theoretically.[14–21] Catalysts have been studied by the RDA method in a number of investigations.[13,22–29] Many catalysts of different chemical composition have been investigated in the Laboratory of Structural Research Methods at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences. This review presents the results of the investigation of catalyst carriers and metallic catalysts.

The X-ray diffraction RDA method is based on the relation between the atomic density (ρ) radial distribution function and the intensity of the coherent scattering of X-rays $i(s)$ in the diffraction experiment:

$$4\pi r^2\rho(r)=4\pi r^2\rho_0+(2r/\pi)\int_{s_{min}}^{s_{max}} i(s)s\sin(sr)ds, \quad (1)$$

$$\rho_0=\sum_{A=1}^{m}(n_AK_A)^2dL/M,$$

$$i(s)=\left[I(s)/N-\sum_{A=1}^{m}n_Af_A^2(s)\right]\Big/f_e^2(s),$$

where $\rho(r)$ is the spherically symmetrical atom distribution function, d the pyknometric density, L the Avogadro number, M the molecular weight, $I(s)$ the coherent component of the scattered diffraction beam, r the radius-vector of the inverse lattice, $\rho_0(r)$ the average density obtained for a completely random distribution of atoms, i.e. in the absence of interference, K the effective number of electrons, f_e the atomic unit factor, and N the number of atoms in the agglomeration.

In the case of binary systems, where the atoms of one system (phase) form separate groups since they are surrounded only by atoms of the same system, the formula has the following general form:[30,31]

$$\rho(r)=C_A\rho_{AA}(r)+C_B\rho_{BB}(r)+2C_AC_B\rho_{AB}, \quad (2)$$

where ρ_{AA}, ρ_{BB}, and ρ_{AB} are the partial RDA functions and C_A and C_B are the concentrations of individual phases.

It is useful to use Eqn. (2) instead of Eqn. (1) for comparable values of C_A and C_B. In deposited metallic catalysts, the concentration of the metal is low relative to the carrier ($C_B \ll C_A$), so that Eqn. 1 can be used.

For the calculation of the RDA curves, it is essential to have at one's disposal certain experimental and reference characteristics of the test substance. Such experimental data are (1) the set of data for the intensity of scattering by the specimen; (2) the set of data for the intensity of phonon scattering; (3) information about the thickness of the specimen and the pressing density (these quantities are important for systems consisting of light atoms); (4) chemical composition of the specimen ($n_A...n_m$) per molecule; (5) pyknometric density.

Data from reference sources include (1) the number of electrons in the atoms; (2) the absorption coefficients of the atoms for the given X-ray irradiation; (3) radiation wavelength; (4) atomic factors of the atoms. The RDA curves are plotted in terms of the variables $4\pi r^2\rho$ and $f(r)$, where r is expressed in Ångstroms and the electron density ρ in electron^2 Å^{-3}.

The quantitative parameters of the structure are the equilibrium interatomic distances (the values of r to which correspond the electron density peaks), the coordination numbers Z (determined from the areas of the coordination peaks), the averge quadratic atomic shifts (determined from the widths of the coordination peaks), as well as the distance over which the correlation in the disposition of atoms disappears [the distance r starting from a certain value $\rho(r) = \rho_0$]. The experimental areas of the coordination peak corresponding to the given distance r can be compared with the theoretical values calculated from the formulae

$$\Pi_T=2n_AZ_{AB}K_AK_B;\ \Pi_T=n_AZ_{AA}K_A^2, \quad (3)$$

where n_A is the number of atoms of kind A, which depends on the chemical composition, and Z_{AB} the coordination number, i.e. the number of atoms of kind B in the spherical shell bounded by the distances r and $r + d$ from the centre of the atom of kind A.

When the reliability criteria concerning the normalisation of the intensity curves hold and there is only a slight deviation from the series of approximations involved in the derivation of the principal formulae (the isotropic nature of the accumulation of atoms, the homogeneity of the medium, and infinite extent of the volume ensuring a statistically equiprobable environment of the atoms), the positions of the coordination peaks on the RDA curves are determined to within $\Delta r/r = \pm 0.5\%$ and the accuracy of the determination of the areas is to within ±5%.

Analysis of the RDA curves makes it possible not only to obtain the standard information described above but also to estimate the size of the crystallites when the latter is less than 30 Å. The determination is based on the fact that the form of the interference function for a high dispersity of the crystallites depends on their size. The form of the peaks on the scattering intensity curve and their resolution vary as a function of size.[32,33] For example, if the size of the metal crystallite with a face-centred cubic (FCC) lattice is 30 Å, then only 24 out of the 35 diffraction peaks are resolved. A change in the scattering intensity curve leads to a change in the RDA function. The coordination numbers in spherical particles of a metal with a face-centred cubic structure, whose diameters were multiples by factors of 3, 5, 7, etc. of the diameters of the individual atoms, have been evaluated by a statistical calculation.[34] With decrease in the size of the particles, there is a steady decrease in the area of the coordination peaks. For a particular size, there are consistent ratios of the areas. This feature has been used to estimate the sizes of highly disperse particles.[35–41] For a platinum particle diameter of 8 Å, the area of the first coordination sphere is half the value calculated for an infinite crystal, while the area of the second sphere is smaller by 30%; for a diameter of 30 Å, these areas are smaller by 15 and 25% respectively.

A characteristic feature of the calculation of the RDA curves by Moroz[20] is double normalisation (with respect to the far region of angles and with respect to the areas under the scattering intensity curves) and the use of experimental scattering factors. Criteria were developed for the reliability of the RDA curves as regards the normalisation of the X-ray scattering intensity and the intermediate parameters of the calculation.[20,42]

Experimental errors leading to failure of the reliability criteria were analysed, including the errors in the measurement of the intensity over a wide range of angles and at a single point (incorrect allowance for the contribution of the background and Compton scattering, the presence of fluorescent emission) and also the errors in the specification of the chemical composition.[20]

At the same time, procedures were developed for taking into account the contribution of the carrier to the overall X-ray scattering intensity curve and the RDA curve for the catalyst. Comparison of the curves for the intensity of the scattering of X-rays by the catalyst and the carrier is difficult owing to the different depths of the "working layer", because the catalyst contains as a rule a highly absorbing component. These disadvantages can be avoided if corrections are introduced in the analysis of the scattering intensity

curves for the background, polarisation, and absorption, and when the change to electronic units is made. The change to electronic units for the scattering intensity curve is an intermediate stage in the calculation of the RDA function and the construction of the difference intensity curve (DIC) then becomes possible.[20,42]

The determination of the dispersity of the active component in highly disperse deposited catalysts (D < 30 Å) is based on the analysis of the difference RDA curves. In principle, scattering intensity data are obtained by the RDA methods in the same way as in the usual precision measurements: the scattered X-ray intensity is measured over a wide range of angles with similar accuracies using monochromatic radiation. Short-wavelength molybdenum radiation with λK_{α_1} = 0.71 Å is usually employed. The intensity is measured for angles up to 2θ = 160°, which corresponds to $S_{max} = 4\pi \sin\theta_{max}/\lambda$ = 17.41 Å.

The use of a monochromator leads to the loss of up to 80% of the intensity. The monochromator, ensuring a better relation between the signal and the background, does not transmit Compton (incoherent) scattering for angles θ > 20°. For smaller angles, the monochromator transmits the entire Compton scattering, but in this region the Compton scattering itself is small.[27,43]

Conditions for an automated experiment with computer calculations have been described. The experiment lasts ~50 h and requires the stable operation of the apparatus (diffractometers of the DRON-3,4 or HZG-4C, B, A type are usually employed). The successful application of the RDA method requires that the following conditions be maintained:

1. The structure of the system components under consideration must be simple; the set of different interatomic distances must be small and the coordination numbers must be large.
2. Heavy atoms, whose percentage content is high, must be present in the system.
3. The components must have a perfect structure (absence of defects and vacancies). Analysis of the RDA curves does in fact make it possible to discover the presence of imperfections in the structure as a result of the comparison of the observed and calculated curves.
4. Accurate chemical analysis is essential.
5. A model of the postulated structure is needed.

The RDA method examined has been used successfully in the study of highy disperse systems of different chemical composition. However, the rigorous requirements which must be met by the experiment (monochromatisation, correct allowance for incoherent scattering, duration of the experiment) and by the preliminary treatment of data (careful normalisation of the scattering curves) and the ambiguity of the interpretation of the RDA curves limit the possibilities of this method in normal X-ray laboratories.

A high-speed method for the determination of atomic radial distribution functions, based on the *a priori* assumption that the functions of the background incoherent and independent gas scattering are monotonic, is being developed at present. This method does not require the measurement of the background and the knowledge of the intensity of the Compton scattering. The structure-sensitive part of the intensity curves is isolated with the aid of the cubic B-spline minimised by the method of least squares.[44] The method has been tested on polycrystalline silver and palladium.[45] The Fourier analysis of the structure-sensitive part of the intensity curve is used to obtain radial distribution functions by a procedure similar to that used in the Fourier transformation of the function of the long-range fine structure of the X-ray absorption spectrum in the EXAFS method, used to obtain structural information.[46,47] The proposed method makes it possible to accelerate and simplify the procedure involving the collection and treatment of experimental data (the experiment can be carried out without a monochromator, with a β-filter, and the normalisation of the intensity curves is also not needed). However, it cannot be used to establish the structural parameters of unknown materials, because it does not permit the determination of the absolute values of the coordination numbers. This method can be employed to analyse the changes in the structural characteristics in a series of specimens.

2. The method based on the full-profile X-ray analysis

About 20 years ago, a new effective method for the interpretation of powder diffraction data, called the Rietveld method,[48] appeared in neutron diffraction. It was subsequently used also in X-ray diffraction.[49–52]

The FPA method is based on the minimisation of the difference between the experimental and calculated diffraction patterns at any point on the X-ray diffraction pattern profile.

The function

$$\Phi = \sum_i^N W_i (y^e - y^t)^2,$$

is minimised by the methods of least squares. Here y^e and y^t are respectively the experimental and calculated intensities at the ith point of the profile, w_i is the weighting function, and N the number of points on the profile. Next, a sequence of corrections to the parameters of the specified model, converging to zero, is calculated. The summation in terms of the matrix elements of the least squares method is carried out over all the points on the profile included in the calculation. A series of matrices with the specified weighting factor are added to the matrix thus constructed. These matrices take into account the limitations to the ranges of variation of the interatomic distances and the equality of the bond lengths between various atoms, atoms in special positions being included in the calculation.[53] Since a non-linear relation between the parameters is fitted by a linear relation in the least squares method, it is essential to carry out several refining cycles.

The unreliability factors are used to estimate the reliability of the model:

$$R_p = \sum_i^N |Y_i^e - kY_i^t| \Big/ \sum Y_i^e \quad \text{(profile-based factor)}$$

and

$$R_I = \sum_i^N |I_i^e - kI_i^t| \Big/ \sum I_i^e \quad \text{(intensity-based factor)}$$

The factor R_P is found by summation over all the points of the profile and R_I by summation over the intensities of the diffraction lines. R_P usually exceeds R_I by a factor of two, while R_I is in its turn greater than the unreliability factor R_F, used in the single crystal method, by a factor of 1.5–2.

We used a computer program written in FORTRAN for the BESM-6 computer,[53,54] which includes the program published by Clark, et al.[55]

The entire X-ray diffraction pattern can be represented as a linear combination of the profiles of individual peaks. The overall intensity at each point on the pattern is described by the expression

$$Y_i^t = k \sum_j^N Y_j \Omega_{ij} + Y_i^\Phi,$$

where Ω_{ij} is the peak shape function, k the reduction coefficient, Y_i^b the background at the ith point, and Y_j the intensity of the jth reflection.

A line diagram based on the specified model is used for the construction of the theoretical profile (this requires the knowledge of the unit cell parameter, the symmetry space group, and the atomic coordinates).

The theoretical intensity is calculated by the formula

$$I_{hkl}=F_{hkl}^2 LPGn,$$

where L, P, and G are the Lorentz, polarisation, and geometrical factors respectively, n is the repeatability factor, and F_{hkl}^2 the structure factor. The structure factor is calculated in a general form in accordance with the formula

$$F_{hkl}^2=\left[\sum_{j=1}^{N} f_j\mu_j T_j \exp 2\pi i(hx_j+ky_j+lz_j)\right]^2$$

where x_j, y_j, and z_j are atomic coordinates, f_j is the atomic factor, μ_i the multiplicity of the atoms, T_j the thermal multiplier, and h, k, and l are the reflection indices.

Next, the line diagram is smeared by the function of the profile, which has parameters depending on the reflection angle. The neighbouring reflections contribute to the intensity at each point on the diffraction pattern. The main difficulty in the application of the Rietveld method involves the description of an individual profile of a reflection, since, in contrast to neutron diffraction, where Pearson's *VII* functions are used successfully, a similar unique theoretically well-founded function has not yet been proposed in X-ray diffraction. This is associated with the fact that the diffraction peaks corresponding to different reflection angles have different shapes and the experimental dependence of the peak half-width on the angle θ is not monotonic owing to effects caused by the real structure of the polycrystalline material (microdistortion, smallness of the coherent scattering regions, anisotropy, packing defects).[50,56–58] The majority of investigators[56,59–61] assume that a single profile is described most successfully by the generalised Pearson function:

$$P_{ij}=2\left(\frac{2^{1/m}-1}{\pi}\right)^{1/2}\frac{\Gamma(m)}{\Gamma(m-1/2)}H_j^{-1}\left[1+4\frac{(2\theta_i-2\theta_j)^2}{H_j^2}(2^{1/m}-1)\right]^{-m},$$

where Γ represents gamma-functions, H_j is the peak half-width (the width of the peak at the level of half its height); the power exponent m may be refined.

In our calculations, we used the version with $m = 2$ whereupon the Pearson function becomes a modified Lorentz function:

$$ML(2\theta_i, 2\theta_j)=\frac{2^{1/2}-1}{\pi H_j}\left[1+\frac{4(2^{1/2}-1)}{H_j^2}(2\theta_i-2\theta_j)^2\right]^{-2}.$$

According to Vainshtein's formula,[14] the dependence of H_j on θ_j has the form

$$H_j^2 = u\tan^2\theta + v\tan\theta + w.$$

The parameters u, v, and w are found from individual reflections and are refined.

In the FPA method, there are also other approaches, in particular the synthesis of the diffraction profile on the basis of specified instrumental, spectroscopic, and physical experimental parameters.[62] All the calculations are carried out in terms of Fourier coefficients, which ensures sufficient accuracy and speed. This approach made it possible to determine not only the structure but also the substructure parameters of substances.[63]

The FPA method is useful in the solution of many problems involving the refinement of structures whose type is already known. Such problems include the distribution of isomorphous impurities, the ordering of defects, the distribution of cations in spinels and other compounds, etc.[64–70] However, examples of the application of this method in the determination of unknown structures of new compounds also exist.[71–73]

The following structural parameters can be determined by the FPA method: (1) the atomic coordinates in fractions of the cells x, y, and z; (2) the overall thermal parameter (Q); (3) individual isotropic thermal factors of the ith atom; (4) the coefficient of the occupation of a given site by the ith atom (n_i); (5) the scaling coefficient (k).

In addition, a series of profile parameters, determining certain characteristics of the specimen and of the recording, can be refined: (1) the line half-width parameters u, v, and w; (2) the overall shift of the X-ray diffraction pattern relative to the origin z; (3) the lattice parameters A, B, C, α, β, and γ; (4) the asymmetry parameter P; (5) the texture parameter G; (6) the ratio of the intensities of the radiation components K_{α_1} and K_{α_2} (after passage through the monochromator, $I_{K_{\alpha_1}}$ and $I_{K_{\alpha_2}}$ may not be 2).

The experimental data obtained by the FPA method as well as the RDA method consist of measurements for individual points. The scanning step is determined by the line width (usually 0.01–0.05°). The use of Soller slits is obligatory. For a reliable determination of the profile parameters, it is recommended that individual peaks and non-doublet K_β radiation be employed.[67]

3. The method involving the determination of substructural characteristics

The method involving the determination of substructural characteristics (sizes of crystallites and their microdistortions, parameters determining the size distribution of crystallites), based on the harmonic analysis of the diffraction peak profiles, can be applied to systems of virtually any chemical composition in which the size of the crystallites is 30–1000 Å. An important feature is the fact that the substructural characteristics listed above refer directly to the component investigated (metal, oxide, salt, etc.) in the system under consideration.

The role of all the experimental factors influencing the profile of the diffraction maximum, such as the width of the slits on the collimator in the tube and in the counter, the focussing conditions etc. has been examined in detail.[74,75]

For a clear-cut differentiation of the profiles of the diffraction lines for the phase investigated, it is essential to carry out precision measurements of the line intensity at each point, which is achieved by scanning over the points with accumulation of a large number of counts. The lines are focussed using the 1:2:0.25 slit on the goniometer and monochromatised non-doublet CuK_β radiation (the monochromator is a flat graphite plate) in the range of angles exceeding by a factor of ~5 the half-width of the diffraction maximum. This is necessary in order to avoid additional errors associated with the numerical analysis of a profile of complex shape. The wide range of scanning angles ensures a satisfactory

determination of the line "tails", which is essential for the accurate determination of the Fourier coefficients. The correct determination of the profile of the instrumental line is very important.[76] Corondum (α-Al_2O_3) or silver black are chosen as reference standards. Their line profiles are described by the function

$$b^2 = u\tan^2\theta + v\tan\theta + w,$$

where u, v, and w are constants and θ is the Wulff–Bragg angle.

The substructural characteristics of deposited catalysts must be determined in four stages. The first stage consists in the separation of the diffraction maxima of the active component from the background due to the presence of the carrier. In the course of such treatment, the catalyst and carrier intensity curves are normalised and the background due to the carrier can be fitted by a polynomial. In the case of a single-phase system (for example, a metallic black) the problem simplifies and involves the usual separation of the background from the diffraction maximum.

The second stage reduces to the isolation from the experimental curve of the intensity of the profile associated with the physical broadening of the line (allowance for the instrumental line width). The third stage involves the finding of the fraction of the physical broadening of the line associated solely with the fine dispersity of the system (allowance from microdistortions). Warren's method is used for this purpose.[77] The method involving the expansion in Fourier series of the functions describing the profiles of the diffraction maxima of the reference standard and the test specimen is used in the second and third stages.

The parameters of the size distribution of the crystallites or the distribution function are found in the fourth stage. The profile of the diffraction maximum depends in principle on the crystallite size distribution function. However, according to Guinier,[78] the distribution of the lengths of sections in the crystallite (chords) perpendicular to the reflecting plane can be determined directly from the X-ray line profiles. It has been suggested[79] that the *hkl* line profile, determined by the reflection from crystallites, coincides with the profile of the diffraction line which arises in the presence of a set of parallel and incoherent linear sections. The ratios of the lengths of these sections must be the same as those of the chords of the grains perpendicular to the reflecting [h, k, l] plane. According to Bertaut's formula,[79] the intensity of the diffraction maximum is

$$I(x) = \int_0^\infty \frac{\sin^2 \pi A m x}{(\pi A x)^2} q(m)\, dm,$$

where $x = \theta - \theta_y$ is the angular scattering relative to the centre of gravity of the lines for the angle θ, $q(m)$ the function of the probability of the distribution of the lengths m of the chords perpendicular to the reflecting plane of the lattice in the set of crystallites, $A = (2\cos\theta)/\lambda$, θ is the Wulff–Bragg angle, and λ the radiation wavelength. The use of this equation presupposes that only the part of the physical broadening caused by the small size of the crystallites enters into the diffraction maximum profile. The profile is deduced from Fourier coefficients and normalised:

$$f_N(x) = f(x) \Big/ \int_{-\infty}^{\infty} f(x)dx.$$

The normalised function has a number of properties.[80] Thus, for $x = 0$ (at the maximum), we have $f_N(0) = 1/\beta = DA$, where $D = \lambda/2\beta\cos\theta$ is the average effective size of the crystallites (according to the Selyakov–Scherrer procedure) and β is the integral half-width of the line profile. The normalised function $f_N(x)$ is related to the function $I(x)$ by the expression

$$I(x) = (M_1/A) f_N(x),$$

where M_1 is the first moment of the chord length distribution function $q(m)$. The moment of any order of the chord length distribution function

$$M_n = \int_0^\infty m^n q(m)\, dm, \qquad M_2 = I(0)$$

can be expressed in terms of M_1:

$$M_{n+2} = (n+1)(n+2) M_1 \int_0^\infty m^n h(m)\, dm,$$

where $h(m)$ is the cosine component of the Fourier transformant $f_N(x)$.

Thus, knowing the diffraction maximum profile, it is possible, in principle, to determine the parameters characterising the size distribution of the crystallites, because the moments of the chord distribution curve can be determined on the basis of these data. The function itself can be deduced from the moments of the distribution curve. The quantity $V = M_2 - M_1^2$ characterises the variance of the distribution. In a study[8] using various methods of describing the distribution, such as the δ-function, the Gaussian function, the overall logarithmic distribution, and the lognormal distribution, it has been shown that the last distribution describes correctly the distribution of the chords in metallic particles on different carriers. The quality of the fit is characterised by the reliability coefficient. In our investigation,[81] it was also suggested that the chords present in the set of crystallites obey the lognormal distribution law (LND):

$$q(m) = \frac{1}{\sigma\sqrt{2}\,\pi m} \exp - \left(\frac{\ln m - \ln \mu}{2\sigma^2} \right).$$

The parameters μ and σ of the distribution can be obtained from the moments of the distribution curve $q(m)$ by means of the formula

$$\mu = M_1^2/\sqrt{M_2}, \quad e^{\sigma^2} = M_2/M_1^2.$$

A computer program was devised to interpret the experimental data. The following input information is used: (1) the intensities of two X-ray lines, of the specimen and the reference standard, the initial and final scanning angles, the scanning steps for the specimen in the reference standard, and the number of Fourier coefficients which must be calculated; (2) the range of the expansions; (3) the positions of the line maxima (either the position itself is specified or the centre of gravity is calculated); (4) the lattice parameter and Young's modulus. Young's modulus is required for the calculation of the microdistortions using the two lines corresponding to reflections from the [h, k, l] plane in different directions.

The calculated output data are as follows: (1) the Fourier coefficients of the initial lines of the specimen and the standard, the Fourier coefficients of the true physical broadening of each line, and the Fourier coefficients of the broadening due to the block structure

and microdistortions; (2) the curves deduced for the true physical broadening and the block structure normalised with respect to area; (3) the moments of the chord size distribution curve; (4) the distribution of the microdistortions; (5) the average particle size calculated from the Selyakov–Scherrer formula using the integral half-width of the function of the broadening induced by the block structure; (6) the positions of the centres of gravity of the initial lines.

Knowing the LND parameters μ and σ, it is possible to find (1) the most probable size of the crystallites m_0, (2) the average size of the crystallites in the bulk phase m, and (3) the area of the surface formed by the set of crystallites.

Thus the method involving the determination of substructural characteristics, based on the harmonic analysis of the diffraction peak profiles, yields information about the sizes of the crystallites, which exceed by a factor of 10^3 the wavelength, the microdistortions of the crystallites equilibrated in the bulk phase, and the parameters determining the size distribution of the crystallites. An important case of the breakdown of order in the crystal is that of the planar disorder. This is particularly important for close-packed structures or structures made up of planar networks superimposed in accordance with a definite law. The deviations from the general law governing the deposition of layers relative to one another in such structures influence significantly the diffraction line profiles.[76,78]

In principle all the characteristics obtained by the method considered, apart from the size of the microdistortions, can be determined with the aid of an electron microscope. However, the electron microscope method is local in scope and requires the availability of a large statistical set of data. Furthermore, the electron beam can affect small particles with a low melting point. The surface area of metals on carriers can also be determined by the chemisorption method. However, it is subject to a series of limitations determined by the assumptions underlying it. The application of this method presupposes the selective nature of the adsorption, the knowledge of the stoichiometric coefficient for the chemisorption of the adsorbate, and the availability of information about the number of surface metal atoms. The method involving the determination of substructural characteristics is usually employed to establish the size of the crystallites and of the microdistortions equilibrated within the bulk of the crystallite. We were able to supplement this information by data concerning the size distribution of crystallites.[81–83]

III. Structural and substructural characteristics of catalyst carriers

1. Aluminium oxides

(a) Low-temperature forms

The dehydration of the initial aluminium hydroxides above 473 K gives rise to the formation of different low-temperature forms of the oxides, depending on the nature of the hydroxides: amorphous, χ, γ, ρ, and η. In terms of their structure, these oxides are defective spinels, in the structure of which 21.33 cations are distributed among 24 cationic sites. In conformity with the requirements of stoichiometry and electroneutrality, they are described by the general formula $Al_{8/3}\square_{1/3}O_4$. The differences between the forms are manifested by the distribution of vacancies among the cationic sites. It has been suggested that the vacancies in γ-Al_2O_3 are located preferentially in octahedra, while those in the η-forms are in tetrahedra.[84–89]

The diffraction patterns of the low-temperature forms of aluminium oxide, obtained from pseudoboehmite, bayerite, and gibbsite, differ only slightly from one another. Characteristic regions exhibiting differences in the diffraction pattern correspond to each form. Analysis of these differences constitutes the basis of quantitative phase analysis.[20,90,91]

The RDA curves for the low-temperature forms differ from one another less than the corresponding scattering intensity curves (the RDA curve for the amorphous phase obtained from the deposited hydroxide is an exception).[20,92–94] This indicates the similarity of their structures and the equality of the interatomic distances and of the coordination numbers in the first coordination spheres.

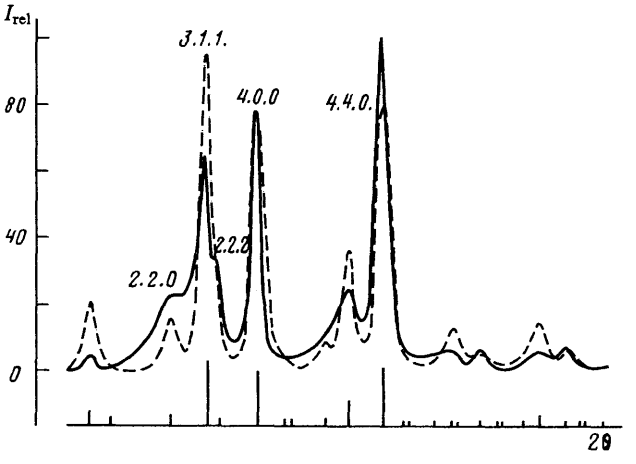

Figure 1. Fragments of the experimental (continuous line) diffraction pattern of η-Al_2O_3 and the pattern calculated on the basis of the defective spinel model with vacancies (dashed curve).[96]

We investigated by the FPA method the structures of the low-temperature oxides obtained from boehmite, pseudoboehmite, and bayerite.[95,96]

Models of defective spinels with different distributions of vacancies were used as the initial models for the calculation of the diffraction patterns: in octahedra—$Al[Al_{13.33}\square_{2.67}]O_{32}$ and in tetrahedra—$Al_{5.33}\square_{2.67}[Al_{16}]O_{32}$. The calculations were carried out within the framework of the space group $Fd3m$ with the origin of coordinates at a tetrahedral cation. Fig. 1 presents the experimental diffraction pattern of η-Al_2O_3 and the pattern calculated on the basis of the spinel with vacancies model. Evidently the most intense experimental line is 4.4.0, whereas according to the calculation the most intense line should be 3.1.1. Furthermore, the experimental intensity of the 2.2.2 line is appreciably higher than the calculated intensity. The difference between the calculated and experimental densities is also significant: the calculated density is 3.62 g cm^{-3}, while the experimental densities range from 3.35 to 3.42 g cm^{-3} for different forms. The unreliability factor R is about 40% for both models described by the general formula $Al_{21.23}\square_{2.67}O_{32}$. A change in the distributon of vacancies between the tetrahedral and octahedral sites does not reduce R.

In the real structures of the low-temperature oxides, an appreciable proportion of the anions exist as OH^- groups. Having included these groups in the structure, it is possible to describe the oxides by the general formula $Al_2O_3.nH_2O$, where $0 < n < 0.6$. According to this formula, the ratio of the numbers of cations and oxygen atoms is altered and this makes it possible to consider formally another spinel structure with a greater number of cationic vacancies. By varying the number of these vacancies in the range from 2.67 to 6.5, which corresponds to a number of water molecules between 0 and 0.6, it is possible to reduce the R factor to ~30% for the optimum number of vacancies of about 5. Variation of the distribution of vacancies among the cationic sites within the limits indicated does not reduce the R factor.

The space group $Fd3m$ permits the existence of two pairs of cationic sites when the origin of coordinates is selected at the point $\bar{4}3m$: it is possible to select the coordinates A(0; 0; 0) or A*(0.5; 0.5; 0.5) for the eightfold site (tetrahedra) and B(0.625; 0.625; 0.625) or B*(0.125; 0.125; 0.125) for the sixteenfold site (octahedra). The use of only the coordinates A* and B* is equivalent to a shift of the origin of coordinates, which naturally does not alter the R factor. A model of the type $A^*_{x_1}A_{x_2}B^*_{y_1}B_{y_2}O_{32-z}(OH,...)_z$ was examined. It follows from steric considerations that the use of type A* coordinates is possible only when the four nearest octahedral cations B are removed simultaneously. The disposition of the cations B* requires in its turn the removal of two nearest cations A displaced relative to one another by a vector with the coordinates 0.25; 0.25; 0.25. The B* atom is then located at the centre of the vector.

Several models of the structures of the low-temperature oxides were calculated. The data for modelling the η-Al_2O_3 structure are presented in Table 1, which also indicates the unreliability factors and the calculated densities. It follows from the Table that the lowest unreliability factor corresponds to the structural formula

$$A^*_{1.5}A_{6.75}B^*_{1.0}B_{10.0}O_{32-z}(OH,\ldots)_z,$$

where A and B are the spinel cationic sites and A* and B* are the non-spinel cationic sites.

Table 1. Modelling of the η-Al_2O_3 structure.

Parameter	1	2	3	4
x_1	–	–	–	1.5
x_2	5.66	8.0	7.75	6.75
y_1	–	–	–	1.0
y_2	16.0	13.66	11.5	10.0
R	45.6	44.7	34.1	10.1
d, g cm^{-3}	3.60–3.70		3.33–3.35	

Note. The following notation has been adopted for the models: 1, $A_{5.66}\square_{2.33}B_{16}O_{32}$; 2, $A_8B_{13.66}\square_{2.33}O_{32}$; 3 and 4, $A^*_{x_1}A_{x_2}B^*_{y_1}B_{y_2}.O_{32-z}(OH,...)_z$.

Table 2 presents the structural formulae and data for the distribution of cations in the low-temperature oxides. It is striking that anionic modification of the low-temperature oxide (inclusion of OH groups in the anionic skeleton) entails cationic modification (new positions of the aluminium cations). Such compounds are referred to as "protospinel" compounds.[97]

Table 2 shows that the fraction of tetrahedral cations is almost the same in all the forms (0.4–0.46). The greatest number of filled tetrahedra (8.5) combined with the smallest number of filled octahedra (10.0) occurs in the $\gamma_{\pi/\sigma e}$-Al_2O_3 form. In terms of the ratio of the numbers of tetrahedra and octahedra the oxides can be arranged in the series $\gamma_{\pi/\sigma e} > \eta > \gamma_{\sigma e}$.

Table 2. Structural formulae and the distribution of cations in low-temperature aluminium oxides.

Form of oxide	Fraction of tetrahedra (T)	Fraction of octrahedra (O)	T/O	A+B	A*+B*	$\frac{A+B}{A^*+B^*}$
$\gamma_{\sigma e}$	0.40	0.60	0.66	14.5	3.75	3.9
$\gamma_{\pi/\sigma e}$	0.46	0.54	0.85	15.75	2.75	5.7
η	0.43	0.57	0.75	16.75	2.5	6.7

Note. The following forms of the oxides were examined:

$\gamma_{\sigma e} - A^*_{1.75}A_{5.50}B^*_{2.0}B_{9.0}O_{22.75}(OH,\ldots)_{9.25}$;

$\gamma_{\pi/\sigma e} - A^*_{1.75}A_{6.75}B^*_{1.0}B_{9.0}O_{23.5}(OH,\ldots)_{8.50}$;

$\eta - A^*_{1.50}A_{6.75}B^*_{1.0}B_{10.0}O_{23.75}(OH,\ldots)_{6.25}$.

Thus on the basis of the real diffraction pattern and using the method of the full-profile analysis, we established that the low-temperature forms γ- and η-Al_2O_3 cannot be described as spinel-type structures with a statistical or regular distribution of vacancies. If the space group $Fd3m$ is adopted as a basis, then the above forms can be regarded as structures in which two allowed tetrahedral and two allowed octahedral sites are filled statistically. Each form has its own characteristic number of anions consisting of hydroxy-groups or other residual groups of the type NO_3^-, Cl^-, etc.

The OH groups were regarded[98] as the structural elements of the low-temperature forms, but it was assumed that there are vacancies in the cationic sublattice: $Al_{20}\square_4O_{28}(OH)_4$. Using the general Debye formula for the scattering intensity and comparing the synthesised and experimental diffraction patterns, Espinat, et al.[99] confirmed the validity of the model of γ-Al_2O_3 described above.

(b) High-temperature forms

The high-temperature δ- and θ-forms of aluminium oxide are also used widely as carriers for catalysts of high-temperature processes. They are produced from γ- and η-Al_2O_3 by dehydration at temperatures above 1100 K. It has been shown by the RDA method[94] that, together with the loss of OH groups, dehydration involves a rearrangement of the structures associated with a decrease and increase in the filling of the octahedral and tetrahedral cationic sites respectively. Under these conditons, new cationic sites, uncharacteristic of the low-temperature forms, are filled. The high-temperature aluminium oxides differ in the filling of the cationic sites and are described by the general formula $E_RA^*_{x_3}A_{x_4}B^*_{y_3}B_{y_4}O_{32-f}(OH,...)_f$, where $R + x_3 + x_4 + y_3 + y_4 < 21.33$ and f is the number of structural OH and other groups. The

formation of the δ- and θ-forms can be regarded as a result of the structural compensation for the partial removal of hydroxy-groups and other anionic "impurities" during the complete dehydration of the hydroxides to anhydrous α-Al_2O_3.

(c) Promoted aluminium oxides

The refinement of the structures of the low-temperature aluminium oxides made it possible to put forward a hypothesis concerning the mechanism of the formation of the solid solutions and non-stoichiometric spinels obtained when cations and anions are introduced. Since all the ionic sites in the structures of the oxides are characterised as regards their positions in the cell and the degree of their filling, it is possible to construct models of the hydroxide oxide compounds modified by cations and anions.

The polymorphic transformations occurring on aluminium oxides have been investigated[100–106] and the phase compositions and structures of the low-temperature oxides promoted by divalent and trivalent cations (Mg^{2+}, Ni^{2+}, Cu^{2+}, Cr^{3+}) have been analysed. It has been shown[102–104] that the low-temperature solid solutions are formed in these systems as a result of the filling of the vacancies in the bulk-phase structure of the spinel and by the substitution of certain tetrahedral and octahedral sites in the structure of the protospinel. The substitution of aluminium by a divalent cation in the protospinel structure, without a distinct preference for an octahedral or a tetrahedral environment, leads to the breakdown of the electroneutrality of the Al_2O_3 molecule. The excess charge can then be compensated either by an increase in the number of hydroxy-groups in the anionic skeleton (on formation of mixtures of hydroxides by coprecipitation) or by the removal of some of the anions, i.e. OH^- and NO_3^- (during heat treatment). In both cases, a general disordering of the structure, in particular of the anionic skeleton, is observed, which is manifested by a frequently noted broadening of the diffraction maxima. Another way of compensating for the excess charge is also possible. This can be achieved if the cations occupy preferentially the tetrahedral sites and involves a rearrangement of the cationic skeleton. Such rearrangement can be attained by the migration of aluminium from the A* and B* sites to the A and B sites respectively and the disposition of the divalent cations in the A sites. This results in the formation of a normal spinel of the type AB_2O_4. The location of the divalent cation in a tetrahedral site A does not require structural compensation, because it corresponds to the arrangement typical for a spinel. In such systems an increase in temperature does not entail the formation of the intermediate δ- and θ-forms of Al_2O_3.

The distribution of cations in the structure of an alumino-magnesium spinel with a non-stoichiometric composition was refined[107] by the FPA method. The magnesium and aluminium cations were detected at sites uncharacteristic of a spinel. These cations are regarded as point defects. It was established by the method involving the determination of substructural characteristics that the dominant type of defects in the specimen is packing defects caused by half-dislocations, whose concentration is virtually identical with the concentration of the detected point defects. The presence in the specimen of specific extended defects, whose orientation is identical with that of the half-dislocation vector, was confirmed by high-resolution electron microscopy. The non-stoichiometric aluminomagnesium spinel was investigated by a version of the FPA program, in which provision is made for the possibility of refining individual profile parameters of the diffraction peaks. The solution of this problem can also be assisted by the application of the versions used in other studies.[68,108]

2. Carbon carriers for catalysts

Carbon materials are widely used as sorbents, but recently porous carbon materials have come to be used also as carriers for metallic catalysts and as catalysts themselves. The study of the structural and substructural characteristics of these materials is extremely important for the elucidation of their adsorption and texture characteristics in order to achieve an understanding of the chemistry of their surfaces. The carbon materials investigated include Sibunit, Altunit, activated charcoals (from Saran plastic and birchwood), acetylenic carbon black, and brown coal semicoke.[20,109–111]

The following characteristics were determined for Sibunit: degree of crystallinity K = 0.65, fraction of aromatic carbon A = 1.0, degree of three-dimensional order γ = 0.3, size of crystallites in the plane of aromatic layers L_a = 35 Å, size of crystallites in the direction at right angles to the plane of aromatic layers (thickness of packets of layers) L_c = 40 Å. The size distribution of the particles was determined for Altunit by X-ray diffraction, which yielded a variance of the distribution V = 230 Å^2, the average particle size L = 20 Å, and the most probable particle size m_0 = 10 Å. It was established that microdiffraction does not occur in Altunit. It was suggested that Silbunit has a graphite-like structure, while Altunit has a diamond-like structure. The interatomic distances r and coordination numbers were calculated for these structures and were determined from the RDA curve (Tables 3 and 4).

Examination of Tables 3 and 4 showed that Tibunit has a somewhat disordered graphite structure while Altunit has the diamond structure. A globule 35 Å in diameter is a coherently scattering element in Sibunit, which corresponds to ~100 unit cells. The layered structure is retained in such a globule, but the interlayer distance along the c axis has increased owing to the azimuthal disorientation of the graphite networks. Together with the three-dimensionally ordered crystalline carbon, the specimen contains also carbon in the form of two-dimensional hexagonal formations, i.e. the entire carbon is aromatic (A = 1).

The diamond structure of Altunit is characterised by an increased unit cell parameter a (Δa = 0.007 Å). This change is apparently associated with the high dispersity of the material (the size of the crystallites is ~20 Å). An important characteristic of Altunit is the absence of microdistortions equilibrated in the bulk of the crystallite. The [size] distribution of the particles in this material is fairly narrow.

Carbon carriers also include activated charcoals differing in their porous structure: Saran and birchwood charcoals, brown coal semicoke, and acetylenic carbon black.[112] The Saran charcoal has the most perfect structure; the highest degree of three-dimensional order (γ = 0.3) and high degrees of aromaticity and crystallinity are characteristic of this material. The RDA curves for the above carbon materials show that the Saran charcoal is also distinguished by a more pronounced long-range order than, for example, acetylenic carbon black, which exhibits a weak three-dimensional order and a low aromaticity and crystallinity.

IV. Structural and substructural characteristics of deposited and non-deposited monometallic catalysts

The development of X-ray diffraction methods for the study of highly disperse systems and refinement of the structures of catalyst carriers have made it possible to carry out precision analyses of highly disperse metal–carrier systems. In the course of such investigations, it was essential to answer the question whether the metal–carrier system is additive and whether it is permissible to use the structural and substructural characteristics of highly disperse non-deposited metals (blacks) in the study of deposited particles. Can blacks serve as reference standards for the construction of difference RDA curves? What is the role of the carrier in the stabilisation of the active component?

Table 5. Substructural characteristics of metal blacks.[81,82]

Crystallographic direction	L, Å		$10^{-2} \cdot V$, Å^2		m_0, Å		$10^3 \cdot \varepsilon$	
	Pt	Pd	Pt	Pd	Pt	Pd	Pt	Pd
[111]	38	370	9.8	111	16	330	3.8	1.2
[100]	38	215	4.8	50	22	180	3.8	1.4

The study of the structural and substructural characteristics of highly disperse and non-deposited metals (Pt, Ir,[35,81] Pd,[82] and Ni[112]) showed that, as the size of the crystallites decreases from 700 to 40 Å, the coordination peaks (CP) on the RDA curves are broadened and their area diminishes. The mean square displacements of the atoms relative to the equilibrium position are ~3% of the shortest distance. Analysis of the RDA curves showed that the blacks exist in a polydisperse state, i.e. the coordination peak areas on these curves do not exhibit an unambiguous dependence on dispersity. The substructural characteristics of the non-deposited metals depend significantly on the average size L of the crystallites (Table 5): for large values of L, a wider size distribution of the crystallites is observed, mainly in the direction of the growth of the particles [111], while small particles are isotropic. Small crystallites are distinguished by greater microdistortions, which alter the structural characteristics—the unit cell parameter (by 3×10^{-3} Å) and the coordination numbers.[35]

The substructural characteristics of the non-deposited and deposited highly disperse metals were compared for aluminoplatinum catalysts and platinum blacks.[83] Model catalysts containing 3.8 wt.% Pt on γ-Al_2O_3 and blacks heat-treated at different temperatures were used as the objects of study. Table 6 shows that the black and the non-deposited aluminoplatinum catalyst, heat-treated at the same temperature (773 K), are characterised by significantly different average sizes of the crystallites and variances of the size distributions of the particles. The size distribution of the platinum particles in the non-deposited catalyst is narrower.

Table 6. Comparison of the substructural characteristics of highly disperse deposited and massive metals.[83]

Specimen, heat treatment temperature	Pt, wt.%	S_{sp}, m^2 g^{-1}	Substructural characteristics			Microdistortions, $10^3\varepsilon$
			L, Å	$V \cdot 10^{-2}$, Å^2	m_0, Å	
Pt/Al_2O_3, 773 K	3.8	88±8	46	3.7	35	–
Pt/Al_2O_3, 1103 K	3.8	1	160	96	100	–
Pt black, 773 K	–	6±2	150	154	70	1.4
Pt black, 333 K	–	–	38	9.8	20	3.8

The structural characteristics of the non-deposited metals were obtained by the RDA method. Table 7 indicates the interatomic distances and the coordination peak areas as well as the sizes of the crystallites (L) for aluminoplatinum catalysts containing 2.4 and 7 wt.% Pt on γ-Al_2O_3. Analysis of the Table shows that only a certain proportion of platinum is present in the face-centred cubic structure of the metal and varies within the range 0.5–0.7. The ratios of the coordination peak areas corresponding to different coordination spheres (26:58:62:102 and 112:245:234:465) for catalysts with platinum contents of 2.4 and 7 wt.% respectively are close to the theoretical ratios 1:2:2:4. This shows that the metal particles are ordered and well crystallised.

Thus it follows from the comparison of the substructural and structural characteristics of the non-deposited and deposited metals that the carrier influences significantly the state of the metallic highly

disperse particles: the structure of the deposited particles is closer to ideality (the changes in the interatomic distances and coordination numbers characteristic of the blacks are not observed and there are no microdistortions). It becomes clear why the affinity of the adsorption isotherms on the deposited catalysts holds only when the crystallised black is used as the reference standard:[113] the metal on the carrier surface apparently exists in a micro-single crystal state, i.e. the similarity of the adsorption properties is a consequence of the identity of the structural and substructural characteristics.

Table 7. Theoretical and experimental interatomic distances (r) and coordination numbers for deposited aluminoplatinum catalysts.

*P_e/P_c is the ratio of the experimental and calculated coordination peak areas.

Comparison of the structural and substructural characteristics of the deposited and non-deposited metals shows that highly disperse blacks cannot serve as reference standards for the construction of the difference RDA curves in the study of the phase composition of deposited catalysts.

Catalysts containing 1.5–30 wt.% of platinum, iridium, and palladium on γ-, χ-, η-, and θ-Al_2O_3 [36–38,40,114–117] and on carbon carriers[39] were also investigated, the dispersity of the active component was estimated, and data were obtained for the phase compositions of the catalysts at different stages of their preparation. The dispersity and composition of the active component depend on the conditions in the preparation of the catalyst: when they are prepared by the method involving the impregnation of carriers with a solution of the metal-containing component, the temperature and composition of the gas phase play a significant role. After impregnation with a chlorine-containing substance and drying in air, a complex between the carrier and the $(MCl)_6^{2-}$ anion is formed in the catalyst, some of the chloride ions in the complex being replaced by hydroxy-groups. Activation by oxidative treatment at 723 K leads to the decomposition of the complex and an interaction phase, incorporating the metal ion, arises between the carrier and the active component. This phase has a spinel-like structure.[36,115] Metal ions are not distributed statistically on the surface of the carrier but are incorported in its structure. The reduced catalysts contain not only the metallic phase but also the interaction phase.

Fig. 2*a* presents fragments of the diffraction scattering intensity curves on the η-Al_2O_3 carrier and the 10 wt.% Ir/η-Al_2O_3 catalyst as well as the difference intensity curve (DIC). On the latter, there is a diffraction maximum due to iridium (0.2.2) (2θ = 69°2′) and the maximum (4.4.0) of the protospinel phase, the unit cell parameter of which has increased by 0.01 Å compared with that of the carrier. The position of the 0.2.2 line coincides with the theoretical position calculated for the iridium single crystal with a face-centred cubic latice. The RDA curve was plotted on the basis of the difference intensity curve (Fig. 2*b*). Together with the peaks corresponding to the interatomic distances in the face-centred cubic lattice of iridium (r = 2.7, 3.84, 4.70, 5.43, 6.07, 7.18 Å), the RDA curve contains a peak due to the protospinel interaction phase (r = 3.3, 4.2, 5.2, etc. Å). The amount of iridium incorporated in the form of ions in the interaction phase is determined by the overall content of the deposited metal, the structure of the carrier, and the temperature and composition of the gaseous medium. For a large iridium content in the ionic form, the specimens exhibit an enhanced chemisorption capacity in relation to hydrogen, which is associated with the additional adsorption of hydrogen on the modified carrier.[37,38]

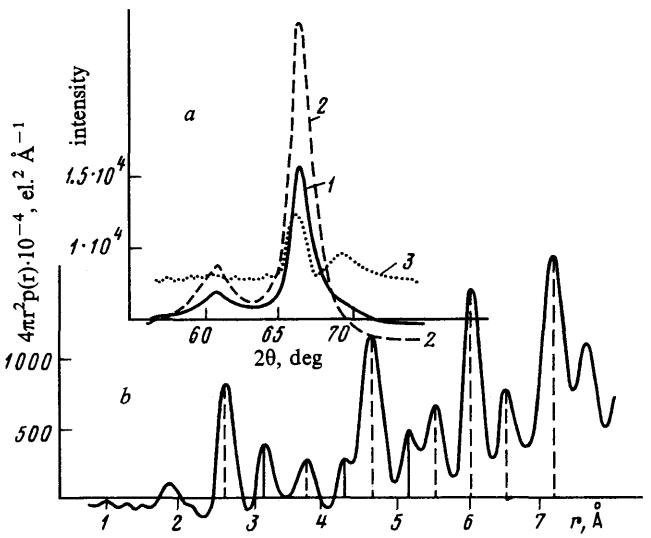

Figure 2. Fragments of the curves for the diffraction scattering of X-rays by the 10% Ir/η-Al_2O_3 catalyst (curve *1*) and the carrier (curve *2*) (in counts) and the difference intensity curve (curve *3*) (in electronic units) (*a*) as well as the difference RDA curve calculated from the difference intensity curve[42] (*b*).

The study of different deposited metallic catalysts showed[20] that in the general case the metal can exist in the following states: (a) as metallic particles distributed on the carrier surface; (b) as oxide particles or as an oxide film on the surfaces of large crystallites; (c) as the phase due to the interaction with the carrier, which is formed on activation (heat treatment with air) of the catalyst. The existence of these states and their thermal stability together with diffusional atom (particle) migration processes influence one of the most important characteristics of the deposited catalyst—the dispersity of the active component.

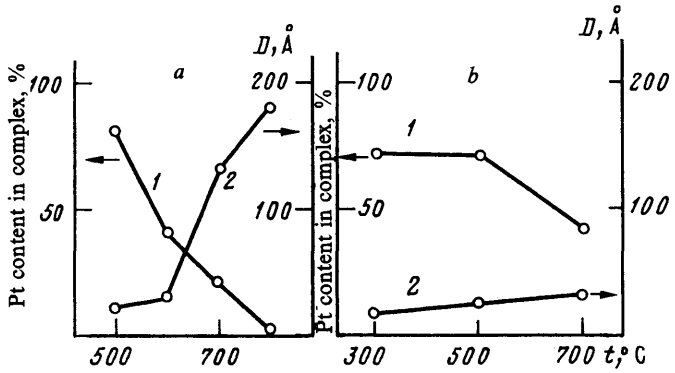

Figure 3. Dependence of the amount of Pt^+ (line *1*) and the Pt^0 particle size (line *2*) on the heat treatment temperature of the aluminoplatinum catalyst in oxidising (*a*) and reducing (*b*) gaseous media.[129]

Table 8. Certain characteristics of platinum catalysts on various carriers.

Carrier	Specific surface of carrier $m^2\ g^{-1}$	Pt^0/Pt^+	*L*, Å
γ-Al_2O_3	140	0.6	30
η-Al_2O_3	350	0.5	30
θ-Al_2O_3	70	0.4	30
SiO_2	300	1.0	100
C	600	0.4	30
$ZnAl_2O_4$	12	1.0	350

Fig. 3 presents the dependences of the sizes of the platinum crystallites *D* in the aluminoplatinum catalyst and of the amount of platinum incorporated in the interaction phase on the temperature in various gaseous media. In an oxidising medium (Fig. 3*a*), an antiparallel relation is observed between the amount of Pt^+ in the carrier structure and the dispersity of the metallic particles distributed on the surface. Evidently, the decomposition of the spinel-like phase results in the concentration of atoms on the surface and in the sintering of the active components. The decrease in the amount of platinum bound to the carrier apparently lowers the number of sites where the metallic particles are fixed on the carrier surface, which entails the sintering of these particles. A similar explanation was given, for example, in a study[118] of the role of ions as "energy traps" for metallic particles. In a reducing medium (Fig. 3*b*), a decrease in the amount of platinum bound to the carrier does not cause a sharp alteration of the sizes of the crystallites, because above 773 K an increase in the dispersity of the active component due to the dissolution of hydrogen in platinum is observed.[114] During phase transformations in the carrier, the interaction phase also decomposes, this being accompanied by the appearance of highly disperse metallic particles.[38] The Pt^0 and Pt^+ active centres exhibit definite catalytic activity: Pt^0 is active in the cyclohexane dehydrogenation reaction and Pt^+ is active in the dehydrocyclisation of n-heptane.[119,120] Table 8 presents the results of the comparison of the platinum impregnation catalysts deposited on sections of the carrier differing in their chemical nature and in their specific surfaces.

The Table shows that the amount of metal incorporated in the interaction phase is determined not by the surface area of the carrier but by its structure. The bulk-phase structure of the carrier determines also the number of reactive groups which can participate in the formation of the sites where highly disperse zerovalent metal particles are fixed.

V. Determination of the phase composition of deposited bimetallic catalysts

It is fairly difficult to obtain information about the structure of highly disperse bimetallic deposited catalysts, because mainly a comparative method is used for this purpose: the RDA curves for the carrier, the active component with the carrier, and the modifying element with the carrier are compared with the RDA curves for the bimetallic catalyst. The results of the X-ray diffraction study are therefore mainly qualitative and concern the phase composition. We shall consider the study of platinum–rhenium, platinum–tin, and nickel–tin catalysts.

1. Platinum–rhenium catalysts

Platinun–rhenium catalysts on γ-Al_2O_3, obtained by the impregnation method, were investigated by Ushakov, et al.,[121] who compared specimens containing only platinum, only rhenium, and a combination comprising 2 wt.% Pt + 0.8 wt.% Re. Analysis of the difference curves showed that (1) in both the bimetallic and aluminorhenium catalysts there is no metallic rhenium phase; (2) the areas of the coordination peaks for the platinum structure in the bimetallic catalyst are smaller than in the aluminoplatinum catalyst; (3) the areas of the coordination peaks for the carrier structure in the bimetallic system increase for the octahedral distances (Fig. 4). This permitted the conclusion that the rhenium in the bimetallic catalyst is present in the oxidised state (during preparation, the carrier interacts with rhenium ions) and the dispersity of platinum increases.

Analysis of the diffraction patterns recorded accurately by a procedure involving the accumulation of 2×10^5 counts did not reveal the shift of the diffraction maxima characteristic of the platinum–rhenium alloy. Platinum–rhenium catalysts on silica gel, obtained by the method involving the successive impregnation of the carrier with NH_4ReO_4 and H_2PtCl_6 solutions and the deposition of the organometallic complexes $[Re(OC_2H_5)_3]_3$ and $Pt(\pi\text{-}C_4H_7)_2$, were also investigated.[122]

Fig. 4 presents the RDA curves for the two specimens investigated. Im the impregnation specimen, the active component exists in a fairly coarsely disperse state: all the coordination peaks correspond, as regards their areas and positions, to the structures of the metallic rhenium and platinum, the Pt–Re alloy phase not being observed. The RDA curve for the catalyst obtained by the immobilisation of the platinum particles on the rhenium ion-modified silica gel surface has only the first coordination peak of the face-centred cubic structure of platinum. Hence it follows that platinum crystallises in a highly disperse state (the crystallite diameters are ~6 Å). The state of rhenium can be inferred from the coordination peak at r = 2.48 Å. This value of r corresponds to the

Re–Re distance in the trinuclear rhenium complexes used for the deposition of low-valence ions on the silica gel surface. The conclusions reached were confirmed by other physical methods (EXAFS, X-ray photoelectron spectroscopy, chemisorption).[123]

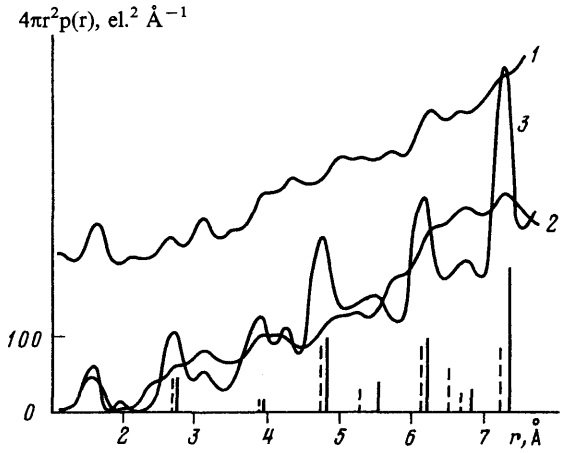

Figure 4. RDA curves for the SiO_2 carrier (curve *1*) and the platinum–rhenium catalysts obtained from organometallic compounds (curve *2*) and by the impregnation method (curve *3*).[123]

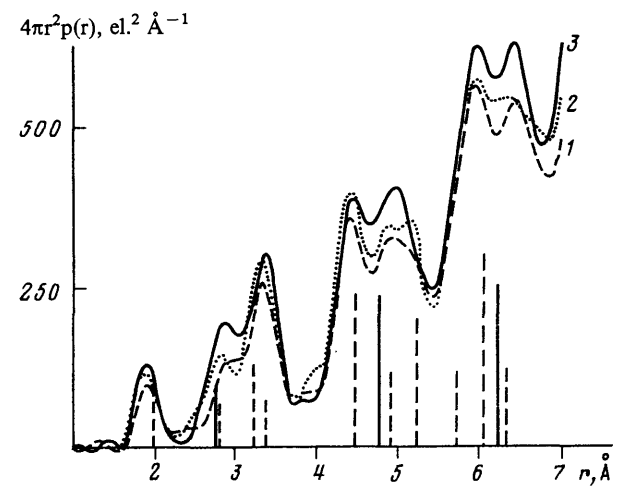

Figure 5. RDA curves for the γ-Al_2O_3 carrier (curve *1*), the aluminotin catalyst (curve *2*), and the aluminoplatinum–tin catalyst (curve *3*).[124]

2. Platinum–tin catalysts

In the course of the development of a thermostable and selective catalyst for the aromatisation of paraffinic hydrocarbons,[124,125] it was observed that the aromatising activity and stability of the catalysts synthesised by the interaction of platinum tetrachloride with low-valence tin ions stabilised on the aluminium oxide surface is appreciably higher than that of the reference catalyst prepared by the impregnation method. In order to elucidate the causes of the modifying effect of tin, a study was made of specimens containing 2.5 wt.% Sn and 2.6 wt.% Pt + 3.9 wt.% Sn on γ-Al_2O_3. The form of the RDA curves (Fig. 5) indicates the absence of the metallic tin phase and of Pt–Sn alloys.

The dispersity of the crystalline platinum phase is high (the size of the crystallite is ~10 Å) and tin is incorporated in the carrier surface, forming a spinel-like phase (the areas of the coordination peaks corresponding to the A–B, B–O, and B–B distances increase). Mössbauer spectroscopic data also confirmed that tin does not form an alloy with platinum but is present in the carrier structure. The effective charge on the platinum atoms decreases in the presence of Sn^{2+} ions (X-ray photoelectron spectroscopic data), which alters the adsorption and catalytic properties of platinum. The coordinatively unsaturated tin ions on the carrier surface are centres for the stabilisation of platinum atoms. The increase in the energy of the interaction of the active component with the carrier is indicated by the thermal stability of the active phase (the dispersity of platinum is close to the limiting value and persists for a long time up to a reduction temperature of ~873 K).

When silicon oxide modified by tin acetate is used as the carrier,[126] the phase composition of the active component is different: part of the tin (~$^1/_3$) is reduced to the zerovalent state, forming the Pt_3Sn alloy, while the remainder is bound chemically to the SiO_2 surface. Thus the state of tin on silica gel is different than on γ-Al_2O_3. The catalytic properties are likewise different: the catalysts on γ-Al_2O_3 propagate the hydrogenolysis and aromatisation reactions at temperatures above 673 K and are inactive up to this temperature in benzene and cyclohexane hydrogenation reactions, whereas catalysts on SiO_2 are active in the former reaction already at 373 K and in the latter at 523 K.

The platinum–tin catalysts on a zinc–aluminium spinel are used for the single-stage dehydrogenation of lower paraffins to diolefins in water vapour at atmospheric pressure.[127] The study of the genesis of the phase composition of a catalyst containing 0.4–1 wt.% Pt + 1–5 wt.% Sn at all stages of their preparation showed that the gaseous medium used in the preliminary heat treatment affects significantly the composition of the catalyst. Reduction directly after drying of both monometallic and bimetallic catalysts (H_2, 848 K) leads to the formation of inactive intermetallic compounds with zinc (ZnO enters into the composition of the carrier as an excess phase), the composition of these compounds being determined by the ZnO content. After activation in an oxidising medium with water vapour, the X-ray diffraction patterns of the platinum–tin and monometallic platinum catalysts show the platinum lines corresponding to the normal unit cell parameter. Tin is then present in an oxidised state. With increase in the zinc content, there is also an increase in the dispersity of platinum (the particle size diminishes from 130 to 60 Å) and there is also a decrease in the fraction of well crystallised platinum. After activation, there is no interaction of the active components with one another and with the carrier and the SnO_2 and Pt phases are present on the carrier surface.

A solid solution of tin in platinum with a face-centred cubic lattice is formed during the dehydrogenation reaction. For the ratios Pt:Sn = 1:3 and 1:5, the intermetallic compound Pt_3Sn with a primitive cubic cell is formed, whereas in the presence of a high platinum content the PtSn and $PtSn_2$ alloys are produced.

An important feature of the catalysts investigated is that the platinum–tin alloys are stable only in the reaction medium and are produced solely when acted upon by the latter. The regeneration of

the catalyst (elimination of carbonaceous deposits) leads to the decomposition of the alloys. However, when a new dehydrogenation cycle is carried out, the platinum–tin alloys are reformed already in the first minutes.

The role of the modifying additive is interesting. The tin in the platinum catalysts deposited on a spinel can play a dual role—it can serve either as a promoting agent, increasing appreciably the activity and selectivity of platinum in the lower paraffin dehydrogenation reaction (alloys containing $\leqslant 25$ at.% of tin, having the platinum structure, are then formed in the catalyst) or behaves as a catalytic poison (on formation of alloys with a high tin content). Similar results were obtained for catalysts deposited on a magnesium–aluminium spinel.

3. Nickel–tin catalysts

The addition of tin to aluminonickel catalysts alters significantly the mode of reaction of unsaturated hydrocarbons: nickel catalysts accelerate the hydrogenolysis reaction, while nickel–tin catalysts on γ-Al_2O_3 exhibit an aromatising activity at high temperatures, which is typical of the Pt/Al_2O_3 catalysts.[124]

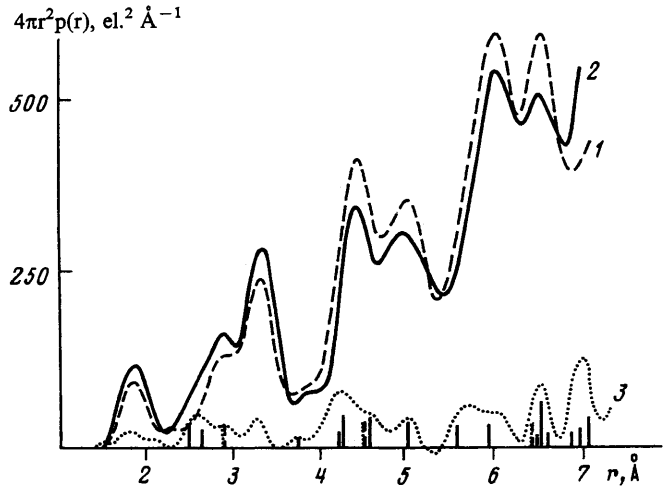

Figure 6. RDA curves for the γ-Al_2O_3 carrier (curve *1*) and the aluminonickel–tin catalyst (curve *2*) as well as the difference RDA curve (curve *3*).[128]

Diffractometric studies[128] of nickel–tin catalysts (1.7 wt.% Ni + 3.5 wt.% Sn on aluminium oxide) showed that the α-Sn phase with a particle size of 50 Å and a metallic nickel phase are formed in the specimens reduced at 823 K. Metallic nickel phases with a face-centred cubic structure (r = 2.50, 4.30, 5.56, and 6.58 Å), metallic α-Sn phases (r = 2.97, 3.17, 4.57, and 6.49 Å), and metallic nickel phases with a hexagonal structure (r = 2.66, 3.75, 4.33, 4.60, 5.08, and 5.93 Å) are detected on the difference RDA curve (Fig. 6). The stabilisation of the last structure is known to require the obligatory presence of admixtures of other metals. Indeed, data concerning the effect of temperature on the relative magnetisation of nickel–tin catalysts show that their Curie point is lower by 40 K than for the catalyst without the additive. This confirms the formation of a nickel–tin alloy (containing 2% of tin). X-Ray spectroscopic data and analysis of the Mössbauer spectra also confirm the presence of a Ni–Sn alloy in the catalysts investigated, but the Mössbauer spectroscopic data indicate also the presence of Sn^{2+} in the carrier structure. The RDA curves also have maxima corresponding to the interatomic distances in the phase in which the tin interacts with aluminium oxide (r = 1.76 and 3.30 Å). The surface Sn^{2+} ions on the carrier are apparently centres for the stabilisation of highly disperse alloy particles.

VI. Conclusion

Thus, despite the apparently small amount of information contained in the initial diffraction data (the diffraction peaks are small, diffuse, and frequently superimposed on another), an appropriate formulation of the experiment with interpretation of the results by modern computer techniques makes it possible to obtain a lot of useful data on the phase composition (RDA method) and the structural (FPA method) and substructural (RDA and MDSC methods) characteristics of the test objects.

During the last decade, the long-range fine structure of the X-ray absorption spectra of a given chemical element (EXAFS spectroscopy) began to be studied widely in the investigation of the structure of its local environment.[46,47] This method has many advantages over the X-ray RDA method: (1) selectivity, associated with the possibility of obtaining independent RDA curves for the local environment of each chemical element in the specimen; (2) the possibility of determining not only the interatomic distances and coordination numbers but also the kind of atoms in the vicinity of the specified atom. A powerful source of X-rays (synchrotron radiation) is usually employed in this method, which makes it highly sensitive and rapid. Such a source can be used also in the X-ray diffraction method. However, the EXAFS method is inferior to the X-ray diffraction RDA method in that the information obtained with its aid concerns mainly 1–2 coordination spheres in the structure, which significantly hinders the analysis of the structural characteristics. On the other hand, one obtains by the EXAFS method interatomic distances which are not absolute but involve a phase shift. Problems arise also in the determination of the coordination numbers.

Despite the existence of a number of difficulties concerning also the very principles of the EXAFS method and the procedures used to extract structural information, at the present time it is widely employed in the study of catalysts.[47] The data for metallic deposited catalysts obtained by this method in the main agree with the results obtained previously by the X-ray diffraction RDA method. It is apparently useful to combine the two methods.

The theory of the equilibrium isotope effects of hydrogen

D A Knyazev, N F Myasoedov, A V Bochkarev
Timiryazev Moscow Agricultural Academy
Institute of Molecular Genetics, Russian Academy of Sciences, Moscow

ABSTRACT. The present state of the theory of the equilibrium isotope effects of hydrogen has been examined using a new approach developed by the present authors, namely the coordinate analysis of isotope effects. The mathematics of the theory have been described briefly. The conditions under which the isotopic effect is localised have been formulated. The relationship of the isotope effects in protium–deuterium and protium–tritium replacements has been refined. Particular attention has been made to clear methods for interpreting the parameter $\ln\beta$, making it possible to reveal the relationship between the isotope effect and intramolecular properties, and to systematise isotope effects on the basis of concepts having a clear physical significance. The isotope effects for the principal classes of hydrogen compound have been analysed and systematised. The factors determining the magnitude and nature of the variation in the equilibrium isotope effect have been established.

The bibliography contains 66 references.

I. Introduction

The use of deuterium and tritium as isotopic tracers makes it possible to solve research problems in the most varied branches of physics, chemistry, and biology. These studies must take account of chemical isotope effects,[1] which may be anomalously large for the isotope pairs protium/deuterium and more particularly protium/tritium. The differences in the chemical behaviour of protium, deuterium, and tritium are themselves used as an effective means of studying the molecular and dynamic aspects of chemical and cellular mechanisms.[1] This approach is based on the fact that the equilibrium isotope effects are determined by the specific features of the chemical bonds and the structural characteristics of molecules. The prediction of the separation coefficients of the hydrogen isotopes in chemical exchange systems remains an important problem.

The statistical thermodynamics of isotope effects must solve three main problems: 1, the establishment of the quantitative relationship between isotope effects and the geometric parameters and force field of a molecule; 2, the interpretation of available experimental material on this basis in terms of molecular structure; and 3, the prediction of the magnitude of isotope effects in systems which have not been studied experimentally. From the viewpoint of statistical thermodynamics, the isotopic replacement of hydrogen is the most interesting general case, since hydrogen effects are large and can be measured accurately. Moreover, the theoretical results obtained for hydrogen replacement are applicable to the replacement of the atoms of all other elements. In addition, the extremely large amount of data that has been accumulated on hydrogen effects can be used to analyse the thermodynamics of isotopic exchange.

II. Basic postulates of the theory of equilibrium isotope effects of hydrogen

The theory of equilibrium isotope effects is based on statistical thermodynamics and the theory of molecular vibrations. In the present work, we shall restrict ourselves to an examination of the isotope effects of hydrogen in the harmonic oscillator–rigid rotator approximation. This is related to the fundamental fact that the decisive contribution to the isotope effect at room temperature is made by the harmonic vibrational component of the isotopic differences in the thermodynamic functions, so that all the basic regularities in the isotope effects can be explained in the above approximation. Allowance is made for anharmonicity only by introducing a correction, which may alter the numerical values slightly but which cannot lead to the appearance of qualitatively new phenomena.

1. Chemical isotopic exchange. Calculation of the separation coefficient

The term equilibrium chemical isotope effect denotes the deviation of the distributions of isotopes between chemical forms (components of the system) in the state of thermodynamic equilibrium from those corresponding to equal probabilities. The isotopic exchange of hydrogen atoms between the components AH_n and BH_m (A and B are arbitrary molecular residues, and m and n the numbers of equivalent hydrogen atoms of a given type) involves molecular exchange reactions of the type[2]

$$AH_{n-i+1}D_{i-1}+BH_{m-j}D_j \rightleftharpoons AH_{n-i}D_i+BH_{m-j+1}D_{j-1}, \qquad (1)$$

and also homomolecular isotopic exchange reactions. Each of these reactions is characterised by its own individual equilibrium constant. The isotope effect is revealed in the equilibrium constants of reactions (1) deviating from the equal-probability isotope distribution.

The quantity used as a measure of the thermodynamic isotope effect is the separation coefficient α, defined for the replacement of protium by deuterium as

$$\alpha_{D/H} = \frac{([D]/[H])_A}{([D]/[H])_B} \quad (2)$$

To calculate the separation coefficient α by statistical thermodynamics it is necessary to establish its relationship to the equilibrium constants of reactions (1). The separation coefficient α is given by the equation:[2,3]

$$\alpha = \beta_{A^*/A}/\beta_{B^*/B}, \quad (3)$$

where A* and B* are the heavy isotopic forms of the molecules A and B.

The quantity $\beta_{A^*/A}$ (the "β-factor") [the term "ratio of the reduced partition functions" and the notation $(s/s')/f$ are also used] characterises the thermodynamic non-equilibrium distribution of the isotopes only in the molecule of the given substance A. The physical significance of the $\beta_{A^*/A}$-factor is that it is the equilibrium constant of the hypothetical isotopic exchange reaction between the substance AH_n and the ideal monatomic gas D.

The β-factor is a basic concept in the theory of isotope effects. The advantage of using the β-factors is that the calculated values of the β-factors of molecules and Eqn. (3) can be used to calculate the separation coefficients of the systems which they form. The concept of the β-factor is also convenient for analysing isotope effects in terms of molecular structure, since it makes it possible to restrict the examination to one molecule.

In a number of cases a molecule contains hydrogen in different non-equivalent groups. Thus the molecule of propionic acid CH_3CH_2COOH contains three groups of hydrogen atoms: the three hydrogen atoms of the methyl group, the two hydrogen atoms of the methylene group, and the hydrogen atom of the carboxyl group. The hydrogen atoms of these groups differ from the viewpoint of their chemical behaviour, and each group must be characterised by its own individual value of the β-factor. It is possible in principle to have intramolecular (intrastructural) isotope effects, that is the isotopic enrichment of individual groups by intramolecular exchange. Intrastructural effects are valuable as a means of study in those cases where it is possible to be confident that true equilibrium has been established (for example in geochemical systems). When true equilibrium has been established with respect to several non-equivalent groups, the separation coefficient can be estimated using the concept of the overall β-factor of the molecule (β_Σ), proposed by Galimov; the method for calculating β_Σ from the β-factors of individual groups has been described.[4]

2. Isotope effects and the theory of molecular vibrations

From the viewpoint of mechanics, an n-atom molecule is a system of n material points of mass m_i connected by elastic forces. This system has $N = 3n$ degrees of freedom, of which $3n-6$ correspond to vibrations ($3n-5$ for a linear molecule). In the harmonic approximation, the frequencies of these vibrations are given by the matrix equation

$$\hat{G}\hat{F}\hat{L} = \hat{L}\hat{\Lambda}, \quad (4)$$

where $\hat{G}$ is the kinetic energy matrix, expressed in terms of the generalised momenta, and $\hat{F}$ the potential energy matrix in generalised coordinates. The elements of the matrix $\hat{G}$ (the so-called kinematic coefficients) can be calculated if the geometric parameters of the molecule and the masses of the atoms are known. The elements of the matrix $\hat{F}$ (the force constants) are the values of the second derivatives of the potential energy with respect to the generalised coordinates at the point corresponding to the equilibrium geometric configuration of the molecule. The matrix Λ is the diagonal matrix of the eigenvalues of the matrix $\hat{G}\hat{F}$, which with an accuracy corresponding to a constant coefficient are equal to the squares of the frequencies of the vibrations ($\lambda_i = C\nu_i^2$, where C is a constant which depends on the chosen dimensions). The matrix $\hat{L}$ (the so-called matrix of the modes of the vibrations) is the matrix of the eigenvectors of the matrix $\hat{G}\hat{F}$, and is the matrix for changing from generalised to normal coordinates. The generalised coordinates usually employed to solve Eqn. (4) are the so-called natural vibrational coordinates, that is the deviations of the geometric parameters of the molecule (bond lengths and valence and dihedral angles) from their equilibrium values.

To take better account of the symmetry and specific features of the molecule, it is usual to introduce as coordinates the deviations from the equilibrium values of all the bonds and valence angles in the molecule (complete system of natural coordinates). The number of coordinates is then greater than the number of vibrational degrees of freedom. In this case, zero frequencies appear in the solution of the vibrational problem.

The natural vibrational coordinates make it possible to relate the vibrational-spectroscopic properties of a molecule to the concepts of the classical theory of chemical structure, such as the chemical bond, molecular fragments, their properties, etc. In particular, the force constants expressed in natural coordinates have the property of transferability, that is they change little in series of similar molecules.

In isotopic replacement, the potential energy of a molecule and hence the force constant matrix remain unchanged (to a high approximation), and changes take place only in the kinematic coefficients, which depend on the masses of the atoms. For replacement by a heavier isotope, the vibrational frequencies can only decrease. The sums and products of the frequencies of the vibrations of the isotopic forms of a molecule are related by various rules.[5]

3. Calculation of ln β in the harmonic approximation

In practice, it is more convenient to deal not with the β-factor itself but with its logarithm. The value of ln β in the harmonic oscillator–rigid rotator approximation is calculated using the equation:[3]

$$\ln\beta = \sum_{i=1}^{N}\ln\beta_i = \frac{1}{l}\sum_{i=1}^{N}\ln\left[\left(\operatorname{sh}\left(\frac{u_i}{2}\right)\Big/u_i\right)\Big/\left(\operatorname{sh}\left(\frac{u_i^*}{2}\right)\Big/u_i^*\right)\right] = \frac{1}{l}\left\{\sum_{i=1}^{N}\ln\frac{u_i^*}{u_i} - \frac{1}{2}\sum_{i=1}^{N}(u_i^*-u_i) + \sum_{i=1}^{N}\ln\frac{1-\exp(-u_i)}{1-\exp(-u_i^*)}\right\}.$$

Here and subsequently, $u_i = hc\nu_i/kT$ represents the dimensionless so-called reduced frequencies, h is Planck's constant, c the velocity of light, ν_i the vibrational wavenumbers, cm^{-1}, N the number of vibrational degrees of freedom of the molecule, and l the number of atoms replaced; the superscript "*" indicates that the corresponding

quantity is associated with the heavy isotopic form. The last two terms on the right-hand side of Eqn. (5) reflect the contribution made to $\ln\beta$ by the vibrational degrees of freedom of the molecule; the second term, with an accuracy corresponding to a certain factor, is the difference in the energies of the zero-point vibrations, and the third term reflects the contribution of vibrational excitation. The first term on the right-hand side of Eqn. (5) reflects the contribution of translational and rotational motion, and is expressed in terms of the vibrational frequencies using the Teller–Redlich theorem.[6]

4. Analysis of the accuracy of the basic assumptions

The accuracy of Eqns. (3) and (5) is determined by the accuracy of the assumptions forming the basis of the theoretical premises from which they are derived, primarily the Born–Oppenheimer approximation and the harmonic oscillator–rigid rotator approximation. Deviations from the Born–Oppenheimer approximation lead to the appearance of the so-called "electronic isotope effect", which has been studied in detail.[7–10] It is revealed to the greatest extent for ions, and also for the simplest molecules. Thus for the gas-phase reaction

$$D^+ + H_2 \rightarrow H^+ + HD\,,$$

the electronic isotope effect is 15% of the value of the equilibrium constant at 300 K.[7] For the gas-phase reaction

$$D_2 + 2HCl \rightleftarrows H_2 + 2DCl\,,$$

this error in K_{equil} is 3.3%.[11] In other systems in which the deviations can be related unambiguously to the electronic isotope effect, such high values have not been observed. For most molecules at temperatures around 300 K, the separation of the electronic component of the isotope effect in the Born–Oppenheimer approximation does not introduce a significant error.

When considering the separation of, and separate allowance for, the contributions of the vibrational and rotational motion, it should be noted that the influence of this assumption on the accuracy has been studied in detail. All possible corrections related to this assumption have been calculated for molecular hydrogen and a number of simple hydrogen-containing molecules,[12] and it has been shown that the influence of this factor does not exceed 1% of $\ln\beta$. The correction for the effect of quantisation of the rotation, and the correction for the contribution of the nuclear–spin component,[13] are significant only for molecular hydrogen and only at low temperatures ($T < 100$ K).

The anharmonicity of the vibrations must be considered, since vibrations involving the hydrogen atom have the greatest anharmonicity. A special study[14] of this question showed that the anharmonicity does not in fact make such significant differences to the value of $\ln\beta$ as usually assumed. In particular, if $\ln\beta_{D/H}$ is calculated using the so-called frequencies "corrected for anharmonicity", then the result differs by not more than 6.5% from the value obtained using the experimentally observed frequencies. The difference between the wavenumbers "corrected for anharmonicity" and the observed values may reach 200 cm^{-1} (for the O–H and N–H stretches). The small difference in the values of $\ln\beta$ for such a large difference in the wavenumber is related to the fact that, in accordance with Eqn. (5), there is partial compensation of the systematic shift of the wavenumbers for the two isotopic forms.

A similar result is obtained by comparing $\ln\beta$ calculated using Eqn. (5) with the value obtained by direct summation with respect to the vibrational–rotational energy levels.[15] It is necessary to avoid calculating the separation coefficient using $\ln\beta$ values obtained in different approximations, since in this case compensation will not take place, and the error in the value of α may be considerable.

Particular mention must be made of the error introduced by the ideal gas approximation (that is when no account is taken of the phase state of the substance). For hydrogen compounds, this question is related, apart from anything else, to the tendency of many of them to associate by hydrogen bond formation, accompanied by changes in the geometry and force field of the molecule. The values of α calculated theoretically for an ideal gas may differ from the values measured experimentally in the liquid or solid phases. It is of interest to estimate the magnitude and sign of this error for different chemical exchange systems involving hydrogen-containing molecules.

The change in the logarithm of the β-factor of a substance with change in the phase state is equal to the logarithm of the separation coefficient for the phase transformation. Neglecting the correction for non-ideal character and other small corrections, for the chemical isotopic exchange reaction

$$AH + BD \rightleftarrows BH + AD$$

we have

$$\ln\alpha_l - \ln\alpha_g = \ln\beta^l_{AH/AD} - \ln\beta^l_{BH/BD} - \ln\beta^g_{AH/AD} + \ln\beta^g_{BH/BD} = \ln(p_{AH}/p_{AD}) - \ln(p_{BH}/p_{BD})\,. \quad (6)$$

Equations taking account of the small corrections have been published.[16]

Sufficient data on the equilibrium vapour pressure above isotopic forms are now available to make possible their evaluation.[17] Eqn. (6) shows that the maximum error from neglect of the phase effect arises when for the exchanging forms A and B the distillation effects have different signs, for example when for form A the vapour pressure $p_{AH} > p_{AD}$ and for B, $p_{BH} < p_{BD}$. In this case the two contributions in the right-hand side of Eqn. (6) have the same sign.

The group of compounds for which $p_D > p_H$ consists mainly of substances which are not associated in the liquid phase, but also substances which are associated both in the vapour and in the liquid (organic acids and hydrogen fluoride). Thus for $CHCl_3$ at 283 K, the ratio p_D/p_H is 1.016, and for other similar substances the value calculated for one atom being replaced at room temperature is even smaller. For compounds which form hydrogen bonds only in the liquid, usually, $p_H > p_D$; the greatest isotopic vapour-pressure difference is shown by alcohols and hydroperoxides. For t-butyl hydroperoxide, $\ln(p_H/p_D) = 0.08$ at 300 K (highest known value). Combined with the above value for chloroform, this gives $\ln\alpha_l - \ln\alpha_g = 0.10$. Since for the chloroform–t-butyl hydroperoxide system the logarithm of the separation coefficient is small (~ 0.1), we find that the relative error in the determination of $\ln\alpha$ for this case is more than 100%. At the same time it must be borne in mind that, usually, the separation coefficients for systems of practical importance are large, and for them the error is smaller than that given above. Since for each specific class of substance the sign of the error is known and its approximate value can be estimated, it is obvious that the calculation of the β-factors for the gas phase combined with data on the vapour pressure of the isotopic forms of

model classes of compound can be used to estimate the separation coefficient in condensed phases with an accuracy sufficient for practical purposes.

Another important assumption made in the derivation of Eqns. (3) and (5) is the so-called rule of the geometric mean, analysed below. Here it may be noted that for all compounds except molecular hydrogen, the error introduced by departure from this rule does not exceed 1% (at 300 K).

When considering reactions involving the isotopic forms of molecular hydrogen when homomolecular exchange takes place, however, the departures from this rule are large, and Eqns. (3) and (5) cannot be used. In this case it is necessary to take separate account of all reactions of type (1) and reactions of homomolecular exchange with corresponding constants. The required equations have been published.[18,19]

Before analysing numerical data on $\ln\beta_{D/H}$, the following summary is appropriate. It was noted above that the accuracy of the harmonic oscillator–rigid rotator approximation and the rule of the geometric mean is ~2%. The absolute values of the vibrational frequencies are determined experimentally for the gas phase with an accuracy of ~1 cm^{-1}. At the same time, published data give estimates of the accuracy of the frequencies of 1–35 cm^{-1}. This is related to the fact that many spectra have been obtained for condensed phases; moreover, various wavenumbers are not observed experimentally, and are estimated using approximate isotope rules.

The values of the error in $\ln\beta_{D/H}$ given subsequently in the Tables include only the error in the initial vibrational frequencies, and were obtained from the equation:

$$\delta \ln\beta = \sum_{i}^{N}\left(\frac{\partial \ln\beta}{\partial\nu_i}\delta\nu_i + \frac{\partial \ln\beta}{\partial\nu_i^*}\delta\nu_i^*\right).$$

The values given for ν_i and $\delta\nu_i$ are the most reliable recommended published values.[20,21]

In most cases the errors in the $\ln\beta$ data are smaller than those given below. Cases where the vibrational frequencies are determined with large errors are encountered, however. Thus the calculation of $\ln\beta_{D/H}$ from published[20] frequencies for $HDCO/H_2CO$ gives the value 1.99, and for D_2CO/H_2CO the value 2.13, whereas according to the rule of the geometric mean the difference between them should not exceed 1%. According to data from other sources,[22] the value of 2.13 is close to the true value, so that the published[20] frequencies for HDCO are incorrect.

Thus to guarantee reliability of the error in $\ln\beta$, we have taken for $\delta\nu_i$ the largest values of the estimate of the error in the frequencies given in the works cited.[20,21] The influence of errors in the original data on the error in the β-factor has been studied by other workers.[23,24] Calculation of the error in $\ln\beta_{D/H}$ on the basis of an estimate of the inaccuracy of the vibrational frequencies gives an error of about 2%, which corresponds to the error of the harmonic approximation. From this it is apparently meaningless to speak of a value of $\ln\beta_{D/H}$ with an accuracy of better than 1%. The values of $\ln\beta$ obtained from experimental spectroscopic data are therefore given below to two decimal places. We are interested, however, not only in the actual numerical values of α for specific systems but also in the correlations between $\ln\beta$ and the parameters of the force field and the structure of the molecule. In the theoretical analysis, therefore, the values of $\ln\beta$ are given with an extra significant figure.

5. Relationship between the equilibrium isotope effects for proton–deuterium and protium–tritium replacement

In recent years, tritium has been used increasingly as an isotopic tracer in research work. The trend, observed in the eighties, towards the preferential use of stable isotopes compared with radioactive tracers has not affected the use of tritium, which continues to increase rapidly. It is therefore often necessary to have data on the β-factors of the tritiated forms of compounds. In most cases these data are not available, since spectroscopic studies are carried out mainly using the deuteriated forms.

This gives considerable interest to the problem of the relationship between the values of the equilibrium isotope effects with respect to different atoms, that is the problem of calculating the magnitude of the tritium effect from the known deuterium effect, and *vice versa*.

For different molecules, the ratio

$$\gamma = \ln\beta_{T/H}/\ln\beta_{D/H}\ , \qquad (7)$$

is almost constant.[25–27] A detailed analysis of Eqn. (7) has been carried out.[28,29] It has been shown that γ depends on the factors on which $\ln\beta$ depends, that is the geometry of the molecule, the masses of its atoms, and the force field (that is on its nature), and on temperature. By varying the parameters of a molecular model it is always possible in principle to obtain the maximum and minimum theoretical limits of γ (lower limit 1.33, upper 1.44). It should be emphasised that the published observation[25,28,29] that the value of γ for real molecules is constant and is related not to the properties of Eqn. (7) but to the fact that the values of the masses of the atoms and the force constants in real molecules lie in fairly narrow ranges.

The analysis[28,29] of the behaviour of the ratio γ for a representative large number of molecules has established that γ is highly characteristic with respect to the type of bond (that is to the nature of the atom directly joined to the hydrogen being replaced).

Table 1. Recommended values of γ for molecules of different types at different temperatures.

Molecule	*T*, K			
	100	200	300	400
H*F	1.435	1.429	1.423	1.416
H*Cl	1.436	1.427	1.417	1.407
H*Br	1.436	1.426	1.414	1.402
H*I	1.436	1.424	1.410	1.396
HOH*	–	1.412	1.407	1.400
CH_3OH*	1.418	1.410	1.402	1.396
CH_3SH*	1.419	1.407	1.396	1.386
H_2*O	1.434	1.426	1.418	1.418
H_2*S	1.419	1.407	1.396	1.385
H_2*Se	1.442	1.428	1.415	1.402
H*CN	1.417	1.409	1.403	1.396
C_2H_4*	1.418	1.407	1.397	1.389
NH_3*	1.432	1.422	1.413	1.404
PH_3*	1.433	1.418	1.405	1.394
AsH_3*	1.432	1.415	1.401	1.388
SbH_3*	1.428	1.409	1.394	1.381
CH_4*	1.421	1.409	1.398	1.388
SiH_4*	1.419	1.402	1.388	1.377
GeH_4*	1.420	1.402	1.388	1.376
SnH_4*	1.420	1.401	1.386	1.373

Note. The asterisk indicates the atom being replaced.

In addition, γ also depends on the number of equivalent atoms being replaced (it increases with increase in this number). The influence of other factors is insignificant.

Since γ is characteristic, the most correct method of finding $\ln\beta_{T/H}$ is by direct calculation from $\ln\beta_{D/H}$ using the relationship $\ln\beta_{T/H} = \gamma\ln\beta_{D/H}$. The recommended values of γ for molecules of different types are given in Table 1, compiled using published data.[29] The contributions to $\ln\beta$ from individual frequencies do not necessarily satisfy Eqn. (7). Moreover, Eqn. (7) can be used as a criterion of the correctness of regarding molecular fragments as individual molecules, and also for verifying the reliability of data on the vibrational frequencies of D- and T-forms.

Thus the use of Eqn. (7) makes it possible, for isolated molecules, to restrict the study to only the deuterium or only the tritium equilibrium isotope effect.

III. Theoretical methods for interpreting isotope effects

1. Approximate representations of the β-factor

Although Eqn. (5) is fairly convenient for calculations, it is not suitable for interpreting the data obtained in the study of isotope effects. This is related primarily to the fact that the vibrational frequencies depend on all the characteristics of a molecule, and not only on the characteristics of the atom being replaced and its immediate environment. The association of a frequency with a given vibrational coordinate, reflected in its assignment, is in general provisional. Each vibration involves a change in not one but all of the natural coordinates (bonds and angles), and each coordinate makes its own contribution to the form of a given vibration. An assignment is usually made with respect to the natural coordinates making the greatest contribution to the given vibration. The distribution of the contributions depends on the masses of the atoms, and the assignment of the frequencies often changes on deuteriation. For this reason it cannot be expected that the contributions of the ith pair of vibrational frequencies to $\ln\beta$, denoted $\ln\beta_i$ in Eqn. (5), will effectively describe the dependence of $\ln\beta$ on the nature of the molecule. It is more correct to interpret the quantity $\ln\beta$ in terms of the structural elements of molecules, that is the bonds between the atoms and the valence and dihedral angles, and this requires appropriate representations.

There are now more than 30 published papers dealing with the development of methods for interpreting isotope effects on the basis of the approximate representation of $\ln\beta$ as an analytical function of the force field and the geometry of the molecule. Historically, the first such representation was the expansion of $\ln\beta$ with respect to the force constants, carried out by Bigeleisen and co-workers.[3,30] This approximation is too crude for the study of most characteristics of isotope effects, so that it was necessary to develop more complex methods of interpretation, primarily the approximation of $\ln\beta$ by polynomials, proposed by Bigeleisen and Ishida,[31–33] and its improved versions.[34–38]

The most general form of the Ishida–Bigeleisen representation is the equation:

$$\ln\beta = \sum_{j=1}^{M} W_j A_j \sum_{i=1}^{N} (u_i^{2j} - u_i^{*2j}), \qquad (8)$$

where u_i represents the reduced frequencies. The sum with respect to i in this equation, with an accuracy corresponding to a temperature-dependent coefficient, is equal to $\Delta\,\mathrm{tr}(\hat{G}\hat{F})^i$, so that $\ln\beta$ is clearly expressed in terms of the geometric parameters and force constants. The numbers A_j are the Bernoulli coefficients, and W_j represents the so-called "modulating factors". The appearance of the coefficients W_j in the expansion (8) is related to the need to increase the rate of convergence of this series; for this purpose, the authors cited resort to scaling of the reduced frequencies by dividing them by the highest frequency in the spectrum of the molecule being considered.

An unsatisfactory feature of the polynomial approximation is its indeterminacy, which is revealed, in particular, by the fact that the relative values of the contributions to $\ln\beta$ from different molecular parameters depend on the value taken as u_{max} in the analysis of $\ln\beta$ for a large number of molecules, and more particularly on the chosen number of terms in the expansion of M.

Bigeleisen and co-workers[33,39] used another method of interpretation, which they called the method of "total effects". The method can be described as follows. The value of $\ln\beta$ for the molecule is calculated using data on its geometry and force field. One of the force constants is then put equal to zero, and a new value of $\ln\beta$ is calculated. In practice, this cannot be done directly, because of the appearance of imaginary frequencies, and the value of $\ln\beta$ with a zero force constant is estimated by extrapolation. The difference between the total value of $\ln\beta$ and the value obtained with a force constant equal to zero is taken as the contribution made to $\ln\beta$ by this constant. This contribution is then associated with the corresponding coordinate (bond, angle, coordinate interaction). Thus the value of $\ln\beta$ in the method of "total effects" is represented as the sum of the products of the crude estimates of the partial derivatives of $\ln\beta$ with respect to the force constant and the finite increase in the argument (in the present case the actual force constant). The proposed method is clearly one of the forms of the crude approximation of $\ln\beta$ as a function of the molecular parameters, so that it does not differ fundamentally from the method of orthogonal polynomials. From our viewpoint, it is less satisfactory than the method of orthogonal polynomials primarily because it has been less developed theoretically. The accuracy of the method of "total effects" for the replacement of protium by deuterium is not very high, and for molecules of medium complexity having out-of-plane vibrations it is equal to 4–6% at 300 K.

Another approach is that of Wolfsberg and co-workers.[40,41] This approach represents the application of perturbation theory to the calculation of $\ln\beta$, where the quantity taken as the zeroth approximation $\ln\beta_0$ is obtained by neglecting all the non-diagonal terms in the matrices $\hat{G}$ and $\hat{F}$. The basic principle of the method is that $\ln\beta_0$ is represented as the sum of contributions with respect to the "zeroth" frequencies ν_{0i} and ν^*_{0i}, each of which (since the matrix of the zeroth approximation $\hat{G}_0\hat{F}_0$ is diagonal) can be associated with a corresponding vibrational coordinate (bond, angle, etc.). For this, naturally, the values of the zeroth approximation $\ln\beta_0$ must be close to the exact value of $\ln\beta$ (that is the matrix $\hat{G}\hat{F}$ should not contain significant non-diagonal elements).

The concept of "zeroth frequencies" ν_{0i} leads to serious methodological difficulties. Thus for the methane molecule, the use of the complete system of natural coordinates gives ten "zeroth frequencies" ν_{0i}, whereas this molecule has only nine vibrational degrees of freedom. This difficulty arises as a result of the methodological inconsistency of the Wolfsberg method. In fact, since $\ln\beta$ is represented in terms of the geometry and force field, this

method still uses the concept of the contributions of the vibrational frequencies.

The methods considered, for all their differences, reduce to the representation of $\ln\beta$ as a simple algebraic function, which after transformation is reduced to the form of a power series with respect to the molecular parameters, for example the force constants. The series is terminated after account has been taken of the first few terms.

It has been shown[42] that all expansions of this type are "non-physical", that is from the coefficients of this series and from the calculated contribution made by a molecular parameter, nothing can be said about the contribution which this parameter in fact makes to $\ln\beta$. This is related to the fact that the value of the derivative of $\ln\beta$ with respect to the parameter, obtained from the expansion, depends decisively on the number of terms of the expansion taken into account.

This conclusion follows from Eqn. (5) itself, in which the molecular parameters appear via the frequencies ν_i. The latter are described by the branches of a multiple-value function $\nu_i = [\lambda_i(\zeta_1,...,\zeta_N)]^{1/2}$, where ζ represents the molecular parameters, the dependence on which is being considered. In this case, however, in accordance with the theory of power series, the radius of convergence of the power expansion of $\ln\beta$ cannot be greater than the distance from the point at which the derivative is calculated to the nearest branch point of the function $[\lambda_i(\zeta_1,...,\zeta_N)]^{1/2}$. The positions of these unique points have been studied for a number of molecules,[42] and it has been shown that the change in the assignment of frequencies with change in a parameter takes place close to them. Thus attempts to expand $\ln\beta$ in a Taylor series are not promising; if however approximate power expansions are used, then with increase in the accuracy and hence in the number of terms taken into account, this expansion approaches a Taylor series; since this series is diverging, the terms of higher powers make increasing contributions to $\ln\beta$, distorting the structure of the contributions of the molecular parameters and concealing the real reason for the variability of $\ln\beta$. This was previously noted[43] for the expansion in series of orthogonal polynomials.

Since it is impossible to construct a universal analytical expansion of the β-factor, there remain two possibilities: either to construct transcendental universal expansions suitable for the analysis of particular cases, or to represent $\ln\beta$ directly as the sum of the contributions of structural elements using numerical methods.

2. Representation of $\ln\beta$ as an infinite transcendental series

An accurate representation of $\ln\beta$ in the harmonic approximation as the sum of the terms of an infinite series of functions which are clearly and simply determined by the force constants, the geometry, and the masses of the atoms of the isotopic forms of the molecule has been proposed.[44,45] The representation has the form

$$\ln\beta = \sum_{p=1}^{\infty} \ln\beta_p = \sum_{p=1}^{\infty} \frac{1}{l} \ln \cdot$$

$$\cdot \left[1 + \frac{(\varkappa/p)^2\Delta\sigma_1 + (\varkappa/p)^4\Delta\sigma_2 + \ldots + (\varkappa/p)^{2N}\Delta\sigma_N}{1 + (\varkappa/p)^2\sigma_1^* + (\varkappa/p)^4\sigma_2^* + \ldots + (\varkappa/p)^{2N}\sigma_N^*}\right]. \qquad (9)$$

The quantities σ_p are equal to the sums of all the principal minors of pth order of the matrix $\hat{G}\hat{F}$, $\sigma_i = \sigma_i^* + \Delta\sigma_i$, $\varkappa = h/4\pi^2kT$.

The expansion (9) converges for all positive u_i. The existence of a simple equation for estimating the error for a restricted number of terms taken into account, the fact that the signs of the logarithmic terms are constant, and the rapid decrease in the contributions of these terms with increase in p distinguishes the expansion (9) from familiar approximate expansions. Eqn. (9) has been used successfully[44-46] to analyse the regularities of the behaviour of $\ln\beta$.

3. The representation of the vibrational component of $\ln\beta$ as the sum of the contributions of structural elements of the molecule

As noted above, it is most correct to interpret the quantity $\ln\beta$ in terms of the contributions of the structural elements, that is the bonds between atoms and the valence and dihedral angles.

A clear and accurate representation of the differences in the heat capacities and internal energies of isotopic forms as the sums of the contributions with respect to the vibrational coordinates corresponding to the above structural elements has been proposed.[47] A similar representation of the isotopic difference in the vibrational components of the entropies and the vibrational component of $\ln\beta$ has also been proposed.

To construct this representation we note that the logarithm of the β-factor, with an accuracy corresponding to an additive constant, is the difference, divided by kT, between the free energies for the two isotopic forms of the molecule AX_l and AX_l^*, calculated for one atom being replaced:

$$\ln\beta_{AX_l/AX_l^*} = \frac{1}{l}\left[\frac{F_{AX_l} - F_{AX_l^*} + F_X - F_{X^*}}{kT}\right]. \qquad (10)$$

Here, $(F_X - F_{X^*})kT$ is the difference between the free energies of the isotopes of the hypothetical monatomic gas X (which is constant for a given type of isotopic replacement).

For the difference between the internal energies of the isotopic forms we can write:

$$\Delta U = U^* - U = kT^2\left(\frac{\partial \ln(Q^*/Q)}{\partial T}\right), \qquad (11)$$

where Q is the partition function. Adopting the Born–Oppenheimer approximation and the harmonic oscillator–rigid rotator approximation, we have $Q = Q_tQ_rQ_v$ (subscripts; t = translational, r = rotational, v = vibrational motion). The translational and rotational motions do not contribute to the isotopic difference in the energies. Thus their zero-point energy (the energy at the absolute zero) is equal to zero, and the ratios Q^*/Q for the translational and rotational partition functions are independent of temperature, and the derivatives of these ratios with respect to T are equal to zero. Thus the difference in the internal energies of the isotopic forms is equal to the difference in the vibrational energies.

Substituting in Eqn. (11) the expression for Q_v taking account of the energy of the zero-point vibrations gives[47]

$$\Delta U = \sum_{i=1}^{N}\left[\frac{hc\nu_i^*}{2}\operatorname{cth}\frac{hc\nu_i^*}{2kT} - \frac{hc\nu_i}{2}\operatorname{cth}\frac{hc\nu_i}{2kT}\right] = E^* - E, \qquad (12)$$

where E is the vibrational energy of the molecule in the harmonic approximation. We now introduce the system of natural vibrational coordinates corresponding to the above structural elements of the molecule.

The vibrational energy of the molecule can be represented as[48]

$$U_v = \mathrm{tr}\,\hat{\Sigma}\hat{F} \tag{13}$$

where $\hat{F}$ is the force constant matrix, and $\hat{\Sigma}$ the matrix of the mean-square amplitudes of the vibrations.

According to the Binet–Cauchy theorem,[49] the trace of the product of two matrices A and B is equal to the sum of the paired products of the corresponding elements

$$\sum_{i,j} a_{ij}b_{ij} \ .$$

Thus

$$U_v = \mathrm{tr}\,\hat{\Sigma}\hat{F} = \sum_{i,j}\sigma_{ij}F_{ij}, \tag{14}$$

where σ_{ij} represents the elements of the matrix of the mean-square amplitudes in natural coordinates, and F_{ij} the force constants.

The relationship (14) can be represented in the following clear form.[47] We write the matrix $\hat{A}_{U_v}$, whose elements are the products of the corresponding elements of the matrices $\hat{\Sigma}$ and $\hat{F}$:

$$\hat{A}_{U_v} = \begin{pmatrix} \sigma_{11}F_{11} & \sigma_{12}F_{12} & \ldots\ldots & \sigma_{1N}F_{1N} \\ \sigma_{12}F_{12} & \sigma_{22}F_{22} & \ldots\ldots & \sigma_{2N}F_{2N} \\ \ldots\ldots & \ldots\ldots & \ldots\ldots & \ldots\ldots \\ \sigma_{1N}F_{1N} & \sigma_{2N}F_{2N} & \ldots\ldots & \sigma_{NN}F_{NN} \end{pmatrix} \tag{15}$$

This matrix is obviously symmetrical. According to Eqns. (14), the sum of all the elements of the matrix (15) is equal to the vibrational energy U_v of the molecule. The term at the intersection of the ith column and the jth row of matrix (15) represents the contribution made to the vibrational energy by the interaction of the ith and jth vibrational coordinates. In particular, the terms on the diagonal of matrix (15) represent the contributions due to the interaction of each vibrational coordinate with itself.

The matrix (15) readily gives the representation of the isotopic difference in the energies as the sum of the contributions with respect to the coordinates. Thus

$$\Delta U = \Delta\,\mathrm{tr}\,\hat{\Sigma}\hat{F} = \mathrm{tr}(\Delta\hat{\Sigma})\,\hat{F},$$

since the matrix $\hat{F}$ remains unchanged on isotopic replacement (here, $\Delta\hat{\Sigma}$ is the matrix $\hat{\Sigma}^* - \hat{\Sigma}$).

Thus we can write the matrix

$$\hat{A}_{\Delta U} = \hat{A}^*_{U_v} - \hat{A}_{U_v}, \tag{16}$$

made up of the elements $\Delta\sigma_{ij}F_{ij}$, where the term at the intersection of the ith column and the jth row represents the contribution made to the isotopic difference in the energies by the interaction of the ith and jth vibrational coordinates. The sum of all the elements of matrix (16) is equal to ΔU.

To obtain the corresponding expansion with respect to vibrational coordinates for the difference in the heat capcities ΔC_V, we have to differentiate the matrix (16) with respect to temperature. This can easily be done by representing the matrix $\hat{\Sigma}$ as $\hat{\Sigma} = \hat{L}\hat{\Delta}\tilde{\hat{L}}$, where $\hat{L}$ is the matrix of the modes of the vibrations, the tilde above the letter denotes transposition of the matrix, and $\hat{\Delta}$ is the diagonal matrix with the elements[48]

$$\delta_{ii} = [h/8\pi^2 c\nu_i]\,\mathrm{cth}[hc\nu_i/2kT] \ .$$

From this we have[47]

$$\Delta C_v = C_v^* - C_v = \left(\frac{\partial\,\Delta U}{\partial T}\right)_v = \mathrm{tr}\left(\frac{\partial\hat{\Sigma}^*}{\partial T} - \frac{\partial\hat{\Sigma}}{\partial T}\right)\hat{F}. \tag{17}$$

Here,

$$\partial\hat{\Sigma}^*/\partial T = \hat{L}^*(\partial\hat{\Delta}^*/\partial T)\hat{\tilde{L}}^*;\ \partial\hat{\Sigma}/\partial T = \hat{L}\,(\partial\hat{\Delta}/\partial T)\,\hat{\tilde{L}},$$

where $\partial\hat{\Delta}/\partial T$ is the diagonal matrix with the elements

$$\frac{\partial\delta_{ii}}{\partial T} = h^2/\{16\pi^2T^2k\,\mathrm{sh}^2[hc\nu_i/2kT]\} \ .$$

Using the Binet–Cauchy theorem, we can represent the trace of the product of the two matrices in Eqns. (17) as the matrix

$$\hat{A}_{\Delta C_V} = \hat{A}^*_{C_{V_v}} - \hat{A}_{C_{V_v}},$$

whose (i,j)th element is the product of the (i,j)th element of the matrix $(\partial\hat{\Sigma}^*/\partial T - \partial\hat{\Sigma}/\partial T)$ and the (i,j)th element of the matrix $\hat{F}$. The matrices

$$\hat{A}_{C_{V_v}} \text{ and } \hat{A}^{\Delta}_{C_V}$$

are respectively the representations of the vibrational heat capacity and the isotopic difference in the total heat capacities as contributions with respect to the coordinates.

For the isotopic difference in the entropies we have

$$\Delta S = (S_0^* - S_0) + \int_0^T \frac{(C_V^* - C_V)}{T}\,dT = (S_0^* - S_0) + \\ + \mathrm{tr}\left[\int_0^T\left(\frac{\partial\hat{\Sigma}^*}{\partial T}\right)\frac{dT}{T} - \int_0^T\left(\frac{\partial\hat{\Sigma}}{\partial T}\right)\frac{dT}{T}\right]\hat{F} \\ \int_0^T\left(\frac{\partial\hat{\Sigma}}{\partial T}\right)\frac{dT}{T} = \hat{L}\left\{\int_0^T\left(\frac{\partial\hat{\Delta}}{\partial T}\right)\frac{dT}{T}\right\}\hat{\tilde{L}} \ . \tag{18}$$

Here,

$$\int_0^T\left(\frac{\partial\hat{\Delta}}{\partial T}\right)\frac{dT}{T} - \ ,$$

is the diagonal matrix with elements on the diagonal

$$\frac{hc\nu_i}{2T}\,\mathrm{cth}\,\frac{hc\nu_i}{2kT} - k\ln\mathrm{sh}\,\frac{hc\nu_i}{2kT} \ .$$

The corresponding matrix $\hat{A}_{\Delta S_v}$ is easily obtained from the second term in Eqn. (18) in the same was the matrices $\hat{A}_{\Delta U}$ and $\hat{A}_{\Delta C_v}$ were constructed.

We introduce the matrix

$$\hat{A}_{\ln\beta_v} = -\frac{\hat{A}_{\Delta F_v}}{kT} = -\frac{\hat{A}_{\Delta U} - T\hat{A}_{\Delta S_v}}{kT} \quad . \tag{19}$$

The matrix obtained is symmetrical, and the term at the intersection of its ith row and jth column represents the contribution of the interaction of the ith and jth vibrational coordinates to $\ln\beta$. The sum of all the elements of the matrix $\hat{A}_{\ln\beta_v}$ is equal to $\ln\beta_v$, that is

$$\ln\beta = \ln\beta_t + \ln\beta_r - \frac{3}{2}\ln\frac{m^*}{n} + \sum_{i,j} a_{ij}, \tag{20}$$

where a_{ij} denotes the (i,j)th element of the matrix $\hat{A}_{\ln\beta_v}$.

The use of the representation (20) makes it possible to analyse $\ln\beta$, and hence the isotope effect, in terms of the vibrational coordinates, and not the vibrational frequencies. The representation (20) is exact. An example for the case of the molecule of formaldehyde H_2CO (H_2CO/HDCO replacement) is given in Fig. 1.

