Abstract. The dynamics of vibrational relaxation and vibrational predissociation processes, forbidden by the classical adiabatic Ehrenfest principle, are examined. A general approach to the calculation of rate constants for processes represented by total collision and half-collision models is formulated. Simple models which make it possible to understand the characteristics of the processes discussed are described and are extended to the case of real three-dimensional motion. Examples providing a fairly complete illustration of the present understanding of dynamic tunnelling processes are presented. The bibliography includes 45 references.

I. Introduction

The vibrational relaxation of molecules in gases is an energy exchange process between the vibrational degrees of freedom of a molecule and the translational and rotational degrees of freedom as a result of collisions between molecules and the particles of a heat reservoir. The mechanism of this process is especially simple in the case of diatomic molecules where there is only one vibrational degree of freedom and there is no intramolecular energy exchange in the intervals between successive collisions.

The experimental studies of energy transfer processes involving diatomic molecules have been some of the first investigations which laid the foundations for a new field in chemistry—chemical physics (see, for example, Kondrat'ev[1]). At the present time, these processes continue to be investigated vigorously by methods which permit the measurements not only of thermal rate constants for transitions between specified vibrational states of the molecules $n \to n'$ but of also the state-to-state rate constants for transitions between specific vibrational and rotational states: $n, j \to n', j'$.

We shall confine ourselves to the discussion of the mechanisms of purely vibrational transitions and methods for the calculation of the rate constants $k_{nn'}(T)$. We shall begin with the fact that the distribution of energy among rotational and translational degrees of freedom is canonical, i.e. is described by a Boltzmann distribution with a temperature T. We shall also assume that the heat reservoir consists of a monatomic inert gas A. The elementary collision step

$$\mathrm{A} + \mathrm{BC}(n) \to \mathrm{A} + \mathrm{BC}(n') , \qquad (1)$$

as a result of which the vibrational energy of the molecule changes by an amount $\Delta E_{nn'} = E_{n'} - E_n$, is thus discussed. The energy $\Delta E_{nn'}$ is either converted into the energy of the translational motion of A and BC and into the rotational energy of BC in the case of a deactivating collision ($\Delta E_{nn'} < 0$) or is borrowed from these degrees of freedom in the case of an activating collision ($\Delta E_{nn'} > 0$). We shall designate the rate constant for process (1) by $k^{\mathrm{rel}}_{nn'}(T)$.

Together with vibrational relaxation processes, the processes involving the so-called vibrational predissociation of weakly bound (usually van der Waals) complexes are widely investigated nowadays:

$$\mathrm{A} \cdots \mathrm{BC}(n) \to \mathrm{A} + \mathrm{BC}(n') . \qquad (2)$$

In process (2), a weak bond between the atom A and the molecule BC is ruptured as a result of the conversion of part of the vibrational energy of the molecule BC into the energy of the relative motions of A and BC. We shall designate the rate constant for process (2) by $k^{\mathrm{diss}}_{nn'}(T)$.

Clearly the mechanisms of processes (1) and (2) have much in common. In recognition of this fact, a terminology has been established in modern literature according to which process (1) is referred to as a total collision and process (2) as a half-collision.

We shall consider below the mechanisms of the total collision (1) and the half-collision (2) from a single standpoint within the framework of the so-called method of optimum trajectories. In this method, the dynamics of the collision is characterised by a single trajectory, which describes the relative motion of A and BC and the rotation of BC. The possibility of operating with one trajectory and not with a large set of trajectories, normally employed in the theoretical study of the dynamics of molecular processes,[2-4] is associated with the specific features of the vibrational relaxation and predissociation: processes of both types are forbidden in classical terms. At the same time, the optimum trajectory is not a fully classical object because it requires the introduction of the concept of the evolution of a classical system during an imaginary time interval.

Henceforth we shall consider for simplicity two limiting cases where the molecule BC is homonuclear (or 'almost' homo-

nuclear) or where it is highly asymmetric (for example, the molecule of a hydrogen halide). The preferred VT (vibrational–translational) or RT (rotational–translational) mechanisms can be isolated in this way from the overall mechanism of the so-called VRT process (vibrational–rotational–translational energy exchange). It is found that the vast majority of molecules can be assigned, from the standpoint of the energy exchange mechanism, to one of these groups. The present article does not claim to represent a complete survey of the theoretical questions associated with relaxation and predissociation processes to which a very extensive literature is devoted nowadays. Thus the interpretation of the existing experimental results within the framework of the models described above has been described in recent reviews.[5,6]

This review is constructed as follows. First the characteristic features of the dynamics of processes forbidden by the classical adiabatic Ehrenfest principle are discussed. Next we formulate a general approach to the calculation of the rate constants for processes which represent the total collision and the half-collision, and simple models which make it possible to understand the characteristics of the processes discussed are described and also extended to real three-dimensional collisions. The review ends with examples which illustrate fairly completely the present understanding of the dynamic tunnelling processes.

II. Vibrational relaxation and vibrational predissociation as classically forbidden processes

The transitions between the vibrational levels n and n' of a molecule BC in the region of thermal energies are as a rule forbidden in classical terms. This means that the solution of the classical problem of the vibrational activation or deactivation in process (1) leads to the following result: none of the multidimensional trajectories, beginning at an arbitrary point in the phase space corresponding to the classical vibrational state $N = \hbar(n + \frac{1}{2})$, ever reaches a point in the phase space which would correspond to the final vibrational state $N' = \hbar(n' + \frac{1}{2})$. For process (2), this fact means that any trajectory which describes in the initial state the complex with the vibrational energy corresponding to the classical state $N = \hbar(n + \frac{1}{2})$ in the final state describes dissociation products in which the change in the vibrational energy of BC is less than a single vibrational quantum.

The classical unattainability of the final state n' shows that processes (1) and (2) are in a certain sense tunnel processes. However, this type of tunnelling, referred to in the literature as dynamic tunnelling, differs significantly from the familiar tunnelling through a potential barrier.[7–9] Tunnelling through a potential barrier has no classical analogy, whereas the energy exchange in process (1) and the dissociation in process (2) do have classical analogies. However, these analogies do not permit the determination by the usual quasi-classical method of the probability of the transition from a solution of the classical problem, as was done, for example, within the framework of the classical S-matrix method based on the correspondence principle.[10,11]

At the same time, the classical prohibition of the $n \to n'$ transitions means that the quantum probability of processes (1) and (2) is low and it is therefore possible to employ a particular version of the perturbation theory for its calculation. In principle, this is indeed so. However, the application of this approach in practice is extremely complex, since the wave functions of the initial and final states, taking into account the strong interaction between the relative translational motions A–BC and the rotation of BC are not known with adequate accuracy. In other words, before solving the problem of the vibrational transition, one must solve fully the problem of the energy exchange between the translational and rotational degrees of freeedom at the level of the determination of the wave functions of the rotational inelastic scattering (and not only at the level of the calculation of the probabilities of the translational–rotational transitions which are determined solely by the asymptotic behaviour of the scattering wave functions).

Since the relative motions of A and BC and the rotation of BC under typical conditions satisfy the quasi-classical conditions, it is desirable to formulate a method which would operate with classical trajectories describing the motion in terms of these degrees of freedom. However, the following difficulty arises in this instance. If the classical description is adopted, then, for a very small change δN in the classical initial vibrational action N, the projection of the total exact multidimensional trajectory (for a vibrational non-elastic process) onto the translational–rotational subspace is located very close to the vibrational-elastic trajectory. In a quantum description, the minimum change in the quantum number $\delta n = n' - n$ cannot be less than unity and the corresponding change in the classical action $\delta n \times \hbar$ cannot therefore exceed δN. Under such conditions, the significance of the unperturbed trajectory becomes obscure even when the probability of the transition is very low. One of the possible ways of retaining the classical description of motion in terms of translational and rotational degrees of freedom is provided by the method of optimum trajectories (OT) which is described briefly below. This method has been applied to the description of the dynamics of the vibrational relaxation of molecules in a solid matrix, non-radiative transitions in molecules, and the photodissociation of molecules in a number of studies.[12–14]

For a specified vibrational transition $n \to n'$, the OT method defines the 'classical' trajectory of the translational–rotational motion (i.e. the pathway which satisfies the classical equations of motion) along which the system evolves during a complex time interval; this trajectory need not necessarily be either continuous or real. When the trajectory has been found, the probability of the transition is determined within the framework of perturbation theory. An important property of the OT method is the possibility of a comparatively simple averaging over the initial canonical distribution, since the quantum operator of the evolution and the operator of the Boltzmann distribution have the same (exponential) form. In calculations on the system dynamics, the canonical averaging is carried out with a displacement along the time axis by the imaginary increment $i\hbar/kT$.

The OT method is one of the versions of the so-called semiclassical methods based on the subdivision of all the degrees of freedom of the system under consideration in two subsystems —quantum and classical. The interaction between these subsystems is described within the framework of the non-stationary quantum perturbation theory. The simplifications arising in this instance are evident. Instead of a general consideration of the quantum problem for the entire system, an approach in stages is proposed: one solves initially the dynamic problem only for the classical subsystem, after which the simplified dynamic problem is solved for the quantum subsystem. However, the non-trivial question of the adjustment for self-consistency of the motions of the above two subsystems arises under these conditions. The OT method, discussed below, makes possible such adjustment for consistency.

The idea of the OT method in relation to the calculation of the rate constants for processes (1) and (2) will now be expressed in concrete terms. Other methods for the description of vibrational energy transfer processes have been described in books and reviews.[15–17]

III. Correlation functions for the interaction and the rate constants for relaxation and predissociation

We shall begin the consideration of the computational methods for the first-order time-dependent perturbation theory having assumed that the relative motion of A and BC and the rotation of BC are described in classical terms, while the BC vibrations are described in terms of quantum mechanics. We shall call this approximation semiclassical (SC). The potential energy surface for the system considered depends on three coordinates— the

distance R between the atom A and the centre of gravity of the molecule BC, the distance r between the atoms B and C, and the angle γ between the vectors $\boldsymbol{R}$ and $\boldsymbol{r}$. Instead of the variable r, it is frequently convenient to use another variable $x = r - r_e$, i.e. the deviation of the distance r from its equilibrium value r_e in a free molecule BC.