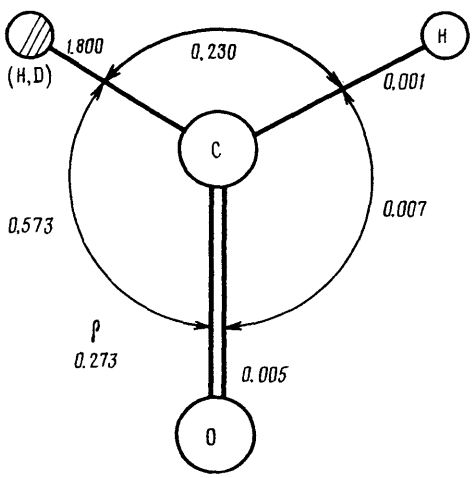

Figure 1. Representation of the vibrational component of $\ln\beta_{D/H}$ for the formaldehyde molecule (H_2CO/HDCO replacement) as the sum of the contributions of the structural elements; $\ln\beta_{dis}$ is the contribution of coordinates at a distance from the replacement centre; $\ln\beta_{n-d}$ is the contribution of the non-diagonal interactions.

$$\ln\beta_{dis} = 0.013 \quad ,$$
$$\ln\beta_{n-d} = 0.006 \quad ,$$
$$\ln\beta = 2.200 \quad ,$$

The natural vibrational coordinates used (see Fig. 1) are the changes in all the valence bonds and angles, and also the coordinate of the out-of-plane vibration ρ (the displacement of a bond from the plane). One of the coordinates (a valence angle) is redundant, and the calculation gives one frequency equal to zero.

4. Matrix representation of the translational–rotational contribution and the total value of $\ln\beta$

The representation examined in the previous paragraph makes it possible to write $\ln\beta$ as the sum of the elements of the matrix $\hat{A}_{\ln\beta_v}$ and the contribution Ω (the Teller–Redlich term), determined by the translational and rotational degrees of freedom of the molecule:

$$\ln\beta = \sum_{ij}{}' a_{ij} + \Omega, \tag{21}$$

where

$$\Omega = \Delta S_t/k + \Delta S_r/k - \frac{3}{2}\ln\frac{m'}{m} = \frac{1}{2}\ln\frac{\det\hat{G}'}{\det\hat{G}} \quad , \tag{22}$$

(m is the mass of the atom being replaced).

The Teller–Redlich term Ω is determined by the geometry and the distribution of the masses in the molecule as a whole. In particular, this contribution cannot be transferred in homologous series.

Nevertheless, there is no difficulty in constructing an accurate representation of the Teller–Redlich term and the total value of $\ln\beta$ as the matrix of the contributions of the interactions of the structural elements of the molecule, analogous to the matrix (19) for $\ln\beta_v$. To construct the required representation,[46,47] it is sufficient to note that the value of $\ln\beta \to 0$ as $T \to \infty$. The Teller–Redlich term is independent of temperature, so that Eqn. (21) gives

$$\lim_{T\to\infty} \ln\beta_v = -\Omega \quad , \tag{23}$$

which leads to the required matrix representation for the term (22) (the matrix $\hat{A}_\Omega$):

$$\hat{A}_\Omega = -\lim_{T\to\infty}\hat{A}_{\ln\beta_v} = \begin{pmatrix} \lim\limits_{T\to\infty} a_{11} & \cdots & \lim\limits_{T\to\infty} a_{1N} \\ \cdots & \cdots & \cdots \\ \lim\limits_{T\to\infty} a_{1N} & \cdots & \lim\limits_{T\to\infty} a_{NN} \end{pmatrix}. \tag{24}$$

Eqns. (24) and (21) readily give the matrix representation for the total value of $\ln\beta$:

$$\hat{A}_{\ln\beta} = \hat{A}_{\ln\beta_v} + \hat{A}_\Omega, \tag{25}$$

where each element of the matrix $\hat{A}_{\ln\beta}$ is the sum of the corresponding elements of the matrices $\hat{A}_{\ln\beta_v}$ and $\hat{A}_\Omega$.

The matrices $\hat{A}_\Omega$ and $\hat{A}_{\ln\beta}$ for the formaldehyde molecule (H_2CO/HDCO replacement) have been published.[46] The principal contributions to the value of $\ln\beta$ are made by the following coordinates: the bond CH* (contribution 1.484), the valence angle H*CO (0.377), the out-of-plane vibration ρ (0.168), and the valence angle H*CH (0.160). The contributions of the other coordinates and of the interactions between the coordinates are small.

Thus in the works cited[46,47] a complete and accurate representation of the logarithm of the β-factor as the sum of the contributions of the structural elements of the molecule was constructed for the first time.

5. The use of the representations of ln β to analyse isotope effects. The analysis of the rule of the geometric mean

If a molecule contains a group of l equivalent atoms, the following rule applies approximately when they are successively replaced by the atoms of an isotope[50–52]

$$\ln\beta=\frac{1}{x}\ln f_{(AD_xH_{l-x}/AH_l)}=\frac{1}{l}\ln f_{(AD_l/AH_l)}, \qquad (26)$$

where f is the ratio of the partition functions with respect to the states of the isotopic forms indicated in brackets.

It can be seen from Eqn. (26) that the rule of the geometric mean states that $\ln f$ is linearly dependent on the number of atoms x being replaced or, which is the same thing, that the value of $\ln\beta$ is independent of x.

We can take as a measure of the deviation from the rule (26) the difference between the actual value of $\ln\beta_{AD_xH_{l-x}/AH_l}$, calculated using Eqn. (5), and the estimate of this quantity obtained from the value for the completely substituted form using the rule of the geometric mean:

$$\delta=\frac{1}{x}\ln f_{(AD_xH_{l-x}/AH_l)}-\frac{1}{l}\ln f_{(AD_l/AH_l)}. \qquad (27)$$

We define the relative deviation as $\delta_{rel}=\delta/\ln\beta_{(AD_l/AH_l)}$. We can consider a molecule of the type H_2A, where A represents an arbitrary molecular group. Eqn. (9) has been used[53] to obtain the following equation for δ:

$$\delta=\frac{1}{2}\sum_{k=1}^{\infty}\ln\left[1+\frac{(\varkappa/k)^4(p_2-q_2)+\ldots+(\varkappa/k)^{4N}(p_{2N}-q_{2N})}{1+(\varkappa/k)^2p_1+\ldots+(\varkappa/k)^{4N}p_{2N}}\right], \qquad (28)$$

where

$$q_1=\sigma_1^{AH_2}+\sigma_1^{AD_2},\quad q_2=\sigma_2^{AH_2}+\sigma_1^{AH_2}\sigma_1^{AD_2}+\sigma_2^{AD_2},\ \ldots,\ q_{2N}=\sigma_N^{AH_2}\sigma_N^{AD_2}$$

$$p_1=2\sigma_1^{AHD},\quad p_2=2\sigma_2^{AHD}+(\sigma_1^{AHD})^2,\ \ldots,\quad p_{2N}=(\sigma_N^{AHD})^2.$$

In Eqn. (28), account is taken of the fact that in the harmonic approximation we always have $p_1=q_1$. Since at temperatures which are not too low the series (28) converges rapidly and since it is usually necessary only to estimate the value of δ, we can restrict ourselves, at $T=300$ K, to the first term of the expansion.

Eqn. (28) shows that the deviation from the rule of the geometric mean is related to the difference in the values of p_i and q_i for $i\geqslant 2$. In other words, in terms of the force field and the geometry of the molecule, fulfilment of the rule of the geometric mean is due to similarity in the values of p_i and q_i.

It should be noted that p_i-q_i for $i\geqslant 2$ depends only on higher powers of the difference in the reciprocal masses $(\Delta\mu)^i$, $i\geqslant 2$. Thus the inaccuracy of the geometric-mean rule is essentially a non-linear effect.

From the form of the expressions for p_i and q_i it is clear that the relative magnitude of the numerator of the terms in the series (28) relative to the denominator is greater, the greater the number of frequencies in the molecule undergoing an appreciable shift on isotopic replacement. This is due to the fact that the numerator of the terms in Eqn. (28) depends on the differences p_i-q_i, which are determined by the isotopic shifts of the frequencies, whereas the denominator contains the quantities p_i, which depend only on the absolute magnitude and number of the frequenices. Thus with increase in the number of frequencies in the molecule remaining unchanged or changing only slightly on isotopic replacement, the denominator of the terms of the series (28) will increase much more rapidly than the numerator, with a corresponding decrease in the values of δ and δ_{rel}.

Thus the greatest deviations from the geometric-mean rule should be expected for the H_2 molecule and small molecules of the type H_3B, in which the hydrogen atoms being replaced are joined to one central atom B, so that all the vibrations are vibrational modes of hydrogen and undergo a marked shift on isotopic replacement. The molecules of this type include molecules (H_2O, H_2S, NH_3) of practical interest for chemical exchange.[54] For organic molecules (except CH_4), it is clear that the deviations from Eqn. (26) should be negligible.

6. Localisation of the isotope effect of hydrogen

In the examination of the dependence of ln β on the remoteness of the substituents it should be borne in mind that isotopic replacement is equivalent to a perturbation which can be regarded as small in all cases except the case of the replacement of hydrogen atoms. This perturbation influences the whole molecule, but the influence is different for its different parts, decreasing with increase in the distance between the vibrational coordinates and the atom being replaced. It is possible, however, to have strong interaction between vibrational coordinates separated from one another, as a result of the fact that the frequencies of the vibrations to which these coordinates contribute are similar (resonance interaction).

This raises the question of the accuracy with which the fragmentary model reproduces the value of the β-factor of the whole molecule. The importance of this question follows from the fact that fragmentary models (see Fig. 2) are used to calculate isotope effects, particularly for complex molecules, and frequently this approach is the only one possible. It is therefore necessary to know the magnitude of the errors introduced by this approximation. In particular, it is important to know whether the value of the β-factor is influenced significantly by accidental resonance of the vibrations of the atom being replaced with the vibrations of coordinates at a distance.

This question has been studied in relation to the kinetic isotope effect. For example, a calculation[55] for a number of systems involving comparison with "truncated" models showed that the "removal" of an atom separated by more than two bonds from the atom being replaced introduces practically no error in the calculation of the kinetic isotope effect. No theoretical analysis of the problem has been published, however, and the case of resonance has not been studied.

The representation (9) has been used[56] to analyse the question of the "extent" of the isotope effect. To study this problem, the model four-atom molecule represented in Fig. 2 was examined. The following natural coordinates were introduced: the changes in the bond lengths r_1, r_2, and R, the changes in the valence angles φ_1 and φ_2, and the out-of-plane twisting coordinate χ. The calculation was carried out using force constants and geometric parameters characteristic of saturated hydrocarbons. To obtain the fragmentary model from the original molecule, the matrix of kinematic coefficients $\hat{G}$ was left unchanged, but the rows and columns of the force constant matrix of the original molecule were multiplied by a weighting factor x if these columns and rows corresponded to a natural coordinate including the atom removed.

The calculation was carried out for two cases: in the first case, an atom separated by three bonds ("third neighbour") from the atom being replaced was "removed" (x was taken as zero); in the second case, in addition, an atom separated by two bonds ("second neighbour") from the atom being replaced was also removed.

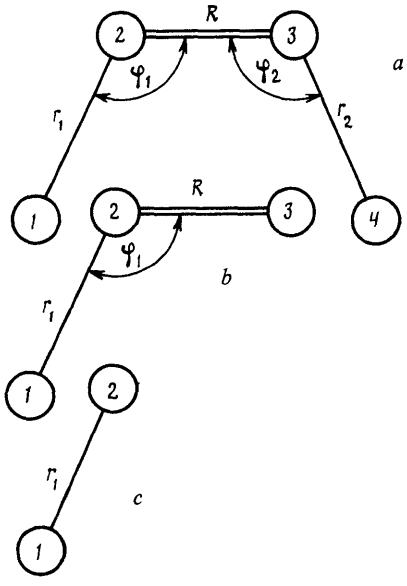

Figure 2. Fragmentary models.

The influences of the removal of the second and third neighbours differ significantly in scale. The removal of an atom separated by three bonds from the atom being replaced introduces a small error. The influence of an atom separated by two bonds from the atom being replaced cannot be neglected, however.

In the multiplication, described above, of the force constants for the coordinates removed by the factor x, the quantities ∂_i in Eqn. (9) can be represented as

$$\sigma_i=\sigma_i^{(0)}+\sigma_i^{(1)}x+\sigma_i^{(2)}x^2+\ldots+\sigma^{(N-m)}x^{N-m}, \qquad (29)$$

where $\sigma_i^{(0)}$ includes only the force constants and geometric parameters relating to the coordinates closest to the atom beign replaced. After substituting Eqn. (29) in Eqn. (9) and reducing similar terms in the numerator and denominator, Eqn. (9) takes the form

$$\ln\beta=\ln\beta_0+\delta(x), \qquad (30)$$

where $\delta(x)$ is a correction. Here, the term $\ln\beta_0$ in the right-hand side includes only the force constants and geometry of the remaining part of the molecule and is therefore the principal component of $\ln\beta$ (the contribution of the immediate environment of the atom being replaced). The second term in the right-hand side of Eqn. (30) depends on x, and for $x = 1$ it is a correction reflecting the contribution of molecular fragments at a distance.

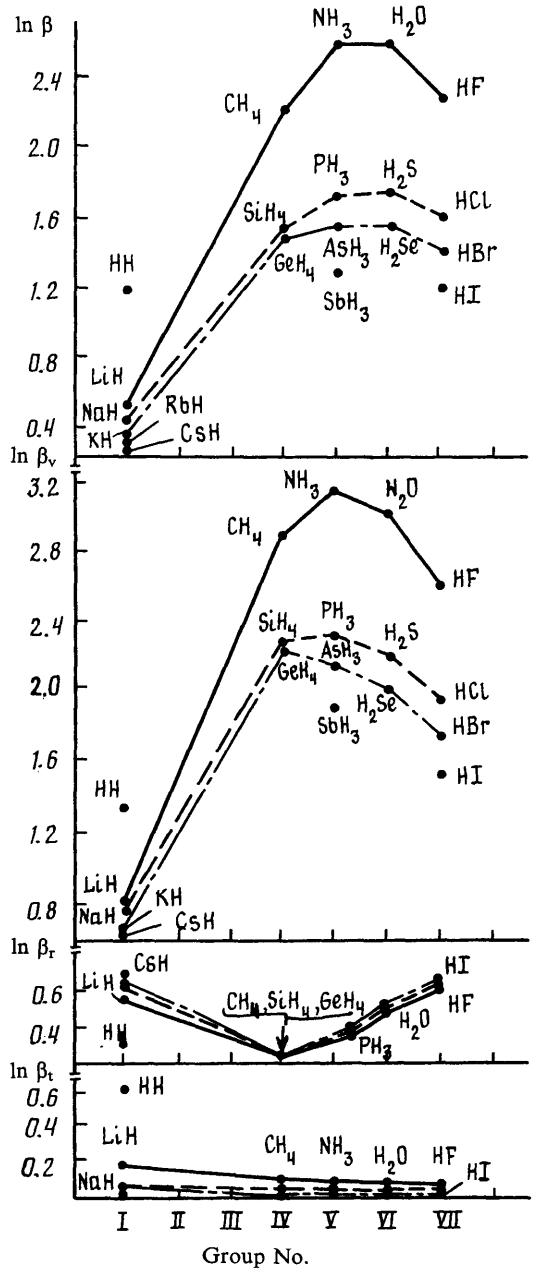

Figure 3. Components of $\ln\beta$ for normal hydrides.

Eqn. (30) has also been analysed.[56] At room temperature the isotope effect is localised at the replacement centre, as shown by the small size of the correction in Eqn. (30). The correction increases with decrease in temperature, however, and at 30 K its value is comparable with that of $\ln\beta_0$. This reflects the increasing delocalisation of the isotope effect with decrease in temperature, revealed by the fact that remote coordinates begin to make a significant contribution to $\ln\beta$.

The representation of Eqns. (29) and (30) also makes it possible to solve the problem of expressing $\ln\beta$ as the sums of the contributions of the first, second, and higher environments of the atom being replaced.[56]

IV. Analysis of quantitative data on the β-factors of hydrogen compounds

1. Dependence of $\ln\beta_{D/H}$ on the nature of the atom directly joined to the hydrogen atom being replaced. Analysis of $\ln\beta_{D/H}$ for normal hydrides

It is known empirically that the values of the ratio of the reduced partition functions (the $\beta_{D/H}$-factor) of the isotopic forms of molecules is determined primarily by the nature of the atom directly joined to the hydrogen atom being replaced. To study this relationship it is natural to consider the large number of so-called normal molecular hydrides of the *s*- and *p*-elements (that is the molecular hydrides of a given element with the general formula EH_n). The normal hydrides can serve as a model for examining more complex compounds, and therefore represent a key group in the chemistry of the isotopes of hydrogen.

Attempts have been made to obtain a phenomenological description of $\ln\beta$ for normal hydrides,[2] and also to interpret $\ln\beta_{D/H}$ in terms of the force field using the approximate methods of interpretation and correlations described above.[57–59]

The values of $\ln\beta_{D/H}$ for normal hydrides were recently re-examined by Bigeleisen.[58] It was concluded that the contribution of each ith vibrational coordinate to $\ln\beta$ is proportional to $(f_{ii}\Delta g_{ii})^{1/2}$, where f_{ii} is a diagonal element of the force constant matrix, nd $\Delta g_{ii} = g_{ii} - g^*_{ii}$ the difference in the diagonal elements of the matrices of the kinematic coefficients for the H- and D-forms of the molecule. It should be noted, however, that although the contribution made to $\ln\beta$ by the valence bond coordinates is in fact approximately linearly dependent on $(f_{ii}\Delta g_{ii})^{1/2}$, this correlation is not completely satisfactory for the valence angle coordinates, particularly for the normal hydrides of groups IV and V.

The representation (20) described above has been used to analyse the behaviour of $\ln\beta_{D/H}$ for normal hydrides.[59] Figs. 3 and 4 give the force constants and the contributions of different coordinates to $\ln\beta$. In the analysis of these data it should first be noted that the Teller–Redlich term $\ln\beta_t + \ln\beta_r + (^3/_2)\ln(m_D/m_H)$, which depends on the geometry and the masses, changes little and does not determine the behaviour of $\ln\beta$ for normal hydrides. The decisive factor is the variability of the vibrational contribution $\ln\beta_v$. For all normal hydrides, a predominant part is played by the contribution made to $\ln\beta_v$ by the H–E valence bond coordinate, and this contribution increases regularly in each period together with the force constant F_{HE} on going from group I to group VII, and decreases regularly in each group with increase in the atomic number of the element.

The contribution made by the angular coordinates depends both on the magnitude of the contribution of an individual valence angle and on the total number of valence angles. This number is equal to 3 for the hydrides of the group IV elements, 2 for group V, and 1 for group VI. On going from group VI to group IV, the contribution made by one angle (see Fig. 4) decreases, whereas the total contribution from the angular coordinates increases, since the total number of angles increases. The part played by the number of angles is extremely significant, and the total contribution made to $\ln\beta_v$ by the angular coordinates is greatest for the normal hydrides of the elements of group IV. This contribution does not exist for diatomic molecules, and it is for this reason that $\ln\beta$ for the hydrogen halides is smaller than that for the hydrides of the elements of groups V and VI, despite the larger force constant and the corresponding larger contribution of the H–E bond to $\ln\beta$.

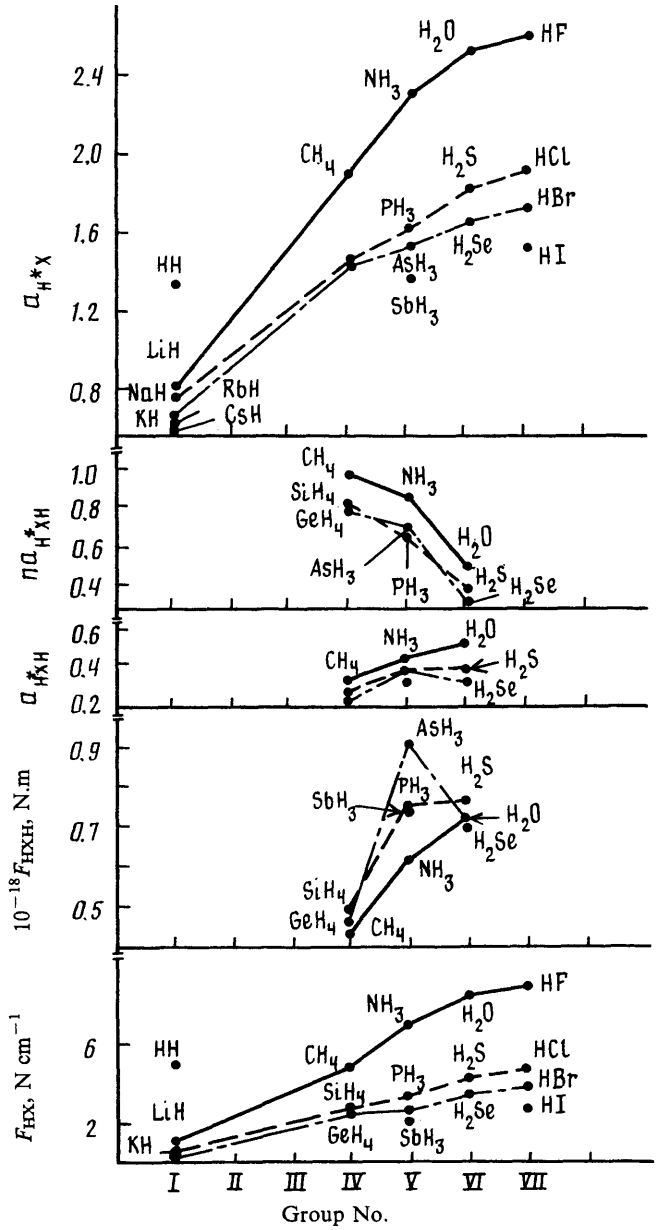

Figure 4. Contributions of different structural elements to $\ln\beta$ for normal hydrides: a_{H^*-X} is the contribution of the H*–X bond, a_{H^*XH} the contribution of the valence angle H*XH, and na_{H^*XH} the contribution of the valence angles with allowance for their multiplicity; F_{HX} and F_{HXH} are the bond and valence angle force constants respectively.

The magnitude of the contribution of the angular coordinates to $\ln\beta$ is not related in simple fashion to the magnitude of the angle force constant F_{HEH}. Here, a significant feature is that the numerical values of F_{HEH} for normal hydrides are comparable with one another. For the hydrides AsH_3 and SbH_3, the values of F_{HEH} and hence the contributions of the angles to $\ln\beta$ are anomalously large, and for AsH_3 this feature is observed when the calculation is carried out using force fields obtained by different authors.[59] Moreover, for these molecules, the values of the non-diagonal elements $F_{(HE,HEH)}$ in the force constant matrix are appreciable. The contribution of the non-diagonal interactions to $\ln\beta_v$ is correspondingly large. In this case the coordinates HE (bond) and HEH (angle) are strongly coupled, and therefore cannot be considered independently. The contributions of coordinates at a distance (bonds and angles not involving the atom being replaced) are small (< 0.06) for the normal hydrides.[59,60]

Thus for the normal hydrides as a class of compound, $\ln\beta_{D/H}$ shows approximately the same dependence on the H—E bond force constant, the contribution of a single angular coordinate, and the number of angular coordinates contributing to $\ln\beta$. As a consequence of the localisation of the isotopic effect, these conclusions apply not only to the normal hydrides themselves, but also to their derivatives.

2. Dependence of $\ln\beta_{D/H}$ on the number, type, and remoteness of the substituents. Compounds of hydrogen with carbon with sp^3-hybridisation

The value of $\ln\beta_{D/H}$ is determined not only by the nature of the hydride-forming element but also by the nature and number of the substituents on the atom joined directly to the hydrogen atom being replaced. The dependence of $\ln\beta_{D/H}$ on the nature and number of the substituents is also large-scale, and comparable with the dependence of $\ln\beta$ on the nature of the hydride-forming atom. For example, for carbon, even without a change in the hybridisation in the compounds CH_3X, the value of $\ln\beta_{D/H}$ may vary from 2.49 (X = $OCOCH_3$) to 2.26 (X = H), which is almost equal to the range of variation of $\ln\beta$ for the normal hydrides from group IV to group VII in period II. The number of substituents has an equally marked influence (see Table 2).

Comparison of the values of $\ln\beta_{D/H}$ for molecules of the type CH_2XY with the values of $\ln\beta$ for CH_2X_2 and CH_2Y_2 molecules shows that for replacement on several different substituents, additivity of $\ln\beta_{D/H}$ may in general not be observed.

The representation (20) has been used[60] to calculate the contributions of vibrational coordinates of different types to $\ln\beta_{D/H}$ for molecules of the form $CH_{4-n-m}Y_nX_m$, where X, Y = F, Cl, Br, I. This set of values of the contributions is sufficiently representative for an analaysis of the relationship being considered. In fact, the range of change in $\ln\beta_{D/H}$ for the methyl group is almost completely covered by the above set. Moreover, this set of molecules can also be regarded as a model set in the general case of isotopic replacement with respect to hydrogen, since the hydrogen effect is localised at ordinary temperatures.

To be definite, and for simplicity, we shall consider the case of the replacement of only one hydrogen atom. Some of the published results[60] are given in Table 2. It can be seen from this Table that the principal contribution to $\ln\beta$ is made by the C—H* bond, and that this contribution remains approximately constant, changing by not more than 5% in the whole set of molecules studied (here and subsequently, the asterisk indicates the atom replaced by the isotope). This range of change is much smaller than the variation in the actual value of $\ln\beta_{D/H}$, but larger than the variation of the force constant F_{CH} in the given set. The explanation is that the vibrational coordinate corresponding to change in the C—H* bond length, subsequently denoted in the text as CH*, shows, particularly for fluorine-containing molecules, considerable dynamic coupling with the coordinates CX and with the valence angle coordinates, so that the magnitude of its contribution to $\ln\beta_{D/H}$ cannot be determined entirely by the force constant of one given coordinate.

Table 2. Values of $\ln\beta_{D/H}$ for halogenomethanes and $CH_2(CN)_2$ (T = 300 K).

$\ln\beta_{D/H}$	2.39	2.38±0.13	2.38	2.37	2.36±0.08	2.31±0.03	2.31±0.04	2.30

In general, and in contrast to the normal hydrides, for substituted methanes the interactions of the vibrational coordinates make a significant contribution to $\ln\beta$. This feature means that in this case the coordinates cannot be considered independently, as confirmed by an analysis of the force constant matrices.

The fairly marked scatter and the non-characteristic nature of the contributions of the valence angles to $\ln\beta_{D/H}$ are obvious. For a given molecule, the scatter in these contributions obtained by calculation from the force fields given by different authors, often exceeds even the scatter in the actual values of $\ln\beta$. This is not surprising, since the numerical value of $\ln\beta$ is determined only by the frequencies, which are obtained unambiguously from the force field, while the values of the contributions of specific coordinates are determined by the force field, which is found unambiguously from the experimental frequencies. In other words, slight scatter in the frequencies or in even individual frequencies may correspond to a large scatter in the values of the force constants. The difference in the force fields is also responsible for the scatter in the values of the contributions.

At the same time it is obvious that the physically correct solution for the force field is unique, and, moreover, that from its physical significance the scale of the variation in the contributions in a set of molecules should not exceed the scale of the variation of $\ln\beta$. It is therefore appropriate to solve the inverse problem, that is to find the values of the contributions of the coordinates by solving the over-determined system of linear equations by the least-squares method for a sufficiently representative set of molecules, using the known values of $\ln\beta_v$. The values of the contributions of the vibrational coordinates obtained in this way may serve as a criterion of the physical correctness of the force fields.

Since the solution of the system of linear equations in this case (the replacement of one hydrogen atom) is in principle unique, it is necessary to fix one of the contributions. The contribution of the CH* bond was chosen as this contribution. The accuracy of the additive scheme indicated corresponds to that of the calculation of $\ln\beta$ from the experimental vibrational frequencies.[60]

For the calculation of the β-factor for carbon replacement, Galimov[61] proposed an empirical additive scheme which has been widely applied, chiefly in the study of geochemical effects. In this scheme, the β-factor itself (and not its logarithm) is calculated, as the sum of the increments in the chemical bonds without allowance for the angles; this is quite permissible for carbon. From what has been said above it is clear that the additive representation is also possible and useful for hydrogen effects, but in this case it is more natural to expand the logarithm of the β-factor with necessary allowance for the valence angles.

Moreover, the dependence of $\ln\beta_{D/H}$ on the number and type of substituents for a given hydride-forming element is obviously determined primarily by the contribution of the valence angles H*EX and by the contribution of $\ln\beta_t + \ln\beta_r$. The electronic influences of the substituents on the force constant and hence on the contribution of the E–H* bond play a secondary role. Even if it is assumed that the contributions of the angles and bonds of each type to $\ln\beta_v$ are unchanged and depend only on the number of substituents, it cannot be expected that $\ln\beta$ will vary linearly with respect to the number of substituents, since the linearity breaks down when account is taken of the rotational contribution (it can readily be seen that the rotational contribution changes non-linearly with change in the number of substituents). There is even less reason to expect linearity when account is taken of the contributions of the interactions between the coordinates.

The new coordinates which appear when substituents are introduced, particularly the coordinates of adjoining angles, make a contribution to $\ln\beta$ which may be either larger than or smaller than the contribution of the coordinates which disappear. Moreover, replacement brings about a change in the contribution of $\ln\beta_t + \ln\beta_r$. Thus with increase in the number of substituents of the same type, the value of $\ln\beta$ may either increase or decrease. The dependence of $\ln\beta_{D/H}$ for the methyl group on the nature of the substituents in compounds of the type CH_3^*R is shown by the data given below (T = 300 K).[57,60,62]

In the analysis of these data it should be borne in mind that they were calculated for the replacement of the three hydrogen atoms in the methyl group, whereas in the calculation for the $CHX_nY_mZ_l$ molecules only one hydrogen atom was replaced. Thus the values of $\ln\beta_{D/H}$ for the compounds CH_3R are 0.5–1% too high, as a result of the inaccuracy of the geometric-mean rule. The variation in $\ln\beta$ for the methyl group for a given substituent X is determined primarily by the rotational contribution and by the value of the force constant of the HCX angle, and to a much smaller extent by the influence of the substituent on the force constants of the C–H and C–X bonds. These factors may act in opposite directions. Thus on going from CH_3F to CH_3I the angle force constant (F_{HCX}/r^2_{CH}) changes from 0.900 N cm^{-1} to 0.651 N cm^{-1}. This also determines the change in $\ln\beta$, which goes from 2.457 to 2.320. On going from F to I, the force constant of the C–X bond also decreases, from 5.535 N cm^{-1} to 2.338 N cm^{-1}, but this factor has less influence on $\ln\beta$. The constant F_{CH}, however, generally changes in the opposite direction in this series, although the change is slight (from 4.878 N cm^{-1} for CH_3F to 5.002 N cm^{-1} for CH_3I).

3. Compounds of carbon with hydrogen with *sp*^{2}- and *sp*-hybridisation. Dependence of $\ln\beta$ on the geometry of the molecule

We can compare the logarithms of the $\beta_{D/H}$-factors of compounds with *sp*^{3}-, *sp*^{2}-, and *sp*-hybridisation of the hydride-forming carbon atom. First of all, the general decrease in the value of $\ln\beta_{D/H}$ for *sp*^{2}- and *sp*-hybridisation compared with *sp*^{3}-hybridisation should be noted. At the same time, the bond force constants F_{CH} and the corresponding contributions of the bonds to $\ln\beta$ are greatest for *sp*-hybridised and smallest for *sp*^{3}-hybridised molecules. The factor responsible for the decrease in $\ln\beta$ on going from *sp*^{3}-hybridisation to *sp*^{2}- and *sp*-hybridisation can therefore only be the decrease in the number of vibrational coordinates contributing to $\ln\beta$. To confirm this, we can consider the contributions of the vibrational coordinates to $\ln\beta$ for monosubstituted derivatives of ethane, ethylene, and acetylene (see Fig. 5).[63]

Fig. 5 shows that the number of coordinates closest to the atom being replaced decreases in the order ethane–ethylene–acetylene, leading to a decrease in $\ln\beta$, despite the increase in the force constants and hence in the contributions made to $\ln\beta_{D/H}$ by each individual vibrational coordinate.

The values of $\ln\beta_{D/H}$ for substituted ethylenes $HR^1C=CR^2R^3$ are given below [the dependence of $\ln\beta_{D/H}$ (on the carbon atom) on the type of hybridisation of the atom directly joined to the atom being replaced (T = 300 K)].[57,60,62]

It should be borne in mind that for replacement in ethylene the substituents R^2 and R^3 are separated by three bonds from the hydrogen being replaced. The influence of the substituents R^2 and

R^3 is therefore weaker than that of the substituent R^1, but stronger than the corresponding influence for the methyl group.

Fig. 5 shows that for ethylene, an appreciable contribution to $\ln\beta$ is made by the out-of-plane coordinates. In substituted ethylenes, the out-of-plane vibrations depend markedly on the substituent.[5]

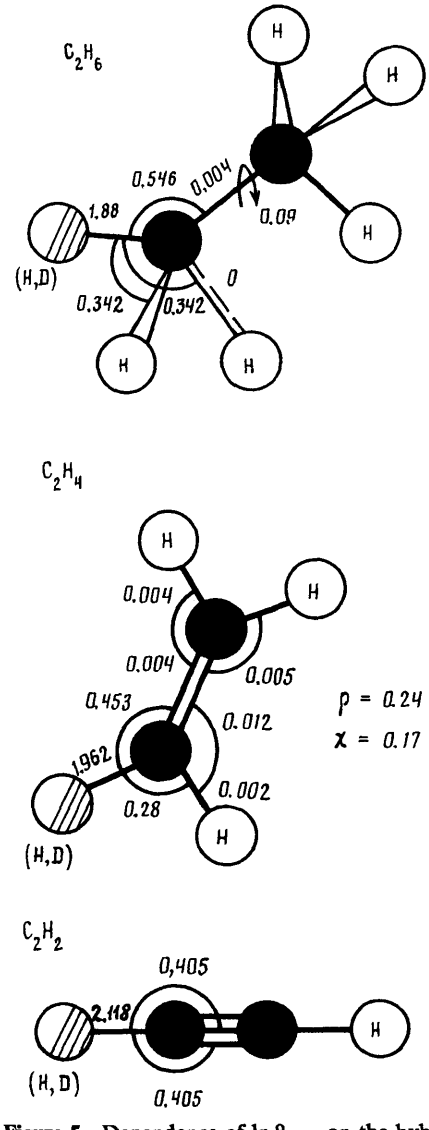

Figure 5. Dependence of $\ln\beta_{D/H}$ on the hybridisation; the change in the contributions of the vibrational coordinates in the series ethane–ethylene–acetylene; only the non-zero contributions are given; the values of $\ln\beta_{D/H}$ are 2.372 (ethane), 2.334 (ethylene), and 2.105 (acetylene); the vibrational components of $\ln\beta_{D/H}$ are 3.222, 3.124, and 2.889 respectively.

The influence of the substituents R^2 and R^3 on $\ln\beta$ is therefore also much stronger than for the methyl group. In fact, the atoms R^2 and R^3 are included in the twisting coordinate χ (rotation of the planes CHR^1 and CR^2R^3 about the C=C bond in different directions) and cannot in this case be regarded as separated neighbours. This must be taken into account in all cases of substitution at a double bond.

Another group of carbon compounds with sp^2-hybridisation consists of compounds of the type  , which can be regarded as substituted formaldehydes. All that has been said about the β-factors of ethylenic compounds applies in this case also, except that in the substituted formaldehydes there is no vibrational coordinate χ. The value of $\ln\beta$ for the formaldehyde is therefore low. In carbonyl compounds, an important part is played by the electronic influences of the substituents. The introduction of electron-acceptor groups such as –OH and –F increases the strength of the H–C bond, leading to an increase in its contribution and hence to an increase in $\ln\beta$.

The relative random error in the value of $\ln\beta_{D/H}$ for compounds with a double bond, particularly carbonyl compounds, is extremely large. This makes it impossible to analyse fine effects. This large error is related to the difficulty of obtaining accurate data on the vibrational spectra of these substances, due to the difficulty of purifying the substances, the indeterminacy (in a number of cases) in the number of conformers, and other factors. These factors make it difficult to interpret the spectrum to obtain an unambiguous assignment of the bands to fundamental vibrations even for simple compounds. Thus in the above case of formaldehyde-D_1 the published set of fundamental frequencies for HDCO is clearly erroneous. The case of this molecule also shows that the calculation of $\ln\beta$ can provide an additional criterion for the correctness of the interpretation of an experimental spectrum.

The error in $\ln\beta$ for complex molecules is generally greater than that for simple molecules. This is also related to the inaccuracy of the spectroscopic data for large molecules. At the same time, because of the localisation of the hydrogen effect, the molecular fragments at a distance do not influence the β-factor significantly. The use of small molecules as models therefore acquires particular further importance because of the higher accuracy of their β-factors.

For compounds of the acetylene series, the $\ln\beta$ values change very little with change in the nature of the substituents, due to the remoteness of the latter. At the same time, when heavy substituents are present, $\ln\beta$ for these molecules is smaller as a result of the decrease in the contribution of the angular coordinates.

In view of the fruitfulness and general character of the approach used, the study can be extended by examining different versions of the C–H bond. $\ln\beta_{D/H}$ has its highest values for sp^3-hybridised molecules, and $\ln\beta$ for methylene groups is higher than that for methyl groups. The value of $\ln\beta_{D/H}$ for isobutane-D_1 is apparently too low, because of the incorrect published[5] assignment of the frequencies of the isotopic forms.

The high values of $\ln\beta$ for benzene is related to the rigidity of its structure and to the significant contribution from the large number of out-of-plane coordinates. Many vibrations of the benzene ring cannot be assigned to one definite bond or angle.[5] Thus as in the case of the halogen-substituted methanes considered above, it is appropriate to examine the benzene ring as a whole, without distinguishing "distant" and "nearest" fragments within it.

On the other hand, alicyclic molecules have lower $\ln\beta$ values compared with open-chain molecules, and $\ln\beta$ decreases with increase in the strain in the ring. This is related to the increase in the H*–C–C angles compared with the tetrahedral angle, which leads to a decrease in their strength and a decrease in their contribution to $\ln\beta$.

4. The values of $\ln \beta_{D/H}$ for compounds of hydrogen with nitrogen and oxygen

In the approach being used, the regularities of the change in the $\ln \beta_{D/H}$ values for compounds of nitrogen and oxygen are the same as for carbon compounds. All that has been said above about the dependence of $\ln \beta_{D/H}$ on the type of hybridisation and the number, nature, and remoteness of the substituents is also applicable to these molecules. The number of compounds of nitrogen and oxygen for which experimental spectroscopic data are available, however, is much smaller than that for carbon compounds. The $\ln \beta_{D/H}$ values for some of these compounds are given in Table 3. The $\ln \beta_{D/H}$ values for the corresponding normal hydrides show that the behaviour of $\ln \beta_{D/H}$ for nitrogen compounds with sp^3-hybridisation is similar to the case of the methyl group, but the $\ln \beta$ values for nitrogen compounds are on the average 0.2 unit greater than for the methyl group with identical substituents. For nitrogen compounds with sp^2-hybridsation, the $\ln \beta_{D/H}$ values are lower, as they should be (thus for NH_3, $_{D/H}$ = 2.21).

Table 3. Values of $\ln \beta_{D/H}$ (T = 300 K) for compounds containing NH and OH bonds.[57,60,62]

N–H bond	$\ln \beta_{D/H}$	O–H bond	$\ln \beta_{D/H}$
$NH(CH_3)_2$	2.71	$HO-NO_2$	2.59±0.02
NH_2-NH_2	2.59	$HO-NH_2$	2.59
NH_2-CH_3	2.58±0.03	HO–F	2.54
		$HO-CH_3$	2.51±0.04
	2.56		
			2.50±0.05
	2.49	HO–Cl	2.44±0.02
NH_2-OH	2.45		
NH_3	2.42		2.42
HN=NH*(cis)	2.40		
HN_3	2.29±0.2	HO–H	2.38±0.02

The $\ln \beta_{D/H}$ values for the O–H bond in oxygen compounds are close to the values for N–H bonds.

Practically all compounds containing NH and OH groups are capable to some extent of forming hydrogen bonds; this leads to a change in the immediate environment of the hydrogen atom being replaced and to a change in the force constants, and also influences $\ln \beta$ (the $\ln \beta$ values given in Table 3 were calculated for the monomers). At the same time, it is known that hydrogen bond formation has only a weak influence on the value of $\ln \beta$. This follows from the low values of the isotope effects of vapour pressure at 300 K. When a hydrogen bond is formed, compensation of the contributions made to $\ln \beta$ by the newly produced degrees of freedom takes place, and this explains the weak influence of association on the β-factor.[64]

In addition to hydrogen bond formation, another specific process is possible for the amino-group, namely protonation, which takes place in practice in aqueous solutions of aminoacids. On protonation of the amino-group, as a result of the increase in the number of vibrational degrees of freedom, $\ln \beta_{D/H}$ increases (2.68 for the ammonium ion, compared with 2.42 for ammonia). It should be emphasised, however, that protonation cannot be regarded simply as the mechanical addition of new structural elements to the molecule, since it is accompanied by a radical rearrangement of the force field. This may change in $\ln \beta$ in either direction. Thus protonation of oxygen and fluorine leads to a considerable decrease in $\ln \beta_{D/H}$. The published[65,66] separation coefficients for the H_3O^+/H_2O system show that $\ln \beta_{D/H}$ for the hydroxonium ion is ~0.3 unit lower thn $\ln \beta_{D/H}$ for H_2O. This is related to the difference in the electronic structures of the O and N atoms, as a result of which the protonation of the water molecule or the removal of an electron from it lead to a decrease in the strength of the bond, a sharp decrease in the force constants, and hence a decrease in $\ln \beta$. These marked changes in $\ln \beta_{D/H}$ on protonation may be significant in isotopic fractionation processes in biological systems.

Cyclopendant ligands

F I Bel'skii, Yu M Polikarpov, M I Kabachnik
A N Nesmeyanov Institute of Heteroorganic Compounds, Russian Academy of Sciences

ABSTRACT. The numerous cyclopendant ligands are described in the review. These contain a cyclic fragment, with donor atoms, with groups added which are capable of coordinating cations. An attempt has been made to systematise the literature data on the methods of synthesis and the properties of cyclopendant ligands. Fundamental results of authors on the application of a quantitative method of assessing the efficiency and selectivity of action of ligands (criteria *A* and *S*) are given.

It has been shown that the use of cyclopendant ligands enables the efficiency and selectivity of complex formation to be increased.

The bibliography contains 182 references.

I. Introduction

Polydentate reagents capable of binding cations with various coordination polyhedra have acquired considerable importance in coordination chemistry in recent years. By this means not only is the binding energy of the donor centres of the ligand added together but a chelate effect is also displayed (mainly entropic in origin). A polydentate ligand makes it possible to close several chelate rings, increasing in this way the binding equilibrium constant, i.e. the free energy of formation of the complex.

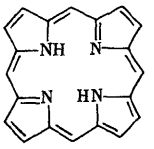
Polydentate reagents are widely used in analytical chemistry, in the technology of separating non-ferrous and rare metals, in processes of flotation and extraction, in the textile industry (mordent dyeing) and in many other areas of science and technology.

Polydentate reagents have acquired great importance mainly because of two properties, viz. the efficiency of binding cations (displayed in the stability if the resulting complexes) and the selectivity of complex-formation. This applies equally both to neutral reagents and to molecules containing both acidic and basic functional groups. The majority of complexones are characterised by a polydentate nature and chain flexibility, which bind donor complex-forming centres. The stability of the resulting complexes is high but the selectivity is comparatively low.

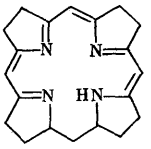
A higher selectivity among cyclic polydentate ligands is possessed by the neutral crown polyethers, basic polynitrogenous macrocycles, cryptands and certain other compounds. The cyclopendant ligands are of interest in this connection and are ligands containing a cyclic (usually macrocyclic) nucleus, frequently including donor centres, to which are added side groups, viz. pendant or lariat groups which also carry donor centres capable of coordination with metal cations.[1,2] Hence the name cyclopendants.†

The simultaneous binding of metal cations with the donor centres of the ring and the pendants frequently achieves high binding stability and selectivity for the cyclopendant ligands. The ligand shape arising in this way may not accommodate every cation.

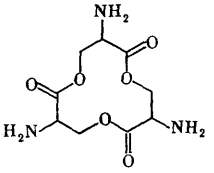
The nature cyclopendant ligands have high binding selectivity. Examples are derivatives of porphin, corrin and polyglycidic ethers, carrying various pendant groups. The variety of cyclopendants, i.e. vitamins, antibiotics, cytochromes, siderophores, etc., is explained by the variety of pendant groups and the central metal ion.



Porphin



Corrin

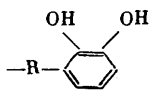


Serine trilactide

The addition of further pendant groups to the plane-coordinated metal complexes porphin and corrin occurs by a form of extra coordination. The pendant substituents occupy an apical position on the *z* axis perpendicular to the plane of the macrocycle.[3] Similar coordination proves to be a most important feature of such compounds as chlorophyll, blood haem, vitamin B-12, etc. With extra coordination the cations of various metals are bound selectively by the donor atoms of the pendant groups. Blood haem coordinates Fe^{3+} ions with the formation of haemin or haematin, chlorophyll acids (*a* and *b*) selectively bind the Mg^{2+} ion with the formation of chlorophyll. In the vitamin B-12 molecule the Co^{2+} ion is coordinated by the four nitrogen atoms of the corrin ring, the CN^- group and the nitrogen atom of a benzimidazole act as extra

† Originates from the Latin pendere (to hang) and the English pendant (a pendant). Occasionally ligands are also known as 'lariatnye' from the English lariat (lasso or rope). It seems to us that the term 'lariat' in relation to the whole ligand precludes the occurrence of donor centres in the ring which are frequently encountered and are reflected in the name cyclopendant. The actual 'pendant' is now widespread in the English language literature.

ligands (see Figures[1,4]). Cytochromes have the same ferroporphin fragment in the molecule. The differences in their properties are caused by the difference in pendant substituents. The phenolic hydroxyls of the pendant groups in the complex enterobactin



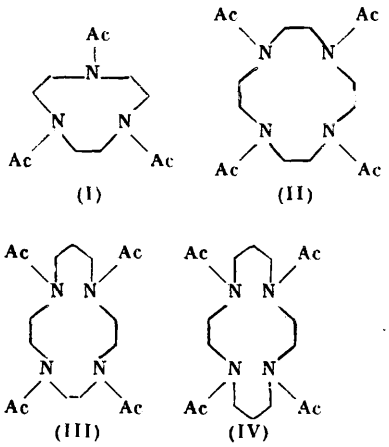
occupy the six coordination positions of the Fe^{3+} cation and form a stable complex.[5] All the natural cyclopendants possess high efficiency of action in addition to high selectivity of complex-formation, forming stable complexes with metal cations. The high stability of such complexes is caused not only by the high binding energy but also by the complete complementarity (spatial fit) of their ligand shape (in the presence of extra coordination) to the coordination polyhedraon of the cation in question.[3]

It is necessary to bear in mind the general principles of complex-formation. The equilibrium of this process is determined by the free energy of complex-formation $A = RT \lg K_{st}$ [sic], where K_{st} is the stability constant.‡ The energy of the coordination bond [sic] ΔH depends on the free energy and on the entropy. Frequently $\lg K_{st}$ is taken as a measure of the strength of the binding of the ligand and the cation in the complex. The strength naturally depends on the nature of the cation and the character of the ligand. This problem has been well studied in the chemistry of coordination compounds and is not examined in the present paper.

However there are other aspects to complex-formation linked mainly with the entropy factor. In the case of a polydentate ligand with several binding centres (donor centres) in one molecule, the problem of the complementarity of a ligand and the coordination polyhedron of the cation becomes important. If the polydentate ligand possesses a flexible chain of atoms than it can take up a conformation, without a large consumption of energy, corresponding to such complementarity. The strength of the resulting complex will be determined by the binding energy of the cation with the donor centres. With inadequate chain flexibility or with a structure such that the population of the complex-forming conformation (for the given cation) is low, the stability of the complex depends not only on the binding energy but also on the complementarity of the complex-forming conformation i.e. its energy of formation. If two polydentate ligands with the same set of donor centres are compared then the energy of complementarity becomes determining. It is clear that reagents with flexible chains of molecules may not be highly selective. Other conditions being equal (parity of the number and character of donor centres), the introduction of more rigid links into the chain of a polydentate ligand increases selectivity.

II. The first synthetic cyclopendants

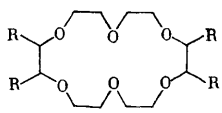
These ligands recall the natural ligands since they contain a cyclic fragment with added pendant groupings possibly acting as extra ligands. In 1975 Hama and Takamoto[6] synthesised and studied the complex-formation of the ligand (I) with transition metals (TM) and also with Cd^{2+} and Pb^{2+}. In 1976 Stetter and Frank obtained and investigated the complex-forming ability of complexones (II)–(IV) in relation to the alkaline earth metals (AEM) and the TM.[7]



Here and subsequently Ac = CH_2COOH.§

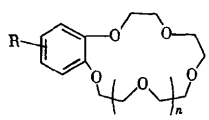
In the same year Behr and collaborators synthesised and investigated ligands (V) with ions of NH_4^+, K^+, $MeNH_3^+$ and $PhCH_2CH_2NH_3^+$ (25 °C, water).[8] The complex-formation of ligands (VI) with Na^+ and K^+ ions at 25 °C in acetone has been studied.[9]

The extraction[10] and complex-forming[11] properties of ligands of formula (VII) in relation to NH_4^+ and the alkali metals have been investigated.



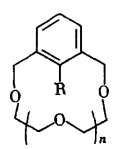
(V)

R = 1. C(O)NMe$_2$
2. COOH etc.



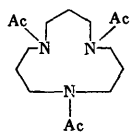
(VI)

n = 1,2, R = NH_2, COOH, COOMe etc.



(VII)

n = 1 to 4, R = COOH, OH, CH_2OH etc.



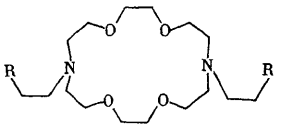
(VIII)

Takahashi and Takamoto in 1977 obtained and investigated (spectroscopically) the complexes $[ML]^0$ of Fe^{3+}, Cr^{3+}, and Co^{3+} cations with ligands (I) and (VIII).[12] In the same year Chang obtained ligands (IX)[13] and in 1978 Takagi and co-workers synthesised and studied the complex-formation of ligand (IX) (R = COOH) with ions of the AEM and TM.[14] Finally, in 1979 ligands (X) and (XI) were synthesised and complexes of (X) with

‡ The values of stability constants of complexes with the various cations used in this study were taken as a rule from reference literature, in which they had been critically assessed.

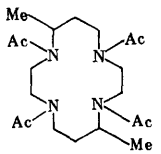
§ Note that the symbol Ac in the literature usually denotes the acetyl residue CH_3CO-. Here Ac = $-CH_2COOH$.

TM were isolated.[15] Ligand (XI), an analogue of enterobactin, binds Fe^{3+} ions effectively.[16]

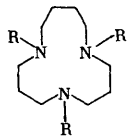


(IX)

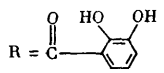
R = CN, CH_2NH_2 [13]
R = COOH [14]



(X)



(XI)

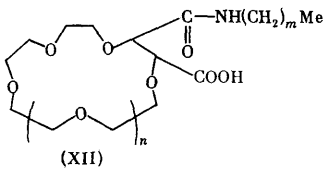


The reagents indicated were the first representatives of the synthetic cyclopendants. A great number of ligands with various groups were obtained later. The polyalkylenepolyamines, crown-ethers and crown-polyaza-polyethers with several modifications and various pendant groups form part of practically all new (synthesised up to 1988) cyclopendant reagents.

III. Cyclopendants: derivatives of oxygen macrocycles (crown-ethers)

Values of $\lg K_{st}$ have been determined for complexes of ligand (V, 2) with NH_4^+, K^+, $MeNH_3^+$ and $PhCH_2CH_2NH_3^+$ cations in water at 25 °C and are 3.51, 5.48, 2.88 and 2.41 respectively.[8] Pendant COOH groups evidently participate in the coordination since the ligand without these groups, 18-crown-6, forms complexes with NH_4^+ and K^+ ions with $\lg K_{st}$ = 1.1 and 2.06.[17]

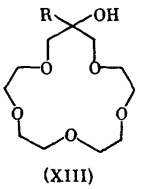
The complex-formation of ligands of formula (XII) with n = 1, m = 7 and 17; n = 1 and 2, m = 3, 7 and 13 with ions of Na^+, K^+ and Rb^+ has been investigated.[18]



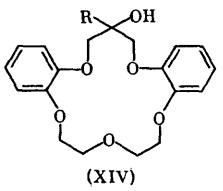
(XII)

The length of the hydrocarbon chain (variation of m) has no effect on the stability of the complexes. An increase in the size of the ring (transition from n = 1 to n = 2) leads to an increase of all the stability constants and a shift in the maximum efficiency of complex-formation towards cations of larger ionic radius.

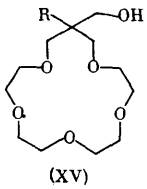
The ligands (XIII)–(XV) have been synthesised[19] and extraction and association constants with Na^+ and K^+ picrates were found. The substituents R showed an electronic and a steric effect on the extraction process.



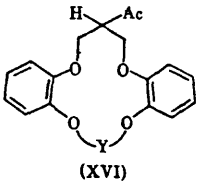
(XIII)



(XIV)



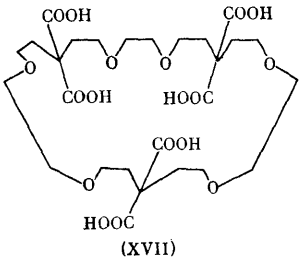
(XV)



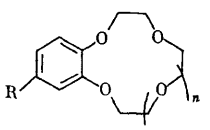
(XVI)

R = H, Me, Ph, n-$C_{10}H_{21}$ etc.
1. Y = CH_2CH_2; 2. Y = $(CH_2)_3$; 3. Y = CH_2OCH_2;
4. Y = $CH_2OCH_2OCH_2$.

The ligands (XVI) are efficient extractants for Na^+, K^+, Rb^+ and Cs^+.[20] The stability constants for (XVI, 3) with Ca^{2+}, Na^+ and K^+ ions have been determined.[21]



(XVII)

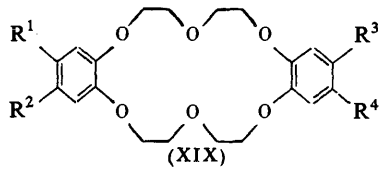


(XVIII)

1. n = 1 to 4, R = PPh_2 [Ref. 23]; 2. n = 2 to 3, R = = $CH(OH)CH_2NHMe$ [Ref. 24]; 3. n = 2, R = COOH, CH_2OH etc. [Ref. 25]; 4. n = 2, R = OH [Ref. 26].

The acid (XVII) was synthesised as a reagent for the UO_2^{2+} ion.[22] Ligands (XVIII) contain various numbers of donor oxygen atoms and various pendant groups R. Equilibrium constants were determined for compounds (XVIII, 1) (with various ring sizes) for the extraction of Li, Na^+, K^+ and Cs^+ picrates. The equilibrium constant for the ion of large ionic radius, K^+ and Cs^+, was increased for these compounds as n was increased. The pendant groups of ligands (XVIII, 1 and 2) seemingly do not participate in coordination with these cations since the corresponding compounds without the pendant groups in the molecule possess practically the same extraction and complex-forming properties.[23,24] Ten ligands (XVIII, 3) with various pendant groups have been synthesised.[25] Their extraction properties in relation to the picrates of Li^+, Na^+ and K^+ have been studied. Complexes of Li^+, Na^+, K^+, Rb^+, Mg^{2+}, Ca^{2+} and Ba^{2+} with ligand (XVIII, 4) of composition ML, ML_2, and M_2L have been obtained.[26] X-Ray structural analysis (XSA) of the complex $[KCNS(L)_2]$ showed that the K^+ ion in it was coordinated with ten donor atoms of the ligand. The pendant group and the CNS^- anion did not participate in coordination.

Cyclopendants based on dibenzo-18-crown-6 of formula (XIX) have been synthesised and investigated.



(XIX)

1. $R^1=R^2=R^3=R^4=H$ [Ref. 27]; 2. $R^1=R^4=H$, $R^2=R^3=NH_2$ [Ref. 28]

3. $R^1=R^4=H$, $R^2=R^3=N=CH-$ [Ref. 28];

4. $R^1=R^2=R^3=R^4CH_2PPh_2$ [Ref. 27];

5. $R^1=R^3=H$, $R^2=R^4=\overset{O}{\overset{\|}{C}}NHP(OH)^2$ [Ref. 29]

6. $R^1=R^3=H$, $R^2=R^4=NHP\begin{matrix}A\\ \|\\ O\quad B\end{matrix}$ (A, B = OEt, OBu, OPh) [Ref. 30];

7. $R^1=R^3=H$, $R^2=R^4=NHP(Me)(Ph)$ [Ref. 30].

The complex-formation of ligands (XIX, 2 and 3) with the ions Cu^{2+}, Co^{2+} and K^+ has been studied.[28] It was established that both pendant NH_2 groups of ligand (XIX, 2) participate in coordination with Co^{2+} and Cu^{2+}. The ring oxygen atoms do not participate in the coordination with these cations. The complex [(L)KI], in which K^+ is in the plane of the macrocycle, forms a chelate with the Co^{2+} ion of the same spectral type (infra-red: IR) as does free (XIX, 3). Stability constants for complexes of the alkali metals with ligand (XIX, 4) and dibenzo-18-crown-6 (XIX, 1) have been compared.[27] The pendant groups $CH_2P(O)Ph_2$ hinder the coordination of the cations investigated with the ring oxygen atoms (Table 1).

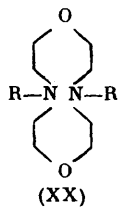
Table 1. Values of $\lg K_{st}$ for complexes $[ML]^+$ of ligands (XIX, 1 and 4) (solvent, ethanol : chloroform 1 : 1, T = 25 °C).[27]

Cation	(XIX.1)	(XIX.4)
Li^+	3,48	3,09
Na^+	3,97	3,86
K^+	4,51	3,95
Cs^+	3,49	3,47

The complex-forming properties of ligands (XIX, 5–7) have not been investigated.[29,30] In the complex $[(CoCl_2)_2KCl(L)]$ the K^+ ion is in the plane of the macrocycle but the Co^{2+} ions are bound only with the oxygen atoms of the pendant groups [L = (XIX, 4)].[27] As an extractant, ligand (XIX, 4) is better in separation factor for the U/Am pair than the best of a large series of reagents.[31]

IV. Cyclopendants based on crown-polyaza-polyethers

These compounds contain a cyclic polyaza-polyether fragment, the pendant groups being added at the nitrogen atoms. Ligands (XX) have been synthesised.[32]

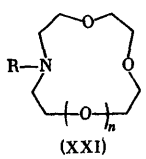


(XX)

1. $R = CH_2CH_2\overset{O}{\overset{\|}{C}}NMe_2$
2. $R = (CH_2)_3\overset{O}{\overset{\|}{C}}NMe_2$
3. $R = CH_2CH_2OH$
4. $R = CH_2COOH$

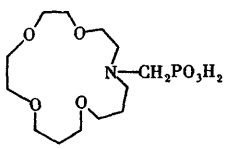
X-Ray structural analysis of the free ligand (XX, 2) showed that its donor atoms (N and O) are disposed at the vertices of an octahedron. The thermodynamic parameters ($\lg K_{st}$, $\Delta H°$ and $\Delta S°$) have been determined for ligands (XX, 1–3) with ions of the alkali and alkaline earth elements and Ag^+.[32] Evidently the pendant groups participate in the coordination with cations since the stability of the resulting complexes depends strongly on the nature of these groups. Thus ligand (XX, 1) forms far more stable complexes with a given cation than (XX, 2 and 3). Compound (XX, 4) has been mentioned[33] without citing its synthesis and properties.

Complex-formation of ligand (XXI, 1) with ions of the alkaline earth metals has been studied.[34]



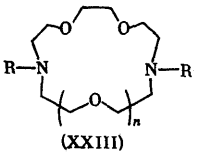
(XXI)

1. R = CH_2CH_2OH, n = 1;
2. R = CH_2  , n = 2, 3;
3. R = $CH_2PO_3H_2$, n = 2.



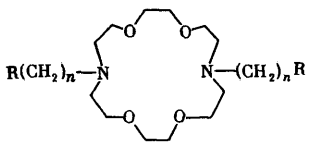
(XXII)

Moving from n = 2 to n = 3 leads to a change in the selectivity of extraction of alkaline earth metals by ligands (XXI, 2).[35] The complex-forming ability of ligands (XXI, 3), (XXII) and (XXIII, 4) with $CH_2PO_3H_2$ as pendant group was investigated in water in relation to the Na^+ ion.[36]



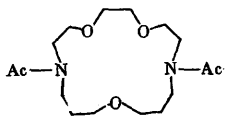
(XXIII)

1. $n=2$, R=$CH_2PO_3H_2$ [36];
2. $n=1$, R=Ac [38];
3. $n=2$, R=Ac [37, 39];
4. $n=2$, R=CH_2Ac [14];
5. $n=2$, R = [43]; etc. [40–42].

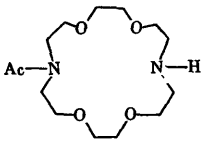


(XXIV)

$n=1-3$, R=PO_3H_2, COOH, NH_2 etc.



(XXV)



(XXVI)

The synthesis of ligands (XXIV) has been described, their ability to dissolve $BaSO_4$ was recorded in the same paper.[37]

The complex-formation of ligands (XXIII, 2–4) has been studied in relation to a large number of cations. The stability constants of complexes of (XXIII, 2–4), (XXV) and (XXVI) are given in Table 2. The stability of complexes of other ligands of formula (XXIII) has not been determined.[40–42]

Table 2. Values of $\lg K_{st}$ for complexes [ML] of ligands (XXIII, 2–4), (XXV) and (XXVI).

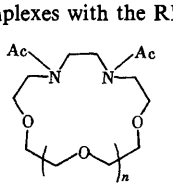
Cation	(XXIII,2)	(XXIII,3)	(XXIII,4)	(XXV)	(XXVI)
K^+	1.7	3.9	–	–	–
Mg^{2+}	7.4	–	<2	<2	–
Ca^{2+}	8.7	8.4	4.0	7.7	–
Sr^{2+}	7.9	8.3	4.4	7.7	–
Ba^{2-}	7.3	7.6	3.8	7.7	–
Co^{2-}	13.7	–	see*	7.0	–
Ni^{2+}	12.2	7.4		7.5	5.4
Cu^{2+}	16.0	14.5	~6–7	>14	10.5
Zn^{2-}	14.1	8.4	see*	8.0	5.4
Cd^{2+}	13.0	11.1	–	–	7.8
Pb^{2+}	12.9	13.6	8.1	–	10.4
La^{3+}	10.1	12.2	–	–	6.6
REE	10.3–11.9	10.8–12.2	–	–	6.0–7.4

Note. The numbers given are rounded up to tenths. Experimental conditions: T = 25 °C, μ = 0.1 (Me_4NCl), solvent was water.
*Complex-formation was so weak that at $a > 1$ the ions of Co^{2+}, Ni^{2+} and Zn^{2+} precipitated as hydroxides (a is the number of equivalents of alkali per mole ligand).

The increase of the cyclic fragment on going from ligand (XXIII, 2) to ligand (XV) is accompanied by a reduction in the stability constant of the complexes of all cations apart from Ba^{2+}, the most bulky of the cations being compared. A reduction in the stability constant of the complexes also occurs on increasing the length of the pendant group on going from (XXIII, 3) to (XXIII, 4). The removal of one pendant group in ligand (XXVI) compared with (XXIII, 3) leads to an appreciable reduction in the stability of the complexes. This means that carboxyl pendant groups participate in the coordination.[44] An increase in the cyclic fragment with the simultaneous inclusion of one more donor oxygen atom in it involves a reduction in the stability of complexes of ligand (XXIII, 3) with cations of small ionic radius and an increase in the stability of complexes with cations of larger ionic radius compared with ligand (XXIII, 2). For cations of ionic radius > 1.1 Å and rare earth elements (REE) the complexes of ligand (XXIII, 3) are more stable, for all the remainder the complexes of (XXIII, 2) with a smaller cyclic fragment are the more stable. The stability constants of complexes of REE with ligand (XXIII, 3) fall continuously from Ce^{3+} and Lu^{3+} with the reduction in ionic radius of these cations.[39] In contrast, the complex-formation of REE ions with ligand (XXIII, 2) is maximal at the Eu^{2+} ion.[45] The rare earth elements of larger and smaller ionic radii form less stable complexes with this ligand.

The cyclopendant ligands based on crown-polyazapolyethers display interesting complex-forming properties. Usually the complexes with the classical complexones of Sr^{2+} are less stable than the complexes of Ca^{2+}. Ligands (XXIII, 3) and (XXV) form complexes of practically identical stability with Ca^{2+} and Sr^{2+}, but ligand (XXIII, 4) chelates Sr^{2+} more efficiently than Ca^{2+}. Ligand (XXV) shows a very high difference in stability constants for the complexes of the small Mg^{2+} ion and the bulky Ca^{2+} ion. It is interesting that Co^{2+} and Ni^{2+} form complexes of lower stability than the ions of the alkaline earth metals with the ligands (XXIII, 3), (XXV) and (XXIII, 4) (see Table 2), which is also unusual for complexones of linear structure. This may be caused by the fact that the ions of the transition metals have a lower ionic radius than the ions of the alkaline earth metals. The stability constants of the complexes of Ca^{2+}, Sr^{2+}, and Ba^{2+} with ligand (XXV) do not depend on the ionic radius of the cation.

Chang and collaborators investigated the kinetics of the dissociation of complexes of lanthanides with ligands (XXIII, 2 and 3).[46,47] The complex-formation of REE ions with ligands (XXVII) with different sizes of cyclic fragment has been investigated.[48] The value of $\lg K_{st}$ for complexes of (XXVII, 1) increased continuously with the reduction in ionic radius from La^{3+} to Lu^{3+}. An increase in the ring size led to an increase in the stability of the complexes of REE with ligands (XXVII, 1–3) but transfering from ligand (XXVII, 3) to (XXVII, 4) did not cause a further increase in K_{st} for the complexes with the REE.



(XXVII)

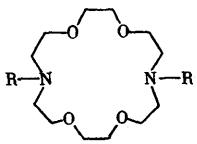
1. n = 0
2. n = 1
3. n = 2
4. n = 3

The complex of the Cu^{2+} ion with ligand (XXIII, 3) has been investigated by XSA.[49] It was found that Cu^{2+} is in a square plane formed from two nitrogen atoms of the ring and two oxygen atoms of the carboxyl groups.

The selectivity factor of a ligand in relation to Zn^{2+} and Ca^{2+} ions is important in medicine when checking the elimination of Pb^{2+} ions from animals.[50]

$$\lg K_{st\ Pb^{2+}} / \lg K_{st\ Zn^{2+}} = \varphi_1 \text{ and } \lg K_{st\ Pb^{2+}} / \lg K_{st\ Ca^{2+}} = \varphi_2.$$

For example, the size of φ_1 is 1.6 for ethylenediaminetetraacetate (EDTA). With the aim of obtaining a reagent with a high selectivity factor the ligand (XXIII, 5) mentioned above, containing a crown-diaza-polyether ring and pendant α-pyridylmethyl groups, was synthesised.[43] Values of the stability constants are given in Table 3 for ligands (XXVIII) with five different pendant groups.



(XXVIII)

1. R = H; 2. R = CH_2CHMe (OH); 3. R = CH_2COOH;
4. R = CH_2–(N-heterocycle); 5. R = CH_2CH_2SH

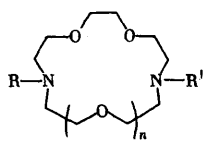
A characteristic feature of these ligands is their ability to chelate efficiently cations of large ionic radius. This leads to very high values for φ_1 and φ_2 [particularly with pendant (4)]. The stability constants for complexes of the small Zn^{2+} ion and the bulky Cd^{2+} and Pb^{2+} differed sharply.

Table 3. Values of $\lg K_{st}$ for complexes [ML] of ligands (XXVIII) with various pendant groups (T = 25 °C).

Cation	1	2	3	4	5*
Ca^{2+}	1.74	3.59	8.39	3.63	7.0
Sr^{2+}	2.60	4.05	8.29	4.87	–
Ba^{2+}	2.97	4.65	7.63	4.99	–
Ni^{2+}	–	–	7.39	8.80	–
Cu^{2+}	6.10	5.97	14.49	13.55	–
Zn^{2+}	3.10	3.00	8.42	6.96	16.3
Cd^{2+}	5.25	7.64	11.07	10.96	22.9
Pb^{2+}	6.80	8.57	13.55	11.67	26.1
La^{3+}	3.00	3.24	12.21	3.58	–

* Predicted values for ligand (XXVIII, 5).[43]

The preferential complex-formation of ligands (XXVIII, 1–5) with cations of large ionic radius leads to the result that ions of Sr^{2+} and Ba^{2+} are chelated more efficiently than Ca^{2+} ions by groups 1, 2 and 4 which is unusual for the classic complexones and is important in medical investigations.



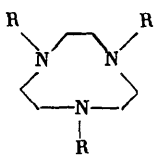
(XXIX)

1. R=R′=CH_2COOH, n=2
2. R=R′=CH(Me)COOH, n=2
3. R=R′=CH_2COOH, n=1
4. R=H, R′=CH_2COOH, n=2

The kinetics of the reaction of Cu^{2+} ion with ligands (XXIX, 1–4) have been studied.[52]

V. Cyclopendants: derivatives of nitrogenous macrocycles

1. Cyclopendants based on 1,4,7-triazacyclononane



(XXX)

1. R = H [73]
2. R = $CH_2PO_3H_2$ [55,·56]
3. R = $(CH_2)_2PO_3H_2$ [57]
4. R = CH_2COOH [6, 12]
5. R = $(CH_2)_2OH$ [58]
6. R = $(CH_2)_2NH_2$ [59, 60]
7. R = $(CH_2)_3NH_2$ [61]
8. R = CH_2CHOH (Me) [62]
9. R = $(CH_2)_2SO_3H$ [63]
10. R = $CH_2P(O)Ph_2$ [64–66]
11. R = CH_2–(N-heterocycle) [90, 91]

The stability constants of the complexes of a large number of cations with (XXX, 2) and (XXX, 3) have been determined, consequently it is possible to compare quantitatively the efficiency and selectivity of their complex-formation.

2. Means of assessing the efficiency and selectivity of ligands

A quantitative assessment of the complex-forming ability of ligands has been given.[67–69] The efficiency is the mean value of the sizes of $\lg K_{st}$ for complexes of composition ML.

$$A = \left(\sum_{i}^{n} \lg K_i\right) / n.$$

As a measure of the selectivity of action of a ligand the mean difference of $\lg K_{st}$ of complexes ML for all the cations taken in pairs.

$$S = \left[\sum_{i=1}^{n}\sum_{i=j}^{n} (|\lg K_j - \lg K_i|)\right] / n(n-1),$$

where n is the number of cations compared. The simplest algorithm for the calculation is the following.[68]

$$\Delta = \begin{vmatrix} \lg K_1 - \lg K_2 & & & \\ \lg K_1 - \lg K_3 & \lg K_2 - \lg K_3 & & \\ \lg K_1 - \lg K_4 & \lg K_2 - \lg K_4 & \lg K_3 - \lg K_4 & \ldots \\ \ldots & \ldots & \ldots & \ldots \\ \lg K_1 - \lg K_n & \lg K_2 - \lg K_n & \lg K_3 - \lg K_n & \ldots \lg K_{n-1} - \ln K_n \end{vmatrix}$$

The sum of the absolute values of all the differences in brackets is

$$\Delta = \frac{1}{2}\sum_{i=1}^{n}\sum_{i=j}^{n} |\lg K_i - \lg K_j|, \quad S = 2\Delta / n(n-1).$$

Other means of assessing selectivity are given in the literature. Occasionally a selectivity factor is used in studies on cryptates and crown-ethers which is the ratio of the stability constants for complexes of two cations, i.e. K_1/K_2.[70–72] In this of course only two cations are compared, the choice of them is arbitrary. The selectivity of action of ligands is assessed as the ratio of the stability constants of the complexes with ions of NH_4^+ and K^+.[72] On examining only two cations with stability constants K_1 and K_2 the previous formula is transformed into

$$S = \lg (K_1/K_2).$$

Certainly the values of A and S depend appreciably on the set of cations being compared, consequently to use them as a characteristic of the complex-forming ability of a ligand is only possible for the same set of cations. It is necessary to consider this when assessing the data calculated in the manual for efficiency and selectivity.[73]

3. Efficiency and selectivity of complexones of triazacyclononane derivatives

Values of $\lg K_{st}$ for complexes and A and S for complex-formation are given in Table 4 for ligands (XXX, 2), (XXX, 3) and (I). The values of the stability constants for the complexes of the remaining ligands (XXX) with the given cations in water were not determined.

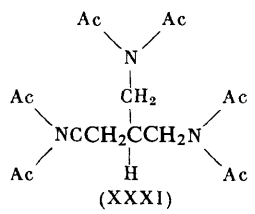
The selectivity of action of complexones (I), (XXX, 2) and (XXX, 3) is explained with the aid of a model of the spatial fit of the ligand shape (in an energetically favourable conformation) with the stereochemical requirements of the cation.[1,57] On coordination the metal cation falls into the cavity formed by the ligand as into a basket, the bottom of which is the nitrogen heterocycle and the walls are the pendant groups. Only a cation of suitable ionic radius may be placed in the basket cavity. This also determines the selectivity of complex-formation of the given ligands. The existence of a basket structure was confirmed by X-ray data on the complex of (XXX, 2) with the Fe^{3+} ion which has a very high stability ($\lg K_{st}$ = 29.6 [56]). The Fe^{3+} (ionic radius r = 0.64 Å) in a complex of composition $[FeH_3L]^0$ is in fact in the cavity of this ligand as in a basket.[74]

The complexone (XXX, 2) is selective, other conditions being equal, for cations of small ionic radius¶ such as Mg^{2+}, Zn^{2+} and Fe^{3+} with which it forms stable complexes. On turning to a cation with larger ionic radius, such as Ca^{2+}, Cd^{2+} or La^{3+}, the stability of the complexes is reduced by many orders of magnitude.[56] A large difference is shown in the values of K_{st} for complexes of Mg^{2+} and Ca^{2+}. Usually complexes of Ca^{2+} are more stable than complexes of Mg^{2+} with a small difference in the values of their stability constants. It is rare to encounter cases when the complexonate with Mg^{2+} is more stable than the complexonate with Ca^{2+} and their stability constants differ by one to two orders of magnitude. Only the *N*-oxide of nitrilotris(methylphosphonic acid) chelates the Mg^{2+} ion more effectively, the difference in K_{st} values being 2.6 log. units.[76] The difference of about 5 orders of magnitude observed for (XXX, 2) is unprecedented. It also shows the highest difference of all the complexones in the stability constants for the complexes of Zn^{2+} and Cd^{2+}.[73]

Cations of large ionic radius form fairly stable complexonates with the acid (XXX, 2). Calculations by molecular mechanics showed that just one low energy conformation is possible for this ligand, a 'ladle' in which two pendant groups continue as though forming the internal cavity of the ligand but one is tilted away like the handle of a ladle. The cavity of the ladle is larger and may take up huge cations occupying five of their coordination positions. When octahedral coordination is characteristic of the cation, the sixth place is occupied by the remaining monodentate ligand.

The Cu^{2+} ion also has a small radius but it is inclined to be pentacoordinate and forms a complex in the form of a ladle with (XXX, 2) (XSA data).

The size of the cavity of a complexone basket, into which the metal cation is placed, may vary either with a change in the size of the cyclic fragment or with a change in the length of the pendant groups. The complexone (XXX, 3) with phosphonoethyl pendant groups was synthesised to study this effect. The nitrogen atoms and the phosphorus are separated by ethylene bridges. The efficiency of complex-formation of this complexone is lower than that of (XXX, 2). Evidently this is linked with the lower stability of the six-membered chelate rings formed by it with the pendant groups compared with the five-membered formed by the phosphonomethyl pendant groups of complexone (XXX, 2). However the stability constants of both complexes are equal for the copper cation which requires a ligand shape of a tetragonal pyramid (see Table 4). The selectivity of action of the new cyclopendant in relation to the second group of cations is greater than for acid (XXX, 2). Complexones (XXX, 2) and (XXX, 3) have the same set of donor centres consequently the difference in complex-formation with various TM is impossible to explain by the non-uniformity of the covalent binding energy. This means that the spatial factor has a leading role. There is a very large difference in stability for the complexes of Co^{2+} and Ni^{2+} with (XXX, 3). Usually the complexes of Ni^{2+} are somewhat more stable than the complexes of Co^{2+} and have a small difference in stability constant.[73] Complexone (XXXI) shows the maximum difference in size of K_{st} for these cations, $\lg K_{st}$ [CoL] = 13.8 and $\lg K_{st}$ [NiL] = 18.0.[77] Complexone (XXX, 3) gives the same difference in stability constants but in this case the Co^{2+} complex is more stable than the Ni^{2+} complex.



(XXXI)

Table 4. Values of $\lg K_{st}$ for complexes [ML] and values of A and S.

Cation	(XXX.2)	(XXX.3)	(I)	Cation A, S	(XXX.2)	(XXX.3)	(I)

*** For the set of cations Mg^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}.

¶ Values of the ionic radii have been reported.[75]

Lengthening the small chain linking the nitrogen atom and phosphorus in (XXX, 3) increases the size of the basket, corresponding to the selectivity of complex-formation, when compared with complexone (XXX, 2). The larger octahedron characteristic of Co^{2+} requires a larger volume for the cavity than the tetrahedron characteristic of Ni^{2+} (at almost the same ionic radius). As a result, complexone (XXX, 3) fits better with the Co^{2+} ion than with the Ni^{2+} ion and this difference leads to the observed selectivity of action. Complexone (XXX, 3) forms a much less stable chelate than (XXX, 2) with the Mg^{2+} ion, which is too small for the cavity of ligand (XXX, 3). On the other hand, evidently the Ca^{2+} ion is too large for the basket of this ligand without even considering the more voluminous ions of Sr^{2+} and Ba^{2+} (the binding here is undoubtedly ionic). The stability constants of the complexes of (XXX, 2) with Co^{2+} and Cd^{2+} were no different, but for the new complexone the complex with the more bulky Cd^{2+} ion was significantly more stable than the complex with Co^{2+} (see Table 4). The difference in stability constants for (XXX, 2) with the small Zn^{2+} ion and the larger Cd^{2+} ion was very great but for (XXX, 5) it was far less. The bulky Mn^{2+} ion forms a more stable complex than Ni^{2+}. This leads to a breaking of the Irving–Williams series[78] which is characteristic of the traditional complexones. It is therefore seen that the size of the basket for complexone (XXX, 3) is somewhat larger than that for (XXX, 2).

When investigating the complex-formation of ligands (XXX, 1) and (XXX, 3) with Cu^{2+} and Zn^{2+} ions in water it was shown[58] that hydroxyethyl substituents, although playing no part in coordination, reduced the complex-forming ability of the amines as a result of electronic and steric effects. Since complexes are formed in the case of ligand (XXX, 5) which are more stable than the complexes of the free amine (XXX, 1), it must be deduced that the problem of the participation of the hydroxyethyl pendant groups in coordination with cations remains open.

The thermodynamics of complex-forming of complexone (I) with Mg^{2+}, the AEM and Cu^{2+} ions, have been investigated (Table 5).[81]

Table 5. Thermodynamic parameters for complex-formation of complexone (I) with certain cations (T = 25 °C).

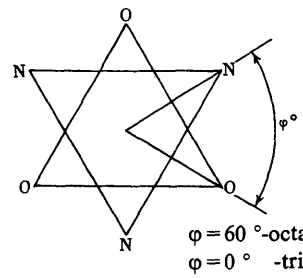
Cation	$\lg K_{st}$	$\Delta H°$, kcal mole^{-1}	$\Delta S°$, kcal mole^{-1} K^{-1}
Mg^{2+}	9.69	+0.4	45
Ca^{2+}	8.92	−5.9	21
Sr^{2+}	6.83	−2.1	24
Ba^{2+}	5.10	−1.38	18.6
Cu^{2+}	21.63	−13.4	54

The greater stability of the complex of (I) with Mg^{2+} compared with Ca^{2+} is caused purely by the entropy factor. It might be supposed that for complexone (XXX, 2) also, the greater stability of the Mg^{2+} complex compared with that of Ca^{2+} is caused by the entropy factor, when the conformation of the free ligand is ideal for the approach of the small Mg^{2+} ion.

According to XSA data the complexes of ligand (I) have the conformation of a basket for which 1,4,7-triazacyclononane serves as the base and the pendant carboxyl groups the walls.

In 1982 Wieghardt and collaborators obtained a large series of complexes of composition $[M^{III}L]$ and $Na[M^{II}L]$, where L = (I), M^{III} = Al^{3+}, Cr^{3+}, Mn^{3+}, Fe^{3+} and Co^{3+} and M^{II} = Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+} and Cu^{2+}.[84] The authors examined the complexes $[Cr^{3+}L]$, $[Fe^{3+}L]$, $Na[Cu^{2+}L]2NaBr.8H_2O$ by XSA in this study. It was shown that only in the complex with VO^{2+} was ligand (I) pentadentate (one carboxyl group did not participate in coordination). In all the remaining complexes all the donor atoms of the ligand participated in coordination (Scheme 1).

Scheme 1



φ = 60 °-octahedron
φ = 0 ° -trigonal prism

Later, XSA was carried out on complexes of (I) with Ni^{2+} and Ni^{3+} ions.[86] The reaction of (I) with Ni^{2+} occurs even in dilute HNO_3. The complex $[NiL].H_3O$ (crystalline) was isolated from this solution the XSA of which showed that all the nitrogen atoms and the oxygen atoms of the carboxyl groups coordinated with the Ni^{2+} ion and the hydroxonium ion is separate from the complex anion. In dilute HNO_3 the blue $[Ni^{2+}L]H_3O$ complex is converted into the rose $[Ni^{3+}L]$ complex of trivalent nickel (Table 6).

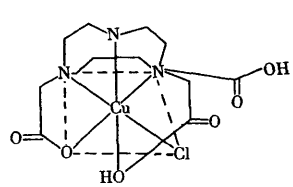
Table 6. Crystal lattice parameters for complexes of ligand (I) with certain cations from XSA data.[84,86]

Cation	φ (Scheme 1), deg	Mean bond length, Å	
		M–N	M–O
Ni^{3+}	53.1	1.93	1.91
Ni^{2+}	48.0	2.04	2.08
Cr^{3+}	49.0	2.06	1.96
Cu^{2+}	26.6	2.12	2.07
Fe^{3+}	25.0	2.18	1.96

The geometries of the complexes of Ni^{3+} and Cr^{3+} with (I) are close to tetrahedral and the geometries of the complexes of ligand (I) with Cu^{2+} and Fe^{3+} ions are close to a trigonal prism. The protonated complex $[CuClLH_2]$ has a ladle conformation.[87]

One of the protonated groups of ligand (I) turns away to the side. Two nitrogen atoms, one chlorine atom and one oxygen atom of the deprotonated carboxyl group are coordinated to the Cu^{2+} ion in the equatorial plane (Scheme 2).

Scheme 2



One nitrogen atom of the ring and an oxygen atom of one of the protonated carboxyl groups are in the axial positions with longer bonds. Such a structure for the complex of Cu^{2+} with complexone (I) may be caused by steric hindrance arising in the coordination of the 1,4,7-triazanonane fragment with the Cu^{2+} ion. It was established by XSA [88,89] that in the complexes of (XXX) with $CuCl_2$ and $CuBr_2$ two nitrogen atoms and two halogen atoms are located in the equatorial plane and the third nitrogen atom occupies the fifth apical position with a longer coordinate bond length. According to XSA of the complex $[CoL](ClO_4)_3$ with ligand (XXX, 6) the Co^{3+} ion is in the plane of the ligand as in a basket with the three-nitrogen ring serving as the base and the pendant ethylamino groups as the walls.[59] The complexes of Co^{3+} and Ni^{2+} of composition $[CoL]Br_3$ and $[NiL]Br_2.H_2O$ with ligand (XXX, 7) containing pendant propylamino groups in the molecule have the structure of a regular octahedron (according to XSA data).[61]

Wieghardt and collaborators have synthesised a large number of complexes of ligand (XXX, 11) with the TM, Cr^{3+}, Fe^{3+}, Pd^{2+}, Ru^{2+} and Ru^{3+}.[90] X-Ray structural analysis was carried out on complexes of $[NiL](ClO_4)_2$, $[MnL](ClO_4)_2$, $[PdL](PF_6)_2$ and $[FeL](ClO_4)_2$ with this ligand.[90,91] The complexes of Mn^{2+}, and Fe^{2+} and Ni^{2+} ions with (XXX, 11) were coordinated with three ring nitrogen atoms and three nitrogen atoms of the α-pyridylmethyl pendant groups. The Pd^{2+} ion was pentacoordinated, one pendant group did not participate in chelation.

Table 7. Values of $\lg K_{st}$ for complexes [ML] of cyclopendant complexones and EDTA, *A* and *S*.

Cation *A*, *S*	(XXXII.2)	(XXXII.3)	(II)	EDTA
Be^{2+}	–	15.9	13.6	9.2
Mg^{2+}	7.3	<2	11.0	8.8
Ca^{2+}	10.3	<2	15.9	10.6
Sr^{2+}	9.8	<1	12.8	8.7
Ba^{2+}	8.8	<1	11.3	7.8
Mn^{2+}	16.9	12.4	17.8	13.8

Pb^{2+}	23.3	16.3	19.9	17.9
A *	9.0	–	12.8	9.0
S *	1.7	–	2.7	1.6
A **	21.9	18.3	18.6	17.0
S **	3.8	7.0	1.0	2.0

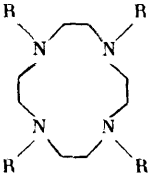
* For the set of cations Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}.
** For the set of cations Mn^{2+}, Ni^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}.

The Ni^{2+} ion in the complex of composition $Na[NiL.H_2O].5H_2O$ (L = XXX, 9) has a distorted octahedral structure. Three ring nitrogen atoms and an oxygen atom of the $CH_2CH_2SO_3^-$ group were in a square plane. The apical positions were occupied by a second $CH_2CH_2SO_3^-$ group and a water molecule. One pendant group was not coordinated to Ni^{2+}. The complex of copper ion of composition $Na[CuL].3H_2O$ is a distorted pyramid, two ring nitrogen atoms and two oxygen atoms of $CH_2CH_2SO_3^-$ groups form the base and at the vertex of the pyramid is a third nitrogen atom bound to a pendant group uncoordinated to Cu^{2+}.[63] The protonated complex of (XXX, 2) of composition $[CuH_4L].H_2O$ has the same structure according to XSA data[92] as does the complex of Cu^{2+} with ligand (XXX, 9). Two nitrogen atoms and two oxygen atoms of $CH_2PO_3H^-$ groups are at the base of the square pyramid and the third ring nitrogen atom, bound to a protonated pendant group, occupies the apical position. As is seen, a ladle conformation is characteristic for the protonated complexes of ligands (I) and (XXX, 2) and the complex of (XXX, 9) with the Cu^{2+} ion. In this conformation one pendant group of these complexones is turned away to the side and does not participate in chelation.

The coordination of 1,4,7-triazacyclononane with the Cu^{2+} ion occurs, as a rule, in the same manner. Two nitrogen atoms of the cyclic fragment are located in the equatorial plane and the third nitrogen atom occupies the apical position. The coordination of all three ring nitrogen atoms in one plane seemingly encounters difficulties and does not take place.

4. Cyclopendants based on cyclene

The following cyclopendant complexones are known which contain a 1,4,7,10-tetra-azacyclododecane (cyclene) fragment.



(XXXII)

1. R = H [73];
2. R = $CH_2PO_3H_2$ [67];
3. R = $CH_2CH_2PO_3H_2$ [93];
4. R = CH_2COOH [94, 95];
5. R = CH_2CH_2OH [96, 97];
6. R = $CH_2CH_2P(O)Ph_2$ [149].

The formation of more stable complexes with cations of small ionic radius was observed for complexone (XXX, 2) with a nine-membered ring. In (XXXII, 2) the size of the cyclic fragment is larger, consequently a shift of the maximum efficiency of complex-formation in the direction of cations with a large ionic radius might be expected. In reality the overall tendency towards complex-forming ability for this complexone is the formation of stable chelates with cations of relatively large size. In contrast to (XXX, 2) compound (XXXII, 2) gives a more stable complex with Ca^{2+} than with Mg^{2+}. For cations with an ionic radius less than 0.7 Å the complexes of ligand (XXX, 2) are the more stable. Ions with an ionic radius 0.7–0.8 Å form complexes of approximately the same stability but cations of larger size form more stable complexes with (XXXII, 2) (Table 7). The exception is the Cu^{2+} ion (small size) which gives an extremely stable complex with this complexone.

All the cyclopendant organophosphorus complexones, containing a tetra-aza-amine fragment, such as cyclene and 1,5,8,12-tetra-azacyclotetradecane (cyclam), form especially stable complexes with the Cu^{2+} ion, possibly with four ring nitrogen atoms in square coordination. The simultaneous presence in these complexones of a cyclic tetra-amine fragment and pendant alkylphosphonyl groups evidently leads to the high value for the stability constant of the complexes with Cu^{2+}. The carboxyl-containing analogues, ligands (II) and (IV), give complexes with $\lg K_{st}$ 19.0 and 18.6 respectively with the Cu^{2+} ions.[94] The unsubstituted cyclene and cyclam form

complexes with $\lg K_{st}$ equal to 23.3 and 26.5 respectively with the Cu^{2+} ion,[96], i.e. the pendant Ac^- behave as if interfering with coordination. The complex of (XXXII, 2) with the bulky La^{3+} ion is far more stable than the complex of this ion with complexone (XXX, 2). It is possible that this enables a coordination number of eight, natural for La^{3+}, to be put into effect. Seemingly, ligand (XXXII, 2) has a large plane size which leads to an increase in the metal–nitrogen distance on arranging the cation above the plane of the nitrogen atoms (the cations are not located within the plane). Hence its ability to form highly stable complexes with such cations as Cd^{2+}, Hg^{2+}, Pb^{2+} and La^{3+}.

The stability constants for the complexes of Zn^{2+}, Cd^{2+} and Hg^{2+} with complexone (XXXII, 3) with ethylphosphonic acid pendant groups differ significantly from the stability constants of Mn^{2+}, Co^{2+} and Ni^{2+} with the same complexone. None of the known complexones give such a large difference.[73] This ligand forms the most stable complex with the Cu^{2+} ion among all the cyclopendant organophosphorus complexones. It does not form complexes with Mg^{2+} and the alkaline earth elements although organophosphorus complexones of linear structure with four or more phosphonic acid groups in the molecule form fairly stable complexes with Mg^{2+} and Ca^{2+}.[98] Complexone (XXXII, 3) gives the most stable of the known complexes with the Hg^{2+} ion. It exceeds significantly all previously known complexones in selectivity of complex-formation (see Table 7).

Comparison of the complex-forming ability of the ligands (XXX, 2), (XXX, 3) (XXXII, 2 and 3) etc. shows that steric factors operate in a fairly complicated manner in the chelation of various cations. They cannot be reduced solely to the effect of the ionic radius of the cation and are developed on a background of electronic factors. Thus ligand (XXX, 3) shows a very high difference in the stability constants of complexes of Cu^{2+} and Ni^{2+} ions, which are close to one another in size[75] but differ in the stability of the polyhedra formed by them (octahedron, tetrahedron, square plane). Complexone (XXXII, 3) forms a highly stable complex with Zn^{2+}, which is more stable than the complexes with Co^{2+} and Ni^{2+}, but all three possess ionic radii which are close to one another. With the large cations Hg^{2+} and Pb^{2+}, clearly larger than Zn^{2+}, ligand (XXXII, 3) [like (XXXII, 2)] gives highly stable complexes, particularly with the Hg^{2+} ion ($\lg K_{st}$ = 29.6).

When coordinating with complexones (XXX, 3) and (XXXII, 3) the energy of the covalent bonding of a metal cation with the donor centres of the ligand has a fundamental importance and in the end is strongly dependent on the nature of the cation. Furthermore the structure of the coordination polyhedron of the cation also exerts a strong effect. Ligands with phosphonoethyl pendant groups may seemingly be reshaped under the stereochemical requirements of particular cations and this also makes a contribution to the observed high selectivity of these complexones. Evidently the bonding energy also provides the very high difference in stability constants of the complexes of ligands (XXX, 3) and (XXXII, 3) with the Cu^{2+} ion compared with other transition metals having similar ionic radii.

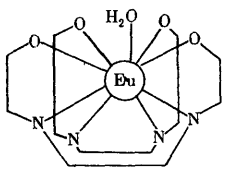
The carboxyl-containing cyclopendant complexone (II) surpasses the organophosphorus complexones in efficiency and selectivity of reaction with the ions of Mg^{2+} and the alkaline earth elements, but is itself significantly surpassed in selectivity of complex-formation with the TM, Cd^{2+} and Pb^{2+} not only by the organophosphorus complexones but also by EDTA, a complexone of linear structure (see Table 7). In contrast to the organophosphorus cyclopendant complexones which are cyclene derivatives, acid (II) forms highly stable water-soluble complexes with the REE. Stability constants are given in Table 8 for complexes of (II), EDTA and diethylene-triaminepenta-acetic acid (DTPA) with REE ions.[99,100]

The complex of (II) with the Eu^{3+} ion of composition $Na[Eu^{3+}L.H_2O].4H_2O$ has been investigated by XSA and ^1H NMR.[101] In this, Eu^{3+} is nine-coordinate with four coordinate bonds from nitrogen atoms lying at the base of prism of mean length 2.71 Å, four from oxygen atoms of the carboxyl groups of mean length 2.34 Å and one bond with a water molecule of length 2.48 Å.

Table 8. Values of $\lg K_{st}$ for complexes [ML] (T = 20 °C, μ = 1.0, NaCl).

Cation	(II)	EDTA	DTPA
Eu^{3+}	28.2	17.3	22.4
Tb^{3+}	28.6	17.9	22.7
Lu^{3+}	29.2	19.8	22.4

The Eu^{3+} ion is in a basket of eight donor atoms of ligand (II). The bond lengths are greater than in complexes of other ligands with the TM.



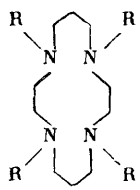
The authors called such a coordination polyhedron a distorted square antiprism.[101] Complexes of the following composition have been investigated by IR and visible spectroscopy: $[Cu(H_2L)]$, $[Ni(H_2L)]$, $[Zn(H_2L)]$, M[Cu(L)] and M[Ni(L)] (M = Ca^{2+}, Sr^{2+}, Ba^{2+}).[102] X-Ray structural analysis was carried out on the first two complexes in the same study. It was shown that they have an octahedral structure. Two nitrogen atoms and two oxygen atoms of carboxyl groups are at the corners of a square plane. On the axis perpendicular to the square plane are two ring nitrogen atoms. Two protonated CH_2COOH groups do not participate in the coordination. X-Ray structural analysis was carried out on the complex $[Cu_2(L)].5H_2O$.[103] The two Cu^{2+} ions in this complex have different coordination spheres. One of them is coordinated in the same way as in the mononuclear complex $[Cu(H_2L)]$. There are two nitrogen atoms and two oxygen atoms at the corners of a square plane. Two nitrogen atoms of ligand (II) are on the axis perpendicular to the square plane. The second Cu^{2+} ion has a square-pyramidal environment. Four oxygen atoms from CH_2COO^- groups lie at the base of the pyramid and a water molecule is found at its apex.

Complexone (II) is the best shift reagent among the ligands (I), (IV), etc. used for the quantitative determination of Eu^{3+} by NMR in water.[104,105] The kinetics of the reaction of (II) with Mg^{2+}, AEM, Ni^{2+}, Cu^{2+} and Zn^{2+} have been studied in water over a wide pH range.[106]

X-Ray structural analysis has been carried out on the complexes $[2Li(L)].Cl_2.2H_2O$, $[Na(L)].CNS$, $[K(L)].SCN$ and $[(L)H_2O]$ with ligand (XXXII, 5).[107] Four cyclene nitrogen atoms and the pendant hydroxyethyl groups participate in the coordination with these cations. For Li^+ one hydroxyethyl participates, for Na^+ three and for K^+ all four. In the monohydrate of this ligand a water molecule is bound to two ring nitrogen atoms and two oxygen atoms of the pendant groups.

5. Cyclopendants based on cyclam

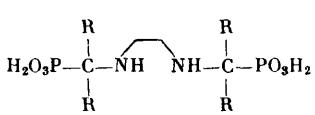
The following ligands containing a 1,5,8,12-tetraazacyclotetradecane (cyclam) fragment are known



(XXXIII)

1. R = H [73]; 2. R = $CH_2PO_3H_2$ [69]; 3. R = CH_2COOH [94]; 4. R = = CH_2CH_2OH [108]; 5. R = $CH_2CH_2NH_2$ [109—114]; 6. R = $(CH_2)_3NH_2$ [112]; 7. R = CH_2CH_2CN [113], 8. R=CH_2— [114, 115]; 9. R = = $CH_2P(O)Ph_2$ [116]; 10. R = $CH_2CH_2P(O)Ph_2$ [116].

Complexone (XXXIII, 2) based on cyclam is significantly lower in complex-forming efficiency than with analogous complexone (XXXII, 2) based on cyclene. With all cations (except Cu^{2+}) a sharp reduction is observed in the stability constants of complexes. A similar reduction in the stability of complexes is also observed for carboxyl-containing complexones on changing from complexone (II) to (IV).[94] Seemingly the reason for the reduction in the stability constants of the complexones in both cases is linked with the size and conformation of the tetra-azacyclic compounds. It might be thought that the cyclic fragment of complexones (XXXIII, 2) and (IV) (cyclam) are conformationally more flexible than the cyclene fragment. If the stability constants of ML complexes of complexone (XXXIII, 2) and ethylenediamine-*N,N'*-bis(methylphosphonic acid) (EDMP),[117] which is an acyclic fragment of complexone (XXXIII, 2), are compared (Table 9) then it is not difficult to understand the parallel change of these values (with the exception of K_{st} for the complexes of Cu^{2+}). EDMP is a complexone of high flexibility.



R = H (EDMP), R = Me (EDIP)

where EDIP is ethylenediamine-*N,N'*-bis(isopropylphosphonic acid).

The observed reduction in the size of the stability constants of the complexes is evidently entropic in origin.

The complexone (XXXIII, 2) forms complexes, which are close to one another in stability (Table 10), with all the cations investigated. Seemingly the size of the cyclic fragment of this ligand is sufficiently large and the ring sufficiently flexible to satisfy the steric requirements of any cations and this also determines its lack of selectivity of action.

Table 9. Values of $\lg K_{st}$ for complexes [ML] of certain cations.

Cation	(XXXIII.2)	EDMP
Mn^{2+}	10.8	7.55
Co^{2+}	15.3	10.8
Ni^{2+}	15.6	12.0

Table 11. Values of $\lg K_{st}$ and $\Delta \lg K_{st}$ for complexes [ML] of Cu^{2+} and Ni^{2+}.

Cation, $\Delta \log K_{st}$	(XXX.2)	(XXXII.2)	(XXXIII.2)	(XXXII.3)	(XXX.3)	(XXXIII.4)	EDIP
Cu^{2+}	21.3	25.4	26.6	27.1	21.3	15.69	20.35
Ni^{2+}	19.4	19.0	15.6	12.0	9.2	7.31	11.13
$\Delta \log K_{st}$	1.9	6.4	11.0	15.1	12.1	8.38	9.22

The selectivity of complex-formation in relation to the copper ion (Cu^{2+}) may be assessed by the difference:

$$\Delta \lg K_{st} = \lg K_{st}(Cu^{2+}) - \lg K_{st}(Ni^{2+}).$$

These values are given in Table 11 for the cyclopendant organophosphorus complexones and for the best of the other cyclopendants in this respect (XXXIII, 4),[108] and also for the linear complexone EDIP.[117]

It follows from the data shown that the ligands (XXXIII, 2) and especially (XXX, 3) and (XXXII, 3) surpass significantly the others in efficiency (A) and selectivity (S) of binding the Cu^{2+} ion.

The complexes of ligand (IV) of composition $[MH_2L]$ ($M = Ni^{2+}$, Cu^{2+} and Zn^{2+}) have been investigated.[102] X-Ray structural analysis of the binuclear complex $[Cu_2(L)].6H_2O$ shows that both Cu^{2+} ions have a square-pyramidal conformation. Two nitrogen atoms and two oxygen atoms of a COO^- group form the base of the pyramid. A water molecule is located at the vertex of the pyramid for one Cu^{2+} ion and a COO^- group for the other. The carboxyl-containing cyclopendants (II) and (IV), in contrast to their phosphorus analogues, form water-soluble complexes with the REE. The values of K_{st} for these complexes increase from 14.5 (Nd^{3+}) to 16.6 (Yb^{3+}).[99] It was established that complexes $[ML]^-$, where $M = Tb^{3+}$, Yb^{3+}, Pr^{3+} and Lu^{3+}, and L = (IV) are conformationally very rigid.[119]

Hay and coworkers[108] investigated the complex-formation of ligand (XXXIII, 4) (Table 10) with Cu^{2+}, Ni^{2+} and Pb^{2+} ions. The values of $\lg K_{st}$ for the complexes were in good agreement with those found previously.[118] X-Ray structural analysis of the complex of this ligand with the Ni^{2+} ion shows that the environment of the Ni^{2+} ion is almost a regular octahedron. Four ring nitrogen atoms are set at the corners of the square and oxygen atoms from CH_2CH_2OH groups are in the perpendicular positions. One pendant group in the complex with Ni^{2+} is deprotonated.

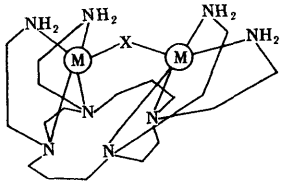
The ligand (XXXIII, 5) has eight donor positions in the molecule and as a rule forms binuclear complexes $[M_2L]$. Protonation constants for this ligand and stability constants were found for complexes with the Cu^{2+} ion of composition $[CuH_2L]^{4+}$ and $[Cu_2L]^{4+}$ (T = 25 °C, μ = 0.5, 0.5 M $NaNO_3$).[120]

X-Ray structural analysis of the complex of composition $[Cu_2L(ClO_4)_2].(ClO_4)_2$ has been carried out.[110] The environment of both Cu^{2+} ions is square-pyramidal. Four nitrogen atoms lie at the base of the pyramid and an oxygen atom of a ClO_4^- group is in the apical position with a much longer bond. A complex of the same structure is also formed with ligand (XXXIII, 5) by the Ni^{2+} ion, viz. $[Ni_2L(ClO_4)_2].(ClO_4)_2$.[111] The complex $[Cu_2L].Br(ClO_4)_3$ has a chain like structure and the bromine atom serves as a bridge between the Cu^{2+} ions, which have a square-pyramidal structure as a result of coordination with two cyclam nitrogen atoms and two nitrogen atoms of the pendant aminoethyl groups. The halogen atom at the vertex is able to complete the building of the square-pyramid in the Cu^{2+} complexes of chain-like structure. The addition constants for halide ion to the $[Cu_2L]$ complex have been found[112,120]

$$[Cu_2L]^{4+} + X^- = [Cu_2LX]^{3+},\ K_{st} = [Cu_2LX]^{3+}/[Cu_2L]^{4+}[X^-],$$

and are 2.6–5.1 for the ions F^-, Cl^-, Br^-, N_3^-, CN^-, OH^- and I^-.

Scheme 3



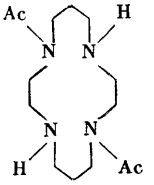
$[M_2L(X)]^{3+}$;
$M = Co^{2+}$, Cu^{2+};
$X = OH^-$ (for Co^{2+}),
$X = F^-$, I^-, NO_3^-,
N_3^-, NCO^- (for Cu^{2+}).

According to XSA data the complexes of Cu^{2+} [121] and Co^{2+} [122] with the ligand (XXXIII, 3) of composition $[M_2L(X)].(ClO_4)_3$ are of a similar structure in which each metal ion has a square-pyramidal environment (Scheme 3). Two ring nitrogen atoms and two pendant aminoethyl group nitrogen atoms are at the base of each pyramid. The X^- anion is at the vertex of the pyramid, common to both metal atoms.

X-Ray structural analysis has been carried out on the complex $[Ni_2LCl].Cl_3.H_2O$.[109] The Ni^{2+} atoms in this complex are not equivalent. One has square-planar coordination with two nitrogen atoms from the cyclam and two from the pendant aminoethyl groups. The second Ni^{2+} ion in the complex has a square-pyramidal environment with a Cl^- ion in the apical position.

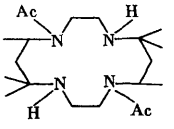
Lengthening the pendant groups leads to a change in complex-formation. The complex of (XXXIII, 6) with Ni^{2+} has a square-pyramidal structure. Four ring nitrogen atoms lie at the base of the pyramid and an amino group from a pendant aminopropyl group is in the apical position.[112]

Hay and Bembi[113] synthesised and investigated the complex of the Cu^{2+} ion with ligand (XXXIII, 7). In the [CuL(NCS)].(NCS) complex the Cu^{2+} ion has a square-pyramidal environment. The four cyclam nitrogen atoms are at the base of the pyramid and the NCS group is in the apical position. The pendant cyanoethyl groups do not participate in the coordination. Complexes of composition $[Cu_2LBr_2].(ClO_4)_2$ [123] and $[Ru(HL).(ClO_4)_3.H_2O$ [124] have been obtained for ligand (XXXIII, 8) and investigated by XSA. In the first complex the Cu^{2+} ion is coordinated with two nitrogen atoms of the pendant α-pyridylmethyl groups and with a bromine atom located on the axis perpendicular to the plane of the square in the corners of which lie nitrogen atoms. In the second complex the Ru^{2+} ion has a distorted octahedral environment with three ring nitrogen atoms and three nitrogen atoms of the α-pyridylmethyl groups. One pendant group in this complex is protonated and does not participate in coordination.

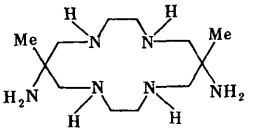


(XXXIV)

Ligand (XXXIV) has not been isolated in the free form since it is slowly converted into the corresponding lactam. However a crystalline complex of composition $[Cu^{2+}(L)]$ has been successfully obtained, XSA of which shows that it has an octahedral structure.[125] Four ring nitrogen atoms are located in the square plane and two oxygen atoms of the pendant groups are in the perpendicular positions.



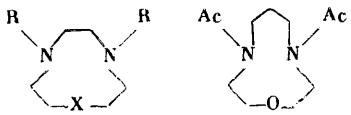
(XXXV)



(XXXVI)

The Ni^{2+} ion in the complex of composition $[Ni(L)].HBr.H_2O$ is coordinated (regular octahedron) with six donor atoms of the ligand (XXXV) (XSA data).[126] The complex-formation of ligand (XXXVI) with Co^{3+}, Ni^{2+} and Cu^{2+} ions has been investigated. According to XSA data the pendant NH_2 groups do not participate in coordination in the complex with Cu^{2+}.[148] The complex of Co^{3+} with this ligand is almost a regular octahedron with very short coordinate bond lengths at 1.94 to 1.95 Å due to chelation of the nitrogen atoms of the ring and pendant groups. The complex of the Ni^{2+} ion is also octahedral but with a large tetragonal distortion. On protonation, the pendant NH_2 groups add on protons and stop participating in coordination. The octahedral complexes of Co^{3+} and Ni^{2+} are converted by this into square-planar or into a *trans*-diaqua cation.

6. Unsymmetrical polyazamacrocyclic cyclopendants



(XXXVII) (XXXVIII)

1. R = CH_2COOH, X = NH; 2. R = CH_2COOH, X = O;
3. R = $CH_2CH_2NH_2$, X = NH; 4. R = $CH_2CH_2NH_2$, X = S;
5. R = $CH_2CH_2NEt_2$, X = O; 6. R = $CH_2CH_2CH_2NEt_2$, X = O.

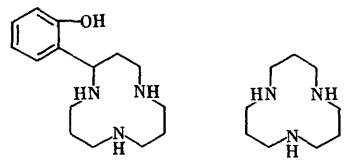
The thermodynamic parameters for complex-formation have been determined for ligand (XXXVII, 2) and (XXXVIII).[85] The increase in size of the cyclic fragment on transfering from (XXXVII, 2) to (XXXVIII) leads to a reduction in the stability of the complexes of the cations investigated, viz. Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}.

For the potentially pentadentate ligands (XXXVII, 1 and 2) complexes $[VO(L)].H_2O$, where L = 1 and $[VO(L)]$ where L = 2 have been obtained in which vanadium is tetravalent. A third complex was obtained by the oxidation of the first complex and in this $[VO_2(L)H].2H_2O$ vanadium is pentavalent.[128] It was shown by XSA that the first and third complexes have a distorted octahedral structure.

The environment of the VO^{2+} ion is square-pyramidal. At the apex of the pyramid is a nitrogen atom with coordinate bond length 2.31 Å. Two nitrogen and two oxygen atoms lie at the base of the pyramid. In the third complex one protonated pendant CH_2CH_2COOH group does not participate in coordination with the VO_2^+ ion. The short lengths for V=O bonds (1.61 Å in the first, 1.63 and 1.64 in the third complex) are characteristic of the double bond in vanadyl ions.

Complexes of composition $[Co^{3+}LCl].(ClO_4)_2$ were obtained by oxidation of the corresponding complexes of Co^{2+} with ligands (XXXVII, 3 and 4). It was shown that the complexes of Co^{3+} with these ligands exist as two isomers in which the chlorine atom occupies either an equatorial or an apical position.[129] On coordination of ligands (XXXVII, 3 and 4) with VO^{2+} and Co^{3+} ions one ring nitrogen atom occupies the apical position, i.e. the disposition of all three ring nitrogen atoms in one plane seemingly encounters steric difficulties, which is also observed for complexes of Cu^{2+} with ligands (XXX, 2), (I) and (XXX, 9) based on 1,4,7-triazacyclononane. The VO^{2+} ion has a coordination number of five since on coordination with ligand(I) one dentate position of this complexone proved to be unused. Ligands (XXXVII, 5 and 6) show a physiological effect on the central nervous system of mice.[130] The complex-forming properties of these compounds have not been studied.

The stability constants of the complexes of compounds (XXXIX) and (XL) with the TM have been determined (Table 12).



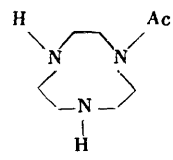
(XXXIX) (XL)

Protonation of complexes of ligand (XXXIX), when the oxygen atom of the pendant hydroxyphenyl group ceases to participate in coordination, shows that this group participates actively in the binding of cations. Ligand (XXXIX) forms far more stable complexes than the free amine. According to XSA data, the complex of this ligand with the Zn^{2+} ion has a trigonal-bipyramidal structure.[82] Two ring nitrogen atoms and the oxygen atom of the phenolic hydroxyl are located in the equatorial plane (triangle) with very short coordinate bond lengths (which shows the strong bonding). A ring nitrogen atom and a molecule of water are located in the apical positions with large bond lengths.

Table 12. Values of $\lg K_{st}$ complexes [ML] (T = 25 °C, μ = 0.1).

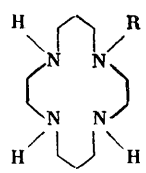
Cation	(XXXIX) [79]	(XL) [80]
Co^{2+}	11.4	–
Ni^{2+}	14.0	10.93
Cu^{2+}	18.4	12.63
Zn^{2+}	12.6	8.75

The ligand (XLI) has been synthesised.[131] Its complex-forming properties were not studied.



(XLI)

The complexes of Ni^{2+} and Cu^{2+} with the following ligands have been investigated.

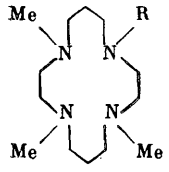


(XLII)

1. R = H; 2. R = CH_2COOH; 3. R = CH_2CH_2COOH;
4. R = $(CH_2)_3COOH$; 5. R = CH_2– ;
6. R = CH_2–  –COOH [131].

The pendant carboxyl groups of ligands (XLII, 2 and 5) participate in coordination. The pendant groups of ligands (XLII, 3, 4 and 6) do not participate in coordination. On reducing the pH the carboxylate groups COO^- are protonated and cease participation in complex-formation with M^{2+}.

Complexes of Ni^{2+} and Cu^{2+} with ligands (XLIII, 1–8) have been synthesised.[133]



(XLIII)

1. R = H; 2. R = CH_2CN; 3. R = $CH_2CH_2NH_2$; 4. R = CH_2CH_2CN;
5. R = $(CH_2)_3NH_2$; 6. R = $CH_2CH_2\overset{\overset{O}{\|}}{C}NH_2$; 7. R = $CH_2CH_2\overset{\overset{O}{\|}}{C}Me$;
8. R = CH_2CH_2COOH; 9. R = Me; 10. R = CH_2COOMe;
11. R = CH_2COOEt; 12. R = CH_2CH_2COOEt; 13. R = $CH_2C(O)NMe_2$;
14. R = $CH_2CH_2P(O)(OEt)_2$; 15. R = $CH_2CH_2P(O)(OEt)(OH)$;
16. R = CH_2COOH; 17. R = $CH_2C(O)NH_2$; 18. R = CH_2CH_2SH;
19. R = $CH_2CH_2NMe_2$.

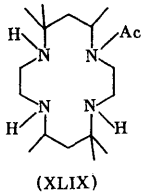
In the complexes of Ni^{2+} and Cu^{2+} ions with ligands (XLIII, 1–8) of composition $[ML].(ClO_4)_2$ the pendant group participates in coordination since, according to spectral data, these cations are pentacoordinated. The cyanoethyl pendant group and the protonated ethyl- and propylamino groups do not participate in complex-formation with Ni^{2+} and Cu^{2+}.

Finally, ligands with the same general formula but with other pendant substituents (XLIII, 9–19) have been obtained and investigated.[134]

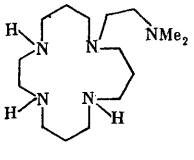
It was established spectroscopically that the pendant groups of ligands (XLIII, 10–18) coordinate the Cu^{2+} ion in the axial position (at the apex of a square pyramid).

X-Ray structural analysis of complexes of composition $[HL.H_2O].2Br$, $[NiL(H_2O)].Br$ and $[NiL(NCS)].H_2O$ showed that the Ni^{2+} ion in these complexes is coordinated (octahedral environment) with five donor atoms of ligand (XLIX) and one water molecule or NCS group.[135]

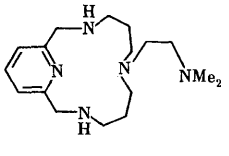
The complexes of Ni^{2+} and Cu^{2+} with ligands (L) and (LI), also containing one pendant group, were obtained by Alcock and collaborators.[136]



(XLIX)



(L)



(LI)

The complexes of ligands (L) and (LI) with Ni^{2+} and Cu^{2+} ions have a trigonal-bipyramidal structure in neutral media which is transformed into square-planar at low pH. The pendant group is protonated by this and stops participating in coordination. The XSA of complex $[Ni(L)].(ClO_4)_2$ showed that it has a trigonal-bipyramidal structure.[136]

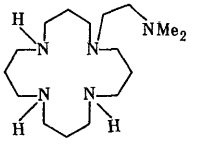
Complexes of Ni^{2+} of composition $[Ni(L)(NCS)].(ClO_4)$ and $[Ni(LH)(NCS)_2].(ClO_4)$ have been obtained and investigated.[137]

One or two (when the pendant group is protonated and does not participate in coordination) NCS^- groups occupy apical positions in hexacoordinated complexes of Ni^{2+}. The thermodynamic parameters have been calculated for the protonation of the complex of Cu^{2+} with ligand (L).

$$[Cu(L)]^{2+}+H^+ \rightleftharpoons [Cu(HL)]^{3+} \quad (L=(L)).$$

Complexes of ligands (L) and (LI) with the Zn^{2+} ion of composition $[Zn(L)].(NO_3)_2$ have also been synthesised. It was shown that the pendant dimethylaminoethyl group participates in coordination in the complexes of ligands with Zn^{2+}.

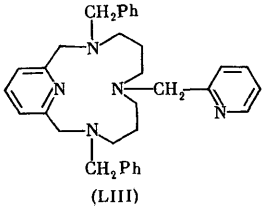
Alcock and collaborators[138] have synthesised and studied the complex-forming properties of ligand (LII) in relation to Ni^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Hg^{2+}.



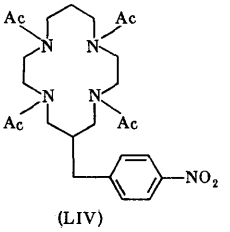
(LII)

It was established that the ions of Ni^{2+}, Co^{2+} and Cu^{2+} were pentacoordinated, i.e. the pendant group participates in coordination. The problem of the participation of the pendant group of ligand (LII) in coordination with Zn^{2+} and Cd^{2+} ions remains unresolved. On acidification, the complex $[Ni(L)].(ClO_4)_2$ is decomposed completely. The square-pyramidal complex $[Cu(L)].(ClO_4)_2$ is transformed on acidification with $HClO_4$ into the square-planar $[Cu(HL)].(ClO_4)_3$ in which the protonated pendant group has ceased participating in coordination [L = (LII)].

The same authors have synthesised and investigated ligand (LIII) having a pendant α-pyridylmethyl group.[139] It was discovered that the pendant group participates in coordination in the complexes $[M(L)].(ClO_4)_2$ (M = Ni^{2+} and Zn^{2+}). Acidification of the blue pentacoordinated complex of (LIII) with Ni^{2+} leads to the yellow $[NiHL].(ClO_4)_3$ complex in which the protonated pendant group does not participate in coordination.



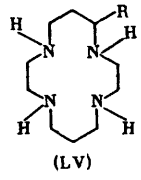
(LIII)



(LIV)

The complex of Cu^{2+} with ligand (LIV) has been studied by XSA.[140] In this complex the Cu^{2+} ion has an octahedral environment due to the ring nitrogen atoms and the two pendant carboxyl groups. The ring nitrogen atoms do not lie in one plane as was observed previously for the complex $[Cu(H_2L)]$ with ligand (II).[102]

Kimura and collaborators have synthesised and investigated the complexes of ligands (LV, 1–4).



(LV)

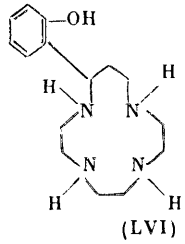
1. R = [140, 141];
2. R = [142];
3. R = [143];
4. R = CH_2OH [144].

The stability constants have been found for the complexes of Fe^{2+} and Fe^{3+} with the ligand (LV, 1).[140] The XSA of the complex with the Ni^{2+} ion shows that Ni^{2+} is in a plane of four ring nitrogen atoms.[141] The oxygen atom of the phenolic hydroxyl is at the vertex of a square pyramid and in this complex occupies an axial position with a very short coordinate bond length. At pH > 6 the phenolic oxygen atom is protonated and ceases to participate in coordination.

According to XSA data the conformation of the complex of Cu^{2+} ion with ligand (LV, 2) is square-pyramidal. Four ring nitrogen atoms are located in the plane of the pyramid and the oxygen atom of the phenolic group is at the vertex. The $K_{st}[CuL] = 1 \times 10^{32}$ M^{-1}, but for the protonated complex with the pendant group not participating in coordination $K_{st}[CuHL] = 2.5 \times 10^{29}$ M^{-1}. It is evident from this that the pendant 2-hydroxyphenyl group makes a contribution to the stability of the resulting complex.[145]

For ligand (XXXIX) based on triazacyclododecane the difference in the values of $\lg K_{st}$ of the complexes [CuL] and [CuHL] was 5.8 with the 2-hydroxyphenyl pendant group not participating in coordination.[79]

A reduction in the size of the ring in ligand (LVI) compared with (LV, 1) leads to a change in the structure of the complex formed with the Ni^{2+} ion.



(LVI)

The octahedral Ni^{2+} complex has the following structure. At the vertices of the square cross section are three ring nitrogen atoms and a water molecule. Perpendicular to this square are a ring nitrogen atom and the oxygen atom of the phenolic group. On reducing the pH the protonated pendant group ceases to participate in coordination and the blue high-spin octahedral Ni^{2+} complex is transformed into the yellow square-planar low-spin complex.[147]

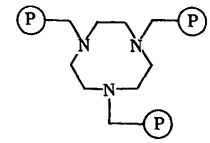
The complex of the Ni^{2+} ion with ligand (LV, 2), with a pyridine substituent, of composition $[Ni(L)H_2O].(ClO_4)_2$ has been studied. According to XSA data the high-spin complex has an octahedral structure.[142] Four cyclam nitrogen atoms are at the vertices of the square and the nitrogen atom of the pyridine ring and a water molecule are on the perpendicular axis. The XSA data on the complexes with the ligands described have been reported.[132] An XSA was carried out on the complex of the Ni^{2+} ion with ligand (LV, 3) which has an imidazole substituent in the molecule.[143] In this complex the Ni^{2+} ion has an octahedral environment. Four nitrogen atoms are found at the vertices of the square and the imidazole nitrogen and an oxygen of the ClO_4^- group are on the perpendicular axis.

The stability constants of the [NiL] complex of ligand (LV, 2) have been determined.[147]

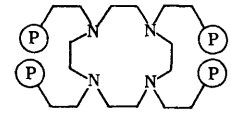
It was established that in the complex of ligand (LV, 4) with $NiCl_2$ four ring nitrogen atoms and the pendant hydroxymethyl group participate in coordination with the Ni^{2+} ion.[146]

7. Polyazacyclopendants with diphenylphosphoryl pendant groups

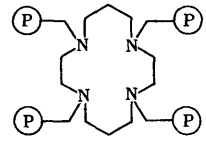
Ligands (XXX, 10), (XXXII, 6), (XXXIII, 9) and (XXXIII, 10) contain cyclic polyalkylene-polyamine fragments considered above and pendant diphenylphosphoryl-methyl and -ethyl groups. These ligands form complexes with ions of the alkali, alkaline earth and transition metals in non-aqueous media by participation of the nitrogen atoms of the cyclic fragment and the oxygen atoms of the pendant groups in coordination.



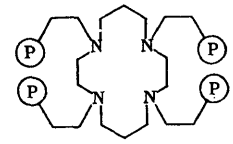
(XXX. 10) [64–66]



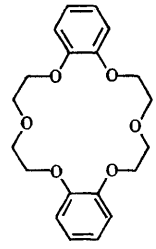
(XXXII. 6) [149]



(XXXIII. 9) [116]



(XXXIII. 10) [116]



(XIX. 1) [149]

Stability constants are given in Table 13 for complexes of these ligands and also (for comparison) for dibenzo-18-crown-6 (XIX, 1) with alkali metals. The selectivity of the ligands with diphenylphosphoryl pendant groups was reduced with the reduction in the conformational rigidity.

Compounds (XXX, 10), (XXXII, 6) and (XXXIII, 10) form complexes with the Li^+ ion exceeding in stability the complexes with all the ligands known until 1988.[150]

It was established that the ring nitrogen atoms and the oxygen of the pendant $P(O)Ph_2$ groups take part in the formation of complexes of the ligands represented with ions of the alkali metals, AEM and TM.[64, 65,151] In contrast to (XXX, 2) with its phosphonic acid pendant groups, the ligand (XXX, 10) is not specific complex-forming agent for the Mg^{2+} ion. It forms a more stable complex with Ca^{2+} than with Mg^{2+}.[64] In complexes of $Co(SCN)_2$ with the ligands (XXX, 10) and (XXXIII, 10) either all or only a portion of the donor atoms of these ligands, depending on the composition, participate in coordination with the Co^{2+} ion.[65,151]

Table 13. Values of $\lg K_{st}$ for complexes $[ML]^+$ (T = 25 °C, THF:$CHCl_3$ 4:1) and A and S of complex-formation for the set Li^+, Na^+, K^+ and Cs^+.[149]

Cation A, S	(XXX.10)	(XXXII.6)	(XXXIII.9)	(XXXIII.10)	(XIX.1)

Compound	pK_1	pK_2	pK_3	pK_4	Reference
 (XXX.1)	<2	6.82	10.42	-	[83]
	4.23	9.02	9.84	-	[73]
 (XXXII.1)	<1	<2	9.7	10.7	[152]
	3.25	6.56	9.08	9.74	[73]
 (XXXIII.1)	1.0	1.7	10.2	11.5	[152]
	6.02	7.28	9.50	10.25	[73]

VI. Acid dissociation of cyclopendant complexones: derivatives of polyazamacrocycles

The mechanism of the acid dissociation has been investigated for phosphonyl- and carboxyl-containing complexones in the molecules of which there are the cyclic polyalkylene-polyamine fragments of triazacyclononane, cyclene and cyclam. In contrast to linear polyamines with highly basic nitrogen atoms, the basicity of the nitrogen atoms in the cyclic fragment of cyclopendant complexones varies within very wide limits and a zwitterionic structure exists involving only some of the nitrogen atoms.

Values of pK_a of some cyclic amines and their linear analogues are shown in Table 14.

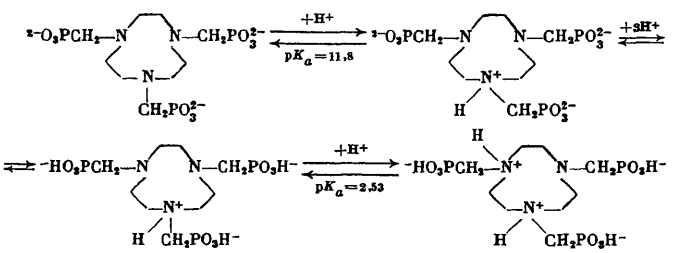
The fission of protons on acid dissociation of cyclopendant complexones with cyclic polyalkylene-polyamines in the molecule may occur both from acid (PO_3H_2 or COOH) groups or from ammonium nitrogen atoms of the cyclic fragment since they have closely similar pK_a values.

Complexones with phosphonoalkyl pendant groups have a different scheme for acid dissociation from that of compounds with carboxyl groups. The phosphonic acid group has two dissociation stages. The size of pK_1 ($PO_3H_2 \rightarrow PO_3H^- + H^+$) is less and of pK_2 ($PO_3H^- \rightarrow PO_3^{2-} + H^+$) is greater than the pK_a of a carboxyl group.[98,153] The phosphonic acid group exerts a different electronic effect on the nitrogen atoms of the cyclic fragment of complexones during the dissociation process.

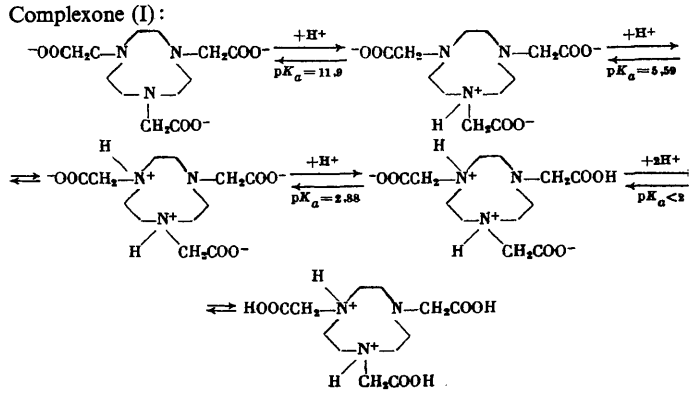
The dissociation sequence of the organophosphorus complexones (XXX, 2), (XXXII, 2) and (XXVIII, 2) has been studied by IR spectroscopy in water and in heavy water.[56,155] Complexones (XXX, 3) and (XXXII, 3) were investigated by ^{31}P NMR spectroscopy in water. ^1H NMR and IR (in D_2O) spectroscopy[154] and ^1H and ^{13}C NMR spectroscopy[156] have been used to study the protonation of the carboxyl-containing complexones (I), (II) and (IV).

The following protonation schemes are proposed.

Complexone (XXX, 2)

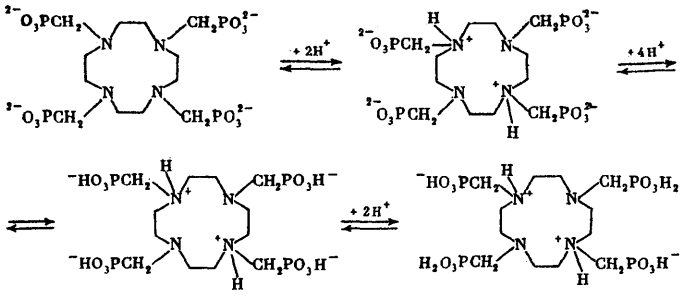


Complexone (I):



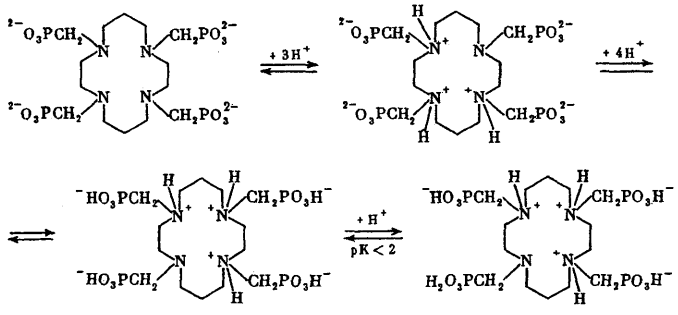
The ring nitrogen atoms of ligand (I) are protonated only at very low pH.

Complexone (XXXII, 2)

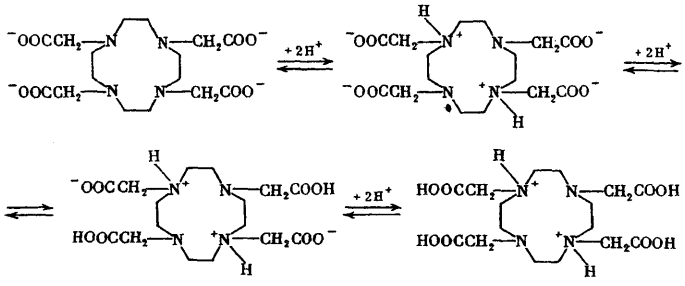


Complexone (XXXII, 2) therefore has a double zwitterion structure in solution. The nitrogen protons dissociate finally at high pH values (pK_7 and pK_8 in Table 15).

Complexone (XXXIII, 2)



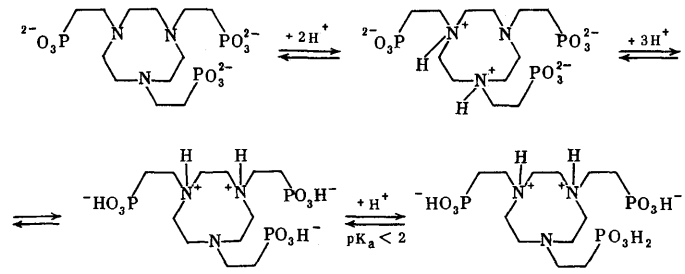
Complexone (XXXIII, 2) has a triple zwitterion structure in solution. All the nitrogen protons are finally split off in one buffer region at very high pH (pK_6, pK_7, pK_8 in Table 15). In the case of the carboxyl-containing complexones (II) and (IV) the size of the cyclic fragment has little effect on the dissociation. Complexones based on cyclene and cyclam have the same dissociation mechanism and the protonation scheme below applies to both (II) and (IV).



With increasing acidity two nitrogen atoms are protonated first and then the two carboxyl groups bound to the unprotonated nitrogen atoms. The remaining carboxyl groups are then protonated. Complexones (II) and (IV) protonate the acid groups first since the nitrogen atoms are less basic than the COOH groups in these molecules.[154]

The mechanism of the acid dissociation of complexones (XXX, 3) and (XXXII, 3) has been investigated by $^{31}P-\{^1H\}$ NMR spectroscopy in water. In the dissociation of the aminophosphonic acids the fission of protons from the PO_3H_2 group is accompanied by an insignificant reduction in the size of the chemical shift (δ) in the ^{31}P NMR spectra.[157] Dissociation of the proton from a nitrogen atom leads, on the other hand, to an increase in δ. This is explained[158] by the fundamental difference in the hybridisation of the nitrogen atoms on going from ammonium to amine and consequently by a change in the shielding of the phosphorus atom. A sharp increase in δ (shift to low field) on fission of the proton bound to the nitrogen atom is observed on dissociation of nitrilotris(methylphosphonic acid) (NTP)[159] and iminobis(methylphosphonic acid).[160]

The sequence of protonation of complexone (XXX, 3) is represented as follows.



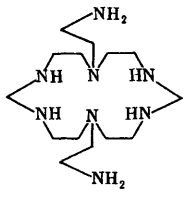
The replacement of the phosphonomethyl pendant groups by phosphonoethyl leads to a definite change in the dissociation mechanism of complexone (XXX, 3) compared with (XXX, 2). The former has the structure of a double zwitterion and the protons bound to the ring nitrogen atoms are split off last.

As is seen the acid dissociation of cyclopendant polyphosphonic complexones (like the polyphosphonic complexones with an open chain) occurs over a very wide pK region, from <1 to 13.5. The formation of complexes within wide limits of acidity of the medium is a characteristic of these compounds. Stable "hydrogen" complexes are formed in acid medium with incomplete displacement of acid group protons by the metal cation. The formation of homo- and heteronuclear complexones (when some of the protons are displaced by one cation and some by another) is also characteristic.[161–171] All these are properties specific to the polyphosphonic complexes.

The complexone (XXXII, 2) has the same order of fission of protons as (XXXII, 3).

VII. Cyclopendants with a large cyclic fragment

These ligands contain more than four nitrogen atoms in the cyclic fragment. The XSA of complexes (LVII) of composition $[La(L)(CF_3SO_3^-)_2]^+$ and $[Yb(L)(CF_3SO_3^-)]^+$ showed that the La^{3+} ion is decacoordinated with eight donor nitrogen atoms of the ligand and two oxygen atoms of the $CF_3SO_3^-$ group.[162]



(LVII)

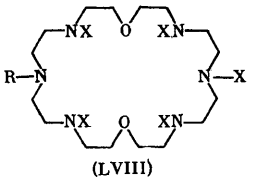
The Yb^{3+} ion complexed with this ligand is nonacoordinated. Eight sites are occupied by nitrogen atoms of the ligand and one by an oxygen atom of the $CF_3SO_3^-$ group. The mean length of the M–N-ring bonds is 2.5–2.6 Å and of the M–N-pendant groups is 2.5 Å, much greater than in cyclopendant complexes with transition metals. This was observed previously when studying the complex of Eu^{2+} with ligand (II).[101]

Table 15. Values of pK_a for the dissociation of phosphonyl- and carboxyl-containing cyclopendant complexones (T = 25 °C, μ = 1.0).[56,57,81,154,93]

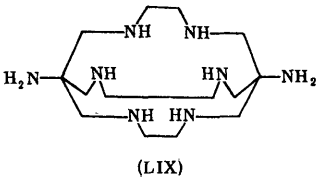
№	Complexone	R	pK_1	pK_2	pK_3	pK_4	pK_5	pK_6	pK_7	pK_8
1		$CH_2PO_3H_2$	<2	2.53	5.38	7.09	8.65	11.8	-	-
2		CH_2COOH	3.16	6.03	10.77	-	-	-	-	-
3		$CH_2PO_3H_2$	<1	<2	4.88	5.73	7.28	8.46	11.5	12.1
4		CH_2COOH	4.18	4.24	9.23	11.08	-	-	-	-
5		$CH_2PO_3H_2$	<2	4.96	6.27	7.67	9.16	11.8	12.8	13.5
6		CH_2COOH	3.38	4.05	10.18	11.56	-	-	-	-
7		$(CH_2)_2PO_3H_2$	<2	5.38	6.21	6.97	8.85	12.3	-	-
8		$(CH_2)_2PO_3H_2$	<2	2.30	6.21	6.84	7.63	8.34	11.2	12.4

Note. For complexones Nos. 2, 4 and 6 the values of pK_a found are for the addition of proton to the carboxylate group of the corresponding zwitterion.

Ligands (LVIII) have been synthesised and contain a cyclic fragment with donor atoms of nitrogen and oxygen and various pendant groups, such as CH_2CH_2CN, $(CH_2)_3NH_2$, PO_3H_2, etc. (X = H or Ts).[52,53]

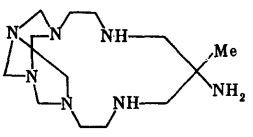


(LVIII)



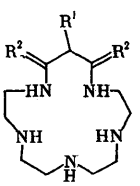
(LIX)

The pendant NH_2 groups of ligand (LIX) do not participate in coordination. The hexacoordinated complexes of Co^{3+}, Fe^{3+}, Ni^{2+}, Mn^{2+}, etc. are formed with ring nitrogen atoms.[173] Complexes have been obtained with ligand (LX) and Ni^{2+} and Ni^{3+} ions.



(LX)

Four ring nitrogen atoms participate in coordination and are located at the corners of a square. The fifth ring nitrogen atom and the pendant group NH_2 do not participate in coordination.[174] It was established that (LXI, 1) does not form complexes with Na^+, K^+, Mg^{2+} and Ca^{2+}.[175] The pendant group R^1 of the ligand (LXI, 2) participates in coordination with Ni^{2+}. The stability constant for the complex of Ni^{2+} with this ligand has been found.[176]

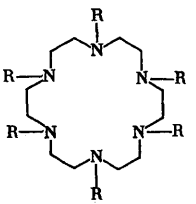


(LXI)

1. $R^1 = (CH_2)_4NH_2$, $R^2 = H_2$;

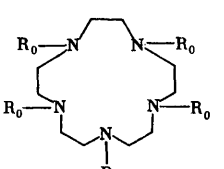
2. $R^1 =$  ; $R^2 = O$.

The complex-formation of ligands (LXII) and (LXIII), which contain bipyridinylmethyl and hydroxyethyl pendant groups in the molecule, has not been studied.[177,178] Martell and collaborators have investigated the complex-forming ability of ligands (LXIV, 1 and 2) with the Fe^{3+} ion.[172,179] The values of $\lg K_{st}$ for complexes [ML] [T = 25 °C, μ = 0.1 (KNO_3)] were 37.6 and 36.0 for (LXIV, 1) and (LXIV, 2) respectively.



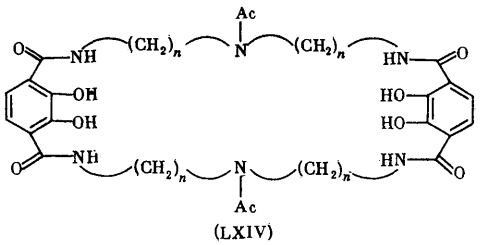
(LXII)

R = 



(LXIII)

$R_0 = CH_2CH_2OH$



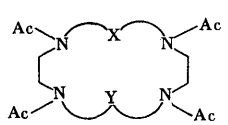
(LXIV)

1. $n = 2$
2. $n = 3$

VIII. Effect of the nature of the pendant groups and the structure of the cyclic fragment of cyclopendants on the efficiency and selectivity of complex-formation

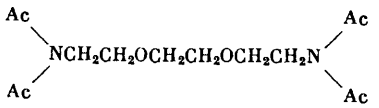
The majority of the ligands investigated contain as acids either phosphonic or carboxyl groups, consequently it is interesting to compare the efficiency and selectivity of complex-formation of the phosphoryl- and carboxyl-containing complexones having the same carbon skeleton. Such comparison were carried out previously but without using the *A* and *S* criteria.[180]

Values of *A* and *S* for complex-formation are given in Table 16 calculated from the stability constants of complexes.[67,69,105,180,181] In contrast to their carboxyl-containing analogues the organophosphorus complexones with two PO_3H_2 groups form low stability complexes with Mg^{2+} and the alkaline earth elements. For the transition metals the organophosphorus complexones exceed the carboxyl-containing in both efficiency and selectivity of complex-formation. There are few data for Mg^{2+} and the alkaline earth elements and it is difficult at present to draw conclusions on the superiority of the organophosphorus or of other complexones. On the whole the acyclic organophosphorus complexones surpass their carboxyl-containing analogues in selectivity by, on average, one order and the cyclopendants by two orders of magnitude.



(LXV)

The effect of change of size and conformational rigidity of the cyclic fragments is shown in the efficiency and selectivity of complex-formation of the cyclopendant complexones. The complex-formation of compounds (LXV, 1–8), having the same pendant groups and various cyclic fragments, has been studied.[94] Values of *A* and *S* are given in Table 17 for two sets of cations. The change in the size of the cyclic fragment has the most striking effect on *A* and *S*. On going from ligand 1 to 2 and 3, and also from 6 to 7 the efficiency falls sharply. The selectivity may increase or decrease during this. The introduction of alkyl substituents into the bridge shows up negatively on the selectivity of action in relation to the second group of cations, the efficiency of binding is reduced to the same extent. There are no such regularities when using the TM although here also an increase in the bulk of the alkyl substituent in the bridge reduces the efficiency of complex-formation (cf. ligands 4, 5 and 6 in Table 17). Complexones (LXV, 1–8) display interesting complex-forming properties. Complexone (LXV, 1) forms the most stable complex with the Ca^{2+} ion of the known complexones ($\lg K_{st} = 15.9$). Complexone (LXV, 3) has the maximal difference in stability constant for complexes with Mg^{2+} and Ca^{2+} (values of $\lg K_{st}$ for these complexes were 3.0 and 9.5 respectively). The best linear complexone in this respect (LXVI) forms complexes with Mg^{2+} and Ca^{2+} cations with $\lg K_{st}$ 5.21 and 10.97 respectively.[182]



(LXVI)

Table 16. Values of *A* and *S* of complex-formation of organophosphorus and carboxyl-containing complexones.

* $\lg K_{st}$ for complexes of Mg^{2+} and the alkaline earth elements < 2.
** Data.[144]

The increase in dentate number in the case of ligand 8 did not lead to an increase in the value of A but this compound forms a more stable complex with the Ba^{2+} ion than with Ca^{2+} and Sr^{2+}, which is also unusual for the classic (linear) complexones.

Table 17. Values of A and S of complex-formation of compounds (LXV, 1–8).

№ Ligand in (LXV)	X in (LXV)	Y in (LXV)	A	S	A	S
			Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}		Cu^{2+}, Co^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}	
1	CH_2CH_2	CH_2CH_2	12.8	2.7	19.0	0.6

Heteroprostanoids: synthesis and biological activity

F A Lakhvich, F S Pashkovskii, E V Koroleva
Institute of Bioorganic Chemistry, Academy of Sciences of Belorussia, Minsk

ABSTRACT. Data on the synthesis and biological activity of the hetero analogues of prostaglandins are examined and systematised. The relationship between the structure and the activity of the heteroprostanoids is discussed.

The bibliography contains 170 references.

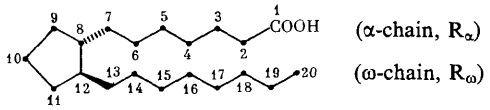
I. Introduction

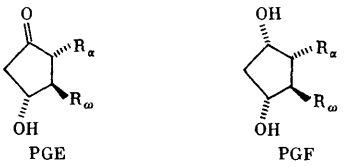
The prostaglandins (PG) are a unique class of natural low molecular bioregulators which are synthesised in practically all tissues and organs of animals and man and play an extremely important role in normal functioning and pathology.

In chemical structure they are unsaturated polyhydroxy acids, derivatives of the hypothetical twenty-atom prostanoic acid.

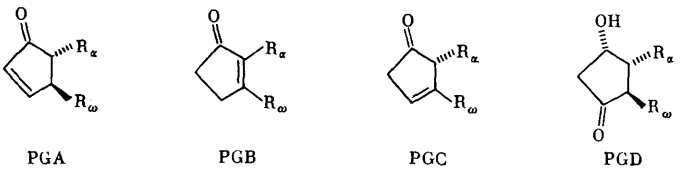


prostanoic acid

The C_7-carboxyalkyl chain of prostaglandins is known as the α-chain and the C_8 alkyl the ω-chain. The character of the functionality of the five-membered ring determines the type of prostaglandins. Prostaglandins of the E and F type are referred to as primary PG and prostaglandins of types A, B, C and D form the group of secondary PG.



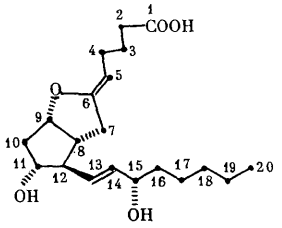
primary PG



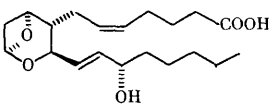
secondary PG

Three series of natural PG can be distinguished. The first is characterised by the presence of one Δ^{13}-*trans*-double bond, the second contains an additional Δ^5-*cis*-double bond. The PG of the third series contain a further Δ^{17}-*cis*-double bond in addition to those mentioned. The number of multiple bonds in the side chains corresponds to the subscript number (PGE_1, PGE_2 etc.).

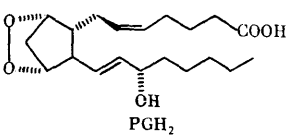
Prostacyclin (PGI_2), 6,9α-epoxy-11α,15α-dihydroprosta-5(*Z*),13(*E*)-dienoic acid, prostaglandin endoperoxides (PGG_2, PGH_2) and thromboxane (TxA_2), like the primary PG, are biosynthetic products of the arachidonic acid cascade and the most important biomolecules of its metabolism.



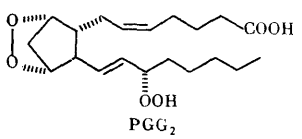
prostacyclin (PGI_2)



thromboxane A_2 (TxA_2)



PGH_2



PGG_2

prostaglandin endoperoxides

The extremely low content of PG, cyclic endoperoxides and prostacyclin in nature, the exceedingly wide spectrum of biological action and the chemical and metabolic instability of preparations based on them, are factors stimulating the development of synthetic

methods for obtaining these and modified compounds (analogues of the natural prototypes) with more specific and prolonged action for the needs of medicine and agriculture.

The heteroprostaglandins occupy an important place among the multitude of analogues synthesised. These are compounds in which one or several carbon atoms of the prostanoid skeleton are replaced by heteroatoms (nitrogen, oxygen, sulphur). The synthesis and biological activity of such compounds form the subject of the present review. Also considered are the heteroanalogues of the cyclic endoperoxides (PGH) and prostacyclin (PGI) in which the oxygen atoms of the endoperoxide and the *cis*-enol ether fragments are replaced in addition to replacing carbon atoms of the skeleton by nitrogen and sulphur.

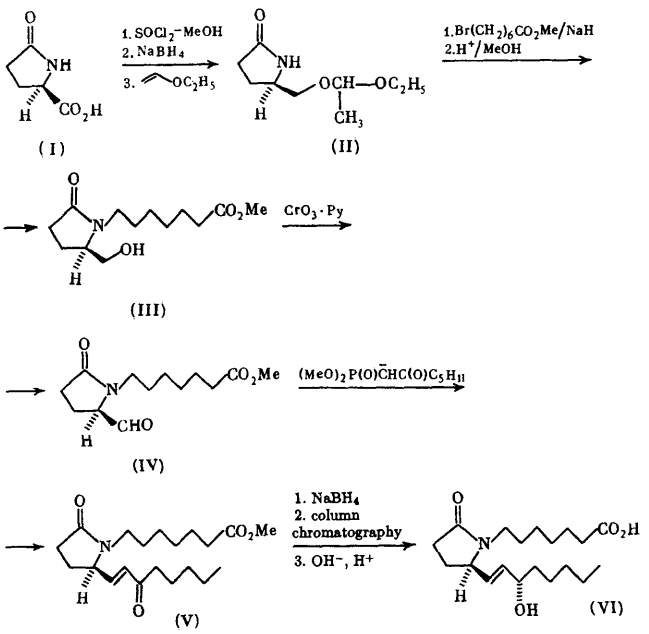
In contrast to the reviews published previously,[1-3] which are devoted mainly to detailed analysis of actual synthetic schemes for PG heteroanalogues, cyclic endoperoxides and prostacyclin, attention is paid in the present review chiefly to an analysis of the methodology of forming the heteroprostanoid skeleton and also to the dependence of biological properties on structure.

II. Synthesis of heterocyclic prostanoids

Construction of the heteroprostanoid skeleton is based on the following main approaches: 1) the regio- and stereoselective introduction of the side chains (R_α and R_ω) or fragments of them into the appropriate heterocyclic compounds, 2) synthesis based on acyclic long chain precursors bearing the side chains or intermediates when the heterocyclic system is formed in one of the intermediate or at the very last stage of the synthesis, 3) regioselective introduction of the heteroatom into the cyclic portion of the prostanoid skeleton of 11-norprostanoids.

1. Heteroprostanoids based on heterocyclic precursors

This approach is widely used in the synthesis of heterocyclic prostanoids. It may be illustrated by the preparation of optically active (12*R*,15*S*)-(−)-11-deoxy-8-aza-PGE_1 (VI) from (*R*)-(+)-pyroglutamic acid (I).[4]



After conversion into the (*R*)-ethoxyethyl ether (II) the latter is alkylated with methyl 7-bromoheptanoate. The alcohol (III) formed by removing protection was oxidised (Collins) to the (*R*)-aldehyde (IV). A Wittig reaction of the synthon (IV) with dimethyl-2-keto-heptylphosphonate gives the (*R*)-enone (V) which on reduction with sodium borohydride leads to a mixture of the 15-epimers of the desired 8-azaprostanoid. Chromatographic resolution of the latter and mild hydrolysis of the ester group in the 15*S*-isomer completes the synthesis of (12*R*,15*S*)-11-deoxy-8-aza-PGE_1 (VI).

Other examples are given in Table 1 of heteroprostanoids obtained using analogous schemes published in the last 10–12 years. In the majority of cases the α-chain in the heterocyclic precursor is introduced using classical methods of *N*- and *C*-alkylation (or acylation). The ω-chains in the alkylation products are formed using the Wittig–Horner–Emmons phosphonate condensation after transformation of the functional groups in position 12 (PG nomenclature) into an aldehyde.

Table 1. Heteroprostanoids from heterocyclic precursors.

Type of heteroprostanoid	Initial heterocyclic precursor	Structural formula	Reference

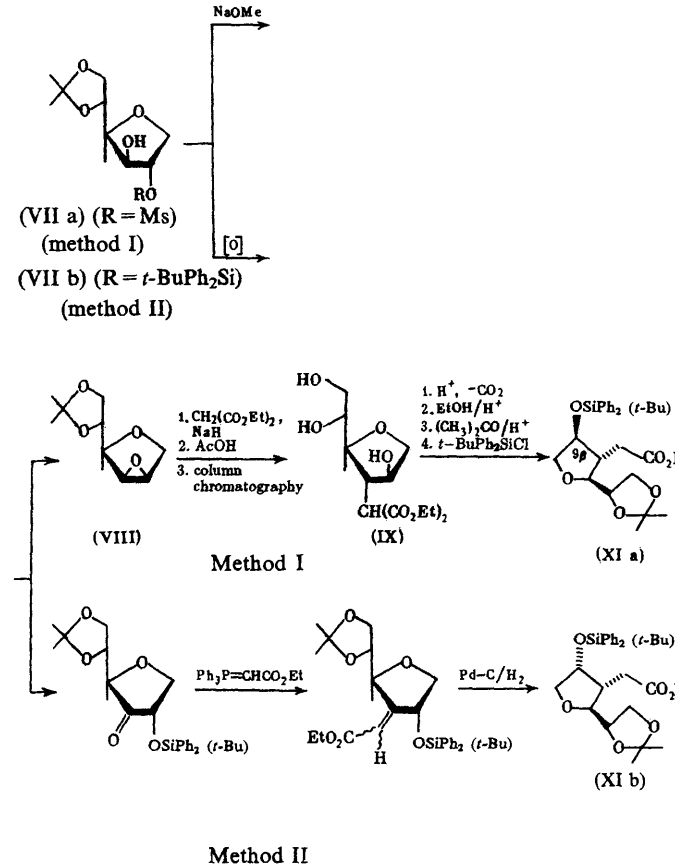
11-Oxa-13-aza-	R = H, CH_3		
8,10-Diaza-			[14]
		 R = H, CH_3	[15]
8-Aza-10-thia-			[16]
8,10,12-Triaza-		 Z = CH_3N; X—Y = CH=CH; R = C_5H_{11}, C_6H_{13}. Z = S; X—Y = CH_2—CH_2; R = *cyclo*-C_6H_{11}	[17, 18]
10-Thia-8,12-diaza-	Z = CH_3N		

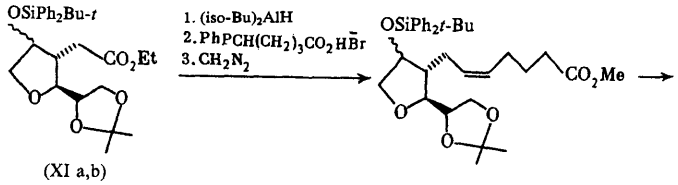
This approach also includes a set of schemes for the synthesis of 11-oxaprostanoids of the $F_{2\alpha(\beta)}$ series from natural heterocyclic compounds, viz. sugars and dihydrosugars.[19–21] The furan ring of the latter is a convenient intermediate for the heterocyclic system for PG 11-oxa analogues. The side chain *cis*-diol, or another analogous group, in the vicinity of the heteroatom of the ring serves as a precursor of the aldehyde function necessary for forming the ω-chain.

The key stage of forming the 11-oxaprostanoid structure from sugars (dihydrosugars) is the replacement of their C(3) hydroxy group by an ethoxycarbonylmethylene group which is an α-chain intermediate. This replacement may be effected by two methods.

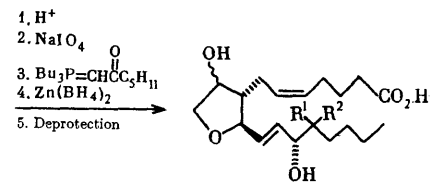
In the synthesis of 11-oxa-$PGF_{2\alpha(\beta)}$ prostanoids (XIIa, b) from derivatives of 1,4-anhydro-D-glucitol (VIIa, b) [19] method I includes the addition of malonic ester to the epoxide (VIII) with isolation of the desired regioisomer (IX) and its subsequent hydrolysis and decarboxylation. Method II comprises the selective oxidation of the C(3) hydroxyl group with subsequent treatment of the resulting 3-keto derivative with the appropriate phosphorane and stereoselective reduction of the exocyclic multiple bond in compound (X). It must be noted that the method of introducing the ethoxycarbonylmethyl group determines the stereochemistry of the chiral centre at position 9 (PG nomenclature).



The diastereomeric synthons (XIa, b) were used for obtaining the desired heteroprostanoids by a sequence of classical conversions.



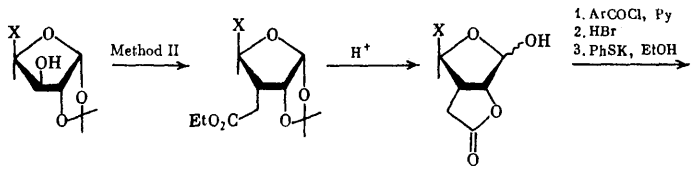
(XI a,b)



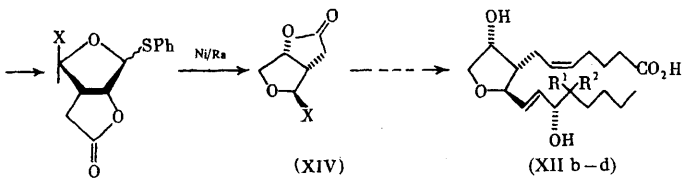
(XII a,b)

a) 9β–OH, b) 9α–OH ($R^1=R^2=H$)

In the synthesis of 11-oxaprostanoids (XIIb–d) from derivatives of D-xylose (XIIIa) and D-glucose (XIIIb),[20] after introducing the ethoxycarbonylmethyl group by method II and acid hydrolysis, the C(1)-glycosidic hydroxyl group was eliminated via the phenylthio derivative by hydrogenolysis over Raney nickel with the formation of oxa analogues of the Corey lactone (XIV).



(XIII a,b): a) $X=CH_2OCH_2Ph$, b) X=



(XIV) (XII b–d)

b) $R^1=R^2=H$, c) $R^1=H$, $R^2=CH_3$, d) $R^1=R^2=CH_3$

An analogous approach was used in the synthesis of 11-oxa-$PGF_{2\alpha}$ (XIIb) starting from 1,4:3,6-dianhydro-D-sorbitol (XV),[21] which was transformed into furanol (XVI) by a known series of conversions.

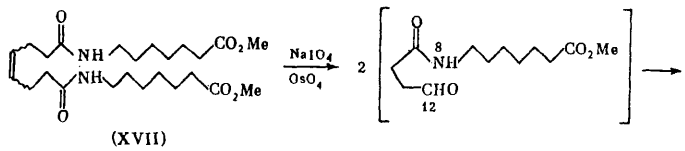
(XII b)

2. Heterocyclic prostanoids from acyclic precursors

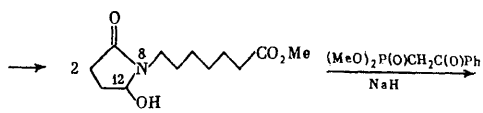
Depending on the molecular fragments used to form the heterocyclic systems, the schemes of synthesis of the heterocyclic prostanoids from acyclic precursors may be subdivided into five main groups, i. e. schemes including 8,12, 8,9, 9,10, 10,11 and 11,12 closure of the heterocycle.

a) Schemes utilising 8,12 closure of the heterocycle

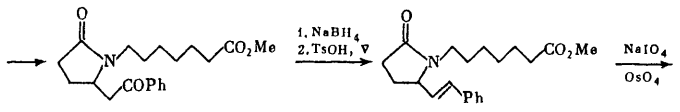
When obtaining the key synthon 11-deoxy-8-azaprostanoids (XXI) from the diamide (XVII), the cyclisation of the long chain precursor occurs after oxidative fission of the (*E,Z*)-multiple bond in the latter. Condensation of the resulting cyclic lactam (XVIII) with the sodium salt of dimethyl phenacylphosphonate gives the ketolactam (XIX). The sequence of conversions (XIX)–(XX)–(XXI) leads to the synthon (XXI).[22]



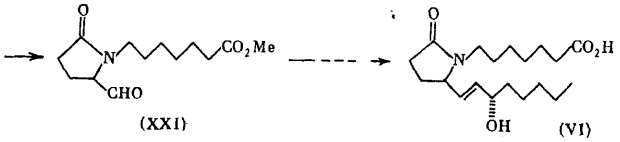
(XVII)



(XVIII)



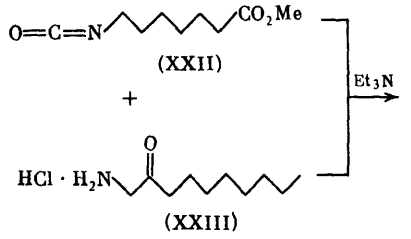
(XIX) (XX)



(XXI) (VI)

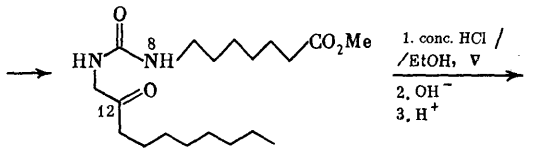
The initial components in the synthetic scheme for the 11,12-dehydro-8,10-diazaprostanoid (XXV) from the isocyanate (XXII) and the β-aminoketone (XXIII) carry the side chains in an already finished form. The formation of the heterocyclic system

occurs in two stages in this case, through the initial formation of the adduct (XXIV) and its subsequent cyclisation.[23]

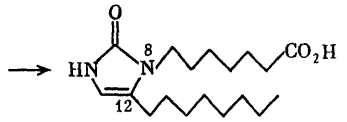


(XXII)

(XXIII)



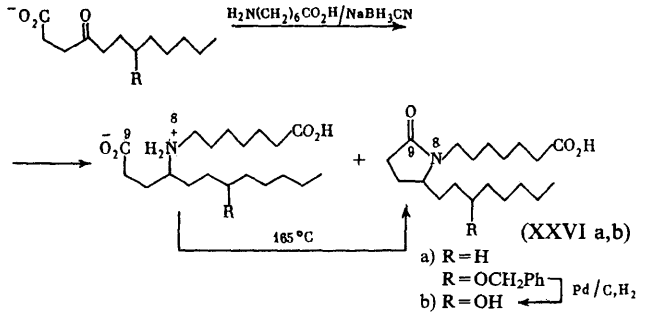
(XXIV)



(XXV)

b) Schemes utilising 8,9 and 11,12 closure of the heterocycle

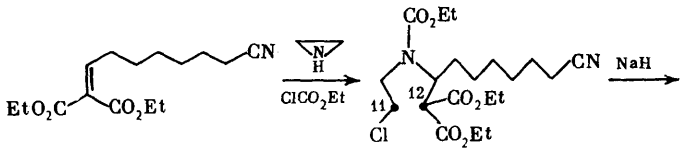
The formation of the heterocycle in the synthesis of 8-aza-9-keto-prostanoic acid (XXVIa) and its 15-hydroxy derivative occurs after the formation (and in part simultaneously with the formation) of the α-prostanoid chain (8,9 closure of the heterocycle).[23]

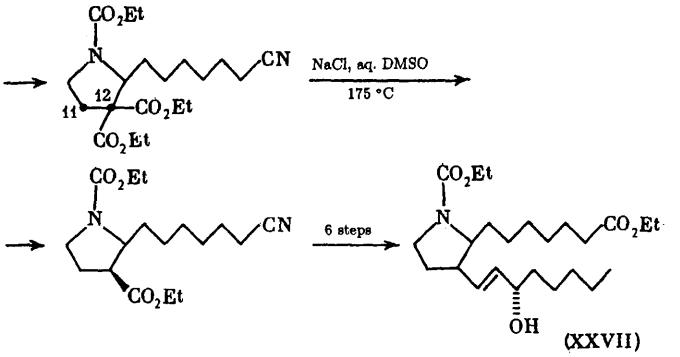


(XXVI a,b)

The 11,12 closure of the heterocycle utilises the previously known schemes of synthesis of the 9-aza- (XXVII) and 9-thia- (XXVIII) prostanoids. The key stages are the following:

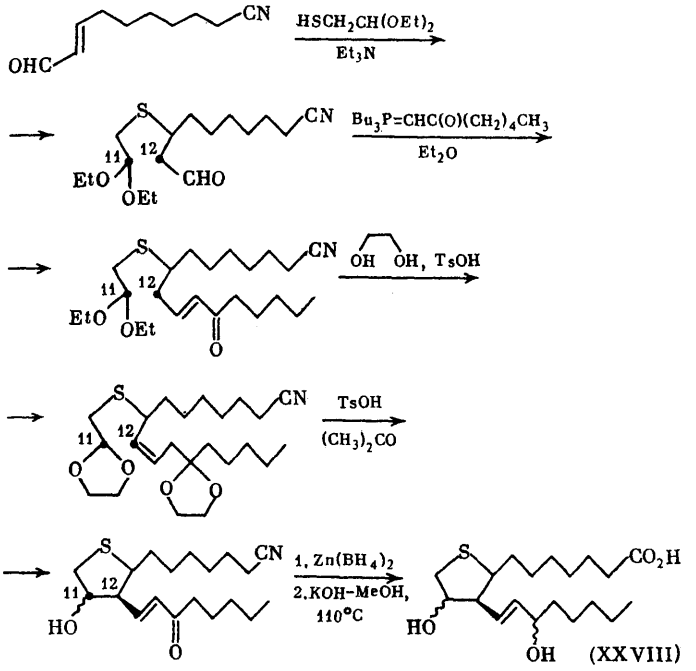
9-*N*-carbethoxy-11-deoxy-PGE$_1$ (XXVII) [24]





(XXVII)

9-deoxy-9-thia-PGE$_1$ (XXVIII) [25]

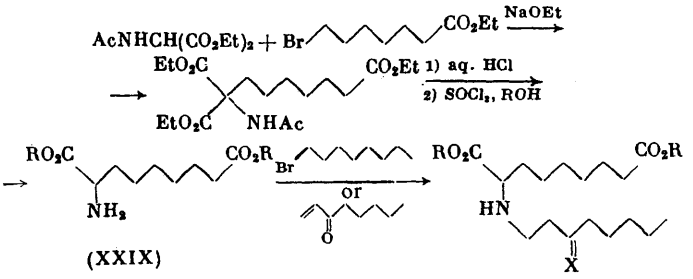


(XXVIII)

As is evident from the schemes the heterocyclic fragment may be formed at various stages of building the prostanoid skeleton.

c) Schemes utilising 9,10 and 10,11 closure of the heterocycle

Schemes for obtaining prostanoids with nitrogen atoms at the junction positions of the ring and the side chains mainly belong to this group. The key synthons for these heteroanalogues are long chain α-amino esters and amino diesters, the standard synthetic scheme for which is shown using the examples of amino diesters of azelaic acid (XXIX) and their *N*-alkyl derivatives (XXX).[26]



(XXIX)

(XXX) (X = H_2, O)

Table 2. Synthesis of heteroprostanoids, including 9,10 and 10,11 closure of the heterocycle.

Type of heteroprostanoid	Precursor	Reagent	Condensation product	Structural formula	Reference
12-Aza-			 (XXXI)		[27]
		$HO_2CCH_2CO_2Et$, DCCI	 (XXXII)		[26]
10,12-Diaza-		HCNO	 (XXXIII)	 X = H; OH, R = C_5H_{11}, X = OH, R = *cyclo*-C_6H_{11}	[28–30]
		MeNCO or MeNCS	 X = O, S (XXXIV)	 X = O, S	[31]
8,10-Diaza-		HCNO	 (XXXV)	 R = H; OH	[29]
8,12-Diaza-, 8,10,12-diaza-, 10-oxo-8, 12-diaza-		$EtO_2CH_2CO_2H$, DCCI	 (XXXVI)	 Z = CH_2, NH, O; X = H; H, OH; R = C_5H_{11}, *cyclo*-C_6H_{11}	[18]
		HCNO	 (XXXVII)		
		$COCl_2$	 (XXXVIII)		
11-Aza-	 (XXXIX)	$O_2NCH_2CO_2Me$, Triton B		 (XL) R = H, Me	[32]

Examples are given in Table 2 of the preparation of heteroprostanoids using these and related synthons.

A characteristic of this group of schemes is the formation of the products (XXXI)–(XXXVIII) by the condensation of a series of reactants at the nitrogen atom of the amino diesters and a cyclisation stage. It must be indicated that for certain schemes, including thermal cyclisation, assignment to this group is arbitrary since the preparation of condensation products and closure of the heterocycle is usually carried out in one step.

The scheme for obtaining 11-azaprostanoids (XL) from the precursor (XXXIX) is also assigned to this type.

d) Schemes utilising mixed closure of the heterocycle

The synthesis of the 8,10-diaza (XLI), 10-oxa-8-aza (XLII) and 10-oxa (XLIII) analogues does not include the formation of condensation products of type (XXXI)–(XXXVIII). The overall reaction is as though the reagent was inserted between positions 8,11, 8,10 and 10,12 of the long chain prostanoid precursors [(8,9 + 10,11), (8,9 + 9,10) and (10,11 + 11,12) closure of the heterocycle respectively].

[Ref. 34]

(XLIII)

Examples are given in Table 3 of the formation of heterocyclic prostanoid fragments from long chain synthons containing vicinally located functional groups or a double bond in positions 8 and 12 of the future prostanoid structure. Closure of the heterocycles in the analogues being considered are (9,10 + 10,11) and (8,9 + 11,12).

3. Heterocyclic prostanoids from PG 11-nor analogues

The ring expansion reaction of 11-norprostanoids (XLIVa, b) was used in the synthesis of 9-oxa (XLVa) and 9-aza (XLVIa) analogues of PGE_2 and also 9,13-dioxa- (XLVb) and 13-oxa-9-aza- (XLVIb) prostanoids. In all cases the introduction of the heteroatom into the prostanoid skeleton occurred with complete regioselectivity.[5,41]

b) X = O–, $R^1 = -CH_2OPh$, $R^2 = -H$, $-SiMe_2(t\text{-Bu})$

III. Heteroanalogues of the α- and ω-chains

The synthesis of the 13-oxaprostanoids (XLVIII)–(L) is based on the initial formation of the vinyl ether (XLVII) carrying both prostanoid chains with the heteroatom in the appropriate position. Construction of the cyclic portion of prostanoid (XLVIII) occurs as

Table 3. Synthesis of heteroprostanoids by a mixed closing of the heterocycle.

Type of heteroprostanoid	Long-chain bifunctional precursors	Reagents	Cyclisation products	Structural formula	Reference

(XLIX) (L)

However functionalised five-membered precursors are used in the majority of schemes for the synthesis of 7- and 13-heteroprostanoids. The heteroatom may be introduced into the composition of the former or into a functional group of a fragment of the prostanoid chains.

The key stage in the formation of the heteroprostanoid fragment of the 13-azaprostanoids (LIIIa–d) is the addition of aliphatic amines at the carbonyl group of the keto ester (LI) with subsequent reduction of the resulting azomethines (LIIa–d).[42]

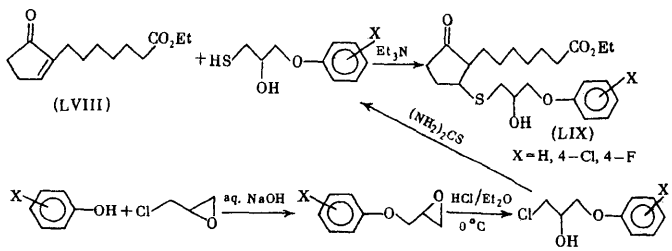
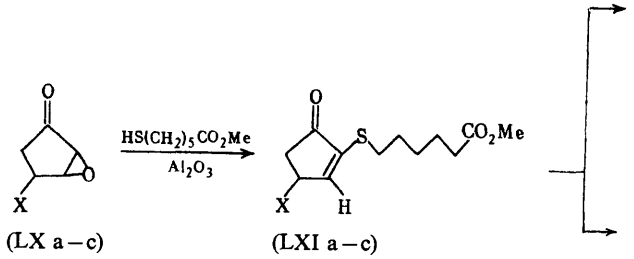
The most widespread method of forming 13-thiaprostanoids includes the addition of mercaptans, corresponding to the ω-chain, to the multiple bond of 2-alkyl substituted cyclopentenones. For example 13-thia-16-aryloxy-17,18,19,20-tetranor-PGE_1 (LIX) was synthesised from the classical synthon (LVIII).[44]



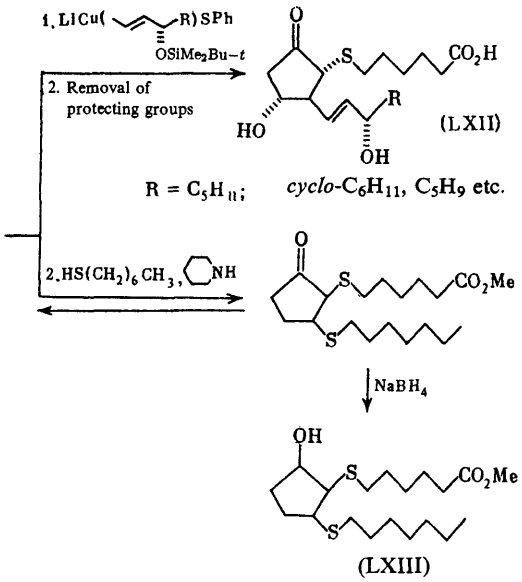
(LVIII) (LIX)
X = H, 4-Cl, 4-F

An analogous scheme was used in the synthesis of the bicyclic 13-thiaprostanoids,[45] and also 11-hydroxy-13-thia analogues.[46]

The 7-thiaprostanoids (LXII) were obtained from the cyclic epoxyketones (LXb, c).[47,48] The addition of a mercaptan corresponding to the structure of the ω-prostanoid chain to the enone (LXIa) leads to a 7,13-dithiaprostanoid of low stability due to a retro-Michael reaction. Reduction of the 9-keto group gives the stable analogue (LXIII).[49]

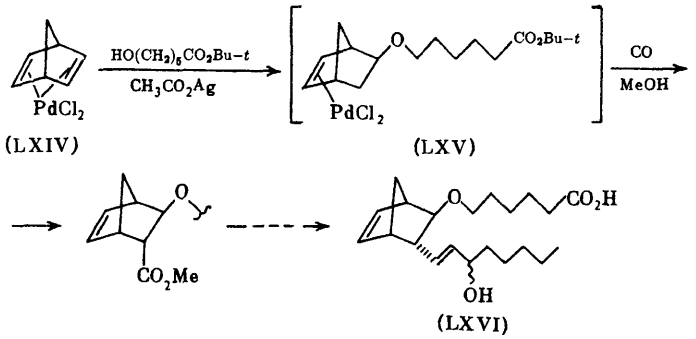


a) X = H,
b) X = OTHP,
c) X = OSiMe$_2$(*t*-Bu)

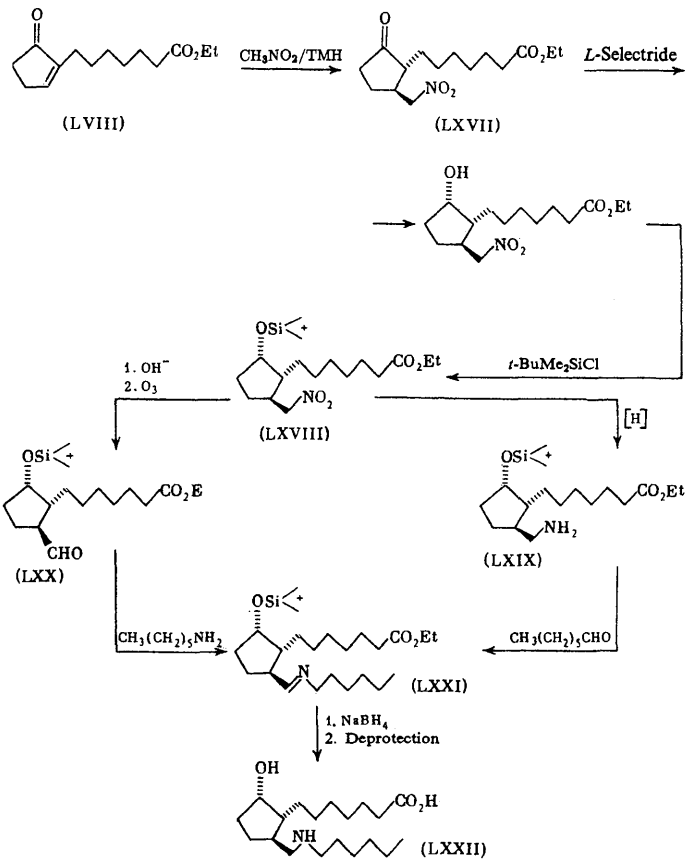


The most widely used approach to obtaining 7-oxa-PG analogues is the alkylation of cyclopentanoid synthons at the 8-hydroxyl function with alkyl halides corresponding to the α-chain structure.[50]

The bicyclic 7-oxaprostanoid (LXVI) was obtained by oxypalladation of the norbornadiene complex (LXIV) with ε-hydroxycaproic ester and subsequent direct carbonylation of the intermediate (LXV).[51]



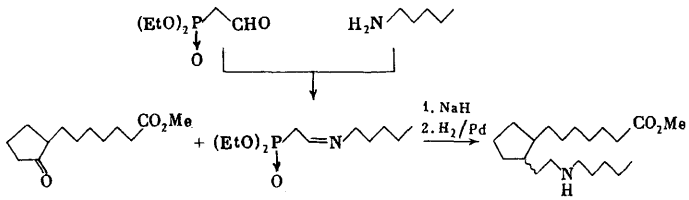
The principle of constructing sidechains analogous to that considered for 7- and 13-heteroprostanoids with other positions of the heteroatom may be illustrated by the example of the synthesis of the 14-azaprostanoid (LXXII).[52] The Michael addition of nitromethane to the cyclopentenone (LVIII) leads to the nitromethyl derivative (LXVII). After the selective reduction of the 9-keto group with L-Selectride and protection of the resulting alcohol, the formation of the ω-chain is effected by two methods. One is by reduction of the nitro group in compound (LXVIII) and subsequent condensation of the amino derivative (LXIX) with hexanal. The other is by the ozonolysis of the nitronate of the ester (LXVIII) with the formation of the aldehyde (LXX) and its further reaction with hexylamine. The final stage of the synthesis is the borohydride reduction of the azomethine (LXXI) formed in both cases.



Methods which have been used to join fragments of the heteroprostanoid chains include nucleophilic substitution of tosylates (mesylates) with the appropriate alkyl sulphides (13, 14 and 15-thiaprostanoids[53]), radical and Michael addition of alkyl mercaptans at a terminal multiple bond (4-thia, 5-thia and 6-thia analogues[48]), alkylation of phenoxides or alkoxides with various alkyl halides (3-oxaprostanoids[54]), alkoxyenamination with a hemiacetal (4-oxa-5-azaprostanoids[55]) and the formation of amide (13- and 14-aza- [56,57]) and sulphonamide bonds (benzenesulphonamidoprostanoids[57–62]).

An alternative approach to prostanoids of this type is the addition of an independently formed heteroprostanoid chain to a

cyclopentanoid synthon as in the synthesis of the 15-azaprostanoid methyl ester (LXXIII).[42]



(LXXIII)

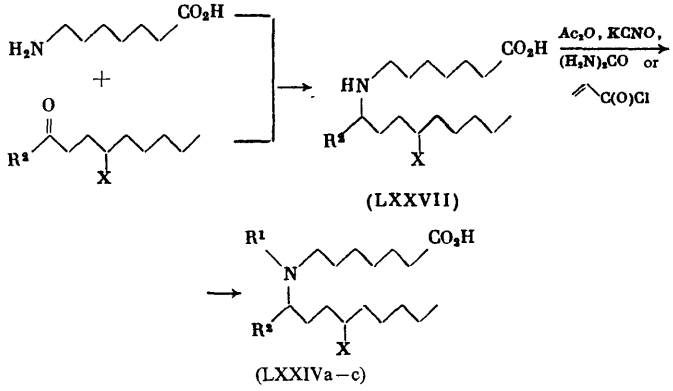
IV. Heteroanalogues of secoprostanoids

From the point of view of structural features the secoprostanoids are as though the acyclic precursors of prostanoids. Nevertheless such 'unfinished prostanoids' display marked prostaglandin-like activity. This group of biologically active compounds did not receive attention in the previous reviews so we saw the need to deal with this problem.

The synthesised heteroanalogues are referred to as 11,12-,[63–67] 8,12-[68,69] and also furan-containing secoprostanoids.[70]

The 11,12-secoprostanoids are mainly *N*-acyl-*N*-alkyl-7-aminoheptanoic acids of the type of (LXXIVa–c), 7-(*N*-alkylmethanesulphonamido)heptanoic acids (LXXIVd), 8-alkylthio(sulphinyl, sulphonyl)-12-hydroxyacids (LXXVa–c), and also 8-acetyl-12-hydroxy-13-aryloxy(thioaryl, alkoxy)tridecanoic acids (LXXVIa, b).

The heteroanalogues (LXXIVa–c) were obtained through the reductive alkylation of 7-aminoheptanoic acid with aldehydes and ketones corresponding to the ω-prostanoid chain and subsequent reaction of the resulting substituted aminoheptanoic acids (LXXVII) with acetic anhydride, potassium cyanide, urea or acryloyl chloride.[63]

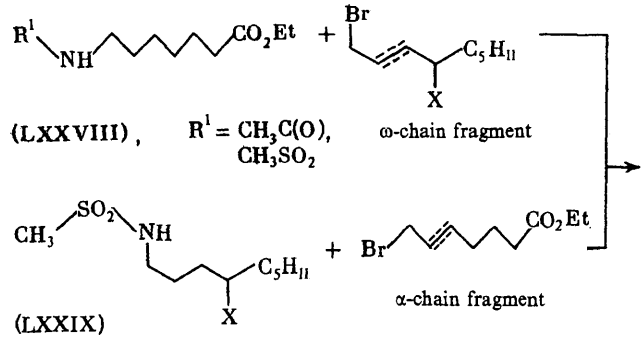


(LXXIVa–c)

a) $R^1 = CH_3C(O)$, b) $R^1 = H_2NC(O)$,

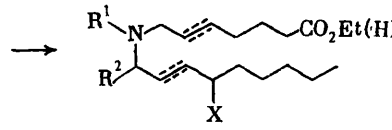
c) $R^1 =$; $R^2 = H, Ph, CH_3$; $X = H$

An alternative variant is the alkylation of the acetyl- and methanesulphonylamides (LXXVIII) and (LXXIX) with halogen derivatives corresponding to the structure of the α- or ω-prostanoid chain.[63,64]



(LXXVIII), $R^1 = CH_3C(O)$, CH_3SO_2; ω-chain fragment

(LXXIX); α-chain fragment

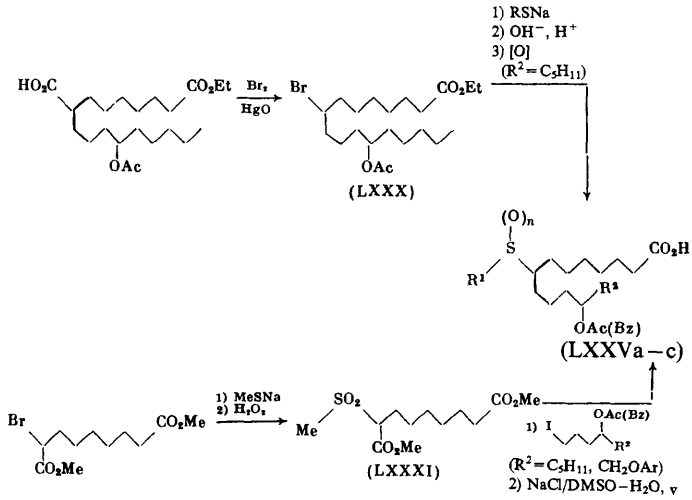


(LXXIV a,d)

a) $R^1 = CH_3C(O)$, $R^2 = H$;

X = H, OAc(OH) d) $R^1 = CH_3SO_2$, $R^2 = H$

The secoprostanoids (LXXVa–c) are formed by the reaction of haloester (LXXX) with various thiolates and also by alkylation of the sulphone (LXXXI).[65]



(LXXXI)

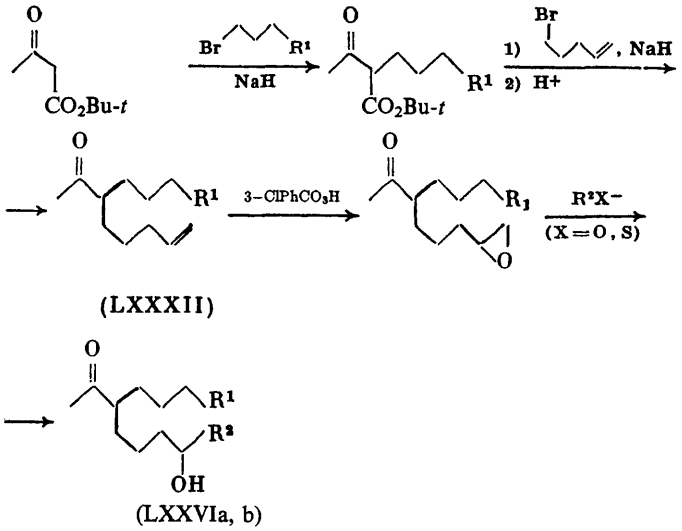
(LXXVa–c)

a) $n = 0$ to 2, $R^1 = Me$, $R^2 = C_5H_{11}$;

b) $n = 0.2$, $R^1 = HO(CH_2)_2$, $R^2 = C_5H_{11}$;

c) $n = 2$, $R^1 = Me$, $R^2 = CH_2OAr$.

The 8-acetyl-12-hydroxy-13-aryloxy(thioaryl, alkoxy)tridecanoic acids (LXXVIa, b) were obtained from the key synthons (LXXXII) through epoxidation of the latter and fission of the epoxide ring with phenoxides, phenylthiolates and alkoxides.[66,67]



(LXXXII)

(LXXVIa, b)

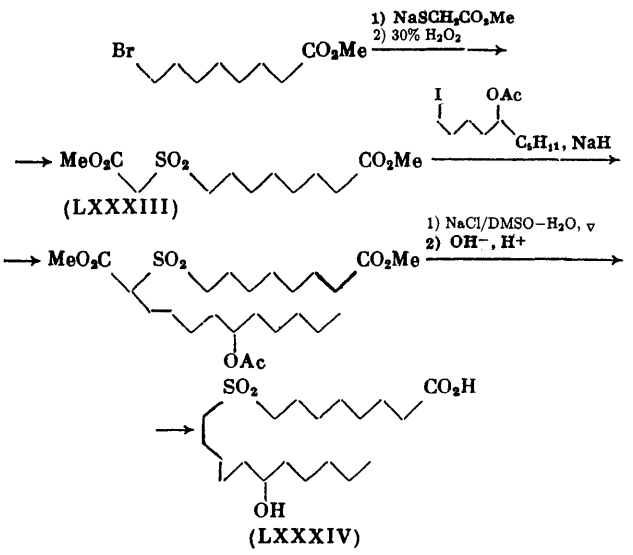
a) $R^1=(CH_2)_3CO_2H$, $R^2=CH_2OAr(CH_2SAr)$;

b) $R^1=$  CO_2H, $R^2=CH_2O(CH_2)_2Me$.

A series of 7-*N*-alkylmethanesulphonamide secoprostanoids, containing *O*- and *S*-phenylene fragments in the ω-chain, was obtained from the methanesulphonamide (LXXVIII), $R^1 = MeSO_2$ using an analogous approach.[66]

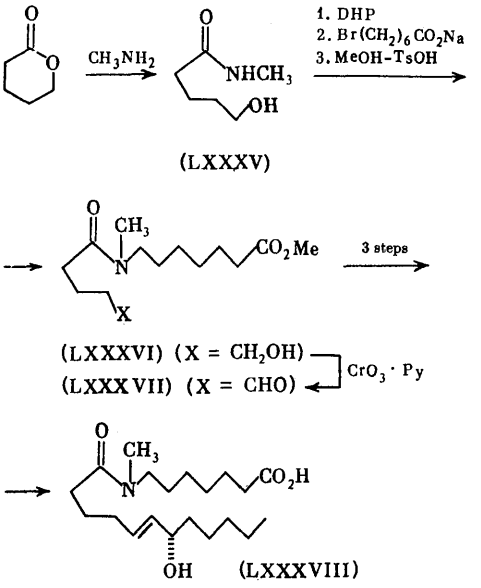
Analogues of 8,12-secoprostanoids synthesised include the 9-sulphonyl (LXXXIV),[65] 8-aza (LXXXVIII), 10-oxa (XC) [68] and the 10-aza and 8-oxa analogues.[69]

The key stage in the formation of the sulphonyl analogue (LXXXIV) is the alkylation of the diester (LXXXIII) in the α-position with an ω-prostanoid chain fragment.[65]



(LXXXIV)

The 8-azasecoprostanoid (LXXXVIII) was obtained through fission of δ-valerolactone with methylamine to form (LXXXV), alkylation of the latter with 7-bromoheptanoic acid, oxidation of the hydroxyl function in the derivative (LXXXVI) and formation of the ω-chain from the aldehyde (LXXXVII) by classical methods.[68]



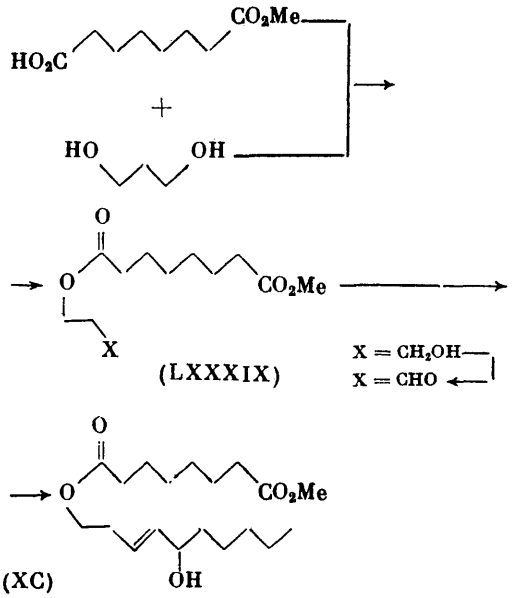
(LXXXV)

(LXXXVI) (X = CH_2OH)

(LXXXVII) (X = CHO)

(LXXXVIII)

The 10-oxa analogue (XC) was synthesised from the hydroxy ester (LXXXIX) to which the ω-chain was attached in an analogous manner.[68]



(LXXXIX)

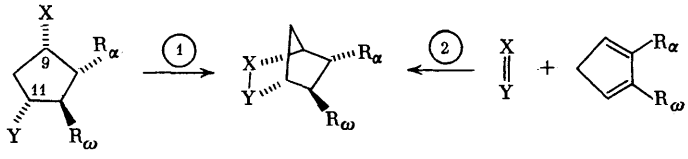
(XC)

The principle of forming the 10-aza- and 8-oxasecoprostanoids was analogous to that considered for the 8-aza and 10-oxa analogues.[69]

V. Heteroanalogues of cyclic endoperoxides

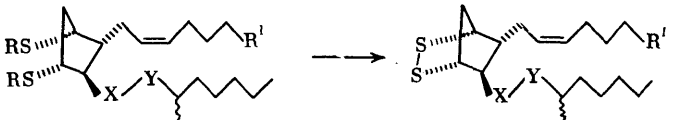
The main problem in the synthesis of heteroanalogues of the cyclic endoperoxides (PGH, PGG) is the replacement of the chemically unstable cyclic endoperoxide group by a more stable one. Of the large number of PGH and PGG analogues obtained up to the present time only those in which one or both oxygen atoms of the endoperoxide grouping are replaced by other heteroatoms (nitrogen, sulphur) are considered in the review.

The formation of the appropriate endocyclic bridging groups of such analogues is effected by two main approaches. The first is through the chemical bond of the functional groups at positions 9,11 of the prostanoid molecule and the second is through a 1,4-cycloaddition of dienophiles, carrying a bridging group in some form or other, to a variously substituted cyclopentadiene.



The first approach was used in the synthesis of dithia, epoxyimino and methyleneimino analogues of PGH.

The key stage in the synthesis of the dithia analogues (XCIIa–c) of PGH is the formation of a disulphide bridge in the appropriate 9,11-dimercapto substituted prostanoids (XCIa–d).[71–73]



(XCI a–d) OH(THP,Ac) (XCII a–c)

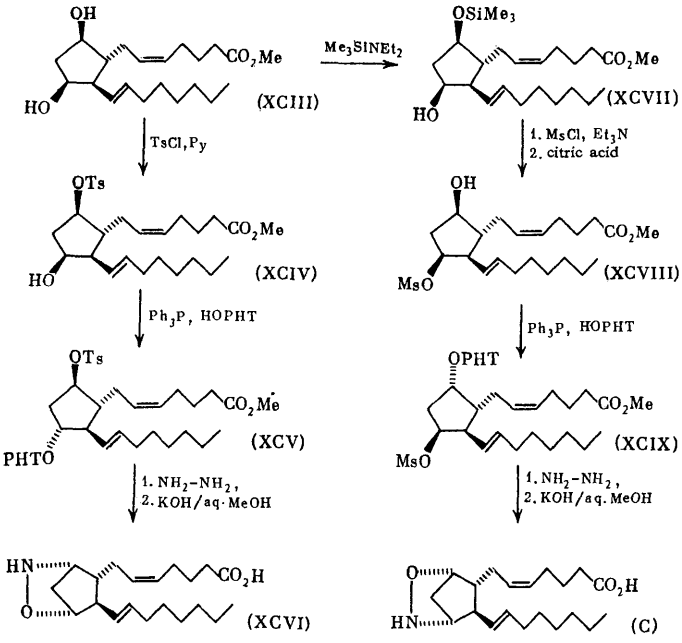
a) $R^1 = CO_2Me$, $X—Y = CH\overset{E}{=}CH$

b) $R^1 = CO_2Me$, $X—Y = C\equiv C$

c) $R^1 = CH_2OAc$, $X—Y = C\equiv C$

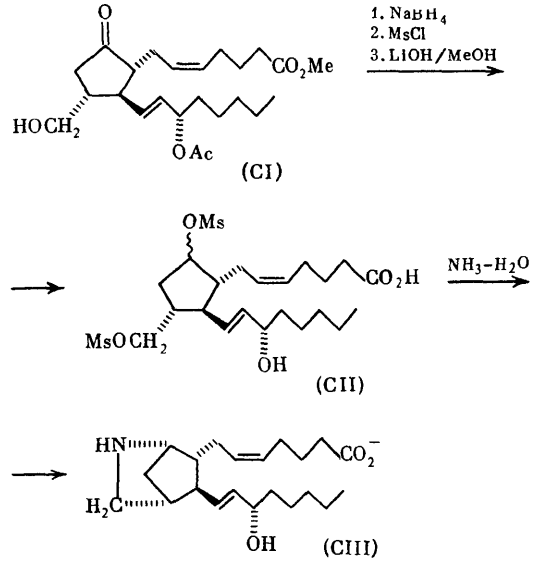
(XCI)	R^1	X–Y	R	Reagent
a	CO_2Me	$CH\overset{E}{=}CH$	H	MnO_2
b			Me	O_2, MeONa/MeOH
c	CO_2Me	$C\equiv C$	Ac	K_2CO_3/MeOH
d	CH_2OAc			

The regioisomeric 9,11-epoxyimino analogues (XCVI) and (C) were obtained from 15-deoxy-11β-$PGF_{2\beta}$ (XCIII).[74] The regioselective tosylation of the less screened 9-hydroxyl group in 11β-$PGF_{2\beta}$ leads to the derivative (XCIV). Subsequently on treatment with triphenylphosphine, *N*-hydroxyphthalimide and diethyl azodicarboxylate compound (XCIV) gave the *N*-alkoxyphthalimide (XCV) from which the epoxyimine (XCVI) was formed on removing the phthalimide protection. In a similar manner the selective trimethylsilyl protection of the 9-hydroxy function of 11β=$PGF_{2\beta}$ leads to the derivative (XCVII). Mesylation of the C(11) alcohol group and removal of silyl protection gives compound (XCVIII) from which the regioisomeric epoxyimine (C) is formed through the alkoxyphthalimide (XCIX).



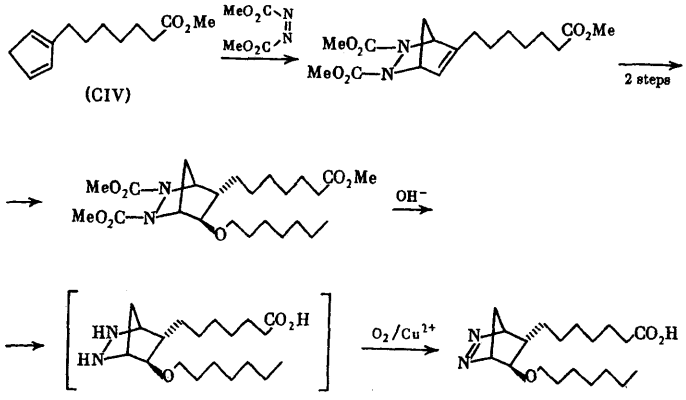
PHT = phthalimido

The methylenimino analogue (CIII) was obtained from the 11-hydroxymethylprostanoid (CI).[75] Reduction of the 9-keto group in the latter and mesylation of the resulting diol leads to the bismesylate (CII), which on reaction with 40% aqueous ammonia gives the ammonium salt of methyleneimino-15-deoxy-PGH_2 (CIII).



A second approach was used in the synthesis of 9,11-azo analogues of the cyclic endoperoxides. The cyclic system of the latter was formed by the Diels–Alder addition of dimethyl(diethyl) azodicarboxylate to a substituted cyclopentadiene of type (CIV). Forming the bridge with the azo group was effected by the alkaline hydrolysis of both methoxycarbonyl(ethoxycarbonyl) groups of the

bicycle and then direct air oxidation of the intermediate hydrazine derivatives in the presence of a divalent copper salt.[76]



VI. Heteroanalogues of prostacyclin

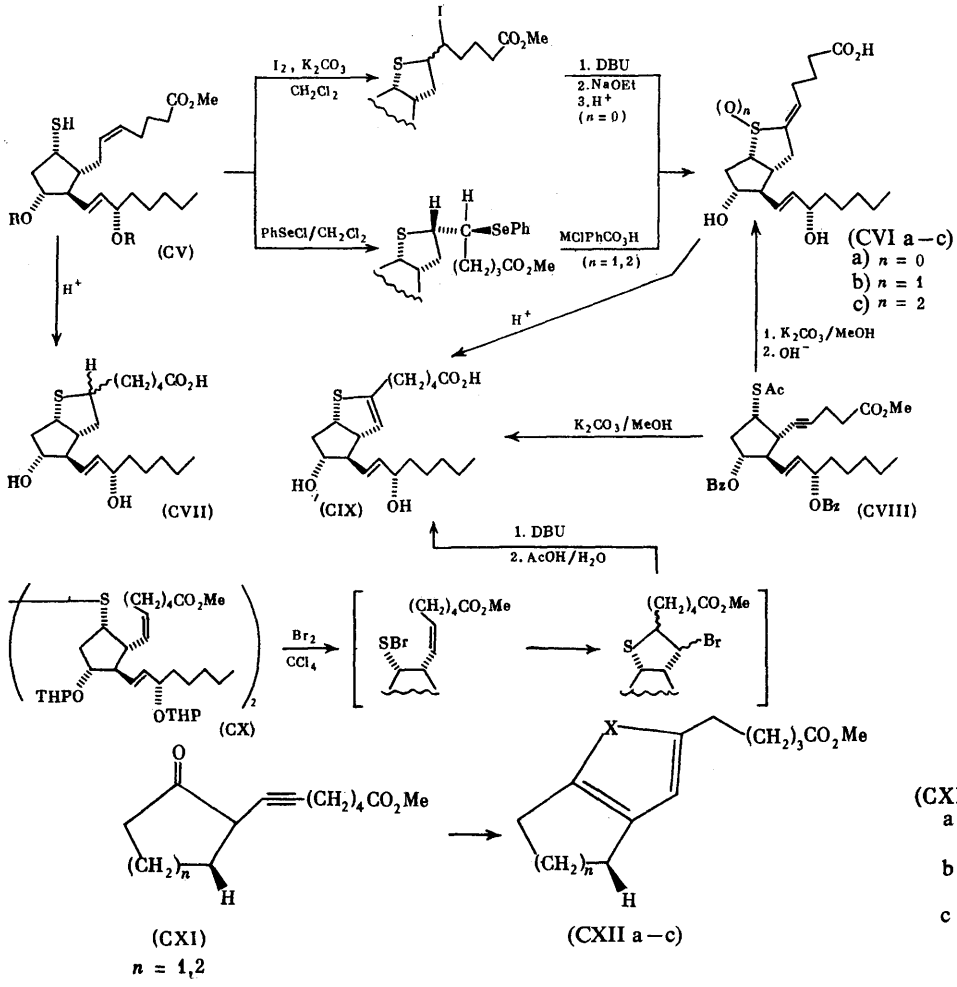
Heteroprostacyclins are described in the literature with heteroatoms at the most varied positions of the molecule. Among those appearing in publications in the last decade it is possible to name 3-oxa,[77–82] 3-aza(thia),[79] 4-thia,[83] 5-aza,[84] 11-oxa,[85] 11-thia,[86] 12-aza,[87] 13-oxa(thia),[88–90] 13-aza[91] and *o*-phenylene analogues.[81,92]

The methods of synthesising such prostacyclin analogues are no different in principle from the methods of forming the basic skeleton of the heteroprostanoids considered above and the synthesis of the *cis*-enol ether system in them is effected by classical means. Consequently in the present review only the modification of the heteroatom of the enol ether fragment is examined. The main purpose of the modification is the replacement of the chemically and metabolically unstable enol ether group by biologically equivalent and/or isosteric structures which are more stable and may have promising use in medicine.

The formation of an enol ether modified with a heteroatom in such heterocyclic PGI analogues was effected using mainly three approaches.

1. Formation of the heterocycle with the participation of the activated multiple bond of the α-chain.

This method is widely used when constructing the enol ether system of natural prostacyclin. Applying it to the 9-mercapto-5,6-*trans* derivatives of $PGF_{2\alpha}$ (CV) leads to the 9-thiaprostacyclins (CVIa–c), (CVII).[93,94] The analogue (CVIa) is also formed by intramolecular attack of the thioacetate grouping at the triple bond in the derivative (CVIII).[95]

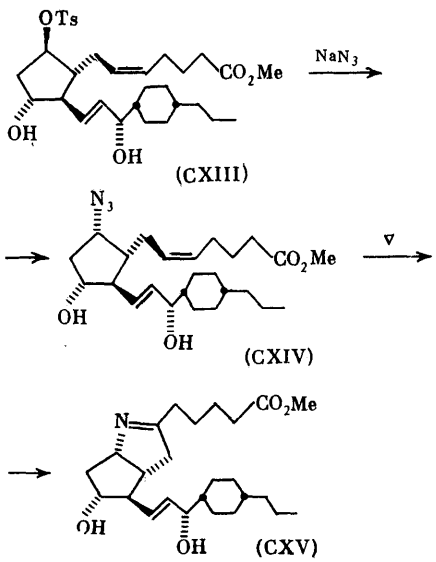


(CXII)	Reagent	X	n
a	H_2S/HCl	S	1,2
	$PhNH_2$,	PhN	1,2
b	Py·HCl, $Hg(O_2CCF_3)_2$	–	–
c	Ac_2O, *p*-TsOH	O	2

The 9-thiaprostacyclin (CIX) was obtained from the disulphide (CX).[96] In this case cyclisation occurs as a result of attack by the Δ^6-double bond at the activated sulphenyl bromide grouping. The same analogue was obtained on cyclisation of the thioacetate (CVIII) by the action of potassium carbonate in methanol,[97] and also on treatment of the 9-thiaprostacyclin (CVIa) with acid.[98]

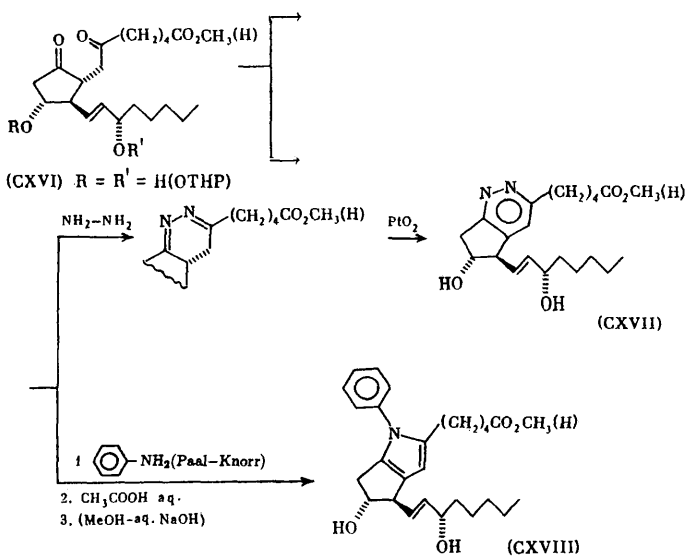
The simplest thiophene (CXIIa), pyrrole (CXIIb) and furan (CXIIc) analogues of prostacyclin were synthesised from the readily accessible 4-alkynylketones (CXI).[99]

The 9-azaprostacyclin (CXV) was obtained using as the key stage the pyrolysis of the azide (CXIV) formed from the tosylate (CXIII).[100]

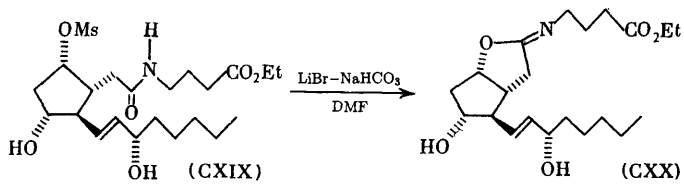


2. Formation of the heterocycle with the participation of other functional groups of the α-chain.

Construction of the heterocyclic systems of the pyridazoprostacyclin (CXVII) and the pyrrole analogue (CXVIII) was effected from the 1,4-dicarbonyl system of 6-keto-PGF_1 (CXVI).[101,102]

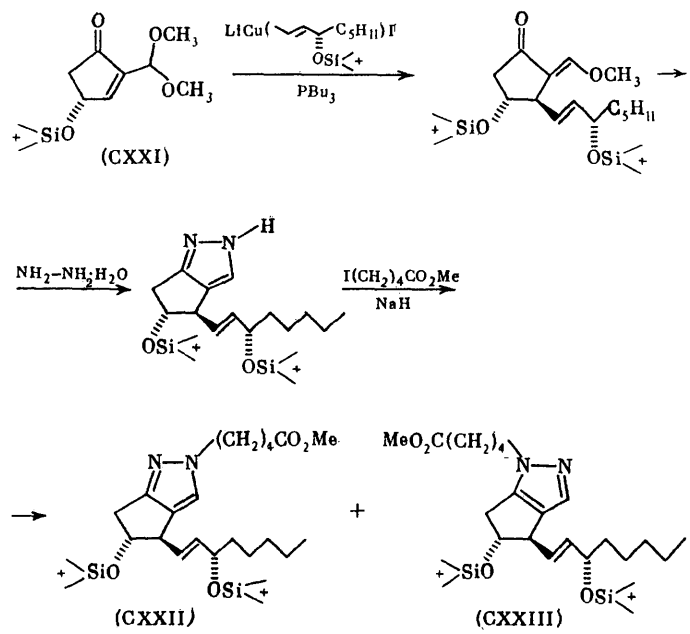


The 5-azaprostacyclin (CXX) was obtained by the cyclisation of the 9-mesyl derivative of the 5-aza-6-ketoprostanoid (CXIX) with a mixture of lithium bromide and sodium hydrogen carbonate.[103]

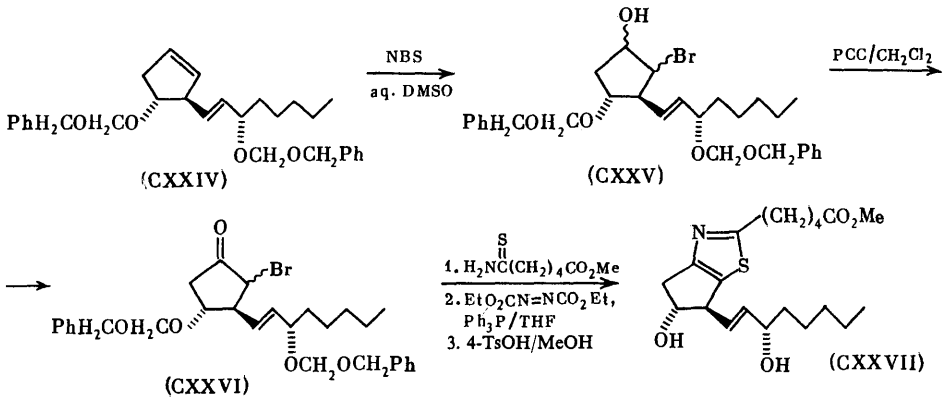


3. Formation of the heterocycle from functionalised derivatives of cyclopentane.

The synthesis of the pyrazole analogues (CXXII) and (CXXIII) from the precursor (CXXI) belongs to this group of schemes.[104]

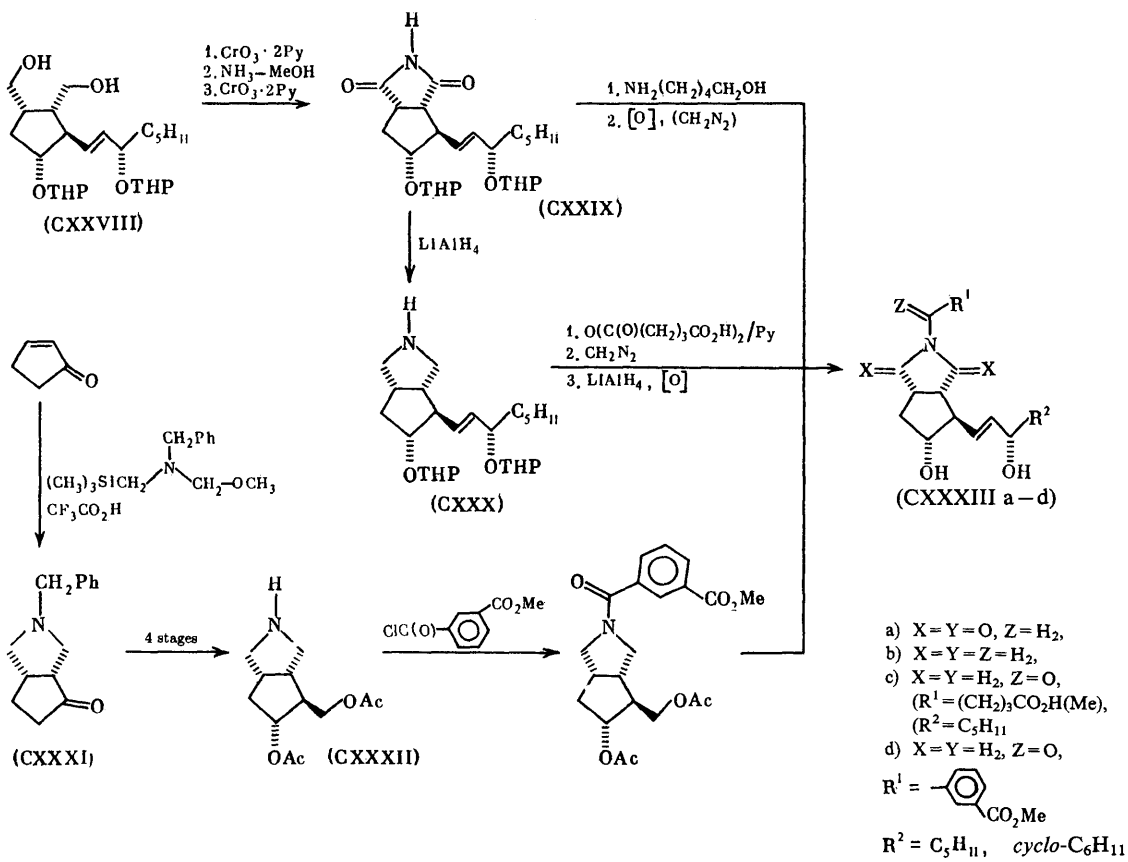


The regiospecific formation of the bromohydrin (CXXV) takes place by the reaction of *N*-bromosuccinimide with compound (CXXIV). Oxidation of the bromohydrin leads to the formation of the bromoketone (CXXVI) which is converted into the thiazolylprostacyclin (CXXVII) by reaction with adipic acid thioamide and subsequent dehydration.[105,106]

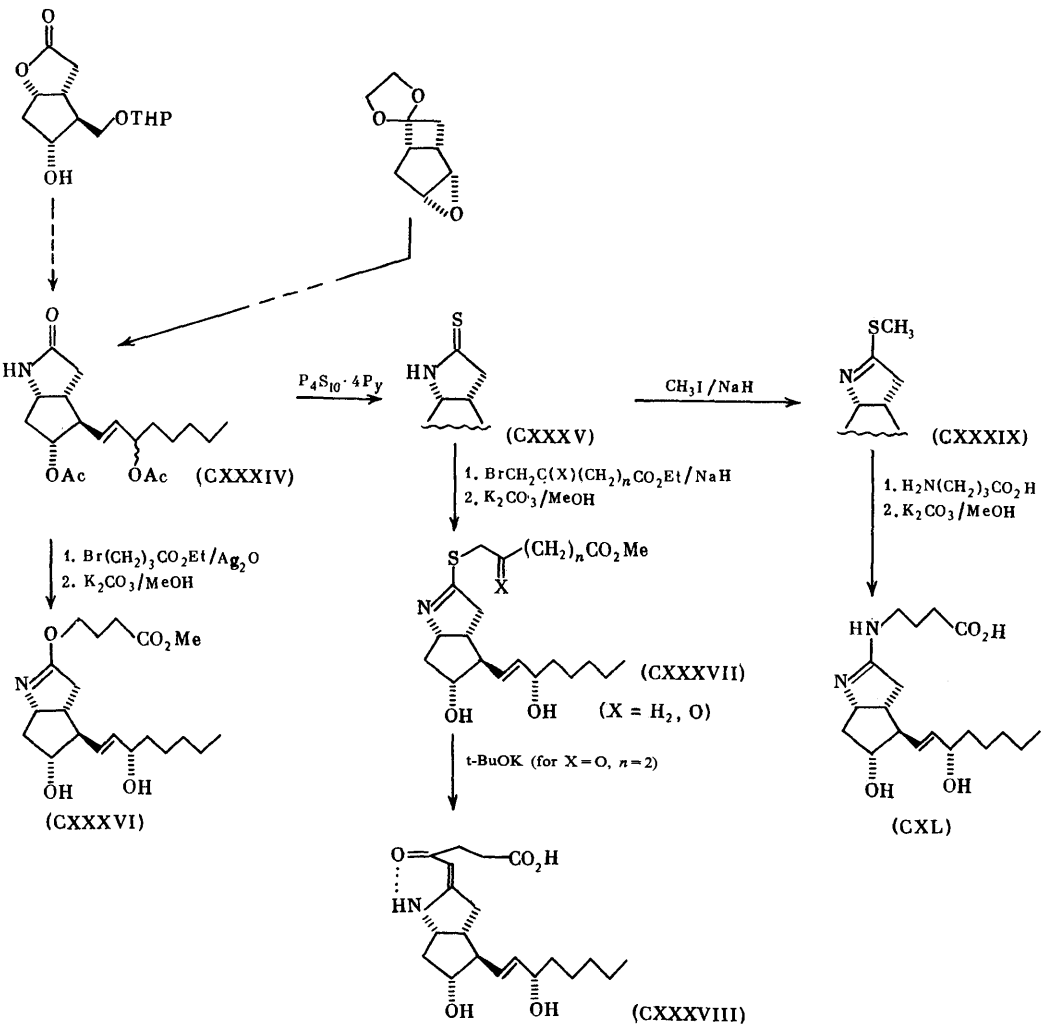


The 6-aza analogues (CXXXIIIa–d) were synthesised by the alkylation (acylation) of the succinimide precursor (CXXIX) [formed from the diol (CXXVIII) in three stages] or from its reduction product (CXXX) and also from the bicyclic diacetate (CXXXII) obtained from the ketone (CXXXI).[107,108]

The β-heteroiminoprostacyclins (CXXXVI)–(CXXXVIII) and (CXL) were synthesised from the lactam (CXXXIV) which may be obtained from the Corey lactone or from the ethylene ketal of 2,3-epoxybicyclo[3.2.0]heptan-6-one. On reaction with the Lawesson reagent the lactam (CXXXIV) was converted into the thiolactam (CXXXV). Alkylation of compounds (CXXXIV) and (CXXXV) leads to the analogues (CXXXVI) and (CXXXVII). The further transformation of compound (CXXXVII) leads to



4-keto-9-deoxy-9-aza-PGI_2 (CXXXVIII). Ammonolysis of compound (CXXXIX) with γ-aminobutyric acid gives the amidine (CXL).[109,110]



VII. Biological activity of heteroprostanoids

Among the numerous data in the literature on the biological activity of PG heteroanalogues we will discuss chiefly those which refer to the modification of the natural structure affecting the biological properties in a favourable manner, i.e. increasing any form of activity (narrowing the spectrum of action) or increasing the metabolic stability of the compound (prolonging its therapeutic effect).