In the zeroth approximation, we have a five-dimensional trajectory $\boldsymbol{Q}(t)$ which describes the rotational non-elastic collision of A with BC for a fixed vibrational quantum number of BC ($\boldsymbol{Q}$ designates the set of coordinates which specify the relative positions of A and BC in space—three coordinates for translational motion and two coordinates for rotational motion). If $V_{nn'}(\boldsymbol{Q})$ is a matrix element of the interaction which relates the vibrational states n and n', then the probability of the first-order transition is

$$P_{nn'}^{\mathrm{SC}} = \left| \int V_{nn'}[\boldsymbol{Q}(t); \boldsymbol{Q}_i, \boldsymbol{P}_i] \exp(\mathrm{i}\omega_{nn'}t) \frac{\mathrm{d}t}{\hbar} \right|^2 , \tag{3}$$

where the time integral is with respect to the classical five-dimensional trajectory. Here account has been taken explicitly of the fact that the probability $P_{nn'}^{\mathrm{SC}}$ depends on the coordinates $\boldsymbol{Q}_i$ and the momenta $\boldsymbol{P}_i$ of the system before the collision. Eqn. (3) shows that the probability of the transition is proportional to the square of the Fourier component of the matrix element of the interaction energy at the vibrational transition frequency. The rate constant is determined from the probability of the transition by integrating it with respect to the initial collision parameters.

A more convenient representation is obtained after a series of transformations, which express the rate constant for the transition simply as the Fourier component of a bilinear combination of the matrix elements of the interaction at the vibrational transition frequency, i.e. the following relations are valid:

$$k_{nn'}^{\mathrm{SC}}(T) = [F(\beta)]^{-1} W_{nn'}^{\mathrm{SC}}(T) , \tag{4}$$

where F is the partition function for the system in the initial state and $\beta = 1/kT$;

$$W_{nn'}^{\mathrm{SC}}(T) = \int_{-\infty}^{\infty} G_{nn'}^{\mathrm{SC}}(T, t) \exp(\mathrm{i}\omega_{nn'}t)\mathrm{d}t , \tag{5}$$

where $G_{nn'}^{\mathrm{SC}}(T, t)$ is the classical autocorrelation function of the matrix element of the interaction:

$$G_{nn'}^{\mathrm{SC}}(T, t) = \int \mathrm{d}\Gamma_0 (2\pi\hbar)^{-s} \exp[-\beta H(\boldsymbol{P}_0, \boldsymbol{Q}_0)] \times$$
$$\times V_{nn'}\left[\boldsymbol{Q}\left(\frac{t}{2}\right); \boldsymbol{Q}_0, \boldsymbol{P}_0\right] V_{n'n}\left[\boldsymbol{Q}\left(-\frac{t}{2}\right); \boldsymbol{Q}_0, \boldsymbol{P}_0\right] , \tag{6}$$

where $H(\boldsymbol{P}_0, \boldsymbol{Q}_0)$ is the hamiltonian of the A–BC system (excluding the vibrations of BC), which contains the potential energy $U(R, \gamma)$ for the interaction between A and the molecule BC corresponding to the equilibrium internuclear distance. In Eqn. (6), the integration with respect to the phase space of $\mathrm{d}\Gamma_0 = \mathrm{d}^s\boldsymbol{Q}_0\,\mathrm{d}^s\boldsymbol{P}_0$ is extended over the entire phase volume of the reactants (s is the number of degrees of freedom; in our case $s = 5$).

Evidently the translational and rotational degrees of freedom enter symmetrically into Eqn. (6), so that the latter is applicable to the calculation of both $k_{nn'}^{\mathrm{rel}}(T)$ and $k_{nn'}^{\mathrm{diss}}(T)$. In the former case, H represents the hamiltonian of the translational–rotational motion of the collision partners and F designates the products of the translational and rotational partition functions; the corresponding dimensions of $k_{nn'}^{\mathrm{rel}}(T)$ are $\mathrm{s}^{-1}\ \mathrm{cm}^{-3}$. In the second case, H is the hamiltonian of the van der Waals complex and F is the partition function of the complex taking into account its rotation as a whole and the hindered rotation of BC in the complex; $k_{nn'}^{\mathrm{diss}}(T)$ is expressed in s^{-1}.

If the transition $n \to n'$ is forbidden in classical terms, then the rate constant is exponentially small. This means that the overall expression for $k_{nn'}^{\mathrm{SC}}$ (here $k_{nn'}^{\mathrm{SC}}$ denotes both $k_{nn'}^{\mathrm{rel}}$ and $k_{nn'}^{\mathrm{diss}}$ calculated in terms of the semiclassical approximation) assumes the form

$$k_{nn'}^{\mathrm{SC}} = \Phi_{nn'}^{\mathrm{SC}} \exp(-\Psi_{nn'}^{\mathrm{SC}}) , \tag{7}$$

where $\Phi_{nn'}^{\mathrm{SC}}$ is the pre-exponential factor and $\Psi_{nn'}^{\mathrm{SC}}$ is a function which greatly exceeds unity in absolute magnitude and increases with increase in the energy transferred; it depends on the parameters of the interaction potential and temperature. The pre-exponential factor $\Phi_{nn'}^{\mathrm{SC}}$ also depends on these parameters but to a much lesser extent than the exponential part of Eqn. (7). From the symmetry of the probability of the transition, it follows that $\Phi_{nn'}^{\mathrm{SC}} = \Phi_{n'n}^{\mathrm{SC}}$ and $\Psi_{nn'}^{\mathrm{SC}} = \Psi_{n'n}^{\mathrm{SC}}$.

It is seen from Eqn. (7) that the rate constants for the forward ($n \to n'$) and reverse ($n' \to n$) processes are the same, i.e. $k_{nn'}^{\mathrm{SC}}(T)/k_{n'n}^{\mathrm{SC}}(T) = 1$, which conflicts with the principle of detailed balance:

$$\frac{k_{nn'}(T)}{k_{n'n}(T)} = \exp(-\beta E_{n'} + \beta E_n) . \tag{9}$$

Thus the semiclassical approximation is valid subject to the condition that the energy transferred $E_{n'} - E_n$ is small compared with kT, i.e. when the right-hand side of Eqn. (9) is close to unity. This condition does not usually hold for vibrational relaxation at not unduly high temperatures; it is even less likely to hold for vibrational predissociation when the temperature of the van der Waals complex is very low.

The semiclassical approximation (SC) can be refined by going over to the quasiclassical approximation (QC). The latter can also be used in our approach, since the quasiclassical wave functions can be constructed on the basis of an assembly of classical trajectories.[19] The required refinement is achieved by replacing the classical autocorrelation function by its quasi-classical analogue. The corresponding expression for G^{QC} is

$$G_{nn'}^{\mathrm{QC}}(T, t) = \int \mathrm{d}^s\boldsymbol{Q}' \int \mathrm{d}^s\boldsymbol{Q}'' \{V_{nn'}(\boldsymbol{Q}') V_{n'n}(\boldsymbol{Q}'') B(\boldsymbol{Q}', \boldsymbol{Q}'') \times$$
$$\times \exp[\mathrm{i}A_t(\boldsymbol{Q}', \boldsymbol{Q}'') - \mathrm{i}A_{t+\mathrm{i}\beta}(\boldsymbol{Q}', \boldsymbol{Q}'')]\} , \tag{10}$$

where A_t represents the classical action along the rotational–translational trajectory from the space–time point $-t/2$, $\boldsymbol{Q}'$ to the space–time point $t/2$, $\boldsymbol{Q}''$, while $A_{t+\mathrm{i}\beta}$ represents the action along another trajectory, which begins at the point $(t + \mathrm{i}\beta)/2$, $\boldsymbol{Q}'$ and terminates at the point $(t + \mathrm{i}\beta)/2$, $\boldsymbol{Q}''$. The complex quantity added to time ensures the canonical averaging of the transition probability. The multiplier B is expressed in terms of the determinants of the second-derivative matrices:

$$B(\boldsymbol{Q}', \boldsymbol{Q}'') = (2\pi\hbar)^{-s} \mathrm{Det}\left[\frac{\partial^2 A_t}{\partial Q_m \partial Q_k}\right] \mathrm{Det}\left[\frac{\partial^2 A_{t+\mathrm{i}\beta}}{\partial Q_m \partial Q_k}\right] . \tag{11}$$

Thus Eqns. (4) and (5) are replaced by

$$k_{nn'}^{\mathrm{QC}}(T) = F(\beta)^{-1} W_{nn'}^{\mathrm{QC}}(T) , \tag{12}$$

$$W_{nn'}^{\mathrm{QC}}(T) = \int_{-\infty}^{\infty} G_{nn'}^{\mathrm{QC}}(T, t) \exp(\mathrm{i}\omega_{nn'}t)\mathrm{d}t . \tag{13}$$

It follows from Eqns. (12) and (13) that

$$k_{nn'}^{\mathrm{QC}} = \Phi_{nn'}^{\mathrm{QC}} \exp(-\Psi_{nn'}^{\mathrm{QC}}) , \tag{14}$$

where $\Phi_{nn'}^{\mathrm{QC}} \gg 1$, but now $\Phi_{nn'}^{\mathrm{QC}} \neq \Phi_{n'n}^{\mathrm{QC}}$, and $\Psi_{nn'}^{\mathrm{QC}} \neq \Psi_{n'n}^{\mathrm{QC}}$. It can also be shown that the rate constants for the forward and reverse processes satisfy the principle of detailed balance:

$$\frac{k_{nn'}^{\mathrm{QC}}(T)}{k_{n'n}^{\mathrm{QC}}(T)} = \exp(-\beta E_{n'} + \beta E_n) . \tag{15}$$

The calculation of the integral (10) requires the preliminary determination of a large number of trajectories describing the rotational non-elastic processes and subsequent integration with respect to the initial and final states, i.e. the problem of the calculation of the rate constant still remains extremely complex. However, under certain conditions it can be simplified: instead of a large number of trajectories one seeks one trajectory [it is called henceforth the optimum trajectory (OT)] and the probability flux is determined within a comparatively narrow flux tube along the OT. All the properties of this flux are determined by the properties of the OT and also by the additional characteristics of the motion along the optimum trajectory, which are contained in the so-called monodromic matrix.