The biological actions of prostaglandins can be divided into several main types. 1. The effect on the vascular and non-vascular smooth musculature, the contracting or relaxing activity. 2. The gastroprotective effect, including the regulation of secretion of gastric juice both as a result of a change in tone of the smooth muscle tissue and of the effect of PG on water and electrolyte transport in them. 3. The hormonotropic action, including the regulation of gland function by internal secretion stimulating the synthesis of hormones. One of the most important forms of biological activity of PG belongs to this direction, viz. the luteolytic effect, the action on the reproductive system through the regulation of ovarian function. 4. The pro- or anti-inflammatory action. The anti-inflammatory effect is probably linked with the inhibition of natural PG biosynthesis. 5. The induction and inhibition of platelet aggregation. 6. The anti-PG effect of synthetic prostanoids consists of a weakening of the effect of natural PG. The synthetic analogue is, as a rule, an antagonist of the appropriate receptor for the natural PG.

It is assumed that PG acts as a complex with the cell receptor of a given organ on an adenylate cyclase system, increasing or reducing its activity and thereby changing the rate of conversion of ATP into adenosine 3′,5′-phosphate, i.e. changing the content of c-AMP in the tissues of an organ. Consequently PG-like activity is assessed according to the ability to bind to a receptor or according to the change in c-AMP content and a comparison is made with the dose of natural PG equivalent in effect. Tests are used to assess the metabolic stability of a prostanoid which measure the affinity for enzymes responsible for metabolism (15-hydroxy-PG-dehydrogenase, Δ^{13}-PG-reductase, etc.). The anti-PG effect, linked with the action on the process of biosynthesis of prostaglandins from arachidonic acid, is displayed in the ability to inhibit the enzymes of PG biosynthesis (PG-synthetase, PG-isomerase).

Table 4. Types of biological action of the heteroprostanoids.

Heteroprostanoids	Biological action	Active concentration g ml^{-1}	Reference
	Contraction of rat uterus muscle	$0\times5-1\times10^{-7}$	[27]
 PGE$_1$	Ditto	5×10^{-7} 1×10^{-9}	[129]
 (XL) PGF$_{2\alpha}$	Contraction of trachea	4×10^{-6} 4×10^{-7}	[32]
 (VI)	Bronchdilator	1×10^{-6}	[4]
 (XLII)	»	5×10^{-5}	[33]
PGE$_2$ 	Increase of tone of smooth muscle organs Ditto Strengthening of spasmogenic reactions caused by PGE$_2$ Reduction of rat arterial pressure	10^{-9} $10^{-5}-10^{-6}$ $10^{-6}-10^{-7}$ $0\times5-1\times10^{-3}$	[151]
 (CXLI)	Weakening of activity on trachea	$4\times10^{-6}-5\times10^{-4}$	[36]
 (CXLII) PGE	Ditto	$5\times10^{-4}-2.5\times10^{-3}$	
 (XLIII)	Effect on smooth muscle	10^{-8}	[111, 112]

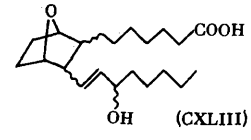
1. Effect on vascular and non-vascular smooth muscle. Gastroprotective, hormonal and pro- or anti-inflammatory activity of heteroprostanoids

Many synthetic heteroprostanoids show activity on smooth muscle characteristic of PG. However both the size and the sign of the effect depend on the form of the target tissue, which is the specificity of a given prostanoid (Table 4). For example, the 11-aza analogues (XL) do not display a contractive activity on guinea pig and rat ileum but contract the trachea like PGE_2 and also cause rhythmic venous contraction.[32]

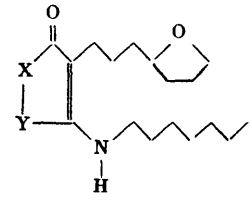
The 9,11-dioxa analogues (CXLI) and (CXLII) display strong relaxant activity.[36] The range of active concentrations of these analogues in relaxing the trachea is 0.004 – 2.5 mg ml^{-1}, i.e. they are approximately 100 times more potent than the natural PGs. The given compounds do not exert a relaxant effect on bronchospasm, they do not affect blood pressure and do not cause intestinal disorders (in contrast to PGE_2) in tests *in vivo*. The 10-oxa-11-deoxy analogues (XLIII) are patented as stimulants in certain species, they may be used in gastro-intestinal disorders and are non-toxic.[111]

A link can be traced between structure and activity of the synthetic heteroprostanoids. The methyl esters of the 10-oxa-11-deoxy-PGE analogues are inactive in the interruption of pregnancy,[112] and the acids of the 11-deoxy-E_1 and E_2 series have moderate contracting activity at concentrations of 10^{-7} g ml^{-1} and low toxicity.[34,113] The 11-methyl derivatives of this series inhibit the secretion of gastric juice in dogs and possess anti-hypertensive activity.[114]

The configuration of substituents at the chiral centres of the molecule affect the biological activity even more appreciably. In the 10-oxa-9,9-dicarba analogues of PGH_1 (CXLIII), which possess vasocontracting and broncho-stimulating activity in many tests *in vitro*, the configuration at C(8, 12,15) has a significant effect.[115,116] Thus the 15β-hydroxy derivatives are most active towards the stimulation of the vascular and respiratory musculature and in the case of the 8-isoconfiguration this effect is strengthened. The contracting activity is appreciably reduced in the 15α-hydroxy derivative and in the case of the natural 8,12,15-configuration. a vasodilatation is observed. These same principles are observed in experiments *in vitro* on trachea and smooth muscle. The 11-oxa-13-azaprostanoid (CXLIVa) at a dose of 10 mg kg^{-1} displays a marked antiadrenergic effect (70% relative to control) and also restores the frequency of cardiac contractions and normalises impaired atrioventricular conduction in the adrenaline arrhythmia model in guinea pigs. Compounds (CXLIVb, c) display an antioedemic effect in the carrageenan inflammation model in the rat.[13]



(CXLIII)



a) X = CH_2, Y = O; b) X = O, Y = $CH(CH_3)$; c) X = $CH(CH_3)$, Y = O.

(CXLIVa – c)

Bronchodilating activity is characteristic of numerous derivatives of 3-, 5- and 16-oxa analogues of PGE and PGF. The 3-*O*-hetero analogues have been patented as antiasthmatics,[117] and the 13-thiaprostanoids of the E_1 and E_2 series as hypotensive agents.[46]

A comparative assessment has been carried out of the activity of several synthetic aza and thia analogues in their ability to bind to PG receptors of the appropriate tissues or in the size of the change in c-AMP concentration (Table 5).[23,63] As is seen from the table a hundredfold concentration of the 11,12-seco-aza analogue (CXLV) is necessary for the display of activity comparable to PGE_1. Compound (CXLVI) was the most active among the 8-aza analogues but it was ten times less potent than PGE_1. The most potent of the tested series, the 11,12-seco analogue (CXLVII), was five times less potent than PGE_1 and comparable with tetrahydro-PGA_2 in stimulating c-AMP, although both PGE_1 and tetrahydro-PGA_2 bound more strongly to the receptor of lipocytes than (CXLVII). However on detailed investigation of the biological properties of (CXLVII) it was shown[65] that the compound is not a substrate of 15-hydroxy-PG-dehydrogenase and therefore has enhanced metabolic stability. Furthermore it was established in tests *in vivo* that the analogue (CXLVII) has a higher specificity of action, it is inactive in relation to gastric secretion and is not an antihypertensive agent.

Table 5. Comparative assessment of the activity of synthetic heteroanalogues of the prostaglandins.[23,63,65]

Compound *	c-AMP concentration, mg ml^{-1}				Binding to lipocyte receptor, relative to PGE_1
	1.0	10	25	10^3	
PGE_1	54	60	62	62	1
Dihydro-PGE_1	10	25	26	—	—
Tetrahydro-PGA_1	10	25	26	—	10
	2	11	14	23	833

Table 5 (contd.).

Compound *	c-AMP concentration, mg ml^{-1}				Binding to lipocyte receptor, relative to PGE_1
	1.0	10	25	10^3	
	1.4	—	8	25	390
 (CXLVI)	5.2	—	27	37	60
 (CXLVII)	14	—	27	38	670
	1	—	23	27	1110
	4	—	40	57	7140

*Activity of PGE_1 at *c*-AMP concentration 10^{-2} mg ml^{-1} was 8, at *c*-AMP 10^{-1} it was 25. Activity of (CXLVII) at 10^{-1} mg ml^{-1} was 2.

The 15α-isomer of (+)-7-oxa-$PGF_{1\alpha}$ (CXLVIII) at a concentration of 100 μg mol^{-1} displays 10% activity of PGE_1 in stimulating adenylate cyclase and has 5% activity of $PGF_{1\alpha}$ in stimulating smooth muscle.[118] The 15β-isomer at a concentration of 1 μg ml^{-1} inhibits the action of $PGF_{1\alpha}$ at a concentration of 250 ng ml^{-1}.

The 9,11-dideoxy (CXLIX) and 9,11,15-trideoxy (CL) derivatives of 7-oxa-PG are antagonists of the action of PGE_1 and $PGF_{1\alpha}$ on smooth muscle.[119] These examples demonstrate the effect on activity of the number of hydroxyl groups and their configuration at C(15). The inhibitory activity is reduced as the degree of hydroxylation of the compound increases.

The 7-thia-$PGF_{1\alpha}$ analogue (CLI) shows 10% activity of $PGF_{1\alpha}$ in the extent of binding to the corpus luteum receptor and stimulates adenylate cyclase while its 9β-, 11β-, 8β- and 12α-isomers with unnatural chirality display only 1% of the activity of the analogue with the natural configuration.[120] The 9,11,15-trideoxy-7-thia derivative (CLII) is an inhibitor of contractions and an inhibitor of adenylate cyclase. The values of I_{50} of 15 μM for (CLII) and 5 μM for (CLI) in the inhibition of placenta PG-15-dehydrogenase show that these compounds also regulate the concentration of the natural PG *in vivo*.[120] The relatively little studied group of 9- and

11-oxa-PG analogues which showed 0.05–0.005 of the activity of PGE_2 [121,122] and the 11-thia analogues[123] must be regarded as promising biologically active heteroanalogues.

The 10-oxaseco analogue (CLIII) shows high efficiency (approximately equal to the activity of PGE_2 and 30% of that of PGE_1) in the inhibition of gastric juice secretion.[68] The same activity was displayed by the 10,12-diaza analogues of PGE.[124] The 16-phenoxy-PGs proved to be good therapeutic preparations for the treatment of various lesions of the gastro-intestinal tract.[125,126] In preliminary tests the 7,13-dithia analogues of groups E, F and D displayed antiulcer activity without side effects.[49]

A luteotropic effect among the heteroanalogues of PG was detected only for the 5- and 16-oxa analogues[127,128] although compounds more potent and selective than PGF_2 were discovered amongst them.

As already mentioned, an inflammatory effect is characteristic of the natural PGs. At the same time certain heteroanalogues display clearly marked anti-inflammatory activity. Thus the 12-aza analogue of PGE (CLIV) is similar in activity to hydrocortisone.[129] The 9,11-dithia analogue (CLV) [36] is nine times more potent than aspirin and is a potential nonsteroidal anti-inflammatory agent. This compound is an inhibitor of PG-synthetase on which apparently the anti-inflammatory effect is based. Anti-inflammatory activity is also possessed by the 9,11-dioxa analogues.[36] A series of heteroanalogues of endoperoxides has been patented as anti-inflammatory agents.[130]

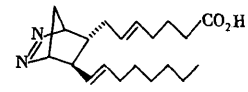
2. The induction and inhibition of platelet aggregation by heteroanalogues of endoperoxides, prostacyclins and PGE

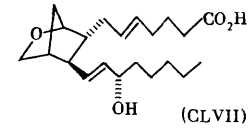
After discovering the fact that the endoperoxides have a significantly stronger effect on the respiratory and vascular smooth muscle than PGE_2 and PGF, the attention of investigators was turned to these unstable intermediate products of the biosynthesis of the primary PGs. Interest in this was strengthened when the ability of endoperoxides to induce rapid and irreversible aggregation of platelets (an action uncharacteristic of the primary PGs) was discovered[131] and it was established that the endoperoxides are metabolised to prostacyclin (PGI_2) and thromboxane A_2 (TxA_2) which are opposite to one another in their action. Prostacyclin is an inhibitor of platelet aggregation and relaxes smooth muscle. Thromboxane A_2, like PGH_2 and PGG_2, is produced in the process of platelet aggregation, but is far more active in inducing aggregation and as an inhibitor of PGE_1-stimulated c-AMP. The extreme instability of these three intermediate prostaglandins, their high potency and reputed role in the biological action of PGs caused the interest in the synthesis of more stable analogues, including heteroanalogues, which might serve as models for studying the mechanism of PG action.

The 9,11-diaza analogues of the endoperoxide (CLVI), like PGG_2, cause a rapid and irreversible platelet aggregation at concentrations of $10^{-5}-10^{-6}$ M. They are almost eight times more potent than PGG_2, seven times more potent than PGH_2, are metabolically more stable and are also 1500 times more potent than PGE_2 in contracting smooth muscle.[132]

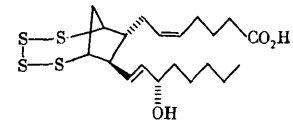
The epoxymethano analogue (CLVII) is an efficient broncho-constricting agent, it is 3–7 times more potent than PGG_2, but less potent in platelet aggregation.[133,134] The 9,11-dithia-PGH_2 analogue (XCIIb) [71,72] is very potent in contraction of the aorta (24 × PGH_2 and 5000 × PGE_2) and is an inducer of platelet aggregation. The endotetrasulphide PHG_2 analogue (CLVIII) causes platelet aggregation in spite of the presence in the structure of the bulky S-containing group which however does not hinder the binding with the endoperoxide receptor.[3] On the other hand the heteroanalogues of PGH_2 without a 15-hydroxy grouping (XCVI), (C) and (CLIX) display inhibitory activity in relation to thromboxane A_2 synthetase and are antagonists of platelet aggregation induced by PGH_2 or by arachidonic acid.[74,135,136] Endoperoxides of such structure have been patented as anti-inflammatory and antithrombotic agents.[137] The epoxymethano (CLX) and the carba analogues of PGH_2 with a heteroatom at position 14 proved to be inhibitors of platelet aggregation.[138]



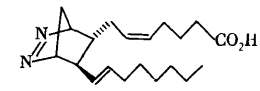
(CLVI)



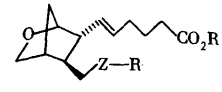
(CLVII)



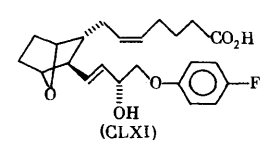
(CLVIII)



(CLIX)



(CLX) Z = O, NH



(CLXI)

The oxabicyclo[2.2.1]heptane prostanoids with natural α- and ω-chains are known as potential analogues of thromboxanes. Their analogue (CLXI), containing a 16-fluorophenoxy fragment in the

ω-chain, has high TxA_2-like activity and at a concentration of 4×10^{-11} M is 100 times more potent than the standard agonist, viz. 9,11-epoxymethano-PGH_2.[139] The 12β-isomer is the most active among the isomers with the natural configuration. In the absence of a hydroxyl function from the ω-chain these prostanoids display the opposite activity. Thus the alkyl thioethers of 7-oxabicyclo-[2.2.1]heptane (CLXII) are antagonists of the thromboxane receptor.[53] They possess inhibitory activity towards TxA_2 synthetase and are 30–40 times more potent than ethanol in inhibiting platelet aggregation. The amidocarbamates, amides and diamides of 7-oxabicycloheptanes have also been patented as inhibitors of platelet aggregation.[140] The recently synthesised sulphonamido derivatives of bicycloheptane prostanoids (CLXIII) are also antagonists of the thromboxane receptor.[57,60]

The diametrically opposite biological action of PGI_2 to the action of TxA_2 and the endoperoxides PGH_2 and PGG_2 in platelet aggregation forms a basis to affirm that the balance between the activities of these two groups of arachidonic acid metabolites determines thrombosis and haemostasis. However, in spite of the large number of studies on the biochemistry and physiology of PGI_2 there is still no definite theory on the mechanism of its action. It was shown that like PGE prostacyclin increases the concentration of c-AMP in blood.[141,142] The increase in the c-AMP level, as proposed, must inhibit hydrolysis of arachidonic acid phospholipid ester and thereby moderate the release of arachidonic acid and its metabolism to endoperoxide.

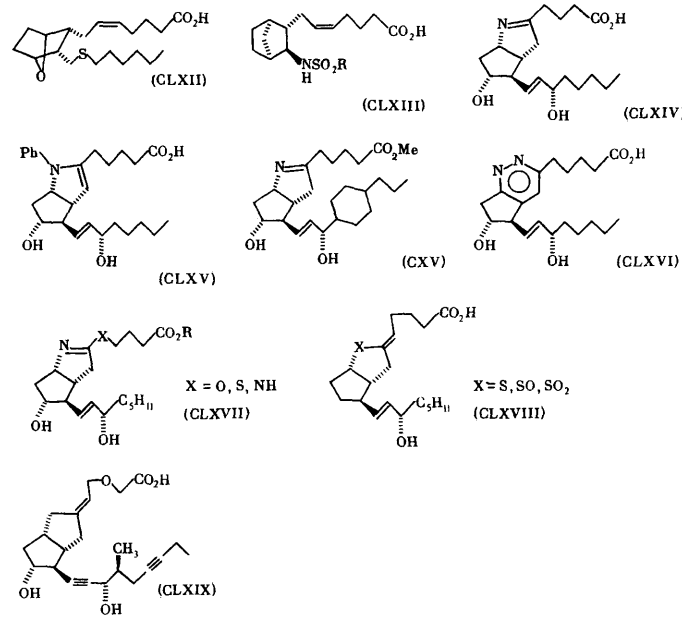
The synthesis of stable analogues of prostacyclin is an urgent problem. Since the instability of PGI_2 is linked primarily with the presence of the enol ether fragment and the carboxyl function near to it, the synthesis of analogues of PGI in which the oxygen of the ring was replaced by nitrogen or sulphur has been effected.

The prostacyclin analogues (CLXIV) and (CLXV) are equivalent to PGI_2 in activity although compound (CLXIV) in contrast to PGI_2 inhibits the synthesis of leucotrienes.[102,143,144] The promise of the recently synthesised azaheteroprostacyclin OP-2507 (CXV) as an anticerebral ischaemic agent is linked with the antithromboxane activity displayed by it.[100] The 6-aza analogues of PGI obtained recently display weak activity.[108] It is considered that among the stable analogues of prostacyclin the greatest activity is possessed by analogues with a sp^2-hybridised atom at C(6), for example compounds (CLXVI)–(CLXVIII).[101] Furthermore the stereochemistry of the upper chain at the Δ^5-double bond affects the activity. The most active proved to be the configuration with a *trans* orientation of the heteroatom and the hydrogen atom at C(5).[93,94,145]

Further modification of the enol ether fragment was effected by the synthesis of 4-keto-9-deoxy-9-aza-PGI analogues.[110]

The potency of these compounds as inhibitors of ADP-induced platelet aggregation was less than a quarter of that of PGE_1 and was 0.01 of the potency of PGI_2. The similarity of the ^1H NMR parameters of this group of compounds and of prostacyclin indicates significant conformational similarity but seemingly, due to the rigidity of the vinyl amide system, the carboxyl group is prevented from reaching the binding centre of the PGI_2 receptor.

The thia analogues are less potent than PGI_2 and the aza-analogues[71,131,132] in platelet aggregation and in contrast to PGI_2 possess vasocontracting activity. It was noted that the inhibitory activity was reduced from the 6,9-thia analogues to the 6,9-sulpho analogues.[93,94]



The most promising among the prostacyclins proved to be its carba analogue, iloprost, consequently synthetic efforts are directed to the further modification of iloprost. In the prostacyclin series, as for PGE, it was discovered that the introduction of a heteroatom into position 3 increases the metabolic stability of a compound[78–80,146,147] since in this case the first metabolic process is blocked, viz. the oxidation in the β-position relative to the carboxyl group.[79] The potency of compounds is reduced at the same time but this is compensated successfully by modification of the lower chain, particularly by introducing alkyl fragments into the ω-chain. The stable and five times more potent 3-oxaprostacyclin (CLXIX) was thus obtained.[78]

In addition to the prostacyclins, 8-aza-11-desoxy-PGE_1,[148] 10-aza analogues,[37] 12-aza-PGE analogues[129] and 9,11-diaza analogues[29] display inhibitory activity in platelet aggregation. The 3-oxa-4,5,6-trinor-3,7-*m*-phenylene analogue of PGE_1 is 30 times more active than PGE in inhibiting platelet aggregation. Anti-aggregatory activity is possessed by azacyclic analogues of the primary PG derivatives, viz. pyrazolidine- and piperazinediones,[18] hydantoin and imidazole derivatives.[28–30]

The reduction in the activity of isomers having an unnatural configuration at the chiral centres 8 and 15 is explained[18,30,116] by the important role of the configuration of the α-chain and the 15-hydroxyl group in anti-aggregatory activity. It must be affirmed that anti-aggregatory activity is observed for the analogues of primary PG identical in configuration to the natural PGs.

13-Azaprostanoic acid (13-APA) possesses unique anti-aggregatory activity and at a concentration of 10^{-5} M is a specific inhibitor of platelet aggregation induced by arachidonic acid, PGH_2 and its epoxymethane analogue.[42,149]

At the same time 13-APA does not inhibit aggregation induced by ADP or thrombin. In a detailed experimental investigation of this unique specificity of 13-APA it was established that 13-APA does not inhibit aggregation by the production of c-AMP, as is assumed for prostacyclin and PGE_1, which in contrast to it are not so

selective in the inhibition of platelet aggregation. Furthermore it was established experimentally that 13-APA is not an antagonist of the action of PGI_2 and PGE_1, since they, although not stimulating adenyl cyclase, do not interfere with the production of c-AMP. In the arachidonic cascade (the metabolic pathway for AA) three places have been proposed at which inhibition of platelet aggregation by 13-APA may occur. There are 1) inhibition of cyclo-oxygenase (PG-synthetase) which transforms AA into the endoperoxide. This action is similar to the action of the non-steroidal anti-inflammatory agents aspirin and indomethacin. 2) Inhibition of thromboxane synthetase and the consequent blocking of the transformation of PGH_2 to TxA_2 like the action of imidazole and the aza analogues of endoperoxide (XCVI), (C) and (CLIX).[74,135,136] 3) Direct inhibition of the thromboxane–endoperoxide receptor. It was established experimentally that 13-APA does not inhibit either the synthesis of endoperoxide or the synthesis of thromboxane but possibly selectively blocks the reaction of TxA_2 and PGH_2 with the platelet receptor. This hypothesis is confirmed by the structural similarity of 13-APA with the unstable PGs, which are active in aggregation, and the sensitivity of the inhibiting activity to molecular and stereochemical modification.[149] When analysing the data on the antiprostaglandin activity and the inhibitory capabilities of the heteroprostanoids it is possible to separate certain structural elements responsible for the development of these properties. Thus the absence of a 15-hydroxyl function is necessary[150] for the development of antagonistic activity or, when discussing isomers, an unnatural configuration for the 15-hydroxyl function.[118–120] The inhibitory action of a compound is also seemingly linked to a significant degree with the absence of a 15-hydroxyl group i.e. anti-inflammatory action,[36,137] inhibition of biosynthesis,[71,74,135,136,150] inhibition of the effect of the natural PGs [29,119] and the inhibition of platelet aggregation.[28,149,150] It has already been mentioned that inhibitory activity is reduced with an increase in the extent of hydroxylation of a compound.[119] From the fairly few examples available it may be suggested that the replacement of the 9,11-carbon atoms by a heteroatom or blocking the free hydroxyl functions in these positions in combination with the absence of a 15-hydroxyl group, will give a compound with anti-inflammatory or other antagonistic activity.[36,74,135,137]

When explaining the appearance of PG-like activity or the activities of PGH_2 and PGI_2 considerable importance is attached to the conformity of the stereochemical configuration of a modified PG to the configuration of the natural PGs.[30,116,118] This applies to any modification of the PG molecule including modification by a heteroatom. To increase metabolic stability it is expedient to modify that part of the molecule which is subject to change in the metabolic process. Seemingly a decisive role in all cases is played by retaining a qualitative similarity between an analogue and the natural PG which itself will be closest to the PG receptor of a cell.

After preparation of the manuscript for publication several publications have appeared on the theme of the review.[152–170]

Supercritical fluid chromatography

M S Vigdergauz, A L Lobachev, I V Lobacheva, I A Platonov

ABSTRACT. The characteristic features of supercritical fluid chromatography (SCFC) are examined and there is a brief historical note concerning the development of the method. Information concerning the use of supercritical fluid chromatography in the analysis of objects of different nature is presented in the form of a table. The roles of the mobile and stationary phases in the separation process and the characteristic features of the apparatus and of the use of the method in physicochemical research are discussed.

The bibliography includes 364 references.

I. Introduction

In the classification of chromatographic methods in terms of the state of aggregation of the mobile phase (MP) employed, one speaks of gas and liquid chromatography. Supercritical fluid chromatography (SCFC) occupies an intermediate position since a supercritical fluid differs in its properties from those of both a liquid and a gas.

Depending on the nature of the eluent and the conditions under which it operates, one can distinguish the following versions of chromatographic separation:[1] gas chromatography proper (the eluent consists of the usual gases at pressures close to atmospheric); barochromatography (the mobile phase consists of the usual gases at elevated pressures); vapour chromatography (using vapours of volatile liquids); supercritical fluid chromatography (the pressure and temperature of the mobile phase exceed somewhat the critical parameters); density chromatography (the pressure amounts to hundreds and thousands of atmospheres).

The transition to fluid chromatography can be achieved also by transforming the liquid eluent by means of the appropriate changes in temperature and pressure. The distinctive features of the SCFC method are determined mainly by the state of the mobile phase. The following may be included among them:

(1) Specificity of the apparatus (possibility of using individual units comprising liquid and gas chromatographs).

(2) The use of additional devices ensuring the transition of the fluid to the liquid state (employing detectors traditional for liquid chromatography) or gas state (employing gas-chromatographic detectors).

(3) The high solvent power of the fluid which limits the number of suitable stationary phases (SP).

(4) The sharp alteration of the properties of the mobile phase in the vicinity of the critical points, which makes it difficult to obtain stable results for small changes in the separation parameters.

(5) The need to attain effective hermetic seals in all parts of the chromatograph and in the connections.

Examination of the driving and inhibiting factors as well as of the elementary step underlying the separation show that in supercritical fluid chromatography the more detailed classification used in gas and liquid chromatography is also possible.[2]

In all cases (gas and liquid chromatography and SCFC) the driving factor is the stream of mobile phase and the inhibiting factor is physical sorption.

Like gas and liquid chromatography, SCFC can be divided into fluid-adsorption and fluid-liquid chromatography.†

II. Historical note

The first study using a mobile phase in the supercritical state was carried out in 1962.[3] Freons (150–170 °C, pressure up to 136 kg cm^{-1}) were used as the mobile phases. Porphyrins, which are not susceptible to gas-chromatographic analysis because of their thermal instability, were eluted under supercritical conditions. Later the range of eluents employed was expanded, making it possible to analyse polynuclear aromatic hydrocarbons with boiling points up to 600 °C.[4] However, the method was not widely used for many years. a sharp increase in interest in SCFC occurred in the 1980's–1990's. Thus, since 1985 about 400 studies have been published, including two monographs[5,6] and about 20 reviews[7–26]. A number of communications were devoted to the use of the method for the analysis of biologically important organic compounds,[27] its advantages and disadvantages,[28] and also its role in analytical chemistry.[22,28–31] Numerous communications[27,32–127] about the method were delivered at the St. Petersburg Conferences starting in 1985. The first symposium on SCFC was held in 1987.[128]

III. The mobile phase

Substances which are thermally stable above the critical temperature, which undergo no changes on contact with the stationary phase (the latter has a large surface area and can exhibit a

† As in other versions of partition chromatography, in fluid-liquid chromatography adsorption by the solid carrier may make a significant contribution to the separation.

catalytic activity), and which have suitable critical parameters (pressure and temperature) can be used as mobile phases in SCFC. There exists a fairly large list of substances which can be employed as eluents in fluid chromatography.[129] However, in practice only a few of them are commonly used (Table 1). Eluents whose transition to the critical state requires a high temperature or pressure (water with P_{cr} = 226.8 kg cm^{-2} and T_{cr} = 374.4 °C; benzene with P_{cr} = 43.8 kg cm^{-2} and T_{cr} = 288.9 °C) are hardly employed in practice. Many hydrocarbons, for example pentane, isomerise or undergo other reactions when adsorbents with a large surace area are used as the stationary phase[1] (changes occur also in the sorbates), which affect significantly the separation characteristics. Being in the supercritical state, the mobile phase acquires a high solvent power and the diffusion coefficients of the substances dissolved in it are also high under these conditions. This makes it possible to treat the fluid as a mobile phase combining the advantages of the solvent in liquid chromatography with those of the carrier gas in gas chromatography. The main requirements which must be met by the mobile phase in SCFC, as in gas and liquid chromatography, are inertness towards the substances analysed, the stationary phase, and the material of the column and the connections and also compatibility with the detector. The most widely used mobile phase is CO_2 (Table 2). Ethane,[211] butane,[145,176] n-pentane,[25,26,138,176,182,187,203,245] nitrogen oxides,[26,184,189,202,205,215,237,290] fluorine derivatives of sulphur,[186,215,241307,320] hydrocarbons,[126,193] and the intert gases[185,267] are more rarely used. The preferential employment of the non-polar CO_2 as the mobile phase can be accounted for both by the low values of its critical parameters (31.3 °C, 72.9 atm), which makes it possible to carry out the analysis at the usual temperatures, and by the possibility of controlling its selectivity by introducing modifying agents of different nature using a number of procedures:[309,311] methanol,[148,170,179,182] isopropyl alcohol,[156,159,163,170,182] chloromethanes,[159] nitromethane,[163] dioxane,[187] etc. Another advantage of CO_2 as the mobile phase is also the possibility of using virtually all the classical types of detector in conjunction with it (the ionisation-flame detector, the UV detector, mass spectrometers, IR spectrometers, etc.—Table 2). The absence of such advantages in other mobile phases is evidently one of the reasons for their limited application. The difficulties arising in the analysis of polar compounds, which are not fully removed even when modifying agents are employed, must be included among the disadvantages of CO_2. The possibility of obtaining inverted micelles in supercritical fluids such as ethane and propane has been investigated.[311–314] The core of the micelle is capable of being solvated by water, which gives rise to the possibility of the solubilisation in it of polar compounds and their subsequent effective separation during partition between the water-solvated micelles and the non-polar stationary phase. Polar compounds (such as a neutral azo-dye and a protein—cytochrome *c*), which do not dissolve in the pure fluid and in the water-saturated fluid, can dissolve in such a mobile phase. The maximum separation in CSFC is attained with programmed temperature and pressure. It is to be expected that the properties of the mobile phase can vary appreciably over a wide temperature and pressure range and the behaviour of the fluid resembles the behaviour of the mobile phase in liquid or gas chromatography. At the critical pressure and temperature, the mobile phase passes from one state of aggregation to another, which is accompanied by a sharp alteration in the nature of the separation. Fig. 1 presents the dependences of the logarithms of the relative retentions of naphthalene and anthracene on the reciprocal of the absolute temperature using hexane as the mobile phase.[315] It is seen that, on attainment of critical conditions, there is a sharp jump in the relative retention, indicating a change in the state of aggregation of the mobile phase. Thus, contrary to the traditional ideas about the passive role of the mobile phase in the gas-chromatographic process, one may claim that the change in the state of aggregation of the mobile phase alters also the selectivity of the separation. The posibility of controlling the selectivity by altering the state of aggregation of the mobile phase was also noted previously. Solid—liquid, mesomorphous, etc. transitions were achieved in this connection.

Table 1. Properties of certain mobile phases used in supercritical fluid chromatography.[129]

Compound	T_b, °C	T_{cr}, °C	P_{cr}, kg × cm^{-2}	ρ^*, g cm^{-3}
Carbon dioxide	—78.5	31.3	72.9	0.448
Nitrous oxide	—89.0	36.5	71.4	0.457
Ethane	103.6	9.9	50.5	0.227
Butane	—0.5	152.0	37.5	0.228
Pentane	36.3	196.6	33.3	0.232
Methanol	64.7	240.5	78.9	0.272
Isopropyl alcohol	82.5	235.3	47.0	0.279
SF_6	—	45.6	37.1	0.750

*ρ = density of supercritical fluid.

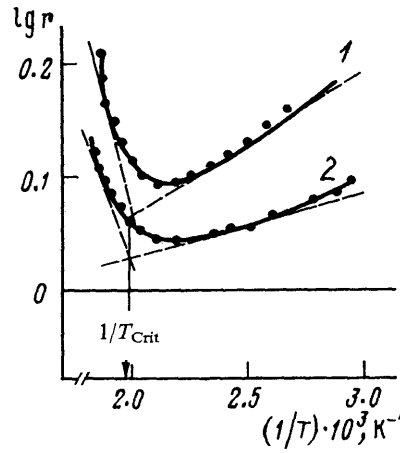

Figure 1. Dependence of the logarithms of the relative retentions of naphthalene (curve *1*) and anthracene (curve *2*) (with benzene as the standard) on the reciprocal of the absolute temperature (average pressure in the column 10 kg cm^{-2}, mobile phase—hexane, 15 × 0.4 cm stainless steel column filled with Silasorb 600).[315]

IV. The stationary phase

Packed columns are used in the fluid-adsorption version and both packed and capillary columns are used in the fluid-liquid version. In the case of capillary columns, cross-linked polysiloxanes are most

often employed as the stationary phase (Table 2): diphenylsiloxane, methylphenylsiloxane, methylsiloxane,[131,153] OC-17,[133,137] OV-225,[137] polysiloxane with grafted *N*-naphthylaminoacid ester,[155] etc. Azo-t-butane[131] or other compounds of a similar type are used as cross-linking agents. Adequate attention has been devoted to problems of the synthesis of stationary liquids for SCFC satisfying the requirements of the virtually complete insolubility in the fluid and thermal stability. Such liquids are cyanoethylphenylvinylmethylpolysiloxane,[316] oligoepoxyethane-containing polysiloxane phases,[317] and chiral stationary phases.[149,166,179] Studies on the swelling of the stationary phases, used in the SCFC with capillary columns, in the fluid and the influence of this process on the retention characteristics are of special interest. In particular, the dissolution of a number of individual mobile phases (pentane, CO_2) and binary mobile phases (methanol–pentane, CO_2–2-propanol) in polysiloxane stationary phases with different ratios of the phenyl and methyl components (OV-1, DV-5, SE-54, OV-17, SE-33) has been investigated.[318–321] In all cases, the soluiblity and adsorbability of the mobile phase diminish with increase in pressure. On raising the pressure above a certain value (which is 260 °C for pentane[320]), the influence of the pressure becomes insignificant. The high solvent power of the mobile phase makes more stringent the requirements as regards the technique of the preparation of the capillary columns.[322–324] Thus it has been shown[322] that the stability of the stationary phase film is directly proportional to the viscosity of the solution. In order to improve the quality of the columns, it is recommended that volatile solvents be employed, raising the temperature of the column during the deposition of the liquid. It is also proposed that a modifying agent can be used to maintain the required viscosity. However, stringent requirements must also be met by such a modifying agent. In experiments with packed columns in the fluid-adsorption version, stationary phases based on silicon dioxide are generally employed: silica gel,[126,180,182,184–186,196,237,255] LiChrosorb Si,[175,183] LiChrosorb Si60,[26,187,197,217,263] LiChrosorb Si 100,[214,224,245,252] PSG porous glass beads,[226] and PRP-I polymeric sorbent.[125] Alumina is hardly used,[295] evidently because of its high catalytic activity under the conditions of the existence of the fluid. In experiments with packed columns, preference is given to grafted sorbents. In this case the sorbents consist of various silica gels with grafted NH_2,[125,173,180,193,233] C_{18},[64,125,175,218] CN,[125,196] and chiral groups,[194,198] as well as others used traditionally in liquid chromatography.

Table 2. Conditions in the separation of mixtures in a stream of supercritical fluid.

System analysed	Mobile phase	Stationary phase, column, detector	Refs
Chlorine-containing compounds, pesticides, n-alkanes, polybutadiene (M = 500), triacylglycerides	Pentane, CO_2	Quartz columns more than 15 m long and with an internal diameter less than 100 μm coated with polymethylphenyl-siloxane ethers (5 or 50% of phenyl)	[Ref. 25]
Polyaromatic hydrocarbons, PS-800 polystyrene	1,4-Dioxane, pentane, C_2H_6, CO_2, N_2O	25 cm × 4.6 mm columns with LiChrosorb Si60; UV detector	[Ref. 26]
Mixture of N,N'-dimethyl aniline, *N*-methylaniline aniline, quinoline, 1,2,3,4-tetrahydroquinoline		IRFT	[Ref. 121]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column, detector	Refs
Lipids	CO_2	IRFT	[Ref. 122]
Fluorocarbon grease	CO_2	9.4 m × 30 μm columns with a 0.20 μm layer of DV-1; FID	[Ref. 123]
Various organic substances	Fluid with 1–2% Ar	Chromatographic separation with subsequent condensation on a cooled (12 K) gold-plated cylinder; the component (argon) matrix formed is analysed on an IR spectrometer	[Ref. 124]
Altemaria toxins in produce (grain, fruit, vegetables)	CO_2 + methanol, CO_2 + isopropyl alcohol	Packed columns filled with SG containing grafted C_1, C_8, C_{18}, NH_2, CN, and other groups; UV detector	[Ref. 125]
Ferrocene derivatives, mixtures of metal acetylacetonates	CO_2 and Freon 23 modified with methanol	Packed columns filled with SG, SG containing grafted C_{18} and phenyl groups or PRP-1 polymeric sorbent; UV detector	[Ref. 126]
Polyphenyls: *o*-, *m*-, and *p*-terphenyls, *o*, *o'*-quaterphenyl, *m*, *m'*-quaterphenyl	CO_2	19.5 m × 100 μm quartz columns coated with a 0.4 μm layer of DV-5 (5% phenylmethylsiloxane); IRFT	[Ref. 130]
Napthalene, phenanthrene, pyrene, and benzopyrene	CO_2	5 m × 25(50) μm quartz columns coated with a 0.15 μm layer of cross-linked SE-54; IRFT	[Ref. 131]
Involatile and thermally unstable compounds	CO_2	MS	[Ref. 132]
n-Alkanes, alcohols	CO_2	20 m × 50 μm quartz columns coated with a 0.25 μm layer of OV-17 SP; FID	[Ref. 133]
Lipids, wax, siloxane oligomers, urine extracts	CO_2	10 m × 50(100) μm quartz columns coated with a 0.2 μm layer of DV-1701 (lipids, urine extracts) or a 0.2 μm layer of DV-5(wax); 20 m × 100 μm quartz columns with a 0.4 μm layer of DV-5 (oligomers)	[Ref. 134]
Triglycerol esters	CO_2	10 m × 50 μm quartz columns with a 0.1 μm layer of methyl-phenyl siloxane 50% phenyl) and a 0.2 μm layer of methyl siloxane	[Ref. 135]
Carbamates and acid pesticides, mixtures of alkanes, triacylcylcerides, oils	CO_2	Quartz columns 2–5 m long with an internal diameter less than 75 μm coated by a 0.15 μm layer of cross-linked SE-54	[Ref. 136]
Triglycerides (T_{36}, T_{48}, T_{42}, T_{54})	CO_2	10 m × 100 μm quartz columns (in a steel tube with a 0.2 μm layer of SE-54, RSL-300, OV-225, and poly(ethylene glycol); FID	[Ref. 137]
Azoaniline and anthraquinone dyes	Pentane	20 m × 50 μm quartz columns with a 0.25 μm layer of cross-linked SE-54; UV detector	[Ref. 138]
Labile carboxylic acids, prostaglandins	CO_2	12 m × 50 μm quartz columns with a 0,25 μm layer of cyanopropylpolysiloxane (and 15 m × 50 μm columns); FID	[Ref. 139]
Glycerol tetraesters	CO_2	10 m × 75 μm columns with a 0.25 μm layer of cross-linked methylphenylpolysiloxane; FID	[Ref. 140]
Medicinal preparations (steroids, therapeutic antibiotics, cannabinoids)	CO_2	13–18 m × 50 μm columns with cross-linked SE-33; FID	[Ref. 141]
Polyaromatic nitrocompounds (polar fraction of diesel extracts)	CO_2	15 m × 50 μm columns with a 0.25 μm layer of cross-linked n-octylpolysiloxane and biphenylpolysiloxane; nitrogen-selective detector	[Ref. 142]
Mono, di, and triglycerides	CO_2	5 and 19 m × 100 μm columns with a 0,25 μm layer of dimethyldiphenylpolysiloxane and cyanopropylmethyldiphenylpolysiloxane: FID	[Ref. 143] [Ref. 144]
Napthalene, phenanthrene, chrysene, picene	Butane, CO_2	Quartz columns of different lengths and with different diameters with a 0.5 μm layer of cross-linked methylsiloxane; fluorescent detector	[Ref. 145]
Isomers of antioxidants, caffeine, sodium arachidonate, testosterone, cholesterol	CO_2	3 m × 0.1 mm columns with a 0.4 μm layer DV-5; redox-chemiluminescent detector	[Ref. 146]
Components of wax, metabolites of triazine pesticides, high-molecular-weight polyaromatic compounds, abietic acid	CO_2	10 m × 50 μm columns with a 0.5 μm layer of SB-phenyl-5; MS	[Ref. 147]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column, detector	Refs
49 compounds used in agro-chemistry	CO_2 modified with methanol	20 m × 100 μm columns with SE-33 and SB-cyanopropyl-25; UV detector	[Ref. 148]
N-pentafluoro-propionylisopropyl esters and the D- and L-isomers of methionine	CO_2	20 m × 200 μm columns with a 0.15 μm layer of polysiloxane cotaining 7% of a chiral amide; FID	[Ref. 149]
Extract of acid herbicides, mixture of volatile and involatile components	CO_2	19.5 m × 100 μm columns with a 0.4 μm layer of DV-5; FID	[Ref. 150]
Oligo- and poly-saccharides (18 glucose fragments)	CO_2	10 m × 65 μm columns with a 0.2 μm layer of DV-1; FID	[Ref. 151]
Squalane (lipid standard), 1,3-distearin, 1,2-dipalmito-stearin	CO_2	10 m × 75 μm columns with cross-linked methylphenylpoly-siloxane (50% of phenyl); FID and MS	[Ref. 152]
Pyrrolizidine alkaloids	CO_2	10 m × 50 μm columns with SB-biphenyl-30; MS	[Ref. 153]
C_{10}, C_{24}, and C_{36} normal hydrocarbons, crude petroleum, napthalene, hydrogenated triglycerides	CO_2	16.5 m × 50 μm columns with a 0.25 μm layer of SE-54 deactivated by polymethyl-hydrosiloxane	[Ref. 154]
Norephedrine derivatives, amino acids	CO_2	10 m × 50 μm columns with *N*-napthyl--amino acid ester grafted on polymethyl--siloxane; FID	[Ref. 155]
Mixture of hydrocarbons, caffeine, polyethylene-propylene	CO_2	10 m × 50 μm columns with a 0.25 μm layer of SB-biphenyl-30; extraction with supercritical fluid; FID	[Ref. 156]
Mixture of glycerides, mixture of hydrocarbons	CO_2 with $HCOOH + H_2O$	10 m × 50 μm columns with a 0.2 μm layer of polysiloxanes; FID	[Ref. 157]
Pesticides and metabolites, dimpylatodiisocyanato-toluene, Triton X-100, tetrahydrocannabinol	CO_2	15 m × 50 μm columns with a 0.25 μm layer of SB-methyl-100; FID; thermionic detector	[Ref. 158]
Phenanthrene, chrysene, picene, coronene, naphthalene and their derivatives	CO_2, CO_2 + + 2-propanol, $CO_2 + CH_2Cl_2$	10 m × 50 μm columns with a 0.25 μm layer of 100% methylpolysiloxane; UV detector	[Ref. 159]
Coal tar, polymeric additives	CO_2	Columns with methylpolysiloxane (10 m × 50 μm) and SG containing grafted C_{18} groups (25 × 4.6 mm); FID	[Ref. 160]
Pyrethrin	CO_2	IR spectrometer	[Ref. 161]
Caffeine, cocaine, codeine, sulphonamides, pesticide carbamates	CO_2	Columns of different lengths with an internal diameter of 50 μm; MS	[Ref. 162]
Coal tar extract, pyrene, ovalene	CO_2 CO_2 + + 2-propanol, CH_3NO_2	10 m × 50 μm columns with a 0.25 μm layer of 100% cross-linked methylpoly-siloxane; UV detector	[Ref. 163]
Surfactants, polyglycols (M = 1200), dimethyl-polysiloxane	CO_2	3–20 m × 50 μm columns with SB-bi--phenyl-30 and SB-methyl-100; FID	[Ref. 164]
Wax, crude petroleum	CO_2	20 m × 100 μm columns with a 0.1 μm layer of cross-linked VR-1; FID	[Ref. 165]
Isopropyl esters of 3,5-dinitrobenzamides	CO_2	5–10 m × 50 μm columns with a cross-linked polymeric chiral SB; FID	[Ref. 166]
Sulphur-containing poly cyclic compounds	CO_2, CO_2 + + N_2O	10 m × 50 μm columns with a cross-linked SE-30; plasma detector	[Ref. 167] [Ref. 168]
Explosive (traces)	CO_2	6.8 m × 0.05 mm columns with a 0.25 μm layer of super-cross-linked SB-octyl-50; thermoenergetic detection	[Ref. 169]
Polycyclic aromatic hydrocarbons and their nitro-derivatives	CO_2, CO_2 + + methanol	25 cm × 1.3 mm columns with Spher C_{18}; UV detector	[Ref. 170]
Poly(ethylene oxide), Triton X-305, polycaprolactone diol, epoxy-polymers	CO_2, CO_2 + + methanol, CH_3CN	25 cm × 4.6 mm columns, polystyrene SP, PRP-1, and LiChrosorb Si 100; UV detector	[Ref. 171]
Mixture of polyaromatic hydrocarbons	CO_2, CO_2 + + 7 modifying agents	20 cm × 4.6 mm columns with SG containing grafted diol groups; 15 cm × × 4.5 mm columns with SG containing grafted octyl groups; UV	[Ref. 172]
Polyaromatic hydrocarbons extracted from coal tar	CO_2	Series-connected packed columns filled with silica gel containing grafted amino-groups and octadecyl groups	[Ref. 173]
Coffee extract from roasted coffee grains, coffee grain powder	CO_2	Extraction with supercritical fluid followed by separation; UV detector	[Ref. 174]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column detector	Refs
Mixture of polyaromatic hydrocarbons, mixture of phenol derivatives, mixture of unsaturated mono-aromatic hydrocarbons	CO_2, CO_2 + + polar modi-fying agents	15–25 cm × 4.6 columns filled with SG containing grafted C_{18} groups and LiChrosorb Si 60; UV detector	[Ref. 175]
Polyaromatic hydrocarbons	Propane, butane pentane, iso--butane	UV detector	[Ref. 176]
High-boiling residues from North Sea petroleums	CO_2	25 cm × 1.3 columns with CP-Spher Si; 30 cm × 2.1 mm columns with Spher-5 containing grafted cyano-groups; 25 cm × 1.3 mm columns with SG impregnated with 1% $AgNO_3$ solution; FID	[Ref. 177] [Ref. 178]
Phosphine oxide enantiomers	CO_2, CO_2 + + alcohols, CO_2 + alcohol mixtures	10 cm × 4.6 mm steel columns filled with the chiral Pirkle phase (LiChrosorb with grafted NH_2 groups); UV detector	[Ref. 179]
Unpurified urine extract, medicinal drugs, multi-component mixtures of polar and non-polar substances	CO_2	20 cm × 2.1 mm columns filled with SG or Spherosorb containing amino- and nitrile groups; MS	[Ref. 180]
Sucrose polyethers in a mixture with aliphatic acids	CO_2	10 m × 65 μm columns with a 0.20 μm layer of DV-1; FID	[Ref. 181]
Aromatic hydrocarbons	CO_2, CO_2 + + methanol	Packed columns filled with SG, Develosil ODS, and a chiral SP; UV detector	[Ref. 182]
Mixture of xanthines, carbamates, sulphon-amides, steroids, and ergot alkaloids	CO_2, CO_2 + + methanol or methoxyethanol	10 cm × 4.6 mm columns filled with LiChrosorb or Spherosorb containing grafed NH_2 groups; MS	[Ref. 183]
Group analysis of petroleum	NO, CO_2	3 columns with Spheri-5-cyano-MPLC, SG CP-Spher, SG impregnated with $AgNO_3$; FID	[Ref. 184]
Polyaromatic hydrocarbons in extracts of aerosol particles in diesel engine exhaust gases	CO_2	Extraction with supercritical fluid followed by separation on 15 cm × 4.6 mm columns with Develosil ODS-5; UV detector	[Ref. 127]
2-Methyl-1, 4-naptho--quinone, acenapthene--quinone phenan-threnequinone	CO_2 + methanol	25 cm × 1 mm columns filled with SG; IRFT	[Ref. 185]
Group analysis of petrols and petroleum products (up to 350 °C)	SF_6 CO_2	25 cm × 1 mm columns with SG; FID 25 cm × 4.6 mm columns with SG and SG impregnated with $AgNO_3$; FID	[Ref. 186] [Ref. 178]
Oligostyrene PS 800 (M = 810), mixture of napthalene, anthracene, pyrene, and chrysene	Pentane, 1,4-dioxane	25cm × 4.6 mm columns with LiChrosorb Si 60; UV detector	[Ref. 187]
Polyaromatic hydrocarbons from diesel fuel exhaust gases	CO_2, CO_2 + + methanol	Extraction with supercritical fluid followed by gas-chromatographic analysis	[Ref. 188]
Aromatic aldehydes and ketones, polyaromatic hydrocarbons, epoxy-acrylate oligomers	Xenon	17 m × 150 μm columns coated by cross-linked SE-54; IRFT	[Ref. 189, 190, 191]
Mixtures of petroleum and coal origin	CO_2	Semi-preparative SCFC, columns with an internal diameter of 30–70 μm filled with SG containing grafted NH_2 groups; UV detector, FID	[Ref. 192]
Mixture of aniline and its derivatives, mixture of phenols, ethers, and alcohol	CO_2, CO_2 + + methanol, Freon-23	25 cm × 4.6 mm columns filled with SG containing grafted NH_2 and phenyl groups; UV detectors, IRFT	[Ref. 193]
Racemic mixtures of t-butyl esters of *N*-acetylamino-acids	CO_2, CO_2 + + methanol, methyl ether	25 cm × 4 mm columns filled with a chiral sorbent (*N*-formyl-L-valylaminopropyl grafted to SG); UV detector	[Ref. 194]
Polydimethylsiloxane, acenapthenequinone	CO_2	19.5 m–100 μm columns with a 0.4 μm layer of DV-5; IRFT	[Ref. 195]
Polyaromatic hydrocarbons, aromatic amines, alkyl-benzenes, chlorobenzenes, dialkyl phthalates, azo-compounds	CO_2 + modifying agents	Packed columns filled with SG and SG containing grafted diol and CN groups; FID	[Ref. 196]
Oligostyrenes PS 8000	CO_2 + 1,4--dioxane	25 cm × 4.6 mm columns with LiChrosorb Si 60	[Ref. 197]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column, detector	Refs
Optical isomers of α-aminoacid derivatives	CO_2, methanol	20 cm × 4 mm columns with a chiral SP (SG with grafted *N*-formylvaline); UV detector	[Ref. 198]
Sulphur-containing heterocyles in vacuum cracking residues	CO_2	Extraction with supercritical fluid followed by gas -chromatographic analysis	[Ref. 199]
Liquid crystal mixtures	CO_2	Packed columns with SG containing grafted C_{18} groups; UV detector	[Ref. 200]
8 esters	CO_2	12.5 cm × 5 mm columns filled with Spherisorb ODS-2; UV detector	[Ref. 201]
Polyaromatic hydrocarbons in ash, dust, and river bottom deposits	N_2O, CO_2, N_2O + methanol	Extraction with supercritical fluid followed by gas-chromatographic determination	[Ref. 202]
Polystyrene oligomers	Pentane	1 m × 260 μm columns with Develosil ODS; UV detector	[Ref. 203]
Polyaromatic hydrocarbons	CO_2	22 cm × 4.6 mm columns filled with SG containing grafted C_{18} groups and 15 cm × 4.6 mm columns with Develosil ODS-5	[Ref. 204]
Polyaromatic hydrocarbons, nicotine, and related compounds in cigarette ash, etc.	CO_2 or N_2O	Extraction with supercritical fluid followed by gas-chromatographic determination	[Ref. 205]
Polyaromatic hydrocarbons	CO_2, CO_2 + + modifying agent	25 cm × 4.6 mm columns filled with LiChrosorb Si 100; UV detector	[Ref. 206]
Anthraquinone in paper and wood	CO_2	Extraction with supercritical fluid followed by HPLC analysis	[Ref. 207]
Styrene oligomers A500 and A1000, components of OU-17 Nonidet P-40 detergent	methanol, diethyl ether	Columns with Develosil-100-5 and Develosil ODS-5; UV detector	[Ref. 208]
Racemic amides and phosphine oxides	CO_2, CO_2 + CH_3OH, C_2H_5OH	25 cm × 4.6 mm columns (SP with grafted β-cyclodextrin); 25 cm × 4.6 mm columns with Pirkle covalent phase [(*R*)-*N*-3, 5-dinitro-benzoylphenylglycine]; UV detector	[Ref. 209]
Ferrocenes	CO_2	25 cm × 1 mm columns with Shimpak Diol-150; detector—emission spectrometer with atomisation in a plasma	[Ref. 210]
Polystyrene standard (M = 1574)	CO_2, ethane	UV detection	[Ref. 211]
n-Alkanes, alkyl aryl ketones, terpenes, polyaromatic hydrocarbons	CO_2	20 cm × 3 mm columns with Spherisorb ODS-2; FID	[Ref. 212]
Polyaromatic hydrocarbons	CO_2	Extraction with supercritical fluid followed by gas-chromatographic analysis	[Ref. 213]
Polyaromatic hydrocarbons	alkanes, CO_2	25 cm × 4.6 mm columns with LiChrosorb Si 100	[Ref. 214]
Aerosols in a stream of eluent	CO_2, N_2O, pentane, benzene, SF_6	Detection by laser light scattering method	[Ref. 215]
Mixtures of docosane and pyrene, triacylglycerides, fructose and sucrose, opium alkaloids	CO_2, CO_2 + polar modifying agents	10 – 20 cm × 4.6 mm columns filled with Sorbax BP Sil, Micropak MCH, Spherisorb containing grafted NH_2 groups, SG containing grafted C_{18} groups	[Ref. 216]
Polyaromatic hydrocarbons, petroleum products	CO_2	15 – 50 cm × 1 mm columns (Sorbax BP Sil); 15 cm × 4.6 mm columns (LiChrosorb Si 60); 15 cm × 4.6 mm columns (Spherisorb ODS-2); 15 cm × 4.6 mm columns (SG XOA 800); FID	[Ref. 217]
Phthalates, styrene oligomers, polyaromatic hydrocarbons	CO_2	10 cm × 0.3 mm columns filled with Develosil ODS-3K and ODS-5K; UV detector	[Ref. 218]
Binary mobile phases	CO_2 with organic modifying agents	20 cm × 4.6 mm columns filed with Sg containing diol groups; UV detector and detection in the visible region of the spectrum	[Ref. 219]
Complex organic compounds on various adsorbents; resins, foil, dust, Spherocarb, etc.	CO_2, isobutane, methanol and binary MP	Extraction with supercritical fluid	[Ref. 220]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column, detector	Refs
Baldenon (a steriod preparation), medicinal drugs with a COOH group	CO_2	10 m × 5 μm and 5 m × 25 μm columns with grafted SB-methyl and SB-octyl phases; MS	[Ref. 221]
Napthalene, fluorene, phenanthrene, pyrene	CO_2	25 cm × 4.6 mm columns filled with grafted Spherisorb ODS-2 carrier	[Ref. 222]
Polyaromatic hydrocarbons	CO_2	Packed columns having an internal diameter of 4.6 mm with SG and SG containing grafted C_{18}, diol, diphenyl[biphenyl], and napthyl-ethyl groups; UV detector	[Ref. 223]
Polystyrene standards, mixture of aromatic hydrocarbons	Pentane, dioxane	25 cm × 4.5 mm columns filled with LiChrosorb Si 100; UV detector	[Ref. 224]
Thermolabile herbicides from sandy, loamy soils	CO_2, CO_2 + + methanol	Extraction with supercritical fluid	[Ref. 225]
Styrene and methylphenylsiloxane oligomers	Methanol, diethyl ether	Packed columns with PSG-10 porous glass beads (d = 11.5 μm, pore size 178 Å)	[Ref. 226]
Benzyl chloride	CO_2	15 cm × 4 mm columns with Silasorb 600 Silasorb containing grafted C_{18} groups	[Ref. 227]
Solid samples	CO_2	Extraction with supercritical fluid	[Ref. 228]
"Maoming" oil shale		Extraction with supercritical fluid	[Ref. 229]
Polyethylene PE-70	CO_2	10 cm × 1 mm and 20 cm × 1 mm columns SG containing grafted poly--siloxane	[Ref. 230]
Steroids, benzodiazepines opiates	CO_2	16 m × 100 μm SCFC columns with SPB-1; 30 m × 250 μm gas-liquid chromatographic columns with DV-5; detection based on ionic mobilities	[Ref. 231]
Sulphonoamide preparations and antibiotics	CO_2, CO_2 + isopropyl alcohol	10 cm × 1 mm columns with cyanodeltabond; 15 cm × 1 mm columns with Spherisorb 5ODS2; 7 m column with SB-cyanopropyl-25, SB-methyl-100, and SB-biphenyl-30	[Ref. 232]
Amines, Azaarenes	CO_2	25 cm × 4.6 mm and 25 cm × 1 mm columns with grafted amino-groups and nitrile groups; FID, IRFT	[Ref. 233]
Enantiomers of 3-thienylcyclohexylglycollic acid	CO_2, CO_2 + + methanol	25 cm × 4.6 mm columns with Cyclobond CSP and chiral OB gel; UV detector	[Ref. 234]
Phenmedipham, aldicarb	CO_2	10 m × 100 μm columns with SB-methyl-100; IRFT, FID	[Ref. 235]
Alkaloids from the leaves of *Catharanthus roesus*	CO_2 + methanol	10 cm × 4.5 mm columns with Spherisorb; UV detector, MS	[Ref. 236]
Ketoacids from urine	NO	10 m × 50 μm columns with cross-linked SE-30; thermionic detector	[Ref. 237]
Siloxane liquids, fats	CO_2	10 m × 50 μm columns with a 0.2 μm layer of DV-5 and 25 m × 100μm columns with a 0.2 μm layer of SE-24; FID	[Ref. 238]
Herbicides, pharmaceutical preparations	CO_2	6 m × 50 μm columns with a 0.25 μm layer biphenylyl-siloxane; MS	[Ref. 239, 240]
Group analysis of petrols and middle distillates of fuel	SF_6 + CO_2	25 cm × 1 mm columns with SG; 25 cm × × 2.1 mm columns with $AgNO_3$-treated Nucleosil SA; FID	[Ref. 241]
Hydroxyethylated alcohols	CO_2	Columns 5 m long containing methylpolysiloxane; FID	[Ref. 242]
Polystyrene oligomers, pyridine, phenol	CO_2	Packed columns with SG of diferent porosity (70 – 1100 Å) containing grafted C_{18} groups (2 – 17%); UV detector	[Ref. 243]
Solid samples containing organic compounds		Extraction with supercritical fluid followed by gas-chromatographic analysis	[Ref. 244]
Napthalene, anthracene, pyrene, chrysene	Pentane	24 cm × 4.6 mm columns with LiChrosorb Si 100; UV detector	[Ref. 245]
Group separation of petroleum components	CO_2	8 – 10 and 15 m × 200 μm columns with a 0.15 μm layer of liquid crystal poly--siloxane	[Ref. 246]
Enantiomers of 1,2-aminoalcohols	CO_2 + ASCCI	10 × 30 cm × 4.6 mm columns with CS, GN phase; UV detector	[Ref. 247]
Mixtures of polymers, aldicarb and its metabolites, mixtures of monomers, dimers, and trimers of diisocyanatotoluene	CO_2	15 m × 50 μm columns with SB-biphenyl--30; 12 m × 50 μm columns with 50% cyanopropyl-siloxane; 20 m × 50 μm columns with SE-63;FID	[Ref. 248]
Analysis of traces of organic substances	CO_2	Capillary columns with poly-siloxane SP; all types of detectors	[Ref. 249]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column, detector	Refs
Group and individual analysis of petrols	CO_2	SCFC and gas chromatography, 25 cm × 4.6 mm columns with SG; 25 cm × 4.6 mm columns with SG impregnated with $AgNO_3$; 10 cm × × 4.6 mm columns with cation-exhange SG; 25 cm × 4.6 mm columns with SG containing grafted amino-groups; FID	[Ref. 250]
Palladium β-diketonates	CO_2 + methanol	Series-connected 5 cm × 4.6 mm and 30 cm × 4.6 mm columns with LiChrosorb Si 60 and a 25 cm × 4.6 mm column with SG containing grafted C_{18} groups; UV detector	[Ref. 251]
Caprolactonediol and methyl methacrylate oligomers	$CO_2 + CH_3CN$	25 cm × 4.6 mm columns with LiChrosorb Si 100; UV detector	[Ref. 252]
Polyaromatic hydrocarbons in marine deposits	CO_2	25 cm × 1 mm columns with Spherisorb-5; FID photoionisation detector, MS	[Ref. 253]
Oil from lemon peel	CO_2	Extraction with supercritical fluid; MS	[Ref. 254]
8 organophosphorus pesticides	CO_2, CO_2 + + 2-propanol	10 cm × 1 mm columns with SG and SG containing grafted amino-groups and C_{18} groups;MS	[Ref. 255]
Chemical additives to polymers (21 compounds)	CO_2	15 m × 100 μm columns with a 0.5 μm layer of phenylmethylpolysiloxane; FID, IRFT	[Ref. 256]
Components of the smell of natural produce	CO_2	Extraction with supercritical fluid followed by gas-chromatographic analysis	[Ref. 257]
Free aliphatic acids	$CO_2 + H_2O$	10 cm × 1 mm column filled with 7 different SP; FID	[Ref. 258]
Oligosaccharides	CO_2	10 m × 50 μm columns with a 0.2 μm layer of DV-5; MS	[Ref. 259]
Essential oils, petroleum products	CO_2	Extraction with supercritical fluid	[Ref. 260]
Herbicides based on sulphonylurea and their metabolites	CO_2 + polar modifying agents	Extraction with supercritical fluid followed by SCFC analysis	[Ref. 261]
Homologous series of alkylarenes and n-alkanes	CO_2, CO_2 + + methanol, CH_3CN	15 cm × 4.6 columns with styrene–di--vinyl-benzene copolymer (PLRP-S); UV detector	[Ref. 262]
Metal carbonyls, highly viscous motor oils, standard aromatic hydrocarbons	CO_2, CO_2 + + methanol, CH_3CN	Extraction with supercritical fluid followed by SCFC analysis	[Ref. 263]
Ecdysteroids, phytoecdysteroids	CO_2 + methanol	2 cm × 4.6 mm columns with SG; UV detector, MS	[Ref. 264, 265]
Basic nitrogen-containing substances	CO_2, CO_2 + + methanol	25 cm × 1 mm columns with Deltabond; FID	[Ref. 266]
Terpenes	Xenon	40 cm × 100 μm columns with Spherosil--XOA-800 SG; UV detector	[Ref. 267]
Methyl palmitate	CO_2, CO_2 + + 1-hexanol	10 m × 100 μm columns with a 0.5 μm layer of SB-methyl-100; IRFT	[Ref. 268]
Aromatic hydrocarbons	CO_2	10, 15, and 25 cm × 2.1 and 4.6 mm columns filled with SG containing grafted C_{18} groups	[Ref. 269]
Poly(methyl-3,3,3-tri--fluoropropyl)siloxane	CO_2, CO_2 + + 2-propanol	MS	[Ref. 270]
Mixtures of nitro-derivatives of diphenylamine and aniline	CO_2	10 cm × 1 mm columns with a sorbent containing cyano-propyl groups, 10 m × 100 μm column with a 0.25 μm layer of SB-cyano-propyl-25; IRFT	[Ref. 271]
Diuron and its metabolites	CO_2 + methanol	15 cm × 4.6 mm columns filled Rosil C_{18}; UV detector	[Ref. 272]
Benzene derivatives (6 compounds)	CO_2, CO_2 + + methanol	30 cm × 4.6 mm columns filled with SG containing grafted C_{18} groups; 17.5 cm × 4.6 mm columns with a polydivinyl--benzene sobent containing C_{18} groups; UV detector	[Ref. 273]
Polychlorinated biphenyls, polyaromatic hydrocarbons, heterocycles, $C_{12}-C_{24}$ alkanes	CO_2	Extraction with supercritical fluid from polyurethane foam followed by chromatograph-linked mass-spectrometric analysis	[Ref. 274]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column, detector	Refs
Pesticides	CO_2	Extraction with supercritical fluid followed by HPLC analysis	[Ref. 275]
Explosives, side products	CO_2	25 cm × 1 mm columns with Deltabond containing cyano-groups: IRFT	[Ref. 276, 277]
8 nitro-derivatives	CO_2	1.5–2.5 cm × 1 mm columns, Deltabond containing grafted cyano-groups	[Ref. 277]
Aminoacids	$CO_2 + CH_3OH$, H_2O, CH_3NH_2	15 cm × 4.6 mm columns filled with SG of the Nucleosil-100 type	[Ref. 278]
Docosanol and palmitic acid	CO_2 + methanol	15 cm × 4.6 mm columns filled with Sorbax ADS and LiChrosrob RP-18; vaporisation light scattering-based detection	[Ref. 279]
Mixtures of steroids	CO_2	10 m × 100 μm column with SB-cyano--propyl-25;IRFT	[Ref. 280]
α-Pinene and its oxidation products	CO_2	Extraction with supercritical fluid followed by SCFC analysis	[Ref. 281]
Oil triacylglycerides	CO_2	5 m × 50 μm columns with a 0.2 μm layer of DV-5; MS	[Ref. 282]
Anthracene, dichlorobi--phenyl sulphone, triazopan,vitamins, steroids	CO_2	Packed 10 cm × 1 mm and capillary 6 m × 50 μm columns; photoionisation detector	[Ref. 283]
Tocopherols from wheatgerm	CO_2 + alcohol	Extraction with supercritical fluid followed by HPLC analysis of fractions	[Ref. 284]
Complex organic compounds	CO_2 + methanol	15 cm × 4.6 mm columns filled with Nucleosil containing grafted C_{18} groups or with Rosil containing aminopropyl groups; MS	[Ref. 285]
Sulphor-containing antioxidants and heterocycles isolated from objects in the environment	CO_2	3.5 m × 100 columns with a 0.4 μm layer of DV-5; chemiluminescence detector of atomic sulphur	[Ref. 286]
Sesquiterpenes	CO_2	25 cm × 4.6 mm columns filled SG of the Nucleosil-100 or Spherisorb type; IRFT	[Ref. 287]
Ethoxyethylated alcohols, inositol triphosphate, peroxides	CO_2	10 m × 50 μm columns with a 0.5 μm layer SB-methyl-100; FID and MS	[Ref. 288]
Phenylthiohydantoin derivatives of aminoacids (24 compounds)	CO_2 + modifying agent	25 m × 4.6 mm columns filled with Sorbax containing grafted cyano-groups; UV detector	[Ref. 289]
Steroids in plasma and urine	N_2O	10 m × 50 μm columns with polymethyl--hydrosiloxane; thermionic detector	[Ref. 290]
Sulphur-containing organic compounds	CO_2	20 m × 100 μm columns with a 0.2 μm layer of DV-1701; flame-photometric detector	[Ref. 291]
Polyaromatic hydrocarbons	CO_2	10 m × 50 μm columns with a 0.5 μm layer of SB-phenyl-5; MS	[Ref. 292]
Trimethoprim, hexoestrol, diethylstilboestrol, dienoestrol, sulphamethazine in pig kidneys	CO_2	Extraction with supercritical fluid followed by SCFC analysis	[Ref. 293]
Biphenylylmethylsiloxane	CO_2	4 m × 0.5 mm columns with SB-phenyl-5; UV or fluorimetric detector	[Ref. 294]
C_{21}, C_{24}, C_{26}, C_{28}, C_{31} n-alkanes, caffeine	CO_2	10 cm × 1 mm columns filled with Al_2O_3 in the alcoholic form and Deltabond containing grafted cyano-groups	[Ref. 295]
Organic components of river or ground water	CO_2	1.8 mm × 0.25 mm columns with Spheri--sorb ODS, 10 m × 50 μm columns with a 0.25 μm layer of cross-linked SE-30, concentration on Sep-PAK C_{18}; UV detector, FID	[Ref. 296]
Organic isocyanates	CO_2	Columns with an internal diameter of 10 μm SP: SB-methyl-100 (0.5 μm), SB-biphenyl-30 (0.25 μm), SB-octyl-50 (0.5 μm)	[Ref. 297]
Napthalene, biphenyl, phenanthrene, n-alkanes	CO_2	10 m × 100 μm columns with BP-1 and 12 m × 100 m columns with BP-10; FID	[Ref. 298]
Aromatic hydrocarbons from furnace and diesel fuel	CO_2	Columns filled with SG; FID	[Ref. 299]
Azaarenes	CO_2 + methanol	SG with grafted amino-groups UV	[Ref. 300]
Polymethylphenylsiloxane oligomers	Alcohol + C_6H_{14}	detector 10 cm × 0.35 mm columns; IRFT	[Ref. 301]
Herbicides and pesticides ($\overline{M}$ = 200–350)		Comparison of the characteristics of the determination by the HPLC and SCFC methods using capillary and packed columns; FID, UV detector , selective detector of nitrogen and phosphorus	[Ref. 302]

Table 2 (continued).

System analysed	Mobile phase	Stationary phase, column, detector	Refs
Aromatic hydrocarbons	CO_2	25 cm × 4.6 mm columns filled with SG containing grafted C_{18} groups; UV detector	[Ref. 303]
Up to C_{90} n-alkanes from Polywax 655, oil, triglycer--ides esters of cholesterol and aliphatic saturated and unsaturated acids	CO_2	5–25 m × 0.2–0.53 mm columns with a 0.1–0.25 μm layer of polymethyl- and polymethylphenyl-siloxanes (comparison with gas-liquid chromatography on capillary columns)	[Ref. 304]
Mixtures of mineral oils, polydimethyl-siloxanes, etc	CO_2	10 m × 0.1 mm capillary columns; FID	[Ref. 305]
Benzoic and isophthalic acids and their methyl esters	11 different MP	Capillary columns with internal diam-eters of 77 and 100 μm with DV-5 and Carbowax; UV detector, IRFT	[Ref. 306]
1-Decanol and its deriva-tives (7 compounds)	SF_6	5 m × 100 μm columns with methylpoly-siloxane; FID	[Ref. 307]
2,3,7,8-Tetrachlorodibenzo-*p*-dioxin from specimens of aqueous deposits	CO_2 + methanol	Extraction with supercritical fluid	[Ref. 308]

Note. SG = silica gel; FID = flame-ionisation detector, MS = mass spectrometer, IRFT = IR spectrometer with Fourier transform, ASCCI = acetonitrile solution of the counterion and the $N(C_2H_5)_3$ $[N(C_2H_5)_3H^+?]$ competing ion, HPLC = high performance liquid chromatography.

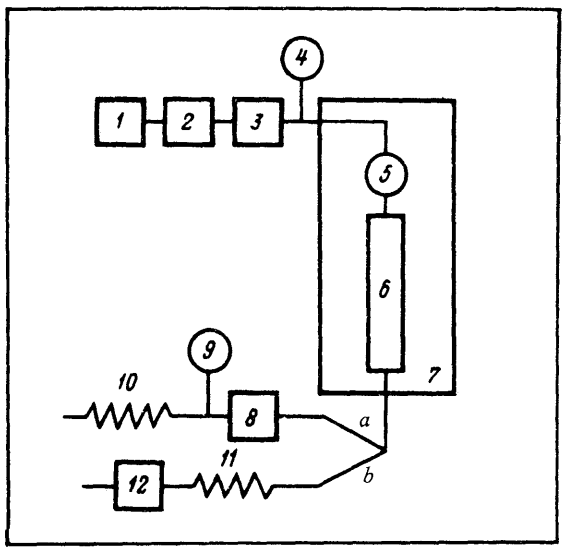

Figure 2. Block diagram of the fluid chromatograph: *1*, cylinder; *2*, pressure reducer; *3*, pump; *4*, manometer; *5*, metering tap; *6*, chromatographic column; *7*, column thermostat; *8*, UV detector; *9*, reference manometer; *10* and *11*, restrictors; *12*, ionisation detector.

V. Apparatus

The formation of the fluid can be regarded as transition from one state of aggregation of the mobile phase to another (from liquid to gaseous and conversely). The separation of various mixture requires the correct combination of individual units comprising liquid or gas chromatographs. Here it is necessary to ensure, on the one hand, a stable high pressure in the system and, on the other, the possibility of detection in the fluid flow. A block scheme of an SCF chromatograph is illustrated in Fig. 2. One may note two principal aspects of the construction of the apparatus: the improvement of the design of the detectors and of the intermediate devices for the connection of the SCF chromatograph to other instruments for physicochemical research and also the development of the restrictor technology and of the technique for the injection of the sample.[325,326] The technique of the injection of the sample in SCFC with capillary columns is approximately the same as in gas chromatography: sample injection with stream splitting, injection with stream splitting and maintenance for a period of time, direct injection, and injection with extraction by the supercritical fluid.[327] In view of the small diameter of the capilliary columns in SFC (50–100 μm compared with 200–500 μm in gas chromatography), the use of automated systems with a programmed sample injection cycle (from 50 μs to 2 s) is promising.[328] The loop-type metering taps with stream splitting generally adopted in high performance liquid chromatography, are widely used.

The high pressure necessary to maintain the mobile phase in the supercritical fluid state hinders the application of detectors traditionally employed in high performance liquid chromatography (HPLC) or gas chromatography. Flame-ionisation detectors (FID) and UV detectors are most often used for detection in SCFC (Table 2). The columns are connected to the detecting systems via a restrictor which is placed before or beyond the detector in order to prevent a sharp change in the pressure in the system. For detection in a stream of liquid, the restrictor is placed beyond the detector (for example, in the case of UV detection). If a FID is used in the chromatograph, the placing of the restrictor beyond the column makes it possible to direct the stream of the mobile phase immediately into the detector. Quartz capillaries (straight capillaries, tapering capillaries,[329] and capillaries coiled into a helix) and partly fused ends of the columns (the so called integral restrictors[134]) can function as restrictors. The study of the effectiveness of capillary restrictors[329–331] showed that the restrictor must be heated, which makes it possible to eliminate the losses of the compounds being analysed and to control the linear flow rate of the mobile phase in the column by programming the temperature. The FID are used in SCFC virtually without any modifications. Certain complications arise when UV detectors are employed because their cell is not always designed for the necessary pressure. A detecting device for SCFC designed for pressures up to 500 kg cm^{-2} has been proposed.[332] Its working cell consists of a section of a capillary with a remote polyimide coating and three optical wave guides perpendicular to its axis. UV beams are directed into the cell through one of them but the other two are used for the simultaneous observation of the fluorescence and the absorption of UV radiation. For the combination of the SCF chromatograph with a mass spectrometer,[333–338] an appropriate interface is essential. Judging from the existing reviews,[334] there is reason to believe that appreciable advances have been made in this field. As in the classical versions of chromatography, in the analysis of sulphur and phosphorus compounds by SCFC a flame-photometric detector is used[339] which makes it possible to detect nanogramme amounts of sulphur and phosphorus. IR spectrometers, as a rule combined with Fourier transformation, play a notable role as detectors.[340–342] Such detectors are most convenient in experiments with CO_2 as the mobile phase. Carbon dioxide is transparent over a wide range,

which permits the determination of many organic compounds. An advantage of the use of CO_2 is also that the sensitivity of the detection can be greatly increased by combining the IR spectrometer with a microcope.[130] The pure sorbate is introduced onto the surface of a ZnSe plate transparent in the IR region (under normal conditions, CO_2 is converted into the gaseous state), after which its IR spectrum is recorded. Plasma detectors,[168,343,344] ion-conducting polymer membranes,[345] ion mobility spectrometers,[346,347] and ^1H NMR spectrometers[348] are less widely used. As in classical gas chromatography, in certain cases double detection is resorted to in order to obtain universal (for example, using a FID) and specific (using a photometric detector) chromatograms.[349] The use of a combination of these detectors is particularly convenient in the analysis of mixtures with a complex composition. Thus the application of equipment traditional for gas and liquid chromatography in SCFC requires only the construction of special units whereby the columns can be connected to the detectors.[344,350]

VI. Qualitative and quantitative analyses

The development of gas chromatography made it possible to achieve considerable advances in the identification of substances: (1) it became possible to compare directly the signal received from the object analysed with the signal from a standard specimen; (2) an identification system based on the determination of the retention indices of the mixture components was developed.

The use of liquid chromatography for qualitative analysis involves problems caused by the difficulty of determining the retention time of the non-sorbed component.

Most of the problems arising in liquid chromatography are retained in the SCFC, occupying an intermediate position, while the achievements of gas chromatography are little used. One of the main disadvantages of SCFC is the difficulty of maintaining reproducible separation conditions, which is associated with the sharp alteration of the properties of the fluid near the critical point. Another disadvantage is caused by the necessity to use adsorbents and sorbents with grafted groups, whose characteristics are not as satisfactorily reproducible as in gas chromatography. Reference specimens are most often employed for the purpose of identification.[150,151,153,157] In the analysis of complex objects of unknown composition, group separation with subsequent individual analysis of the fractions, for example, by gas chromatography with capillary columns[199,213,231] or HPLC,[153,275] is frequently employed. In the latter case, the approaches adpted in HPLC are used in SCFC. Attempts have been made to set up standard retention index scales. In particular, compounds belonging to the homologous series of alkyl aryl ketones (ranging from acetophenone to octaphenone) and normal alkanes (from dodecane to tetracosane) have been used for this purpose.[262] The application of both scales leads to comparable results, but the former must be regarded as more universal because it can be employed when polar modifying agents are added to the mobile phase (for example, CO_2). Modified Kovac indices, calculated from the formula[351]

$$RI = \frac{\lg t'_{R(x)} - \lg t'_{R'(\text{decane})}}{\lg t'_{R'(\text{pentadecane})} - \lg t'_{R(\text{decane})}},$$

where $t'_{R(x)}$ is reduced retention time of the substance analysed, were proposed for estimation of retentions of different kinds.

Smaller difficulties arise in quantitative analysis. The calibrating plot[167,216,230] and internal standard[202] methods are most often used in SCFC for the treatment of the signal. The calculation is based either on the area of the chromatographic peak or on its height.

VII. Extraction by the supercritical fluid

The supercritical fluid has a number of characteristic features as an extractant: (1) its viscosity is virtually identical to that of the gas and its diffusion coefficient is greater and its density is smaller than those of the liquid (this makes the extraction time several times shorter); (2) its solvent power depends greatly on the temperature and pressure, which permits its deliberate alteration.

Such properties of the fluid promote the rapid extraction of a wide range of organic compounds (polyaromatic hydrocarbons, diuron, linuron, caffiene, medicinal drugs, insecticides, herbicides, etc.) from ash, town dust, soil, river and sea bottom deposits, etc.[188,202,205,207,213,220,225,229,244,254,257,260,261,274,275,281,284,308,352]

Table 3 presents certain examples of the use of extraction by a supercritical fluid. As a rule a degree of extraction of 80–95% is attained after only 20–30 min from the start of extraction. The change in pressure and temperature (and hence in the solvent power of the extractant) during the extraction process gives grounds for the assumption that extraction by the supercritical fluid is an additional separation stage during which individual fractions of the substances analysed may be isolated. Thus fractions comprising sulphur-containing heterocycles (with different numbers of rings) have been isolated from the vacuum residues in the catalytic cracking of petroleum,[199] caffeine has been isolated from coffee extract and coffee grains,[174] polyaromatic hydrocarbons have been isolated from town dust,[220] etc. Extraction by the supercritical fluid can be carried out after preliminary concentration of the substance to be analysed on different adsorbents (synthetic resins, polyurethane foil, carbon sorbents, Tenax GT,[188,220,274] and glass wool[275]), which makes it possible to reduce the detection limit. A convenient feature of the use of a supercritical fluid for extraction also consists in the fact that the extract may be analysed not only by SCFC but also by HPLC [174,207,275,284] or gas chromatography.[199,205,213,244,257,281] The gas-chromatographic analysis of the extract as a rule presupposes the cryogenic concentration of the sample at the inlet to the column[205,244,257] or the absorption of the substances present in the sample by an appropriate solvent into which an internal standard has been introduced.[150] The subsequent analysis is performed by the usual gas-chromatographic procedure. In the extraction of mixtures of known composition, the regime permitting the attainment of the maximum extraction and separation can be selected on the basis of preliminary calculations of the solubilities of the substances analysed in the supercritical fluid using the available formulae.[353] The employment of extraction by a supercritical fluid for the automatic preparation of samples for analysis not only by chromatographic but other (for example spectroscopic) methods is likewise promising. Thus extraction by a supercritical fluid can be included in any multistage analytical scheme.

VIII. Physicochemical aspects of the use of supercritical fluid chromatography

The study of the equilibrium in the fluid-sorbent system, which makes it possible to determine the thermodynamic characteristics of the dissolution of a number of substances, is of considerable

interest.[342,353,354] Special versions of fluid chromatographs have been proposed for physicochemical research.[355] They can be used also for analytical purposes. The diffusion coefficients (simple and binary) of compounds such as unsaturated aliphatic acid esters and benzene and its derivatives have been determined in supercritical CO_2 [355,356] and chlorotrifluoromethane and sulphur hexafluoride.[357] The heats of desorption of toluene, phenol, naphthalene, anthracene, and other aromatic hydrocarbons have been determined in the temperature range 307–353 K and at pressures up to 200 kg cm^{-2} using CO_2 as the mobile phase.[358] The heat of desorption increment per C_2H_4 group is $\sim$2.507 kJ mol^{-1}. The effect of density on the enthalpy and entropy of transfer in SCFC has been investigated[359] using CO_2 as the mobile phase and the cross-linked SE-54 and OV-17 stationary phases. The change (decrease) in the enthalpy of transfer of the test substance with increase in the density of the mobile phase (CO_2) has been confirmed for sorbates such as normal alcohols and normal alkanes. The enthalpies found by the authors[359] (−24.7 to −35.2 kJ mol^{-1} for OV-17 and −16.3 to −36.0 kJ mol^{-1} for SE-54) agree with the literature data obtained by liquid chromatography (for high densities) and gas chromatography (for low densities). The intermediate position of SCFC was yet again confirmed. An attempt was made to devise a single theory of adsorption chromatography using homogeneous adsorbents and adsorbents characterised by a discrete distribution on their surface of energetically or structurally different adsorption centres.[264,360–363] The mobile phase can be a gas, a liquid, or a supercritical fluid.

Table 3. Extraction with supercritical fluid.

Object analysed	Isolation and determination conditions, extractant	Refs.
Plastic materials, corn ears, control mixtures of hydrocarbons	CO_2, subsequent analysis—SCFC (10 m × 50 μm columns with a 0.25 μm layer of SB-biphenyl-30)	[Ref. 156]
Coffee extract (roasted grains)	CO_2, subsequent analysis—HPLC (SG and SP) with grafted C_{18} groups, $CH_3OH + H_2O$ as MP	[Ref. 174]
Contaminants in the environment preadsorbed on TENAX GC (SRM 1650 standard and polyaromatic hydrocarbons from diesel fuel up to coronene inclusive)	CO_2 and $CO_2 + CH_3OH$. Direct extraction from adsorbing cartridge (30 min); subsequent analysis—gas chromatography (cryogenic concentration at inlet to 30 m × 320 μm column with a 1 μm layer of DV-5)	[Ref. 188]
Polyaromatic hydrocarbons from ash, town dust, and river bottom deposits	Ethane, CO_2 and N_2O, CO_2 and N_2O with CH_3OH, the extract is collected in a vessel with a solvent containing the internal standard; analysis on 60 m × 250 μm columns with a 0.25 μm layer of DV-5	[Ref. 202]
Anthraquinone from kraft-paper, pine wood fillings	CO_2 (20 min), analysis–HPLC using 15 cm × 3.5 mm columns with Bondapak C_{18}, CH_3CN–pH 6.8 buffer mixture as MP	[Ref. 207]
Polyaromatic hydrocarbons (SRM 1649 standard)	CO_2; possibility of extraction of all the substances from the matrix, quantitative extraction and concentration of traces, selective extraction of individual fractions, and multistage extraction. Analysis—gas chromatography (15 m × 250 μm column with a 0.25 μm layer of SE-54)	[Ref. 213]
Chrysene, benzanthrone, 1-nitro-pyrene, dibenzocarbazole, coronene etc, SRM 1649 standard)	CO_2, isobutane, and $CH_3OH - CO_2$ from adsorbents (KhAD-2, polyurethane foil, Spherocarb); desorption of polar compounds with $CO_2 + CH_3OH$ mixture and desorption of high molecular-weight compounds with isobutane; analysis—gas chromatography (15 m × 250 μm with cross-linked SE-54)	[Ref. 220]
Herbicides from loamy soils	CO_2, $CO_2 + CH_3OH$; analysis—SCFC (capillary columns with SB-cyanopropyl-25 and packed columns with Partisil-5, ODS-3)	[Ref. 225]
Natural products, aromatic hydrocarbons	CO_2; automatic isolation of substance from matrix and sample preparation (Milton Roy SPA system)	[Ref. 228]
"Maoming" oil shale	Supercritical liquid in the presence of H_2O and toluene with subsequent collection of individual fractions (soluble in cyclohexane, toluene, etc)	[Ref. 229]
Polyaromatic hydrocarbons (in impregnated wood, town dust, river deposits), phenols from aerosols in forest fires, nicotine from tobacco, scent components, biological markers	CO_2, N_2O, ethane; subsequent analysis—gas chromatography (30 m × 320 μm columns with a 1 μm layer of DV-5 and 60 m × 250 μm columns with a 0.25 μm layer of DV-5); cryogenic concentration of the sample is carried out at the inlet to the column	[Ref. 244]
Oil from lemon peel	CO_2; extractor—empty 35 mm × 4.6 mm column; analysis—gas chromatography (25 m × 200 μm column with CBP 20)	[Ref. 254]
Components of the smell of natural products	CO_2, extractor (0.1 ml) combined with the gas chromatograph evaporator, after reduction of pressure, the extract is subjected to cryogenic concentration at the inlet to a 30 m × 320 μm column with a 1 μm layer of DV-5	[Ref. 257]
Standard aromatic hydrocarbons (in heptane)	CO_2, $CO_2 + CH_3OH$; extractor connected to a 6-way metering tap in place of metering loop and is provided with autonomous heating; no "memory" effect	[Ref. 263]
Polyaromatic hydrocarbons (from napthalene to perylene), polychlorinated biphenyls	CO_2; sample extracted from filter, extract concentrated to 1 ml and analysed (20 m × 250 μm columns with a 0.25 μm layer of DV-5)	[Ref. 274]
Pesticides from glass wool (5 substances)	CO_2; CO_2 passed through extractor, the eluate being directed to series-connected 18 × 1.5 mm column with RP-18 or 14 × 1.5 mm columns with Si 60 on which the sample is fractionated	[Ref. 275]
Tocopherols from wheat germ	CO_2 + alcohol; extract concentrated on a 50 × 10 mm column with SG from which it is directed to seperation (20 cm × 20 mm column); the collected fractions are analysed by HPLC	[Ref. 284]
2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDBD)	CO_2, NO, and their mixtures with CH_3OH; 100% extraction from bottom TCDBD deposits achieved, gas chromatographic analysis (30 m × 250 μm columns with a 0.17 μm layer of cross-linked SE-54)	[Ref. 308]

Note. SG = silica gel.

The development of the SCFC method confirms the view that chromatographic separation is a single process occurring over a broad spectrum of experimental conditions (with a gas, a supercritical fluid, or a liquid as the mobile phase). The chromatographic separation of any objects can be achieved using the same apparatus. By varying the experimental conditions (pressure and temperature), it is possible to select an effective procedure for the solution of a specific analytical problem.

Vinyl cations

V D Nefedov, E N Sinotova, V P Lebedev
St Petersburg State University

ABSTRACT. Methods of obtaining vinyl cations, which are derivatives of the ethenyl cation $H_2C=C^+H$ and have the high reactivity of intermediate species, are examined. Particular attention is given to the nuclear chemical method of obtaining free vinyl cations. Data on the reaction of vinyl cations (including free cations) with different classes of compounds containing *n*, π, and σ reaction sites have been correlated.

The bibliography includes 138 references.

I. Introduction

Vinyl cations (VCs) are carbocations that form a class of reactive intermediate species whose parent is the ethenyl (or vinyl) cation $H_2C=C^+H$.[1–7]

Vinyl cations are formed in electrophilic addition reactions to alkynes and allenes, and also by heterolysis of the (C=)C–X bond of vinyl compounds.

The electrophilic addition of water to acetylenes and allenes has been known since the 1870's.[5] At first, however, VCs were not regarded as independent species since it was thought that the presence in them of a charge in combination with an unsaturated bond on the central carbon atom made such intermediates extremely unstable. The idea that the reaction occurs via the formation of VCs was apparently first put forward to explain the formation of an alkyl acetate in the hydration of alkoxyacetylenes in an acidic medium.[5a]

The idea that VCs were unstable was based on the extremely low rates of solvolysis of vinyl halides even under conditions that permit the formation of primary alkyl cations. Nevertheless, the first direct evidence for the existence of VCs was actually obtained in the solvolysis of 1-arylvinyl bromides.[8]

The discovery and practical research application of vinyl compounds containing groups that could readily be eliminated—anions of fluoroalkylsulphonic acid, such as triflate (trifluoromethanesulphonate) anion and nonaflate (nonafluorobutanesulphonate) anion—constituted a stage of fundamental importance in the chemistry of VCs. Since the rate of solvolysis of these esters is higher than that of vinyl halides by a factor of 10^6-10^8, it was thus possible to obtain simple alkylvinyl cations and cyclic VCs with small strained rings.[7,9,10]

Recently, after preparing vinyl compounds containing a ferrocene group on the double bond, which has a strong stabilising effect, it was possible to observe directly the formation of VCs by means of ^1H NMR spectroscopy.[11–13]

A number of reviews attesting to the considerable interest in the problem of VCs have appeared.[1–7,14] In these reviews the methods of generating VCs, their stability, rearrangements, and the mechanisms of reactions involving VCs are widely discussed. On the other hand, these studies, which were excellent at the time, no longer reflect the current state of knowledge concerning the chemistry of VCs.

An attempt has been made in the present review to correlate the existing data, including the most recent information about the methods of obtaining VCs (principally photochemical and nuclear chemical methods) and the reactions of VCs, including those occurring in a free state.

II. Methods of generating vinyl cations

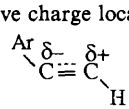
1. Electrophilic addition to alkynes and allenes

a) Alkynes

A study of the mechanism of electrophilic addition to alkynes initiated by Lewis acids showed that initially an ion pair consisting of the anion of the acid and a VC is formed, having a linear or almost linear structure. At the same time the most stable of the possible cations is predominantly formed.[1–7,15–21] The possibility of internal migration in the ion pair and steric separation of the ions predetermine the diversity of products of the alkylation,[16,17] halogenation,[22–24] hydrohalogenation,[1–7] and acylation[25–34] of alkynes.

It was established from a detailed study of the mechanism of hydration of alkynes that the overall rate of this reaction is determined by the rate of the stages involving protonation of the triple bond. This is suggested, in particular, by the substantial kinetic isotope effect that occurs in the hydrolysis of different acetylenic compounds: $k_{H_2O}/k_{D_2O} = 1.7-4.0$.[1–7,35,36]

The results of recent studies of the hydration of substituted alkynes point to the possibility of a considerable acceleration of the addition of a proton to aromatic alkyne molecules under photoexcitation conditions.[37] It is assumed in this case that in its lowest singlet state S_1^* an alkyne molecule acquires a bent structure in which the carbon atoms of the triple bond have an intermediate sp^2-sp character. The bond becomes partially polarised, with the negative charge localised on the β-carbon atom:

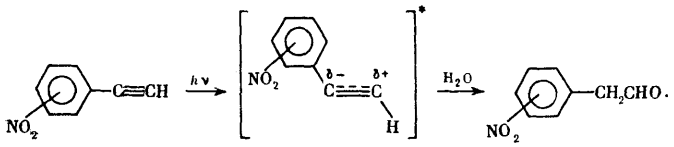


Consequently it is the β-carbon atom that undergoes attack by the proton to form a VC. The activation energy of addition of the proton in this case is much lower than the energy of activation for protonation of alkynes in the ground state. The resulting electronically excited cation rapidly reacts with a water molecule, giving a ketone as the product of photohydration:

$$ArC\equiv CH \xrightarrow{h\nu} [ArC\equiv CH]^{+} \underset{k_{-H}}{\overset{k_H}{\rightleftharpoons}} ArC^{+}=CH_2 \xrightarrow{H_2O} ArCOCH_3 .$$

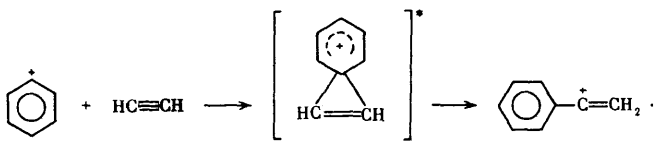
The occurrence of a kinetic isotope effect (k_{H_2O}/k_{D_2O}) indicates that protonation of the acetylene is the rate-limiting stage of photohydration.

In the photohydration of nitrophenylacetylene, an aldehyde rather than a ketone is formed, i.e. protonation does not follow Markownikoff's rule:



This occurs because the nitrophenylacetylene molecule, as a result of the absorption of light (λ = 254 nm), is converted to the T_1 triplet state, in which the distribution of charges on the carbon atoms of the triple bond is the reverse of that in aromatic alkyne molecules in the S_1^* state.[37]

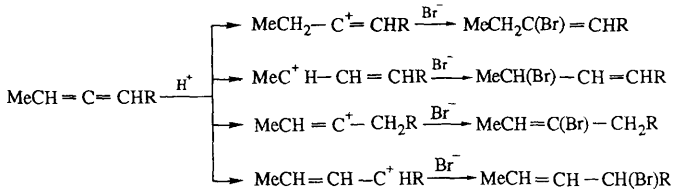
It appears that the alkylation of alkynes in the gas phase also occurs via the formation of VCs. According to the results of Fornarini and Speranza,[38] attack on an acetylene molecule by a free phenyl cation obtained by the nuclear chemical method (see below), yields first an excited bridged phenylvinyl cation, which rapidly isomerises to the more stable 1-phenylvinyl cation:



In a recent study of the kinetics of hydration of acetylene in an acidic medium, results indicating the possible formation of an unsubstituted ethenyl cation in solution were obtained.[39]

b) Allenes

In the addition of electrophilic species to allenes each of the three carbon atoms joined by a cumulated bond can serve as a nucleophilic site. When electrophiles add to the terminal carbon atoms of the cumulated bond, a VC is formed, while attack on the central carbon atoms gives an allylic ion. The direction of attack of electrophiles to allenes is mainly determined by the ability of the substituents to stabilise these ions.[40–44] Thus, in the electrophilic addition of hydrogen bromide to 1,3-dialkylallenes, all possible regioisomers are formed:[45–46]



R= Me, Et, Pr, C_5H_{11}.

In the majority of cases studied the yield of allyl bromides is considerably greater than that of vinyl bromides.

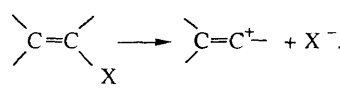
In the photohydration of arylallenes a proton attacks the central atom of the allene group. However, this is due to the presence of a negative charge on the central carbon atom in the allene group of arylallene in an excited state rather than to the effect of the aryl group on the stability.[37]

c) Anchimeric assistance of multiple bonds

Solvolysis of homoallenyl or homopropargyl esters by an S_Ni mechanism is accompanied by the formation of compounds that contain three- or four-membered rings. In the solvolysis of cyclic acetylenic or allenic esters bicyclic compounds are formed.[47–50] According to existing theories,[47–50] as a result of intramolecular attack on a nucleophilic group with a triple or allenic bond by the carbocation centre of the primary cation, cyclic VCs are formed, which participate in the reaction to give the observed cyclic products. In particular, in the solvolysis of homoallenic or homopropargyl esters the formation of a common intermediate, possibly a bicyclobutonium ion, is postulated.[50–52] Stabilisation of cyclic VCs with small rings is achieved through overlap of the vacant orbital of the carbocation centre with the electrons of the C(2)–C(3) σ-bond.[50]

2. Heterolysis of the (C=)C–X bond

Heterolysis of the (C=)C–X bond in vinyl compounds is regarded as an alternative method of obtaining VCs:



This process occurs in the solvolysis of vinyl compounds by an S_Ni mechanism and by the photolysis of vinyl derivatives. Heterolysis of a special type takes place when electron impact and nuclear chemical methods are used.

Reduction of the activation barrier for heterolytic dissociation and formation of intermediate complexes is assisted by those electronic and steric factors that govern the stability of the cations (VCs) and the groups being eliminated. Amongst these are, primarily: different electronegativities of the atoms of the bond to be cleaved; electron-donating effects of the substituents (+*I*, +*C*, anhimeric assistance) that allow delocalisation of the positive charge of the carbocation centre; electron-withdrawing properties of the substituents of the group being eliminated, through which the basicity of X^- is reduced.

The effect of polar properties of the medium which govern the solvation of the ions should be added to those factors already given which assist a reduction in energy of activation of heterolysis of the (C=)C–X bond.

a) Solvolysis of vinyl compounds

As in the case of aliphatic compounds, the rate-limiting stage in S_N1 nucleophilic substitution at an unsaturated carbon atom is cleavage of the (C=)C–X bond.

An increase in stability of the VC and the group being eliminated leads to an increase in the rate of unimolecular substitution in vinyl compounds. The values of log k correlated with the σ^+ constants of the substituents on the double bond in virtually all of the reported cases for this reaction. In terms of its absolute magnitude, the reaction parameter ρ^+ has quite a high negative value, and for arylvinyl derivatives it varies from -6.6 to -2.0 (for aliphatic systems it varies from -7.7 to 0).[53] This phenomenon demonstrates, on the one hand, that a strongly polarised intermediate (vinyl cation) is formed at the intermediate stage of the reaction, and on the other hand, that special stabilisation is required for VCs, which are less stable than their saturated analogues.

Stabilisation of VCs is considerably assisted by groups that have donor properties, including ferrocenyl, aryl, cyclopropyl, vinyl, and allyl. The greatest effect for the stabilisation of VCs occurs when such a group is introduced into an α-position conjugated with the carbocation centre. Quantum-chemical calculations show that an increase in stability of α-arylvinyl cations results from overlap of the HOMO of the π-electron system of the aromatic ring with the vacant 2p orbital of the carbocation centre. In this case a shift in electron density from the ring to the carbocation centre is recorded, which gives rise to positive charges on the carbon atoms at the *ortho* and *para* positions of the aryl group.[54–58]

There has been comparatively little study of ethynylvinyl systems as π-electron systems. An ethynyl group, when it is conjugated with carbocation centre, can destabilise a VC through its electron-withdrawing inductive effect ($-I$ effect). At the same time this group can participate in resonance delocalisation of the positively charged ion, which overall stabilises the cation. According to calculations, ethynyl and methyl groups have comparable stabilising effects.[55] It is assumed that in the 1-ethynylvinyl cation, these effects due to the presence of a triple bond balance each other out. In a study of the solvolysis of ethynylvinyl systems it was established that the response to the question as to whether the electron-withdrawing effect or resonance stabilisation of charge predominates depends on the nature of the substituent on the α-carbon atom of the triple bond.[59–61]

Alkylvinyl halides usually do not undergo an S_N1 type of solvolysis; the solvolysis of brosylates and tosylates takes place very slowly.[1–7] For this reason a study of the effect of alkyl substituents on the rate of reaction has only been possible with the use of the trifluoromethanesulphonate or nonafluorobutanesulphonate ions, which have sufficiently high stability as a result of significant charge delocalisation through the $-I$ effect of the fluorine atoms. The low reactivity of alkylvinyl compounds indicates that stabilisation of VCs by alkyl groups (hyperconjugation effect) is not sufficiently effective. Thus, a study of the effect of alkyl groups at the double bond on the rate of S_N1 solvolysis of alkylvinyl triflates showed that replacement of a methyl group by an ethyl group causes a slight increase in the rate of reaction, which is of a similar magnitude when R = iso-Pr and when R = t-Bu.[62]

Solvolysis of vinyl compounds which are mono- and di-substituted at the β-position but unsubstituted at the α-position, occurs at a low rate and usually gives rearrangement products even when aryl or cyclopropyl groups are used as substituents. At the present time it is thought that the most probable mechanism for solvolysis of compounds of this type is a mechanism involving successive elimination and addition and not involving the formation of a VC.[1–7]

The steric effects of the β-substituents are exhibited most clearly in the solvolysis of α,β-disubstituted vinyl compounds, although it is not always possible to distinguish them from the inductive effect. In a VC the carbocation carbon atom is sp-hybridised and the σ-bonds to it have a linear configuration. In the initial vinyl compound, the carbon atom attached to the substituent and the leaving group (α-atom) is sp^2-hybridised. Hence an increase in the size of the substituent on this atom must give rise to considerable steric repulsion between the substituents on the α- and β-atoms of the vinyl group. This undoubtedly assists the formation of a VC; the rate of solvolysis of the vinyl compound should also increase. In fact, the rate of solvolysis of (*E*)-1-anisyl-2-alkylvinyl bromides increases in the series

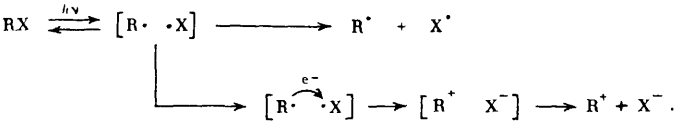
$$H < MeM < p\text{-}MeOC_6H_4 < t\text{-}Bu$$

approximately by a factor of 10^3. At the same time the rate of solvolysis of the (*Z*)-isomers remains virtually unchanged.[63]

As has already been mentioned, one of the factors in the stabilisation of VCs is anchimeric assistance of substituents due to the presence in the initial molecule of a centre of nucleophilicity that is not conjugated with the reaction site. When β-mercapto groups are present in vinyl compounds, acceleration of solvolysis occurs. It may be assumed from the formation of a considerable number of cyclic products (thiophenes) that S_N1 solvolysis of β-arylmercapto-vinyl derivatives takes place as a result of anchimeric assistance from the sulphur atom to form an intermediate thiirenium ion, which has greater stability than a linear VC.[1–7]

b) Photochemical methods for obtaining vinyl cations

The photolysis of vinyl compounds can result in the formation of VCs. According to Kropp and McNeely,[64,65] the formation of VCs is due to electron transfer in the primary radical pair formed on excitation of a vinyl halide molecule:



It is evident that heterolytic cleavage of the bond between the atoms requires a greater consumption of energy than the homolytic cleavage that accompanies the formation of a radical pair. Therefore, ionic products are generally formed with lower yields.[66–68]

A considerable increase in yield of the products of the reactions between photogenerated VCs and nucleophiles can be achieved through oxidation of vinyl radicals by reacting the latter with Cu(II) salts.[69]

Cu(II) salts are capable of almost completely suppressing the formation of products of the photolysis of vinyl halides by a radical mechanism. It is assumed[69] that oxidation with Cu(II) salts is most likely to occur via the formation of an intermediate complex between a vinyl radical and Cu(II), which is supported by the formation of vinyl ethers with a nonrearranged skeleton during photolysis.

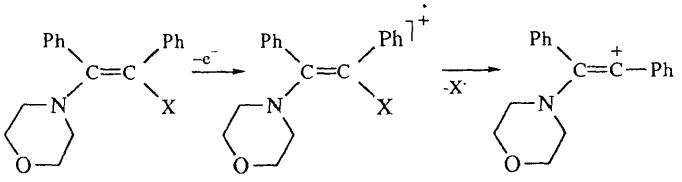
An undoubted advantage of the photochemical method of generating VCs is the possibility of obtaining cations, including primary cations,[65] in a greater variety of nucleophilic media and under milder conditions (absence of strong acids, lower

temperatures) than in the case of solvolysis. However, the reactivity of the cations obtained by this method is higher than that of the cations formed as a result of solvolysis, which may be due to a difference in their energy states. The results of four studies,[14,70–72] according to which the extent of degenerate rearrangements of photogenerated triarylvinyl cations is substantially lower than in species of this type obtained by solvolysis, may be cited as an example. One of the most likely explanations for this phenomenon is that photoexcited VCs evidently have a greater reactivity and the rate of their reaction with nucleophiles is substantially higher than the rate of their isomerisation.

c) Electron impact method

Electron impact, which involves the formation of cations as a result of the fragmentation of the initial vinyl compound on exposure to an electron beam, has found extensive application in research into the thermodynamic properties of simple VCs and in the study of molecular ion reactions.[73–79]

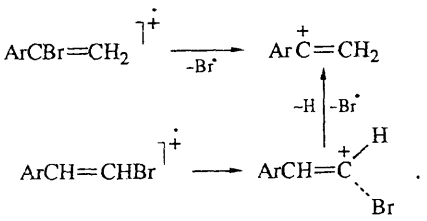
Vinyl cations with a relatively complex structure were obtained by fragmentation of 2-morpholino-*cis*-stilbenyl halide on exposure to a beam of accelerated electrons:[6]



X = Br, Cl.

From a comparison of the relative yields of the VCs in this case it was possible to conclude that atomic chlorine is eliminated with greater difficulty than atomic bromine.

A study of the dissociative ionisation of α- and β-aryl-substituted vinyl bromides showed that monomolecular loss of a Br· radical by the radical cation of the β-bromo derivative is accompanied in the transition state by a rapid 1,2-shift of hydride ion via the double bond to form the more stable secondary 1-arylvinyl cation:[56]



A study of the structures of the species obtained by impact activation with the use of labelled ^{13}C bromine derivatives made it possible to conclude that primary cations are not formed by electron impact.[56]

d) Nuclear chemical method of obtaining vinyl cations

The nuclear chemical method (NCM) occupies a special place amongst those methods used to generate carbocations.[80–83]

On β-decay of a covalently bonded tritium atom that forms part of a hydrocarbon and its conversion to helium, positively charged RHe^+ molecular ions are formed in different energy states and in which the charge is localised on the helium atom. The large difference in ionisation potential between the helium atom and radical R· (approximately 14 eV) causes the positive charge to migrate to the organic fragment. At the same time the neutral helium atom and charged R^+ fragment separate. At the final stage spatial separation of these species occurs, resulting in the formation of free R+ carbocations:

It has been established experimentally that as a result of the β-decay of tritium that is contained in hydrocarbons, singly charged R^+ ions are formed with a yield of the order of 70–80%†, most of which occur in the ground state or in energy levels close to it.[80,81]

During β-decay of tritium there is a marked (twofold) relative change in charge on the nucleus of the daughter He atom—the highest for nuclei undergoing β-decay. However, additional ionisation of the daughter atom as a result of perturbation of the electron shell does not occur, since as a result of the doubling of charge on the nucleus, the electrostatic interaction between the electron and nucleus increases accordingly. This leads to a sharp decrease in yield of species with a charge greater than +1. It should also be stressed that there are no daughter ions having higher charges, because of the impossibility of a cascade of vacancies (the Auger effect) occurring in this case. The latter favourably distinguishes the β-decay of tritium from the decay of radionuclides of other elements such as halogens, whose decay in the form of halogen derivatives of hydrocarbons can also lead to the formation of carbocations.[80,81]

The carbocation nature of the R^+ species obtained by NCM has been demonstrated by numerous experiments, in which their reactions with various nucleophiles were studied (aromatic compounds, ethers and esters, alcohols, etc.).[80–83]

The nature of the processes that occur in molecular systems during β-decay of tritium governs a number of unique features of NCM.

1. During β-decay of tritium that is contained in hydrocarbons, carbocations of a given structure are formed with a strictly determined initial localisation of charge, including that which does not correspond to the most stable state of the ion. The structure of the carbocations is determined by the structure of the initial hydrocarbon and the position in it of the decaying tritium atom

2. The carbocations being generated occur in a free state, i.e. they do not have a counterion or equilibrium solvent cage. The released β-particle (nuclear electron), which provides electrical neutrality to the system as a whole, cannot be regarded as a counterion since it is separated by a distance such that its Coulomb interaction with the carbocation is negligible.

3. With the use of NCM it is possible to obtain carbocations and study their reactions in media of all compositions in the gas, liquid, and solid states. The rate of formation of carbocations in the system is determined by the number of molecules of the tritiated compound (the ion source) and the number of tritium atoms in a molecule of the compound, and it does not depend on external conditions

† The remaining percentage is made up by a large number of ionic and neutral fragments of a different nature. Since the individual contribution of each does not exceed 2–3% and they have a very variable nature, the yields of their reaction products are small.

(temperature, pressure, state of aggregation), since the method is based on radioactive decay processes:

$$dN_{R+}/dt = kq\lambda N_{RT},$$

where dN_{R+}/dt is the rate of formation of carbocations; k is the number of tritium atoms in the molecule (ion source); $q = 0.7-0.8$, a coefficient representing the proportion of effective conversions leading to the formation of a carbocation during tritium decay; λ is the decay constant of tritium, equal to 1.8×10^{-9} s^{-1}; N_{RT} is the number of molecules of the tritiated compound in the system.

4. Reactions in free cation–molecule systems are in best agreement with models used in quantum-chemical calculations of the reaction route (see Section IV).

5. This method presents excellent opportunities for obtaining various reactive species (carbocations, their silicon and germanium analogues, nitronium and nitrenium ions, etc., and halogen ions formed during decay of tritium contained in HHal) in order to study their reactions.

Tritiated hydrocarbons serve as sources of carbocations. In a special case these may be hydrocarbons containing a single tritium atom. However, it is then impossible to monitor the behaviour of cations since the concentration of the reaction products of these ions with given substrates is extremely small. Thus, with an initial activity of the carbocation source of 4×10^7 Bq, about 10^{13} ions are formed over 10–30 days, which corresponds to about 10^{-10} mol of their reaction products. The only method used for determining such small quantities of products is a radiochemical method that is based on the use of hydrocarbons containing at least two tritium atoms as an ion source. The decay of one of these atoms results in the formation of a cation, while the other atom, remaining in the product molecule, can be used for identification of this product chromatographically with detection of its radioactivity‡. We should stress that in contrast to mass spectrometry and ion cyclotron resonance, the radiochemical method can be used to record neutral compounds and, what is very important, distinguish their isomeric forms.

Recently the possibility of using β-decay to obtain reactive species including the case where one radioactive atom forms part of the initial molecule and gives a stable isotope of a neighbouring element, for example, $^{14}CO_2 \xrightarrow{\beta} {}^{14}NO_2^+$, was demonstrated. The yield of products of the reactions that occur with the participation of NO_2^+ can be determined by high-performance liquid chromatographic (HPLC) methods.[84]

NCM was successfully used to generate a number of aliphatic and aromatic C_1-C_{10} carbocations and for studying their reactions with various types of nucleophilic reagents.[80–83,85,86] Subsequently, vinyl[87,88] and ethynyl[89] cations were obtained by the same method. To date the ethenyl cation[88] and 1- and 2-phenylvinyl cations[87] have been obtained. Doubly tritiated ethylene THC=CHT and styrene PhTC=CHT have been used as sources of VCs. β-Decay of tritium in the alkene leads to the formation of free VCs as a result of heterolysis of the C–He bond in the primary molecular ion:

$$RTC{=}CHT \xrightarrow{\beta} R\overset{+}{C}{=}CHT \text{ (or } RTC{=}\overset{+}{C}H)$$

R = H, Ph.

‡ The probability of simultaneous decay of two tritium atoms is negligible, being dependent on the square of the decay constant of tritium.

The ethenyl cation has low thermodynamic stability. Therefore previously it was only possible to detect its formation and reactions through the use of electron impact in the gas phase at low pressures.[77–79] With the application of NCM it was possible to study the reactions of this ion with benzene and methanol in the liquid phase,[88,90] hydrogen and methanol in the gas phase,[91] and with a number of arenes in the gas and liquid phases.[92]

As a result of the nonequivalence of the positions of the tritium atoms in the side chain of the styrene-T_2 molecule, the cations formed through processes initiated by β-decay have different structures and the positive charge on them is localised at different positions. Since decay of each of the tritium atoms is equally probable, the initial number of isomeric 1- and 2-phenylvinyl cations must be the same.

According to quantum-chemical calculations, the heat of formation of 2-$C_8H_7^+$ is higher than that of 1-$C_8H_7^+$.[60,62] Consequently, the 2-$C_8H_7^+$ ion is more reactive. Moreover, its isomerisation to 1-$C_8H_7^+$ by a hydride 1,2-shift is to be expected. The possibility of this isomerisation was examined in the case where generation of 1- and 2-phenylvinyl cations was achieved by dissociative ionisation of the corresponding bromides through electron impact.[56] However, it was shown by MNDO calculations that the isomeric forms of a phenylvinyl cation are separated by a potential barrier of 80 kJ mol^{-1}. As according to theory the vast majority of cations obtained by NCM occur in ground energy states, it is clear that isomerisation of the 2-$C_8H_7^+$ ion to 1-$C_8H_7^+$ must be a difficult process. Hence the difference between the yields of products obtained by reaction of each of the cations with given nucleophilic reagents may be solely dependent on their different reactivities (see Section IV).

III. Reaction of vinyl cations with nucleophilic reagents

According to their definition, VCs constitute a type of carbocation. The carbon atom of the carbocation centre of a VC is formally trivalent and has a vacant orbital§. Therefore VCs, like aliphatic cations, can attack those parts of molecules with increased electron density, namely, atoms with an unshared electron pair (*n*-donors), multiple bonds (π-donors), and σ-bonds. Moreover, VCs can exhibit the properties of Brønsted acids, having the ability to transfer a proton to a specific nucleophile.

1. Reactions of vinyl cations with *n*-donors

The main products of an S_N1 reaction involving the solvolysis of vinyl compounds in oxygen-containing solvents are vinyl ethers and ketones. A number of authors explain the formation of these products by the fact that intermediate oxonium ions are formed during reaction (by analogy with aliphatic ions) as a result of the addition of the VC to the oxygen atom of the solvent. The route of the subsequent decomposition of the oxonium ions depends on the composition of the medium and on steric factors.[94–101]

For the solvolysis of vinyl compounds in alcohols or acids the most typical reaction is formation of vinyl ethers as products of the deprotonation of oxonium ions. The alternative possibility for

§ When considering the structure of the parent cation of this class — the ethenyl cation — nonempirical calculations[93] have shown that it probably possesses a bridged structure, which is estimated to be 12 kJ mol^{-1} more stable than a linear structure.

decomposition of oxonium ions with elimination of R groups and formation of an alcohol (ketone) virtually never occurs. Such selectivity in the course of the reactions of VCs with HOR molecules is evidently due to the impossibility of forming a stable intermediate involving an R group in a nucleophilic medium. This is caused, firstly, by the considerable steric hindrance which arises during the formation of a complex between an eliminated R group and the solvent (or buffer base) compared to similar complexes involving a proton. Secondly, according to the principle of hard and soft acids and bases (HSAB), interaction of the protonised hydrogen atom of an oxonium ion with the oxygen or nitrogen atoms of a nucleophile (solvent, buffer base) is energetically more favourable.

In the solvolysis of 1-anisyl-2-methylpropene-1-yl bromide or tosylate in trifluoroethanol (TFE), the sole product formed is an ether, which is consistent with the idea that an oxonium ion is formed, transferring a proton to a solvent molecule:

$$AnCX{=}CMe_2 \longrightarrow An\overset{+}{C}{=}CMe_2 \xrightarrow{TFE} AnC(OCH_2CF_3){=}CMe_2$$

An–anisil, X = OTs, Br.

The solvolysis of vinyl compounds on treatment with acids sometimes results in the formation of ketones. For example, in the acetolysis of 1-anisyl-2-methylpropen-1-yl bromide in the presence of sodium acetate as a buffer base, a ketone was identified amongst the reaction products:[94,95]

$$AnCBr{=}CMe_2 \longrightarrow An\overset{+}{C}{=}CMe_2 \xrightarrow[-H^+]{HOAc} \longrightarrow AnC(OAc){=}CMe_2 \xrightarrow{HOAc} AnCOCHMe_2.$$

However, it was established that formation of the ketone is not due to decomposition of the oxonium ion through separation of the R group but results from a side reaction in which an initially formed ether is converted to the ketone on treatment with the acid.

In a study of the solvolysis of halogen derivatives of *p*-methoxystyrenes in 80% aqueous ethanol, it was established that when there are no substituents at the β-position, a ketone is the sole product, whereas both a ketone and an ether are formed from the β,β-dimethyl derivative.[95] The authors specially noted the fact that the reaction conditions excluded the possible occurrence of a side reaction involving hydrolysis of the resulting ether and its conversion to a ketone.

The effect of a buffer base on the reactions of VCs was studied by Grob and Nussbaumer.[102] The ratio of the yields of ether to ketone as solvolysis products of the *cis*- and *trans*-isomers of 1-anisyl-propen-1-yl bromide in 80% ethanol increases with an increase in concentration of triethylamine:

$$(E)\text{- or } (Z)\text{-}AnC(Br){=}CHCH_3 \xrightarrow[H_2O]{EtOH} AnCOC_2H_5 + \\ + AnC(OEt){=}CHCH_3. \quad (1)$$

The buffer bases are used to suppress processes competing with the S_N1-type monomolecular nucleophilic substitution which result in the formation of similar products. An $Ad_E{-}E$ process that takes place with an electrophilic addition–elimination mechanism may be examined in this connection. At the first stage protonation of the vinyl compound and formation of a trisubstituted carbocation occur. The ion is then attacked by the nucleophile, resulting in the elimination of HX and the formation of a substitution product. The introduction of a buffer base can suppress the development of an $Ad_E{-}E$ mechanism since the base reacts with the proton.

However, the effect of the buffer bases is evidently more complex, since solvolysis of the vinyl compounds can occur by an electrophilic addition–elimination mechanism even when a buffer is present in the system.[103] It is to be expected that buffer bases not only create favourable conditions for S_N1 solvolysis but are also capable of reacting with the primary products of the reactions between VCs and HOR molecules, namely, oxonium ions. This explains the increase in yield of enol ethers and the decrease in yield of ketone in reaction (1), with an increase in concentration of triethylamine.[103]

The reaction of VCs with anions leads directly to the formation of neutral products. These processes occur most frequently in the electrophilic addition to acetylenes or allenes.

In the electrophilic addition to substituted acetylenes the direction of attack of the anion on the double bond of the VC at the first stage depends to a considerable extent on the size of the substituents at the α- and β-positions of the cation. This occurs because steric strain in the developing vinyl system increases as a result of the relative steric effect of the substituents.[104–107]

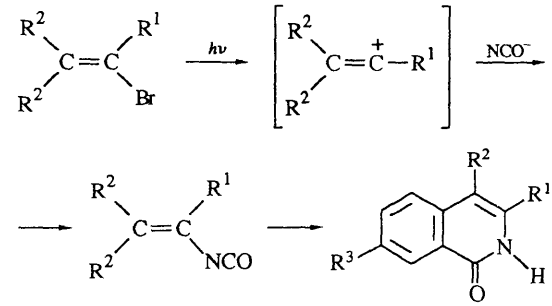
The reaction of VCs with anions during solvolysis has been examined in a number of studies.[6,108,109] In solvolytic systems reactions of VCs may be regarded solely as competing processes for the interaction of cations with the eliminated X^- group and solvent and/or with an added conjugate base $(OR')^-$ and solvent:

$$RX \longrightarrow X^- + R^+ \begin{cases} \xrightarrow{(OR')^-} ROR' \\ \xrightarrow{HOR'} ROR' + H^+. \end{cases}$$

From a study of the effect of additions of a common ion on the rate of solvolysis it was possible to derive a series of reactivity of certain anions that act as *n*-donors towards the 1,2-dianisyl-2-phenylvinyl cation:

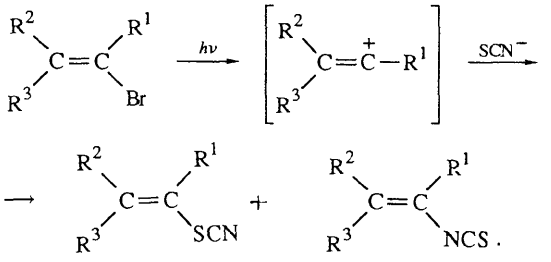
$$Br^- > Cl^- > AcO^- > CH_3SO_2O^- > AcOH.$$

Studies were conducted on the reactions of triarylvinyl cations obtained by photolysis of the corresponding bromides with ambident nucleophiles such as cyanate and thiocyanate anions.[70] The main products of the reaction between the cations and cyanate ion proved to be isoquinolones:



$R^1 = An$; $R^2 = Ph$, *p*-An; $R^3 = H$(when $R^2 = Ph$), OMe(when $R^2 = p$-An).

The reaction with thiocyanate anion occurs by two routes, which is caused by the presence of the two reaction sites on the anion—the sulphur atom and the nitrogen atom:



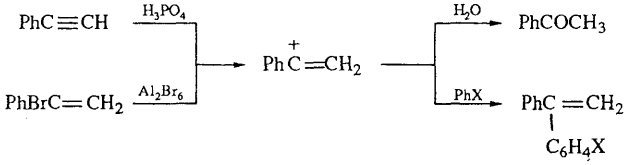
It should be noted that the VC mainly attacks the sulphur atom of the thiocyanate anion. This is due to the fact that the sulphur atom is a softer reaction site than the nitrogen atom and, according to the HSAB principle, attack by a soft reactant such as triarylvinyl cation is energetically more favourable on the sulphur atom.

2. Reactions of vinyl cations with π-electron systems

a) Aromatic compounds

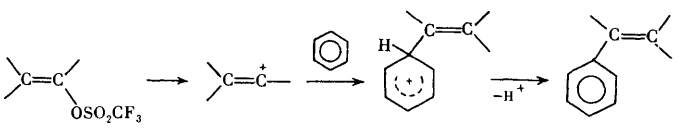
Although they are of undoubted practical interest, the reactions of VCs with π-electron systems have received very little study. This is primarily related to the question of using vinyl and acetylenic compounds as vinylating agents in electrophilic substitution reactions in aromatic systems.

In a study of the reaction between toluene and α-bromostyrene or phenylacetylene in the presence of Al_2Br_6 or H_3PO_4 it was found[110] that products derived from the replacement of a hydrogen atom at the *ortho* and *para* positions of the benzene ring of toluene and also acetophenone are mainly formed in this reaction. Vinylation of anisole with phenylacetylene in H_3PO_4 also results in the formation of the *ortho* and *para* derivatives. These results are consistent with the proposed formation of an intermediate of a 1-phenylvinyl cation:



Trisubstituted vinyl bromides in the presence of silver tetrafluoroborate as a catalyst were used as the vinylating agent in substitution reactions in a series of aromatic compounds, making it possible to obtain vinyl-substituted arenes in high yield.[69]

When alkylsulphonates are used it is possible to carry out the alkylation in the absence of Friedel–Crafts catalysts.[111] Vinyl triflates were very promising in this respect. The results are consistent with the assumption that the reaction takes place by a mechanism whose first stage is elimination of the $CF_3SO_2O^-$ anion from vinyl triflate to give a VC. The subsequent reaction with arene results in the formation of a phenonium ion (σ-complex), which is converted to the substitution product after elimination of a proton:



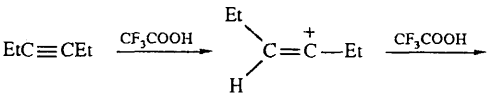
The σ^+ constants of Brown are the most suitable for a determination of the effect of a substituent on the rate of vinylation with vinyl triflates. The value of $\rho = -2.57$ obtained for the reaction parameter indicates that a positive charge develops on the reaction site.

On the other hand, the absence of a kinetic isotope effect in this reaction suggests that vinylation of arenes by vinyl triflates occurs by an electrophilic substitution mechanism. The ratio of the rate constants of reactions involving normal and perdeuterated benzenes ($k_H/k_D = 0.98$) is consistent with the ratios $k_H/k_D = 0.90$ for nitration and $k_H/k_D = 1.13$ for benzylation.

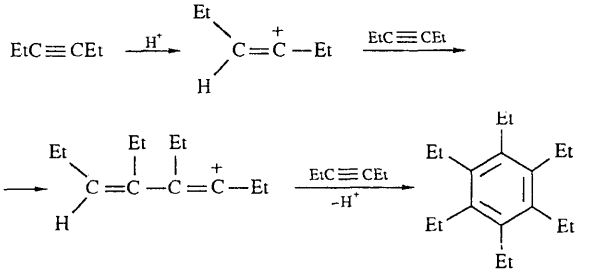
The absolute value of the reaction parameter ρ for alkylation of vinyl triflates is one of the lowest in a series of electrophilic substitution reactions of aromatic compounds.[111] This is due to the high reactivity of the alkylating agent—a vinyl cation—and hence indicates its lack of selectivity towards different monosubstituted arenes containing both electron-donating and electron-withdrawing substituents.

b) Alkenes and alkynes

In the reaction between hex-3-yne and trifluoroacetic acid, isomeric vinyl trifluoroacetates are formed in almost equal quantities and are stable under the reaction conditions:[112]



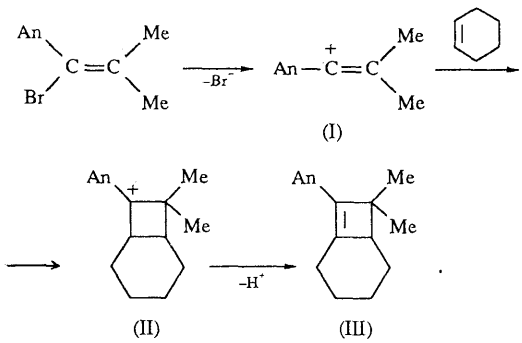
These products are formed as a result of the nonstereospecific addition of trifluoroacetic acid to the linear hexene-3-yl cation. On increasing the concentration of hex-3-yne, hexaethylbenzene is formed. This product most probably occurs as a result of the reaction of the hexen-3-yl cation with an alkyne molecule, which leads to the formation of a homoallylic ion[31–34] and then to trimerisation:



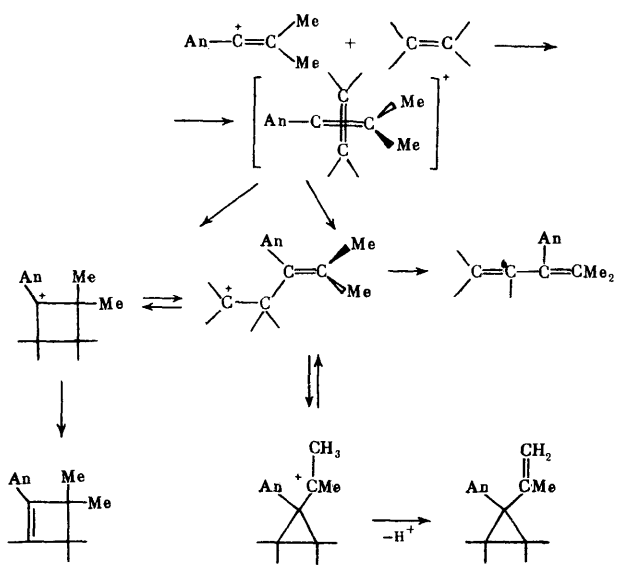
The mechanism of cycloaddition of VCs to olefins was studied in detail by Hanack, et al.[113–117]

On treatment of 1-anisyl-2-methylpropen-1-yl bromide with silver tetrafluoroborate in cyclohexene, compound (III) was obtained in 60% yield. It is evidently formed through the involvement of cation

(II), which occurs as a result of the concerted or stepwise cycloaddition of VC (I) to cyclohexene:



In the reaction between VCs and certain olefins, cyclopropane derivatives were isolated together with cyclobutene derivatives:[116,117]



The formation of cyclobutenes is apparently due to the presence of silver ions in the reaction medium. Silver very readily forms complexes with unsaturated organic compounds and may serve as a catalyst for the process that leads to the formation of cyclobutene derivatives. If VCs are obtained by solvolysis of triflates in the absence of silver ions, cyclopropane derivatives are mainly formed, as a result of [2 + 1] cycloaddition. When silver salts are introduced, the formation of cyclobutenes occurs again. The results obtained suggest that cycloaddition of VCs to olefins occurs by a successive addition mechanism.

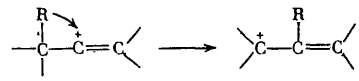
3. Reactions of vinyl cations with the electrons of σ-bonds

Reactions of this type include the conversions of VCs in which the carbocation centre of the cation makes its vacant orbital available to the pair of electrons participating in the formation of a σ-bond between atoms, such as C–H or C–C. There is only a limited number of such reactions, but of these the rearrangement of VCs and the deprotonation of VCs with the formation of acetylenes may be singled out.

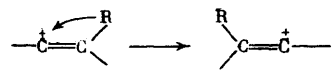
a) Rearrangements of vinyl cations

Rearrangement of VCs takes place as a result of 1,2-shifts of groups of atoms:

1) transfer of groups to a double bond with the formation of allylic cations:



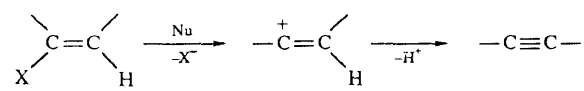
2) displacement of groups between carbon atoms forming a double bond, with the result that one VC is isomerised to another



Comprehensive information on the rearrangements of VCS and essential examples can be obtained from a monograph[4] and two reviews;[6,14] therefore they are not included in this review.

b) Deprotonation of vinyl cations

In the solvolysis of β-unsaturated vinyl compounds, in many cases acetylenes are formed together with ketones and/or ethers:



From a study of the mechanism of elimination reactions in a series of vinyl compounds undergoing solvolysis it was possible to establish that the ratio of the yield of products of an S_N1 reaction to that of products of $E1$ deprotonation depends to a considerable extent on the structure of the VC, the nature of the solvent in which solvolysis is occurring, and the basicity of the reaction medium.

As was mentioned in the examination of solvolytic methods for generating VCs, a decrease in steric strain in the initial vinyl compound through the formation of a VC with an *sp*-hybridised carbocation centre assists heterolysis of the (C=)C–X bond. In this case the yield of alkynes must increase with increased size of the substituents; elimination of a proton from the cation reduces the steric strain to an even greater extent. On the other hand attack by a nucleophile on the carbocation centre has the reverse effect.[8,63,98,118,119]

In addition to steric factors, the basicity of the reaction medium has a considerable effect on the ratio of substitution to elimination products. This can be illustrated in the case of the hydrolysis of *p*-aminobromostyrene in ethanol at different pH values.[120] With an increase in pH from 3.8 to 13.1 the yield of *p*-aminophenylacetylene increases from 16 to 85%, which on the whole is consistent with the HSAB principle. The carbocation centre of the cation is classed as a soft reaction site, whereas a hydrogen atom which has a partial positive charge is a hard reaction site. Since interactions between centres of the same type are energetically more favourable, the use of hard strongly basic nucleophiles favours the removal of a proton from the vinyl cation, which is reflected in an increased yield of alkynes.

IV. Reactions of free vinyl cations

As was mentioned in our description of the nuclear chemical method of generating carbocations, these cations occur in the free state, i.e. they do not have a counterion or equilibrium solvent cage and their reactions are classed as ion–molecule reactions (IMRs).

The rate of the reactions between ions and molecules is extremely high; in the majority of known cases the rate constants of IMRs are $10^{-12}-10^{-8}$ cm^3 mol^{-1} s^{-1}, which are many orders higher than the constants for reactions between neutral molecules. The low of zero values of the energy of activation and the high collision cross-sections account for this. As a consequence the cross-sections of IMRs (10^{-14} cm^2) match the cross-sections for collisions between ions and species of the medium.[80–84]

In the interaction between a thermolysed molecule and ion, an associated state, or "long-lived complex", develops, in which a statistical exchange of energy between different vibrational degrees of freedom occurs. In this case excitation of the internal degrees of freedom of the reacting species occurs and the complex is converted to a vibrationally excited state. Further conversion of the "long-lived complex" depends on the nature of the distribution of its internal energy and the degree of complexity of its transformation to the corresponding activated complex and then to the reaction products.

In the gas phase species have a long mean free path and in the intervals between collisions they may be regarded as free. At low densities when there is no interaction between the species, the distribution of the latter is random and the activation barrier for unimolecular decomposition or isomerisation of the activated complex in the gas phase may be surmounted through the energy of its collisions with species of the medium.

A completely different pattern occurs in the reaction between free cations and molecules in condensed phases (liquid phase and solid vitreous phase, which occurs as a result of a marked cooling of the liquid below the freezing point)¶.

A short mean free path is typical of the species in a condensed phase. Each molecule of liquid is surrounded by a given number of its immediate neighbours, but thermal movement results in disruption of the order arising on interaction between the species themselves.

Let us examine which processes occur in a liquid with the "instantaneous" formation in it of a carbocation as a result of the β-decay of tritium forming part of a hydrocarbon molecule.

A carbocation is formed at the concluding stage of nuclear chemical processes on cleavage of the C^+-He bond in the initial RHe^+ ion. Cleavage of this bond occurs over a period of $10^{-14}-10^{-13}$ s, which is of the same order of magnitude of time for atomic vibrations in a molecule.[80–84] It is evident that over approximately the same period of time the initial structure of the ion is transformed to an equilibrium state through vibrational relaxation.

The ion inherits the solvent cage of the mother molecule, which is not in equilibrium with the ion. In order for this cage to be reorganised, the following must change:[121]

a) the average radius of the cage, if it is assumed to be spherical;

b) the coordination number;

c) the symmetry of the quasi-crystalline structure of the cage, i.e. its shape;

d) the position of molecules with a permanent dipole;

e) the magnitude of the induced dipole moment and the induction energy, which change as a result of a charge developing;

f) the energy of the dispersion interaction, related to the polarisability of the ion.

The rate of these changes accompanying the formation of a carbocation is variable, $10^{-15}-10^{-10}$ s being required to accomplish them. The most rapid are the electronic forms of polarisation (10^{-15} s) and dispersion interactions (10^{-13} s). Orientational polarisation occurs more slowly (10^{-11} s) and the reorganisation of complexes of molecules fixed by hydrogen bonding is even slower (10^{-10} s). Hence, as a result of the very rapid redistribution of charges when a carbocation is suddenly formed, inductive polarisation of the medium by the field of the charge mainly occurs without any change in the spatial distribution of the species. In this sense a carbocation obtained by the nuclear chemical method can be regarded as being in a free state and the formation of the ion as a special Franck–Condon transition. It is clear that in condensed phases the excess energy of a "long-lived complex" is dispersed extremely rapidly by collisions with the surrounding species of the medium. The existence of an ion-dipole interaction between the complex and molecules of the medium increases the probability of such a transfer of energy to an even greater extent. For these reasons the reactions of a "long-lived complex" in solution are determined almost exclusively by the lowest vibrational energy level of this complex.

One of the most fruitful concepts that relates the electronic structure of molecules and ions to their behaviour in chemical reactions has been the frontier orbital theory of Fukui.[122] According to this approach, the frontier orbitals of reacting species play a decisive role in chemical interactions. It was shown by the PMO method that the interaction of the HOMO of one of the reactants (electron donor) with the LUMO of the other reactant (acceptor) makes a predominant contribution to the attractive energy.[123–125] In this case a reaction which results in the formation of a bond between atoms with the maximum charge densities in their frontier orbitals (reaction sites) becomes the most probable. This does not exclude a different coordination of the reactants with respect to each other and a reaction occurring by an alternative route involving other atoms and other reaction sites.[126]

It should be noted that the use of quantum-chemical methods of determining reactivity is most justified for free species, such as in gas-phase reactions (the "isolated molecule" approximation).

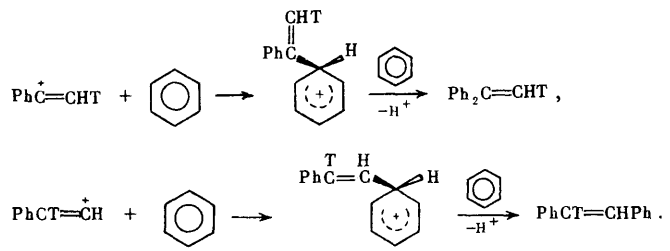
Since low or zero energies of activation and high rates are typical of ion-molecule reactions, the interaction between free cations and molecules in condensed phases may be regarded to the first approximation as the interaction of two free species which also results in the formation of a vibrationally excited "long-lived complex" or a polarised capture complex. Assuming a rapid transfer of energy to molecules of the surrounding medium, this phenomenon makes it sufficiently valid to use different quantum-chemical models, including PMO theory, for predicting the reactivity of free cations generated by the nuclear chemical method.

1. Reaction of free vinyl cations with aromatic and oxygen-containing compounds

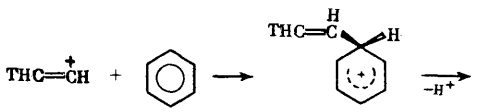
The reactions of free ethenyl and phenylvinyl cations obtained as a result of decomposition of the tritium atoms in doubly tritiated ethylene and styrene (see Section II.4) have been investigated in several studies.[85,87,88,90–92,126,127] Ethenyl cations were generated in benzene and methanol in the liquid state. Phenylvinyl cations were

¶ At the present time the state of a supercooled liquid in which the structure of the initial liquid is preserved is usually regarded as a solid vitreous state.

obtained in the presence of benzene and oxygen-containing compounds with the general formula ROR′ (R, R′ = H, Et) in the gas, liquid, and solid states. It was established in this case that the state of aggregation of the reaction system affects the route of the reactions between free vinyl cations and nucleophiles. The main products of the reaction between free phenylvinyl cations and benzene were 1,1-diphenylethylene, *trans*-stilbene, and isomers of phenylstyrene (see Section IV.2):



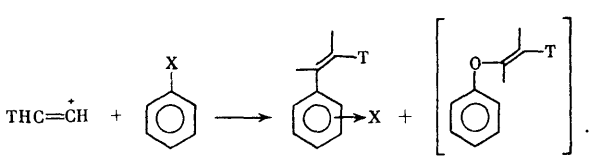
Attack on a benzene molecule by an ethenyl cation results in the formation of styrene:



The formation of diphenylethylene, stilbene, and styrene is consistent with the idea that arenonium ions (σ-complexes) are formed at an intermediate stage of the reaction.

Recently the reactivity and selectivity of free ethenyl cations towards substituted arenes such as toluene, anisole, fluoro-, chloro-, and bromo-benzene in the liquid and gas phases were studied by the method of competing reactions.[92]

In liquid-phase systems the predominant route was exothermic attack by an ethenyl cation on the π-electron system of an aromatic compound. As a result of this attack, an excited arenonium ion (σ-complex) is formed, being deactivated by collisions with molecules of the surrounding medium and undergoing deprotonation to form substituted styrenes. Anisole acts as an ambidentate nucleophile in reactions with an ethenyl cation since, in addition to the phenyl group, the unshared electron pair of the oxygen atom of the methoxy group also undergoes electrophilic attack, resulting in the formation of an oxonium ion. It is converted to phenyl vinyl ether as a result of reaction with another molecule of substrate. However, the efficiency of this process is very low. In reactions with halobenzenes the ethenyl cation exclusively attacks the phenyl group:



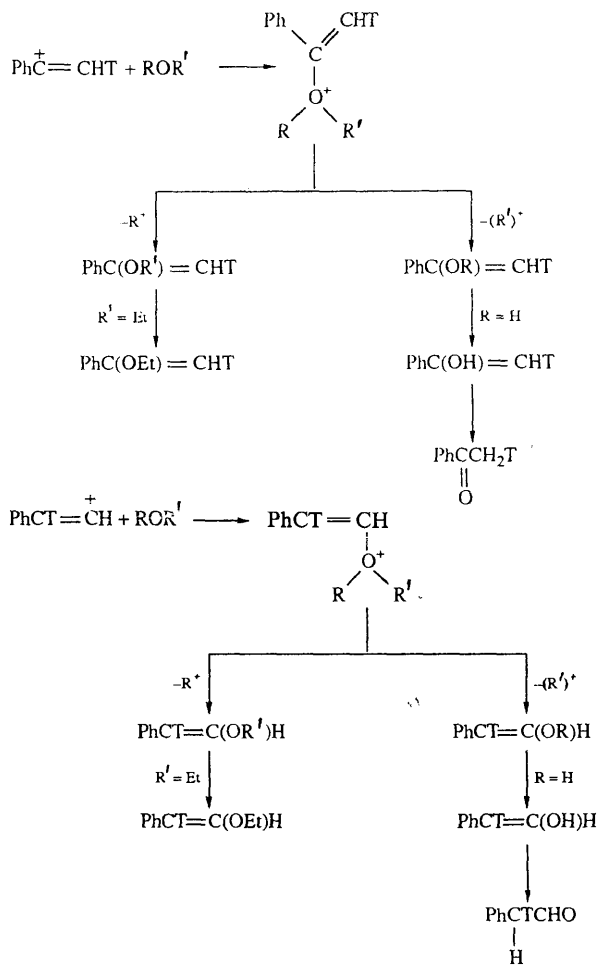
X = Me, OMe, F, Cl, Br X = OMe

The nucleophilic reagents that have been studied can be arranged in the following series of reactivity towards the ethenyl cation in the liquid phase: PhOMe > PhCl > PhMe.

The results obtained from studies on gas-phase reactions of free ethenyl cations with arenes are consistent with the hypothesis that isomeric conversions of their primary reaction products—arenonium or onium ions—take place. In this case the latter occur in an excited state for a considerable time as a result of the difficulty or impossibility of their deactivation through collisions.[80–81,128] Therefore, in contrast to liquid-phase reactions, the isomeric composition of substituted styrenes in gas-phase reactions approximates to the thermodynamically stable composition with a predominance of *meta* isomers. Similar results were obtained in a radiochemical study of ion-molecule reactions of free methyl and phenyl cations with certain alkylbenzenes.

Oxonium ions are known to act as adducts in electrophilic addition reactions of aliphatic carbocations to molecules with the general formula ROR′ (R, R′ = H, Alk).[80,81] The results of four studies[92,124,125,129] are also consistent with the idea that these intermediates are formed as a result of attack by free ethenyl and phenylvinyl cations on the unshared electron pair of the oxygen atom of an ROR′ molecule.

From a quantitative determination of the yields of products formed in the liquid phase it was possible to conclude that the oxonium ions decompose preferentially with the detachment of an alkyl group Et^+ (or Me^+). Thus, in the case of 1- and 2-phenylvinyl cations the yields of acetophenone or phenylethanol were approximately ten times higher than the yields of 1- or 2-ethoxystyrenes respectively:[129]



Formation of an ion by an S_N1 mechanism is accompanied by a substantial reorganisation of the surrounding medium with a change in the orientation of the molecules of the medium and their relative configuration. The cation is in thermodynamic equilibrium with the medium.

In contrast to this, when cations are generated by NCM in condensed phases, the molecules of the medium hardly change their spatial configuration at all relative to the ion formed because of the high rates of nuclear chemical processes. Since for IMRs extremely high reaction cross-sections are typical and virtually every collision of the reacting species results in reaction, the excited intermediate complex between an ion and molecule (an oxonium ion in this case) appears to be isolated from the surrounding medium. As a result, the transfer of excitation energy from the complex to the medium is difficult. Therefore, the complex mainly decomposes by a unimolecular mechanism with formation of the thermodynamically most stable species (an alkyl cation), while elimination of a proton is forbidden. To a certain extent this resembles the reaction of carbocations in the gas phase, such as the reaction of free methyl cations with alcohols and ethers.[80-81] The presence of ethers amongst the products of reactions between free phenylvinyl cations and ethanol in the liquid phase is an indication of the contribution of a bimolecular mechanism for decomposition of the oxonium ion through the transfer of a proton to a substrate molecule. This is due to the occurrence of hydrogen bonding in alcohols.

In competing reactions of free phenylvinyl cations with ethanol and water in equimolar quantities, the ratio of yields of ether to ketone was approximately 0.1 : 1, which indicated the higher reactivity of ethanol relative to water.[129] This is consistent with results on the solvolysis of anisylvinyl halides in 80% aqueous ethanol,[130] which is also supported by a study of reactions involving free triarylvinyl cations produced by flash photolysis.[131] In the latter study it was established that the nucleophilicity of alcohols decreases in the series: MeOH > EtOH > iso-PrOH > (H_2O) > t-BuOH. The ratio of rate constants of reactions between the 2,2-diphenyl-1-anisylvinyl cation and methanol and t-butanol is 12 : 1, while in the case of reactions of the trianisylvinyl cation it is 21 : 1. This variation in reactivity is evidently due to an increase in steric hindrance in the intermediate complex. The low reactivity of water is probably due to the fact that its molecules and the molecules of the solvent — acetonitrile — in which flash photolysis was conducted from clusters via hydrogen bonds, and this makes water less nucleophilic. However, the question as to whether this series of reactivity of alcohols and water is retained when the composition of solution is changed was not discussed by Kobayashi, et al.[131]

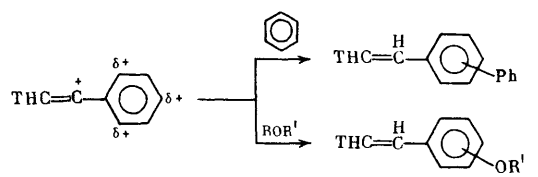
Free VCs of the type $R^1R^2C{=}C^+R^3$ ($R^1{-}R^3$ = Ph, An, Me) which are obtained by flash photolysis of the corresponding bromides in acetonitrile have a characteristic band (λ = 355 nm) in their absorption spectrum and a lifetime of 1 – 20 μs.[132] The rate constants of reactions between nucleophilic reagents (*N*-methyl and *N*-vinyl-2-pyrrolidone styrene, *n*-butyl vinyl ether, α-methylstyrene, methyl methacrylate, tetrahydrofuran, ethers, and aliphatic alcohols) and cations are $10^5 - 10^8$ litre mol^{-1} s^{-1}. The composition of the products has not been studied. The highest reactivity of the 1-(*p*-anisyl)-2,2-dimethylvinyl cation has been attributed to the high positive charge on its carbocation centre and low steric hindrance (in the series of VCs studied).

2. Participation of aryl groups in reactions of free substituted vinyl cations

As was demonstrated by quantum-chemical calculations of the electron densities on the atoms of phenylvinyl cations, the 1-phenylvinyl cation is stabilised through overlap of the vacant 2*p* orbital of the carbocation centre and the HOMO of the phenyl group, occurring as a result of the Ph group rotating through 90°. This causes the carbon atoms at the *ortho* and *para* positions of the phenyl group to be activated. The $2p_y$ orbitals of these atoms participate in the formation of the LUMO of the cation, which results in a positive charge developing at these positions.

The 1-phenylvinyl cation can be regarded as a multicentre electrophile. The 2-phenylvinyl cation is a single-centre electrophile as its LUMO is formed almost completely from $2p_y$ atomic orbitals of the carbocation centre, on which the main positive charge is localised.[55,57,58]

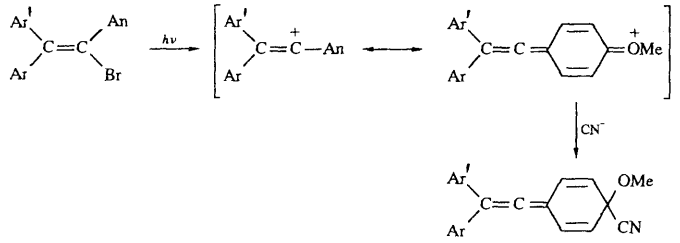
By regarding the interaction between carbocations obtained by NCM and molecules as an interaction between free species whatever their state of aggregation might be, the formation of "long-lived complexes" involving each reaction site may be assumed.[58,87,126-128] This can explain the replacement of a hydrogen atom at the *ortho* and *para* positions of the phenyl group of phenylvinyl cations and the formation of their reaction products with benzene — *o*- and *p*-phenylstyrenes — as well as the formation of hydroxy- and ethoxystyrenes when they react with ROR′ compounds (R, R′ = H, Et):



In a condensed state, in contrast to gas-phase reactions, interaction between phenylvinyl cations and benzene does not lead to the formation of *o*-phenylstyrene. Furthermore, the reaction sites at the *ortho* position of the phenyl group in 1-$C_8H_7^+$ in the addition of this cation to ROR′ molecules had no recorded effect on the process. This is presumably due to the fact that in a condensed state the conversion of *ortho*-oriented complexes to reaction products encounters a number of difficulties caused by electronic repulsion of the vinyl residue in the sterically strained molecule of the *ortho* isomer and the need to disrupt the conjugation between the vacant orbital of the carbocation centre and the HOMO of the phenyl group of 1-$C_8H_7^+$. In the gas phase these barriers are readily surmounted, since the resulting complexes occur in a vibrationally excited state.[58,87,126-128]

A study of the flash photolysis of arylvinyl bromides has supported the idea that α-aryl groups participate in reactions of the resulting VCs.[131-133] Thus, because of the delocalisation of positive charge and the development of additional reaction sites, the addition of cyanide or alkoxide ions becomes possible not only to the carbocation centre of the 1-(*p*-anisyl)-2,2-diarylvinyl cation but also to the α-anisyl substituent, which is accompanied by *ipso*-substitution

of the methoxy group. The intermediate of *ipso*-substitution—diarylmethoxycyanovinylidenecyclohexadiene—was identified by ^{1}H NMR[133–135] and isolated from the reaction mixture.[136,137]



In the photolysis of 1-(*p*-anisyl)-2,2-diarylvinyl bromide in solutions of MeOH, EtOH, and PrOH in the presence of NEt_3, pyridine and $NaHCO_3$, *ipso*-substitution does not take place.[134] Diphenylvinylidenecyclohexadienone acetal—a product of *ipso*-substitution—is stable in neutral and weakly acidic media, while in an acidic medium it decomposes to form a 2,2-diphenyl-1-alkoxyphenylvinyl cation, which made it possible to study the reaction of the latter with methanol, water, anisole, and bromide and thiocyanate ions.[138]

3. Free-cationic polymerisation

One of the most important reactions of carbocations with olefins is cationic polymerisation. The process is initiated by the addition of an ion to an olefin molecule, as a result of which a new carbocation is formed that is also capable of attacking an olefin molecule.

This question has not been studied in relation to VCs except in the specific case of the free-cationic polymerisation of styrene in bulk and also in its solutions in cyclohexane and methylcyclohexane by phenylvinyl cations generated by NCM.[124] The polymers obtained had a high molecular weight—10^6 in the polymerisation of pure styrene and 10^5 in 10% solutions of these solvents. They had a unimodal molecular weight distribution. The latter circumstance provides evidence that polymerisation is initiated by species of the same nature, namely, phenylvinyl cations. On lowering the temperature to −78 °C the molecular weight of the polymer increased, which also pointed to the cationic nature of the processes occurring. However, the possibility of radical cations which may be formed as a result of radiolysis of components of the solution participating in these processes cannot yet be excluded categorically.

V. Conclusion

Vinyl cations, which were discovered more than 25 years ago, have become the subject of intense experimental and theoretical study, and they have currently gained general recognition.

Vinyl cations, as has been convincingly demonstrated in a considerable number of studies, are in many respects similar to the well-studied alkyl and aryl cations. They may be obtained by methods that are similar to those used for generating saturated cations, such as by electrophilic addition to the triple bond of acetylenes and the cumulene bond of allenes, including intramolecular attack on the double bonds of the carbocation centre formed as a result of solvolysis. The method based on heterolysis, in particular solvolysis of the (C=)C−X bond in vinyl compounds, has been used the most extensively.

Unique opportunities are presented by the nuclear chemical method of generating VCs in a free stage. This is related to the application of the β-decay of tritium that is covalently bound in vinyl compounds (a free state is taken to mean a state that is characterised by the absence of a counterion and an equilibrium solvent cage).

According to quantum-chemical calculations that have been confirmed experimentally, VCs mainly have a structure with a linear or quasi-linear configuration of the σ-bonds at the carbocation carbon atom. Cycloalkenyl cations with small rings (C_3−C_6) in which this linear structure does not occur have been theoretically predicted and obtained.

Studies on the rearrangements of VCs using labelled atoms clearly attest to the possibility of bridged VC structures being formed, especially as a result of the migration of aryl groups.

The results collected to date demonstrate that VCs act as typical electrophilic reagents. Because of the presence of a vacant 2*p* orbital, VCs participate in reactions with *n* and π-donors and they are capable of attacking the σ-electrons of C−C or C−H bonds.

The role of the individual groups of substituents in VCs and their saturated analogues appear to be similar in many respects. However, VCs have greater reactivity as intermediates than aliphatic cations. The reactions in which VCs participate take place with lower selectivity. The main characteristics of VCs are governed by the presence of a rigid double bond, which to a considerable extent affects the stereochemistry of many reactions involving VCs.

N-Functionalised carbodiimides

M V Vovk, L I Samarai
The Institute of Organic Chemistry of the Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. A systematic review is presented on the synthesis and the physical and chemical properties of *N*-acyl, *N*-sulphonyl-, *N*-phosphoryl- and *N*-alkenyl-carbodiimides.

The bibliography contains 90 references.

III. Physical and chemical properties 301

I. Introduction

Organic carbodiimides are important members of the heterocumulene class of compound. Being highly reactive, they are key starting materials in organic synthesis and, in addition to this, possess of a whole range of properties which have been usefully applied. Since the discovery of the first carbodiimides by Weit in 1874,[1] the chemistry of this class of compound has developed extensively, and data primarily on alkyl and aryl carbodiimides has been surveyed systematically in a number of reviews.[2–5] It is also possible to isolate carbodiimides with functional groups on nitrogen (e.g. RC(O), RSO_2, $R_2P(O)$, $R_2C{=}CR$, R_3Si, etc.), which possess unusual properties quite distinct from unfunctionalised carbodiimides. Most of the work relating to such *N*-functionalised derivatives has been reported during the last 20–25 years and, with the exception of the data relating to *N*-silylcarbodiimides,[6] the information contained therein has not been reviewed.

Up to now, most of the research in this field has been devoted to *N*-acyl-, *N*-sulphonyl-, *N*-phosphoryl- and *N*-alkenyl-carbodiimides. Their syntheses and properties have been examined systematically in the present review.

II. Synthesis of *N*-functionalised carbodiimides

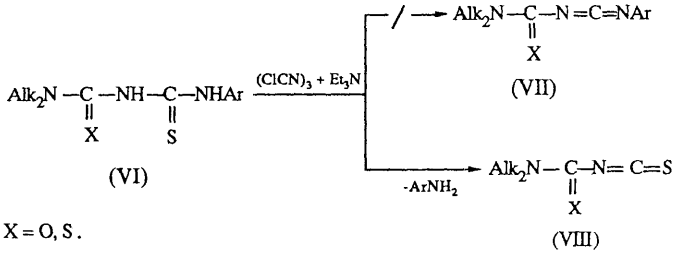
1. *N*-acyl(thioacyl, imidoyl) carbodiimides

Most of the carbodiimides in this category have been prepared by the same methods as used for the synthesis of unsubstituted alkyl and aryl carbodiimides.[4] The commonest route involves dehydrosulphuration of the corresponding thiourea:[7–13]

$$\mathrm{AcylNH{-}C(=S){-}NHR} \xrightarrow[-H_2S]{} \mathrm{AcylN{=}C{=}NR}\ ,\qquad \text{(I)–(V)}$$

R = Alk, Ar.

As seen in Table 1, the yield of carbodiimides (I–V) varies significantly, depending on the nature of the thiourea, the dehydrosulphurating agent, and the reaction conditions. The reaction can be conducted on heating in benzene, acetone or methylene chloride if HgO, PbO or NaOCl is used as the reagent. However, such conditions are unsuitable for preparing *N*-carbamoyl-, *N*-thiocarbamoyl- and *N*-imidoyl-carbodiimides (III–V) which tend to dimerise at elevated temperature. For these carbodiimides, the preferred dehydrosulphurating reagent is cyanuric chloride in the presence of triethylamine, with which reaction can be carried out conveniently at 0 °C; the formation of by-product is minimal and does not complicate the isolation procedure. However, it is not possible to apply this method to the preparation of *N*-(thio)carbamoyl-*N'*-arylcarbodiimides (VII) since the starting (thio)biurets react by cleavage of amine to give the corresponding isothiocyanate (VIII).[9]



X = O, S.

Table 1. *N*-Acyl-, *N*-thioacyl-, and *N*-imidoyl-carbodiimides, AcylN=C=NR (I–V).

Compound	Acyl	Dehydrosulphurating agent	Yield, %	Refs.
(I)	AlkC(O)	HgO	60—90	[7]
		NaClO	см*	[7]
(II)	AlkOC(O)	HgO	37—45	[8]
		$COCl_2 + Et_3N$	см*	[8]
(III)	$Alk_2NC(O)$	$(ClCN)_3 + Et_3N$	53—91	[9]
(IV)	$Ar_2NC(S)$	$(ClCN)_3 + Et_3N$	72—88	[10]
(V)	ArC(=NAr)	$(ClCN)_3 + Et_3N$	72—82	[11, 12]
		$Ph_3P + Et_3N + I_2$	86—95	[13]

*There are no data on the yield.

Mercuric benzamide, diethyl azodicarboxylate–triphenylphosphine and azodibenzoyl–triphenylphosphine[14] have also been used as mild dehydrosulphurating agents for the preparation of *N*-acylcarbodiimides.

A simple route has been devised for the preparation of *N*-ethoxycarbonyl-*N'*-alkylcarbodiimides (IX) as hetero-analogues of *N*-ethoxycarbonylisothiocyanates,[15] which are widely used in the synthesis of heterocyclic compounds. The method is based on the reaction of ethoxycarbonyliminophosgene (X) with sterically hindered primary amines.[16]

$$\underset{\text{(X)}}{EtOC(O)N{=}CCl_2} + AlkNH_2 \xrightarrow[-2HCl]{} \underset{\text{(IX)}}{EtOC(O)N{=}C{=}NAlk},$$

Alk = Pr^i, Bu^i, Bu^t, cyclo-C_6H_{11}.

A similar method has been used for the synthesis of *N,N'*-carbonyldicarbodiimides (XI) as hetero-analogues of *N,N'*-carbonyldiisocyanate.[17]

$$Cl_2C{=}N{-}\underset{\underset{O}{\|}}{C}{-}N{=}CCl_2 + 4AlkNH_2 \xrightarrow[-4HCl]{} AlkN{=}C{=}N{-}\underset{\underset{O}{\|}}{C}{-}N{=}C{=}NAlk.$$

(XI)

Recently, it has been shown that *N*-acylcarbodiimides (XII) and *N*-imidoylcarbodiimides (XIII) can be conveniently prepared by the reaction of trichloromethyl dichlorodiazadienes (XIV) or the isomeric pentachloroethylcarbodiimides (XV) with alcohols and amines, respectively.[18]

$$\underset{\text{(XIV)}}{CCl_3CCl{=}N{-}CCl{=}NR} \xrightarrow[-HCl,\ -MeCl]{MeOH} \underset{\text{(XII)}}{CCl_3\overset{\overset{O}{\|}}{C}{-}N{=}C{=}NR}$$

or

$$\underset{\text{(XV)}}{CCl_3CCl_2N{=}C{=}NR} \xrightarrow[-2HCl]{ArNH_2} \underset{\text{(XIII)}}{CCl_3\overset{\overset{NAr}{\|}}{C}{-}N{=}C{=}NR}$$

R = Pr^i, Ph, 2,4,6-$Me_3C_6H_2$.

A number of *N*-acylcarbodiimides have been obtained by the acylation of monosubstituted cyanamides—the method used by Fromm et al. in 1922 for the preparation of the first member of this class to be characterised, namely (XVII).[19] This was obtained by treatment of the cyanamide (XVI) with benzoyl chloride.

$$\underset{\text{(XVI)}}{N{\equiv}C{-}NHCH_2CH_2OH} \xrightarrow{2PhC(O)Cl} \underset{\text{(XVII)}}{PhC(O)N{=}C{=}NCH_2CH_2OC(O)Ph}.$$

In a subsequent development of the method,[20,21] it was proposed that reaction involves initial formation of an acylcyanamide, isomerisation of which yields the desired carbodiimide. This is not unlike the synthesis of *N*-silylcarbodiimides (XIX), which proceeds via *N*-silylation of the corresponding *N*-acylcyanamide (XVIII).[22,23]

$$\underset{\text{(XVIII)}}{RC(O)NH{-}C{\equiv}N} + Me_3SiCl \longrightarrow [RC(O)N(SiMe_3){-}C{\equiv}N] \longrightarrow \underset{\text{(XIX)}}{RC(O)N{=}C{=}NSiMe_3}$$

R = MeO, EtO.

N-Acyl-*N'*-silyl(stannyl)carbodiimides (XX) are obtained in high yield by acylation of the corresponding silyl(stannyl)carbodiimides (XXI) with carboxylic acid anhydrides or halides,[24,25] or with phenyl isocyanate:[26]

$$\underset{\text{(XXI)}}{R_3MN{=}C{=}NMR_3} + R'COX \xrightarrow{20\ ^\circ C} \underset{\text{(XX)}}{R'C(O)N{=}C{=}NMR_3},$$

R_3M = Me_3Si, Bu_3Sn; R' = Me, CF_3, Ph; X = Cl, MeC(O)O.

Catalytic decarboxylation of isocyanates,[27] which has been widely applied to the synthesis of diarylcarbodiimides, cannot be used for the synthesis of *N*-acylcarbodiimides because of their low thermal stability. However, there is a reference to the *in situ* formation of bis(trichloroacetyl)carbodiimides (XXII) by this route.[28]

$$2CCl_3C(O)N{=}C{=}O \xrightarrow[-CO_2]{} \underset{\text{(XXII)}}{CCl_3C(O)N{=}C{=}NC(O)CCl_3}$$

N-Carbamoylcarbodiimides (XXV) have been prepared by the interaction of isothioureas (XXIII) or chloroformamidines (XXIV) with Ag(I)-cyanate.[9] The isomerisation of the intermediate isocyanatoformamidines (XXVI), takes place by a four-centred mechanism. A similar process was identified earlier during the reversible isomerisation of acylisothiocyanates to thioacylisocyanates.[29]

$$\underset{\text{(XXIII)}}{RN{=}C(SCH_2Ph){-}NMe_2} \xrightarrow{AgOCN} \left[RN{=}C(NMe_2){-}N{=}C{=}O\right] \longrightarrow$$

$$\underset{\text{(XXIV)}}{RN{=}C(Cl){-}NMe_2} \xrightarrow{AgOCN} \left[RN{=}C(NMe_2){-}N{=}C{=}O\right] \longrightarrow$$

(XXVI)

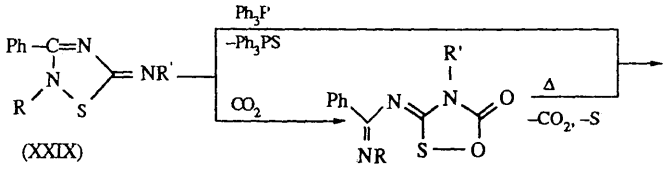
$$\longrightarrow \left[Me_2\overset{+}{N}{=}C(NR){-}C(=O){-}N^-\right] \longrightarrow \underset{\text{(XXV)}}{Me_2NC(O){-}N{=}C{=}NR},$$

R = Bu^t.

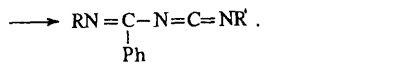
Zimmerman and Olofson devised a novel route to carbodiimides (XXVII) based on the ring opening of 1,2,4-oxadiazolium salts (XXVIII) on treatment with triethylamine.[30]

$$\underset{\text{(XXVIII)}}{Ph{-}C(=N{-}O{-}){=}N{-}} \xrightarrow{Alk_2O^+BF_4^-} Ph{-}C(=N{-}O^+(Alk)){=}N{-}\ BF_4^- \xrightarrow{Et_3N} \underset{\text{(XXVII)}}{PhC(O){-}N{=}C{=}NAlk}.$$

Other five-membered heterocyclic compounds, e.g. 1,2,4-thiadiazolines, may be converted to *N*-imidoylcarbodiimides, e.g. (XXX), by reaction with triphenylphosphine[13] or carbon dioxide.[31]

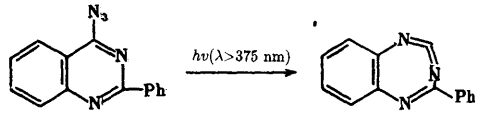


(XXIX)



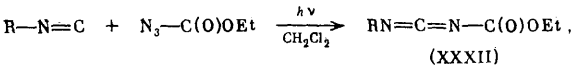
(XXX)

The cyclic imidoylcarbodiimide (XXXI) has been detected spectroscopically as a product derived by photochemical decomposition of 4-azido-2-phenylquinazoline in an argon matrix at 10 K.[32]

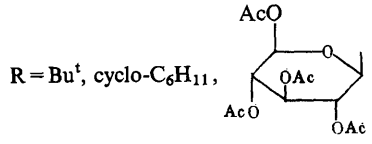


(XXXI)

However, photochemical decomposition of ethyl azidoformate in the presence of isonitriles leads to the corresponding *N*-carbalkoxycarbodiimides (XXXII) in high yield.[33]

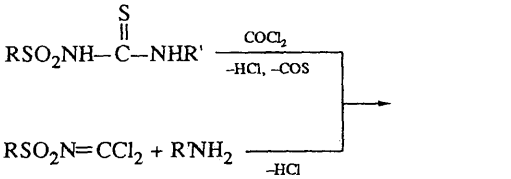


(XXXII)



2. *N*-Sulphonylcarbodiimides

The first representative of this class of compound were prepared by heating the corresponding *N*-sulphonylthiourea with phosgene in toluene or chlorobenzene.[34–39] Reaction proceeds by the initial formation of the corresponding *N*-sulphonylchloroformamidine (XXXIII), dehydrochlorination of which yields the desired carbodiimides (XXXIV).[40–42] The chloroformamidines are also formed as intermediates in the preparation of (XXXIV) from *N*-sulphonyliminophosgenes and primary amines.[43–47]

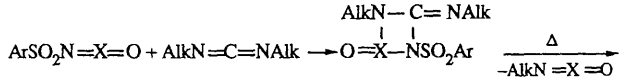


(XXXIII)

(XXXIV)

R, R' = Alk, Ar.

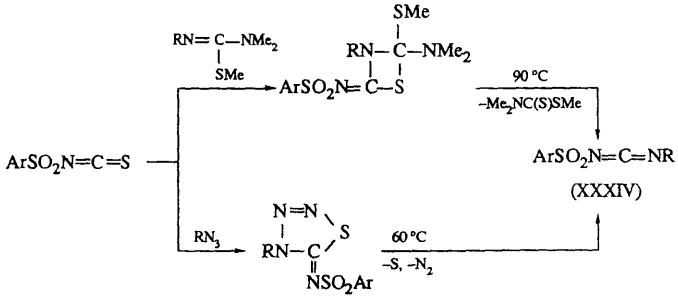
The synthesis of *N*-sulphonylcarbodiimides by metathesis with other types *N*-sulphonylheterocumulene is also worthy of note. Normally, reactions of this type involve initial formation of a [2+2]-cycloadduct, which subsequently decomposes on increasing the temperature. Thus, *N*-sulphonylcarbodiimides (XXXIV) are obtained in high yield by the interaction of *N*-arylsulphonylisocyanates[48–50] or *N*-sulphonylthionylimines[51] with *N,N'*-dialkylcarbodiimides.



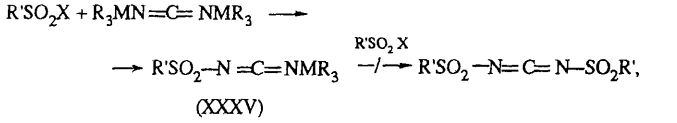
(XXXIV)

X = C, S.

In a similar way, *N*-sulphonylcarbodiimides can be obtained by reaction of *N*-sulphonylisothiocyanates with isothioureas[52] or azides.[53,54]



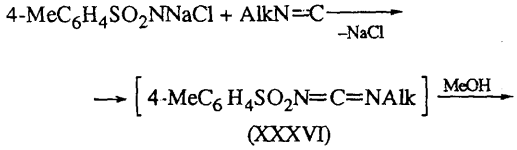
N-Sulphonylcarbodiimides of type (XXXV) have been prepared by sulphonylation of elementoorganic [Group 4] carbodiimides with sulphonyl chlorides.[55,56] However, it is not possible to obtain symmetrical *N,N'*-disulphonylcarbodiimides by reaction of (XXXV) with a second molecule of RSO_2X, presumably because the electron-accepting *N*-sulphonyl group in (XXXV) deactivates the M–N bond.



(XXXV)

X = Cl, NCO; R_3M = Me_3Si, Bu_3Sn, Et_3Ge.

There is also the possibility of preparing *N*-sulphonylcarbodiimides (XXXVI) by the scheme: N + CN→NCN, e.g. from Chloroamine T and alkyl isonitriles.[58] However, the desired carbodiimides have only been identified by subsequent adduct formation, e.g. with methanol.



(XXXVI)

3. *N*-Phosphorylcarbodiimides

By comparison with *N*-acyl- and *N*-sulphonyl-carbodiimides, *N*-phosphoryl analogues are less stable because of their tendency to disproportionate and polymerise spontaneously.

It has been reported that a number of *N*-phosphorylcarbodiimides (XXXVII) may be prepared by elimination of H_2S from the corresponding thiourea with HgO or $COCl_2$ in the presence of molecular sieves.[59]

$$R_2P(O)NH-\overset{\overset{S}{\|}}{C}-NHR' \xrightarrow{HgO \text{ or } COCl_2} R_2P(O)N=C=NR'.$$

(XXXVII)

The same reaction with the thiophosphorylated thiourea (XXXVIII) is more complex, being associated with the formation of an *N*-thiophosphorylisothiocyanate and an *N*-thiophosphoryl-guanidine.[60]

$$(EtO)_2\overset{\overset{S}{\|}}{P}NH-\overset{\overset{S}{\|}}{C}-NHPh \xrightarrow{HgO}$$

(XXXVIII)

$$\longrightarrow (EtO)_2\overset{\overset{S}{\|}}{P}N=C=S + (EtO)_2\overset{\overset{S}{\|}}{P}N=C(NHPh)_2.$$

Dehydrochlorination of *N*-phosphorylated chloroformamidines (XXXIX), obtained either from the corresponding *N*-phosphorylated urea or by treatment of *N*-phosphorylated iminophosgenes with primary amines, affords the corresponding *N*-phosphoryl-*N'*-arylcarbodiimides (XL) in high yield.[61]

$$ArNH-\overset{\overset{O}{\|}}{C}-\overset{\overset{O}{\|}}{N}HP(OAlk)_2 \xrightarrow{PCl_5} ArNH-\overset{\overset{Cl}{|}}{C}=\overset{\overset{O}{\|}}{N}P(OAlk)_2 \xleftarrow{ArNH_2} Cl_2C=\overset{\overset{O}{\|}}{N}P(OAlk)_2$$

(XXXIX)

$$\downarrow Et_3N$$

$$ArN=C=\overset{\overset{O}{\|}}{N}P(OAlk)_2.$$

(XL)

The *N*-phosphorylcarbodiimides (XLI) and (XLII) may be prepared conveniently from metalated *N*-phosphorylcyanamides[62] or by treatment of Ag(I)-cyanamide with phosphorus(V) acid chlorides.[63–65]

$$M[Ph_2P(X)NCN] + R_3M'Cl \xrightarrow[-MCl]{} Ph_2P(X)N=C=NM'R_3,$$

(XLI)

$$Ag_2CN_2 + 2Ph_2P(X)Cl \xrightarrow[-2AgCl]{} Ph_2P(X)N=C=NP(X)Ph_2$$

(XLII)

M = Na, Ag; X = O,S; R_3M' = Ph_3Si, Ph_3Sn, Ph_3Pb, Me_3Sn.

By using diphenylhalogenophosphines in the latter reaction, the desired carbodiimide was isolated in the form of a 1:1:1 adduct, $Ph_2P-N=C=N-PPh_2 \cdot AgHal \cdot solvent$.[63]

Replacement of a trimethylsilyl group in the carbodiimides (XLIII) by a phosphoryl, thiophosphoryl or iminophosphoryl group can only be achieved under forcing conditions.[66–68] Thus, *N*-difluorothiophosphoryl-*N'*-trimethylsilylcarbodiimide (XLIV) is obtained in 35% yield by prolonged heating (50 h) of the reactants at 140–150 °C.[66]

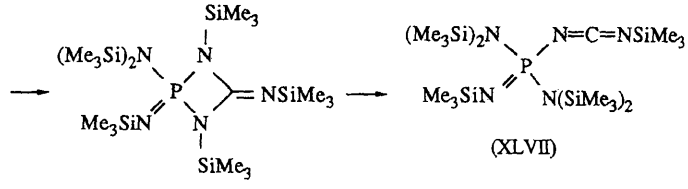
$$Me_3SiN=C=NSiMe_3 + P(S)F_3 \longrightarrow Me_3SiN=C=NP(S)F_2 + Me_3SiF.$$

(XLIII) (XLIV)

On the other hand, reaction of carbodiimides (XLIII) with the aminodiiminophosphorane (XLV) readily affords a [2+2]-cycloadduct (XLVI), which is converted to (XLVII) on standing over a long period.[69]

$$Me_3SiN=C=NSiMe_3 + \begin{matrix}(Me_3Si)_2N \\ \diagdown \\ P=NSiMe_3 \\ \diagup \\ Me_3SiN\end{matrix} \longrightarrow$$

(XLIII) (XLV)



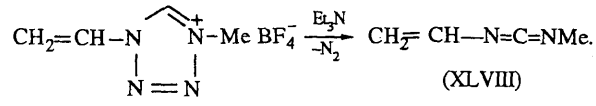
(XLVI)

$$\longrightarrow (Me_3Si)_2N-P(=N-C=NSiMe_3)-N(SiMe_3)_2$$

(XLVII)

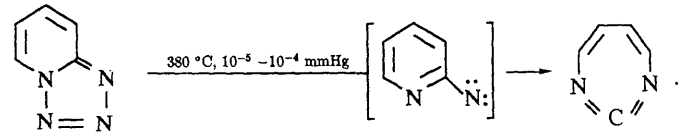
4. *N*-Alkenylcarbodiimides

The highly reactive vinylcarbodiimides were unknown before 1970. The first member of this class of compound—the unstable *N*-methyl-*N'*-vinylcarbodiimides (XLVIII)—was obtained by fragmentation of a tetrazolium salt with triethylamine in sulfolane.[30]



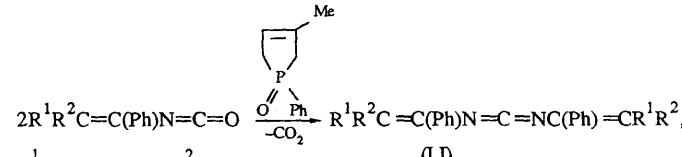
(XLVIII)

According to spectroscopic data, the relatively stable cyclic divinylcarbodiimide (XLIX) is formed by thermal rearrangement of the nitrene (L), obtainable by thermolysis of tetrazolo[1,5-*a*]pyridine at high temperature.[70]



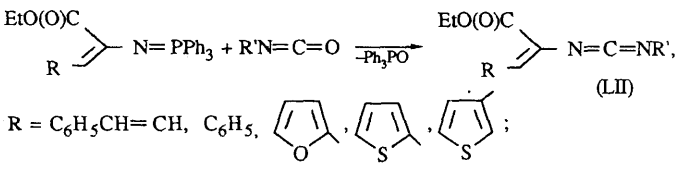
(L) (XLIX)

The stability of *N*-alkenylcarbodiimides increases significantly with substitution in the alkenyl residue. Thus, the stable *N,N'*-bis-(1-alkenyl)carbodiimides (LI) are obtained by catalytic decarboxylation of the corresponding *N*-alkenylisocyanate.[71]



(LI)

The most general and convenient route to *N*-alkenylcarbodiimides (LII) involves aza-Wittig conversion of the corresponding *N*-alkenyliminophosphorane,[72–77] e. g.

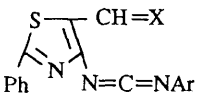


(LII)

R = $C_6H_5CH{=}CH$, C_6H_5, ;

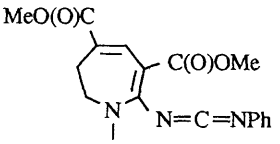
R' = Alk, Ar.

If the carbon–carbon double bond of the *N*-alkenyliminophosphorane is in the form of a pyrrole,[78] pyrazole,[79,80] or pyrimidine[81,82] ring, the corresponding carbodiimides are only formed as intermediates. However, thiazole[79] and azepine[83] derivatives afford stable carbodiimides (LIII) and (LIV).



(LIII)

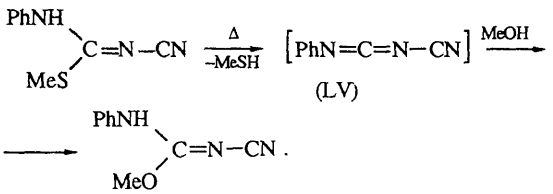
X = O, NAr.



(LIV)

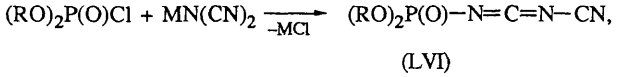
5. Other types of *N*-functionalised carbodiimide

In this category are *N*-cyano- and *N*-amino-carbodiimides which are relatively unstable and, as a rule, are only isolable by derivatisation. Thus, *N*-phenyl-*N'*-cyanocarbodiimide (LV) is formed by thermal elimination of methanethiol from *N*-phenyl-*N'*-cyano-*S*-methylisothiourea.[84]



(LV)

The stability of *N*-cyanocarbodiimides is significantly increased if an *N*-phosphoryl residue is present. Thus, *N*-cyano-*N'*-phosphorylcarbodiimides (LVI) are quite stable.[64,65]



(LVI)

M = Na, K, Ag.

N-Dialkylaminocarbodiimides, $Alk_2N{-}N{=}C{=}NR$, are very unstable, readily dimerising immediately they are formed. A few of these compounds have been mentioned in an earlier review.[85]

III. Physical and chemical properties

1. Physical properties

The majority of *N*-functionalised carbodiimides are crystalline compounds or liquids which may be distilled under a high vacuum. Like unfunctionalised carbodiimides, they are readily soluble in organic solvents, but are less stable on prolonged storage even with the exclusion of atmospheric moisture.

The IR spectra of these carbodiimides are characterised by intense absorption in the region 2130–2170 cm^{-1}, corresponding to the N=C=N function. The nature of the *N*-substituent does not have a significant effect on the position of this absorption band. However, with certain *N*-acylcarbodiimides[17,21] and *N*-sulphonylcarbodiimides,[35] the absorption is shifted into the region 2185–2200 cm^{-1}.

^1H NMR and ^{13}C NMR spectroscopic data are available for *N*-acylcarbodiimides;[17,18,30] ^{31}P NMR data for *N*-phosphorylcarbodiimides,[62,64] and ^1H NMR data for *N*-alkenylcarbodiimides.[35,71,74,75,83]

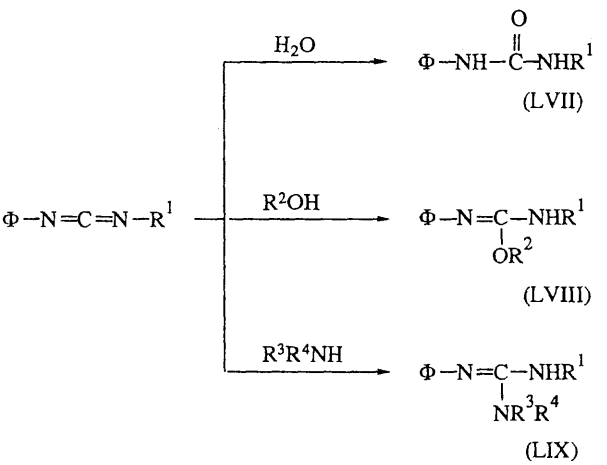
Theoretical calculations have been made on the hypothetical difluorocarbodiimide, F–N=C=N–F, in order to study the geometry of the molecule and its isomerisation.[86]

2. Chemical properties

a) Reactions with nucleophiles

The chemistry of *N*-functionalised carbodiimides is determined to a large extent by the presence of both the heterocumulene bond and the functional group. The electron-accepting acyl, sulphonyl and phosphoryl groups significantly increases the electrophilicity of the heterocumulene bond and facilitate the reactions of these compounds with nucleophiles.

Substituted ureas (LVII),[9,18,40,45,46,52,53,60,62] isoureas (LVIII) [10,12,40,58] and guanidines (LIX) [12,40,42,58] are formed by the reaction of the corresponding *N*-functionalised carbodiimide with water, alcohols (or phenols) and amines, respectively, at room temperature in the absence of a catalyst.



(LVII)

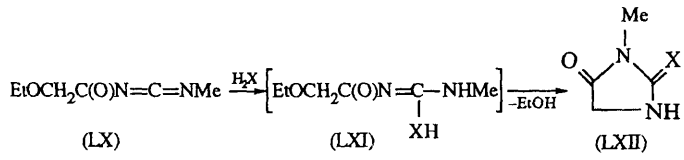
(LVIII)

(LIX)

Φ = $Alk_2NC(S)$, $ArN(=CAr)$, $ArSO_2$, $AlkSO_2$, Alk_2P, $(AlkO)_2P(O)$;

R^1, R^2 = Alk, Ar; R^3 = H, Alk; R^4 = Alk, Ar.

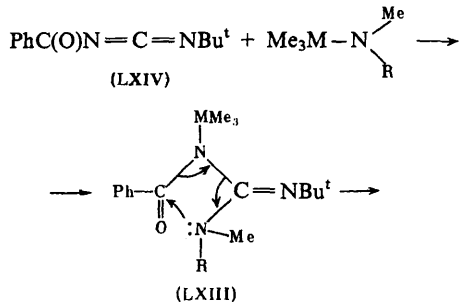
The reaction of carbodiimide (LX) with amines and hydrazines, however, does not stop at adduct formation (LXI); instead, the latter cyclises to give the corresponding hydantoin derivative (LXII) [30] by elimination of ethanol.



(LX) (LXI) (LXII)

X = NAlk, N —NHAlk .

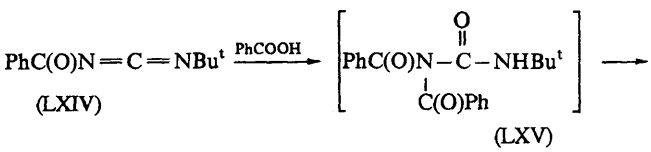
Similarly, the guanidine derivative (LXIII), obtained from carbodiimide (LXIV), fragments with participation of the benzoyl group.[87]



M = Si, Ge; R = Me, Me_3Si.

b) Reactions with electrophiles

The *N*-benzoylcarbodiimide (LXIV) reacts with benzoic acid in conventional manner[4] to give the *N,N*-dibenzoylurea (LXV), which undergoes subsequent cleavage to give the imide (LXVI) and tert-butyl isocyanate.[14]

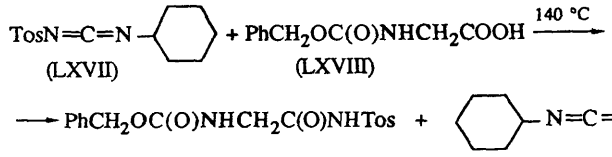


(LXIV) (LXV)

$\longrightarrow [PhC(O)]_2NH + Bu^tN{=}C{=}O$.

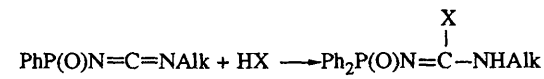
(LXVI)

The *N*-tosylcarbodiimide (LXVII) reacts similarly with *N*-carbobenzoxyglycine (LXVIII).[38]



(LXVII) (LXVIII)

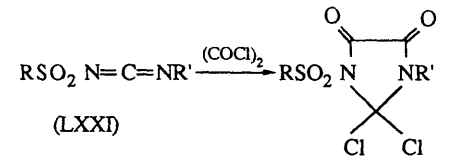
N-Phosphorylated carbodiimides (LXIX) react with inorganic acids by adduct formation across the C=N bond.[88]



(LXIX) (LXX)

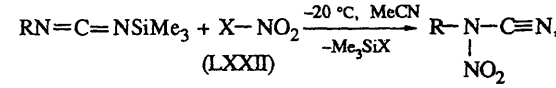
X = Cl, CN .

N-Sulphonylcarbodiimides (LXXI) are slowly acylated with oxalyl chloride, but do not react with phosgene because of the decrease in basicity of the nitrogen atoms of the carbodiimide group.[35,53]



(LXXI)

The reaction of *N*-acyl- or *N*-sulphonyl-carbodiimides with neutral nitrating agents (LXXII) proceeds by cleavage of the Si—N bond rather than by addition across the carbodiimide residue.[22]



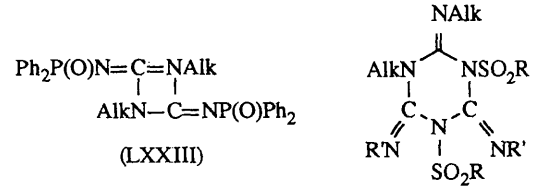
(LXXII)

R = MeOC(O); X—NO_2 = N_2O_5, $(NO_2)_2SiF_6$; R = $MeSO_2$;

X—NO_2 = $(NO_2)_2SiF_6$.

c) Cycloaddition

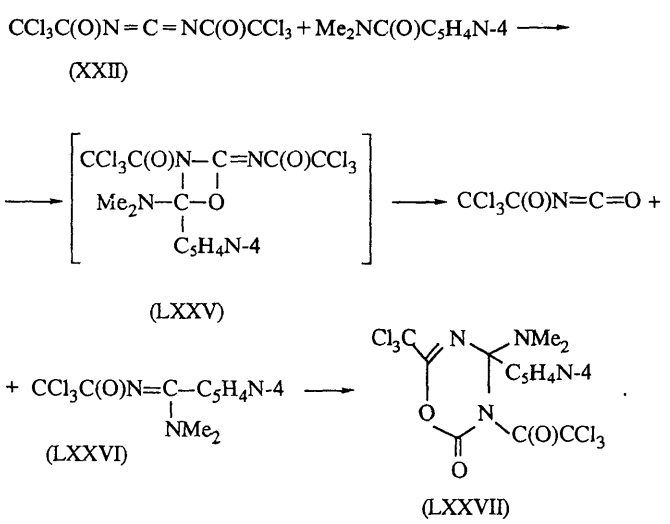
N-Phosphorylated carbodiimides readily dimerise by [2+2]-cycloaddition to give the diazetidines (LXXIII).[88] However, *N*-sulphonylcarbodiimides react with dialkylcarbodiimides to give [2+2+2]-cycloadducts (LXXIV).[49]



(LXXIII) (LXXIV)

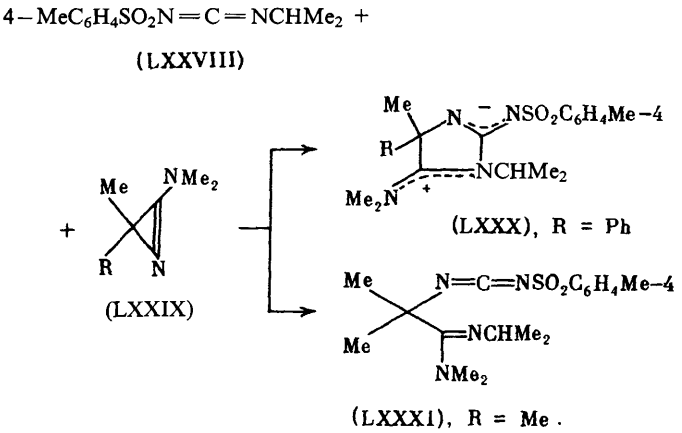
The reaction of bis(trichloroacetyl)carbodiimide (XXII) with *N,N'*-dimethylisonicotinamide leads initially to the adduct (LXXV), which undergoes fragmentation to give trichloroacetyl isocyanate

and the amidine (LXXVI). The latter reacts subsequently to give the oxadiazine (LXXVII).[28]



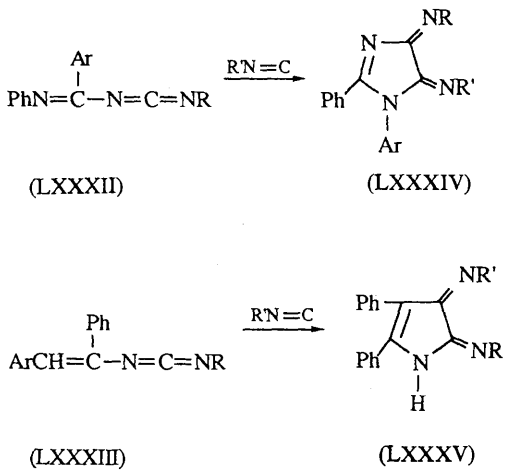
(XXII) (LXXV) (LXXVI) (LXXVII)

The reaction of the *N*-sulphonylcarbodiimide (LXXVIII) with azirine (LXXIX) proceeds by an initial [2+2]-cycloaddition, after which the resulting[2+2]-adduct is converted either to a zwitterionic imidazoline (LXXX) or to a carbodiimide (LXXXI), depending on the nature of the R group on the azirine ring.[89]



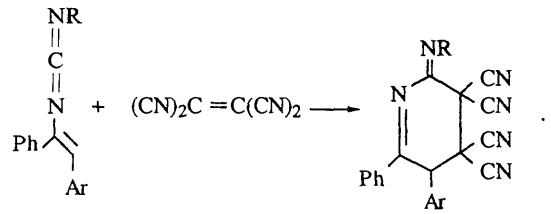
(LXXVIII) (LXXIX) (LXXX), R = Ph (LXXXI), R = Me.

Cycloaddition is particularly favourable with *N*-acyl derivatives, their analogues, and with *N*-alkenyl derivatives which are prone to undergo 1,4-dipole formation. Such compounds are notably of value in the synthesis of various types of heterocycle. Thus, imidoylcarbodiimides (LXXXII) and *N*-alkenylcarbodiimides (LXXXIII) form cycloadducts with isonitriles, namely the respective 4,5-diiminoimidazolines (LXXXIV) and 2,5-diiminopyrrolines (LXXXV).[74]



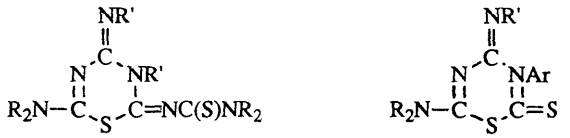
(LXXXII) (LXXXIV) (LXXXIII) (LXXXV)

The interaction of carbodiimides (LXXXIII) with tetracyanoethylene proceeds by [4+2]-cycloaddition to give the tetrahydropyridines (LXXXVI).[72]



(LXXXIII) (LXXXVI)

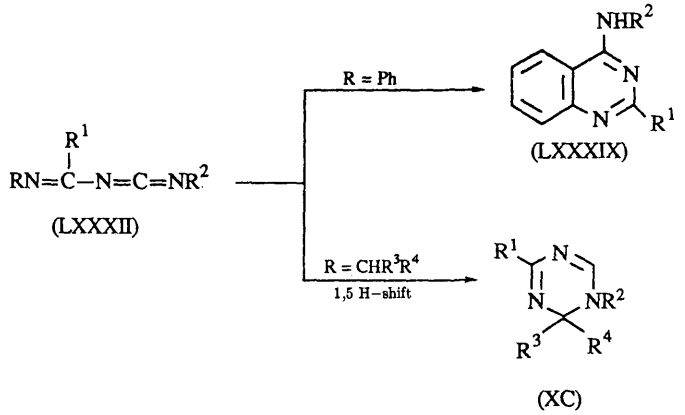
Similarly, dimerisation of *N*-thiocarbamoylcarbodiimides, and reaction of the latter with isothiocyanates, leads to the respective thiadiazines (LXXXVII) and (LXXXVIII).[10]



(LXXXVII) (LXXXVIII)

Recently there has been much interest in the spontaneous intramolecular heterocyclisation of imidoylcarbodiimides (LXXXII).[31] These react with participation of phenyl or alkyl substituent on the

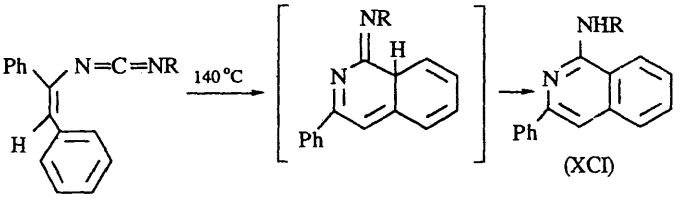
imidoyl nitrogen to give 4-aminoquinazolines (LXXXIX) or dihydro-1,3,5-triazines (XC).



(LXXXII) (LXXXIX) (XC)

R^1 = Ar; R^2, R^3, R^4 = Alk, Ar.

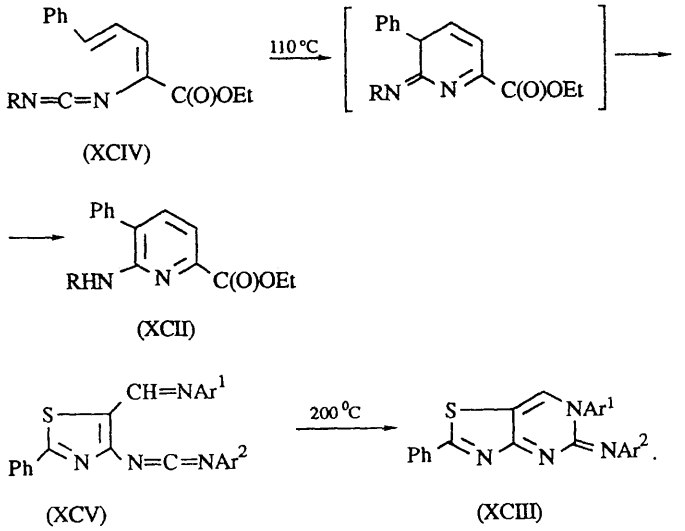
N-Alkenylcarbodiimides (LXXXIII) undergo a similar cyclisation to give substituted quinolines (XCI), but only on heating in xylene.[72]



(LXXXIII) (XCI)

R = Alk, Ar.

The pyridine (XCII) and pyrimidine derivatives (XCIII) have been prepared by a novel route based on the electrocyclisation of carbodiimides (XCIV) and (XCV), respectively.[77,79,82]



(XCIV) (XCII) (XCV) (XCIII)

A recently published review makes reference to a similar type of heterocyclisation based on the intermediate formation of *N*-heteroarylcarbodiimides possessing an alkenyl group on the heterocyclic ring.[90]

From the present review, it is evident that *N*-functionalised carbodiimides possess quite novel properties, as distinct from those of unfunctionalised carbodiimides. The potential for the development of new routes to a variety of acyclic and heterocyclic compounds is clear to see.

Reactions of phosphorus-containing compounds with diazo-compounds and carbenes

B A Khaskin, O D Molodova, N A Torgasheva
All-Union Institute of Chemical Plant Protecting Agents, Moscow

ABSTRACT. The reactions of various phosphorus-containing systems with diazo-compounds and carbenes are presented for the first time in a general form and a systematic account is given of literature data on the reactivities of phosphorus-containing acids, salts, esters, amides, sulphenamides, phosphorus acid sulphenyl halides, phosphorus halides, and derivatives of mono-, di-, and tri-coordinate phosphorus in reactions with diazo-compounds and carbenes.

The differences between the reactivities of diazo-compounds and carbenes in relation to the above groups of organophosphorus compounds are demonstrated.

The bibliography includes 244 references.

I. Introduction

The advances in the study of the reactivities of phosphorus-containing compounds in relation to diazo-compounds and carbenes are considered in the present review. These studies play an important role both in the synthetic and theoretical chemistry of organophosphorus compounds.

The beginning of studies on the reactions of diazo-compounds with phosphorus-containing systems dates back to the second decade of the present century. Systematic investigation of the reactions of phosphorus-containing compounds with carbenes developed in the last 30 years.

Extensive data have now accumulated on this problem and a number of special reviews have been published in both Russian and foreign literature on individual aspects of the interaction of certain phosphorus-containing compounds with diazo-compounds and carbenes, especially on the dual reactivity of phosphoromonothioic, phosphoromonoselenoic, and phosphoroselenothioic acids,[1] the reactions of phosphorus-containing polysulphides,[2] the 1,3-dipolar cycloaddition reactions,[3–5] and the reactions of α-ketophosphoryl compounds.[6]

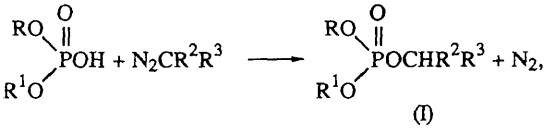
The reactions of different phosphorus-containing systems with diazo-compounds and carbenes are presented in the present review for the first time in a general form and a systematic account is given of literature data on the reactivities of phosphorus-containing acids, salts, esters, amides, sulphenamides, phosphorus acid sulphenyl halides, phosphorus halides, and derivatives of mono-, di-, and tri-coordinate phosphorus in reactions with diazo-compounds and carbenes. Studies concerned with the reactivities of phosphorus-containing diazo-compounds and carbenes are not considered in the review.

II. Phosphorus-containing acids, salts, esters, amides, sulphenamides, phosphorus acid sulphenyl halides, phosphorus halides, and phosphorus-containing polysulphides in reactions with diazo-compounds and carbenes

1. Interaction of phosphoric, phosphonic, phosphinic, and phosphorous acids and their esters with diazo-compounds

The reactions of organophosphorus acids and their esters, containing P–O–H bonds, with diazo-compounds proceed as a rule with evolution of nitrogen and the insertion of a methylene or substituted methylene group in the O–H bond.

Thus in the reactions with diazo-compounds dialkylphosphoric acids form phosphates (I),[7–9] while hypophosphorous acid forms *O*-alkyl esters (II).[10] Even in the presence of a large excess of diazoalkane further reaction does not occur, i.e. there is no insertion in a P–H bond of the ester (II):



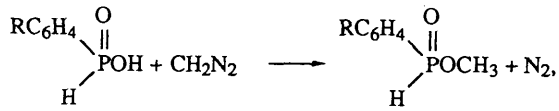
(I)

R = H, Alk(C_1 — C_4), $CH_2C_6H_5$, $(CH_2)_{17}CH_3$;
R^1 = Alk(C_1 — C_4), $(CH_2)_3Br$,
$(CH_2)_{18}CH_3$, $CH_2C_6H_5$; $R^2 = R^3 = C_6H_5$;
$R^3 = C_6H_5$, $R^3 = C(O)C_6H_5$; R^2 = H,
$R^3 = C(O)(CH_2)_{18}CH_3$,

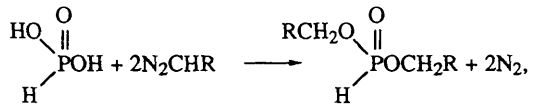
(II)

$R^1 = H, CH_3$.

Arylphosphinic acids[11] and phosphorous acid[12,13] react similarly:

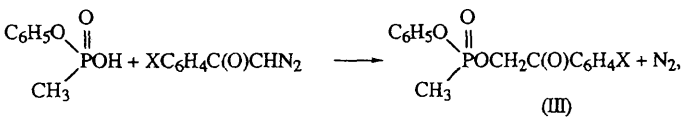


$R = H$, 3-Cl, 3-Br.



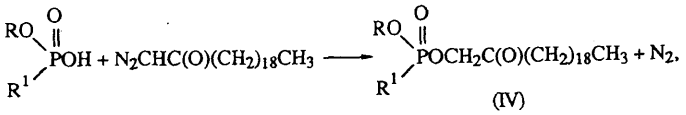
$R = CH_3, C(O)C_2H_5$.

The synthesis of the phosphonates (III) and (IV) by the reaction of phenoxymethylphosphonic acid with aromatic diazoketones and of alkyl(chloroalkyl)phosphonic acid esters with higher alkyl homologues of diazoacetone has been described:[9,14]



(III)

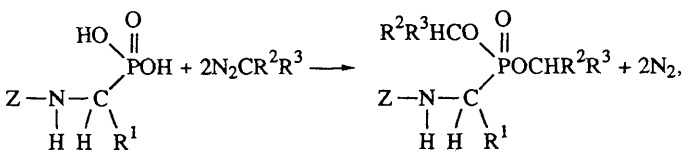
X = H, 4-Cl, 4-CH_3O, 4-NO_2, 4-CH_3, 2-CH_3, 3,5-NO_2,



(IV)

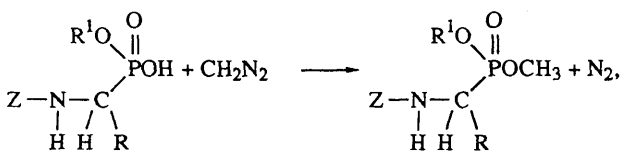
R = H, $(CH_2)_{17}CH_3$, $CH_2C_6H_5$; $R^1 = CH_3$, CH_2CH_2Cl, CH_2Cl.

The phosphonates (V) and (VI) have been obtained from *N*-acylated 1-aminoalkylphosphonic acid or its ester with diazomethane and diphenyldiazomethane:[15–17]



(V)

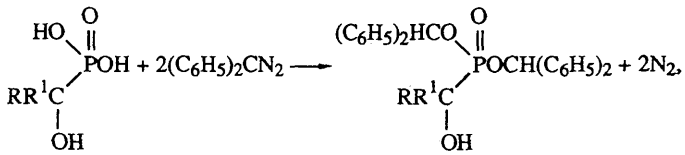
$R^1 = H$, Alk; $R^2 = R^3 = H, C_6H_5$,



(VI)

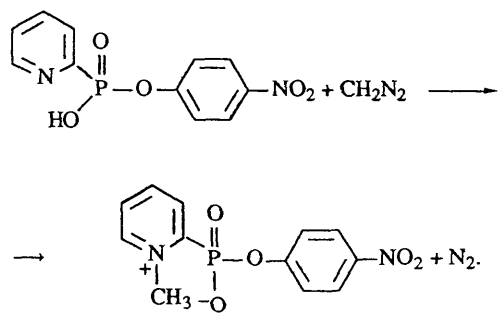
$R = R^1 = H$, Alk, C_6H_5; Z = $CH_3C(O)$, $C_6H_5CH(OH)C(O)$, $CH_3C_6H_4SO_2$, $(CH_3)_3COC(O)$, $C_6H_5CH_2OC(O)$.

The reactions of hydroxyalkylphosphonic acids with diphenyldiazomethane involve the insertion of the diphenylmethylene group only in the acid OH groups:[18]

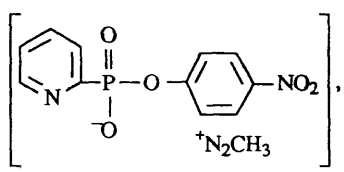


$R = R^1 = Alk, C_6H_5$.

In this connection, it is of interest to note a study[19] where it was shown that the interaction of 4-nitrophenyl-2-pyridylphosphonic acid with diazomethane proceeds selectively with formation of the *N*-methyl derivative:



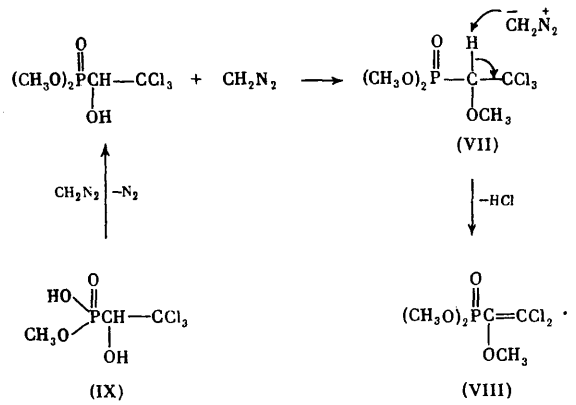
The authors attribute the formation of this product to alkylation by diazomethane at the nitrogen atom via the intermediate formation of the ion pair



where the phosphonate anion is a weaker nucleophile than the pyridinium nitrogen in relation to the methanediazonium cation.

The dimethyl ester of 2,2,2-trichloro-1-hydroxyethylphosphonic acid is methylated by diazomethane at the alcoholic OH group, which has been attributed to the strong electron-accepting influence of the trichloromethyl group, with formation of the dimethyl ester of 2,2,2-trichloro-1-methoxyethylphosphonic acid (VII), the excess diazomethane playing the role of a dehydrochlorinating agent, which leads to the formation of the ester (VIII). The latter has been

obtained also by treating methyl 2,2,2-trichloro-1-hydroxyethylphosphonate (IX) with an excess of diazomethane:[20]

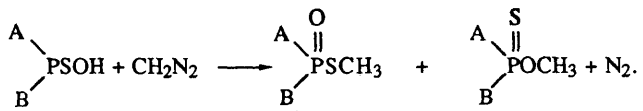


(IX) (VIII)

2. Phosphoromonothioic, phosphoromonoselenoic, and phosphoroselenothioic acids in reactions involving alkylation by diazo-compounds

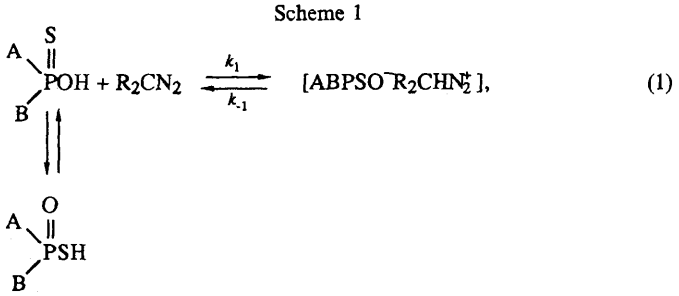
Phosphoromonothioic, phosphoromonoselenoic, and phosphoroselenothioic acids are typical substances involved in triad tautomerism and are therefore convenient objects for the study of the dual reactivities of ambident anions. Their reactions with diazocompounds have been studied by Mastryukova and Kabachnik[21–35] and have been described in detail in a review.[1] Here we shall confine ourselves to the considerations of general information about the results of such investigations.

The study of the reactions of phosphoromonothioic acids with diazomethane showed that alkylation proceeds with the preferential formation of *S*-methyl esters of phosphorothioic acids in 81–95% yield:[22]



The reaction mechanism is presented in Scheme 1 below:[1,21,22]

Scheme 1



$$[ABPSO^-R_2CHN_2^+] \xrightarrow{k_2} [ABPSO^-R_2CH^+] + N_2, \quad (2)$$

$$[ABPSO^-R_2CHN_2^+] \xrightarrow{k_3} ABP(O)SCHR_2 + N_2, \quad (3)$$

$$[ABPSO^-R_2CHN_2^+] \xrightarrow{k_3'} ABP(S)OCHR_2 + N_2, \quad (4)$$

$$[ABPSO^-R_2CH^+] \xrightarrow{k_4} ABP(S)OCHR_2, \quad (5)$$

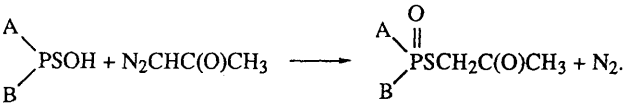
$$[ABPSO^-R_2CH^+] \xrightarrow{k_4'} ABP(O)SCHR_2. \quad (6)$$

In the reversible reaction of phosphorothioic acid with diazomethane [Eqn. (1)], the methanediazonium cation, behaving as the counterion in the ion pair formed, interacts as the attacking electrophile with the ambident anion via a reaction of the S_N2 type [reactions (3) and (4)] or a methyl cation is generated via a reaction of the S_N1 type [reaction (2)], recombining rapidly with the anion [reactions (5) and (6) in Scheme 1].

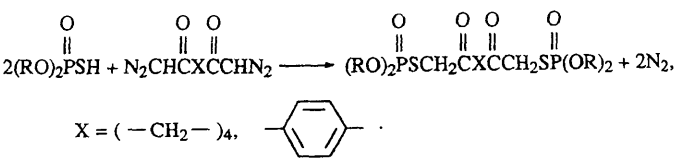
In conformity with the mechanism involving two types of reactions of phosphorothioic acids with diazomethane, it was postulated that the methanediazonium cation attacks only the sulphur atom as the most nucleophilic atom of the triad (S_N2), while the methyl cation attacks the oxygen atom in the same triad (S_N1). Evidently the yields of the *S*- and *O*-methyl derivatives depend on the nucleophilicity of the sulphur end of the triad, which is determined by the electron-accepting properties of the substituents at the phosphorus atom and by the relative rate of decomposition of the diazonium cation within the ion pair, which depends both on the polarity of the solvent and on the stability of the carbonium ion formed.[1,21,22]

The established features of the dual reactivity of phosphorothioic acids were confirmed and subsequently elaborated in reactions of phosphorothioic acids and cyclic phosphorothioic, phosphoroselenoic, and phosphoroselenothioic acids with other diazocompounds.[1,21,23–27]

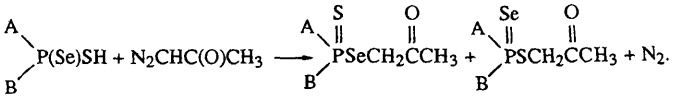
Thus primary diazoketones, in particular diazoacetone, give rise exclusively to the *S*-thiol ester in their reactions with phosphorothioic acids,[30,32] which has been attributed to the high reactivity of the diazonium cation:



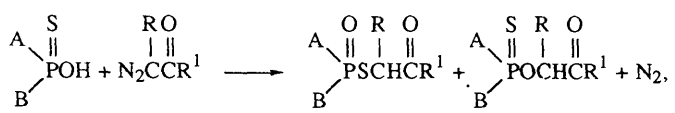
It has been shown recently that, similarly to their reactions with diazoacetone, phosphorothioic acids readily interact with bisdiazoketones: 1,8-bisdiazooctane-2,7-dione and 1,4-bis(diazoacetyl)benzene, affording thiol derivatives of bisphosphorylated products of insertion in the S–H bond of phosphorothioic acids:[39]



Phosphoroselenothioic acids react with diazoacetone to form both Se- and S-isomers, since both ends of the ambident triad are highly nucleophilic:[25]



Diazoacetic ester and a secondary diazoketone (α-phenylbenzoyldiazomethane) react with phosphorothioic acids to form both isomers. The presence of a large amount of the thionic esters (X) was attributed by the authors to some increase in the stability of the corresponding carbonium ions:[30,33]



R =H, $R^1 = OC_2H_5$; $R = R^1 = C_6H_5$.