From the mathematical point of view, the OT method is in fact a generalisation of the stationary phase method for the calculation of quasi-classical matrix elements. Within the famework of this approximation, the optimum trajectory $\mathscr{L}^*$ is sought. It consists of two branches ($\mathscr{L}_i^*$ and $\mathscr{L}_{i+i\beta}^*$), each of which corresponds to the boundary conditions ($-t^*/2$, $\boldsymbol{Q}'^*$; $t^*/2$, $\boldsymbol{Q}''^*$) and ($-t^*/2-i\beta/2$, $\boldsymbol{Q}'^*$; $t^*/2 + i\beta/2$, $\boldsymbol{Q}''^*$) respectively. These conditions ensure a stationary value of the exponent in the exponential function. Next the difference between the actions $A_t - A_{t+i\beta}$ together with the product $V_{nn'}(\boldsymbol{Q}')V_{n'n}(\boldsymbol{Q}'')$ is expanded in series in the vicinity of this trajectory up to second-order terms in the deviations $\delta t = t - t^*$, $\delta\boldsymbol{Q}' = \boldsymbol{Q}' - \boldsymbol{Q}'^*$, and $\delta\boldsymbol{Q}'' = \boldsymbol{Q}'' - \boldsymbol{Q}''^*$, after which the integral with respect to δt, $\delta\boldsymbol{Q}'$, and $\delta\boldsymbol{Q}''$ is calculated.

We obtain as a result the following expression for k:

$$k_{nn'}^{\mathrm{OT}} = \Phi_{nn'}^{\mathrm{OT}} \exp(-\Psi_{nn'}^{\mathrm{OT}}) . \tag{16}$$

It can be shown that it satisfies the detailed balance relation. This expression will be used subsequently to elucidate the dependence of the rate constants on the principal parameters of the interaction between the species involved and temperarture.

IV. Models with a reduced dimensionality for VT and VR processes

In modern molecular dynamics calculations, the so-called models with a reduced dimensionality play a major role. The number of degrees of freedom in these models is reduced to a minimum set for which it is possible to reproduce the principal features of the process considered. The success of such models depends on how simply they can be extended to real cases. We shall describe below two such models: colinear collision of a species A with a harmonic oscillator BC (a model of a VT process) and interaction of a harmonic oscillator BC with a species A, perturbing the rotation of a planar rotator BC (a model of a VR process).

1. Model of a VT Process

The model involving the linear collision of a harmonic oscillator with a structureless species for the description of the vibrational and translational energies was examined by Landau and Teller[20] in 1936. Despite the enormous progress in the description of the dynamics of molecular collisions during the last decade by virtue of the use of computers, this model continues to be of interest because its principal predictions concerning the dependence of the probability of the transition on temperature and the interaction parameters remain in force for a wide range of interactions.

Since the Landau–Teller model is very simple, we shall use it to explain the principal ideas of the OT method and to derive two main relations, referred to in the literature as the law of the energy and momentum gaps. Next we shall supplement the Landau–Teller model by the principal correction for anharmonicity, which is important for the consideration of transitions between not unduly low vibrational states.

We shall consider the colinear collision of a diatomic molecule BC, modelled by a harmonic oscillator with a frequency ω, and a structureless species A (A–BC configuration), which interacts with the species B via an exponential repulsion potential $\exp(-\alpha R_{\mathrm{AB}})$. It is assumed that the vibrational amplitude x is small compared with $1/\alpha$, so that the product αx can be regarded as a small parameter of the perturbation theory.

Within the famework of the semiclassical approximation, one considers initially the motion of a classical subsystem (relative motion), which is described by the simple hamiltonian

$$H_{c1} = \frac{P^2}{2\mu} + A\exp(-\alpha R) , \tag{17}$$

where P is the momentum coupled with R, and μ is the reduced mass of the species involved—A and BC. The transitions in the quantum subsystem (vibrations) are induced by a time-dependent perturbation of the type

$$V(x,t) = \lambda\alpha x A \exp[-\alpha R(t)] , \tag{18}$$

where $\lambda = M_{\mathrm{C}}/(M_{\mathrm{C}} + M_{\mathrm{B}})$, M_{C} and M_{B} being the masses of the atoms C and B respectively. The trajectory $R(t)$ can be found from classical equations of motion by using the hamiltonian (17).

We shall consider initially the probability of the transition $n = 1 \to n' = 0$ averaged with respect to the thermal distribution of the collision energies. Knowing the analytical expression for $\langle P_{10}^{\mathrm{SC}}\rangle$ (see, for example, Nikitin[15]), we obtain the principal corrections to the semiclassical approximation within the framework of the OT method. The application of the stationary phase approximation to the integral (10) makes it possible to determine the points R'^*, R''^*, the optimum kinetic energy in the initial vibrational state E_{t1}^*, and the energy difference $E_{t1}^* - E_{t0}^* = \hbar\omega$. Instead of integrating with respect to the coordinates and time, it is possible to integrate with respect to the coordinates and the energy. The latter is equivalent to the calculation of the matrix element by the Landau method[20] with subsequent canonical averaging of the square of the matrix element. Omitting the intermediate steps, we shall only note that we are seeking a stationary value of the function

$$\begin{aligned}\Psi_{10}(R', R'', E_{t1}) = \alpha R' - \frac{\mathrm{i}}{\hbar}\int_{R_1}^{R'} P(R, E_{t1})\mathrm{d}R + \\ + \frac{\mathrm{i}}{\hbar}\int_{R_0}^{R'} P(R, E_{t0})\mathrm{d}R + \alpha R'' - \frac{\mathrm{i}}{\hbar}\int_{R_1}^{R''} P(R, E_{t1})\mathrm{d}R + \\ + \frac{\mathrm{i}}{\hbar}\int_{R_0}^{R''} P(R, E_{t0})\mathrm{d}R + \beta E_{t1} ,\end{aligned} \tag{19}$$

where R_1 and R_0 are the turning points in classical motion for the translational energies E_{t1} and $E_{t0} = E_{t1} + \hbar\omega$, and the momentum of the relative motion is given by the expression

$$P(R, E_t) = \{2\mu[E_t - A\exp(-\alpha R)]\}^{1/2} . \tag{20}$$

The first three terms in Eqn. (19) arise from the exponent of the first quasiclassical matrix element and the next three terms arise from the exponent of the second element (this yields the square of the matrix element), while the last term arises from the Boltzmann exponential function. The stationary conditions assume the form

$$\left.\begin{aligned} R'^* = R''^* &= R^* , \\ P(R^*, E_{t1}^*) - P(R^*, E_{t0}^*) &= \mathrm{i}\alpha\hbar , \\ t(R^*, E_{t1}^*) - t(R^*, E_{t0}^*) &= \mathrm{i}\beta\hbar , \end{aligned}\right\} \tag{21}$$

where $E_{t0}^* = E_{t1}^* + \hbar\omega$, and $t(R, E_{tk})$ is the classical time required for movement from point R_k to point R:

$$t(R, E_{tk}) = \int_{R_k}^{R} \frac{\mathrm{d}R}{v(R, E_{tk})} .$$

The first Eqn. (21) means that the stationary coordinate points coincide and define the 'transition distance' R^*. The second equation defines the change in momentum between the two parts

of the trajectory at the transition point. The third equation defines the difference between the times required to reach the transition point from the turning points. Hence the optimum energies E^*_{t0} and E^*_{t1} and the optimum turning points R^*_1 and R^*_2 are defined. For the case under consideration, R^* is a real quantity, while the momenta and the time are imaginary quantities. Fig. 1 illustrates the positions of these times in the phase space generated by the real variable R and the complex variable P as well as the two parts of the optimum trajectory (non-elastic transition) and the elastic transition trajectories *00* and *11*.

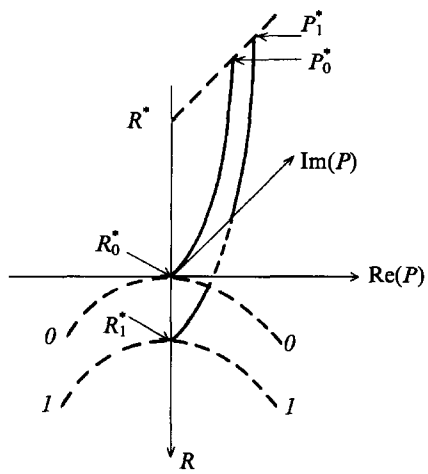

Figure 1. Optimum trajectory for vibrational relaxation in a linear A + BC ($n' = 0$) collision in the 'real coordinate–complex momentum' phase space. R^*_1 and R^*_0 are the turning points for the elastic scattering trajectories in the vibrational states with $n = 1$ and $n = 0$, while R^* is the non-elastic transition point.

In the language of classical trajectories, the vibrational deactivation in process (1) is described as follows. Initially the species approach one another along trajectory *1* from the left and reach the turning point R^*_1; they then 'penetrate' into the classically forbidden region, moving along the complex trajectory $R^*_1 - P^*_1$. At the point P^*_1, there is a sudden change in momentum (from P^*_1 to P^*_0) and the system returns to the turning point R^*_0 at which it 'emerges' from the classical forbidden region. From this point, the particles diverge to the right along the classically allowed trajectory *0*.

The function Ψ^{OT}_{10}, which defines the transition surface, is calculated in terms of R^* and E^*_{t1}, which are found from the second and third Eqns (21) and from the conditions for the conservation of energy, $E_{t0} = E_{t1} + \hbar\omega$:

$$\Psi^{OT}_{10} = \Psi_{10}(R^*, E^*_{t1}). \tag{22}$$

In an explicit form, we have

$$\Psi^{OT}_{10} = \frac{2\pi}{\hbar\alpha}\{[2\mu(E^*_{t1} + \hbar\omega)]^{1/2} - [2\mu E^*_{t1}]^{1/2}\} + \beta E^*_{t1}, \tag{23}$$

where E^*_{t1} is found from the equation

$$\frac{d\Psi^{OT}_{10}(E^*_{t1})}{dE^*_{t1}} = 0. \tag{24}$$

Henceforth we shall be interested in two limits corresponding to high and low temperatures.

In the high-temperature limit, when $\hbar\omega/E^*_{t1} < 1$, the expression for Ψ^{OT}_{10} can be written in the form

$$\Psi^{OT}_{10} \simeq \Psi^{SC}_{10} + \Delta\Psi^{OT}_{10}, \tag{25}$$

where $\Delta\Psi^{OT}_{10} = -\hbar\omega/2kT$ represents a relatively small correction to Ψ^{SC}_{10}:

$$\Psi^{SC}_{10} = 2\frac{\pi\omega}{\alpha v^*} + \beta E^* = 3\left(\frac{\theta^*}{T}\right)^{1/3}, \tag{26}$$

where $v^* = (E^*/2\mu)^{1/2}$ is the optimum relative rate of collision and $\theta^* = \pi^2\mu\omega^2/2\alpha k$ is the characteristic temperature of the model.