The results of kinetic studies on the reactivities of five- and six-membered cyclic phosphorothioic acids in reactions with diphenyldiazomethane, obtained by Pudovik and co-workers,[36–38] are consistent with data for the reactions of phosphorothioic acids with diphenyldiazomethane.[26]

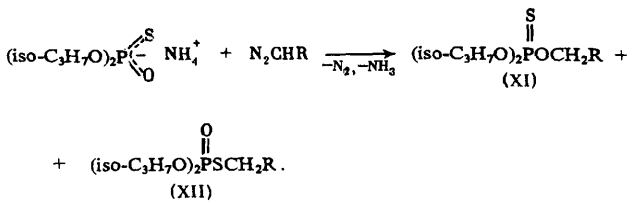
Thus the study of the alkylation of organophosphorus acids with diazo-compounds has made a major contribution to investigations of problems of the dual reactivities of both phosphorothioic and phosphoroselenoic acids themselves and the problem of dual reactivity as a whole.

3. Salts of phosphoromonothioic and phosphorodithioic acids in reactions with diazo-compounds and dihalocarbenes

Among different factors influencing the dual reactivity of ambident anions (polarisation, polarisability, the nature of the attacking agent, and the nature of the bond), the question of the influence of the metal and ammonium cations in ambident phosphorus systems has not so far been considered in the literature.

Khaskin et al.[40] was the first to investigate the dual reactivity of phosphorothioic salts in reactions involving alkylation and acylation by diazomethane, diazoacetone, and diazoacetophenone. It was established that alkali metal salts of phosphorothioic acids and a quaternary ammonium salt of phosphoric acid do not react with diazo-compounds in polar and non-polar solvents.

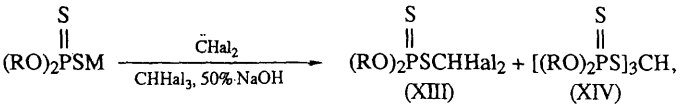
In contrast to this, the ammonium salts of phosphorothioic acids react with diazomethane to form a mixture of thione–thiol esters (XI) and (XII), the yield of the *O*-isomer (XI) increasing with increase in the dielectric constant of the solvent, while the reactions with diazoacetone and diazoacetophenone in both polar and weakly polar solvents afford exclusively the *S*-isomer (XII) with R = $C(O)CH_3$ or $C(O)C_6H_5$, since the formation of an acyl or an arylacyl carbonium ion is unfavourable because of energy factors:[30]



The reaction mechanism under discussion[40] agrees well with the mechanism proposed previously by Mastryukova and Kabachnik for phosphoromonothioic acids (see above).

Dihalocarbenes, generated by the alkaline hydrolysis of haloforms, behave differently in relation to salts of phosphorothioic and phosphorodithioic acids.

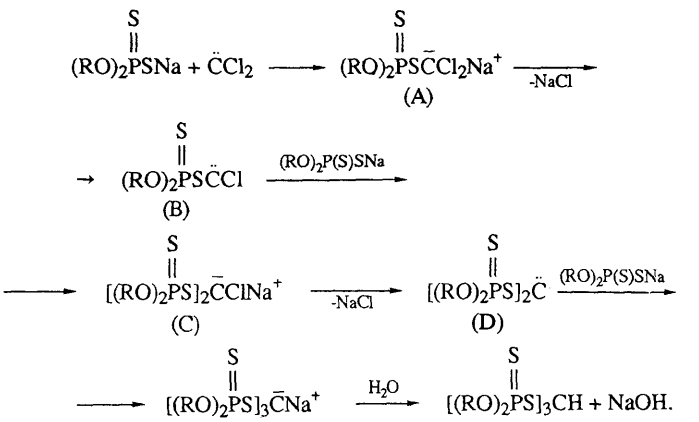
Thus alkali metal salts of phosphorodithioic acids form *O,O*-dialkyl *S*-dihalomethyl phosphorodithioates (XIII) in 20–70% yield as the main product and tris(*O,O*-dialkylthiophosphoryl-thio)methanes (XIV) in 5–20% yields as the side product:[41,42]



M = Na, K; Hal = Cl, Br.

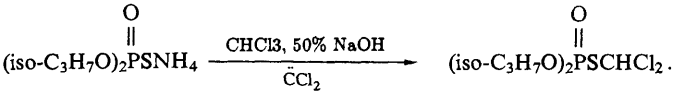
The formation of compound (XIII) is represented as the result of the electrophilic attack by the dihalocarbene in the singlet state, formed at the interface,[43–46] on the sulphur atom in the molecule of phosphorodithioic acid to form an ion pair, which subsequently reacts with water:

Since *O,O*-dialkyl *S*-dihalomethyl phosphorodithioates (XIII) do not react with the initial phosphorodithioic acid salts, the formation of compound (XIV) is represented as the result of the successive generation in the course of the reaction of unstable monothio- and dithio-derivatives of phosphorus-containing carbenes (B) and (D) via the intermediate formation of the ion pairs (A) and (C):



Similar products (XIII) and (XIV) were obtained from *O,O*-dialkylphosphorodithioic acids and bis(dialkoxythiophosphoryl) disulphides also under the conditions of the alkaline hydrolysis of haloforms, where a salt of the phosphorodithioic acid is formed initially.

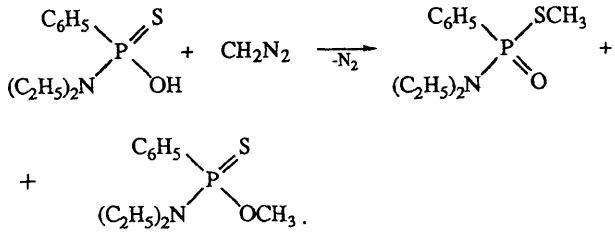
The attempt to extend this reaction to the salts of *O,O*-dialkylphosphorothioic acids and bis(dialkoxyphosphoryl) disulphides was unsuccessful. Only *O,O*-diisopropyl *S*-dichloromethyl phosphate was obtained by this procedure from the ammonium salt of *O,O*-diisopropylphosphorothioic acid in a yield of only about 2% as a consequence of the rapid hydrolysis of the final products:[42]



4. Reactions of the amides of phosphoric, phosphorothioic, phosphonothioic, and phosphinothioic acids and phosphoric acid sulphenamides with diazo-compounds

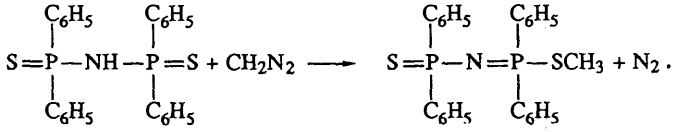
Dual reactivity is also manifested by the amides of phosphorus thio-acids when they are alkylated by diazo-compounds.[47–54]

The reaction of the diethylamide of phenylphosphonothioic acid with diazomethane involves the formation of both the *S*- and *O*-methyl esters of *N*,*N*-diethylphenylphosphonamidothioic acid:[47]

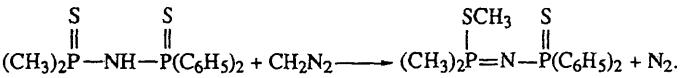


The dimethylamides of cyclohexylphosphonothioic and cyclohexylmorpholinophosphonothioic acids react similarly.[47]

In their study of the methylation of tetraphenyldiphosphinamidothioic acid, Schmidpeter and Groeger[48] established the exclusive formation of the product of alkylation at the sulphur atom — *S*-methyl tetraphenyldiphosphinimidothioate:

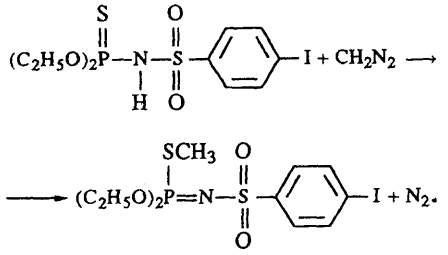


In the case of dimethyldiphenyldiphosphinamidodithioic acid, *S*-methylation with diazomethane takes place at the thiophosphoryl group linked to the methyl substituents:[49]

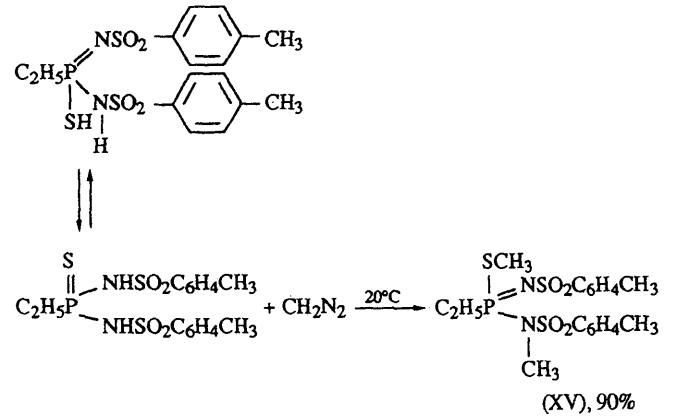


The formation of thiol imidoesters was detected similarly from the shift of the bond vibration band in the IR spectra in the reactions of phosphinothioic acid amides with diazomethane:[50]

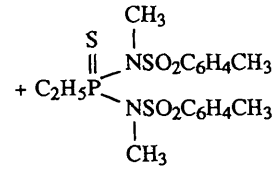
The *S*-methyl ester was also isolated as the main product in the methylation of *O*,*O*-diethyl *N*-(*p*-iodobenzenesulphonyl)phosphoramidothioate:[51]



In contrast to the reactions of phosphorus thio-acid amides presented above, the interaction of ethylphosphonothioic acid bis(*p*-methylbenzenesulphonamide) with diazomethane involves alkylation at both the sulphur and nitrogen atoms. The high yield of the *S*-methyl derivative (XV) together with the insignificant amount of the *N*-methyl derivative (XVI) are associated with the fact that the phosphonothioic acid diamide exists predominantly in the tautomeric imidothiol form:[52]

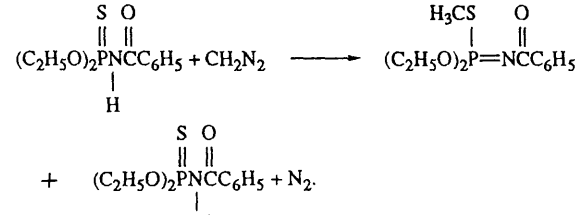


(XV), 90%

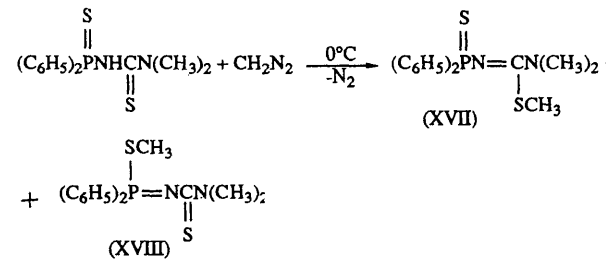


(XVI), 4%.

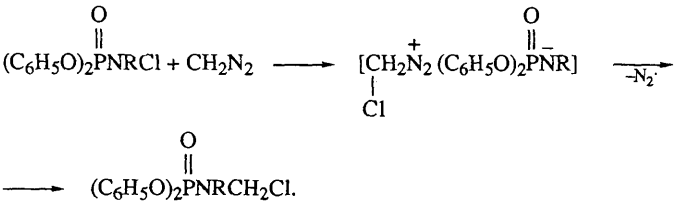
The reaction of *O*,*O*-diethyl *N*-benzoylphosphoramidothioate with diazomethane gives rise to yields of the *S*- and *N*-methyl derivatives in proportions of 5 : 1:[53]



The methylation with diazomethane of the *N*-dimethylthioureide of diphenylphosphinothioic acid takes place to the extent of 74% at the thiocarbonyl group with formation of *S*-methyl diphenylphosphinoisothioureidothioate (XVII) and to the extent of 26% at the thiophosphoryl group with formation of *S*-methyl diphenylphosphino(*N*-dimethylthiocarbamoylimido)thioate (XVIII):[54]

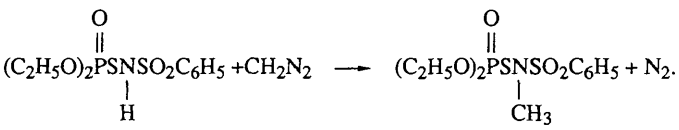


In contrast to the phosphorus thio-acid amides, the amides and sulphenamides of phosphoric acid are not methylated by diazomethane at the oxygen atom of the phosphoryl group. Thus *N*-chloromethylphosphoramidate was obtained from *N*-chlorophosphoramidate, its formation being represented as a result of the formal insertion of the methylene group in the N–Cl bond:[55]



R = Alk, $CH_2C_6H_5$.

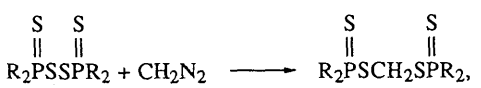
We are aware of only one study of the reactivity of the sulphenamides of phosphorus acids, described in the literature, in which it was shown that the aryl-substituted sulphenamide of diethylphosphoric acid affords the product of the methylation at the nitrogen atom on interaction with diazomethane:[56]



5. Interaction of phosphorus-containing polysulphides, sulphenyl halides of phosphorus acids, and phosphorus halides with diazo-compounds and carbenes

The interaction of phosphorus-containing polysulphides with diazo-compounds and carbenes has been studied only in recent years.[57–69] The review published previously[2] is supplemented here with new experimental data on the reactivities of phosphorus-containing polysulphides and sulphenyl halides of phosphorus acids.

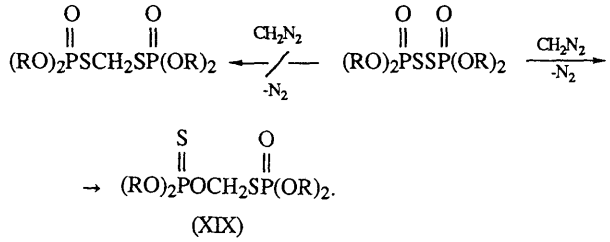
Thus symmetrical bis(dialkoxythiophosphoryl) and bis(diarylthiophosphoryl) disulphides react with diazomethane to form the products of the insertion of methylene in the S–S bond of the disulphides:[57,58]



R = AlkO, Ar.

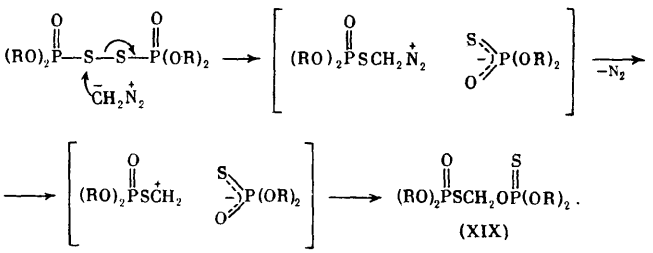
Similar products resulting from the insertion in the S–S bond are formed from aromatic disulphides by reaction with the Simmons-Smith reagent (ICH_2ZnI) and with carboxylic diazoacid esters.[70,71]

It is of interest that, in contrast to bis(dialkoxythiophosphoryl) and bis(diarylthiophosphoryl) disulphides, bis(dialkoxyphosphoryl) disulphides never form products of the insertion of the methylene group in the S–S bond on reaction with an excess of diazomethane in ethereal solution under various conditions (radiation with light from a mercury lamp, in daylight, or in the dark); this reaction leads to the formation, as a result of the phosphoryl–thiophosphoryl rearrangement, of products with an asymmetric structure, namely dialkoxythiophosphoryloxy(dialkoxyphosphorylthio)methanes (XIX):[59,60]

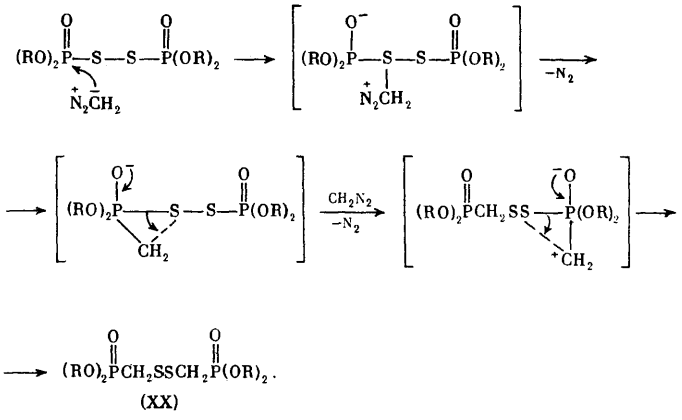


It has been suggested that, at least in the absence of illumination, bis(dialkoxyphosphoryl) disulphides interact with the undissociated diazomethane molecule. In the dark, the reaction is not restricted to the phosphoryl–thiophosphoryl rearrangement but is accompanied by the formation of the product of the insertion of two methylene groups in both P–S bonds of the disulphide with retention of the S–S bond and of the symmetry of the structure of compound (XX).[60] The formation of the products of the phosphoryl–thiophosphoryl rearrangement [compound (XIX)] and of insertion in the P–S bond [compound (XX)] is illustrated by Schemes 2 and 3 respectively:[59,60]

Scheme 2

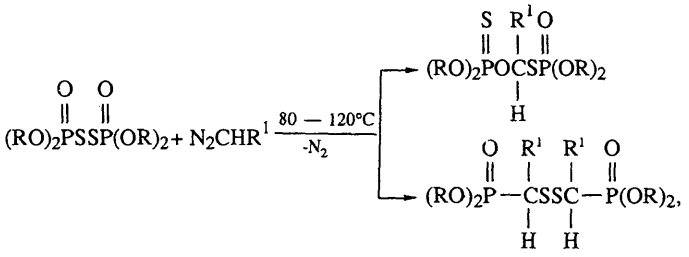


Scheme 3



The reactions of bis(dialkoxyphosphoryl) disulphides with diazoacetic ester and diazoacetone proceed similarly, with formation of the products of the phosphoryl–thiophosphoryl rearrangement

and of insertion in the P–S bond, under conditions which do not promote the formation of the corresponding carbenes:[60,61]

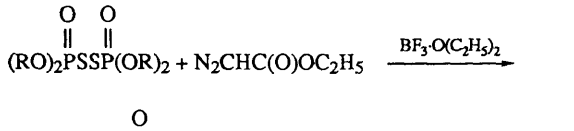


$R^1 = C(O)OC_2H_5$, $C(O)CH_3$.

The two competing reactions proceed at different rates, so that, depending on the reaction conditions, there is a possibility of the formation of one of the reaction products separately or of their mixtures in different proportions.

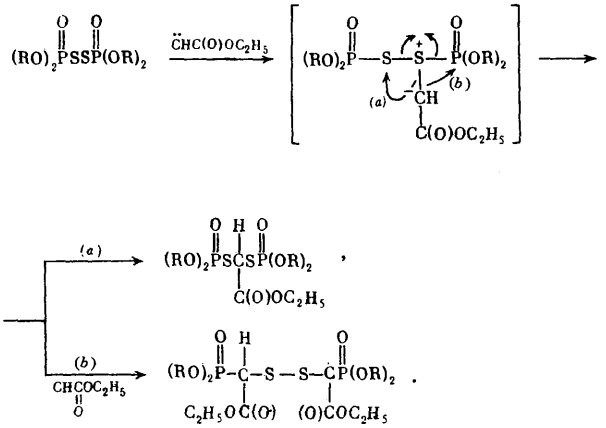
The reaction leads to different results under the conditions of the catalytic generation of ethoxycarbonylcarbene.

Thus the reaction of bis(dialkoxyphosphoryl) disulphides with diazoacetic ester in the presence of catalytic amounts of boron trifluoride etherate results in the formation, even at −20–8 °C, of bis(dialkoxyphosphoryl)ethoxycarbonylmethanes — the products of the insertion of ethoxycarbonylcarbene in the S–S bond:[62]



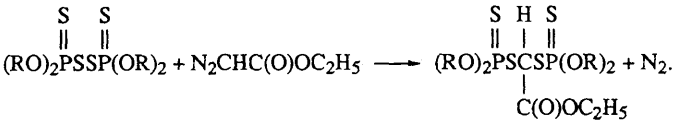
Under the conditions of the catalytic generation of ethoxycarbonylcarbene in the presence of copper powder at 80 °C in benzene or at 80–120 °C without a solvent, the reaction involving insertion in both P–S bonds competes with that leading to the formation of the products of the insertion of ethoxycarbonylcarbene in the S–S bond of the disulphide (Scheme 4):[62]

Scheme 4



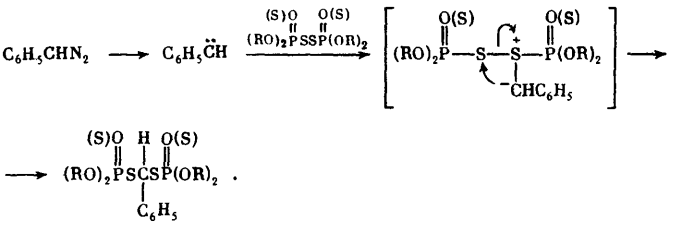
In contrast to diazoacetic ester, diazoacetone reacts with bis(dialkoxyphosphoryl) disulphides at 55–60 °C in the presence of metallic copper to form only the products of the insertion of acetylmethylene in the P–S bonds.[61]

The interaction of bis(dialkoxythiophosphoryl) disulphides with diazoacetic ester both via a non-catalytic reaction (80 °C, benzene) and under the conditions of the thermocatalytic decomposition of diazoacetic ester (Cu, 80 °C) proceeds selectively with formation of bis(dialkoxythiophosphorylthio)ethoxycarbonylmethanes only:[58]

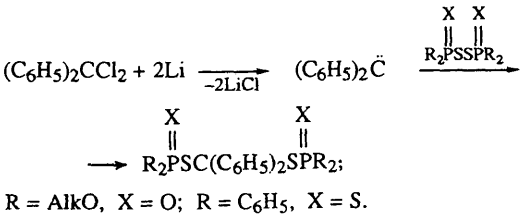


The reaction of bis(dialkoxythiophosphoryl) disulphides with diazoacetone under the conditions involving the generation of acetylcarbene (Cu, 55–60 °C) takes place with formation of the products of insertion in both S–S and P–S bonds,[61] while the reaction with benzoylcarbene afforded only the products of insertion in the S–S bond alone.[63]

It is of interest that the interaction of phenyldiazomethane with bis(dialkoxyphosphoryl) and bis(dialkoxythiophosphoryl) disulphides occurs even at room temperature and involves only the insertion of phenylmethylene in the S–S bond of the disulphide. The authors suggest that the reaction has a carbene mechanism and proceeds via an intermediate sulphonium ylid, whose conversion into the reaction products can occur as a concerted process as a result of a 1,2-sigmatropic rearrangement:[63]



In contrast to phenyldiazomethane, diphenyldiazomethane does not react with phosphorus-containing disulphides either on heating to 90 °C or under the conditions of the photolytic generation of diphenylcarbene. The interaction of bis(dialkoxyphosphoryl) and diphenylthiophosphoryl disulphides with diphenylcarbene, generated by treating dichlorodiphenylmethane with metallic lithium at 20 °C, was achieved. It afforded the products of the insertion of diphenylcarbene in the S–S bond of the disulphide:[63]



R = AlkO, X = O; R = C_6H_5, X = S.

Methylphenylcarbene, obtained from dichloro(methylphenyl)-ethane and metallic lithium, reacts with bis(diethoxythiophosphoryl) disulphide similarly to diphenylcarbene.[63]

The reaction of phosphorus-containing trisulphides and tetrasulphides with diazomethane affords the products of the phosphoryl–thiophosphoryl rearrangement:[64]

$$(RO)_2PS_nP(OR)_2 \xrightarrow[-N_2]{CH_2N_2} (RO)_2POCH_2S_{n-1}P(OR)_2 + (RO)_2POCH_2S_{n-2}CH_2OP(OR)_2;$$

$n = 3,4.$

In the reaction with diazoacetic ester, the rearrangement does not occur, but the products of the insertion of the ethoxycarbonylmethylene group in one of the P–S bonds of the polysulphide are formed in a high yield:[65]

$$(RO)_2PS_nP(OR)_2 + N_2CHC(O)OC_2H_5 \longrightarrow (RO)_2PCH(C(O)OC_2H_5)S_nP(OR)_2 + N_2;$$

$n = 3, 4.$

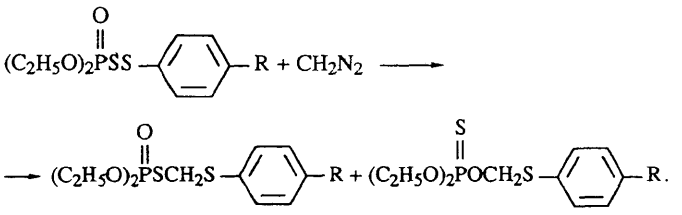
In the presence of an excess of diazoacetic ester, two ethoxycarbonylmethylene groups are inserted in the P–S bonds of polysulphides with partial desulphurisation:[65]

$$(RO)_2PS_nP(OR)_2 + N_2CHC(O)OC_2H_5 \longrightarrow \rightarrow [(RO)_2PC(H)(C(O)OC_2H_5)S]_2 + N_2 + (n-2)S;$$

$n = 3, 4.$

Reactions analogous to those described above have also been considered in relation to thiophosphoryl-substituted trisulphides and tetrasulphides.[66] The products of the insertion of the ethylene group both in one and in two disulphide bonds closest to the phosphorus atom were obtained.

In the case of phosphorus-containing disulphides with an asymmetric structure, namely aryl diethoxyphosphoryl disulphides, the insertion of the methylene group in the S–S bond has been reported, while the products of the phosphoryl-thiophosphoryl rearrangement have been obtained in an insignificant yield:[72–74]



The authors of the above studies suggest that the phosphoryl–thiophosphoryl rearrangement involves interaction with an undissociated molecule of the diazo-compound, while the insertion in the S–S bond is a reaction of the carbene type. As regards the insertion in the P–S bond, the reaction can apparently have both carbene and non-carbene mechanisms.

Thus the reactions of phosphorus-containing polysulphides with diazo-compounds make it possible to obtain organophosphorus compounds which are otherwise difficult to synthesise or were previously unknown, and lead to interesting possibilities for the investigation of carbene reactions in the chemistry of organophosphorus compounds.

Dithio- and monothio-phosphoryl groups

$$-(RO_2)PS(O)-$$

in phosphorus-containing polysulphides behave in many reactions as a pseudo-halogen.[75,76] This is confirmed by the analogous behaviour of thiophosphorylsulphenyl halides and disulphides in reactions with diazo-compounds and carbenes.

The first reports concerning the reactivity of sulphenyl halides derived from phosphorus acids in relation to diazoalkanes appeared in the 1960s. The interaction of diethoxy(thio)phosphorylsulphenyl chlorides with diazomethane and diazoethane has been described.[77,78] α-Chloro-substituted esters of phosphoromonothioic and phosphorodithioic acids were obtained:

$$(C_2H_5O)_2P(X)SCl + N_2CHR^1 \longrightarrow (C_2H_5O)_2P(X)SCH(Cl)R^1 + N_2;$$

$X = O, R = H; X = S, R = CH_3.$

Later, other investigators[79–81] studied the interaction of dialkoxy(thio)phosphorylsulphenyl halides with various diazo-compounds: diazomethane, aryl- and diaryl-diazoalkanes, diazoacetic ester, and mono- and bis-diazoketones. It was shown that the reactions of dialkoxy(thio)phosphorylsulphenyl halides with the above diazo-compounds proceed similarly to those described above, with formation of the products of the insertion of the methylene or substituted methylene group in the S–halogen bond in the sulphenyl halides:

$$(RO)_2PS(O)Hal + N_2CR^1R^2 \longrightarrow (RO)_2PS(O)CR^1R^2Hal + N_2;$$

$Hal = Cl; R^1 = H, R^2 = C(O)OC_2H_5, C_6H_5, C(O)(CH_2)_4C(O)CHN_2,$

$C(O)CH_3, C(O)C_6H_5; R^1 = R^2 = C_6H_5; Hal = Br; R = Alk; R^1 = H;$

$R^2 = C(O)OC_2H_5, C_6H_5; R^1 = R^2 = H, C_6H_5.$

However, in the reaction of dialkoxyphosphorylsulphenyl bromides with diazoacetone and diazoacetic ester, a mixture of phosphorothiolic and phosphorothionic acid esters is formed, i.e., together with the insertion of the acetyl- and ethoxycarbonylmethylene group in the S–Br bond of the sulphenyl

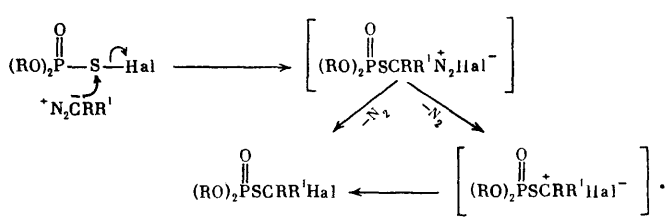
bromide, the products of the phosphoryl–thiophosphoryl rearrangement are formed:

$$(RO)_2P(O)SBr + N_2CHR^1 \longrightarrow (RO)_2P(O)SCHR^1Br + (RO)_2P(S)OCHR^1Br + N_2;$$

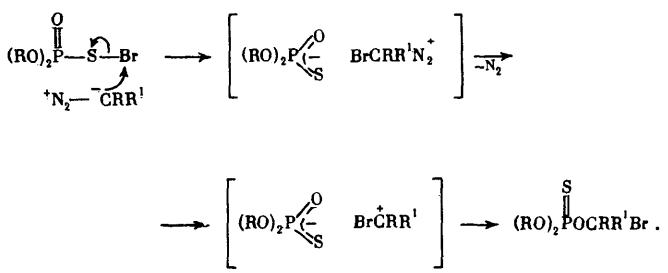
$R^1 = C(O)CH_3, C(O)OC_2H_5$.

The experimental conditions ($t = -50$ to -20 °C, absence of the catalyst or UV irradiation) enabled the authors of the above studies to reject the carbene reaction mechanism and to regard the interaction of dialkoxy(thio)phosphorylsulphenyl halides with an undissociated molecule of a diazo-compound via the intermediate formation of the diazonium cation as a result of nucleophilic attack either on the sulphur atom (Scheme 5) or on the halogen atom (Scheme 6):

Scheme 5



Scheme 6



The exclusive formation of the products of the insertion of the substituted methylene group in the S–halogen bond in the sulphenyl halides is evidence in support of Scheme 5. However, Scheme 6, involving nucleophilic attack on the bromine atom, operates in the reaction of diazoacetone and diazoacetic ester with dialkoxyphosphorylsulphenyl bromides.

As can be seen from the foregoing, the interaction of phosphoryl- and thiophosphoryl-sulphenyl halides with diazo-compounds involves mainly the insertion of the methylene or a substituted methylene group in the S–halogen bond. It is therefore of interest to examine the reactivities of phosphorus halides in relation to diazo-compounds, since this entails the insertion of the methylene group in the P–halogen bond.

Thus Yakubovich and Ginzburg[82] showed in 1952 that, under certain conditions ($t = -60$ °C), the interaction of phosphorus trichloride or tribromide with diazoalkanes proceeds smoothly with formation of haloalkyldihalophosphines:

$$PHal_3 + RCHN_2 \longrightarrow HalCHRPHal + N_2;$$

Hal = Cl, Br; R = H, CH_3.

Phosphorus pentachloride reacts with diazomethane to form tris(chloromethyl)dichlorophosphine, which is converted subsequently into tris(chloromethyl)phosphine oxide in the presence of traces of moisture:[82]

$$PCl_5 + 3CH_2N_2 \longrightarrow (ClCH_2)_3PCl_2 \xrightarrow{H_2O} (ClCH_2)_3P{=}O.$$

Phenylphosphorus tetrachloride behaves similarly:[83]

$$C_6H_5PCl_4 + 3CH_2N_2 \xrightarrow[-40°C]{} [C_6H_5P(CH_2Cl)_2Cl_2] \xrightarrow{H_2O}$$

$$\rightarrow C_6H_5P(O)(CH_2Cl)_2.$$

Phosphorus oxide chloride and phosphorus oxide bromide do not react with diazoalkanes even under the conditions involving the generation of the corresponding carbenes.[82]

III. Phosphines and phosphites in reactions with diazo-compounds and carbenes

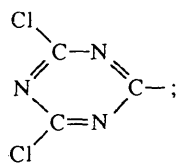
1. Reactions of acyclic trialkyl- and triaryl-phosphines and tertiary cyclic phosphines and their oxides with diazo-compounds

The reactions of trivalent phosphorus derivatives with diazo-compounds were first achieved by Staudinger and co-workers in 1919–1922 for acyclic tertiary phosphines.[84] Later, other workers greatly expanded the range of applications of this reaction.[85–91]

It has been shown in relation to acyclic tertiary phosphines that trialkyl- and triaryl-phosphines react with different acyclic diazo-compounds to form phosphazines:

$$R^1R^2R^3P + N_2CR^4R^5 \longrightarrow R^1R^2R^3P{=}N{-}N{=}CR^4R^5,$$

$R^1 = R^2 = R^3 = C_6H_5, C_2H_5, C_6H_5C_6H_4$; R^4 = H, C_6H_5, $C_6H_5C(O)$, $CH_3C(O)$, $CH_3C(O)O$, $C_2H_5OC(O)$, $CH_3OC(O)$, C_6H_5SO,

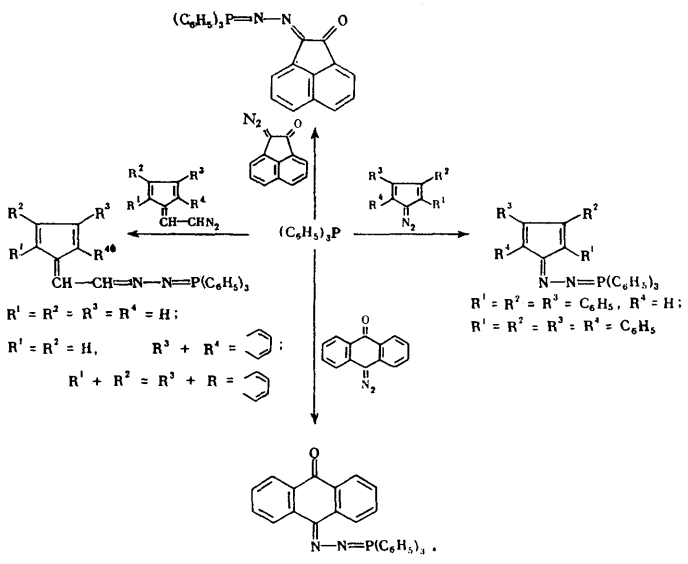


$R^5 = C_6H_5, C_2H_5OC(O), C_6H_5C(O), CH_3C(O), CH_3OC(O)$,

$C_6H_5CH{=}CHC(O)$, $C_6H_5S(O)O$.

The reactions of triphenylphosphine with cyclic diazo-compounds, namely diazoacenaphthene,[92] diazoanthrone,[93] diazoethylidene derivatives of cyclopentadiene, indene, and fluorene,[94] and

diazocyclopentadiene and its phenyl derivatives,[95,96] proceed similarly to form cyclic phosphazenes:



A kinetic study[97,98] confirmed the second order and irreversibility of the reactions of triphenylphosphines and aromatic ring-substituted triphenylphosphines with diazoalkanes and 9-diazofluorene.

It is of interest that the nature of the final product of the reactions of acyclic phosphines with diazo-compounds is influenced by the nature of the substituents at the phosphorus atom. In the presence of a mobile hydrogen atom in the phosphine molecule, phosphazines are not formed. Thus dibutoxyphosphine reacts with diphenyldiazomethane to form a mixture of the isomeric adducts (XXI) and (XXII), while the reactions with diazoacetone and diazoacetic esters afford only one adduct—the hydrazone (XXI):[99]

$$(C_4H_9O)_2PH + N_2CRR^1 \longrightarrow \underset{\text{(XXI)}}{(C_4H_9O)_2PNHN{=}CRR^1} + \underset{\text{(XXII)}}{(C_4H_9O)_2PN{=}NCHRR^1};$$

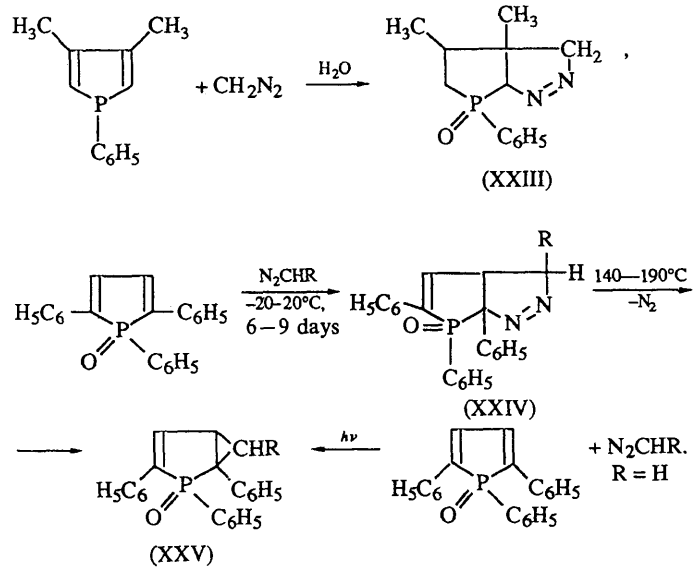
$$R = R^1 = C_6H_5;\ R = H,\ R^1 = C(O)CH_3,\ C(O)OC_2H_5.$$

In contrast to the reactions of acyclic phosphines, the reaction of an acyclic tertiary phosphine, having a mobile hydrogen atom in the α-position, with diazomethane takes place via the phosphoryl group to form a phosphorane:[100]

$$(C_6H_5)_2P(O)CH(SO_2C_6H_5)_2 + CH_2N_2 \longrightarrow (C_6H_5)_2P(OCH_3){=}C(SO_2C_6H_5)_2 + N_2.$$

The reactions of unsaturated tertiary cyclic phosphines and their oxides proceed quite differently.

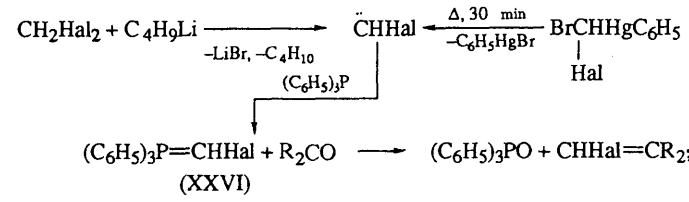
Thus the reactions of 3,4-dimethyl-1-phenylphosphole with diazomethane in the presence of water[101] and of 1,2,5-triphenylphosphole oxide with diazomethane and diazoacetic acid esters[102] proceed as 1,3-dipolar cycloaddition to one of the multiple bonds of the ring with formation of the pyrazoline derivatives (XXIII) and (XXIV) respectively. The cyclopropane derivatives (XXV) were obtained by the thermal decomposition of compound (XXIV). They are formed as a result of the photochemical reaction of 1,2,5-triphenylphosphole oxide with diazomethane:



2. Reactions of trialkyl- and triaryl-phosphines with carbenes

The reactivity of phosphines in relation to carbenes has been studied in fair detail and it has been found that trialkyl- and triarylphosphines are mild carbene trapping agents and that this reaction serves as one of the methods for the synthesis of phosphorus ylids which are used in synthetic organic chemistry for the synthesis of olefins by the Wittig reaction.[93,103–116]

Halomethylenephosphoranes (XXVI) are formed in the reaction of triphenylphosphine with chlorocarbene, generated from methylene chloride by treatment with butyllithium[103–105] or by the thermolysis of phenyl(bromohalomethyl)mercury:[106]



Hal = Cl, Br.

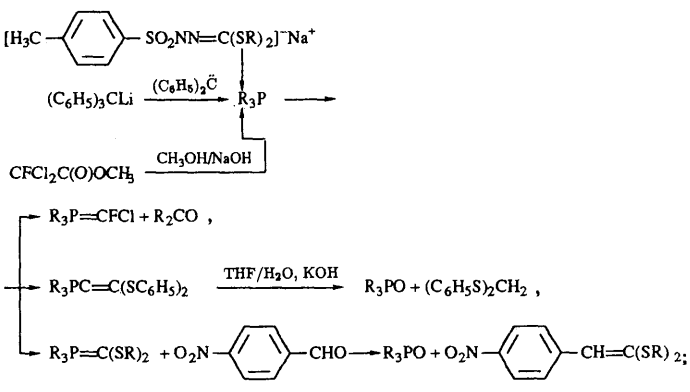
Dihalomethylenephosphoranes (XXVII, Hal = F, Cl, Br) have been obtained from trialkyl- and triaryl-phosphines and dihalocarbenes, generated from haloform by the treatment with potassium t-butoxide,[107–109] by the thermolysis of phenyl(bromodichloromethyl)mercury[110] or the sodium salt of chlorodifluoroacetic

acid,[111] or from dibromodifluoromethane by treatment with lithium butoxide:[112]

$$R_3P + \ddot{C}HHal_2 \longrightarrow \underset{(XXVII)}{R_3P{=}CHHal_2} + R_2CO \longrightarrow R_3PO + Hal_2C{=}CR_2;$$

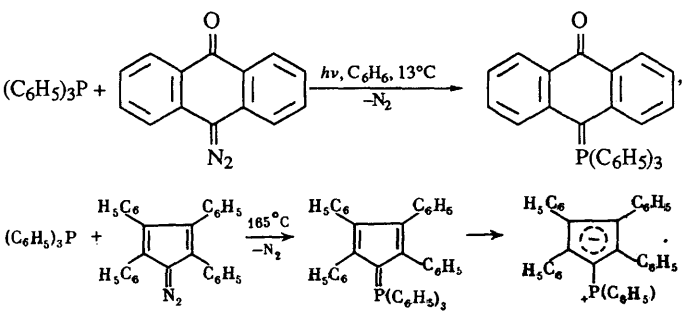
R = Alk, Ar; Hal = Cl, Br, F.

Chlorofluoromethylene, obtained from methyl dichlorofluoroacetate and sodium hydride,[109,113] bis(phenylthio)carbene, generated from tris(phenylthiomethyllithium)[114] and bis(alkylthio)carbene, generated by the thermal decomposition of the sodium salt of tosylhydrazone[115] enter into similar reactions with phosphines:



Phosphorus ylids are formed when the carbene precursor is a diazo-compound, for example, in the reaction with triphenylphosphine under the conditions of catalytic, photolytic, or thermal decomposition of the corresponding diazo-compound:[93,95,96,116]

$$(C_6H_5)_3P + CH_2N_2 \xrightarrow[-N_2]{CuCl} (C_6H_5)_3P{=}CH_2,$$



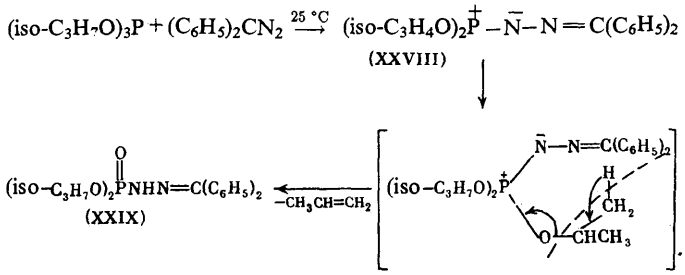
3. Phosphites in reactions with diazo-compounds and carbenes

Kabachnik and Arbuzov[13,117–119] showed that trialkyl phosphites behave similarly to phosphines in reactions with diazomethane and diazoacetic acid esters, forming trialkyl phosphate *N*-methylene- and *N*-ethoxycarbonyl-azines respectively in yields of at least 60%:

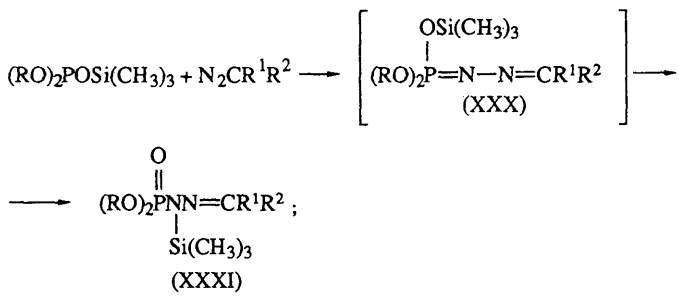
$$(RO)_3P + N_2CHR^1 \longrightarrow (RO)_3P{=}N{-}N{=}CHR^1;$$

R^1 = H, C(O)CH$_3$, C(O)OC$_2$H$_5$.

It has been observed[120] that the reaction of triisopropyl phosphite with diphenyldiazomethane does not stop at the stage involving the formation of benzophenone triisopropylphosphorazine (XXVIII). Instead, a compound with the hydrazone structure, namely diisopropyl *N*-(diphenylmethylene)phosphorohydrazidate (XXIX), is formed in 75% yield, provided that the reaction is carried out under severe conditions:



In the case of dialkyl trimethylsilyl phosphites, the intermediate phosphorazines (XXX) almost wholly isomerise already under experimental conditions with migration of the trimethylsilyl group to the phosphimine nitrogen atom and the quantitative formation of dialkyl *N*-trimethylsilylphosphorohydrazidates (XXXI):[121,122]



$R^1 = R^2$ = H, C$_6$H$_5$; R^1 = H, R^2 = C(O)CH$_3$, C(O)OCH$_3$, C(O)OC$_2$H$_5$.

Phosphorous triamides react vigorously with various acyclic and cyclic diazo-compounds similarly to trialkyl phosphites. About 60 compounds of the class of tris(dimethylamino)phosphorazines were obtained:[123–125]

$$R_3P + N_2CR^1R^2 \longrightarrow R_3P{=}N{-}N{=}CR^1R^2,$$

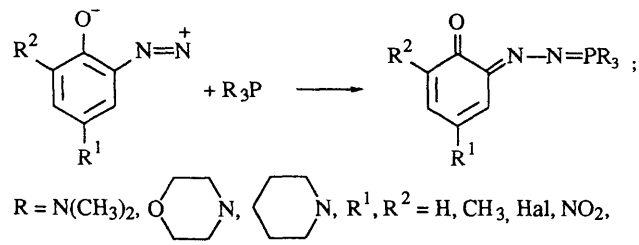
R =  ,  , (CH$_3$)$_2$N, (C$_2$H$_5$)$_2$N; $R^1 = R^2$ = H, C(O)OCH$_3$,

C(O)OC$_2$H$_5$, C$_6$H$_5$, R^1 = H, R^2 = C(O)OC$_2$H$_5$, C(O)OCH$_3$;

R^1 = C(O)CH$_3$, R^2 = C(O)C$_6$H$_5$; $R^1 + R^2$ = (CH$_3$)$_3$C(CH$_2$)$_2$CO$_2$,

o-C$_6$H$_4$(CO)$_2$.

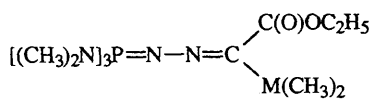
The reaction with *O*-diazoquinone and its various derivatives 4,6-disubstituted in the aromatic ring proceeds similarly:[126]



$R = N(CH_3)_2$, O, N, N, $R^1, R^2 = H, CH_3$, Hal, NO_2, $C(O)CH_3$, $C(O)OCH_3$.

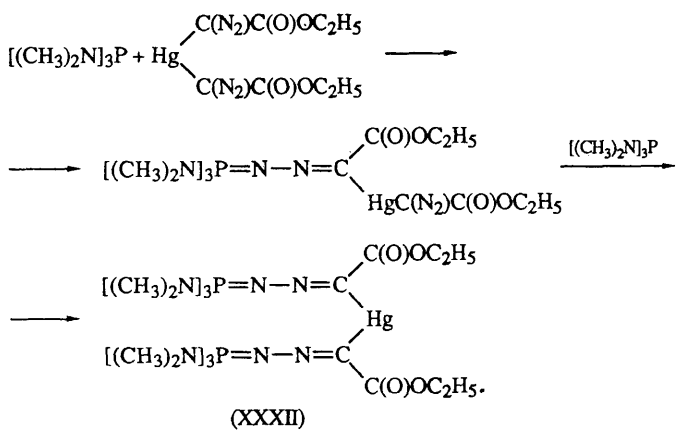
Towards the end of the 1970s, Krommes and Lorberth[124,127] investigated the reactions of phosphorous tris(dimethylamides) with a whole series of organoelement derivatives of diazomethane: $(CH_3)_nMCN_2$ [M = Si, Ge, Sn, Pb, As, Sb, Bi: n = 2, 3; R = H, $C(O)OC_2H_5$].

From the available literature data on the chemistry of organoelement diazoalkanes,[128] it was postulated that the introduction of any element into the molecule of the diazo-compound does not alter the chemical behaviour of organoelement derivatives or diazomethane in their reactions with phosphorous tris(dimethylamides). Indeed, the tris(dimethylamino)phosphorazines



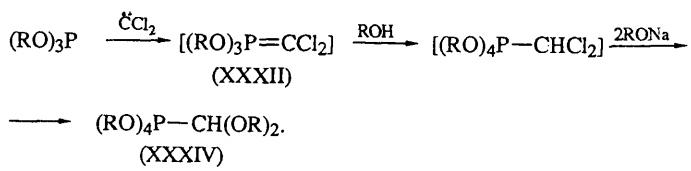
were obtained for M = As or Sb. When R = H, M = Si, Ge, or As, and n = 2 or 3, a mixture of the *cis*- and *trans*-isomers of tris(dimethylamino)phosphorazines is formed.

The interaction of phosphorous tris(dimethylamide) with bis(ethyl diazoacetate)mercury to form the tris(dimethylamino)phosphorazine (XXXII) can proceed in stages:



(XXXII)

As regards the interaction of trialkyl phosphites with carbenes, it was found that, in contrast to phosphines, trialkyl phosphites, in the presence of which dichlorocarbene is generated from chloroform and sodium alkoxide, give rise to the adducts (XXXIII), which undergo further changes and are converted into tetraalkoxy(dialkoxy-methylene)phosphoranes (XXXIV):[129]

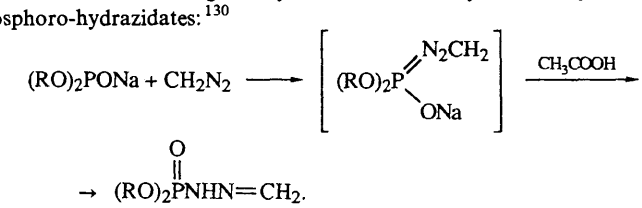


(XXXII) (XXXIV)

Thus a common feature of the reactions of phosphines and phosphites with diazo-compounds is the formation of a new phosphorus–nitrogen bond. Evidently, these reactions are based on addition to the lone pair of the phosphorus atom, probably as a result of the electrophilic attack by the terminal nitrogen atom and the conversion of the trivalent phosphorus derivative into the corresponding pentavalent phosphorus derivative.

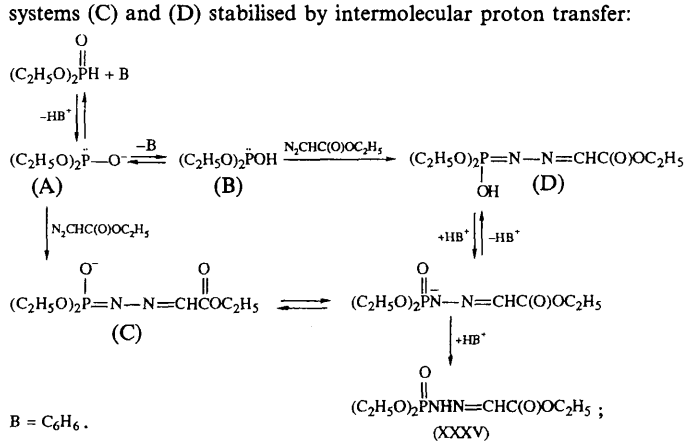
4. Dialkyl phosphites in reactions with diazo-compounds

In contrast to trialkyl- and triaryl-phosphines, trialkyl phosphites, and phosphorous triamides, dialkyl phosphites do not react with aliphatic diazo-compounds under the usual conditions. Only their sodium salts react vigorously to form dialkyl *N*-methylene-phosphoro-hydrazidates:[130]



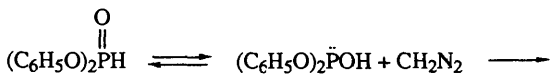
The inability of dialkyl phosphites to react with diazoalkanes has been attributed to the low acidity of dialkyl phosphites, because their tautomeric equilibrium is strongly displaced towards the form with pentavalent phosphorus[131] and the insertion of the methylene group in the P–H bond, specially investigated in relation to hypo-phosphorous acid esters, was not observed.[10]

However, the use of benzene as the solvent, which promotes the shift of the tautomeric equilibrium of diethyl phosphite towards the formation of the trivalent form (B) according to the authors,[119] leads to the interaction between the diethyl phosphite and diazoacetic ester with formation of diethyl *N*-ethoxycarbonylmethylene-phosphorohydrazidate (XXXV). A mechanism is proposed for the formation of the reaction product via the intermediate phosphazine systems (C) and (D) stabilised by intermolecular proton transfer:



B = C_6H_6.

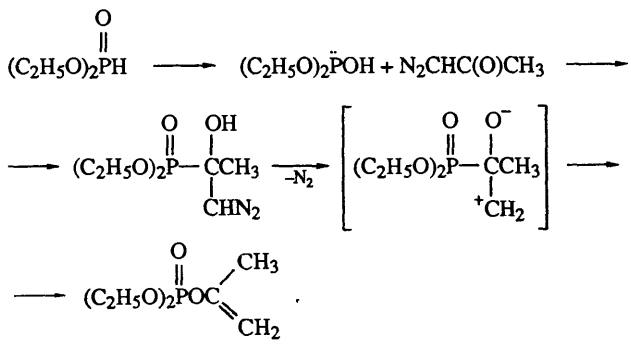
Diphenyl phosphite, which has more acid properties than diethyl phosphite, reacts with diazomethane to form methyl diphenyl phosphite due to the presence of the tautomeric equilibrium between the pentavalent and trivalent forms:[132]



$$(C_6H_5O)_2\overset{O}{\overset{\|}{P}}H \rightleftharpoons (C_6H_5O)_2\ddot{P}OH + CH_2N_2 \longrightarrow$$

$$\rightarrow (C_6H_5O)_2POCH_3 + N_2.$$

The unusual behaviour of diazoacetone in the reaction with diethyl phosphite and the formation of diethyl isopropenyl phosphate have been noted:[87,133]

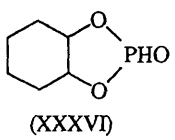


$$(C_2H_5O)_2\overset{O}{\overset{\|}{P}}H \longrightarrow (C_2H_5O)_2\ddot{P}OH + N_2CHC(O)CH_3 \longrightarrow$$

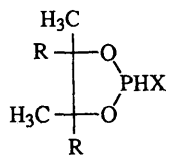
$$\longrightarrow (C_2H_5O)_2\overset{O}{\overset{\|}{P}}-\underset{CHN_2}{\overset{OH}{\overset{|}{\underset{|}{C}}}}CH_3 \xrightarrow{-N_2} \left[(C_2H_5O)_2\overset{O}{\overset{\|}{P}}-\underset{{}^{+}CH_2}{\overset{O^-}{\overset{|}{\underset{|}{C}}}}CH_3\right] \longrightarrow$$

$$\longrightarrow (C_2H_5O)_2\overset{O}{\overset{\|}{P}}OC(CH_3)=CH_2.$$

In contrast to acyclic dialkyl phosphites, the high reactivity of cyclic phosphorous acids and their sulphur and nitrogen analogues (XXXVI)–(XXXIX) in reactions with diazomethane indicates a greater shift of the tautomeric equilibrium of the acid towards the trivalent form, which is the reason for their acid properties:[134,135]

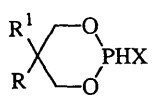


(XXXVI)



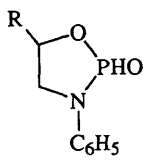
(XXXVII)

R = H, CH_3, X = O, S



(XXXVIII)

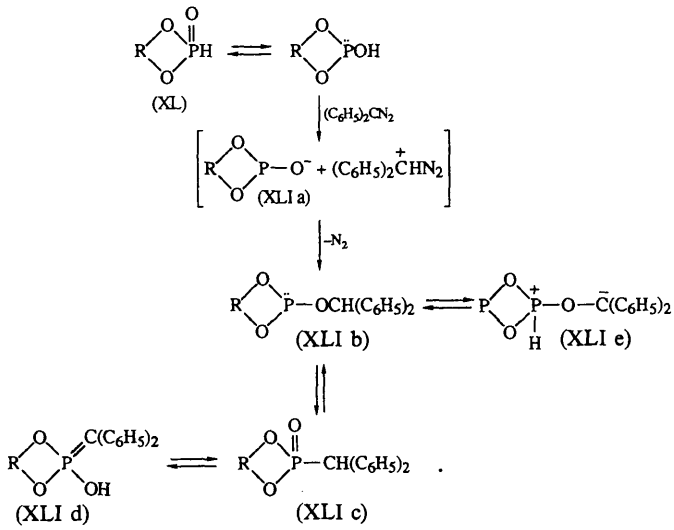
R = CH_3, R^1 = H, X = O;
R = H, R^1 = CH_3, X = S



(XXXIX)

R = H, CH_3.

Thus, when equimolar amounts of 2,3-butylene-, *o*-phenylene, and neopentylene-phosphorous acids (XL) are mixed with diphenyldiazomethane at 20–25 °C, an equilibrium mixture of products (XLIb–e) is formed:



(XL) $\rightleftharpoons$ $\xrightarrow{(C_6H_5)_2CN_2}$ [(XLI a)] $\xrightarrow{-N_2}$ (XLI b) $\rightleftharpoons$ (XLI e)

(XLI d) $\rightleftharpoons$ (XLI c)

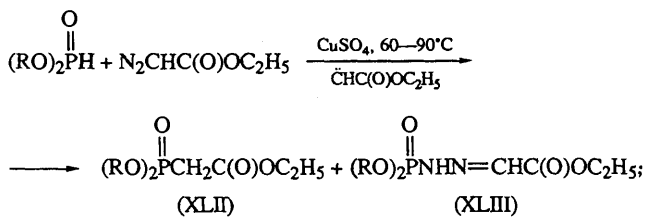
From the entire set of experimental data and the results of kinetic studies of the reactions of cyclic phosphorous acids with diphenyldiazomethane, it was established that the reaction proceeds via a two-stage mechanism. In the first stage, diphenyldiazomethane is protonated with formation of the ion pair (XLIa), while in the second stage the ion pair is converted into the final reaction products (XLIb–e).

Thus the kinetic studies indicate the existence of common mechanisms in the reactions of phosphorous acids and cyclic phosphoromonothioic and phosphorodithioic acids[36,37] as well as acyclic phosphorus monothio acids[22,26] with diazo-compounds.

5. Reactions of dialkyl phosphites and dialkyl phosphorothioites with carbenes

Until the beginning of the 1960s, there was no information in the literature about the reactions of organophosphorus compounds containing a P–H bond in the molecule with diazo-compounds under carbene generation conditions.

The formation of dialkyl phosphonoacetate esters (XLII) and small amounts (5–6%) of dialkyl *N*-ethoxycarbonylmethylene-phosphorohydrazidates (XLIII, R = CH_3, C_3H_7) was achieved for the first time[12,13] in the $CuSO_4$-catalysed decomposition of diazoacetic ester in the corresponding dialkyl phosphites. The authors represent the formation of the phosphorohydrazidates as a result of the interaction of dialkyl phosphites with still undecomposed diazoacetic ester:



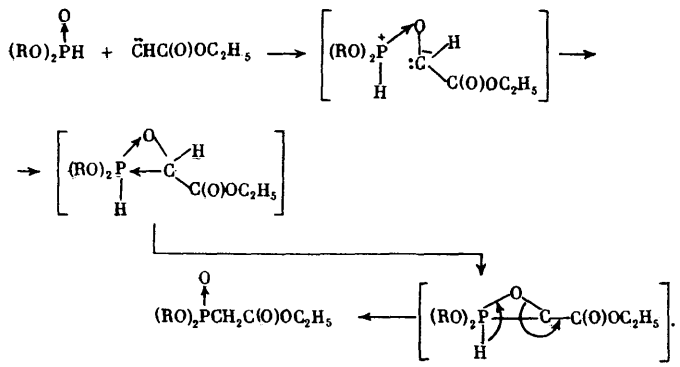
$$(RO)_2\overset{O}{\overset{\|}{P}}H + N_2CHC(O)OC_2H_5 \xrightarrow[\ddot{C}HC(O)OC_2H_5]{CuSO_4,\ 60—90°C}$$

$$\longrightarrow (RO)_2\overset{O}{\overset{\|}{P}}CH_2C(O)OC_2H_5 + (RO)_2\overset{O}{\overset{\|}{P}}NHN{=}CHC(O)OC_2H_5;$$

(XLII) (XLIII)

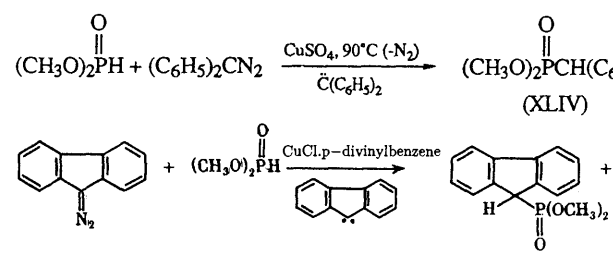
R = CH_3, C_2H_5, C_3H_7.

The mechanism proposed for the formation of compounds (XLII) includes electrophilic attack by the ethoxycarbonylcarbene on the oxygen of the dialkyl phosphite with subsequent redistribution of bonds in the intermediate complex formed:[13]

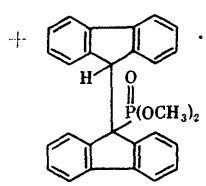


According to the authors, the hypothesis of the possible direct insertion of the ethoxycarbonylcarbene in the P–H bond is no less likely.

The product of insertion in the P–H bond, namely dimethyl diphenylmethylphosphonate (XXIV) [136] and, in the case of diazofluorene, the adducts (XLV) and (XLVI),[137] were obtained similarly in the thermocatalytic decomposition of diphenyldiazomethane in dimethyl phosphite:



(XLV)



(XLVI)

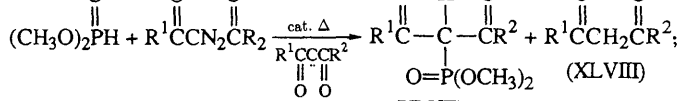
The reactions with diazoindene and 7-diazo-8-naphthene are likewise similar.[137]

As regards diazodicarbonyl compounds, especially diazodiketones which are known to be capable of the specific Wolff rearrangement in the decomposition process,[138] by suppressing this process or by creating conditions promoting the occurrence of the Wolff rearrangement, it is possible to alter the mode of the reactions of diazoketones with organophosphorus compounds.

It has been established that, under conditions promoting the Wolff rearrangement, phosphorus-containing products cannot be isolated. The only reaction product was alkyl 2-oxo-1,2-diphenylpropionate.[139]

In order to suppress the Wolff rearrangement and to make it possible to synthesise the products of insertion in the P–H bond, a study has been made[139–146] of the thermocatalytic decomposition,[139–142], direct photolysis,[142] and photosensitised decomposition[142,144–146] of a whole series of 2-diazo-1,3-diketones in dialkyl phosphites and phosphorothioites.

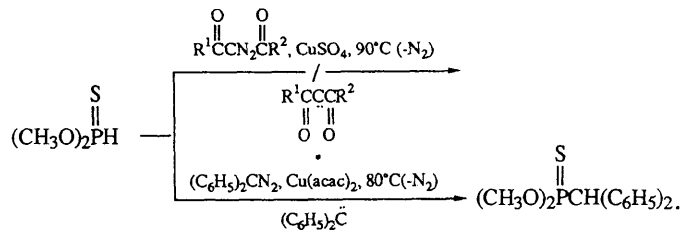
The thermocatalytic decomposition of 2-diazo-1,3-diketones ($CuSO_4$ or copper acetylacetonate; 80–90 °C) in dimethyl phosphite led to the isolation in 16.5–46% yield of 2-phosphono-1,3-diketones (XLVII) — the products of the insertion of the corresponding diketocarbene in the P–H bond of dimethyl phosphite and the products of the reduction of the diketocarbenes (XLVIII). The reaction constitutes a general method for the *C*-phosphorylation of 1,3-dicarbonyl compounds:



(XLVII)

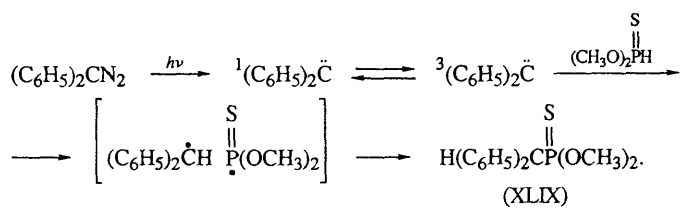
$R^1 = R^2 = CH_3$, OCH_3, C_6H_5; $R^1 + R^2 = (CH_3)_2C(CH_2)_2$.

In the case of dialkyl phosphorothioites, the insertion of diketocarbenes, obtained under similar conditions, in the P–H bond could not be achieved,[142] in contrast to diphenylcarbene:[136]



Until recently, there was no information in the literature about the insertion of photochemically generated carbenes in the P–H bond.

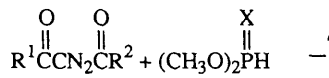
It was not until 1989[136] that the product of the insertion of diphenylcarbene in the P–H bond, namely dimethyl diphenylmethylphosphonothioate (XLIX), was obtained by the direct photolysis of diphenyldiazomethane in dimethyl phosphorothioite. The formation of compound (XLIX) was represented as a reaction proceeding via the mechanism involved in the recombination of the radical pairs generated from the triplet form of diphenylcarbene:[147]



(XLIX)

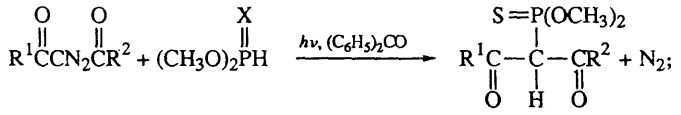
There are no literature data indicating that the diketocarbenes obtained by the direct photolysis of diazodicarbonyl compounds exist predominantly in the triplet form. This is apparently the

reason why the attempt in 1986 to obtain the products of insertion in the P–H bond was unsuccessful:[142]



$R^1 = CH_3$, $R^2 = OCH_3$, CH_3; $R^1 + R^2 = (CH_3)_2(CH_2)_2$; X = O, S.

However, 2-(thio)phosphono-1,3-dicarbonyl compounds — the products of insertion in the P–H bond — were obtained in 6.5–3.9% yields by the photosensitised decomposition of 2-diazo-1,3-dicarbonyl compounds in dimethyl phosphite (phosphorothioite) in the presence of benzophenone:[142,144,145]



$R^1 = R^2 = OCH_3$, X = S; $R^1 = CH_3$, $R^2 = OCH_3$, X = S;

$R^1 = R^2 = CH_3$; X = O, S;

$R^1 + R^2 = (CH_3)_2C(CH_2)_2$, X = S.

Thus the results obtained for the reactions of the photochemically generated diketocarbenes in dialkyl phosphites (phosphorothioites) led the investigators[142,144] to put forward the hypothesis that a triplet carbene is the main intermediate in the insertion in the P–H bond, which was confirmed by a study, using the chemically induced dynamic nuclear polarisation method (^{31}P CIDNP), of the mechanism of the insertion of carbenes in the P–H bond.[145,146]

Thus it is evident from the literature data on the reactions of organophosphorus compounds with a P–H bond in the molecule that the formation of the products of insertion in this bond in the reactions of dialkyl phosphites (phosphorothioites) with diazo-compounds occurs in two cases: (a) under the conditions of the thermocatalytic generation of carbenes and (b) in the photosensitised decomposition of diazodicarbonyl compounds. In the reactions with diphenyldiazomethane, such products are formed under the conditions of direct photolysis owing to the specific properties of the diphenylcarbene generated.

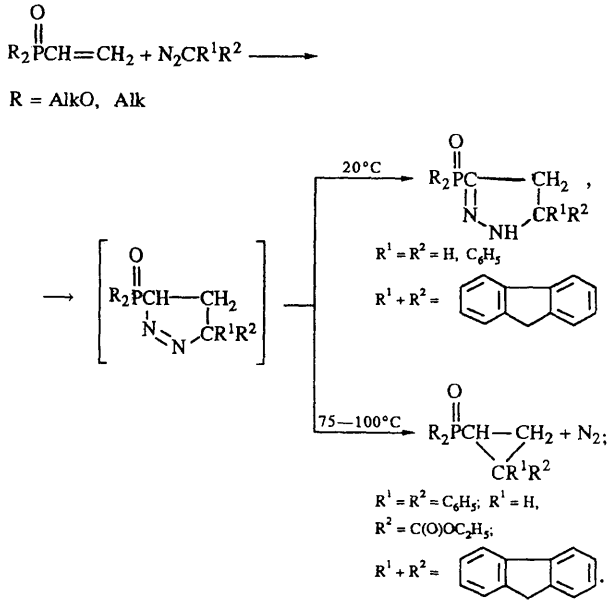
IV. Reactions of diazo-compounds and carbenes with phosphorus-containing systems having multiple bonds

1. Reactions involving the 1,3-dipolar cycloaddition of diazo-compounds and the cycloaddition of alkoxycarbonylcarbenes to phosphorus-containing systems with multiple bonds

A series of studies devoted to the comprehensive investigation of the reactions of aliphatic diazo-compounds and carbenes with unsaturated organophosphorus compounds has been carried out since the beginning of the 1960s by the Kazan School of organophosphorus chemists[148–157,159–161,169–180] and have been described in a review.[3] There exist also communications and reviews by foreign authors.[4,5,158,162–168,181–193]

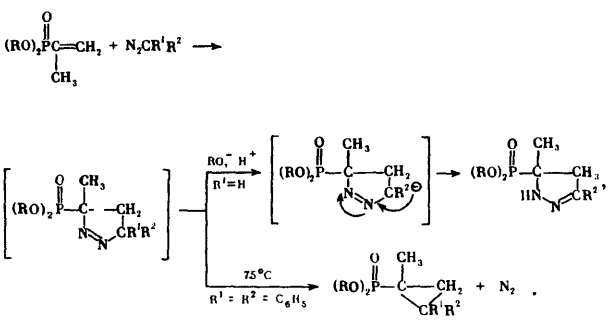
The study of the 1,3-dipolar cycloaddition reactions of diazo-compounds is of considerable interest not only for the elucidation of the reactivity of unsaturated organophosphorus compounds with which the mode of the reactions and the nature of the products formed are associated, but also as a possible way of synthesising five-membered heterocycles.

It has been shown that the 1,3-dipolar cycloaddition of diazomethane, diazoacetic ester, diphenyldiazomethane, and diazofluorene to dialkyl vinylphosphonates[148–153] and of diphenyldiazomethane to tertiary vinylphosphine oxides[154] proceeds via the intermediate formation of phosphorylated 3-Δ^1-pyrazolines, which, depending on the experimental conditions, either isomerise to phosphorylated 3-Δ^2-pyrazolines, or eliminate nitrogen and are converted into cyclopropane derivatives:



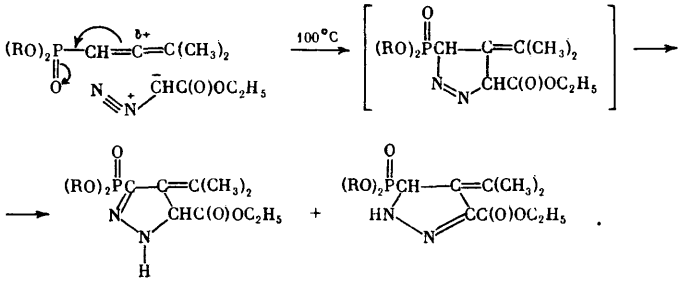
The reactions of diethyl allylphosphonate and diethylallylphosphine oxide with diazomethane and diphenyldiazomethane proceed similarly via the 1,3-dipolar cycloaddition mechanism.[148,154]

As a result of the 1,3-dipolar cycloaddition of diazo-compounds, dialkyl isopropenylphosphonates give rise to either phosphorylated 5-Δ^2-pyrazolines or to cyclopropane derivatives, depending on the experimental conditions:[155–157]



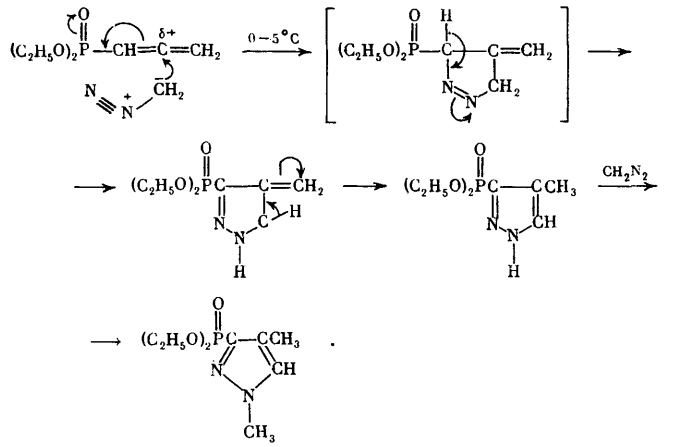
The addition of diazomethane to α-cyanovinylphosphonates takes place similarly with formation of phosphorylated 5-Δ^2-pyrazolines.[158]

The interaction of diazoalkanes with organophosphorus compounds containing cumulated or conjugated double bonds also proceeds via the mechanism involving 1,3-dipolar cycloaddition to the α,β-double bond. The reaction of γ,γ-dimethylallenylphosphonate with diazoacetic ester affords under these conditions a mixture of phosphorylated 3(5)-Δ^2-pyrazolines with exocyclic isopropenyl groups:[159]

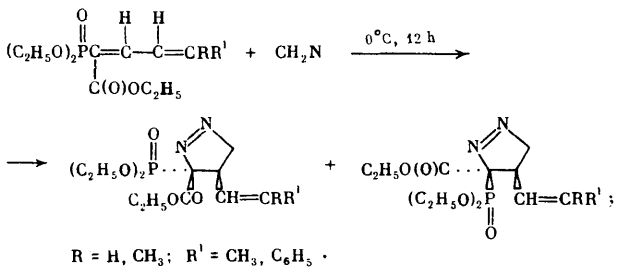


The cycloaddition of diphenyldiazomethane to allenylphosphonate takes place regiospecifically with the exclusive formation of 3-Δ^2-phosphorylated pyrazoline containing an exocyclic methylene group.[160]

In the case of the reaction with diazomethane, the analogous product, namely phosphorylated 3-Δ^2-pyrazoline, fully isomerises during distillation to 3-diethoxyphosphono-4-methylpyrazole. After *N*-methylation with diazomethane, 3-diethoxyphosphono-1,4-dimethylpyrazole was isolated:[161]

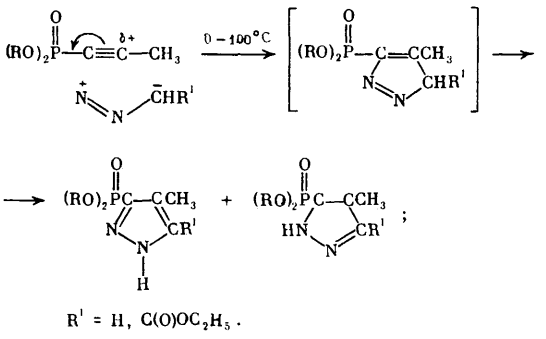


The cycloaddition of diazomethane to diethyl buta-1,3-dienylphosphonates proceeds with formation of a mixture of isomeric phosphorylated 3-Δ^2-pyrazolines, which are stable under the reaction conditions:[162]



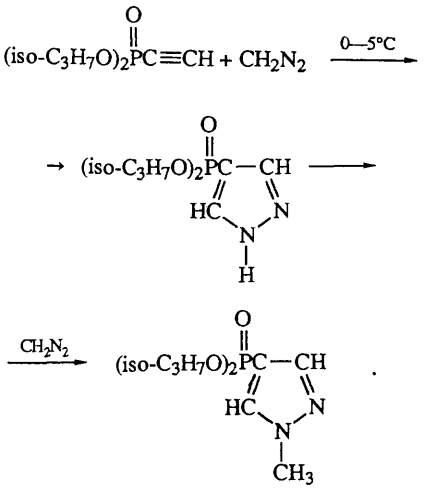
R = H, CH_3; R' = CH_3, C_6H_5.

The 1,3-dipolar cycloaddition of diazoacetic ester and diazomethane to the triple bond of dialkyl propynylphosphonates has been described.[159,161] A mixture of isomeric 3(5)-dialkoxyphosphono-5(3)-ethoxycarbonyl-4-methylpyrazoles was obtained as a result of the reaction:

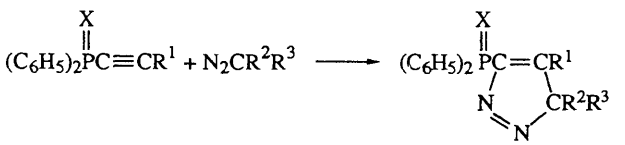


R' = H, $C(O)OC_2H_5$.

Diisopropyl ethynylphosphonate reacts with an excess of diazomethane to form diisopropyl 1-methylpyrazol-5-ylphosphonate only:[163]



The reactions involving the 1,3-dipolar cycloaddition of diazomethane, diazopropane, diphenyldiazomethane, and methylphenyldiazomethane to alkynyldiphenylphosphine oxides (sulphides) and alkynylbis(diphenylphosphine) oxides (sulphides) involve only the triple bond with formation of diphenyl [3*H*]-pyrazol-5-ylphosphonates and diphenyl [3*H*]-pyrazol-5-ylthiophosphonates:[4,164]

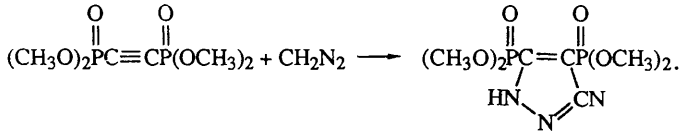


R^1 = H, CH_3, C_6H_5, $P(C_6H_5)_2$; R^2 = R^3 = H, CH_3, C_6H_5;

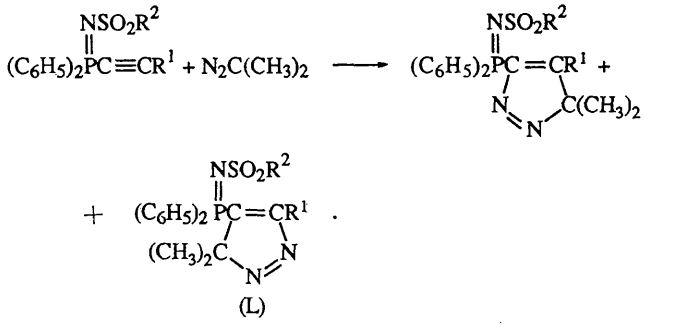
R^2 = CH_3, R^3 = C_6H_5;

X = O, S.

The reaction of tetramethyl acetylenebisphosphonate with diazomethane proceeds similarly:[165]

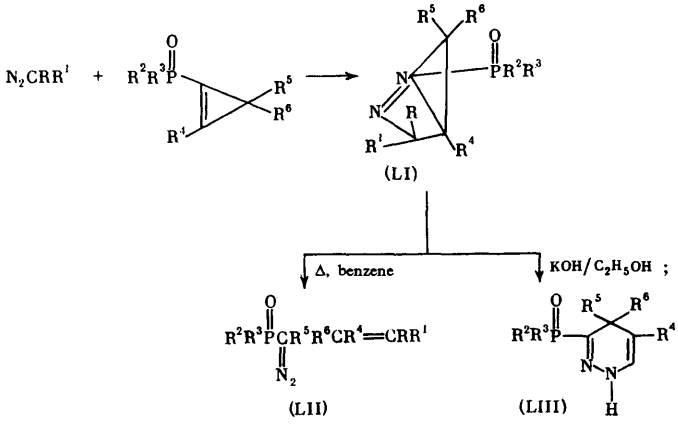


The reaction of *N*-[alkynyl(diphenyl)phosphorandiyl]sulphonamide with diazopropane either affords a mixture of isomeric 3*H*-pyrazoles (if R^1 = C_6H_5 and R^2 = CH_3, C_6H_5, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4, or *p*-$NO_2C_6H_4$) or the cycloaddition takes place regiospecifically with the exclusive formation of the cyclic adduct (L) (if R^1 = H or CH_3 and R^2 = CH_3, C_6H_5, *p*-ClC_6H_4, *p*-FC_6H_4, or *p*-$CH_3C_6H_4$ [164]). The phosphimine bond remains unreactive:



(L)

Regitz and co-workers[166,167] investigated the reactions involving the 1,3-dipolar cycloaddition of diazo-compounds to phosphorylated cyclopropenylphosphonates and cyclopropenylphosphine oxides. It was shown that the reactions proceed regiospecifically with formation of homopyrazolylphosphonates (LI), the cyclic adduct formed isomerising on heating either to allylphosphoryldiazomethane (LII) or to 3-phosphorylated 1,4-dihydropyridazine (LIII) in the presence of a strong base as the catalyst:



(LI)

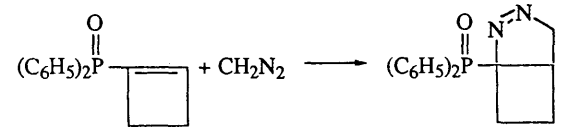
(LII) (LIII)

R = R' = H, CH_3, C_6H_5; R = H, R' = $C(O)OC_2H_5$, C_6H_5;

R + R' =  ; R^2 = R^3 = CH_3O, C_6H_5;

R^4 = H, CH_3, C_6H_5, $P(O)(C_6H_5)_2$; R^5 = H, CH_3, C_6H_5;
R^6 = CH_3, $C(CH_3)_3$.

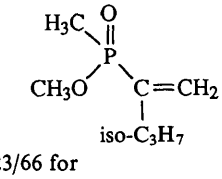
1-Cyclobutenyldiphenylphosphine oxide reacts with diazomethane to form Δ^1-pyrazolinylphosphine oxide:[168]



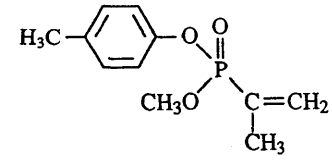
The 1,3-dipolar cycloaddition mechanism is a single-stage many-centre process with cyclic electron transfer as was confirmed in a study of the kinetics of the cycloaddition of diazoacetic ester to allenylphosphonates and allenylphosphine oxides[169] and of diphenyldiazomethane to vinylphosphonates and vinylphosphine oxides.[170,171]

The mutual orientation of the 1,3-dipole and of the dipolarophile in the transition state constitutes an important condition for reactions involving the 1,3-dipolar cycloaddition of diazoalkanes to phosphorus-containing dipolarophiles with a chiral phosphorus atom, which proceeds via a many-centre synchronous mechanism. The stereochemistry of such reactions has been investigated in relation to vinylphosphonates and vinylphosphinates and their α,β-substituted derivatives,[172–176] as well as allenyl- and ethynylphosphonates.[177]

It was shown that the stereospecificity of the reactions, determined by the diastereoisomeric composition of the isomers of 3-phosphorylated Δ^1-pyrazolines (the *threo*/*erythro* percentage ratio) depends both on the immediate steric environment of the chiral centre and on the effective volume of the substituents at the double bond. The approach of the diazoalkane molecule from the less hindered side determines the preferential formation of the *threo*-diastereoisomer, while its approach from the opposite side gives rise to the preferential formation of the *erythro*-diastereoisomer. For example, the ratio of the *threo*- and *erythro*-diastereoisomers varies from 90/10 for

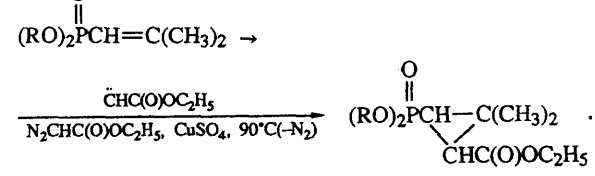


to 23/66 for



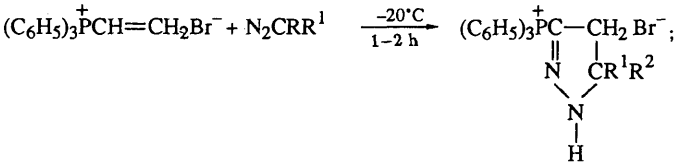
Ref. 172.

The reactions involving the cycloaddition of alkoxycarbonylcarbenes to vinyl- and allyl-phosphonic and vinylphosphoric esters proceed via the carbene mechanism with formation of cyclopropane derivatives. The direct dependence of the reactivity on the nucleophilicity of the double bond has been established:[148,151,178,179,180]



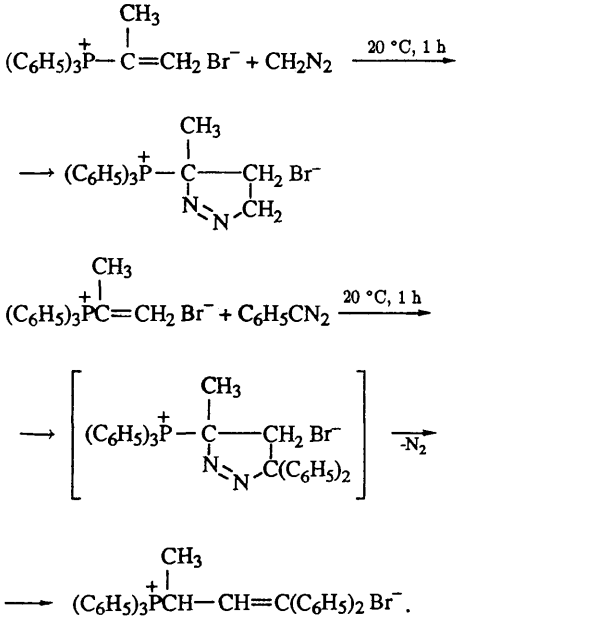
The reactions of phosphonium salts containing multiple bonds with diazo-compounds also involve 1,3-dipolar cycloaddition. It has been shown[5,168,181–183] that the final result of the reaction depends on the structure of the phosphonium salt and the diazo-compound.

Triphenylvinylphosphonium bromide gives rise to triphenyl-3-Δ^2-pyrazolinylphosphonium bromide:[181,182]



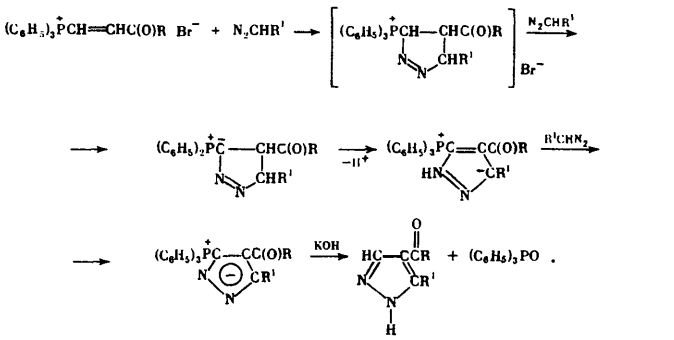
$R = R^1 = H,\ CH_3,\ C_6H_5;\ R = H,\ R^1 = CH_3,\ C_6H_5.$

Isopropenyltriphenylphosphonium bromide reacts with diazomethane to form triphenyl-5-Δ^1-pyrazolinylphosphonium bromide, while in the reaction with diphenyldiazomethane under the same conditions the analogous reaction products proved to be unstable, substituted allyltriphenylphosphonium bromide being formed after the evolution of nitrogen:[182]

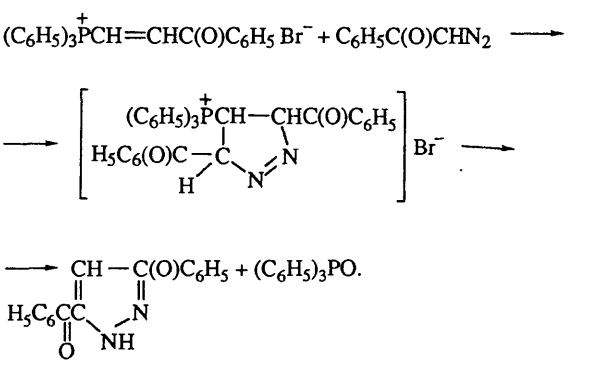


It is of interest that β-substituted triphenylvinylphosphonium and allyltriphenylphosphonium bromides do not react with diazoalkanes.[182] On the other hand, the introduction of an acyl group into the triphenylvinylphosphonium bromide alters its reactivity.

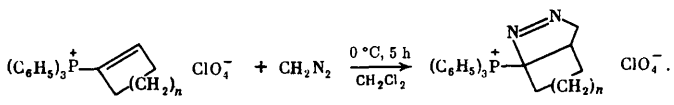
Although the cycloaddition of diazomethane and diazoacetic ester to β-acylvinyltriphenylphosphonium bromide does in fact proceed via the stage involving the formation of the intermediate triphenyl-5-Δ^1-pyrazolinylphosphonium salt, the reaction product isolated was the phosphorus-containing ylide (LIV), which is converted into 4-acylpyrazole on alkaline hydrolysis:[183]



After the reaction of β-acylvinyltriphenylphosphonium bromide with diazoacetophenone, 3,5-diacylpyrazole was isolated:[183]



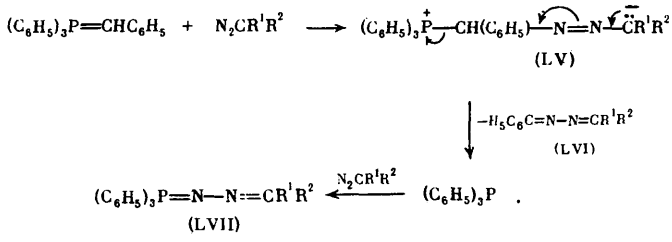
The 1,3-dipolar cycloaddition of diazomethane to 1-cycloalkenylphosphonium salts takes place with formation of bicyclic adducts:[168]



2. Phosphorus-containing ylids in reactions with diazo-compounds and carbenes

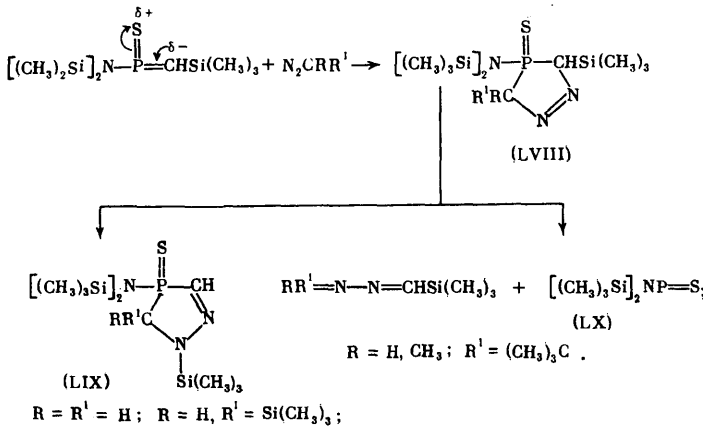
Phosphorus-containing ylids react unambiguously with diazo-compounds depending on the structure of the ylid and the reaction conditions. It has been shown[185,185] that the reaction of benzylidenetriphenylphosphorane with diazoacetophenone and phenyldiazomethane proceeds readily at room temperature with formation of a mixture of the azine (LVI) and triphenylphosphazine (LVII). It is assumed that the reaction proceeds via the intermediate formation of the betaine (LV), its decomposition to the

azine (LVI) and triphenylphosphine, and subsequent interaction of triphenylphosphine with the diazo-compound:

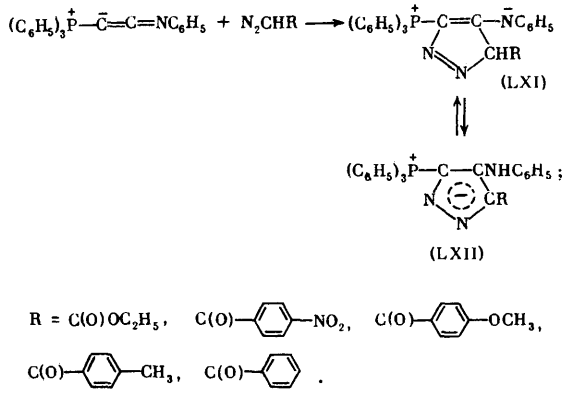


A much more complex reaction occurs between benzoylmethylenetriphenylphosphorane and diazoacetophenone; it leads to 4-benzylidene-2,6-diphenylpyran.[186,187]

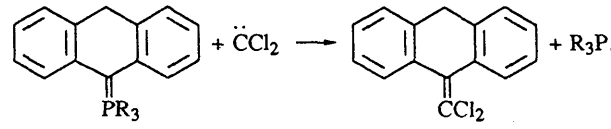
Silylated aminothionophosphorane reacts differently with diazoalkanes. The 1,3-dipolar cycloaddition to the P=C double bond lead to the formation of 3-trimethylsilysl-Δ^1-diazophospholene (LVIII), which either isomerises to 1-trimethylsilyl-Δ^2-diazaphospholene (LIX) as a result of the migration of the trimethylsilyl group or it decomposes to an azine and bis(trimethylsilyl)aminothionophosphorane (LX):[188]



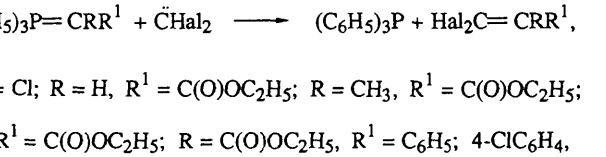
The reaction of *N*-phenylaminoketenylidenetriphenylphosphorane with diazocarbonyl compounds proceeds as 1,3-dipolar cycloaddition with formation of a phosphorylated pyrazoline derivative (LXI), which is involved in a tautomeric equilibrium with the phosphorylated imidopyrazole (LXII):[189]



The interaction of phosphorus-containing ylids with dihalocarbenes proceeds in most cases with formation of the corresponding olefins and phosphines and is believed to occur as a result of the electrophilic attack by the dihalocarbene on the negatively charged carbon atom of the phosphorus ylid.[190–192] The reactions of fluorenylidenetriphenyl(butyl)phosphorane and phosphorus-containing ylids having different electron-accepting groups proceed via the same mechanism:[190–192]



$R = C_6H_5$, C_4H_9;



Hal = Cl; R = H, $R^1 = C(O)OC_2H_5$; $R = CH_3$, $R^1 = C(O)OC_2H_5$;

$R = R^1 = C(O)OC_2H_5$; $R = C(O)OC_2H_5$, $R^1 = C_6H_5$; 4-ClC_6H_4,

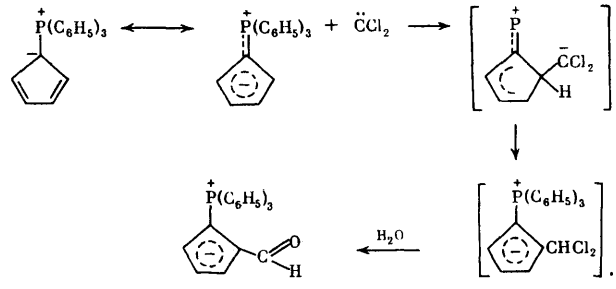
Cyclopentadienylidenetriphenylphosphorane reacts differently with dichlorocarbene, generated from chloroform and potassium t-butoxide at 0 °C; it gives rise to a monoformyl derivative — triphenylphosphonium 2-formylcyclopentadienylide:[193]

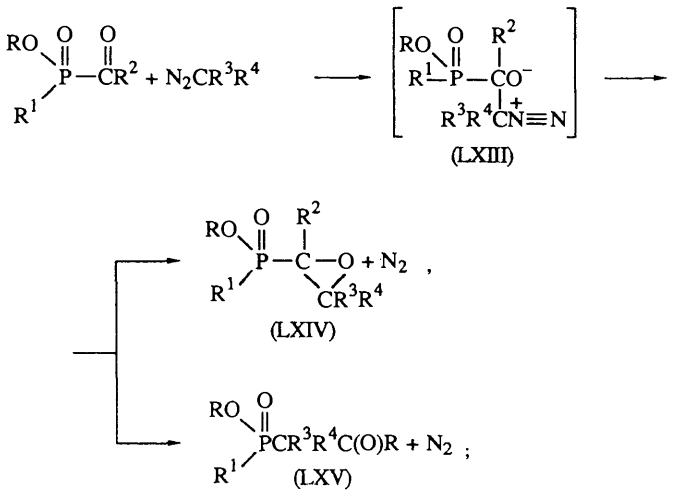


3. Reactions of diazoalkanes with ketophosphoryl compounds and phosphoryl isothiocyanates

The available literature data on the reactivities of organophosphorus compounds containing a carbonyl group with aliphatic diazo-compounds are restricted mainly to those obtained in the studies by Pudovik and co-workers.[194,197–199,202–204] Since the results of these studies have been described in detail in a review[6] and in a review report,[200] we shall confine ourselves to their brief consideration only.

The authors showed that, depending on the nature of the substituent at the carbonyl group and of the diazo-compound, the interaction of α-ketophosphonates and α-ketophosphinates with diazo-compounds proceeds with formation of either phosphorylated

oxiran derivatives (LXIV) or β-ketophosphonates and β-ketophosphinates—the products of insertion in the P—C bond of the initial organophosphorus compound (LXV):[194–200]

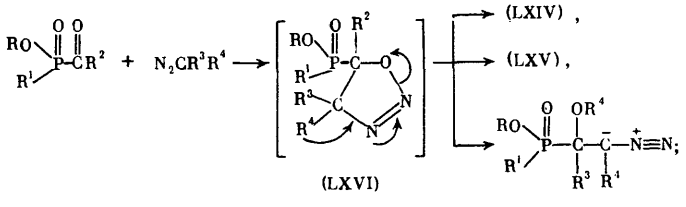


R = Alk; R^1 = AlkO, Alk, C_6H_5; R^2 = CH_3, C_6H_5, X = C_6H_4;

R^3 = R^4 = H, C_6H_5; R^3 = H, R^4 = CH_3.

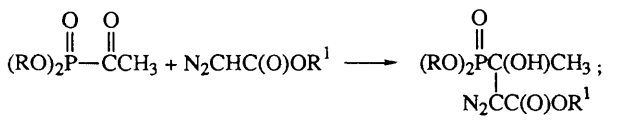
The formation of the reaction products (LXIV) and (LXV) is explained, in conformity with the generally accepted mechanism of the reactions of diazoalkanes with carbonyl compounds,[201] by the stabilisation of the intermediate dipolar ion (LXIII).

However, Pudovik et al.[194] do not exclude also the 1,3-dipolar cycloaddition mechanism with formation of the intermediate 1,2,3-oxadiazoline derivative (LXVI), which, depending on the substitution at the C(4) ring atom, either decomposes with evolution of nitrogen and the formation of the products (LXIV) and (LXV) or isomerises with formation of the phosphorus-containing diazo-compound (LXVII):



R = Alk; R^1 = AlkO, Alk, C_6H_5;
R^2 = CH_3, C_6H_5, X-C_6H_4;
R^3 = R^4 = H, C_6H_5; R^3 = H, R^4 = CH_3.

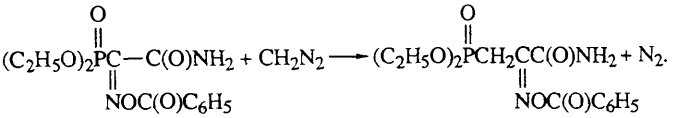
It is of interest that an adduct, similar to compound (LXVII), was obtained by the reaction of diazoacetic esters with acetylphosphonates:



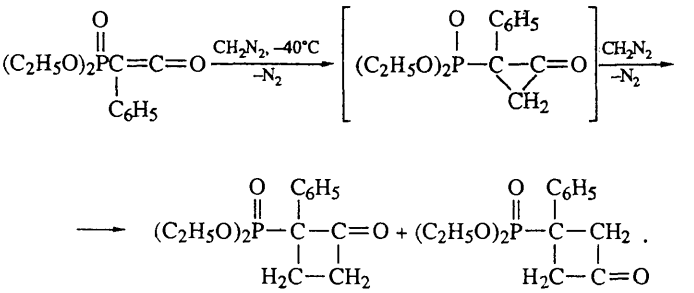
R = R^1 = CH_3, C_2H_5.

Neither the product with the oxiran structure (LXIV) nor the product (LXV) of insertion in the P—C bond were detected in the reaction mixture.[202–204]

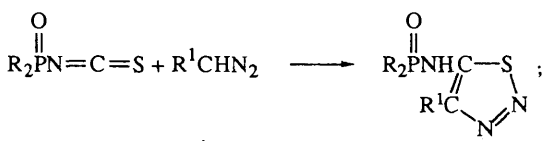
Similarly to the reaction with α-ketophosphoryl compounds, the reaction of acyloxyiminoalkylphosphonate with diazomethane leads to the product of the insertion of the methylene group in the P—C bond:[205]



The interaction of diethylphosphonophenylketene, which is an extremely reactive compound, with an excess of diazomethane involves not the carbonyl group but the C=C double bond and proceeds via the formation of the reactive phosphorylated cyclopropanone and leads to a mixture of isomeric phosphorylated cyclobutanes:[206]



One study is described in the literature,[207] where it was shown that phosphorylated isothiocyanates enter into reactions involving the 1,3-dipolar cycloaddition of diazomethane and phenyldiazomethane with formation of the corresponding 5-phosphinamido-1,2,3-thiadiazoles:



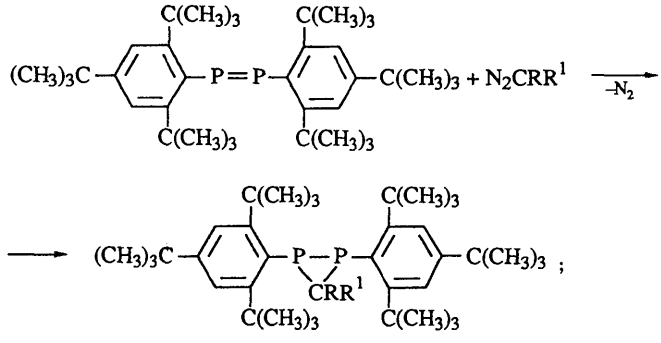
R = C_6H_5, CH_3; R^1 = H, C_6H_5.

V. Derivatives of di- and mono-coordinate phosphorus in reactions with diazo-compounds and carbenes

1. Reactions of diazo-compounds and carbenes with acyclic derivatives of dicoordinate and monocoordinate phosphorus

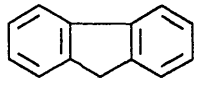
Acyclic derivatives of dicoordinate phosphorus containing the —P=P—, —P=C—, and —P=N— bonds have been investigated in reactions with diazo-compounds and carbenes.

The stable diphosphirans (LXVIII) have been obtained by cyclising a diphosphene, a derivative of dicoordinate phosphorus, with diazomethane at 0 °C [208] and with diphenyldiazomethane and diazofluorene on heating and UV irradiation:[209]



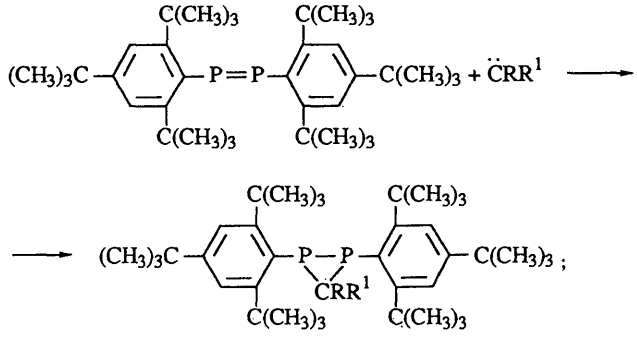
(LXVIII)

R = R^1 = H, C_6H_5; R + R^1 =



.

The hypothesis of the carbene mechanism of the formation of compound (LXVIII) under the conditions involving the generation of diphenyl- and fluorenylidene-carbenes (UV irradiation) was confirmed by the fact that the diphosphirans (LXIX) are formed from the diphosphene and dichloro-, dibromo-, and phenylbromocarbenes:[209]

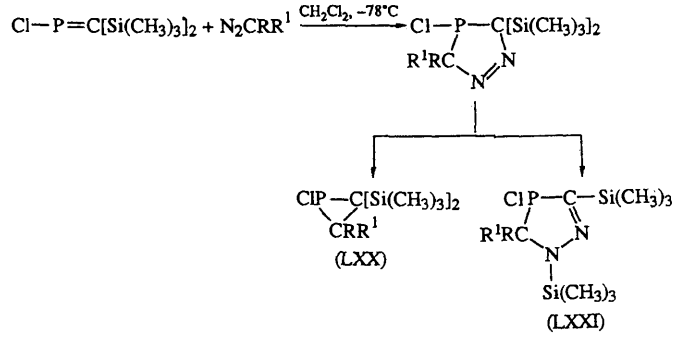


(LXIX)

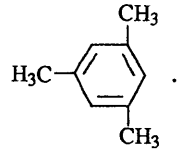
R = R^1 = Cl, Br; R = Br, R^1 = C_6H_5.

The interaction of *P*-chlorophosphaalkenes with diazocompounds, except organometallic derivatives of diazomethane, proceeds as 1,3-dipolar cycloaddition to the P=C double bond of the *P*-chlorophosphaalkene.[210–212] It was shown that the nature of the reaction product formed depends on the structure of the diazocompound and the *P*-chlorophosphaalkene.

Thus the reaction of 1-chloro-2-bis(trimethylsilyl)-1-phosphaalkenes with both mono- and di-substituted derivatives of diazomethane occurs even at a very low temperature with formation of unstable 3*H*-1,2,4-diazaphospholenes at room temperature, which either decompose with elimination of nitrogen and the formation of 1-chlorophosphirans (LXX) or are converted into 4,5-dihydro-1,2,4-diazaphospholenes (LXXI) as a result of the migration of the trimethylsilyl group:[212]

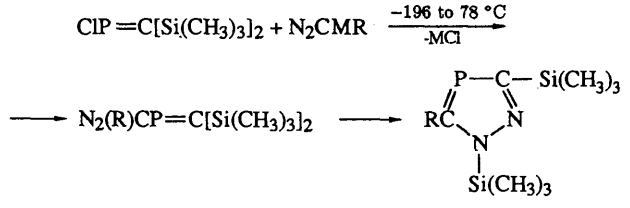


R = H, CH_3; R^1 = t-C_4H_9; R = H, R^1 = $Si(CH_3)_3$.