In the low temperature limit, when $\hbar\omega/E^* \gg 1$, Eqn. (23) becomes

$$\Psi^{OT}_{10} \simeq \Psi^{(0)}_{10} = \frac{2\pi}{\hbar\alpha}[2\mu\hbar\omega]^{1/2}, \tag{27}$$

where $\Psi^{(0)}_{10}$ denotes Ψ^{OT}_{10} at $T = 0$.

It follows from Eqn. (25) that in the high-temperature limit the exponent for the probability of the transition is proportional to the transferred energy $\hbar\omega$. This relation is called the energy gap law. The high-temperature limit is interesting in connection with vibrational relaxation processes. We may note that the Planck constant does not enter into the expression for Ψ^{SC}_{10}, which makes it possible to attribute the classical significance to this quantity. The correction $\Delta\Psi^{OT}_{10}$ characterises the difference between the quasiclassical and semiclassical descriptions.

In the low-temperature limit, the exponent is proportional to the transferred momentum $(2\mu\hbar\omega)^{1/2}$. This relation is called the momentum gap law. The low-temperature limit is interesting in connection with vibrational predissociation processes.

The application of the Landau–Teller model to predissociation processes requires additional comments. The repulsive potential in the Landau–Teller model cannot of course be used in the literal form for the description of the transition from the bound to the dissociated state. However, it is seen from Eqn. (23) that the probability of the transition between the states of the continuous spectrum is determined mainly by the momentum of the final state subject to the condition that it is appreciably greater than the momentum of the initial state. This factor permits the application of Eqn. (27) also to transitions between the bound state and the state corresponding to the continuous spectrum of the potential with a minimum (subject to the condition that the final energy exceeds appreciably the depth of the potential well: $\hbar\omega \gg \epsilon$). It is also seen that the parameter α in Eqn. (27) should be interpreted as the logarithmic derivative of the potential at the turning point relative to the motion in the final state.

We shall now consider the general case of the transition $n \to n-1$ ($n \geqslant 1$) and at the same time we introduce the most important corrections for the anharmonicity of the vibrations. Clearly the latter arise solely due to the marked dependence of the exponent on the vibration frequency (which in the case of an anharmonic oscillator depends on its energy, i.e. on the number of the level). A linear dependence of the transition frequency ω_n on n is usually employed:

$$\omega_n = \omega(1 - 2x_e n), \tag{28}$$

where x_e is the anharmonicity parameter ($x_e \ll 1$). If the factor $\Phi^{SC}_{nn'}$ is calculated in terms of the harmonic approximation and account is taken of the linear (in terms of n) correction for anharmonicity in the exponent $\Psi^{SC}_{nn'}$, then the overall expression for the probability of the vibrational transition or vibrational predissociation can be written in the form

$$P^{r,d}_{n,n-1} = n\exp(\gamma^{r,d}n)P^{r,d}_{10}, \tag{29}$$

where $P^{r,d}_{10}$ are the probabilities of relaxation and predissociation for the transition $1 \to 0$ and the parameters $\gamma^{r,d}$ have a different significance for vibrational relaxation and vibrational predissociation:

$$\gamma^r = \Psi^{SC}_{10}x_e; \quad \gamma^d = \Psi^{(0)}_{10}x_e.$$

The probability of the $1 \to 0$ transition can be written in its turn as follows:

$$P_{10} = A^{OT}_{10}\exp(-\Psi^{OT}_{10}). \tag{30}$$

Eqns. (29) and (30) make it possible to calculate the probabilities of transitions in the A + BC colinear collision. The task of the theory is now to employ the results obtained in order to calculate the rate constants for three-dimensional collisions and for the interpretation of the dynamics of these processes.

2. Model of a VR process

We shall now proceed to the consideration of a model for VR processes.

Recent studies on the mechanism of the vibrational relaxation on collision between an atom A and a highly asymmetric molecule BC (for example, a hydride molecule) made it possible to formulate a comparatively simple model[22] which is to some extent analogous to the Landau–Teller model. The probability of the loss of a vibrational quantum by the BC molecule not as a result of a single colinear collision with an atom A but during a single period of the rotation BC perturbed by the interaction with an atom A is calculated at the same modelling level. The probability of the transition found in this way is then used to calculate the rate constant for the three-dimensional collision in which the vibrational energy of the molecule BC is converted mainly into its rotational energy.

The semiclassical planar rotator model can be introduced as follows. Initially one considers the motion of the classical subsystem (the rotation of BC), which is described by the hamiltonian

$$H_{cl} = \frac{j^2}{2I} + A\cosh^{-2}\left(\frac{\delta\gamma}{2}\right), \tag{31}$$

where j is the angular momentum of the molecule (for a planar rotator, the variable j is coupled with the angle γ), $I = Mr_e^2$ the moment of inertia of the molecule BC (M is the reduced mass of the molecule BC and r_e its equilibrium internuclear distance). The transitions in the quantum subsystem (vibrations) are induced by a time-dependent perturbation of the type

$$V(x, t) = A\delta x A\cosh^{-2}\left[\frac{\delta\gamma(t)}{2}\right], \tag{32}$$

where the trajectory $\gamma(t)$ is found from the classical equations of motion with the hamiltonian (31).

In contrast to the hamiltonian (17), which describes a comparatively simple form of motion for any relation between the total energy E and the coefficient A (mutual approach of A and BC and their subsequent divergence—elastic one-dimensional scattering of the particle A by the rigid 'rod' BC), the hamiltonian (31) corresponds to a more complex type of motion. Namely, when $E > A$, the rotator BC executes hindered rotation and, when $E < A$, it librates. Accordingly, when $\gamma = 0$, the direction of motion of the rotator either does not change or it is reversed after the attainment of fairly small values of γ.

The semiclassical probability of the transition (again for simplicity one considers the transitions $n = 1 \to n = 0$) is described by the general formula (30), in which the exponent and the pre-exponential factor are expressed in terms of the parameters of the model and temperature. The principal corrections to the semiclassical probability of the transition are obtained by using the optimum trajectory method.

Somewhat more complex steps, but in principle analogous to those presented above, lead to the following expression for Ψ_{10}^{OT}:

$$\Psi_{10}^{OT} = \frac{2\pi r_e}{\hbar\delta}\left\{[2M(E_{r1}^* + \hbar\omega)]^{1/2} - [2ME_{r1}^*]^{1/2}\right\} + \beta E_{r1}^*, \tag{33}$$

where the optimum rotational energy E_{r1}^* is found from the equation

$$\frac{d\Psi_{10}^{OT}(E_{r1}^*)}{dE_{r1}^*} = 0. \tag{34}$$

In the case of VR processes, there exist, as in the case of VT processes, two simple limits in Eqn. (33)—at high and low temperatures. We shall not quote them, since they are fully analogous to Eqns. (26) and (27).

We may note two features of the model of VR processes under consideration.

One of them consists in the fact that Eqn. (33) retains the same form regardless of whether it describes the optimum libration trajectory or hindered rotation. This is extremely important because in the three-dimensional generalisation of the model the sharp difference between the two types of trajectory vanishes as a result of the influence of the centrifugal potential.

Another feature of the model of VR processes consists in the fact that the pre-exponential factor in the expression for the probability of the transition oscillates as a function of the rotational energy. This factor, which also exists for more complex models, hinders the averaging of the probability found in numerical calculations.[13] The oscillatory nature of the transition probability is related to the interference of two tunnel amplitudes: one associated with the initial branch of the optimum trajectory (from the turning point to the transition point) and the other associated with the final OT branch (from the transition point to the other turning point). Oscillations of this kind are absent from the Landau–Teller model, since the phase difference between the two transition amplitudes is extremely small in this model. The oscillations in the transition probability vanish after averaging with respect to energy. Such averaging can be achieved most simply within the famework of the OT method.

V. Energy exchange in three-dimensional collisions

Despite the wide-scale use of virtually exact computer calculations in the dynamics of molecular collisions, including the dynamics of the intermolecular energy exchange, the results obtained hitherto are of limited interest, since each refers to a definite potential energy surface selected on the basis of particular considerations. The use of approximate methods, which make it possible to follow comparatively simply the relation between the final result (the rate constant) and the initial parameters of the problem (the potential energy surface), is therefore of undoubted interest. In this section, we shall consider various approximate methods used in the vibrational relaxation and vibrational predissociation theory. The main task is to determine the relative contributions of the A–BC translational motion (taking into account the radial and relative rotational motions) and of the rotation of BC to the interaction inducing the vibrational transition. Significant progress in this respect has been achieved with the use of the OT method.

As mentioned above, the optimum trajectory is a multidimensional classical trajectory, which begins at the turning point of the relative motion in the initial vibrational state of the molecule and then extends over an imaginary time interval into the classically forbidden region of the potential, reaches the transition point, and, undergoing a discontinuity at this point, returns to the turning point in the final vibrational state of the molecule. The potential energy surface in the classically forbidden region is then constructed as an analytical prolongation of the surface from the classically allowed region. In the case considered this surface depends solely on two coordinates—the distance R between the atom A and the centre of gravity of BC and the angle γ between the axis of the molecule AC and the vector $\boldsymbol{R}$.

We shall consider initially VT processes. The main idea of the OT method in relation to VT energy transfer processes dates back to Takayanagy's 'modified quantum number method'[24] formulated for an isotropic potential. If the length $\mathscr{L}$ of the optimum trajectory (i.e. the distance between the turning points and the transition points) is small compared with the radius of curvature $\mathscr{R}$ of the equipotential line on the potential energy surface at the turning point, then one can carry out a local separation of the variables of motion in order to simplify the description of the collision dynamics. This approximation gives

rise to a one-dimensional 'reaction coordinate' directed at right angles to the constant energy surface; the remaining coordinates behave merely as 'observers'.