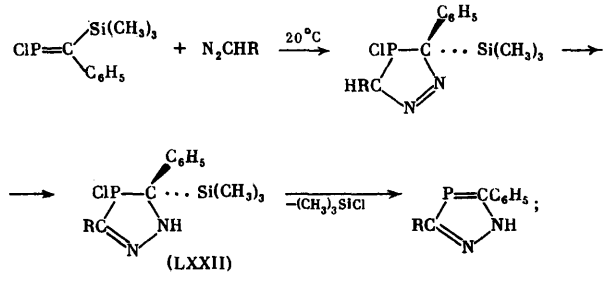
.

Organometallic derivatives of diazomethane react quite differently. The reaction proceeds with retention of the P=C bond of the initial 1-chloro-2-bis(trimethylsilyl)-1-phosphaalkene and the formation of phosphavinyldiazoalkane which cyclises to 1,2,4-diazaphosphole on subsequent heating:[213]



M = Li, $HgC(N_2)OC(O)C(CH_3)_3$; R = $Si(CH_3)_3$, 2, 4, 6-$(CH_3)_3C_6H_2$, $CH_3C(O)O$.

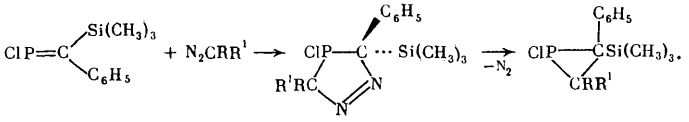
Monosubstituted derivatives of diazomethane react with 1-chloro-2-phenyl-2-trimethylsilyl-1-phosphaalkene at room temperature to form 1*H*-1,2,4-diazaphospholes via the intermediate cyclic adduct (LXXII) and subsequent elimination of chlorotrimethylsilane:[210]



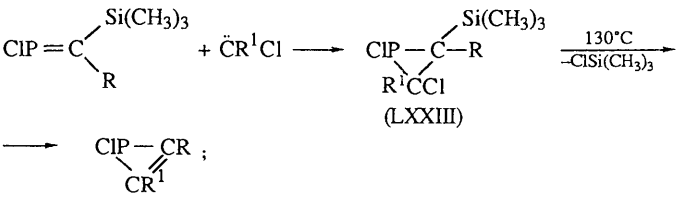
(LXXII)

R = H, C_6H_5, $C(O)OC_2H_5$, $C(O)C_6H_5$.

However, the reaction with disubstituted derivatives of diazomethane proceeds with the exclusive formation of 1-chlorophosphirans:[211]

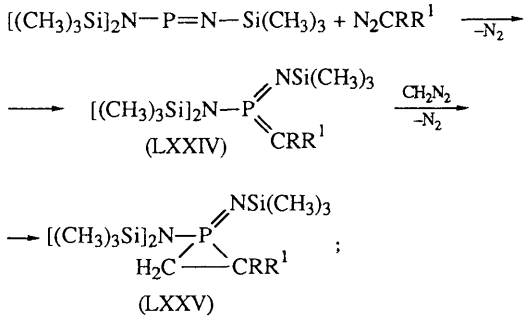


The reaction of *P*-chlorophosphaalkenes with chloro(phenyl)- and chloro(phenoxy)-carbenes has been described recently.[214] The analogous 1-chlorophosphirans (LXXIII) were obtained, their thermal decomposition resulting in the elimination of chlorotrimethylsilane and the formation of 1-chloro-1*H*-phosphirenes:



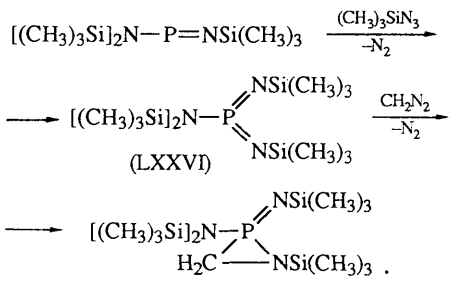
R = C_6H_5, $Si(CH_3)_3$; R^1 = C_6H_5, C_6H_5O.

In contrast to *P*-chlorophosphaalkenes, silylated amino-iminophosphanes react with diazo-compounds not via the 1,3-dipolar cycloaddition mechanism but with retention of the P=N bond and the formation of stable diylide structures. Thus the interaction of bis(trimethylsilyl)aminotrimethylsilyliminophosphane with diazoalkanes leads to the formation of bis(trimethylsilyl)aminotrimethylsilyliminophosphoranes (LXXIV), the subsequent reaction of which with diazomethane, proceeding as 1,2-cycloaddition, results in the formation of bis(trimethylsilyl)trimethylsilylimino-λ^5-phosphirans (LXXV):[215–217]

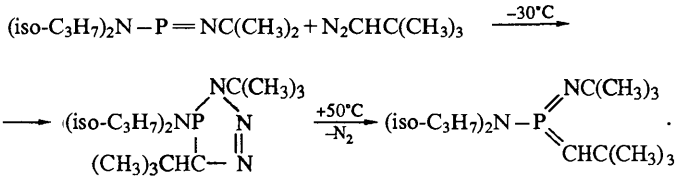


R = CH_3, H; R^1 = CH_3, C_2H_5, $CH(CH_3)_2$, $C(CH_3)_3$.

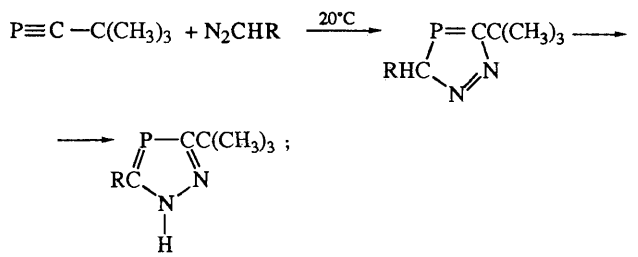
The 1,2-cycloaddition of diazomethane to one of the P=N bonds of aminodiiminophosphorane (LXXVI) leads to the formation of 1,2-λ^5-azaphosphoridine:[215]



An aminoiminophosphorane is also formed on interaction of t-butyliminodiisopropylaminophosphane with t-butyldiazopropane. It is suggested that the reaction proceeds as 1,3-dipolar cycloaddition to the P=N bond with formation of cyclic adducts and subsequent elimination of nitrogen on raising the temperature:[218]



The interaction of diazo-compounds with derivatives of monocoordinate phosphorus has been reported.[219] 1,3-Dipolar cycloaddition to a phosphaalkyne results in the formation of 1*H*-1,2,4-diazaphospholes:



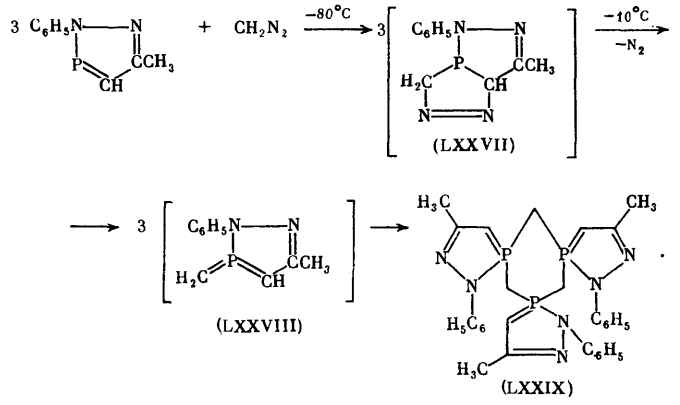
R = H, CH_3, t-C_4H_9, $C(O)C_6H_5$, $C(O)OCH_3$.

2. Reactions of diazo-compounds and carbenes with cyclic derivatives of dicoordinate phosphorus

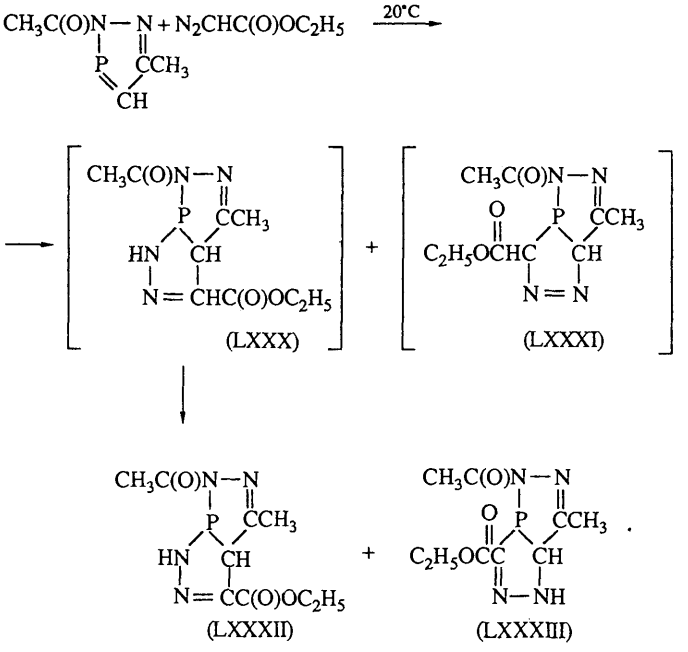
The reactions of five-membered cyclic derivatives of dicoordinate phosphorus with diazo-compounds have been investigated by Arbuzov and co-workers in relation to substituted 1,2,3-diazaphospholes. It was shown that the final reaction product depends to a considerable extent on the structures of both initial reactants and on the experimental conditions.[220–241]

Thus diazomethane readily reacts at room temperature with 5-methyl-2-phenyldiazaphosphole with evolution of nitrogen and the formation of an adduct having the structure of the trimer (LXXIX).[220]

It was later established[221] that this reaction proceeds via the formation of the unstable cyclic [2 + 3]adduct (LXXVII), having the pyrazoline structure, with subsequent elimination of nitrogen, the formation of the reactive phosphorus diylid (LXXVIII), and its subsequent trimerisation:

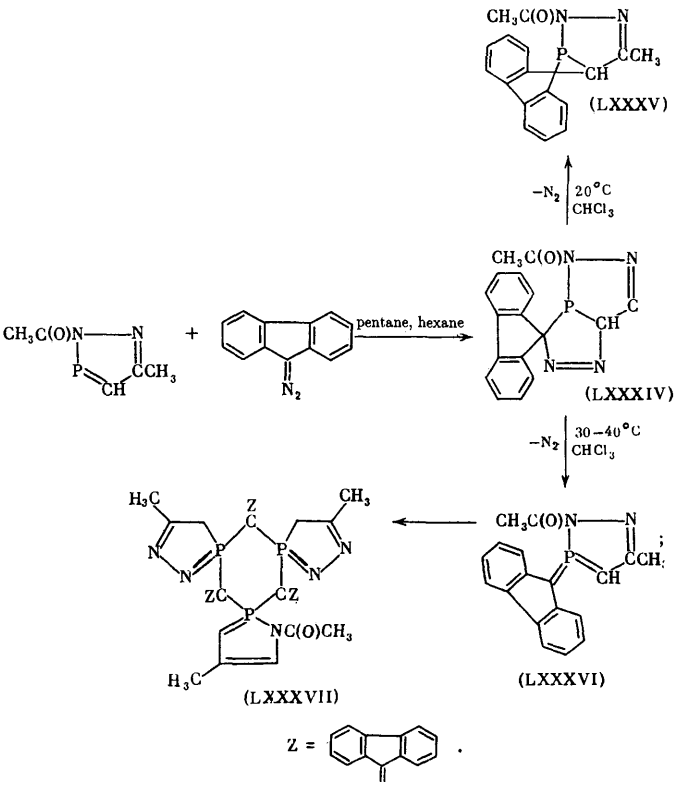


In contrast to the reaction with diazomethane, the reaction of 2-acetyl-5-methyl-1,2,3-diazaphosphole with diazoacetic ester proceeds via the 1,3-dipolar cycloaddition mechanism without the evolution of nitrogen, a mixture of compounds (LXXX) and (LXXXI) being formed, regardless of the nature of the solvent, and isomerising to the Δ^2-phosphapyrazoline derivatives (LXXXII) and (LXXXIII) respectively:[222]



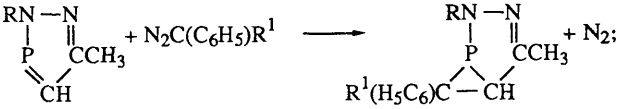
2-Acetyl-5-methyl-1,2,3-diazaphosphole reacts differently with diazoacetone depending on the experimental temperature.[221] At room temperature, the reaction proceeds with evolution of nitrogen and the formation of a trimer, whose structure is similar to that of compound (LXXIX). At 10 °C, the reaction takes place without the evolution of nitrogen and, as in the reaction with diazoacetic ester, a mixture of isomeric derivatives of Δ^2-phosphapyrazoline is formed.

The reactions of 2-acetyl-5-methyldiazaphosphole with 9-diazofluorene, proceeding via the 1,3-dipolar cycloaddition mechanism, proved to be of interest.[220,223] Thus at room temperature in pentane and hexane, the product is the Δ^1-phosphapyrazoline derivative (LXXXIV), which is converted in chloroform at room temperature into the bicyclic phosphiran (LXXXV), while at 30–40 °C it is converted into the trimer of the diazaphosphole ylid (LXXXVII) via a stage involving the formation of the diylid structure (LXXXVI):



The trimer (LXXXVII) is formed without the isolation of the bicyclic compound (LXXXIV) when the reaction is carried out in benzene, methylene chloride, and carbon tetrachloride. In diethyl ether, the reaction proceeds with formation of a mixture of the products (LXXXIV) and (LXXXVII).[220]

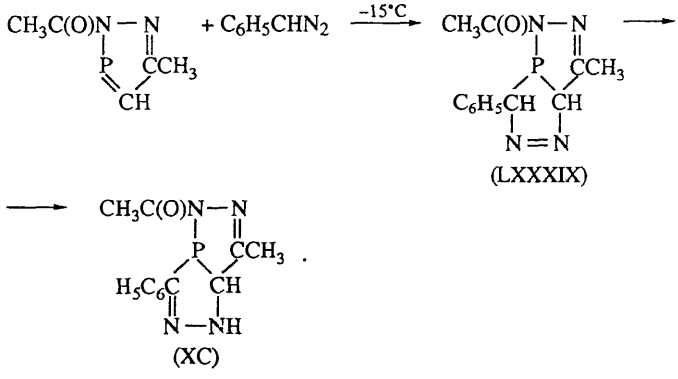
The possibility of cycloaddition to the P=C bond involving a dicoordinate phosphorus atom with formation of stable bicyclic phosphirans (LXXXVIII) was first demonstrated in relation to the reactions of *N*-substituted diazaphospholes with diphenyldiazomethane in different solvents[224–227] and later with methylphenyldiazomethane.[228] The structure of the bicyclic phosphirans was established by X-ray diffraction.[229–232]



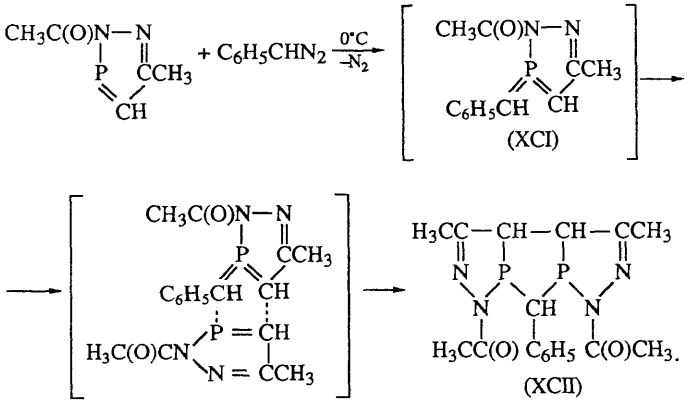
R = C_6H_5, $CH_3C(O)$; R^1 = C_6H_5, CH_3.

In the study of the mechanism of the reaction of 5-methyl-2-phenyl(acetyl)diazaphospholes with diphenyldiazomethane, it was shown that the reaction is of the non-carbene type and proceeds via the 1,3-dipolar cycloaddition mechanism.[233]

In contrast to diphenyldiazomethane, phenyldiazomethane does not give rise to a bicyclic phosphiran in its reaction with 2-acetyl-5-methyl-1,2,3-diazaphosphole. In hexane at −15 °C, the reaction product is the Δ^1-phosphapyrazoline derivative (LXXXIX), which isomerises to the Δ^2-phosphapyrazoline derivative (XC):[234]

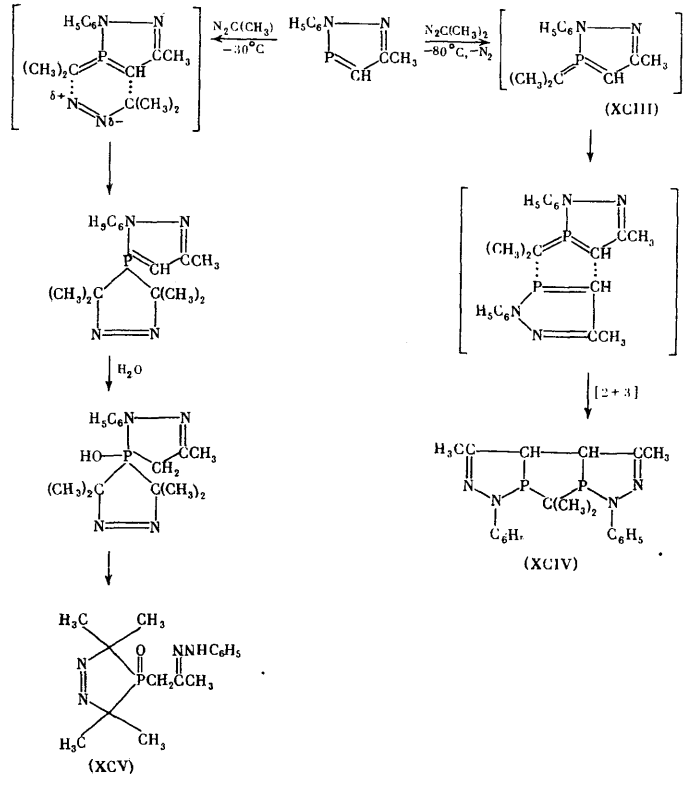


When the temperature is raised to 0 °C and the reactants are added in the opposite order, nitrogen is evolved and the tricyclic compound (XCII) is formed. It is the product of the cyclic [2 + 3]addition of the intermediate diylid (XCI) to the initial diazaphosphole:[234]



The reaction of 5-methyl-2-phenyl-1,2,3-diazaphosphole with diazopropane proceeds, in contrast to the reaction with diphenyldiazomethane, in a much more complex manner with formation of products of different structure as the experimental conditions are varied.[235–239] As in the reaction with phenyldiazomethane, bicyclic phosphirans were not obtained in any of the experiments.

It was established by X-ray diffraction that the reaction of 5-methyl-2-phenyl-1,2,3-diazaphosphole with diazopropane, which proceeds with evolution of nitrogen on intensive cooling, results in the formation of the diphosphorus tricyclic compound (XCIV), whose structure is similar to that of compound (XCII).[235–238] Compound (XCIV) is evidently formed as a result of the 1,3-dipolar cycloaddition of the intermediate reactive phosphorus diylid (XCIII), which behaves as the dipole:

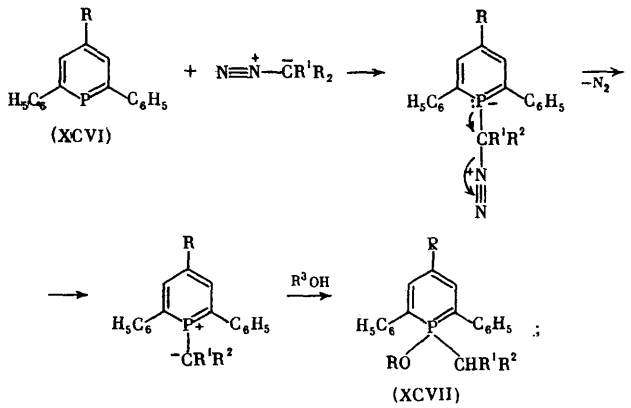


The reaction of 5-methyl-2-phenyl-1,2,3-diazaphosphole with an excess of diazopropane at −30 °C takes place differently and leads to the formation of the phosphorylated phenylhydrazone derivative (XCV), evidently as a result of the 1,3-dipolar cycloaddition of the intermediate phosphorus diylid, acting as the dipolarophile, to the diazopropane molecule.[237]

5-Methyl-2-phenyl-1,2,3-diazaphosphole reacts with 1-diazo-2-methylpropane and 1-diazo-2,2-dimethylpropane to form only a tricyclic diphosphorus compound, whose structure is analogous to that of compound (XCIV).[240]

The reaction of diazo-compounds and carbenes with a six-membered cyclic derivative of dicoordinate phosphorus, such as the trisubstituted phosphabenzene (XCVI), have also been investigated.[242–244] Thus treatment of 2,4,6-trisubstituted λ^3-phosphorins with alcoholic or phenolic solutions of diazo-compounds afforded 39 different derivatives of the λ^5-phosphorins (XCVII).[242,243] It is assumed that compounds (XCVII) are formed as a result of the nucleophilic attack by the diazo-compound on the phosphorus atom of the phosphabenzene with subsequent elimination of nitrogen and

the formation of a dipolar ion, which then reacts with the alcohol or the phenol:

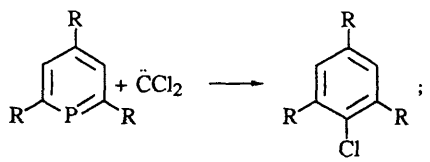


(XCVI) (XCVII)

R = C_6H_5, $C_6H_5CH_2$; $R^1 = R^2 = H$, C_6H_5; $R^1 = H$, $R^2 = C(O)OC_2H_5$;

$R^3 = CH_3$, C_2H_5, $CH(CH_3)_2$, C_6H_5, $C_6H_5CH_2$, $CH_2{=}CH{=}CH_2$, CH_2CH_2Cl, CH_2CCl_3.

The reactions of trisubstituted phosphabenzenes — 2,4,6-triphenyl- and 2,4,6-tributyl-phosphabenzenes — with dichlorocarbene, generated by the thermolysis of $Cl_3CC(O)ONa$ and $C_6H_5HgCCl_2Br$ or obtained from CH_2Cl_2 and $CHCl_3$ in the presence of t-C_4H_9OK, proceed in an unusual way. They result in the formation of trisubstituted benzenes:



R = C_6H_5, t-C_4H_9.

The reaction with chloro(phenyl)carbene, generated from dichloro(phenyl)methane and potassium t-butoxide, takes place similarly. The reaction mechanism has been discussed.[244]

Thus the study of the reactivities of various phosphorus-containing systems in relation to diazo-compounds and carbenes has led to interesting possibilities both for the synthetic organic chemistry of phosphorus and for the development of theoretical ideas in the chemistry of organophosphorus compounds and carbenes.

Compounds containing phosphorus and boron

G N Nikonov, A S Balyeva
Arbuzov Institute of Organic and Physical Chemistry, Kazan

ABSTRACT. This review examines the synthesis and properties of phosphorus-boron-containing compounds containing the fragments P=B, B–C–B, P–N–B, P–O–B, P–C–C–B, P–C=C–B, P=C–O–B, P–C–O–B, P–C≡C–B, and P–$(C)_n$–B, and also phosphorus-containing borohydrides, carboranes, and coordination compounds containing phosphorus- and boron-containing ligands. The interaction of heteroatomic functional groups has received special attention. Wherever possible the acquisition of new properties by the compounds as a result of these interactions has been noted.

The bibliography contains 139 references.

I. Introduction

The introduction of different heteroatom-containing groups into an organic molecule leads to the mutual enrichment of the chemistry of the corresponding classes of organic compounds. One of the most interesting examples of this type is the introduction of phosphorus atoms into organoboron compounds. Phosphorus and boron are known to have different electronic compositions (an atom with an unshared electron pair, an atom with a vacant orbital, a donor and an acceptor, a base and an acid) and have the ability to change reversibly their coordination and to form coordinate bonds with metals, while the variety of properties and types of compounds obtained may be attributed to the diversity of fragments by means of which the phosphorus- and boron-containing groups may be linked. New properties appear as a result of the mutual effect of the functional groups containing these elements. In this regard it is appropriate to examine the currently known classes of P- and B-containing compounds (PBC) and to attempt to follow the change in the interaction of the heteroatoms. In the phosphinoboranes and phosphineboranes a chemical bond is involved in this interaction. When a particular fragment is present between the P and B atoms, the effect of the heteroatomic functions is equivalent to a supplementary interaction, and the type and method of transfer of the latter are determined by several factors, i.e. the remoteness of the heteroatoms from each other, the spatial arrangement, the ability of the separating fragment to "conduct" electronic effects, etc. With such an approach different classes of P- and B-containing compounds may be combined into a single review. A study of the coordination compounds is one of the most promising avenues for the advancement of the chemistry of functionally substituted phosphorus compounds including the phosphorus-boron compounds. The introduction of boron-containing functional groups into a molecule of a phosphorus-containing ligand may lead to fundamental changes in the coordination sphere of the metal. Numerous examples of PBC coordination compounds are considered in the review.

In a study and comparison of the properties of different types of PBC such an approach may be extended also to other systems possessing two or several heteroatomic functions, for example P–Al, As–B, etc.

The currently known phosphorus-boron containing compounds may be separated into three major groups: 1) compounds in which the P and B atoms are linked by a coordinate bond, the phosphineboranes; 2) compounds containing three-coordinate P and B atoms linked directly to each other, the acyclic and cyclic monomeric phosphinoboranes; 3) compounds in which the P and B atoms are separated by some fragment, carbon atoms, heteroatoms, metal atoms, C–O and C–N fragments, etc. The present review focuses on the latter group of compounds which are presently attracting the attention of many research workers. A number of monographs and reviews have examined methods used to prepare and the properties of PBC including those in which the P and B atoms are separated by fragments.[1–7] However in these communications no reference was made to the mutual effect of heteroatom-containing groups leading to the appearance of new properties in the compounds, and in addition the relationship between the interaction of the heteroatoms and the nature of the fragments separating them has not been revealed.

To achieve these objectives the compounds presented below have been classified according to the type of the fragments which separate the phosphorus and boron atoms.

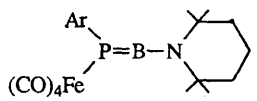
Three types of interaction between the phosphorus-boron-containing functional groups are possible, the interaction being transmitted along the bond system of the separating fragment, the trans-annular intramolecular (coordinate bond P→B), and the trans-annular intermolecular interaction (coordinate bond P→B). These interactions which are evident from the behaviour of the functional groups are determined by the coordination of the P and B atoms,

the type of fragment between them, and by the structural features of the molecule.

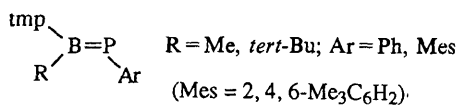
II. Compounds containing fragment P=B

The most obvious route, which can be used to obtain compounds containing the P=B fragment (boraphosphenes), is the interaction of phosphines with haloboranes or halophosphines with boron hydrides in the presence of hydrogen halide acceptors, but this route does not lead to the expected result. In this case phosphinoboranes are usually formed as dimers, trimers, or oligomers. Nevertheless the diphosphadiboretenes may be regarded as original compounds for obtaining boraphosphenes, which is confirmed by the appearance of cation radicals of the corresponding boraphosphenes in their mass spectra.[8,9]

Boraphosphenes were observed in the gas phase for the first time in the mass-spectrometer for (tmpB = PAr)$_2$ (tmp = 2,2,6-tetramethylpiperidino; Ar = 2,4,6-(*tert*-Bu)$_3$C$_6$H$_2$).[10,11] The authors[10] involved in this study suggested that they were able to identify boraphosphene as a complex with iron tetracarbonyl.



The dimer (tmp−PAr)$_2$ was obtained as a result of the interaction of tmpBCl$_2$ and ArP(SiMe$_3$)Li in Et$_2$O at 0 °C. Thermolysis of this compound at 250 °C yielded boraphosphene in the gas phase, which was confirmed by the mass spectra. It followed from *ab initio* calculations of a model molecule of boraphosphene H−B=P−H that the energy minimum for the boraphosphenes corresponds to a structure with a free unshared electron pair at the P atom and a P=B double bond (H−P=B−H) in contrast to the iminoboranes in which the N≡B triple bond is found (H−N≡B−B).[10] In an attempt to obtain boraphosphene by treatment of MeLi or the *tert*-BuLi compound (tmp)B(Cl)PHAr in Et$_2$O at 25 °C a new phosphide anion was found.

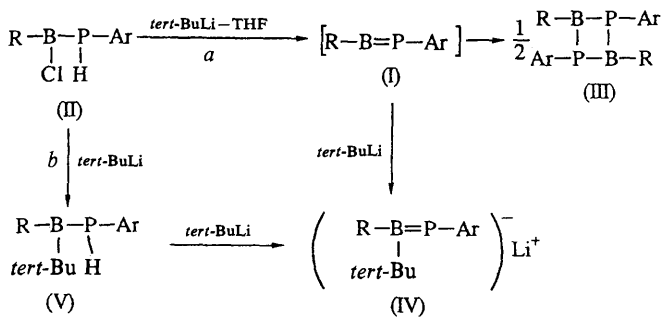


R = Me, *tert*-Bu; Ar = Ph, Mes

(Mes = 2, 4, 6-Me$_3$C$_6$H$_2$).

Thus a series of compounds containing the P=B multiple bond was synthesised. The structural parameters of double-bonded P and B atoms in complexes [Li(Et$_2$O)RPBMes$_2$] (R = Ph, C$_6$H$_{11}$, Mes) and in the ion pairs [Li(12-crown-4)$_2$][RPBMes$_2$], THF, obtained by the action of two equivalents of 12-crown-4 on these complexes have been presented for the first time.[12,13] The environment of the P and B atoms is planar, and a slight twisting is found between the planes in which the atoms lie, and there is a short bond between them (1.823 Å). The P=B bond length is significantly shorter than the known bond lengths in the borophosphines (1.96 Å). The Li ion is coordinated through the P atom. For the complexes the chemical shift in the ^{31}P NMR spectra is equal to +55−73 p.p.m. During the action of the crown ether the signal is displaced to +91−103 p.p.m.

Using chemical methods attempts were made to demonstrate the existence of compounds containing two-coordinate P and B atoms but without an ionic structure. For this the behaviour of borylphosphine in the reaction with *tert*-BuLi was studied.[14]



On account of the absence of compound (V) in the reaction mixture it was concluded that the reaction occurs via route *a*. Certain information is available on the reactivity of the compounds containing a double bond between the P and B atoms. Thus type (I) compounds are air-sensitive and readily react with proton donors such as water and methanol (forming in this case the type (V) structures) and also with alkyl halides and triemthylchlorosilane.[7]

Generalised data on the methods used for synthesis and on the structures of compounds containing the P=B fragment have been described.[15] In these works the synthesis and spectral data of 17 boron-phorphorus-containing compounds, relating to the synthesis of the Li(Et$_2$O)P(R)BR$_2$ type of structures, have been examined in detail. Here it is necessary to distinguish the compound with the P=B−P structure which has two different phosphorus atoms and one boron atom (δ^{31}P 32 and −117.0 p.p.m., the constant J_{P-P} is absent, J_{P-H} = 247 Hz, the P−B bond length is 1.927, and the P=B bond length is 1.810 Å). It has the shortest P=B bond.[13]

Thus of the currently known compounds containing the P=B fragment the only stable compounds are the phosphinidene borates in which the boron atom is three-coordinate. Moreover stabilisation is ensured by the bulky substituents in both heteroatoms.

III. Compounds containing the P−C−B fragment

Substances containing this fragment have long been known.[6,16] Two types of structures are possible, compounds in which the P and B atoms occur in the three-coordinate state, and substances containing a phosphonium cation and a borate anion in the molecule. Only a few representatives of the first type have been described, and furthermore they usually exist as dimers. Thus the interaction of dimethylchloromethylborane with nucleophilic reagents including phosphines has been studied.[16]

The reaction was carried out in sealed ampoules. Borylmethylenephosphine exists as the dimer in the gas phase.

Much more work has been done on the synthesis of boratomethylenephosphonium betaines. The method used to obtain such compounds is based on the reaction of phosphorus ylides with halogen boranes[17–22] or boron hydrides.[22–27]

$$R_3P{=}CHR' + BX_3 \longrightarrow R_3\overset{+}{P}{=}CHR'{-}\overset{-}{B}X_3,$$

R = Me, Et, Ph, R' = H, Alk, X = Hal;

$$Ph_3P{=}CHR' + B_2H_6 \xrightarrow[0°C]{Et_2O} Ph_3\overset{+}{P}\underset{R^1}{CH}\overset{-}{B}H_3;$$

$$Ph_3P{=}CH_2 + H_2RB{\leftarrow}NEt_3 \xrightarrow[-NEt_3]{C_6H_6,\ 80°C} Ph_3\overset{+}{P}CH_2\overset{-}{B}RH_2.$$

The borate alkylidene phosphonium betaines are of interest in that as a result of intramolecular regroupings they may give rise to a phosphine complex with borane in which the alkylidene fragment of the molecule is found to be at the boron atom. This regrouping is used in organic syntheses.[28–30]

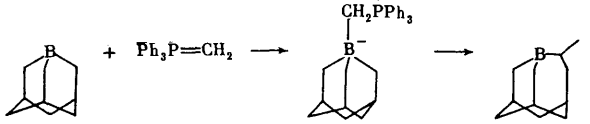
$$R^1CH{=}PPh_3 \xrightarrow{BH_3THF} R^1\underset{\overset{-}{B}H_3}{CH}\overset{+}{P}Ph_3 \longrightarrow$$

$$\longrightarrow R^1CH_2{-}H_2B{\leftarrow}PPh_3 \xrightarrow[-R^5\overset{+}{P}Ph_3\overset{-}{I}]{R^2HC{=}CR^3R^4,\ R^5I}$$

$$\longrightarrow R^1CH_2B\underset{R^2}{\overset{R^4}{(CH{-}CH)_2}}\underset{R^3}{} \xrightarrow[3)H_2O_2/NaOH]{1)\ Cl_2CHOMe,\ 2)LiOCEt_3}$$

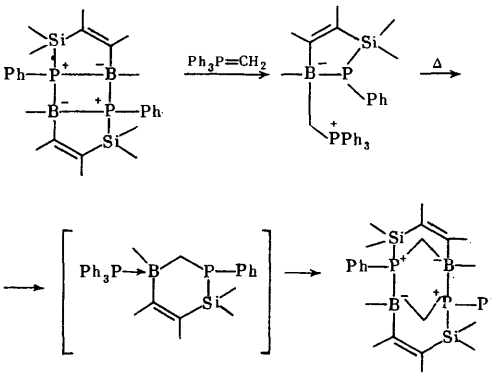
$$\longrightarrow R^1CH_2{-}\underset{HO\ R^2}{\overset{R^4}{C(CH{-}CH)_2}}\underset{\ R^3}{} .$$

An analogous regrouping has been acheived for boradamantane derivatives. On interaction of triphenylphosphine ylide with boradamantane the corresponding phosphonium salt is formed which regroups with a change of the boradamantyl framework into the homodamantyl framework. After triphenylphosphine is removed, 4-alkyl-3-borohomoadamanatane separates out.[31]



The X-ray diffraction analysis of borataphosphonium betaine formed in this reaction shows that certain geometric parameters in the P atom environment differ significantly from the corresponding characteristics of the phosphonium systems and are intermediate between the values observed in them and in the ylide molecules.[32]

The regrouping of the borataalkylenephosphonium salts may involve two phosphorus atoms.[33] In this case one $\overset{+}{P}{-}C{-}\overset{-}{B}$ fragment is disrupted and a new fragment is formed.



By substitution of boron hydride by the haloboranes in reactions with phosphorus ylides it is possible to obtain borylalkylidene phosphoranes,[34] i.e. compounds containing the P=C–B fragment.

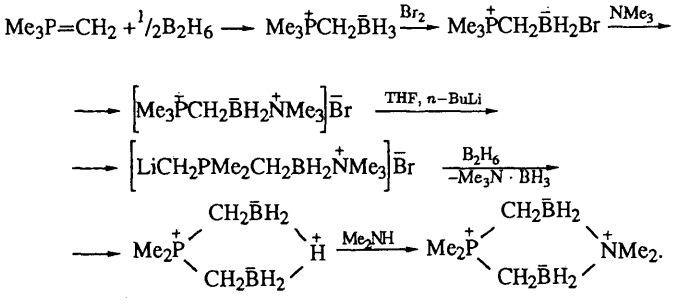
$$R'CH{=}PPh_3 \xrightarrow{R^2_2BCl} R'\underset{Ph_3P^+}{CH}{-}\underset{Cl}{\overset{-}{B}}R^2_2 \rightleftharpoons R'\underset{Ph_3P^+}{CH}{-}BR^2_2Cl^- \longrightarrow$$

$$\xrightarrow[-\ R'CH_2{-}\overset{+}{P}Ph_3Cl^-]{R'CH{=}PPh_3} R'C(=PPh_3){-}BR^2_2 \longleftrightarrow R'C{=}\overset{-}{B}R^2_2.$$

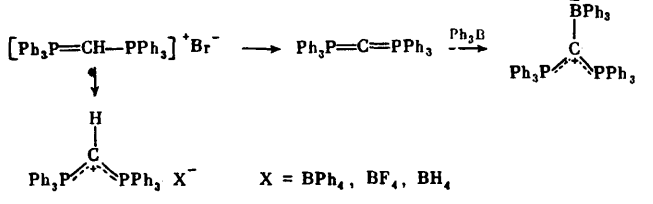
$$\qquad\qquad\qquad

On account of the ability of the borylalkylidene phosphoranes to react with the proton donors and bromine it is possible to obtain deuterated and brominated phosphorus ylides, which in turn provide a means to achieve the stereoselective synthesis of deuterated and bromo-substituted vinyl compounds according to the Wittig reaction.[37]

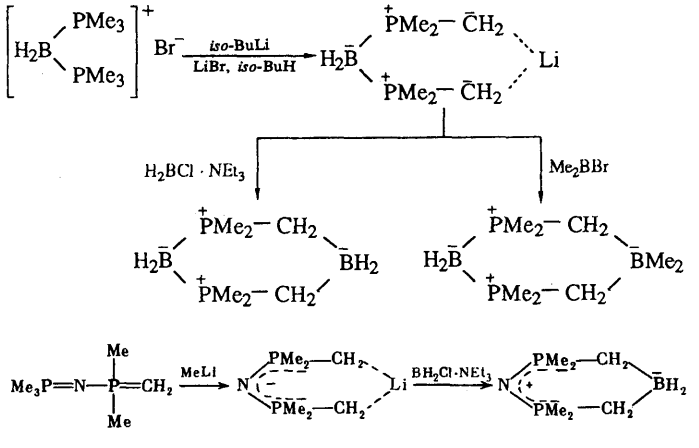
Two novel and unusual heterocycles containing P–C–B fragments were synthesised according to the following scheme:[38]



On account of the ability of the P and B atoms to change their coordination and to form ionic structures it is possible to obtain a diversity of compounds. Thus in the PBC series containing the P–C–B fragment compounds having a mesoionic structure are known.[39,40]

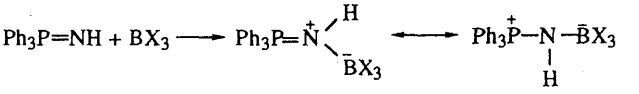


The synthesis of new heterocyclic systems containing P and B atoms in the four-coordinate state, borata-*bis*-(dimethylphosphoniamethylene) borate and nitrido-*bis*-(dimethylphosphoniamethylene)-borate has been studied.[40]

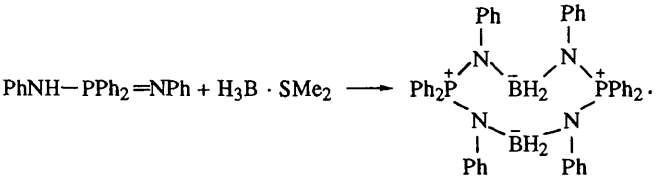


IV. Compounds containing fragment P–N–B

PBS containing such a fragment are most numerous among compounds in which the P and B atoms are separated by one atom. Such compounds were described a considerable time ago. Substances containing 3- or 4-coordinate P and B atoms depending on the original reagents and the synthetic route have been obtained. Thus betaines, which may be presented as two boundary mesomeric structures, were obtained from iminophosphoranes and boranes, triphenylborane or trifluoroborane.[41,42]



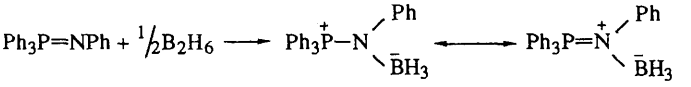
On interaction with a borane complex containing diethylsulphide the amino(imino)phosphoranes form a diazaboraphosphetidine dimer in which there are two atoms of four-coordinate boron and two phosphonium centres:[43]



The structures of phenyl-, *p*-fluorophenyl-, and benzylamino-triphenylphosphorane complexes with boron trifluoride have been studied by i.r. and ^{31}P NMR spectroscopy.[44]

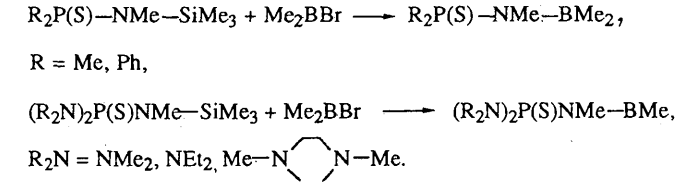
The complexes have the phosphorane structure towards which the phosphonium salt structure makes a significant contribution.

Phenyliminophosphorane forms a complex with diborane and the composition of this complex may also be presented as two resonance structures.[42]



It will be found impossible subsequently to describe the structure of the compounds containing the P–N–B fragment as a simple structure, which can be attributed to the ability of the heteroatoms of the P–N–B system to change reversibly their coordination and to the possibility of charge delocalisation at several atoms.

Borylaminophosphine sulphides are formed on substitution of the trimethylsilyl group in the silyaminophosphine sulphides during the action of bromoboranes.[45]



Use of lithium amides increases the yield to 90%.[45,46]

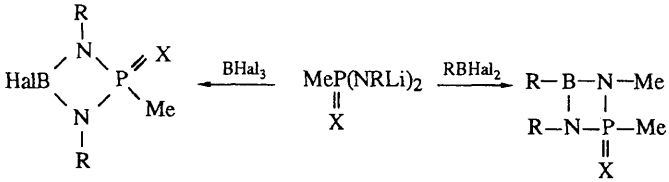
$$Me_2P(S)NRLi + Me_2BBr \longrightarrow Me_2P(S)NRBMe_2,$$

R = H, Me,

$$MeP(X)(NRLi)_2 \xrightarrow{2R_2BHal} MeP(X)(NR{-}BR_2)_2,$$

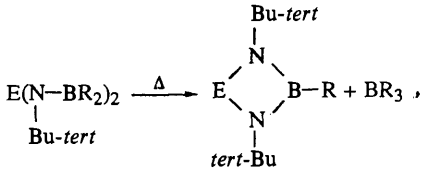
X = O, S; R = H, Me, Et.

It is noteworthy that of the boron dihalides or trihalides it has not been possible to obtain *bis*-(borylamino)methylphosphine sulphides or oxides, since cyclisation to diazaboraphosphetidines occurs.[46]



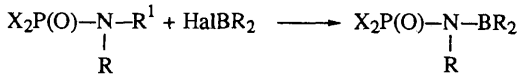
X = O, S.

Certain authors have noted that formation of borylaminophosphine sulphides does not occur on interaction of thiochlorophosphines and silylated aminoboranes.[45] In subsequent studies these authors extended the range of starting reagents,[46–50] using boron trihalides,[46,47] dichloro(silylamino)phosphine sulphide, and lithium phosphamides. Three methods used to synthesise borylaminophosphine sulphides were analysed,[48] and their degradation routes on thermolysis were studied.[47,49] It was shown that 1,3,2,4-diazaboraphosphetidines are formed, when a bulky substituent (*tert*-Bu) is present at the atom.



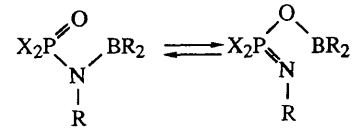
E = PPh, PMe.

A series of phosphoryl aminoboranes obtained by substitution of the hydrogen, silyl group, or lithium at the nitrogen atom in the corresponding oxides of aminophosphines or aminochlorophosphines by the boryl group has been described.[50]



X = Cl, Me, NMe_2; R = Me, Et, Cl, Br; R^1 = H, Li, $SiMe_3$.

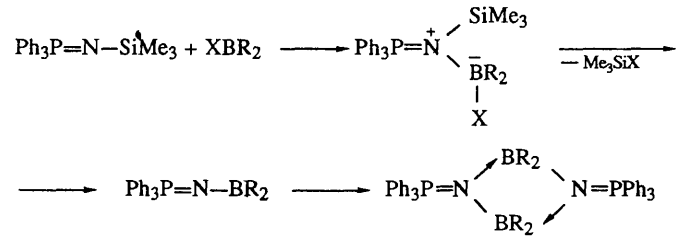
These compounds exist in solutions (X = R = NMe_2) as monomers. When X = Cl or NMe_2 and When R = Me borotrophic tautomerism was observed.



These authors later described the synthesis of borated iminophosphoranes,[51] which were previously obtained during thermal transformations of the triphenylboron complex with iminotriphenylphosphorane.[41]

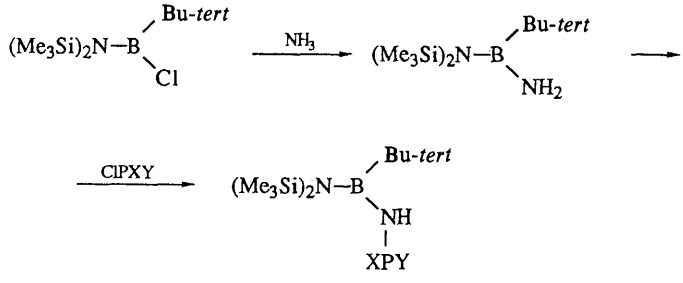
$$Ph_3P{=}\overset{+}{N}H{-}\overset{-}{B}Ph_3 \xrightarrow[-C_6H_6]{\Delta} Ph_3P{=}N{-}BPh_2.$$

Using the same method, the substitution of the silyl group at the nitrogen atom by the boryl group in the reaction with boron halides, it was possible to obtain a series of borated iminophosphoranes, which underwent association into dimers in the solutions but which were monomeric in the gas phase.



X = F, Cl, Br; R = F, Cl, Br, *n*-Bu, Ph.

Although these authors do not recommend the use of silylated aminoboranes and the acid chlorides of phosphorous-containing acids to obtain compounds containing the P–N–B fragment,[45–50] such a synthetic route has previously been described,[52] and the yield of the compounds was 40–90%.



X, Y = NMe_2, Ph, CH_2SiMe_3, $N(SiMe_3)_2$, Cl.

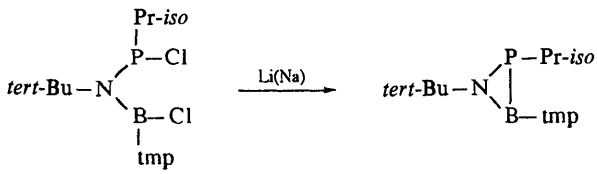
Fluoro(amino)phosphines and their sulphides with halides give phosphinoaminoboranes,[53,54] and derivatives of *tris*, *bis*, and monophosphinoaminoboranes may be obtained depending on the number of halogen atoms at the boron and the ratios of the reagents.

$$F_2PNH_2 + BF_3 \longrightarrow F_2B{-}NH{-}PF_2,$$

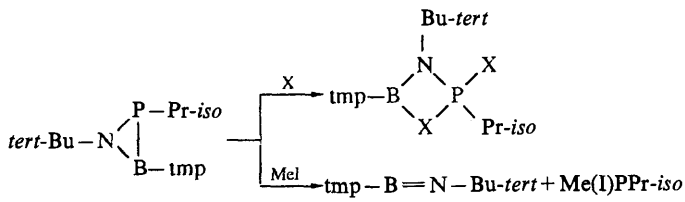
$$nF_2(S)PNH_2 + Cl_nBPh_{3-n} \longrightarrow (F_2(S)PNH)_nBPh_{3-n}$$

$n = 2, 3.$

The most characteristic property of the borylaminophosphine derivatives is their ability to form heterocyclic structures. Cyclisation may arise by the action of some reagent owing to the detachment of the halogen atoms.[55]

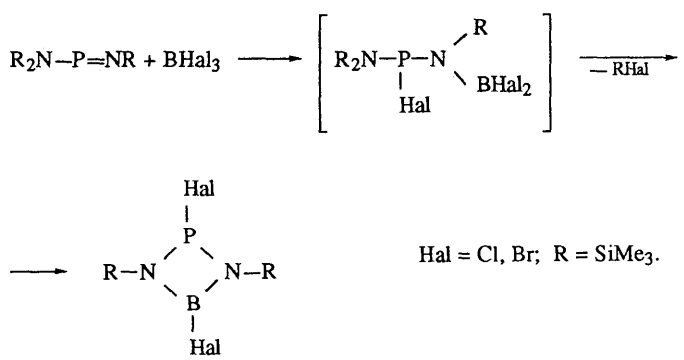


Breakage of the three-membered ring formed by the action of S(Se) or methyl iodide occurs at the P—B bond:



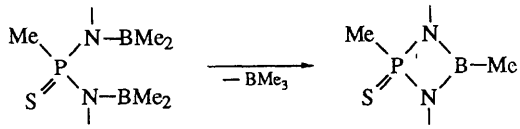
X = S, Se.

The formation of the four-membered ring, diazaboraphosphetidine, may arise as a result of intramolecular cyclisation in the N-boryl(sily)aminophosphines.[56]

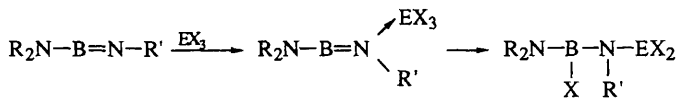


Hal = Cl, Br; R = $SiMe_3$.

Intramolecular cyclisation may appear not only because of the detachment of the halosilane, as in the above example, but also owing to the release of trialkylborane.[57,58]



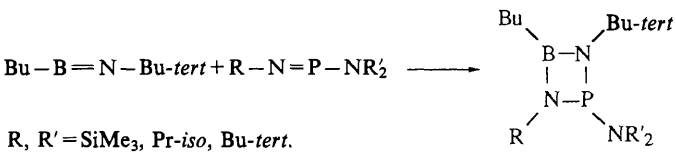
Compounds containing the P—N—B fragment in the molecule have been obtained as a result of the addition of halogenphosphines to two-coordinate boron compounds, amino-iminoboranes. This is a general method and halogenarsines, halogenstibines, and also the $E(OMe)_3$ or $E(OMe_2)_3$ type of derivatives, where E = P, As, Sb, may be used in this reaction. The reaction initially involves complex formation at the imonium atom, after which hetero-aminoboranes are formed,[59,60] as a result of the migration of the substituent from the phosphorus atom (arsenic, tin) to the boron atom.



E = P, As, Sb; X = Cl, Br, F, OMe, NMe_2;

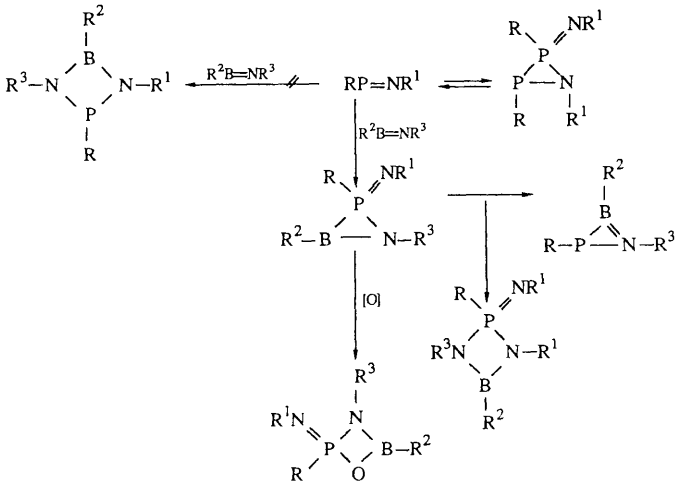
R' = Alk, Ar; R_2 =

The borylaminophosphines may be synthesised by using compounds containing P and B atoms with low coordination numbers. The method is based on the cycloaddition reaction of iminoboranes and iminophosphenes. It has been shown that depending on the radicals the reaction may occur either as a [2 + 2]-cycloaddition, or as a [2 + 1]-cycloaddition. Thus the iminoborane Bu—B=N—Bu-*tert* and aminoiminophosphene react via [2 + 2]-cycloaddition giving rise to diazaboraphosphetidine.[61]

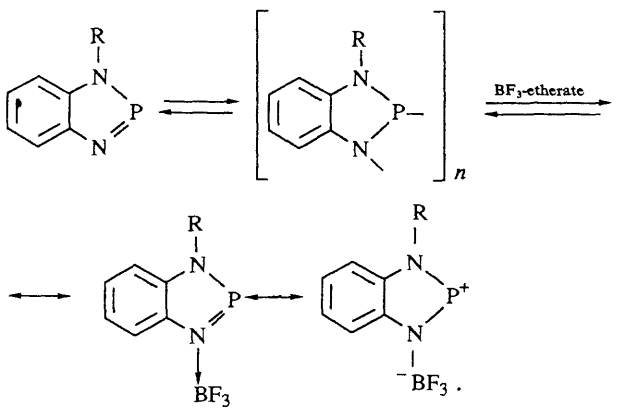


R, R' = $SiMe_3$, Pr-*iso*, Bu-*tert*.

Otherwise the reaction proceeds at the P and B atoms in the case of the alkyl substituents. The iminophosphene RP = NR· undergoes autocyclisation and an iminophosphorane is obtained. When it interacts with iminoborane, [2 + 2]-cycloaddition does not occur, while a reaction analogous to autocyclisation of iminophosphene is acheived. The azaboraphosphyrene formed readily oxidises with the disruption of the P—B bond, giving rise to oxazaboraphosphetidine or it undergoes disproportionation.[62]

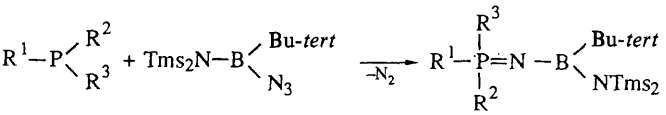


1,3-Diazaphosphols existing as oligomers or tetramers undergo monomerisation by the action of boron trifluoride etherate with the formation of the complexes[63]

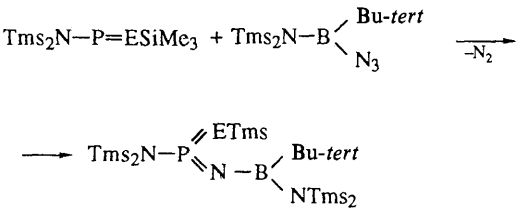


It is proposed that the complex may be described by two boundary structures.

Yet another example of the diversity of the original reagents which may be used to synthesise PBC containing the P–N–B fragment is the interaction of azidoboranes with phosphines leading to the formation of boryliminophosphoranes, and depending on the type of the original phosphorus-containing reagent a four- or three-coordinate phosphorane containing the P=N–B fragment is formed.[64]



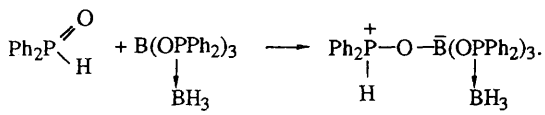
$R^1 = Ph$; $R^2 = Me, NMe_2$; $R^3 = NMe_2, NTms_2$.



E = CH, N.

V. Compounds containing fragment P–O–B

Compounds containing fragment P–O–B have been known since 1951.[65,66] The reactions of phosphoric acid esters with various boron hydrides have been examined in earlier reviews.[67,68] In the P–O–B system the P atom preserves its ability to form complexes with boranes. Thus the compound containing four-coordinate P and B atoms in the P–O–B fragment have been obtained by the following scheme:



The structure of the betaine has been confirmed by X-ray diffraction studies.[68]

Borophosphinites containing strong electron-acceptor substituents have been obtained on disruption of the phosphinite fragment by the action of halogenboranes.[69]

$n = 0, 1, 2$.

The authors note the stability of the borphosphinites to the Arbuzov reaction type of regrouping. Trifluoromethyl groups such as strong electron acceptors increase the acidity of the boron atom as a result of which all three borophosphinites form complexes with dimethyl ether.

Compounds with the P–O–B fragments in which P and B atoms are in the four coordinate state can be obtained by the action of halogenboranes or phosphine[70] or aminophosphine oxides.[71,72]

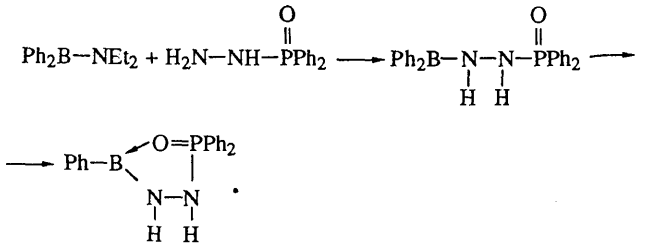
R = Alk, NMe_2; X = Cl, F.

If bromides or iodides of the boranes are used in the reaction with the aminophosphine oxides, it is possible to isolate unusual ions of compounds in which the cation contains an anionic borate fragment.[71]

$$(Me_2N)_3P{=}O + BX_3 \longrightarrow [(Me_2N)_3P{-}O{-}BX_2{-}O{-}P(NMe_2)_3]^+X^-,$$

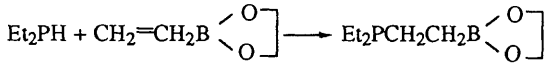
$$(Me_2N)_3P{=}O + R_3NBHI_2 \longrightarrow [((Me_2N)_3P{-}O{-})_2BH{-}NR_3]^{2+}2I^-.$$

Reference should be made to yet another study concerning the formation of aminoboranes but describing the synthesis of a compound with a phosphorus-containing fragment.[73] The spectral data indicated that the boron atom in this compound is in the following state:



VI. Compounds containing fragments P–C–C–B and P–C=C–B

Only a few compounds of this type have been described. Phosphorylation of vinyl derivatives of boron is the most obvious route for the synthesis of these compounds.[74,75]

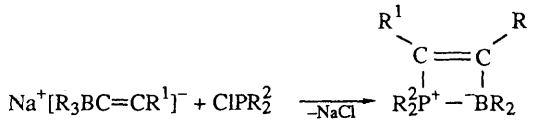


This is a general type of reaction in which silicon, tin, and sulphur hydrides may be added to the ethylene fragment.[74]

There are many reports in the literature describing the synthesis and study of the properties of compounds containing the P–C=C–B fragment. 1,2-Heteroethenes containing P, As, Si, Sn, B, O, N and Al atoms in different combinations are known. Those compounds in which heteroatoms, for example phosphorus and boron atoms, possess different electronic characteristics are of especial interest. Such a combination leads to the appearance of new properties in the compounds.

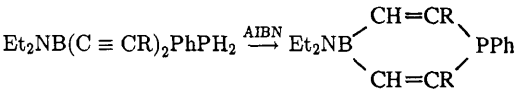
The first member of the borylphosphinoethenes has been described.[76] The principal method used to synthesise compounds containing the P–C=C–B fragment with three-coordinate P and B atoms is the interaction of halogenphosphines or phosphines with alkinyl borates or alkinyl boranes respectively.[76–79] Thus in the reaction of sodium trialkyl(alkinyl)borates with diorganylchlorophosphines, substituted 1-borata-4-phosphoniacyclobutenes-2 were isolated.[76,79]

A four-membered cyclic structure was assigned to these compounds on the basis of ^{11}B- and ^1H-NMR and mass-spectroscopic data and from a cryoscopic determination of the molecular mass and structure of the hydrolysis products. Their structure was subsequently confirmed by an X-ray diffraction analysis,[80] by determination of the dipole moment, and by studying the chemical properties (see below)



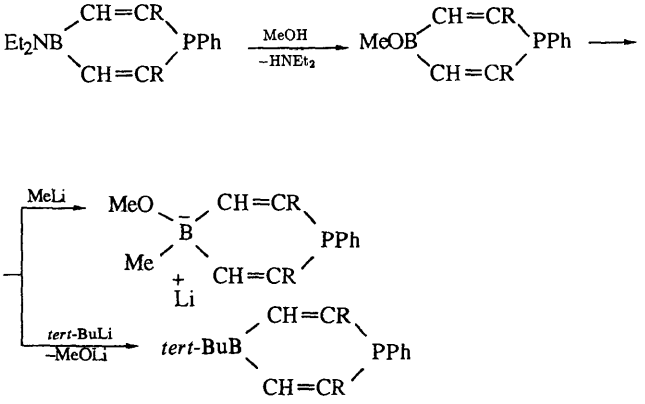
R, R^1, R^2 = Me, Et, Bu, *cyclo*-Hex, Me_3Si.

Addition of phenylphosphine to dialkinyl(diethylamino)boranes is a radical process and leads to the formation of 1,4-boraphosphacyclohexa-2,5-dienes.[77,78]



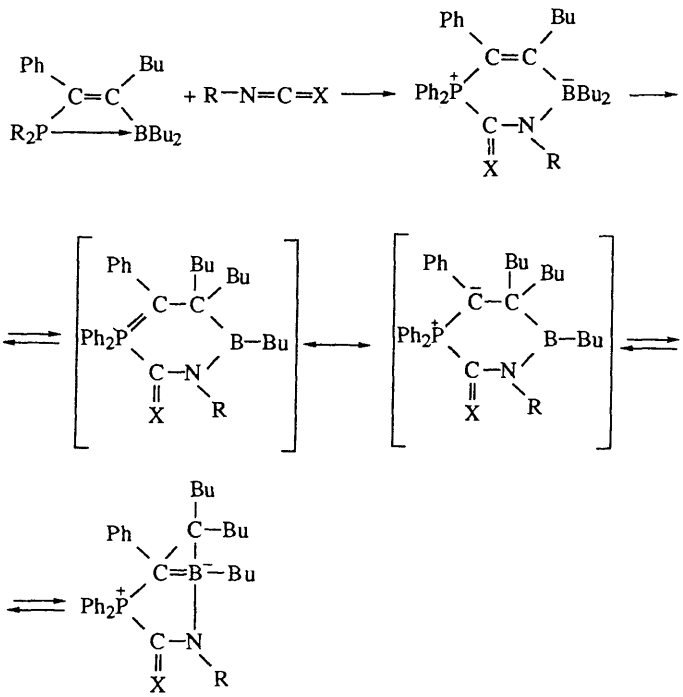
R = H, Me.

These compounds are heat stable but sensitive to oxidation. The reactivity of boron in these compounds is somewhat reduced as a consequence of the coupling of its vacant orbital with that of the unshared electron pair of the N atom, which leads to the absence of intermolecular coordination, although they undergo methanolysis. The resultant methoxy-derivative interacts with alkyllithium compounds, giving rise to borates or B-alkylated derivatives depending on their nature.



The 1-bora-4-phosphacyclohexadienes-2,5 are typically reactive towards tertiary phosphines and together with NMR spectroscopy data there is evidence that the unshared electron pair of the P atom in these rings is not delocalised and the P and B atoms do not have a significant influence on each other. In this regard the heterocycles differ from cyclic compounds containing the P–C–O–B fragment which will be examined below.

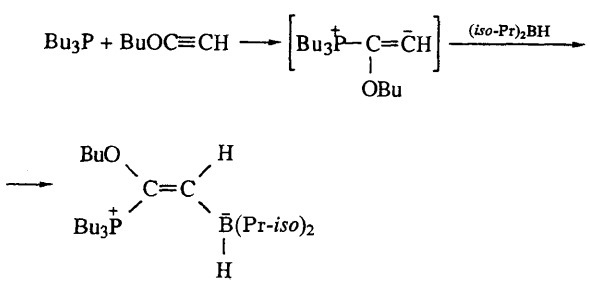
In recent years the authors of the present review have carried out systematic studies of the properties of the 1,2-borylphosphinoethenes,[81–89] and the results obtained have been grouped into one of the sections of a previous review.[4] It has recently been shown that reactions with heterocumulenes are characteristic of the borylphosphinoethenes,[90–93] and these reactions proceed as [4 + 2]-cycloaddition and lead to the formation of 6-oxo(thioxo, imino)-1-aza-5-phosphonia-2-boratacyclohexa-3-enes. These monocyclic betaines undergo anionotropic regrouping leading to the formation of bicyclic betaines, 2-aza-4-phosphonia-1-boratabicyclo[3.1.0]-hexanes. One should particularly note that this is a reversible regrouping and that the reverse process involves the migration of the butyl anion from the sp^3-hybrid C atom to the sp^3-hybrid B atom.



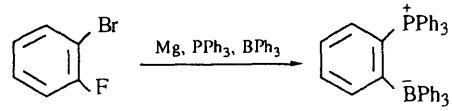
R = Ph; X = NPh, O, S; R = C_6H_{11}, X = NC_6H_{11}.

The structure of the compounds was established by X-ray diffraction studies. The equilibrium processes were studied by NMR and i.r. spectroscopy.

In the studies presented above examples have been described of cyclic betaines containing the P–C=C–B fragment. Such a fragment occurs also in the acyclic molecule 1-borato-2-butoxy-2-phosphonium ethene.[94]

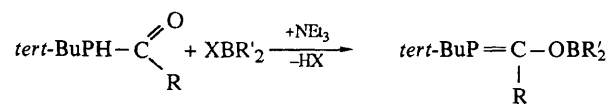


A betaine in which the phosphonium cation and the borate ion are separated by a phenylene fragment was obtained as a secondary product at low yield on interaction of *o*-bromofluorobenzene with Mg, Ph_3P and BPh_3.[95,96]

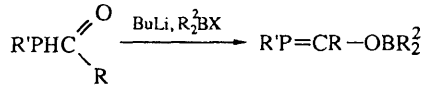


VII. Compounds containing fragment P=C–O–B

This type of compound may be obtained from acylphosphites[97] or from their lithium derivatives[98–100] on interaction with halogenboranes:



X = Cl, Br, R = Alk, R' = Alk, NMe_2;



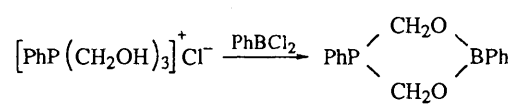
R', R = Alk, Ar; R^2 = Alk, $NAlk_2$.

Germanium, tin and phosphorus halides were used in the reactions, although in these cases not methylenephosphines but hetero-substituted acylphosphines are formed.

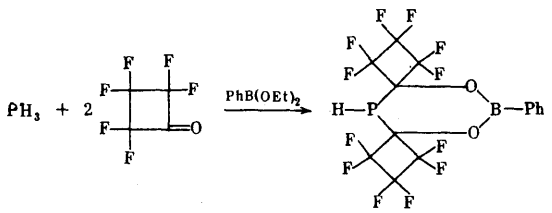
Boryloxymethylenephosphines, i.e. compounds containing a two-coordinate phosphorus atom, constitute an interesting class of hetero-organic derivatives possessing considerable synthetic potential.

VIII. Compounds containing fragment P–C–O–B

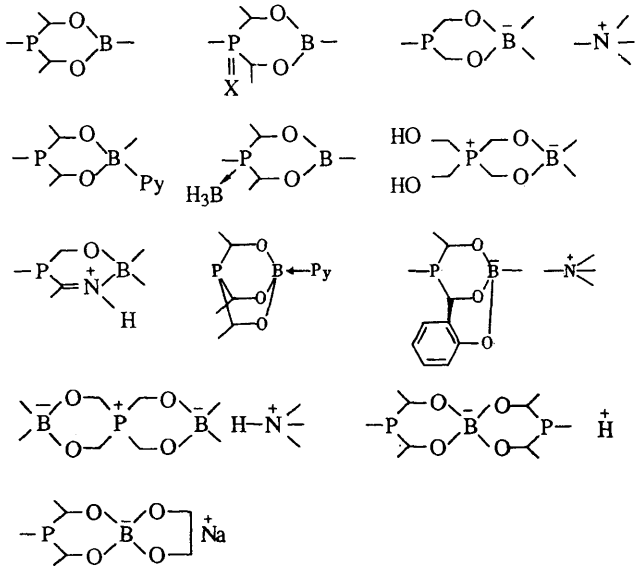
A study of the properties of compounds containing P and B atoms separated by a particular fragment shows that these properties are often determined by the presence of an interaction of heteroatoms, and the nature of the interaction may differ. For chemical compounds containing the P–C–O–B fragment the interaction of the P and B atoms plays a decisive role and is reflected in both the reactivity and the three-dimensional structure of the compounds. The synthesis and properties of the boryloxyalkylphosphines and their analogues are described in a number of articles and reviews.[3,5,90,101] Most of the boroxyalkylphosphines and their derivatives are heterocyclic compounds. The first member in this series was obtained in 1964.[102]



A report was then published which described the synthesis of 1,3,2,5-dioxaboraphosphorinane with hexafluorocyclobutyl substituents in the heterocycle.[103]

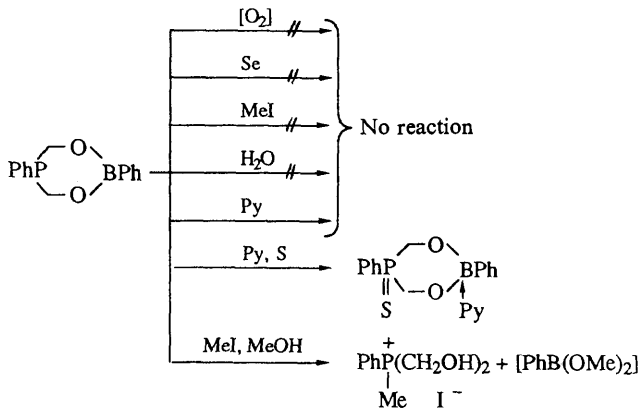


Starting from 1979 a series of studies by B A Arbuzov, O A Erastov, and G N Nikonov was published on the synthesis and properties of boroxyalkyl derivatives of phosphorus. Various heterocyclic compounds containing the P–C–O–B fragment in which the P and B atoms occur in different valence states were synthesised.

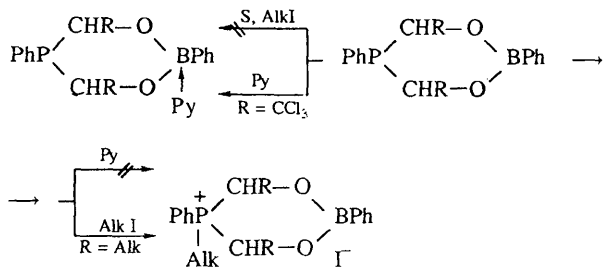


Here we shall emphasise only the properties which illustrate the interaction of the heteroatoms in the P–C–O–B system. They are most clearly apparent in the three-coordinate P and B atoms. Thus the unusually high content of conformer with axial orientation of Ph at the P atom in the conformational equilibrium of 2,5-diphenyl-1,3,2,5-dioxaboraphosphorinone (95%) can be attributed to the n-σ^*-interaction of the unshared electron pair at the P atom and the vacant orbital of the C–O bond. The interaction resulted from the expression of the acceptor properties of the B atom. This type of interaction by the heteroatoms explains satisfactorily the change in content of the stereoisomers or conformers on transition from dioxaboraphosphorinanes to their oxides, sulphides and selenides, which is contrary to the change in ratios of the stereoisomers in the series of dioxaphosphorinanes and their oxides, sulphides and selenides.[101]

The mutual effect of the heteroatoms is even more obviously expressed on examination of the chemical properties of 2,5-diphenyl-1,3,2,5-dioxaboraphosphorinane.[3,101] The presence of three-coordination P and B atoms should confer upon this compound properties typical of tertiary phosphines and phenylboric acid esters. However this compound shows anomalous reactivity. Despite the presence of the phosphine fragment it is not oxidised by atmospheric oxygen, it slowly adds sulphur, forms an unstable selenide, and does not interact with methyl iodide. The reactivity of the oxyboryl fragment also fell sharply, which is reflected in the resistance to hydrolysis even by aqueous methanol and in the absence of complex formation with pyridine. However if it operates simultaneously at two reaction centres (the P and B atoms), the reaction proceeds normally, giving rise to the corresponding derivatives with the same reagents.

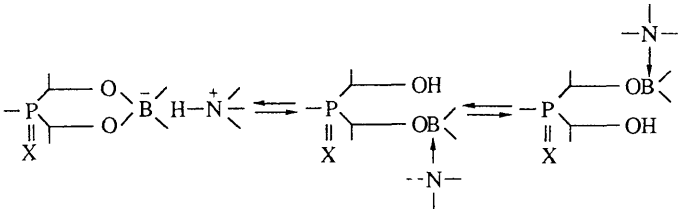


This all indicates the existence of an intramolecular interaction of the heteroatoms (an intermolecular interaction is discounted on the basis of data obtained by using physicochemical techniques). This interaction may be disrupted by varying the nature of the substituent in positions 4 and 6 of the heterocycle. Thus the presence of donor (alkyl) substituents in the 4,6-positions of the 1,3,2,5-dioxaboraphosphinane leads to alkylation by alkyl halides in the absence of methanol. On the contrary 4,6-*bis*-(trichloromethyl)-2,5-diphenyl-1,3,2,5-dioxaboraphosphorinane is not alkylated at the P atom and does not add sulphur, but forms a stable complex with pyridine, despite the three-coordinate P atom.



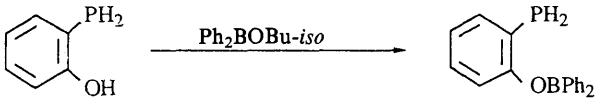
The chemical properties of the boroxialkyl derivatives of phosphorus have been described in a number of reports.[3,101] Reactions with electrophilic reagents leading to an increase in the coordination number of the P atom, the reaction with dipolar reagents (aldehydes) leading to betaines, and reactions with nucleophilic reagents (amines) in which the P–C–O–B fragment is preserved, or disrupted with the formation of aminomethyl derivatives of phosphines, ion-exchange reactions, and thermal transformations, etc. were studied. One of the characteristic features

of the boroxyl derivatives of phosphorus possessing a mobile hydrogen atom is high tautomeric lability, and the tautomeric transformations are caused by the transfer of two particles, a hydrogen atom and a nitrogen atom with the involvement of oxygen and boron atoms, and migration of the boryl grouping also occurs when degenerated tautomerism is taken into account.[3,101]

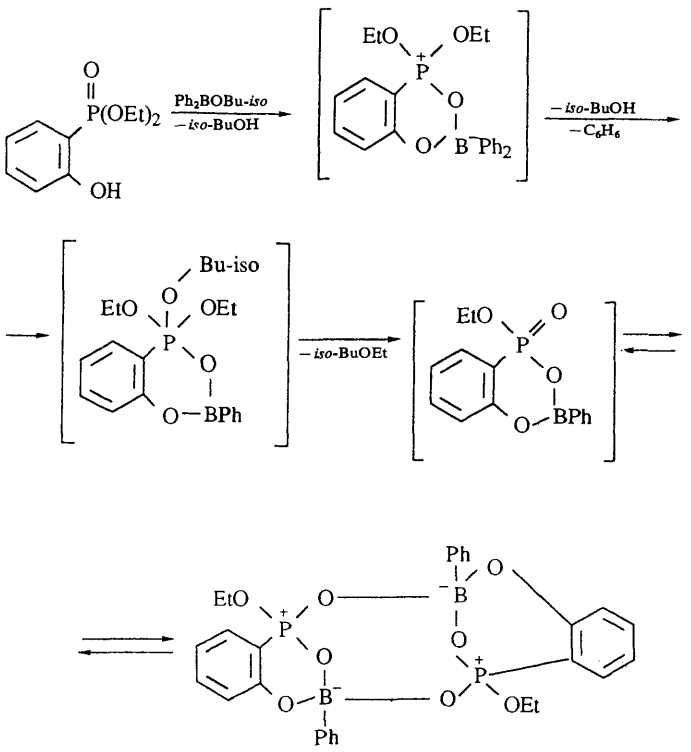


Polymers have been described for this type of tautomerism, ion-complex tautomerism: bicyclo-cyclic ion-complex tautomerism, ion–ion ring-chain, and other.[3,101]

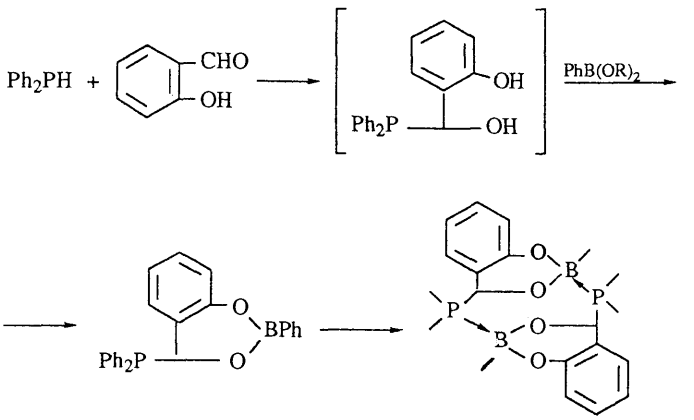
It has been previously shown that borating of *o*-oxyphenylphosphine leads to the formation of *o*-diphenylboryloxyphenylene phosphine and takes place under severe conditions.



The reaction with *o*-oxophenylphosphonate also occurs at high temperatures but in this case the dimer of the corresponding 1,3,2,4-dioxaborophosphinone is formed, which has been shown by X-ray diffraction. The reaction probably takes place with the involvement of isobutyl alcohol formed in the first stage.



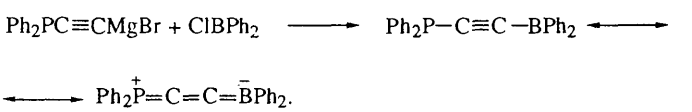
The synthesis of a compound in which the phosphine fragment is the exocyclic substituent relative to the oxyboryl ring has been described. The nature of the interaction of the heteroatoms changed despite the fact that the P–C–O–B fragment was preserved. By combining the data obtained (chemical behaviour, spectral characteristics, RMM, etc.) it was concluded that the P and B atoms undergo intermolecular interaction.[105]



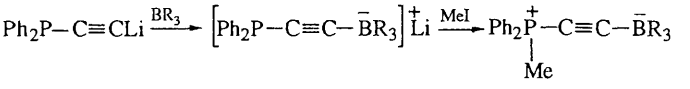
The specific characteristics and the diversity of properties of the boroxyalkyl derivatives of phosphorus can be attribtued to the presence of heteroatoms with opposite electronic behaviour (donor and acceptor) and to the ability of the atoms to change reversibly their coordination and to the presence of an interaction of the heteroatoms transferring in the P–C–O–B system. These features may form the basis of the construction of new structures containing fragments with interacting groups or type A–X–Y–B heteroatoms where A is the donor, B is the acceptor, and X–Y is the fragment with the ability to conduct the interaction of the heteroatoms (C–O, C–N, C–P, C=C, etc.).

IX. Compounds containing fragment P–C≡C–B

Among a large number of acetylene phosphines the synthesis of 1,2-borylphosphinoacetylene with a yield of 64% is presented. Taking into account the ability of the P and B atoms to form betaine structures, the end product structure should be presented as a canonical equation:[106]

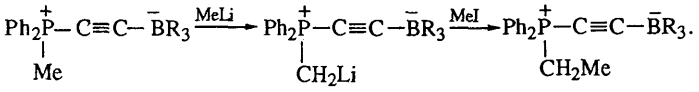


Diphenylphosphinoacetylene may serve as the original compound for the synthesis of phosphinoboratoacetylene[107]



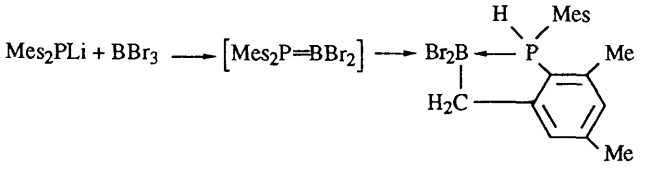
R = CH_2Ph, Ph.

Sequential treatment of this betaine with lithium using MeLi and treatment with MeI leads to the extension of the hydrocarbon chain at the phosphorus atom:

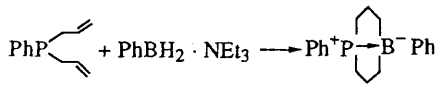


X. Compounds containing fragment P—(C)$_n$—B and others

There are several studies describing P,B-containing compounds in which the P and B atoms are separated by a chain of three carbon atoms and in which these atoms are even more remote from each other. In this case the nature of the interaction of the P and B atoms is different and is manifested as a transannular interaction of the donor and acceptor centres, which leads to the formation of a P→B intramolecular bond. One report is noteworthy in this regard.[108] An attempt was made to obtain dimesitylphosphenylborane from lithium dimesitylphosphide and tribromoborane. However instead a new heterocycle was isolated. The reaction is accompanied by a 1,3-migration of the hydride ion.

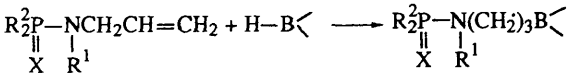


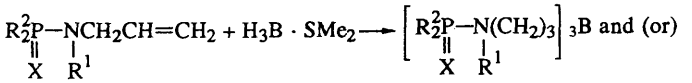
The formation of a strong intramolecular P→B cordinated bond during the hydroboration of dialkylphenylphosphine by triethylaminephenylborane leads to the formation of the bicyclic product, 1-borata-5-phosphoniabicyclo[3.3.0]octane.[109]

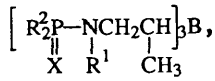


The presence of a coordinate bond in this compound is confirmed by NMR spectra and also by its resistance to oxidation and hydrolysis.

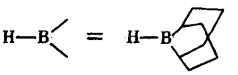
A series of studies has been described of the hydroborination of allyl and propionyl derivatives of N-phosphorylated amines.[110–113]

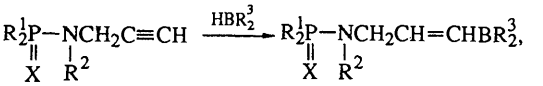






R^1, R^2 = OAlk, Alk, Ar, X = O, S,

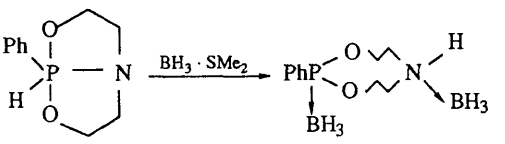




R^1 = OEt, NMe_2; R^2 = Me, CH_2Ph; R^3 = C_5H_{11}, C_6H_{11}, C_8H_{14}; X = O,S.

The hydroboration reactions are regioselective and stereoselective. Compounds in which the boron atom is situated in the δ-position relative to the P atom are formed with a yield of 90–100%. No data are presented on the interaction of the phosphoryl and boryl groups.

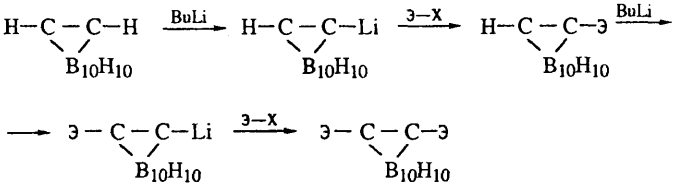
The following is yet another example of a compound containing a δ-atom of boron.[114]



There are also groups of compounds with a different combination of P and B atoms. There are the phosphaborohydrides and coordination compounds in which ligands contain P and B atoms separated by a particular fragment. Compounds of different structure are grouped into one section because the heteroatoms in these compounds are involved in the formation of coordinated or multiple-centre bonds. In line with the general layout of this review only compounds with a fragment between the P and B atoms will be examined.

XI. Phosphaborohydrides

These types of compounds have been known for a long time and have been described in the monograph by B M Mikhailov.[6] However, as before, they continue to attract the attention of research workers. This is because the carborane framework structure imposes certain steric requirements and possesses strong acceptor properties, while on account of the high mobility of the hydrogen atoms at the carbon atoms or in the framework structure different heteroatomic fragments may be introduced via the lithium derivatives.[115,116]



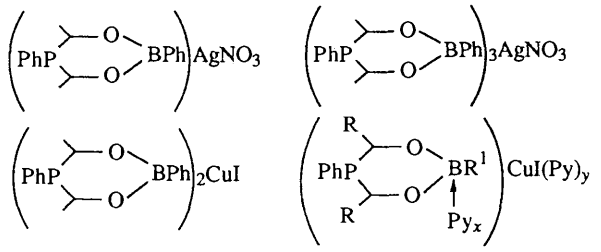
Э = H, As, Si, P.

The opportunity of introducing alkyl or vinyl groups to the C atoms in the *o*-carboranes increases the number of possible compounds. The compounds formed may contain one or two phospha groups separated by one or several carbon atoms from the carborane fragment.

XII. Coordination compounds

On account of the presence of an acceptor or an *o*-carborane group as a functional group in the organophosphorus compound, especially when the P and B atoms interact, these compounds are found to be an interesting type of ligand, and in complexes of these compounds new unusual interactions and bonds may be realised. On the whole all types of PBC compounds may be regarded as potential ligands. The coordination derivatives of PBC may be synthesised by different methods. This is the use of PBC as ligands, the introduction of the phospha group into the coordination compound already containing a boryl fragment in the ligand, or introduction of the boryl group into the complex with a phosphorus-containing ligand.

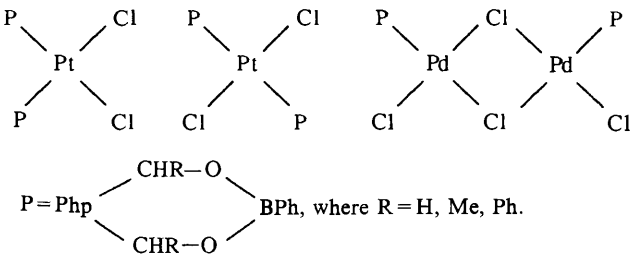
Thus the 1,3,2,5-dioxaboraphosphorinanes have been used as ligands during the synthesis of compounds coordinated to metal salts.[117–119] It was found that Cu(I) and Ag(I) are coordinated at the oxyboryl fragment and depending on the ratio of the reagents complexes of different composition may be obtained.



R = Me, R^1 = Ph, $x = 0, y = 1$
R = Me, R^1 = CBu_3, $x = 0, y = 1$
R = Ph, R^1 = Ph, $x = 1, y = 2$
R = Ph, R^1 = CBu_3, $x = 0, y = 1$

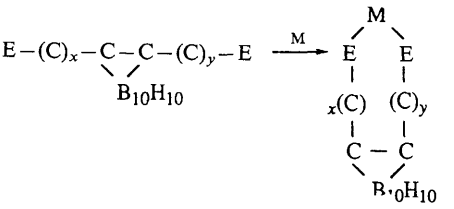
Attempts have been made to determine the three-dimensional structure of the heterocyclic ligands in solutions of the complexes and to correlate the composition and structure of the complexes with the nature of the substituents in the ring.[118]

1,3,2,5-Dioxaboraphosphorinones form complexes with platinum(II) chloride (composition 2:1). Conclusions on the structure of complexes in the solutions have been made from ^{1}H- and ^{31}P-NMR and i.r. spectra in the longwave range and they have been compared with data on the free ligands. The configuration of the central ion differs depending on the substituent in the 4,6-position of the heterocycle.[119]



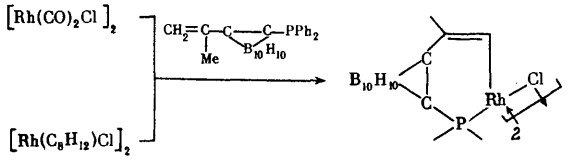
These heterocycles form 1:1 complexes with palladium(II) chloride even in excess of ligand.

Hetero-substituted carboranes are very interesting types of ligands or chelates.[120] The phosphorylated carboranes and their analogues are systematically used as ligands, and phosphorus-containing or such functional groups as for example isopropenyl may be the donor centres involved in the formation of coordination bonds.[115,116,121]



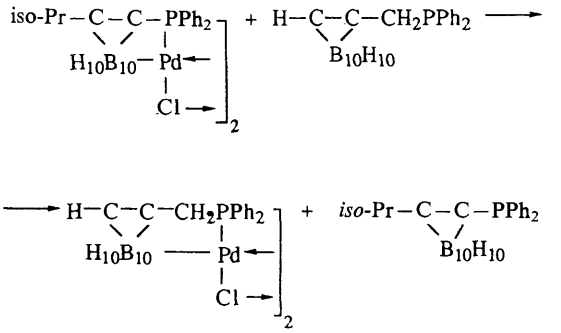
(C) = CH_2, CH_2CH_2, CH=CH etc.
|
Me

$x, y = 0, 1, 2$; E = PR_2, AsR_2, SH; M = Metal

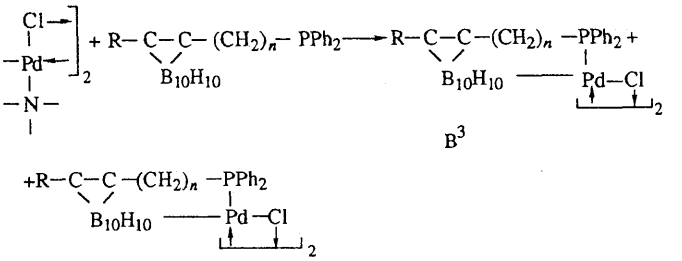


C_8H_{12} = 1.5-cylooctadiene

The metal complexes of phosphorylated carboranes possess the ability to exchange ligands with the involvement of only P-donor molecules. In this case a boron–metal bond is disrupted and formed.[122]



This transition may be attributed to the high stability of the 5-membered ring in comparison with the 4-membered metallo ring. On metallisation of the phorphorylated *o*-carboranes two isomeric products may be formed owing to the formation of the B–Pd bond in a different position of the *o*-carborane.[123]



B^3

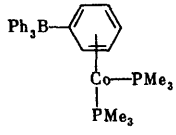
B^4

By using coordination compounds of phosphorus and boron for the synthesis of PBS it is possible to obtain most unusual and unexpected structures in which these atoms are linked by bonds of atypical valency or via metal atoms. For example a unique structure has been obtained on interaction of the triethylphosphine complex of cobalt with sodium tetraphenylborate.[124]

$$Co(PMe_3)_3Br + NaBPh_4 \longrightarrow Co(PMe_3)_4BPh_4 +$$

$$+ \; Co(PMe_3)_2BPh_4 + NaBr.$$

An X-ray diffraction study of the cobalt complex with two phosphine ligands showed the unusual structure of this compound.



Methods have been systematically developed to obtain and study the properties of the $P_x-M-(B_yH_z)$ type of metallo boron hydride complexes where P is the phosphorus-containing ligand, and M = Pt, Os, and Rh, and (B_yH_z) are the boron hydrides, B_6H_9, B_8H_{11}, $B_{10}H_{11}$, $B_{16}H_{15}$ and B_9H_{10}, etc.[125–131] These coordination compounds are formed on interaction of the metal complexes with the anions of the corresponding boron hydrides, for example:[129]

$$[RuCl_2(PPh_3)_3] + [B_{10}H_{10}]^{2-} + 2EtOH \longrightarrow$$

$$\longrightarrow [(PPh_3)_2RuB_{10}H_8(EtOH)_2] + PPh_3 + 2Cl^- + 2H_2.$$

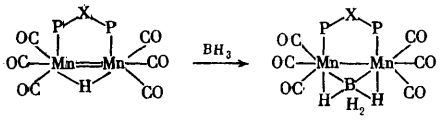
In this type of compound the P atom is linked with the borohydride fragment via a metal atom.

Complexes with a more complicated structure may be obtained in which the substituents are bound in the phosphorus-containing ligand with the borohydride fragment.[129–131]

$$[OsCl_2(PPh_3)_3] + [B_{10}H_{10}]^{2-} + 2EtOH \longrightarrow$$

$$\longrightarrow [(PPh_3)(Ph_2PC_6H_4)OsB_{10}H_7(OEt)_2].$$

The interaction of unsaturated manganese dihydrides containing phosphine ligands with B, Si and Sn hydrides has been studied.[132] When a borane was used, a complex in which the hydride anion enters the inner coordination sphere was obtained.

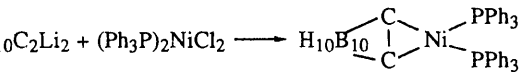


P—X—P = $Ph_2PCH_2PPh_2$, $(EtO)_2PCH_2P(OEt)_2$

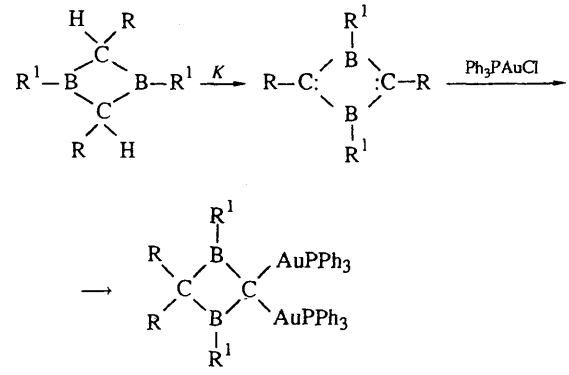
Closo-complexes of the carboranes have been obtained by the interaction of rhodium triphenylphosphine complexes with C-substituted nido-carborane-anions ($C_2B_9H_{12}$).[133,134]

The dilithium derivative of *o*-carborane reacts with the *bis*-(triphenylphosphine)complex of nickel dichloride, expressing the properties of a chelate ligand.[135]

$$o\text{-}B_{10}H_{10}C_2Li_2 + (Ph_3P)_2NiCl_2 \longrightarrow$$

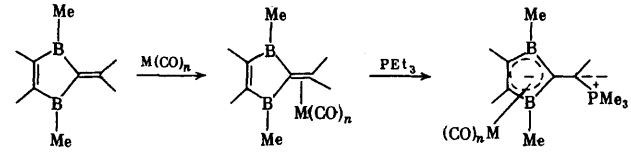


On treatment with metallic potassium 1,2-dihydro-1,3-diboretane gives rise to a dianion, which forms a binuclear complex with the gold triphenylphosphinechloride complex. During complex formation migration of the *tert*-butyl or silyl group in the dianion occurs.[136]



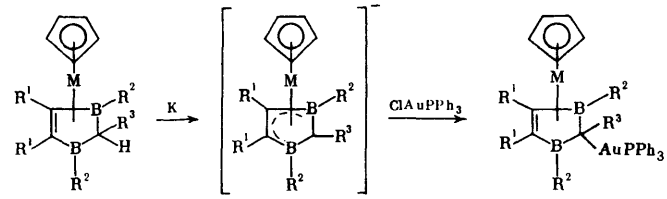
$R^1 = NMe_2$, $N(Pr\text{-}iso)_2$; R = *tert*-Bu, $SiMe_3$.

Coordination compounds containing the phospha- and bora-groups may be obtained also by phosphorylation of organoboron compound complexes with metals.[137,138]



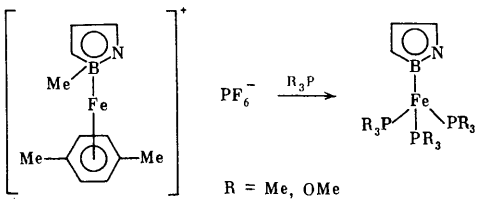
M = Cr, Mo

One example may be given in which on interaction of two complexes, one containing the phosphine ligand and the other with a boron-containing ligand, a third binuclear complex is formed which contains P and B atoms and two different metals.[138]



M = Co, $R^1 = R^2 = Me$, $R^3 = H$; M = Rh, $R^1 = R^2 = Et$, $R^3 = Me$.

The exchange of ligands in the following complex is yet another method used to obtain coordination compounds of PBC.[139]



Most of the above-mentioned coordination compounds containing phosphorylated carborane structures in the ligand have been obtained essentially by an exchange reaction of the ligands at the central ion.

Thus the information presented shows that a large number of quite accessible methods are available to obtain phosphorus-boron-containing compounds leading to the formation of the most diverse cyclic and acyclic structures in which the heteroatoms are bound in different ways and with varied properties which are often dependent on the interaction of the phosphorus-boron-containing functional groups. The nature of these interactions is dependent mainly on the coordination of the heteroatoms and the nature of the fragment, which separates the heteroatoms. When this fragment is a hydrocarbon, for compounds with three-coordinate phosphorus and boron atoms stabilising donor-acceptor interactions through space are most often found, i.e. intermolecular when the heteroatoms are in an α-arrangement and intramolecular when they are in the β- or γ-position, provided that this is not hindered by the rigidity of the binding fragment or the strong *p*-donor substituents at the boron atom. Such interactions reduce the activity of the unshared electron pair of the phosphorus and the vacant orbital of boron, but nevertheless these compounds have a tendency to form very stable betaines. The oxygen atom separating the phosphorus and boron atoms does not hinder the formation of betaine structures, whereas as a result of the partial π-binding with the boron atom the nitrogen atom hinders the donor-acceptor interactions with phosphorus. Even for the betaines the structures with a positive charge on the nitrogen atom and not on the phosphorus atom make a large contribution. Strong donor-acceptor interactions transferring through the system of bonds and stabilising the compounds are also found for the cyclic compounds containing the C–O polar fragment between the heteroatoms. The mutual effect of phosphorus- and boron-containing groups not only changes their reactivity in normal reactions of organophosphorus compounds or organoboron compounds but also in a number of cases leads to a change in their direction. Furthermore processes may occur in which both heteroatoms are involved and in which coordination compounds with unusual bonds are formed, etc. This suggests that this class of compounds has specific characteristics and may be regarded as an independent section of hetero-organic chemistry.

I. Introduction

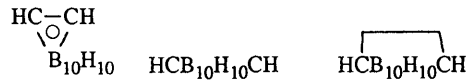
The first reports on the synthesis and properties of carborane-containing polymers were published in 1963.[1,2] Studies on the synthesis and research into the properties of carborane-containing polymers are undergoing rapid development at the present time. These polymers have attracted the attention of research workers because they have a whole series of interesting and valuable properties, such as a combination of high thermal stability and ready solubility. Many of these unusual polymers are capable of withstanding extremely severe conditions, under which normal organic polymers are almost completely degraded.

Carborane-containing polymers are obtained by both polycondensation and polymerisation. Polymers with different structures — polyethers, polycarboranylenes, polyamides, polyphenylenes, polyurethanes, polysiloxanes, polyazoles, and polyphosphazenes, etc. — have been reported.[3–14]

Some recently published reviews[15–18] are concerned with a correlation of the results on the synthesis and research into the properties of carborane-containing polymers.

The chemical structure of the monomer unit of a polymer is known to be one of the main factors governing its properties. Therefore, a study of the dependence of the properties of polymers on the structure of the initial components has both theoretical and practical value, since it makes it possible to carry out the directed synthesis of polymers with predetermined properties. The specific characteristics of icosahedral carborane groups are a negative inductive effect and steric hindrance, which have a considerable effect on the reactivity of monomers and the properties of the polymers obtained.

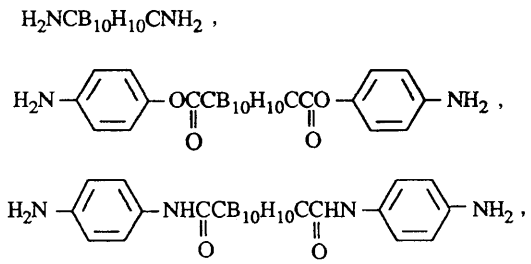
In this review an attempt is made to correlate the theoretical and experimental material on the synthesis and research into the properties of carborane-containing polymers in relation to the specific characteristics of carborane groups. The review covers polymers obtained from the isomeric carboranes which are usually depicted as follows:[19]



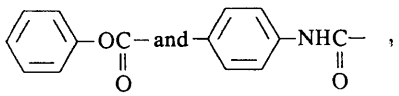
o-carborane *m*-carborane *p*-carborane .

II. Effect of carborane groups on the reactivity of monomers

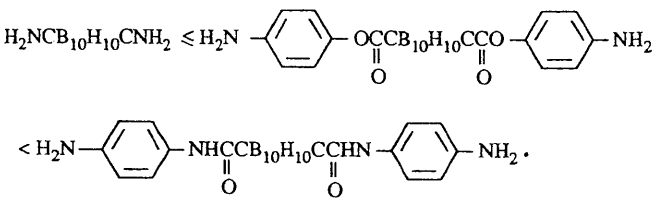
The presence of bulky carborane groups very frequently makes the synthesis of carborane-containing polymers difficult to carry out. However, the reason for the difficulty of synthesis does not arise solely from steric inhibition of polycondensation by the carborane groups (the effective van der Waals radius is equal to 4 Å) but also from the effect of the electron-withdrawing nature of these groups on functional groups in the monomers. Thus, for example, it was established from the kinetic data of acylation of aniline with *m*- and *p*-carboranedicarboxylic acid dichlorides in different solvents that *m*-carboranedicarboxylic acid dichloride is 2–3 times more active than the dichloride of *p*-carboranedicarboxylic acid.[20] This is probably due to the fact that the *p*-carborane group is a weaker electron acceptor than *m*-carborane. In a study of relative reactivity in the acylation of three *m*-carborane-containing diamines with the following structure:



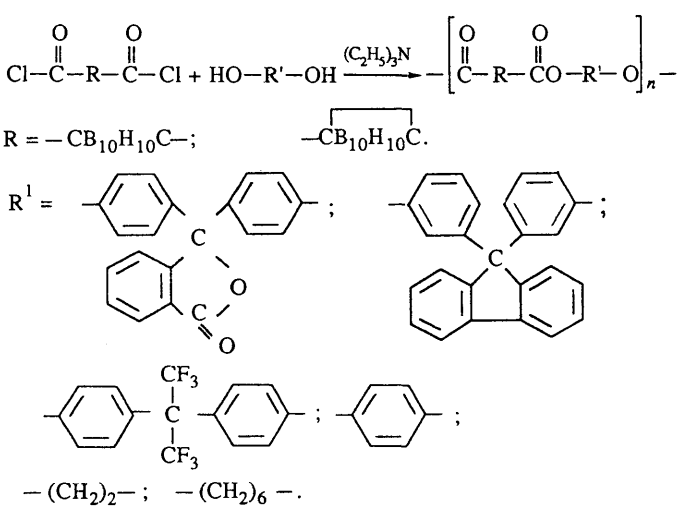
it was shown that introduction of the residues:



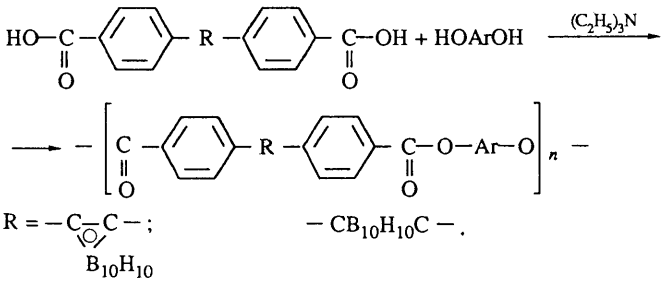
between the amino group and the *m*-carborane cage results in a marked increase in reactivity of the diamines in the following series:[21,22]



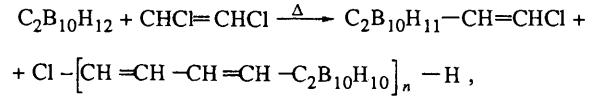
It was established, moreover, that polyesterification of *o*-carborane-containing diols occurs much more slowly than polyesterification of organic diols.[23] If an *o*-carborane group is present in both the diol and dicarboxylic acid, polyesterification occurs at such a low rate that low-molecular-weight compounds are formed.[24,25] However, with a correct choice of the initial reactants and also the synthesis conditions, which made it possible to reduce the steric inhibition of polycondensation and increase the rate of reaction, it proved possible to obtain high-molecular-weight polyesters. For example, if the polycondensation of dichlorides of *m*- and *p*-carboranecarboxylic acids with different diols is carried out in solution in the presence of a catalyst, polyesters with a molecular weight of 20 000 or more are formed:[26–28]



Starting from 1,2- and 1,7-bis(dicarboxyphenyl)carboranes and different dihydric phenols, high-temperature polycondensation in a solution of chlorinated biphenyl at 220 °C or acceptor-catalyst polycondensation in acetone solution gave *o*- and *m*-carborane-containing polyarylates with a molecular weight ranging from 22 000 to 132 000:[29,30]

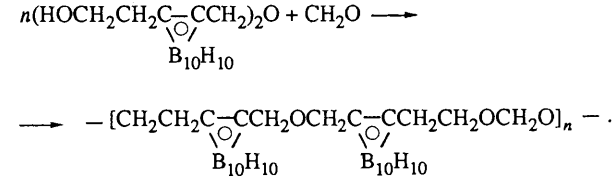


The variation in electron-withdrawing capacity of the groups in the series *o*- > *m*- > *p*-carboranes has an effect on their reactivity towards the addition of 1,2-dichloroethylene.[31] In a study of the kinetics and mechanism of high-temperature condensation of *o*-, *m*-, and *p*-carboranes with 1,2-dichloroethylene according to the reaction:



it was established that *o*- and *m*-carboranes exhibit almost the same reactivity in reactions with 1,2-dichloroethylene while *p*-carborane reacts 1.5 times more slowly than *o*-carborane.

The steric hindrance due to the bulky carborane groups has a very considerable effect on the formation of polyformals.[1] Thus, bis(hydroxymethyl-1-*o*-carboranylmethyl) ether does not react with formaldehyde. When bis(hydroxyethyl-1-*o*-carboranylmethyl) ether is reacted with formaldehyde, an oligomer with a molecular weight of 4400 is obtained:

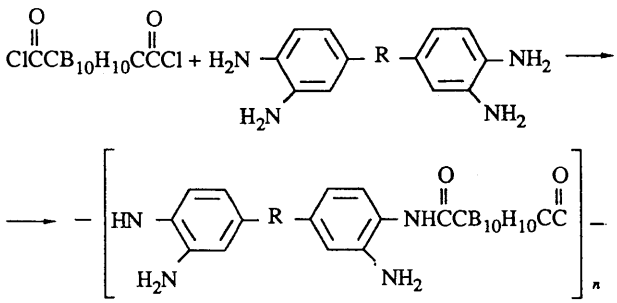


It has been suggested that in order to form polymers it is necessary for the distance between the carborane groups located sequentially to be not less than five carbon atoms at the very least.

The steric hindrance due to a carborane group has a considerable effect on the formation of high-molecular-weight poly(aminoamides).