Thus the use of one-dimensional models for the description of the dynamics of three-dimensional collisions becomes possible. In particular, the Landau–Teller model is of this kind; its extension to three dimensions within the framework of the method indicated can be called the breathing shells model (the BSH model[15]). This model constitutes in its turn a generalisation of more approximate models: models based on the so called approximation of sudden perturbations relative to rotational transitions (the IOSA method[17]) and the breathing spheres model [the BSP model or the SSH model (after Schwartz, Slawski, and Herzfeld who first formulated it)]. In the last two models, the angle γ is assumed to be the 'observer' and the reaction coordinate is identified with the distance R. The BSH model identifies the reaction coordinate with a linear combination of R and γ. In order to apply the one-dimensional Landau–Teller model to the calculation of the rate constant for a three-dimensional collision, we specify a point with the coordinates R^* and γ^*, which is located on the potential energy surface:

$$U(R^*,\gamma^*) = E^*, \tag{35}$$

where E^* is the optimum energy. The probability of the Landau–Teller transition for the OT which begins at a turning point R^*, γ^*, assumes the form

$$\langle P^* \rangle = A(R^*,\gamma^*)\exp(-\Psi^*), \tag{36}$$

where the multiplier A and the exponent depend on R^* and γ^*. In particular

$$\Psi^* = 3\left(\frac{\theta^*}{T}\right)^{1/3}, \tag{37}$$

where $\theta^* = \omega^2\mu^*/2(\alpha^*)^2k$ is the characteristic temperature of the model. In conformity with the BSH model,

$$\alpha^{\mathrm{BSH}} = \frac{|\mathrm{grad}\,U(R^*,\gamma^*)|}{U(R^*,\gamma^*)},$$

$$\mu^{\mathrm{BSH}} = \mu\left\{1 + \frac{(\mu/M)(R^*)^2(\mathrm{d}R^*/\mathrm{d}\gamma^*)^2}{[(R^*)^2 + (\mathrm{d}R^*/\mathrm{d}\gamma^*)^2]r_e^2}\right\}^{-1} \tag{38}$$

where r_e is the equilibrium internuclear distance in the diatomic molecule BC. The energy E^* is related to Ψ^* by the expression

$$E^* = \frac{\Psi^*}{3}kT, \tag{39}$$

whence follows the condition defining implicitly the optimum surface of the turning points $R^* = R^*(\gamma^*)$.

We now rewrite Eqn. (36) as follows:

$$P^{\mathrm{BSH}}(\gamma^*) = A^{\mathrm{BSH}}(\gamma^*)\exp[-\Psi^{\mathrm{BSH}}(\gamma^*)]. \tag{40}$$

The rate constant k^{BSH} is expressed in terms of $\langle P(\gamma^*)\rangle$ as the probability flux through the optimum surface of turning points:

$$k^{\mathrm{BSH}} = 2\pi\int_0^{\pi}\left(\frac{kT}{2\pi\mu^*}\right)^{1/2}(R^*)^2A^{\mathrm{BSH}}(\gamma^*)\times$$
$$\times\exp[-\Psi^{\mathrm{BSH}}(\gamma^*)]\sin\gamma^*\mathrm{d}\gamma^*. \tag{41}$$

It follows from the analysis[25] of the models mentioned above (BSH, IOSA, BSP) that only the first takes into account the dynamic contribution of the rotation of the BC model to the vibrational relaxation or predissociation process, because in terms of the IOSA and BSP approximations the angle γ is assumed to be constant throughout the period of the collision. The change in the angle γ during the motion of the system along the optimum trajectory does actually imply that the rotation participates dynamically in the energy exchange process between the vibrations and other degrees of freedom. It can be shown intuitively that for an interaction with a low anisotropy (for example, the collision of a homonuclear molecule with an atom), the dynamic contribution of the rotation is small. This is true in the sense that allowance for the rotation alters comparatively little (in relative terms) the exponent in Eqn. (16). However, even a small relative change in Ψ can alter appreciably the rate constant. In this sense, a small anisotropy can alter greatly the rate constant and the dependence of the latter on the principal parameters of the given problem is then the same as for the breathing spheres model or the collinear model. It is found that the contribution of the rotation is determined by the parameter Q, given by

$$Q = \frac{\mu(\Delta R)^2}{Mr_e^2}, \tag{42}$$

where ΔR is the difference between the distances separating the turning points for the collinear and T-shaped configurations and M is the reduced mass of the molecule BC. This parameter enters into the exponent as a relative correction and hence the correction to the rate constant for rotation may be significant even when the parameter Q is very small. We may note that the parameter Q was introduced previously as a characteristic of the efficiency of the purely rotational excitation of molecules on collision with atoms.[26]

Thus the following type of temperature variation may be expected for the vibrational relaxation of homonuclear molecules at fairly high temperatures:

$$k_{10} = B\exp\left[-3\left(\frac{\theta^+}{T}\right)^{1/3}\right], \tag{43}$$

where θ^+ denotes the minimum of all the possible values of θ^* (the corresponding OT and its vicinity make the main contribution to k_{10}). The temperature variation of type (43) is known in the literature as the Landau–Teller law.

For further estimates, we resort to a simple formula for $(\theta^+/T)^{1/3}$:

$$\left(\frac{\theta^+}{T}\right)^{1/3} = 8.1\left[\frac{\omega/\mathrm{cm}^{-1}}{2000}\right]^{2/3}\left[\frac{\alpha/\text{Å}^{-1}}{4}\right]^{-2/3}\times$$
$$\times\left[\frac{\mu/\mathrm{a.e.}}{10}\right]^{1/3}\left[\frac{T/\mathrm{K}}{1000}\right]^{-1/3}. \tag{44}$$

For typical values of ω, μ, and T (ω = 2000 cm^{-1}, μ = 20 a.u., and T = 1000 K) and the values of α in the expected range 3.5 Å^{-1} < α < 4.1 Å^{-1}, the parameter $(\theta^+/T)^{1/3}$ is of the order of 10. As a result, Ψ_{10}^{SC} is in the vicinity of 30, which explains the very low probability of vibrational relaxation in a single collision.

We shall now proceed to the consideration of VR processes. When the planar hindered rotator (HR) model is extended to the three-dimensional case, we shall assume that the angle γ is the reaction coordinate and R is the 'observer'. The parameters A and δ in the hamiltonian (31) are functions of R and the probability of the transition in the model case is averaged with respect to R. In such averaging, account must naturally be taken of the contribution of the isotropic interaction $U_0(R)$.

The general expression for the vibrational relaxation rate constant is

$$k_{10} = \left(\frac{8kT}{\pi I}\right)^{1/2}\pi s\int R^2\,\mathrm{d}R\,P_{01}^{\mathrm{HR}}(T,R)\exp[-\beta U_0(R)], \tag{45}$$

where s is the steric factor arising on passing from the planar rotation model to real three-dimensional rotation (s < 1).[27] The temperature variation of the rate constant defined by Eqn. (45) is described by Eqn. (43), in which θ^+ can be calculated by Eqn. (44), having replaced the reduced mass of the colliding pair by the reduced mass of the molecule and the radial potential gradient by the angular gradient:

$$\alpha \to \frac{\delta}{r_e}, \qquad \mu \to M. \tag{46}$$

The parameter δ, characterising the degree of anisotropy of the potential, varies in the range from 3 to 4 for hydrogen halide molecules.[6]

We may note in conclusion that the VT or VR type of any vibrational relaxation process is determined by the parameter Q: in the former case $Q \ll 1$ and in the latter $Q > 1$. In principle, there is a possibility of a situation where $Q \simeq 1$, i.e. when the relative A–BC motion and the rotation of BC are equally important in inducing the vibrational transition, but in systems of practical interest this is usually not encountered.

VI. Examples of vibrational relaxation and vibrational predissociation

Experimental study of vibrational relaxation under thermal conditions usually makes it possible to obtain information about the kinetics of the population of the lowest vibrational levels, from which it is comparatively difficult to extract the dependence of the relaxation rate constant on the number of the vibrational level. The corresponding data can therefore be used mainly for the elucidation of the dependence of the constants k_{10} on the dynamic and kinematic parameters of the partner species and also on temperature. We present below three examples illustrating the negligibly small, appreciable, and dominant contributions of the rotation of a diatomic molecule to the dynamics of vibrational relaxation.

1. Small contribution of rotation (VT process)

The breathing shells model and even its simplest limiting case—the breathing spheres model—describe comparatively well the experimental results of measurements of the rates of vibrational relaxation of homonuclear diatomic molecules in the heat reservoir of inert gas atoms (see, for example, a recent review[5]). As an example, we shall consider the vibrational relaxation of nitrogen in helium:

$$N_2(n=1, \text{thermal } j) + He \rightarrow N_2(n'=0, \text{all } j') + He. \quad (47)$$

In terms of the combination of masses, this system belongs to the light atom–heavy molecule type of system. For a system of this kind, the average collision time is short compared with the average period of the rotation of the molecule ($\mu/M \simeq 1/2$ and the parameter Q is very small). Fig. 2 illustrates the existing experimental data on the high-temperature and low-temperature vibrational relaxation of N_2 on He[28–30] and also the theoretical temperature dependence of the rate constant. The parameter α was chosen to be 3.8 $Å^{-1}$ in conformity with a non-empirical estimate.[31] The theoretical curve in Fig. 2 corresponds to the expression

$$k_{10}(T) = 1.6 \times 10^{-7}\left[\frac{T/K}{1000}\right]^{1/3} \times \exp\left\{-19.6\left[\frac{1000}{T/K}\right]^{1/3} + \frac{1680}{T/K}\right\} \text{cm}^3\,\text{s}^{-1}. \quad (48)$$

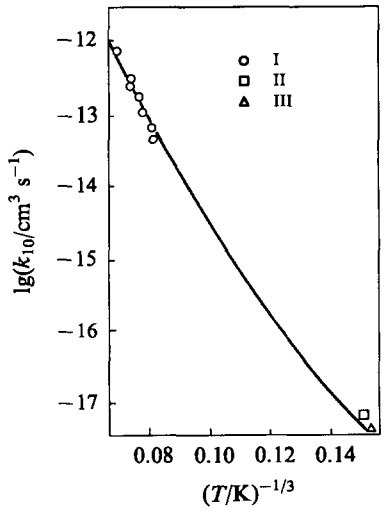

Figure 2. Temperature dependence of the rate constant for the vibrational deactivation of nitrogen by helium. Points I–III represent experimental data obtained in a number of studies.[28–30] Continuous line—results of calculation by Eqn. (48).

We may note the following interesting features of the temperature variation:

(a) The linear high-temperature part of the curve illustrates the Landau–Teller temperature variation [Eqn. (43)], which, as follows from the considerations presented above, permits a semiclassical interpretation.

(b) The low-temperature part of the curve resembles the Arrhenius plot for a chemical reaction rate constant which has been bent by tunnel effects. In this case the above analogy between the two processes is apt, since the curvature of the plot is due to quantum corrections to the semiclassical relation.

(c) The semiclassical approximation with the first quasi-classical correction can describe the variation of the relaxation rate constant over a range of more than six orders of magnitude, the lower limit of the range corresponding to temperatures which are much smaller than the characteristic vibrational temperature of N_2 ($\hbar\omega/k$ = 3360 K). The complete quantum description of the energy transfer process must be used below room temperature.

2. Appreciable contribution of rotation (VT process)

We shall now turn to another example—the vibrational deactivation of H_2 on collision with He. This system belongs to the class of light molecule–heavy atom systems and one may therefore expect an appreciable contribution of the rotation of the molecule to the rate of vibrational relaxation [we have the ratio $\mu/M \simeq 3$ and in this case the parameter Q is appreciably greater than for process (41) but is still less than unity]. However, experimental data for the vibrational relaxation of H_2 on He can be reasonably described within the framework of the IOSA model and even in terms of a rougher approximation—within the framework of the breathing spheres model.[5] The reason for this apparent contradiction is simple. For not unduly anisotropic potentials, a slight variation of the parameter α within the limits of its 'allowed' range of variation makes it possible to reconcile the simple model with experimental data without observing any defects of the model under these conditions. In order to observe the contribution of rotation, it is necessary to carry out a more detailed analysis of the dynamics. Such a problem has been solved and it has been shown[32–34] that an appreciable part of the energy evolved on vibrational deactivation is converted into the rotational energy of the hydrogen molecule. As an illustration of the importance of the rotational transitions accompanying the evolution of vibrational energy, we shall consider the deactivation process not under thermal conditions (equilibrium distribution with respect to translational and rotational energies) but under conditions where the initial energies of all the degrees of freedom are specified:

$$H_2(n = 1, j = 0) + He \rightarrow H_2(n' = 0, \text{all } j') + He. \quad (49)$$

The cross-section of this process is illustrated[35] in Fig. 3 as a function of the collision energy. It is seen from the figure that, when the dynamic contribution of rotation is ignored (the IOSA approximation or the breathing spheres model), then the cross-section is found to be smaller by an order of magnitude than the values obtained in the exact calculation. Analysis of the wave function for relative motion shows[29] that this difference between the cross-sections is induced by very small differences in the interaction potentials corresponding to different rotational states

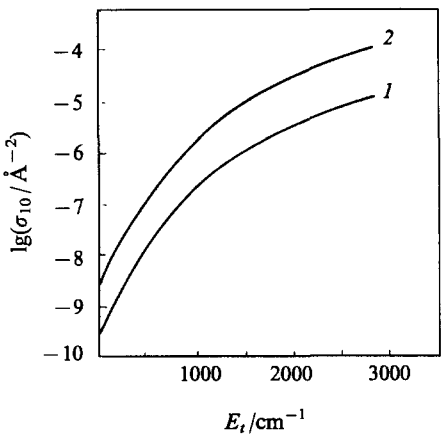

Figure 3. Dependence of the cross-section for the vibrational relaxation of hydrogen by helium on the collision energy:[35] (*1*) theoretical calculation without taking into account the dynamic contribution of the rotation of H_2 to the probability of the transition; (*2*) theoretical calculation taking into account the dynamic contribution of the rotation of H_2.

of H_2. Such a great sensitivity of the cross-section (or rate constant) to small variations in the potential is typical for tunnel processes in general and for dynamic modelling processes in particular.

3. A dominant contribution of rotation (VR process)

The process

$$\text{HF}(n = 1, \text{thermal } j) + \text{Ar} \rightarrow \text{HF}(n' = 0, \text{all } j') + \text{Ar} \quad (50)$$

may serve as an example of vibrational deactivation induced by the rotation of the relaxing molecule.

Experimental data[36–38] together with the theoretical relation,[6] obtained by fitting the hindered rotator model to various potential energy surfaces,[39,40] are presented in Fig. 4. In connection with this figure, we may note two factors. First, any attempt to interpret the experimental data within the framework of the BSP, IOSA, or BSH models would give rise to a discrepancy between the theory and experiment of several orders of magnitude. Second, the use for this system of various potential surfaces described hitherto in the literature leads to a greater scatter of the predicted rate constants compared with the error which is introduced when the planar rotator model potential is fitted to any surface. This illustrates yet again the fact that with the existing uncertainty in the calculations of intermolecular interactions accurate dynamic calculations provide comparatively little information.

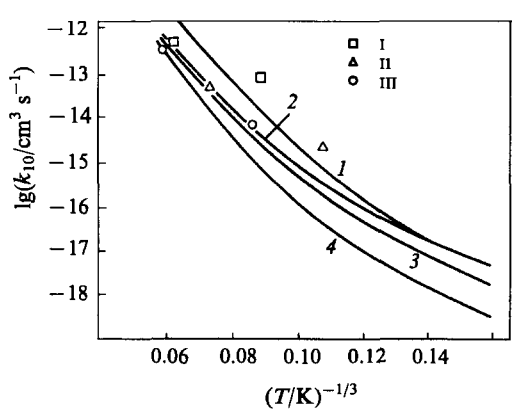

Figure 4. Temperature dependence of the rate constant for the vibrational relaxation of HF by collision with Ar: (I)–(III) experimental data obtained in Refs. 36–38 respectively; (*1*)–(*4*) theoretical calculations with the planar rotator model potential parameters determined for potential energy surfaces calculated in Refs. 39–41.

We shall now proceed to vibrational predissociation processes. In contrast to thermal vibrational relaxation, the study of vibrational predissociation makes it possible to test the dependence of the rate of predissociation on the number of the vibrational level n predicted by the theory, since laser excitation methods make it possible to synthesise the van der Waals complexes BC(n)...A with a wide range of values of n. In this respect, the predissociation of iodine–inert gas complexes, in particular the complex with neon, has been investigated in greatest detail:[42]

$$I_2^*(n)...\text{Ne} \rightarrow I_2^*(n-1) + \text{Ne}\,. \quad (51)$$

Fig. 5 presents the experimental results of the measurement of the rate of vibrational predissociation, which demonstrate a clearly non-linear dependence of the rate on n. This dependence can be fitted very satisfactorily by a function of type (29) and the gradient of the repulsive potentials $\alpha = 4.90\ \text{Å}^{-1}$ can be obtained from the parameters [we may note that this value is twice as high as the value of α quoted by Willberg et al.[42] because the repulsive branch of the Morse potential used in their study is described by the function $\exp(-2\alpha R)$]. The parameter α obtained in this way is only slightly outside the limits of the "expected" range (see above), which is associated simply with the errors of the model that uses a purely repulsive potential for the description of the transition from the bound to the dissociated state.

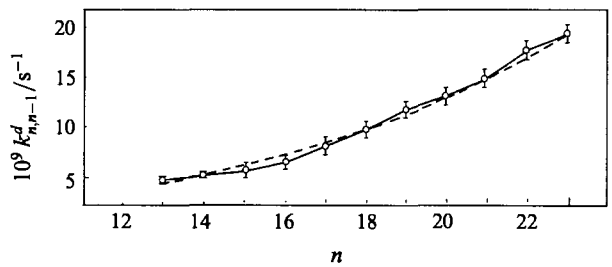

Figure 5. Dependence of the rate constant for the vibrational predissociation of the iodine–neon complex on the vibrational quantum number of the iodine molecule. The continuous curve connects the experimental points,[42] while the dashed curve represents the theoretical relation described by Eqn. (29).

VII. Conclusion

Dynamic tunnelling is a process which is forbidden in classical terms not because the initial and final states are separated by a high potential barrier but because the transition between these states is impossible by virtue of the adiabatic Ehrenfest principle. In the quantum formulation, this principle is expressed in the form of the claim that the probability of the transition betweeen the corresponding states is exponentially small. In many instances, and this applies particularly to vibrational relaxation and predissociation processes, this low probability can be associated with a non-adiabatic transition between two non-intersecting potential energy surfaces. Within the framework of the OT method, such a transition is described as the motion of the system along two trajectories and transition from one to the other takes place in the classically forbidden region of the potential. These trajectories are 'classical' in the sense that they are described by classical equations of motion; at the same time they are not classical in the literal sense because they characterise the motion of the system during an imaginary time. The latter is not a specific feature of dynamic tunnelling, since tunnelling

through a potential barrier can also be described as 'classical' motion in an imaginary time.

The method of optimum trajectories for the calculation of the vibrational relaxation rate constant examined above can be represented as an analogue of the transition state method in relation to the calculation of chemical reaction rate constants. Both methods are based on the same idea: instead of the traditional approach, based on the successive calculation of the probability of the process, its cross-section, and finally its rate constant, in this instance one calculates the average probability flux through the optimum critical surface. In this way, it is possible to avoid the search for the part of the information about the process dynamics which is always contained in the probability and the cross-section but which is lost on averaging with respect to the canonical ensemble in the stage involving the calculation of the rate constant. From this standpoint, the OT method can be regarded as a 'non-reaction' analogue of the so-called theory of reduced dimensionality for the calculation of the rates of 'reaction' events. The latter approach proved extremely fruitful in the theory of chemical reactions.[43-45]

Just as the transition state method makes it possible to calculate the pre-exponential factor for the reaction rate constant in the form proposed by Arrhenius, the optimum trajectories method permits the calculation of pre-exponential factor for the relaxation rate constant in the form proposed by Landau and Teller. At the same time, it is clear that the method of optimum trajectories can be criticised to the same extent as the transition state method: the fundamental question under what conditions the canonical distribution with respect to the degrees of freedom of species before collision can be 'transferred' to the critical surface, which is in the region of their interaction, cannot be regarded as fully solved at the present time.

III.	Thermodynamics of plane-parallel thin liquid films	16
IV.	Conclusion	21

Abstract. Studies on the thermodynamics of plane-parallel thin liquid films (emulsion and foam films) are surveyed. Various approaches to the thermodynamics of planar non-interacting interfaces in thick liquid films (Gibbs dividing surface method, Rusanov's method based on a layer with a finite thickness, Hansen's method) as well as the thermodynamics of plane-parallel thin liquid films based on different models [membrane of zero thickness, membrane of finite thickness, two interacting dividing (as defined by Gibbs) surfaces] are examined. The bibliography includes 56 references.

I. Introduction

The interaction between the particles of a disperse phase in emulsions and foams takes place through thin layers—microscopic liquid films (MLF) of the dispersion medium. This interaction determines the stability and the structural-mechanical properties of disperse systems.

Despite the strikingly non-equilibrium character of processes involved in the formation and breakdown of MLF under real emulsification and foam-formation conditions, equilibrium thermodynamics can serve as a first approximation in the description of the properties of such films, which is more accurate the lower the rate of change of the external perturbing influences compared with the rates of internal relaxation processes (hydrodynamic and adsorption processes, surfactant reconformation processes on interfaces, etc.) in such films. The effects associated with the non-equilibrium nature of the physicochemical processes can be described under such conditions as excess effects compared with standard effects in equilibrium thermodynamics. This guarantees that they are unambiguous.