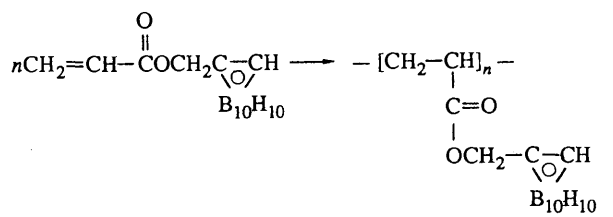
Normally polycondensation of aromatic acid dichlorides with different aromatic tetraamines results in the formation of cross-linked polymers, since the difference between the reactivities of the amino groups at the *ortho* position relative to each other does not change very much after one of them has reacted. When an aromatic acid dichloride is replaced by *m*- or *p*-carboranedicarboxylic acid dichloride, the difference in reactivity between the amino groups at the *ortho* position relative to each other increases after one of them has reacted as a consequence of the steric hindrance caused by the carborane residues. It was therefore possible under certain

conditions to obtain high-molecular-weight polyaminoamides according to the following scheme:[32–35]



R = —O—; —CH_2—; —SO_2—; —$C(CH_3)_2$—; bond.

A polymerisation process is used less frequently than polycondensation to obtain carborane-containing polymers. Not many studies devoted to the homopolymerisation of alkenylcarboranes have been published. The difficulty in conducting this type of synthesis is due to steric hindrance caused by the bulky carborane groups and also the electron-withdrawing nature of the groups, which is responsible for a decrease in electron density on the double bond and hence a decrease in its reactivity. The polymerisation of monomers in which the carborane group is situated some distance from the double bond occurs more readily. For example, 1-acrylyloxymethylene-*o*-carborane readily polymerises in bulk in the presence of 2% benzoyl peroxide at 60 °C:[36]



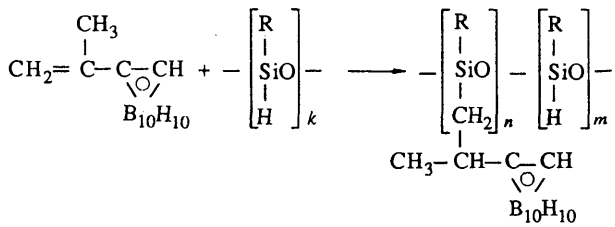
Since the homopolymerisation of carborane monomers occurs with difficulty, there is particular interest in the copolymerisation of carborane-containing compounds with vinyl monomers, making it possible to impart valuable new properties to known polymers through the introduction of carborane cages into their structure. This usually raises the temperature at which polymers start to decompose and increases the yield of carbon residue.

With the aim of modifying low-density polyethylene, the radical copolymerisation of ethylene with isopropenyl-*o*-carborane at a pressure of 1400 kg cm^{-2} and temperature of 160 °C was studied.[37] It was established from the IR spectroscopic data that the rate of copolymerisation and the molecular weight of the polymers decrease rapidly as the content of the *o*-carborane derivative in the reaction mixture increases from 1 to 40 mol%.

A study has been made of the effect of the structure of unsaturated *m*- and *p*-carborane-containing polyesters on their ability to undergo bulk, solution, and emulsion copolymerisation with styrene, acrylonitrile, and 1,1,2-trichloro-1,3-butadiene in the presence of radical and ionic initiators on exposure to γ-radiation or high pressure.[38,39] It was established that the introduction of electron-withdrawing *m*-carborane groups into unsaturated polyesters reduces their reactivity, as a result of which unsaturated polyester-*m*-carboranes in which there is one carborane cage for each unsaturated bond are incapable of undergoing thermochemical cross-linking and only form cross-links on exposure to γ-radiation and high pressure.

In contrast to *m*-carborane-containing polyesters, all polyesters of *p*-carboranedicarboxylic acid undergo copolymerisation with styrene, which evidently may be due to the weaker electron-withdrawing properties of the *p*-carborane cage, having virtually no effect on the reactivity of unsaturated bonds.

Information in the literature about the preparation of carborane-siloxane polymers by polymerisation and copolymerisation methods is sparse. Migration copolymerisation of isopropenyl-*o*-carborane with polyalkylhydroxysiloxanes gave polysiloxanes containing *o*-carborane cages in the side chain.[40,41]



R = CH_3; C_2H_5, C_6H_5; k = *n* + *m*.

Studies showed that without a catalyst there is virtually no reaction below 200 °C and even at higher temperatures the rates of copolymerisation remained low, which may be due to the electron-deficient nature of the carborane cage, which deactivates the adjacent unsaturated bond, and to steric hindrance.

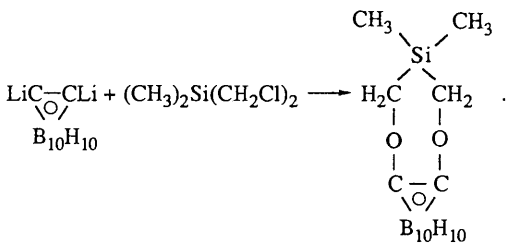
III. Effect of carborane groups on the properties of carborane-containing polymers

In 1963 Grafstein and Dvorak,[42] while attempting to carry out the thermal dehydrodimerisation and dehydropolymerisation of *o*-carborane, found that at 465–500 °C *o*-carborane is isomerised to *m*-carborane, while in 1964 Papetti and Heying,[43] on heating *o*-carborane at 617 °C, obtained a third isomer—*p*-carborane. In neither case were dehydropolymers detected. There are considerable differences in the chemical and phyiscal properties of derivatives of these isomers, which can be classified according to the different configuration of the carbon atoms in the *o*-, *m*-, and *p*-carborane skeleton, resulting in a decrease in electron-withdrawing properties in the series *o*- > *m*- > *p*-isomer,[44,45] and an increase in thermal stability: *o*- < *m*- < *p*-carborane isomer.[46] Moreover, in the series *o*- > *m*- > *p*-carborane isomer, there is a decrease in acidity of the hydrogen atom in the CH group,[47] ease of electrophilic, radical, and exchange halogenation of the B—H bond,[48,49] rate of nucleophilic substitution of the halogen atoms in halogen derivatives of the carborane by other atoms and groups compared to halogen derivatives of benzene and ferrocene.[50] The electron affinity of the carborane system decreases in the same series of isomers as does the ease of cleavage of a C_{carb}—C bond in carborane-containing aldehydes, ketones, acids, and alcohols by nucleophilic reagents. Therefore *o*-carborane derivatives are reduced much more easily than the other carborane isomers, and in the same series the stability towards bases[49,55] and oxidising agents[56] increases, and the volatility of the compounds and in the majority of cases the melting point[19] also increase.

This series of variation in the physicochemical propeties of *o*-, *m*-, and *p*-carboranes and their derivatives is related to the more uniform distribution of electron density in the *p*-carborane cage (all ten boron atoms are equivalent) compared to the *o*- and *m*-carborane cages.

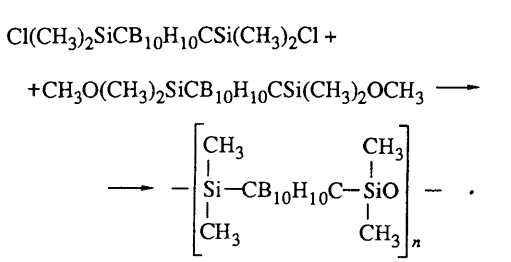
Isomerism of the carborane cage has a considerable effect on the preparation and properties of polymers based on different isomeric derivatives of carboranes.

It follows from a review of the considerable number of studies on the synthesis and research into the properties of carborane-containing polymers that the *m*- and *p*-carborane isomers have a greater tendency to form polymers than the *o*-isomer, since during the development of methods for the synthesis of polymers with *o*-carborane cages in the chain, research workers have frequently encountered steric problems. One of these is typically the tendency of C,C′-difunctional *o*-carborane derivatives to form *exo*-polyhedral rings. This evidently occurs as a result of the adjacent configuration of the carbon atoms in the *o*-carborane cage. The bond between them, with a length equal to that of a single covalent C–C bond (1.64–1.67 Å), is longer than the single covalent C–C bond of alkanes (1.54 Å), thus assisting the formation of *exo*-rings.[57–59] Therefore, the first attempts to synthesise silicon-*o*-carborane-containing polymers with a linear structure were unsuccesful because of the considerable tendency of the initial *o*-carborane-siloxane derivatives to form stable cyclic systems. For example, reaction of *o*-carboranedilithium with dimethyldichloromethylsilane gave a cyclic product instead of the expected polymer:[60]



The lack of success in attempts to synthesise silyl-*o*-carboane with a linear structure stimulated research workers to consider *m*-carborane systems, in which the nonadjacent configuration of the carbon atoms excludes the possibility of exocyclic structures being formed.

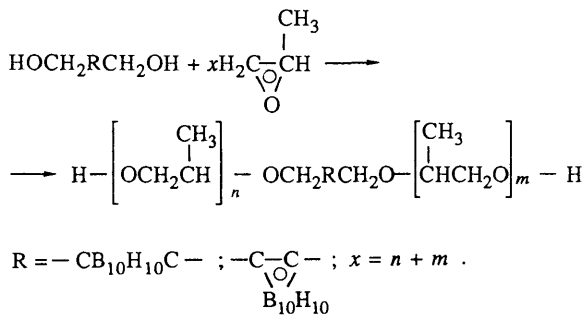
Thus, polycondensation of *m*-carborane-containing chlorosilanes and alkoxysilanes in the presence of a catalyst—ferrous chloride—gave elastomeric *m*-carborane-containing polysiloxanes,[19,61–65] the synthesis of which from the practical point of view may be regarded as an important advance in the development of heat-resistant carborane elastomers.



These polymers (trade name "Dexsil") consist of dialkyl- or diaryl-siloxane units linked by *m*-carborane groups and, in addition to the method already indicated, they are obtained by polycondensation of *m*-carborane-containing disilanol with an active silane such as bis(*N*,*N*-dimethylcarbamato)dimethylsilane or bis(ureidosilanes) or bis(*N*,*N*-dimethylamino)dimethylsilane[11,16,63,64] or directly from *m*-carborane.[65]

There have been reports on the synthesis of "Dexsil" polysiloxanes containing *p*-carborane groups.[66,67] These polymers are elastic materials but more rigid at low temperatures than the corresponding *m*-carborane-containing polysiloxanes.

In the migration copolymerisation of 1,2-bis(hydroxymethyl)-*o*-carborane with epoxypropyltriethoxysilane[68] and 1,2- or 1,7-bis-(hydroxymethyl)-*m*-carborane with propylene oxide[69,70] it was shown that the rate of reaction of propylene oxide with 1,2-bis(hydroxymethyl)-*o*-carborane is higher than with 1,7-bis(hydroxymethyl)-*m*-carborane.

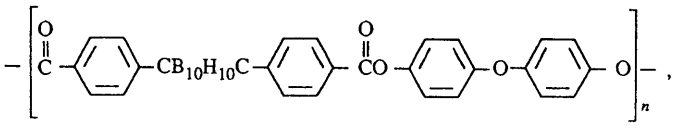


The more pronounced electron-withdrawing nature of the *o*-carborane cage evidently gives rise to a greater proton mobility of the hydrogen atoms of the hydroxyl group and hence assists a higher rate of reaction.

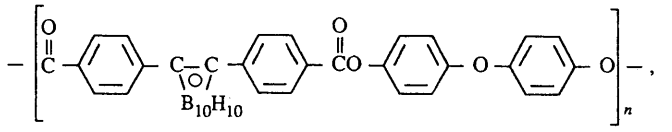
Korshak et al.[4] described the preparation of *o*-, *m*-, and *p*-carborane-containing esters of cellulose by acylating the latter with *o*-, *m*-, and *p*-carboranecarboxylic acid chlorides in toluene in the presence of pyridine at 110 °C. It was established that under these conditions the carborane cage decomposes in *o*- and *m*-carborane-carboxylic acid chlorides to the anion of dicarbaundecaborane while only a small degree of acylation of cellulose occurs (about 2 wt.% boron is introduced). *p*-Carboranecarboxylic acid chloride reacts with cellulose to form a *p*-carborane-containing cellulose ester with about 40 wt.% boron content and which does not dissolve in either organic solvents or in a cuprammonium complex or in cadoxene (a complex between ethylenediamine and cadmium hydroxide). On heating in an inert medium under isothermal conditions at 300 °C for 2 h the "char" residues of *o*-, *m*-, and *p*-carborane-containing cellulose at 48, 39, and 38% of the initial weight respectively. The "char" residue of the initial cellulose under these conditions does not exceed 22 wt.%.

The effect of the isomerism of the carborane cage on the molecular mobility of macromolecules has been demonstrated in two studies.[71,72] It was established that the vibrations of the *o*-carborane cage in polyarylates are more difficult compared to the *m*-isomer because of the greater conjugation of the *o*-carborane residue with the automatic rings and also because of steric effects. This characteristic affects the relaxation processes in carborane-containing

polyesters, and the results of studies on these using different methods suggest that there is an increase in rigidity of the macrochain and an increase in softening point on changing from *m*- to *o*-carborane-containing polyesters, as for example:



$T_{soft} = 240-260$ °C



$T_{soft} = 260-280$ °C.

An essentially ionic form of electrical conductivity is characteristic of carborane-containing polyesters, and the electrical conductivity of *o*-carborane-containing polyesters is higher than those values for the corresponding polyesters with *m*-carborane residues by a factor of 10^1-10^2.[73] All of the polyesters synthesised from bis(hydroxymethyl)-*m*-carborane have a softening point that is lower than that of the corresponding polyesters obtained from bis(hydroxymethyl)-*o*-carborane.[74]

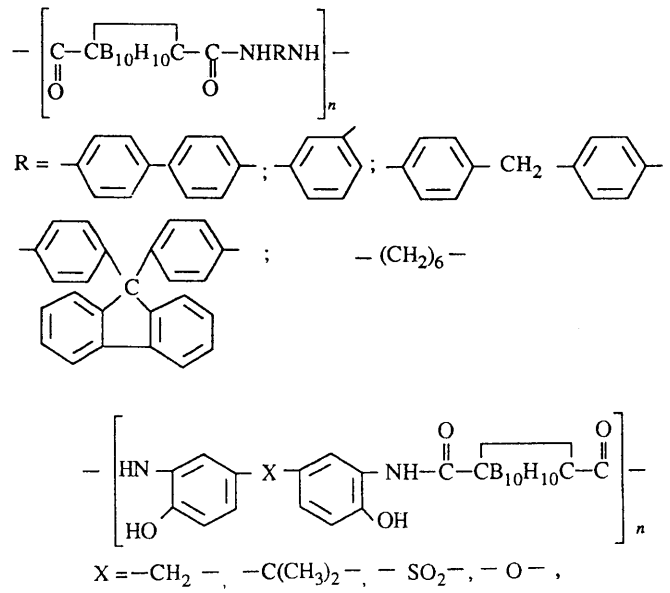
In a study of the properties of solutions of polyarylates obtained by acceptor-catalytic and high-temperature polycondensation from 1,2- and 1,7-(4-carboxyphenyl)carboranes and dihydric phenols such as 4,4′-dihydroxydiphenyl oxide, 4,4′-dihydroxydipyhenyl-2,2-propane, 9,9-bis(4-hydroxyphenyl)fluorene, and 9,9-bis(4-hydroxyphenyl)-10-anthrone, it was established that with similar molecular weight values, polyarylates with 1,7-diphenyl-*m*-carborane residues in the chain have a considerably higher intrinsic viscosity than polymers with 1,2-diphenyl-*o*-carborane residues.[75] The authors were able to conclude from this that polyarylates based on 1,2-bis-(4-carboxy-phenyl)-*o*-carborane are in the form of more compact macromolecular bundles in solution, which can be attributed to both steric factors and to a greater effect from the dipole moment for polyarylates with *o*-carborane groups.

It was established that polyarylates obtained by reaction of *p*-carboranedicarboxylic acid dichlorides with different bisphenols have a softening point that is 40–100 °C higher than that of the corresponding polyarylates of *m*-carboranedicarboxylic acid. However, the "char" residue of *p*-carborane-containing polyarylates at 800 °C is less by 10–20 wt.% than the "char" residue of *m*-carborane-containing polyarylates at the same temperature.[26-28]

In a study of the thermal stability of polyarylates with 1,2- and 1,7-diphenylcarborane residues in the chain in air and in an inert atmosphere under both dynamic and isothermal conditions, it was established thermogravimetrically that carborane-containing polyarylates have a decomposition temperature that is 20–60 °C higher than that of conventional polyarylates.[76] The authors note that all the *o*- and *m*-carborane-containing polyarylates are characterised by a high "char" residue (50–90% of the initial weight of the polymer) when they are heated in air to 900 °C, whereas conventional polyarylates (such as polyarylate D-9) are completely combusted at 650–700 °C. In an inert atmosphere the weight of polyarylates of 1,2- and 1,7-bis(4-carboxylphenyl)-carboranes starts to change at the same temperatures as in air, but their "char" residue after thermal degradation is even higher than on heating in air. On the basis on this the authors assumed that the "char" residue formed on heating *o*-and *m*-carborane-containing polyarylates results not only from oxidation but is generally typical of the thermal degradation of polyarylates of this structure.[76,77]

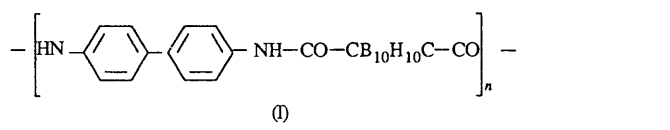
The majority of the *o*- and *m*-carborane-containing polyamides that have been reported are amorphous polymers that are readily soluble in organic solvents, whereas *p*-carborane-containing polyamides have a crystalline structure and an inferior solubility in organic solvents. This is due to the more ordered structure of *p*-carborane-containing polyamides as well as the nonpolar nature of the *p*-carborane cage.[76]

In contrast to infusible *m*-carborane-containing polyamides and poly(hydroxyamides), *p*-carborane-containing polyamides and poly(hydroxyamides) with the following structure:

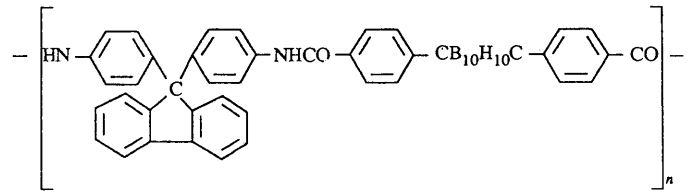


soften at 250–460 °C and 220–270 °C respectively.

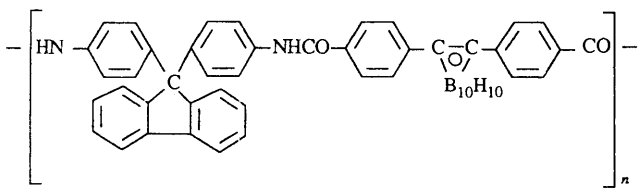
In a review article by Korshak et al.[79] detailed consideration is given to questions concerning the degradation of *o*-, *m*-, and *p*-carborane-containing polyamides with the following structure (under vacuum, in an atmosphere of oxygen, and water vapour at 200–800 °C):



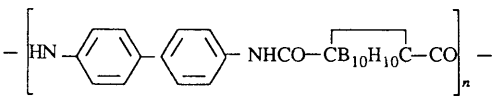
(I)



(II)



(III)



(IV)

It was demonstrated in the review that isomerism of the carborane cage has a considerable effect on the stability of polyamides. It transpired that the *p*-carborane-containing polyamide (IV) has inferior thermal stability compared to polyamides containing *m*- and *o*-carborane residues. Moreover, while the main degradation route in *o*- and *m*-carborane-containing polyamides is decomposition of the *o*- and *m*-carborane residues with evolution of hydrogen, whereby the amide groups become stable towards homolytic and heterolytic cleavage reactions, in *p*-carborane-containing polyamides cleavage of the NH—CO bond mainly occurs, and the principal gaseous degradation product is carbon dioxide.

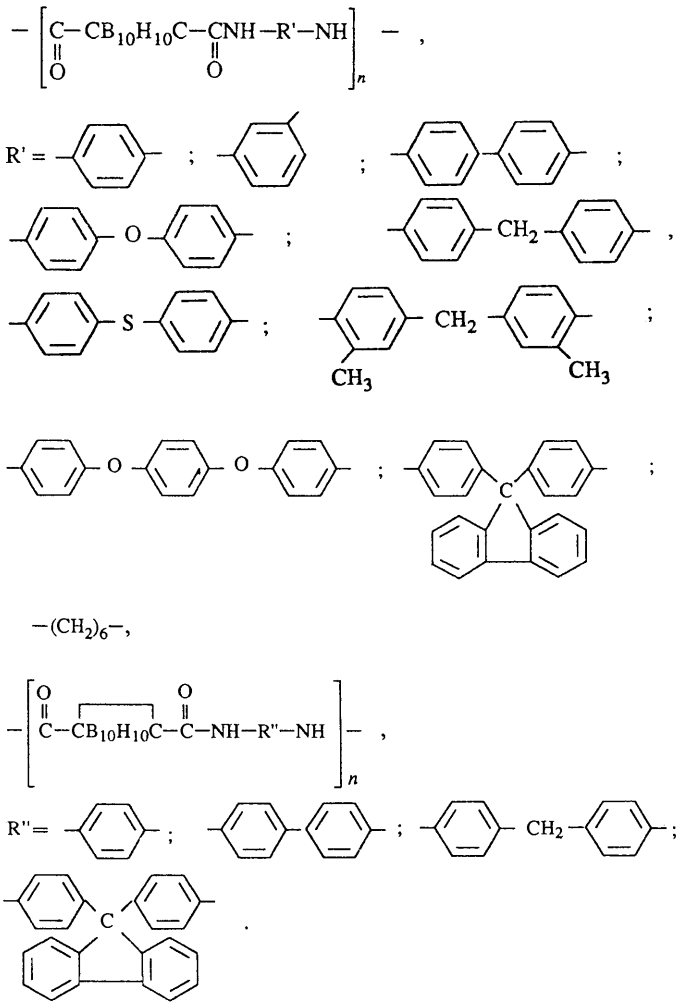
On degration in an atmosphere of saturated water vapour *o*- and *m*-carborane residues undergo more substantial decomposition, as is suggested by the increase in quantities of hydrogen and methane in the hydrolysis products, compared to degradation under vacuum. The degradation of the *p*-carborane-containing polyamide is similar to that of aromatic polyamides, i.e., the presence of excess moisture gives rise to more substantial hydrolysis of the amide groups.

During thermooxidative degradation a decisive factor is the oxidative stability of the carborane cage and, as is suggested by the experimental findings, this is virtually the same for all the isomers.

However, on comparing the degree and rate of degradation of polyamides containing *p*-carborane (IV) and *m*-carborane (I) residues in an atmosphere of oxygen, it should be noted that decomposition of *m*-carborane residues occurs to a much greater extent. Hence the degree of stability of the carborane isomers towards oxygen is not the only factor that governs the oxidation of carborane-containing polyamides, and, like thermal degradation, the electron-withdrawing properties of the carborane cage play a significant role. Although the oxidative stabilities of the *m*- and *p*-isomers of carborane are similar in magnitude, decomposition of the carborane cage and stabilisation of the amide groups occur to a greater extent in the thermal oxidation of the *m*-carborane-containing polyamide (I).

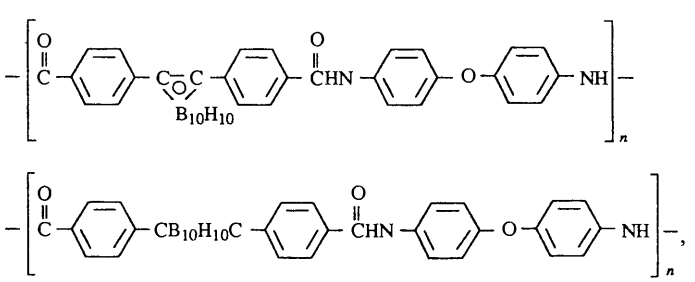
The antifrictional properties of *m*-carborane-containing polyamide (I) and its *p*- analogue (IV) have been studied over the temperature range 250—450 °C.[80] From the results obtained by Korshak et al.[80] concluded that the hydrogen which is formed in considerable quantities during decomposition of *m*-carborane-containing polyamides produces a reducing medium between the frictional surfaces, resulting in inhibition of the oxidative processes that occur at high temperatures. This is to a considerable degree responsible for the improvement in lubricating properties of antifrictional plastics based on *m*-carborane-containing polyamides compared to *p*-carborane-containing polyamides (in which the evolution of hydrogen occurs to a lesser degree over the studied temperature range) and in comparison with polyamides that do not contain carborane residues (which evolve virtually no hydrogen at these temperatures).

Isomerism of the carborane cage has an effect on the chemical stability of known carborane-containing polyamides. Thus, *m*- and *p*-carborane-containing polyamides with the following structure are stable towards boiling water and 40% sulphuric acid:



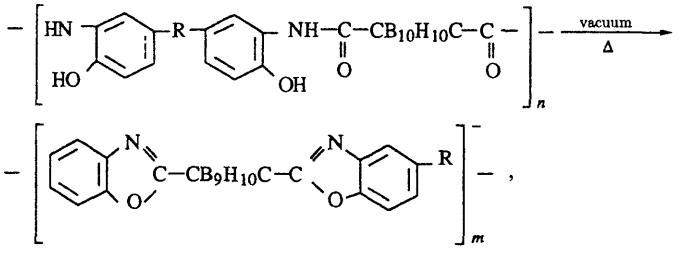
However, on heating in a 40% aqueous alkali solution only alkaline hydrolysis of the macromolecules occurs in *p*-carborane-containing polyamides while in polyamides with *m*-carborane residues decomposition of the *m*-carborane groups occurs together with alkaline hydrolysis.

The molecular mobility properties of carborane-containing polyamides with the following structure:



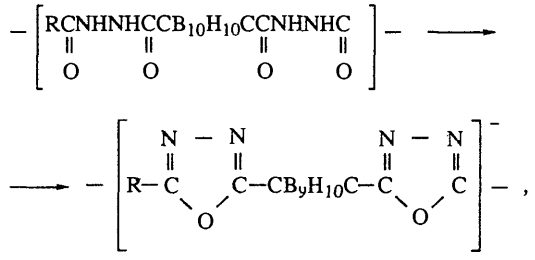
and an investigation of the effect of their structure on electrophysical properties were the subject of a study by Voishchev et al.[81] It was shown that replacement of the *o*-carborane cage by a *m*-carborane cage resulted in a decrease in rigidity of the macromolecules.

The isomerism of carboranes has a considerable effect on the formation of polyheterocycles.[12,15,82–88] Thus, according to the data of differential IR spectroscopy, the cyclohydration of *m*-carborane-containing poly(hydroxyamides) is always accompanied by partial conversion of the *m*-carborane groups to dicarbaundecarborate residues:



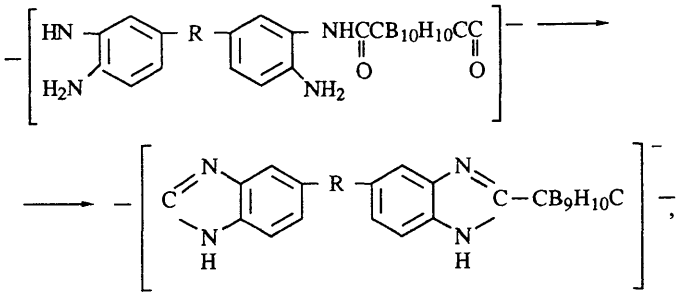
R = —CH_2—, —O—, —SO_2—, —$C(CH_3)_2$—.

The conversion of *m*-carborane groups to dicarbaundecarborate residues also occurs to a greater or lesser extent in the formation of *m*-carborane-containing poly(oxadiazoles):



R = arylene, alkylene;

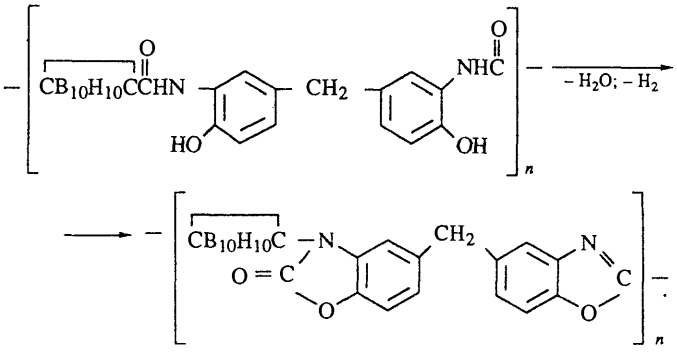
and poly(benzimidazoles):



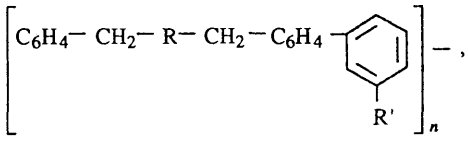
R = —O—, —CH_2—, —SO_2—,

and, according to the authors, apparently takes place via the amide bond.

Since *p*-carborane residues are the most stable of the carborane isomers towards a basic compound, the conversion of *p*-carborane-containing poly(aminoamides) and polyhydrazides to the corresponding polyheterocycles occurs smoothly, without decomposition of the *p*-carborane residues. However, in this case Korshak et al.[88] recorded the conversion of a hydroxyamide structure to a benzoxazole group, which had not been observed previously in polymers:[89]



It follows from the examples given above that the properties of the polymers depend on which of the carborane isomers is present in them. However, in some cases isomerism of carborane has virtually no effect on the properties of the polymers. Thus, in a study of the properties of *o*-, *m*-, and *p*-carborane-containing polyphenylenes with the following structure:

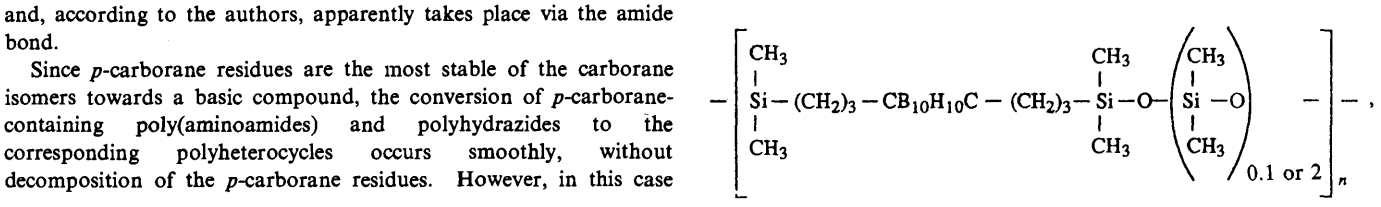


where R = *o*-, *m*-, or *p*-carboranylene and R′ = phenyl, benzyl-*o*-, benzyl-*m*-, or benzyl-*p*-carbonyl, it was established that the solubility of the oligophenylenes synthesised and the thermal stability of the polyphenylenes hardly depend at all on which of the carborane isomers are used to prepare them.[90–93]

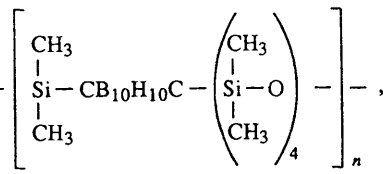
IV. Effect of the configuration of carborane groups in a macromolecule and the structure of the residues directly bonded to them on the properties of carborane-containing polymers

The properties of carborane-containing polymers are dependent on the configuration of the carborane groups in the side chain or main chain of macromolecules and also on the structure of the residues that are adjacent to the carborane groups.

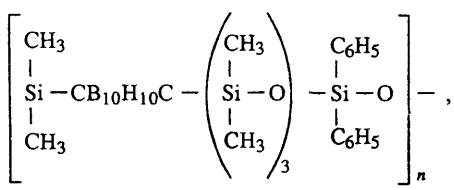
It was established that there is some correlation between the structure of *m*-carborane-containing siloxanes and their properties.[19,94] For example, the thermal stability and oxidative stability decrease with an increase in siloxane groups not bonded to the carborane. Thus, polymers of the type:



are susceptible to thermal oxidation even at 240 °C (in an atmosphere of nitrogen they are stable up to 350 °C).[95] At the same time a characteristic feature of all Dexsil polymers (in which the Si atom is bonded directly to the *m*-carborane residue) is their high thermal stability and resistance to oxidative attack at 300–500 °C.[94,96] This effect is attributed to the result of the inductive stabilisation of the silyl groups through the neighbouring electron-withdrawing *m*-carboranyl groups. Partial replacement of the methyl groups in Dexsil polymers by phenyl groups results in an increase in oxidative stability of the polymers. For example, Dexsil-400:



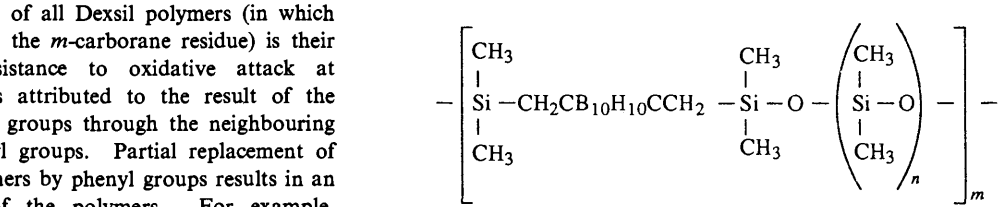
is oxidised at 325 °C, while a polymer with the structure:



is only oxidised at 370 °C.[94]

The presence of trifluoropropyl groups in the Dexsil skeleton imparts the greatest stability to the polymers and stability towards solvents. It was shown that with an increase in the number of siloxane units located between two carborane groups in Dexsil polymers, the softening point of the polymers decreases but the stability towards thermooxidative degradation changes only slightly and remains high (310–340 °C).[96] A feature that distinguishes the thermal degradation of poly(*m*-carboranylene-siloxanes) from that of conventional polysiloxanes is the small content of cyclic oligosiloxanes in the decomposition products.[97] Szekely and Blazgo[97] assume that the large size of the *m*-carborane group inhibits the formation of a helical macromolecular shape and hence decyclopolymerisation of *m*-carborane-containing polysiloxanes is made difficult. It has also been noted that, in contrast to conventional polysiloxanes, Dexsil polymers readily undergo cleavage of the $Si-C_{carb}$ bond by the action of nucleophilic and electrophilic reagents.

It was shown by Kalinin et al.[98] that the presence of methylene bridges between the carborane cage and silicon atom reduces the electron-withdrawing effect of the carborane cage on the silicon atoms, as a result of which the $Si-CH_2-C_{carb}$ system of bonds becomes less polar and hence more stable towards nucleophilic and electrophilic reagents. This is in contrast to the $Si-C_{carb}$ bond, which under identical conditions readily undergoes cleavage with elimination of *m*-carborane. Therefore, the synthesis of poly(*m*-carboranylene-organosiloxanes) was carried out in order to increase the chemical stability of *m*-carborane-containing polysiloxanes.[99] The molecular weight of the resulting polysiloxanes was equal to 171 000–400 000.



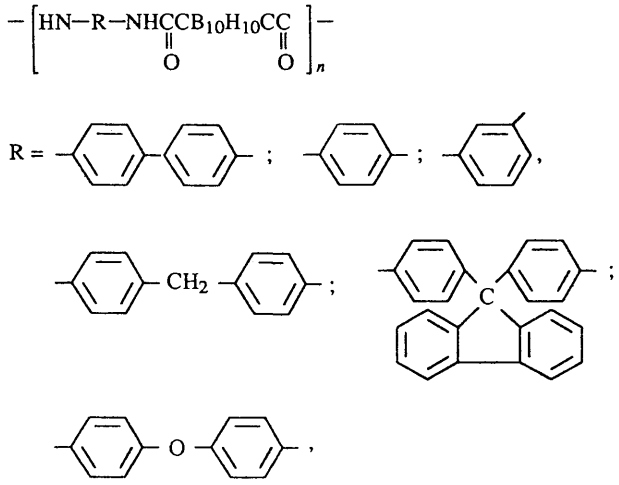
n = 2, 3, 5, 10, 80.

It was established that in terms of thermal stability polyorganosiloxanes with 1,7-bis(dimethylsilylmethyl)-*m*-carborane units are not inferior to similar polymers with 1,7-bis(dimethylsilyl)-*m*-carborane units and they have greater chemical stability than the latter. By changing the length of the organosiloxane block between carborane groups it is possible to vary the physicomechanical properties of the polymers over a wide range.

The properties of carborane-containing polyesters are very markedly dependent on the chemical structure of the organic residues located between the carborane groups. Aliphatic *m*- and *o*-carborane-containing polyesters obtained by reaction between carborane-containing diols and aliphatic dicarboxylic acids are generally low-molecular-weight viscous liquids or brittle materials with softening points at about 100 °C.[3,23,24,100] They are polydisperse[101] and soluble in aromatic hydrocarbons, chlorohydrocarbons, and acetone, and insoluble in aliphatic hydrocarbons, alcohols, and water; and they have an amorphous structure. Replacement of the methylene groups in aliphatic polyesters by CF_2 groups causes a lowering in softening point of these polymers.[3,23,24,100]

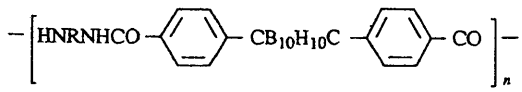
Polyesters synthesised by polycondensation of bis(hydroxymethyl)-*o*-carborane or bis(hydroxymethyl)-*m*-carborane with aromatic dicarboxylic acid dichlorides have greater thermal stability and are less soluble than polyesters obtained from the same diols and aliphatic dicarboxylic acids.[74,101,102] For example, the polyester derived from terephthaloyl dichloride and bis(hydroxymethyl)-*o*-carborane has a softening point of 204 °C,[74] while the softening points of polyesters derived from bis(hydroxymethyl)-*o*-carborane and aliphatic dicarboxylic acids do not exceed 100 °C.[3,23,24,100]

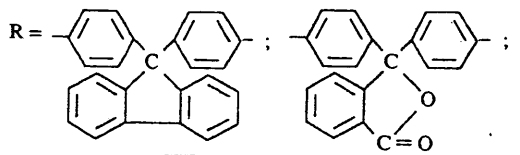
All aromatic *m*-carborane-containing polyamides with the following structure:

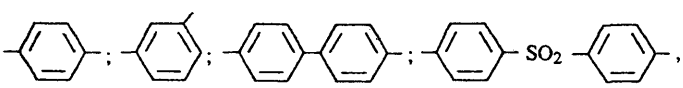


in which the NH—CO bond is adjacent to the carborane group are infusible products.

Polyamides with the structure:



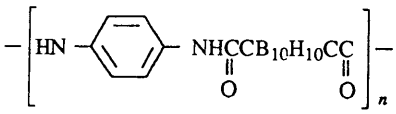




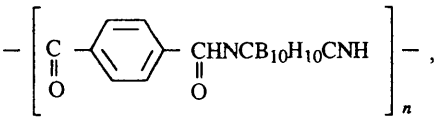
in which the NH—CO bond is separated from the *m*-carborane group by phenylene residues soften over a temperature range of 280—390 °C.

In a study of the thermal degradation of these polyamides over a temperature range of 200—300 °C it was established that the introduction of phenylene residues between the *m*-carborane cage and the NH—CO bond increases the temperature at which degradation of the *m*-carborane groups starts by approximately 100 °C. At the same time the stability of the NH—CO bond towards heterolytic and homolytic cleavage reactions decreases.[103]

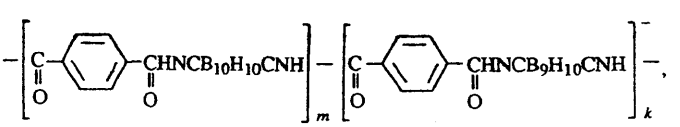
The thermal stability of *m*-carborane-containing polyamides depends to a considerable extent on the manner in which the NH—CO bond is joined to the *m*-carborane group. Thus, a polyamide with the structure:



with a molecular weight of 42000 is stable on heating in air to 230 °C, according to the data of thermogravimetric analysis and IR spectroscopy, while in a polyamide with the structure:

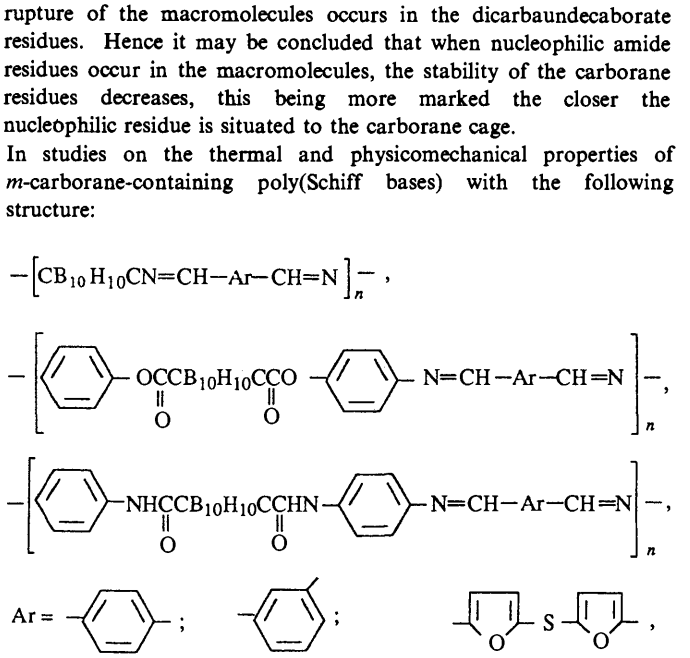


the *m*-carborane residue proved very unstable. Even at 20 °C while this polyamide was being formed, the *m*-carborane groups were partially converted to dicarbaundecaborate groups, according to the IR spectroscopic data. At the same time heterounit polyamides with the following structure were formed:

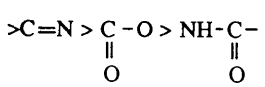


which slowly decomposed on standing. Since carbon dioxide or monoxide are not formed during the degradation of this polymer at room temperature, Korshak et al.[103] maintain that in this case rupture of the macromolecules occurs in the dicarbaundecaborate residues. Hence it may be concluded that when nucleophilic amide residues occur in the macromolecules, the stability of the carborane residues decreases, this being more marked the closer the nucleophilic residue is situated to the carborane cage.

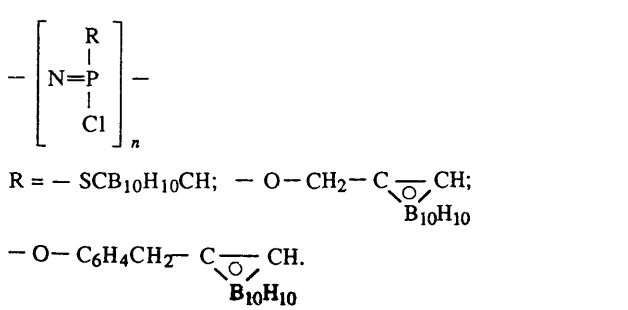
In studies on the thermal and physicomechanical properties of *m*-carborane-containing poly(Schiff bases) with the following structure:



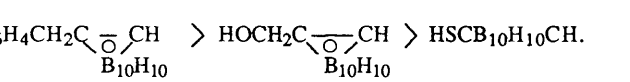
it was established that the chemical and thermal stability in air of these polymers depends on the structure of the organic residues that are adjacent to the *m*-carborane cage and it decreases in the following series:[104,105]



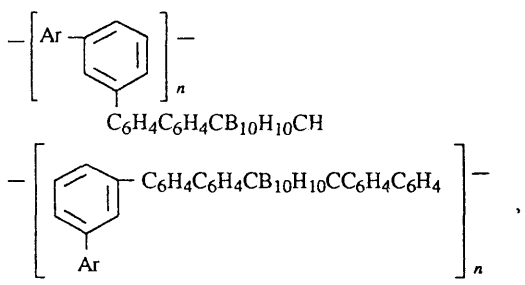
Polymer-like conversions of polydichlorophosphazene with different carborane-containing nucleophiles are used to synthesise the following carborane-containing polyphosphazenes:



Korshak et al. demonstrated that the carborane reagents studied can be arranged in the following series with respect to their favourable effect on the thermal and hydrolytic stability of polyphosphazenes:



Polyphenylenes with the following structure:



containing *o*-, *m*-, and *p*-carborane residues solely in the side chain or solely in the main chain of the macromolecules have been prepared and studied.[90,107–109] Korshak et al. note that the introduction of carborane residues into the side chain of polyphenylenes results in an improvement in their thermal stability but this effect is weaker than in polyphenylenes containing carborane groups in the main macromolecular chain.

Thus, it may be concluded from the above that the properties of carborane-containing monomers and polymers are affected not only by isomerism of the carborane but also by the configuration and structure of the organic residues adjacent to a carborane group.

ABSTRACT. This review is devoted to retro-aldol reactions in steroid chemistry. The mechanism of the two-centred inversion of the *C/D* ring junction is discussed, and its application to the synthesis of cardioaglycones [aglycones of cardioglycosides] outlined. Some stereochemical aspects of introducing a functionalised side chain at C_{17} is also examined.

The bibliography contains 56 references.

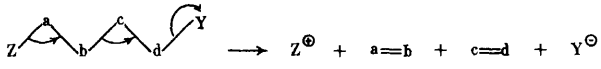
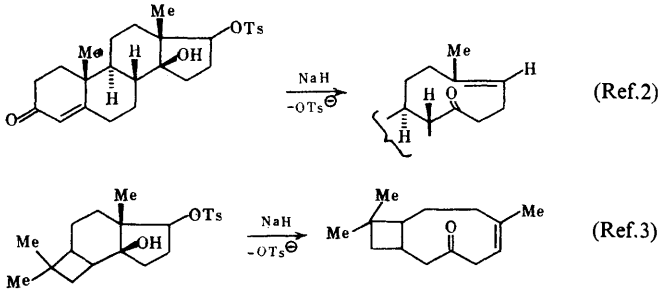
III. The two-centred inversion of the *C/D* ring junction and approaches towards the total synthesis of cardiotonic steroids 368

I. Introduction

Hydroxyl and carbonyl groups on the steroid skeleton often determine biological activity as well as provide appropriate functionality for modifying steroidal structures in the search for compounds with physiological activity. Steroidal β-hydroxyketones are potentially interesting in this respect since there is the possibility of structural elaboration via retro-aldol cleavage. The latter cleavage is a fragmentation-type reaction which is initiated by bases or acids. Removal of a proton or anion proceeds more easily if the leaving group is in an anti-parallel configuration (by a Grob-type fragmentation):[1]



The decarboxylation of β-halogeno- and β-hydroxy-glycidic acids exemplifies this type of fragmentation, as also does, among others, the C-cleavage of 1,3-diol monosulphonates:



(Ref.2)

(Ref.3)

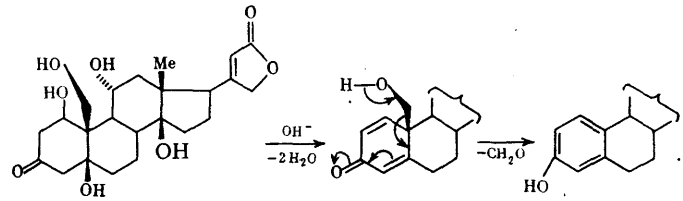
The shift of electron density on keto-enol tautomerism of aldols (−*E* effect in the $\rangle C=O$ group and +*E* effect in the $H-O-C\langle$ group) on treatment with appropriate reagents may be transmitted effectively along a conjugated chain, so that there is the possibility of conjugated retro-aldol processes of a 'remote' type (as is possible with retro-Michael reactions[1]).

Retro-aldol reactions have already been reviewed.[4–6] The present survey is devoted to retro-aldol processes in steroid chemistry and possible applications to the total synthesis of cardiotonic 14β-hydroxy derivatives of estratriene with natural configuration.

II. Retro-aldol reactions in steroid chemistry

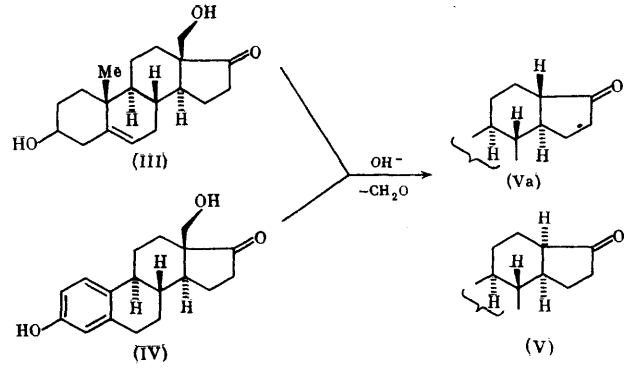
Many reactions of the retro-aldol type are known in steroids which have the basic tetracyclic skeleton (as illustrated in one of the earlier reviews[7]). These can be sub-divided into two categories: 1) retro-aldol cleavage of the side chain and 2) retro-aldol cleavage of the steroid skeleton.

Reactions in the first category have been applied in particular to the synthesis of 18-nor- and 19-nor-steroids, as well as to cleavage of the C_{17} side chain. Thus, the naturally occurring compound (I) is readily converted into the 19-norsteroid (II) via β-elimination of two molecules of water followed by retro-aldol cleavage of formaldehyde.[8] This is the only effective synthetic route to estrone derivatives.



(I) (II)

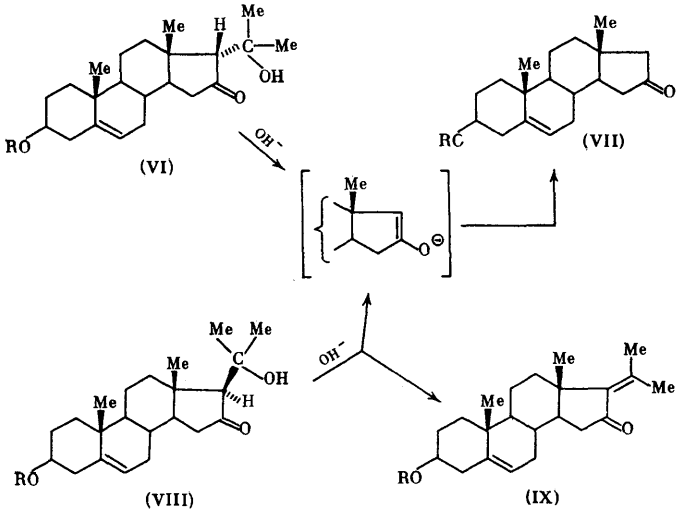
Treatment of 18-hydroxy-17-ketosteroids, (III) and (IV), with base, or pyrolysis of these compounds, also results in retro-aldol cleavage of formaldehyde with the formation of the corresponding 18-norsteroids:[9]



(III) (Va) (IV) (V)

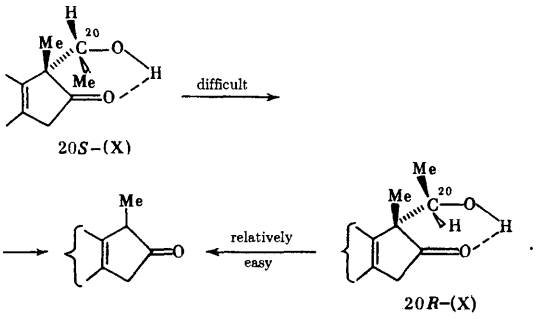
A product (V) with *cis*-fusion at the *C/D* ring junction is formed predominantly. It is possible that the corresponding *trans*-isomer (Va) is formed *in situ*, and then isomerises to the energetically more favourable *cis*-isomer (V) under acid catalysis. Such an isomerisation has, in fact, been observed with *trans*-hydrindan-1-one.[9]

From a stereochemical point of view, it proved interesting to study the behaviour of the C_{17} epimers of 20-methylpregn-5-ene-3β,20-diol-16-one in basic and acidic media. Thus, it has been shown that, even at room temperature in aqueous methanolic K_2CO_3, the 17α-epimer (VI), having a quasi-axial orientation of the side chain, undergoes retro-aldol cleavage of the $C_{17}-C_{20}$ bond to give compound (VII); however, the 17β-epimer (VIII) reacts only on heating with strong base (KOH) to give a mixture of (VII) and the α,β-unsaturated ketone (IX).[10] Under acidic conditions, the reaction proceeds quite differently.† Thus, treatment of hydroxyketone (VIII) with perchloric acid in dioxane fails to undergo retro-aldol cleavage, affording, instead, the α,β-unsaturated ketone (IX) as the only product;[11] however, the 17α-epimer (VI) gives a mixture of (IX) and androst-5-en-3β-ol-16-one (VII).



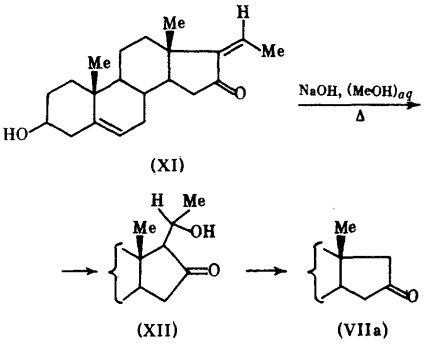
We believe that steric forces may be responsible for the different behaviour of epimers (VI) and (VIII) in basic media. In compound (VI), the approach of the base to the proton at C_{17} is sterically unfavourable as a result of the shielding effect of the angular 18-methyl group. Consequently, the base removes the hydroxylic proton with subsequent retro-aldol cleavage. Evidently, one must also consider the role of stereo-electronic factors. Thus, cleavage of the quasi-axial side-chain at C_{17} in (VI) should proceed more easily than cleavage of the equatorial side-chain in (VIII).[11] On the other hand, as a result of the increased availability of the proton at C_{17} in (VIII), the formation of intramolecular hydrogen bonding between the carbonyl group at C_{16} and the hydroxyl group at C_{20} is more favourable in (VIII) than in (VI), as confirmed by using Dreiding models. This further explains the reluctance of (VIII) to undergo retro-aldol cleavage.

Intramolecular hydrogen bonding may also explain why it is difficult to remove the 17α side-chain of 18-nor-17β-methylpregna-5,13(14)-dien-16-one (X) by retro-aldol cleavage, which only proceeds under forcing conditions (on heating with KOH in methanol):



It is interesting that the formation of a hydrogen-bonded conformer is more likely with the 20*S*-diastereoisomer of (X), having *anti*-oriented methyl groups on C_{17} and C_{20}, than with the 20*R*-diastereoisomer of (X) having the two methyl groups in the *syn*-orientation. Therefore one would anticipate that the 20*S*-diastereoisomer of (X) would be less disposed to undergo retro-aldol cleavage than the 20*R*-isomer. Unfortunately, Akhrem et al.[17] did not establish the absolute configuration at C_{20}. One should also note that the acidity of the OH group of the secondary alcohol (X) is less than that of the tertiary alcohol (VI)—an additional factor which explains the reluctance of (X) to undergo retro-aldol cleavage.[4]

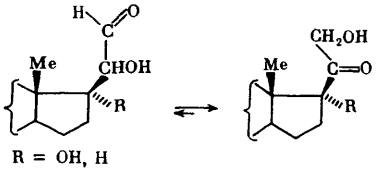
Prolonged heating of pregna-5,17(20)-dien-3β-ol-16-one (XI) in aqueous methanol containing NaOH also leads to 3β-hydroxy-androst-5-en-16-one (VIIa). In this instance, the β-hydroxyketone (XII) is formed initially by Michael addition, and then undergoes retro-aldol cleavage to give the final product (VIIa):[14]



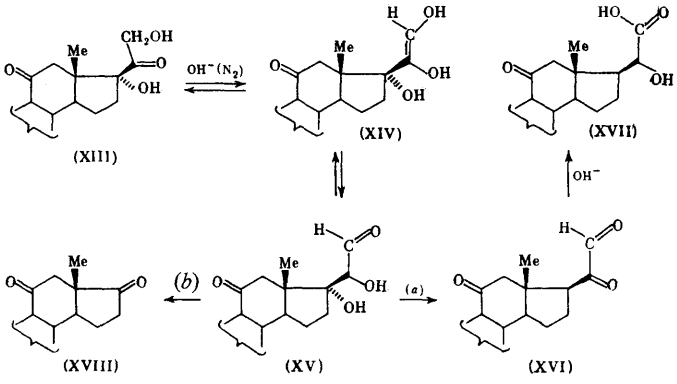
An interesting retro-aldol cleavage has been observed with a corticosteroidal β-hydroketone (XIII). This undergoes a tautomeric shift‡ on treatment with base (in the absence of oxygen) to give the dihydroxyaldehyde (XV), which subsequently cleaves in two ways: a) by initial dehydration to (XVI), followed by benzilic rearrangement to give the acid (XVII); and b) retro-aldol cleavage of the side

† The rate of dehydration of hydroxyketones increases on raising the temperature under acidic conditions.[12]

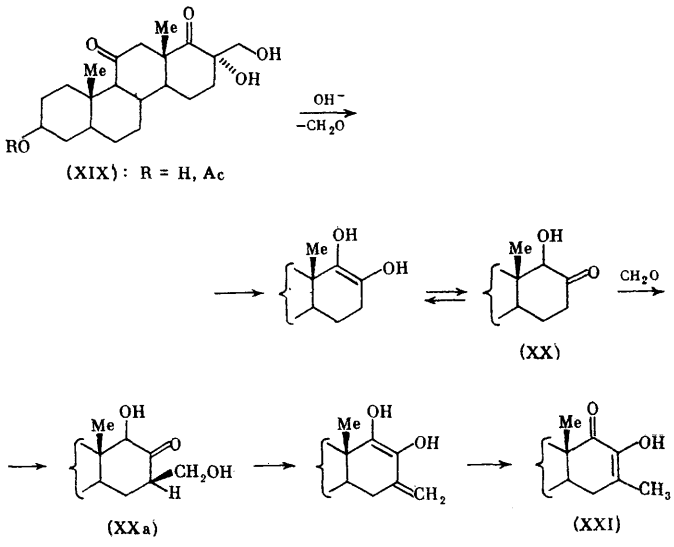
‡ The tautomeric conversion of aldols into the corresponding ketones has been applied to the synthesis of the corticoid side chain:[7]



chain to give the diketone (XVIII).[7,15] Compound (XIII) is also converted to (XVII) in acidic media.

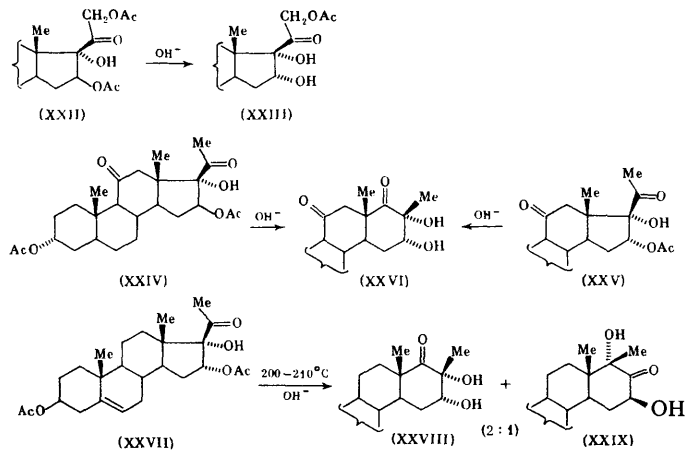


There are also examples of retro-aldol cleavage of formaldehyde from *D*-homosteroids (XIX), followed by its subsequent addition to the resulting ketone (XX). The hydromethyl derivative (XXa) is formed initially, and is then dehydrated to (XXI). This was confirmed by the independent conversion of (XX) into (XXI) on treatment with formaldehyde in basic media.[7]

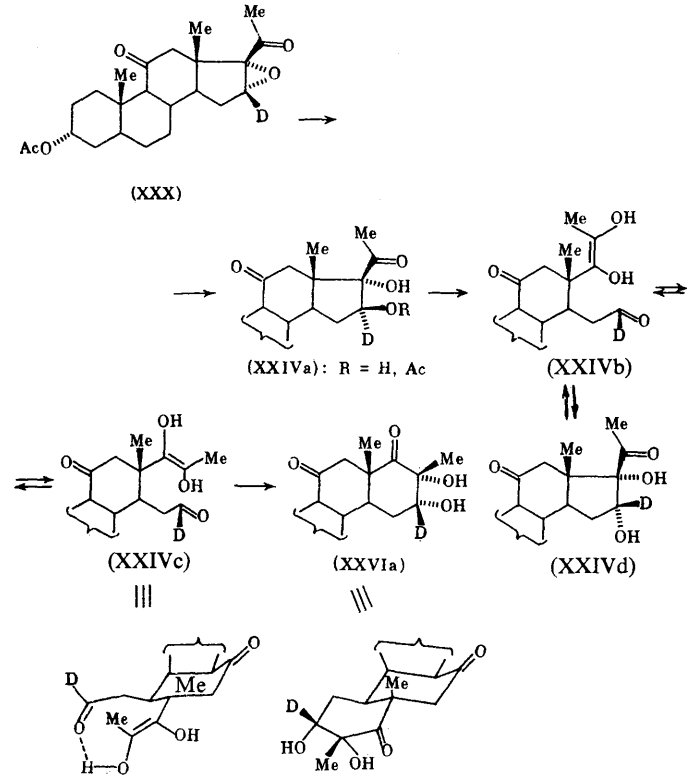


Based on stereochemical considerations, retro-aldol cleavage of the second type (i.e. of the steroid skeleton) may be further subdivided into 1) retro-aldol reactions not involving angular carbon atoms; and 2) retro-aldol reactions involving angular C-atoms (C_5, C_8, C_9, C_{10}, C_{13} and C_{14}).

Those examples in the first category are typified by elimination from C_{16} and C_{17}, but, in principle, retro-aldol cleavage is also possible at C_1, C_2, C_3, C_4, C_6, C_7, C_{11}, C_{12} and C_{15}. Such reactions can also lead to ring expansion or contraction of the skeleton (affording homo- and nor-steroids, respectively). The unusual inversion of configuration at C_{16} on hydrolysis of the 17α-hydroxy-corticosteroid (XXII) to (XXIII) in basic media can also be explained by a retro-aldol mechanism,[16] as also can the conversion of the epimeric 3α,16-diacetoxy-17α-hydroxypregna-11,20-diones, (XXIV) and (XXV), to the same 16α-hydroxy-*D*-homosteroid (XXVI); retro-aldol cleavage of the 11-deoxy-analogues, e.g. (XXVII), which gives a mixture of (XXVIII) and (XXIX), proceeds in a similar way.[17]

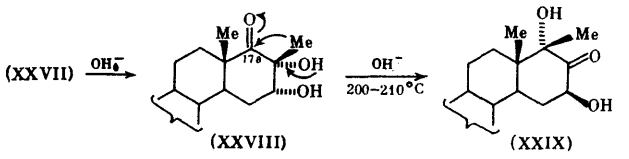


The mechanism of such reactions has been established by labelling experiments.[7]

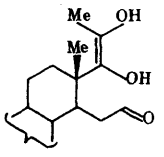


The formation of the *D*-homosteroid (XXVIa) and the epimerisation of (XXIVa) to (XXIVd) can be readily explained by the above scheme. Intramolecular hydrogen bonding in the intermediate 16,17-secosteroid (XXIVc) facilitates retro-aldol cleavage with subsequent formation of the *D*-homosteroid (XXVIa). The 16α-hydroxy and 17β-methyl groups in (XXVIa) are in a pseudoequatorial configuration relative to the *D*-ring (which is thereby stabilised in the boat conformation). The formation of the corresponding chair conformer would have required an unfavourable 1,3-diaxial interaction between the methyl groups at C_{17} and C_{13}.[7]

As has already been shown above, heating compound (XXVII) in basic media affords (XXVIII) as the main product together with (XXIX), in which the methyl group has migrated from C_{17} to C_{17a}.[17] We believe that this occurs as a result of rearrangement of (XXVIII) having a tertiary methyl group at C_{17}:

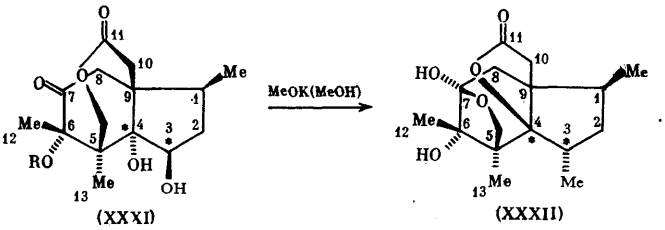


The driving force for this rearrangement is the release of strain energy associated with the 1,3-interaction of the methyl groups in the intermediate secosteroid:

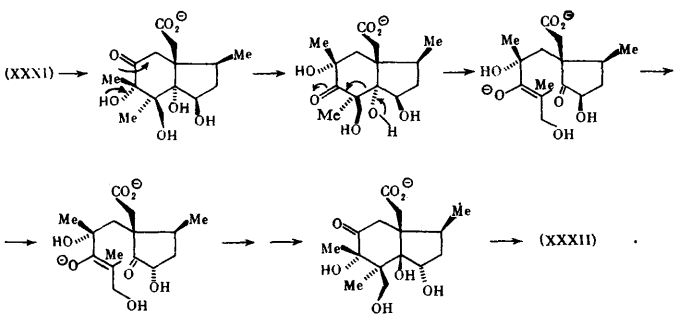


It is worth noting that the migration of the tertiary methyl group usually proceeds more easily under the action of acid. Under these conditions, migration is facilitated by the developing positive charge on the adjacent carbon atom, arising as a result of protonation of the carbonyl oxygen. Akhrem et al., in fact, found that under acidic conditions compound (XXVII) rearranges primarily to give (XXIX), and not (XXVIII).[17]

From X-ray structural analyses and chemical studies, Kouno et al. found that the naturally occurring pseudoanisatin (XXXI), having a complicated substituted hydrindane skeleton, rearranges in the presence of strong base.[18] The product had an unusual configuration at C_3 and C_4, and had been formed by an intramolecular translactonisation to give a stable *peri*-fused γ-lactone ring with simultaneous lactolide ring close involving C_7 and C_5:

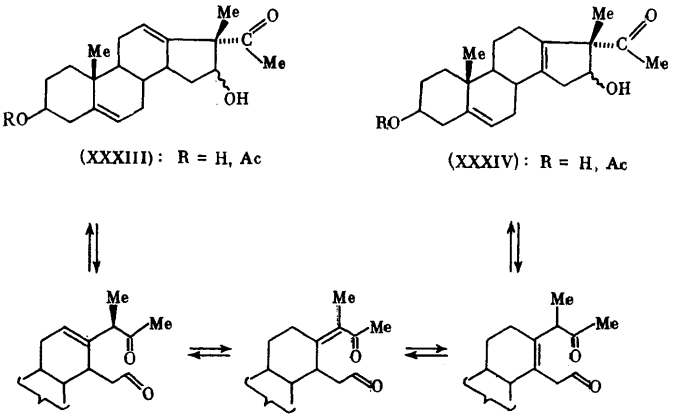


The inversion at C_4 is particularly interesting since, as a result of the reaction, the *trans*-hydrindane ring is converted into the *cis*-form. Barton has proposed a mechanism for this inversion, involving retro-aldol cleavage of the C_4-C_5 bond:[18]



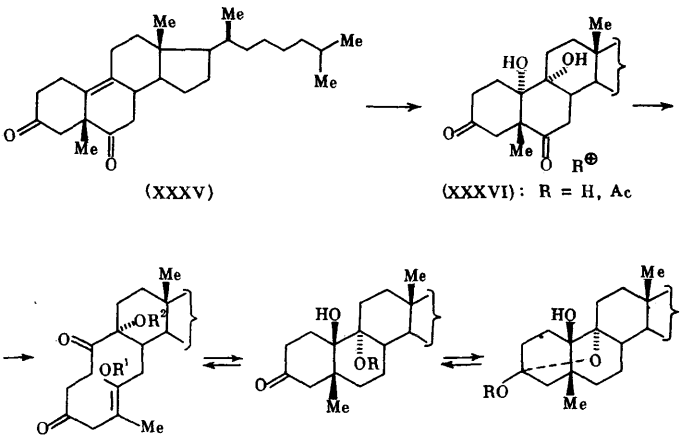
It is considered that the driving force for this rearrangement of pseudoanisatin is the release of strain energy associated with the octahydro-*trans*-indan ring.

In studying the saponification of steroids (XXXIII) and (XXXIV), Herzog et al. discovered that the two compounds were in equilibrium, the double bond shift, $\Delta^{12(13)} \rightleftarrows \Delta^{13(14)}$, being facilitated by a retro-aldol cleavage of the $C_{16}-C_{17}$ bond followed by re-aldolisation.[19]

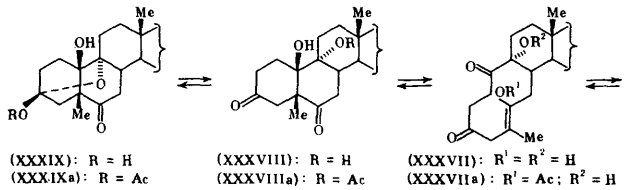


The second sub-category of retro-aldol cleavage, involving the angular carbon atoms, is especially interesting. These reactions lead to isomerisation and a variety of rearrangements.

A study of the dihydroxylation of compound (XXXV) to give (XXXVI) showed that the product subsequently rearranged via retro-aldol cleavage.[20] The *B*-ring of the *cis*-diol (XXVI) is forced into the boat conformation as a result of the steric requirements of the *trans-A/B* fusion. This facilitates retro-aldol isomerisation to give the energetically more favourable *cis-A/B* isomer (XXXVIII) having a chair conformation in ring *B*. This steroid was isolated as the transannular oxido tautomer (XXXIX).



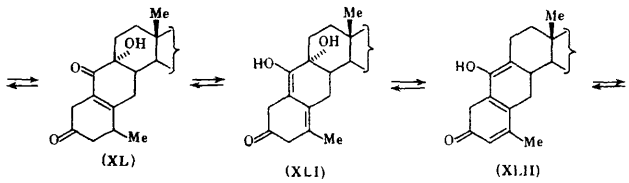
On treatment with base, the oxido compound (XXXIX) rearranges further to give (XL) [presumably via the same intermediate (XXXVII)].[20]



(XXXIX): R = H
(XXXIXa): R = Ac

(XXXVIII): R = H
(XXXVIIIa): R = Ac

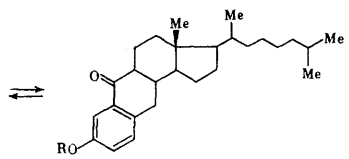
(XXXVII): $R^1 = R^2 = H$
(XXXVIIa): R^1 = Ac; R^2 = H



(XL)

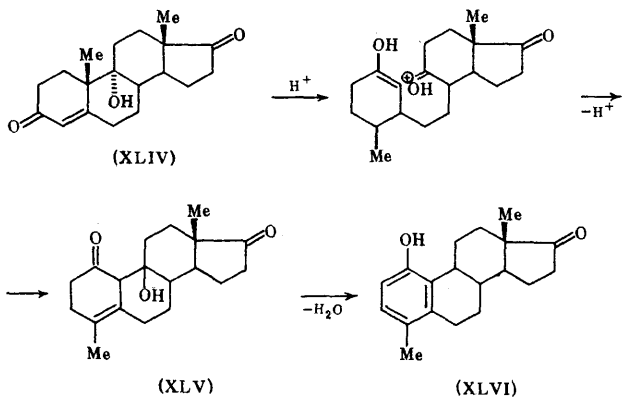
(XLI)

(XLII)



(XLIII): R = H
(XLIIIa): R = Ac

References have also been made to 'remote' retro-aldol reactions, facilitated by conjugation between the keto and hydroxyl group.[21,22] This is exemplified below.

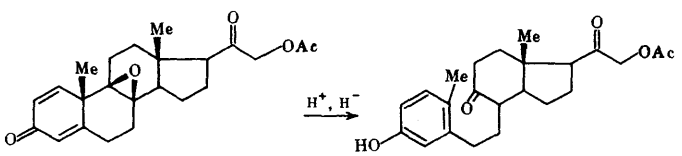


(XLIV)

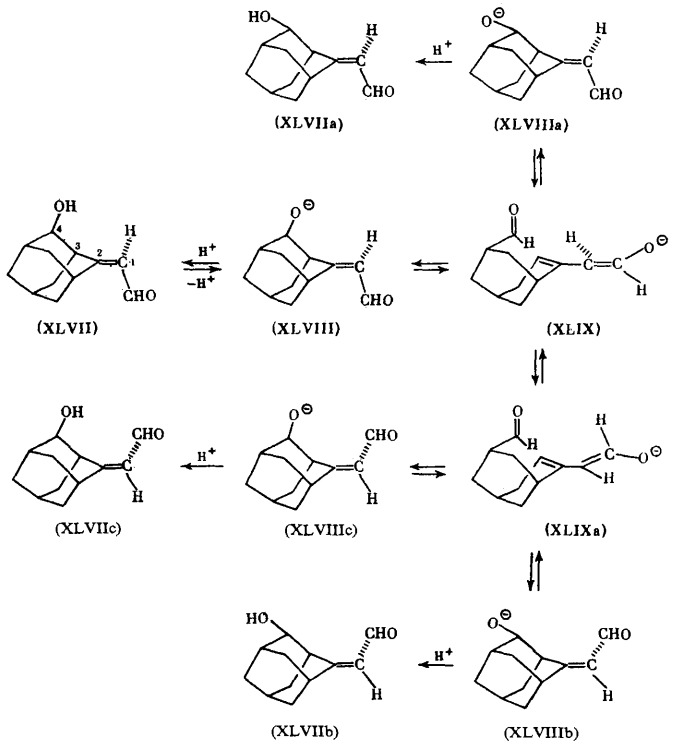
(XLV)

(XLVI)

In such instances, the vinylogous aldol fragment is well disposed to retro-aldol cleavage in acidic media. This is further facilitated by the lack of a labile proton between the functional groups, so that dehydration of the substrate is precluded. However, this is not so in the product (XLV), dehydration of which proceeds readily to give the phenolic ketone (XLVI). Conjugated epoxyketones also undergo such 'remote' retro-aldol cleavage, as illustrated below:[23]



An interesting example of a 'remote' retro-aldol cleavage has been reported in adamantane chemistry. Thus, treatment of (*E*)-(1*R*)-4(a)-hydroxy-2-adamantylideneacetaldehyde (XLVII) with NaH affords anion (XLVIII), which undergoes retro-aldol ring opening to give the isomeric anion (XLIX). The enolate group of the latter is conformationally flexible, so that an equilibrium is established with the stereoisomer (XLIXa). The anions (XLVIIIa–c) are formed by subsequent re-aldolisation, and protonation of the reaction mixture leads to a mixture of all four epimeric hydroxyaldehydes (XLVII, XLVIIa–c) in 33:8:27:32 proportion.[24]



(XLVIIa)

(XLVIIIa)

(XLVII)

(XLIX)

(XLVIIc)

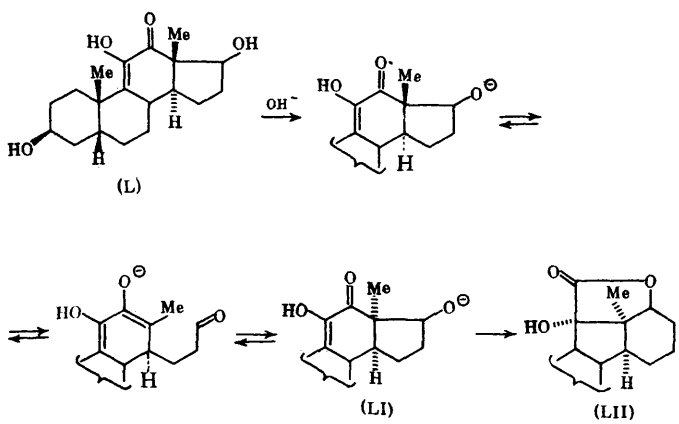
(XLVIIIc)

(XLIXa)

(XLVIIb)

(XLVIIIb)

Retro-aldol reactions may compete with other processes. Thus, the diketone (L), in which benzilic rearrangement is sterically inhibited, undergoes an initial retro-aldol cleavage on treatment with base (NaOH in propanol) to give anion (LI), having the thermodynamically more stable *cis*-*C*/*D* ring fusion.



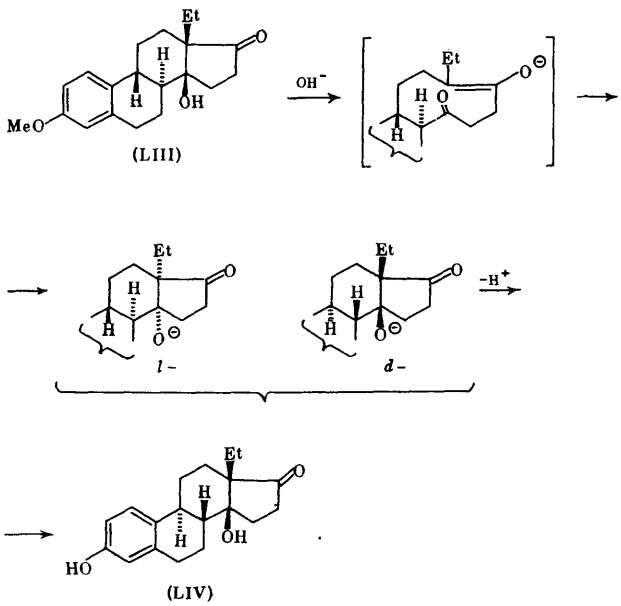
(L)

(LI)

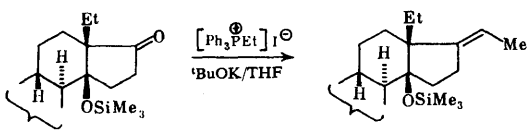
(LII)

The anion (LI) is known to undergo benzilic rearrangement[25] and, on subsequent acidification, affords the 13-*iso*-11;17-lactone (LII). The structure of the latter has been reliably established by X-ray crystallographic analysis.[26]

We have also discovered a novel rearrangement involving the *C/D* ring junction of a 14-hydroxy-17-ketosteroid. Thus, attempted Wittig olefination of the *trans-anti-cis*-hydroxyketone (LIII), obtained by reductive cyclisation,[27] resulted in isomerisation to the abnormal *trans-syn-cis*-isomer (LIV) rather than the expected side-chain formation at C_{17}. The rearrangement involves retro-aldol cleavage of the *C/D* ring junction, as shown below:[28]



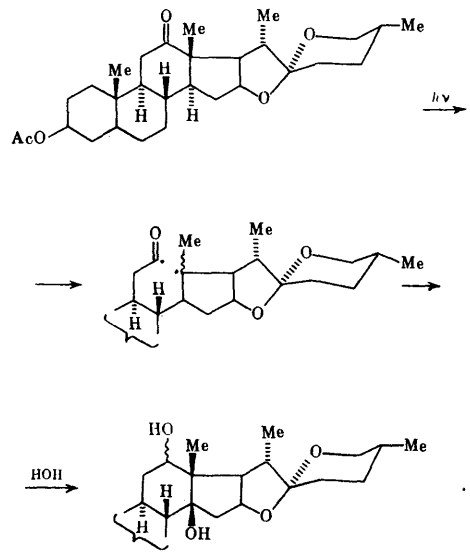
Wittig reaction does take place, however, if the 14-hydroxyl group is protected as the trimethylsilyl derivative:[27]



Strong nucleophiles (not associated with Wittig reagents) also induce the above *C/D* ring inversion[28] to give the same product (LIV) in high yield (>80%).[27] This methodology has proved attractive in the total synthesis of cardioaglycones having the natural *cis-C/D* ring fusion.

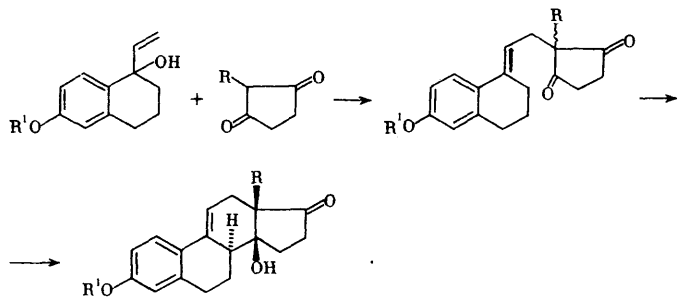
III. The two-centred inversion of the *C/D* ring junction and approaches towards the total synthesis of cardiotonic steroids

By virtue of their positive ionotropic effect on cardiac insufficiency, cardioglycosides have been broadly used medicinally. Their aglycones are steroidal, being characterised by a 14β-hydroxy group (or, in rare instances, by a 14β,15β-oxido group), as well as an unsaturated lactone residue appended at the 17β-position (a butenolide residue in cardenolides, and an α-pyrone residue in butadienolides).[29] The syntheses of such cardioaglycones have been carried out in several laboratories (for examples see Schonfeld et al.[30]). In the construction of the butenolide residue, C_{21}, steroids have been primarily used as starting material,[31] although references have also been given to syntheses based on 17-ketoandrostanes.[31,32] In all of these syntheses, the 14β-hydroxy group has been introduced via the corresponding Δ^{14}-steroid. Welzel and Stein devised a partial synthesis of digoxigenin via photochemical rearrangement of hecogenin, which is readily available from natural (plant) sources.[33] Irradiation initially affords an aldehyde, which then undergoes a Prins cyclisation:



Although it is customary to use cardioglycosides in experimental therapy, the aglycones themselves are also biologically active,[29,30] and the transformations of such aglycones have been studied from both the theoretical and practical viewpoint. Thus, it has been shown that 14β-hydroxy derivatives of estratriene possess inhibitory activity of Na^+,K^+-ATPase and may also have potential cardiotonic activity.[34]

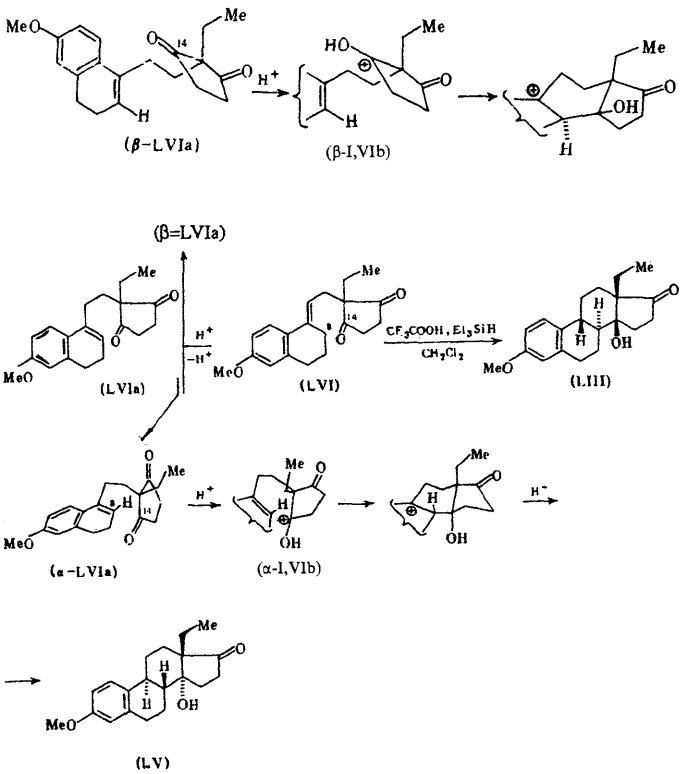
The incorporation of the 14β-hydroxy group in the estrane skeleton can be readily achieved by ring closure of the readily available 8,14-seco-$\Delta^{1,3,5(10),9(11)}$-estratetraene-14,17-dione (Torgov reaction):[35]



We have found that reductive ring closure of the secodiketone (LVI) (by a modified Torgov reaction)[27] leads stereoselectivity to the saturated *trans-anti-cis*-estrane (LIII).[36] The formation of the *trans-syn-cis-* (LIV) [37] and *trans-anti-trans*-isomer (LV) [38] was

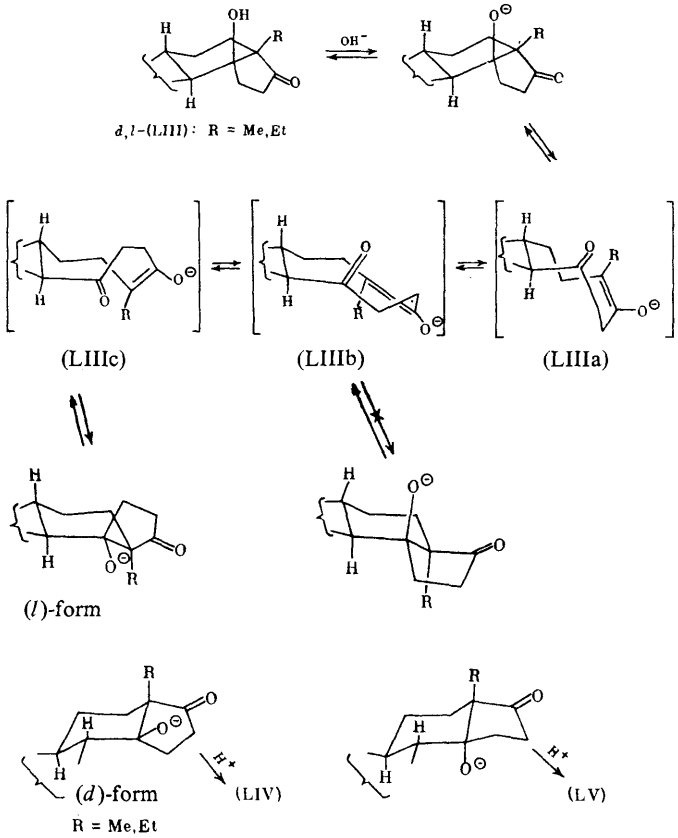
energetically unfavourable (see Scheme 1). Further details of this transformation are available.[39–41]

Scheme 1



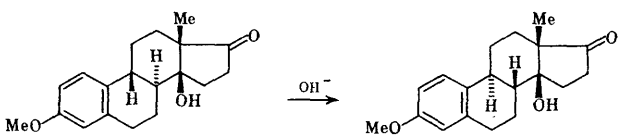
It has also been found that the product of reductive ring closure (LIII) [36] isomerises in the presence of a strong nucleophile (for example, under the conditions of the Wittig olefination) to give the thermodynamically more favourable (by 0.8 kcal/mole) natural isomer (LIV).[33] This isomerisation proceeds via an intermediate 13,14-secosteroid,§ formed as a result of retro-aldol cleavage of the $C_{13}-C_{14}$ bond (Scheme 2).[28] Further details are also available.[39,42]

Scheme 2



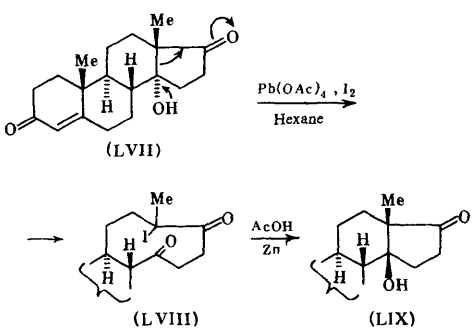
Thus, the (*l*)-diastereomer is obtainable from the *d*-diastereomer, and the (*d*)-isomer from the (*l*)-isomer.[28]

The C_{18}-unsubstituted analogue—(*d,l*)-3-methoxy-14β-hydroxyestra-1,3,5(10)-trien-17-one—under the same conditions also affords the natural isomer¶ as a result of retro-aldol cleavage and re-aldolisation:[44,45]

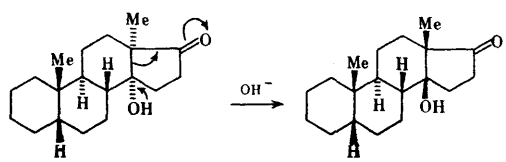


It should be pointed out (with reference to the mechanism depicted in Scheme 2) that although the formation of the 14α-hydroxy isomer (LV) is possible, in principle, its strain energy (31.9 kcal/mole) is significantly greater than that (29.1 kcal/mole) of the 14β-hydroxy isomer (LIV) and that (29.9 kcal/mole) of isomer (LIII).[39] Hence the formation of (LV), although possible on theoretical grounds,[42] is unlikely.

§The anionic form of the 13,14-seco-13(17)-en-17-one should be primarily in the conformation (LIIIc) since molecular models have shown that conformers (LIIIa), and especially (LIIIb), are severely hindered sterically. In actual fact, the 13,14-secosteroid (LVIII), obtained from (LVII), reacts with Zn dust in acidic media to give the natural isomer (LIX) as the sole product:[43]



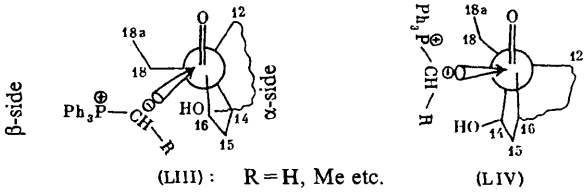
¶We also believe that the 18-retro-14α-hydroxysteroid[46] would isomerise to the natural form under the same conditions:[28]



The synthesis of the 14β-hydroxyestratriene (LIV), having the same configuration as natural cardioaglycones, can thus be achieved in two high-yielding stages—by reductive cyclisation of Torgov's readily available secodiketone, followed by isomerisation of the resulting (LIII). In the development of this method as a route to analogous estratriene and 19-norandrostane aglycones (the latter being obtainable by reduction of the former) with low toxicity, an important consideration was the choice of side-chain functionality at C_{17}. Here, we focussed our attention on stereochemical aspects of incorporating the C_{17} side chain by applying Wittig olefination with 17-oxosteroids (in competition with retro-aldol cleavage) and Grignard addition to the same substrates.

As mentioned above, *trans-anti-cis*-14-hydroxysteroids (LIII) undergo retro-aldol cleavage under the conditions of the Wittig olefination to give, ultimately, the natural isomers (LIV), which may then participate in the Wittig reaction. This interesting result can be explained as follows. As is evident from the Newman projection, based on X-ray crystallographic data,[36,37] the *cis*-orientation of the π-orbitals of the C—O bond (relative to the angular group) in the unnatural isomers (LIII) would necessarily direct *syn*-planar attack of the Wittig reagent,[47] approach of which would be sterically hindered (Scheme 3).[49,50] Replacement of the methyl group at C_{13}, or in the Wittig reagent, by ethyl or by a larger hydrophobic group adds significantly to this steric hindrance, and the Wittig reaction becomes even less likely.

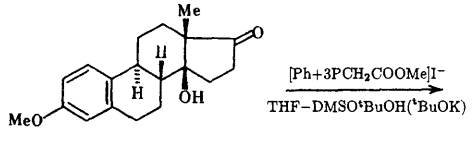
Scheme 3

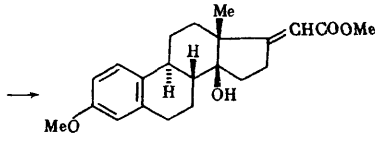


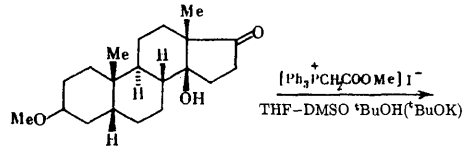
(LIII): R = H, Me etc. (LIV)

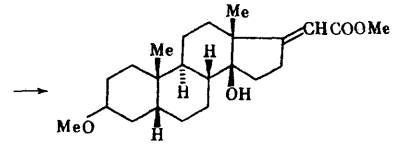
In the natural isomers (LIV), approach of the Wittig reagent from the β-side (*syn*-attack) proceeds considerably more easily to give the intermediate phosphonio-betaine complex (although, even here, large substituents in the vicinity of the reaction centre may still inhibit side chain formation).

Wittig olefination of natural 17-ketosteroids is exemplified below:[51–53]



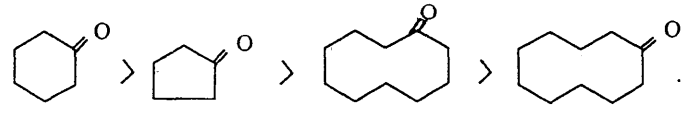






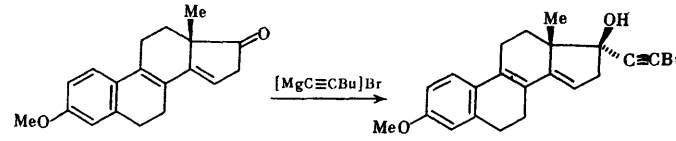
In these reactions, it is important that a hydrophilic group is present in the Wittig reagent, which facilitates olefination via intermolecular hydrogen-bonding with the 14-hydroxy group. The formation of 17-alkylidenesteroids is also favoured because in such instances there would be no repulsion (*syn*) between the substituent at C_{13} and the newly formed side chain at C_{17}.

Suppression of the Wittig reaction with the unnatural isomers (LIII) is apparently due to preferential deprotonation of the axial 14-hydroxy group by the nucleophilic reagent. This induces retro-aldol cleavage to give the corresponding 13,14-secosteroid, which then undergoes conformational isomerisation and re-aldolisation with the formation of the energetically more favourable natural isomers (LIV). The equatorial 14β-hydroxy group in the latter is inert to the incoming nucleophile as a consequence of either shielding by the neighbouring C_{13} axial substituent or the energetically unfavourable reversal of the isomerisation to give (LIII). Furthermore, the formation of the intermediate Wittig betaine complex depends on the size and nature of the cyclic ketone. Thus, it has been established[1] that the reactivity of the keto group decreases in the following order:

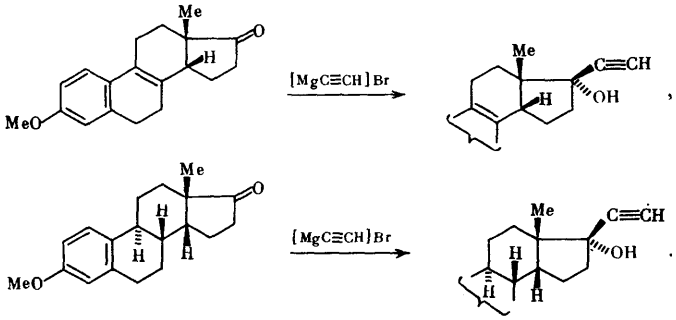


This explains why the keto group of the intermediate anions (LIIIa, b, c) (Scheme 2), which arise during the isomerisation of (LIII) to (LIV), is inert to Wittig reagents.

It is worth noting that, in *cis-C/D*-steroids, the angle ($\theta^{cis} \approx 110-120°$) between the plane of the *D*-ring and the remainder of the steroid skeleton is such that attack of nucleophiles from the α-side (Scheme 3) would be unfavourable.[54] However, in the corresponding *trans-C/D*-steroids and/or those containing endocyclic double bonds, the angle between the planes ($\theta^{trans} = 170-180°$) [55] is such that attack from the α-side is favourable on steric grounds so that the keto group at C_{17} is available for Wittig olefination or nucleophilic addition of Grignard reagents (to give 17β-alkyl derivatives):[50]



It should be further noted that Grignard addition does take place with 17-keto-*cis*-*C*/*D*-steroids having *trans-syn-cis* skeletal fusion or where there is a 8(9)-double bond, i.e. where a 13β-axial alkyl group and an equatorial 14β-hydroxy group or 14β-hydrogen are present:[56]



At the same time, 14β-hydroxyestratrienes of unnatural configuration and/or $\Delta^{9(11)}$-derivatives, where there is a 13β-equatorial and 14β-axial group, are sterically crowded in the vicinity of C_{17} so that the $sp^2 \rightarrow sp^3$ transformation at this atom (on formation of the intermediate Wittig betaine or on addition of Grignard reagents) is inhibited.

***

Steroids having a β-hydroxyketo residue undergo retro-aldol cleavage in basic media. Conformational isomerisation of the products, followed by re-aldolisation, may then take place. This is notably exemplified by the *C*/*D* ring inversion of 14-hydroxy-17-ketosteroids, of which the natural *trans-anti-cis*-isomers readily undergo retro-aldol cleavage in basic media (or under the conditions of the Wittig reaction) to give the corresponding 13,14-secosteroids. Conformational isomerisation of the latter, followed by re-aldolisation, leads to the energetically more favourable isomers having the *trans-syn-cis*-fusion characteristic of natural cardio-active steroids. This isomerisation may be applied in the synthesis of 14β-hydroxyestratrienes and (after reduction of the *A*-ring) analogues of cardioaglycones. 17-Ketosteroids with the natural configuration may be functionalised at C_{17}, e.g. by Wittig olefination or Grignard addition.

Physicochemical application of capillary chromatography

A V Vasil'ev, E N Aleksandrov
Nesmeyanov Institute of Organoelemental Compounds, Russian Academy of Sciences, Moscow
Semenov Institute of Chemical Physics, Russian Academy of Sciences, Moscow

ABSTRACT. The application of capillary gas chromatography in the determination of the free energy, enthalpy, and entropy of sorption, the saturated vapour pressure and activity coefficients, the assessment of the lipophilicity of volatile compounds, and the study of the properties of polymers and liquid crystals is described. The use of reaction capillary chromatography in kinetic studies of conformational conversions, thermal degradation, and photochemical reactions is examined. Studies on the use of capillary columns for determination of the second virial coefficients and viscosity of gases and the diffusion coefficients in gases, liquids, supercritical fluids, and polymers are analysed.

The bibliography includes 114 references.

I. Introduction

High-performance capillary chromatography is a powerful method for the analysis of multicomponent mixtures in chemistry, biology, and medicine and in the monitoring of environmental pollution. Furthermore, the practical value of this type of chromatography is not purely restricted to analytical problems, as it is also a convenient method for the determination of physicochemical parameters, for which packed columns are traditionally used.[1–4] However, with regard to their physicochemical applications, capillary columns have a whole series of advantgages over packed columns, and in recent years they have been increasingly used for the determination of the thermodynamic properties of sorption, the study of the transport properties of gases and liquids, research on polymers and liquid crystals, and also in chemical kinetics.

Open tubular or capillary columns (CCs) were first proposed by Golay.[5,6] They are relatively narrow and long, coiled cylindrical tubes in which the stationary phase is distributed over the inner surface of the walls. Golay pointed out that the main characteristic of CCs is not the small magnitude of their internal diameter (50–800 μm) but their hollowness, which provides them with high permeability.[7] Because of the low pneumatic resistance of capillary columns it is possible to increase their length to 100 m or more and thus increase their efficiency approximately by a factor of 10^2 compared to packed columns. As a result, the accuracy in measuring retention parameters in capillary chromatography is 5–10 times greater than in chromatography with packed columns.[8] The high efficiency of CCs makes it possible to study several compounds in mixtures at the same time and to reduce the need for sample purity. When using capillary column for research, it is sufficient to have microgram quantities of the materials: micrograms of stationary phases and nano- or even pico-grams of volatile sorbates. Because of the lower sorptive capacity of CCs in comparison with packed columns and also their lower adsorption and catalytic activities, it is possible to study low-volatility, thermally labile, and chemically unstable compounds.[9–10] The extremly simple geometry of capillary columns and the possibility of preparing a readily controlled layer of the stationary phases make them ideal for measurement of diffusion coefficients in gases, liquids, and polymers. The aim of this review is to summarise the experience of using capillary columns in physicochemical studies.

II. Determination of equilibrium sorption parameters and related values

Of fundamental importance in gas chromatography is the distribution coefficient of compounds in the system mobile phase–stationary phase, which may be calculated from the chromatographic retention and volumetric phase ratio. From the distribution coefficient and its dependence on temperature and pressure it is possible to determine thermodynamic parameters of sorption, such as the free energy, enthalpy and entropy of sorption, the activity coefficient of the sorbate at infinite dilution in the stationary phase, the saturated vapour pressure and volatility of the sorbate, and finally the mixed second virial coefficient of the sorbate–carrier gas intermolecular interaction.[3]

Sources of systematic errors not orginating from the equipment in the determination of these parameters can result from nonlinearity of the sorption isotherm, solubility of the carrier gas in the liquid phase, nonequilibrium solution of the compound and its adsorption at the phase boundaries of gas–liquid and liquid–phase wall of capillary column.

1. Determination of differential molar free energies of solution

Golovnya and Samusenko[11–13] studied the change in Gibbs potential when different classes of organic compounds were dissolved in poly(ethylene glycol) PEG 40M deposited on the walls of glass CCs that had been deactivated with KF and Na_3PO_4 salts. By calculating the differences in free energies of sorption of compounds with and without the functional groups NO_2, OH, NH_2, Br, SH and CH_3 it was possible to eliminate the undetermined factors related to

the phase ratio in the columns:

$$\delta(\Delta G)_{X,H} = \Delta G_{RX} - \Delta G_{RH} = -RT\ln\left(\frac{t_{RX}-t_M}{t_{RH}-t_M}\right) = -RT\ln(t'_{RX}/t'_{RH}), \quad (1)$$

where t_{RX} and t_{RH} are the retention times of compound RX with functional group X and its hydrocarbon analogue RH (n-octane or benzene), t_M is the hold-up time, t'_{RX} and τ'_{RH} are the adjusted retention times of compounds RX and RH. It was established that the presence of salts and their chemical nature affect the retention of compounds with functional groups that can undergo a specific intermolecular interaction. Unfortunately, it is not clear whether this interaction occurs with ions dissolved in PEG 40M or whether it takes place on the surface of the salt crystals by an adsorption mechanism. The same method was used on glass CCs with the stationary phases OV-101, OV-17, PEG 40M and added KF to determine the increments of methyl groups to the sorption potentials of methylbenzenes,[13,14] methylpyrazines,[15] methylpyridines, methylpiperidines, and branched secondary aliphatic amines.[14,16] From the relationships that were established, the authors developed schemes to predict the retention indices of methylpyrazines[15] and methylpyridines[17] for their identification on columns of varying polarity.

Grigor'eva et al.,[18,19] by using glass CCs with a thick layer of immobilised siloxane SE-54, studied the change in free energy of sorption of mono- and bi-functional carbonyl-containing compounds in relation to the number of their methylene units. An anomalously small retention of the primary homologues was detected for series of methyl and butyl n-alkyl ketones and fatty acid methyl esters. A similar pattern occurs for a series of dimethyl series of α,ω-dicarboxylic acids. The anomalies in the retention of the primary homologues in the above series were not observed when the more polar stationary phases OV-210, PEG 40M, SP-2300 and Silar 10 C were used.

2. Determination of the enthalpy and entropy of sorption

The heat of solution of a sorbate can be determined by studying its retention at different temperatures. On incorporating the Karger relationship:[20]

$$\Delta G = -RT\ln K = -RT\ln(k\beta), \quad (2)$$

the Gibbs–Helmholtz equation can be given in the form:

$$-R\left[\frac{\partial(\ln k\beta)}{\partial(1/T)}\right]_p = \Delta H, \quad (3)$$

where the heat of solution is determined as the gradient of the tangent to the curve of the logarithm of the capacity factor (k) against temperature on $-R\ln k$ and $1/T$ coordinates. It is worth noting that it is not necessary to know the distribution coefficient K in order to determine ΔH, since the phase ratio (β) is virtually independent of temperature.

A number of authors[21,22] determined the heat of solution of light aliphatic and alicyclic hydrocarbons (C_5–C_8) in squalane by using copper and steel capillary columns. When precise measurements of the absolute molar heats of solution were carried out,[22] the linear dependence of the enthalpy of solution on temperature and the nonideality of the gas phase were taken into account (see Section 3). By careful maintenance of a constant temperature (±0.01 °C) and pressure at the column inlet (±0.001 atm), the error in determination of ΔH was not more than 3%. Although the hydrocarbons studied are not very susceptible to adsorption, the latter may in principle affect the accuracy in determination of heats of solution since metal CCs have high adsorptive activity. Moreover, their extensive irregular surface[23] is difficult to cover completely with the stationary phase.

Mohnke and Heybey[24] determined the specific retention volumes of permanent gases and methane in glass CCS with zeolite 5A at different temperatures, and from them calculated the enthalpies of adsorption ΔH_{ads}. In addition they determined the differences between the enthalpies and entropies of adsorption of methane and deuteromethane on a capillary columns with a layer of activated charcoal. Suslov et al.[25] determined the retention indices of hydroxy and amino derivatives of adamantane on glass capillary columns with OV-101 and XE-60 at different temperatures. By using the formulae proposed in two earlier studies,[26,27] Suslov et al.[25] calculated the free energies, enthalpies, and entropies of sorption of the adamantane derivatives from the derived values of the indices and experimental specific retention volumes of n-alkanes.

Berezkin and Korolev[9,10] estimated the error in the gas chromatographic determination of the heats of solution of compounds with varying polarity in thin layers of immobilised siloxane SE-30 resulting from their adsorption on the walls of quartz CCs. By using the "internal standard" method,[28] the authors[9,10] determined the true distribution constants for a number of compounds in the system gas–liquid phase at four temperatures, and from these values they calculated the true heats of solution of these compounds in SE-30. Furthermore, from the chromatographically determined distribution constants of the compounds in the system mobile phase–stationary phase they determined the apparent heats of solution of the same compounds while neglecting adsorption. Comparison of the true and apparent values showed that neglect of adsorption led to a 13–20% overestimation of the experimental heats of solution of polar compounds, while for n-tridecane this difference was 4%. This relatively large contribution of adsorption for polar compounds may be due partly to the low thickness of the phase layer (74 nm) and partly to the effect of the benzoyl peroxide used as an initiator for immobilisation of SE-30.[9,10] The use of this initiator is known to result in a considerable increase in adsorption activity of capillary columns with alkylpolysiloxanes.[29–30]

3. Effect of the nonideality of the gas phase on the equilibrium sorption parameters and a determination of the second virial coefficients of gases

As has already been mentioned, it is necessary to take into account the nonideality of carrier gases in precise physicochemical measurements. This manifests itself particularly clearly in high-performance capillary gas chromatography. Thus, replacement of the "completely ideal" carrier gas H_2 by N_2 produces such a marked change in selectivity for separation of the components of a sample of gasoline on a CC with a poly(dimethylsiloxane) phase that inversion of the peak yield occurs.[31]

At medium pressure and when the carrier gas does not dissolve in the stationary phase, the distribution coefficient depends on the mixed second virial coefficient of sorbate and carrier gas B_{sG}:[32,33]

$$\ln K = \ln K^0 + \frac{2B_{SG} - V_S^\infty}{RT} p_o J_3^4, \quad (4)$$

where K^0 is the distribution constant at zero pressure of carrier gas, V_S^∞ is the molar volume of sorbate in the stationary phase, J_3^4 is the pressure drop factor $\{J_3^4 = {}^3/_4[(p_i/p_o)^4 - 1]/[(p_i/p_o)^3 - 1]\}$, and p_i and p_o are the pressures at the inlet and outlet of the column respectively. In order to calculate the mixed second virial coefficient of sorbate–carrier gas, the second virial coefficient of the carrier gas

must be known.[31] The second virial coefficients frequently serve as reference values in calculations and design in many fields of science and technology.

Huang et al.[34] put forward an original method for the experimental determination of second virial coefficients of gases (B_{GG}) using CCs without a stationary phase. The viscosity of gases and the coefficient (α) of the linear dependence of viscosity on pressure are determined at the same time as B_{GG} with this method. By integrating Poiseuille's equation, in which the pressure and viscosity are presented in the form of exponential series, and neglecting the terms with a higher order of insignificance, Huang et al.[34] derived equation (5), which relates B_{GG}, α, and the viscosity of a gas at zero pressure (μ_0) with the experimental parameters:

$$\frac{64p_o u_o}{p_i^2 - p_o^2} = \frac{d^2(1 + B_{GG}p_o/RT)}{L \quad \mu_0}[1 - (\alpha + B_{GG}/RT)p_o J_2^3], \qquad (5)$$