The difficulty of the thermodynamic description of MLF consists in the lack of a generally recognised definition of the concept of interfacial interaction in the so-called transition region in the film. The forces of the interaction between the surfaces of the film in the transition region vary in magnitude and sign (Figs. 1*a* and 1*b*), vanishing on emerging from the film into the bulk phase α of the Plato region of the film meniscus, where the wedging pressure is zero (Fig. 1*c*). No problems arise in describing the interaction with the central part of the plane-parallel film because thermodynamic methods for plane-parallel liquid films have been developed.[1–10] But the thermodynamics of the transition region of the film have as yet been inadequately developed. In particular, there is no generally recognised way of determining and describing the disjoining pressure in the transition region of the film, which leads to ambiguous and inconsistent estimates of the interaction energy in this region of the film.

If the area corresponding to the transition region of the film constitutes a small fraction of the plane-parallel region, then one can neglect the contribution by the energy of the interaction of the transition region to the overall interaction energy in such a film. However, with decrease in the size of the MLF, the contribution to the interaction energy in the transition region is appreciable and cannot be disregarded. In the latter case, the thermodynamic description of the interaction in the MLF is based on idealised models. For example, the real film, having a complex profile in the transition region, is replaced by a plane-parallel film with a thickness H_f and a radius r_f and two lateral surfaces having a constant average curvature and a constant interfacial tension. The excess amounts of the thermodynamic quantities are then referred to the contact (dividing according to Gibbs[11]) line separating the plane-parallel region of the film from the bulk phase α. For example, the concept of the linear tension, which represents the excess free energy of the film referred to a unit length of the contact line, has thus arisen.[12–14]

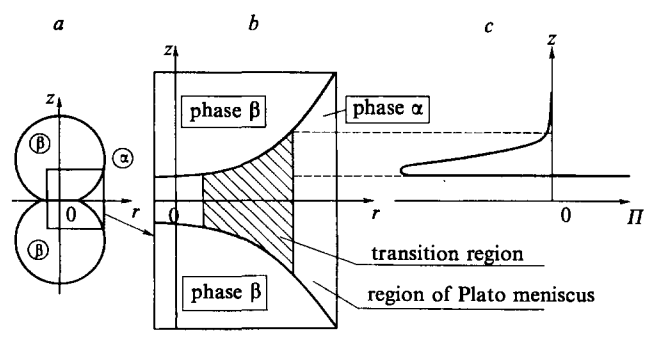

Figure 1. Thermodynamics of liquid films (see text): (*a*) a symmetrical microscopic liquid (emulsion or foam) film arises between two identical flowing (liquid or gaseous) particles of a phase β in a liquid phase α; (*b*) in a symmetrical liquid film one can distinguish a central plane-parallel region, the transition region, and the region of the bulk-phase meniscus of the phase α; (*c*) the disjoining pressure $\Pi(H)$ isotherm in the transition region ($H = 2z$ is the local thickness of the film in the transition region).

represents the excess free energy of the film referred to a unit length of the contact line, has thus arisen.[12-14]

At the same time, it is evident that the use of idealised (reference according to Gibbs[11]) thermodynamic models, which is undoubtedly convenient in a formal thermodynamic description of thin liquid films, does not solve the problem of calculating the excess quantities arising under these conditions (for example, the linear tension) in the films. It is therefore necessary to devise the thermodynamics of the transition region of thin liquid films. Such thermodynamics can be defined as a self-consistent and closed system of concepts and relations between parameters characterising the interfacial interaction in the transition region of the film (for example, the disjoining pressure) and other thermodynamic parameters and functions.[13-15] The thermodynamics of the transition region of the film reduces to the thermodynamics of plane-parallel films and the thermodynamics of free interfaces in the appropriate regions where determinations are carried out.[16]

Problems of the thermodynamics of plane-parallel liquid films, which constitute the basis for the construction of the thermodynamics of the transition region of the liquid films,[13,16,17] are discussed in this review.

II. Thermodynamics of planar free interfaces

We shall consider briefly the principal definitions and postulates of the thermodynamics of planar free interfaces, which in fact constitute the thermodynamics of thick plane-parallel liquid films where the interfaces bounding them do not interact by definition. The thermodynamics of such surfaces, developed by Gibbs,[11] has been described in detail in a number of publications.[8,18-23]

1. Description of the thermodynamic system

We shall consider, with reference to Fig. 2, a multicomponent two-phase thermodynamic system with a volume V containing two liquid phases, α and β (or a liquid phase β and a gaseous phase α) and a planar interface dividing them, whose area $A = Ll$, where L is the length and l the width. Under equilibrium conditions, the temperature T as well as the chemical potentials μ_i of the ith components ($i = 1, 2, ..., N$; N is the number of components) are equal in all parts of the system under consideration. We shall neglect the effect of the force of gravity, i.e. we shall assume that the hydrostatic pressures P_α and P_β in the macroscopic phases α and β are the same and equal to P.

We shall postulate that the right-hand wall of the cell is mobile and that it is acted upon by an external force f_e, which balances the forces of the interfacial tension σ_0 of the planar surface. If necessary, the chemical potentials μ_i of the ith components can be varied or kept constant with the aid of a material source v_i.

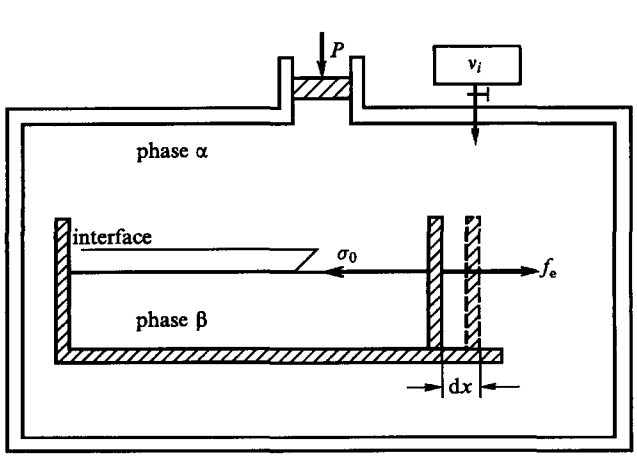

Figure 2. Thermodynamic system containing a flowing (liquid or gaseous) phase β, a liquid phase α, and the interface.

2. Hydrostatic description of the interface

Within the framework of local thermodynamics (which is also known as quasi-thermodynamics or microscopic thermodynamics[21]), one uses a hydrostatic description of the interface, in which the latter is represented as an anisotropic continuous medium in each microscopic volume for which the principal thermodynamic relations hold.[15,19,21-27]

Despite the artificiality of the concept of the interface as a continuous medium with a thickness of ~ 1 nm, such representation is internally consistent, i.e. it constitutes a non-contradictory system of concepts and equations and, furthermore, is extremely clear. In order to formulate the thermodynamic equations, it is necessary to define the concept of the hydrostatic pressure in the medium.

The components of the intermolecular interaction due to the thermal motion of the molecules, short-range forces (Born repulsion, hydrogen bonds), and long-range forces (van der Waals attraction, electrostatic interaction between the electrical double layers) are usually included in the pressure tensor.[28,29] The mechanical equilibrium in the mixture is then fully determined by this generalised hydrostatic pressure tensor and external (for example, gravitational) forces. Sometimes only the short-range intermolecular forces and thermal motion are included in the pressure tensor, with the assumption that the long-range forces are external with respect to the volume elements of the medium.[30-32]

The condition for mechanical equilibrium in the medium is formulated as follows within the framework of local thermodynamics:[8,19,21,22,27,33]

$$\operatorname{div} \boldsymbol{P} = 0, \tag{1}$$

where $\boldsymbol{P}$ is the generalised hydrostatic pressure tensor. In an isotropic medium, the tangential components of the pressure tensor are zero. The normal components of the tensor are equal to one another (Fig. 3*a*):

$$P_{xx} = P_{yy} = P_{zz} = P.$$

In a continuous anisotropic medium, with the aid of which the transition region of the interface is modelled, the tangential components of the pressure tensor are also zero, and the normal components are

$$P_{zz} = P_N(z), \quad P_{xx} = P_{yy} = P_T(z).$$

The qualitative dependence of the components of the pressure tensor $P_N(z)$ and $P_T(z)$ on the coordinate z in the case of a planar interface is presented in Figs. 3*b* and 3*c*. In the region of the bulk phases α and β, these components are equal: $P_N = P_T = P$. In the transition layer with a thickness δ, the component P_N does not change and remains equal to P, while $P_T(z)$ becomes negative and greatly exceeds the compressive pressure P in absolute magnitude. We may note that, in the case of a curved interface, the component

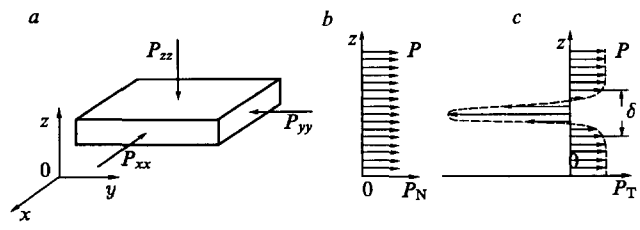

Figure 3. Description of the interface in terms of local thermodynamics: (*a*) different components of the hydrostatic pressure tensor in a system containing an interface; (*b*) and (*c*) dependence of the components P_N and P_T of the hydrostatic pressure tensor on the coordinate z.

P_N does vary in the transition layer with a thickness δ but remains positive (i.e. the pressure P_N remains compressive).

3. Fundamental equation of a system containing a planar free interface

When the mobile lateral wall of the cell (see Fig. 2) moves by dx, the area of the interface increases by $dA = l\,dx$, and the external force f_e executes an amount of work

$$dW_\sigma = \sigma_0\,dA. \tag{2}$$

The volume of the system V may then change by dV and the work performed by forces external to the system is

$$dW_P = -P\,dV. \tag{3}$$

Furthermore, as a result of adsorption on the newly formed surface, the number of moles N_i of the ith components changes by dN_i and the amount of work then performed is

$$dW_\mu = \sum_i \mu_i\,dN_i. \tag{4}$$

Thus the Helmholtz free energy of the system changes by

$$dF = -S\,dT + \sum_i \mu_i\,dN_i - P\,dV + \sigma_0\,dA, \tag{5}$$

where S is the entropy of the system. Eqn. (5) is called the fundamental equation of a system containing a planar free interface.

In the study of the mechanical equilibrium in the energy properties of liquid films, it is convenient to operate with the intensive variables T and μ_i instead of T and N_i. Instead of the Helmholtz free energy F, one therefore uses the grand thermodynamic potential

$$\Omega = F - \sum_i \mu_i N_i,$$

whose differentiation and combination of the resulting expression with Eqn. (5) yields the fundamental equation of the system under consideration in the form

$$d\Omega = -S\,dT - \sum_i N_i\,d\mu_i - P\,dV + \sigma_0\,dA. \tag{6}$$

The following definitions of the interfacial tension σ_0 for a planar free interface follow from Eqns. (5) and (6):

$$\sigma_0 = \left.\frac{\partial F}{\partial A}\right|_{T,V,N_i} = \left.\frac{\partial \Omega}{\partial A}\right|_{T,V,\mu_i}. \tag{7}$$

4. Thermodynamic description of the interface

The interface is described on the basis of different thermodynamic models. The Gibbs method of excess quantities, based on the modelling of the interface by the so-called dividing surface, i.e. an imaginary surface which has a zero thickness but is characterised by a finite surface energy, entropy, mass, etc. has come to be most widely used. This method is convenient also for thin liquid films.

The method based on a layer with a finite thickness, developed by Rusanov[18, 19] and Hansen,[34] and subsequently developed in the studies of Motomura,[35] Markin, Volkov,[36] and others, is convenient for the description of the physicochemical properties of adsorbed surfactant layers. On the other hand, this method is not used for interacting interfaces in thin liquid films.

Brief characteristics of these methods are given below from the standpoint of their possible extension to thin liquid films.

a. The dividing surface method

In this method, a real system with a volume V, containing an interface with a thickness δ (Fig. 4*a*), is replaced by an idealised model consisting of two reference phases α and β separated by a dividing surface of zero thickness and we have

$$V = V_\alpha + V_\beta, \tag{8}$$

where $V_\alpha = Al_\alpha$ and $V_\beta = Al_\beta$ are the volumes of the reference phases. The extensive parameters, the local densities of which change sharply in the transition region, are represented by the sum of the bulk-phase components and surface excess amounts:

$$S = S_\alpha + S_\beta + S_s, \tag{9}$$

$$N_i = N_{i\alpha} + N_{i\beta} + N_{is}, \tag{10}$$

$$\Omega = \Omega_\alpha + \Omega_\beta + \Omega_s, \tag{11}$$

where S_α and S_β, $N_{i\alpha}$ and $N_{i\beta}$, and Ω_α and Ω_β are respectively the bulk-phase entropies, numbers of moles of the ith components, and grand thermodynamic potentials of the reference phases α and β, while S_s, N_{is}, and Ω_s are the excess values of these quantities for the reference phases referred to the dividing surface.

Fundamental equation for a planar free dividing surface. Having substituted Eqns. (8)–(11) in the fundamental equation for system (6), we obtain

$$d\Omega = d\Omega_\alpha + d\Omega_\beta + d\Omega_s, \tag{12}$$

where

$$d\Omega_\alpha = -S_\alpha\,dT - \sum_i N_{i\alpha}\,d\mu_i - P\,dV_\alpha, \tag{13}$$

$$d\Omega_\beta = -S_\beta\,dT - \sum_i N_{i\beta}\,d\mu_i - P\,dV_\beta, \tag{14}$$

$$d\Omega_s = -S_s\,dT - \sum_i N_{is}\,d\mu_i + \sigma_0\,dA. \tag{15}$$

Eqns. (13)–(15) are fundamental for the reference phases α and β and the planar dividing surface respectively. The Gibbs method of excess quantities described here makes it possible to extract from the fundamental equation for a system containing a planar interface the so-called surface component, i.e. Eqn. (15), which describes the thermodynamic properties of the dividing surface. However, one should bear in mind that the excess amounts S_s and N_{is} depend on the location of the dividing surface. The method of establishing this location must be specially stipulated for an unambiguous thermodynamic description of the dividing surface. On the other hand, for constant T and μ_i, the interfacial tension σ_0, defined by the relation

$$\sigma_0 = \left.\frac{\partial \Omega_s}{\partial A}\right|_{T,\mu_i}, \tag{16}$$

is independent of the location of the interface, like the excess grand thermodynamic potential Ω_s. Indeed, bearing in mind that Ω_s is a homogeneous first-order function relative to the extensive parameter A for constant intensive parameters T and μ_i and applying Euler's theorem to Eqn. (15), we obtain

$$\Omega_s = \sigma_0 A. \tag{17}$$

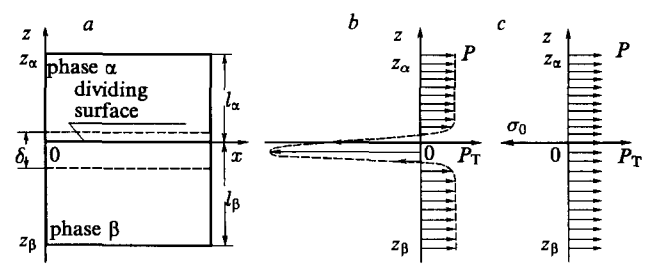

Figure 4. Illustration of the dividing surface (as defined by Gibbs) method in the thermodynamics of a planar free interface: (*a*) open system-containing an interface; (*b*) dependence of the component P_T of the hydrostatic pressure tensor on z; (*c*) result of the replacement of the interface by a dividing surface.

In this connection we may note that, by virtue of the invariance of the function Ω_s as regards the choice of the dividing surface, its use for the thermodynamic description of the interface is preferable to the use of the Helmholtz free energy, whose excess amount

$$F_s = \sigma_0 A + N_i \mu_i, \tag{18}$$

depends on the position of the dividing surface.

The Gibbs–Duhem equation. On differentiating Eqn. (17) and combining it with Eqn. (15), we obtain the familiar Gibbs–Duhem equation for a planar free dividing surface:

$$d\sigma_0 = -S_s dT - \sum_i \Gamma_i d\mu_i, \tag{19}$$

where $S_s = S_s/A$ and $\Gamma_i = N_{is}/A$ are the specific excess entropy and excess number of moles (adsorption) of the ith component referred to the dividing surface. If the procedure used to derive the Gibbs–Duhem equation is applied to the grand thermodynamic potential Ω of a system containing a planar free interface [see Eqn. (6)], we obtain the following expression:[35]

$$A\, d\sigma_0 = -S dT - \sum_i N_i d\mu_i + V dP. \tag{20}$$

Hydrostatic representation of the interfacial tension. Within the framework of the ideas of local thermodynamics it is possible to express the force f with which the system acts on a surface area element $\Delta A = z_\alpha z_\beta l$ (where $l = 1$) of a mobile wall (see Fig. 4*a*) by the component $P_T(z)$ of the pressure tensor in terms of the relation (Fig. 4*b*):

$$f = \int_{z_\beta}^{z_\alpha} P_T(z)\, dz. \tag{21}$$

When the real system is replaced by an idealised system containing two reference phases α and β and the dividing surface, the corresponding force f^{id} (Fig. 4*c*) is

$$f^{id} = \int_{z_\beta}^{z_\alpha} P dz - \sigma_0. \tag{22}$$

The minus sign of σ_0 reflects the direction of the action of the interfacial tension.

The familiar Bakker formula[37] for the interfacial tension of a planar free dividing surface can be obtained from the condition for the mechanical equivalence of the real and idealised systems, i.e. from the conditions $f = f^{id}$:

$$\sigma_0 = \int_{-\infty}^{+\infty} [P - P_T(z)] dz, \tag{23}$$

where the integration limits have been replaced by infinity, bearing in mind that outside the transition region with thickness δ we have the equality $P_T(z) = P$.

The influence of pressure on the interfacial tension. According to Gibbs,[11] the derivative $(\partial\sigma_0/\partial P)_T$ represents a volume decrement associated with the specific expansion of the interface. Such interpretation of the $\sigma_0(P)$ relation apparently follows from the Gibbs–Duhem equation [Eqn. (20)], which can be transformed into

$$d\sigma_0 = -\frac{S}{A} dT - \left(\frac{\Gamma_1}{n_{1\alpha}} \frac{1-\varphi_2}{1-\varphi_1\varphi_2} + \frac{\Gamma_2}{n_{2\beta}} \frac{1-\varphi_1}{1-\varphi_1\varphi_2} \right) dP + \sum_{i=3}^{N} \left(\frac{\Gamma_1}{n_{1\alpha}} \frac{n_{i\alpha} - \varphi_2 n_{2\beta}}{1-\varphi_1\varphi_2} + \frac{\Gamma_2}{n_{2\beta}} \frac{n_{i\beta} - \varphi_1 n_{i\alpha}}{1-\varphi_1\varphi_2} - \Gamma_i \right) d\mu_i, \tag{24}$$

by eliminating the intensive parameters μ_1 and μ_2 (it is assumed that the components $i = 1$ and $i = 2$ correspond to water and oil molecules), where $n_{i\alpha} = N_{i\alpha}/V_\alpha$ and $n_{i\beta} = N_{i\beta}/V_\beta$, $\varphi_1 = n_{1\beta}/n_{1\alpha}$, and $\varphi_2 = n_{2\alpha}/n_{2\beta}$. If one considers a two-component system in which the two components are immiscible, for example with $n_{1\beta} = 0$ and $n_{2\alpha} = 0$, then we obtain from Eqn. (24):[38]

$$\left.\frac{\partial\sigma_0}{\partial P}\right|_T = -\left(\frac{\Gamma_1}{n_{1\alpha}} + \frac{\Gamma_2}{n_{2\beta}} \right). \tag{25}$$

If the dividing surface has been chosen in such a way that either $\Gamma_1 = 0$ or $\Gamma_2 = 0$, we obtain from Eqn. (25)

$$\left.\frac{\partial\sigma_0}{\partial P}\right|_T = -\frac{\Gamma_2}{n_{2\beta}} = -\frac{\Gamma_1}{n_{1\alpha}}. \tag{26}$$

Since $v_1 = 1/n_{1\alpha}$ and $v_2 = 1/n_{2\beta}$ are the molar volumes of components 1 and 2 respectively and the quantities Γ_1 and Γ_2 have the dimensions mol m^{-2}, the right-hand side of Eqn. (26) has the dimensions $m^3\, m^{-2}$ and has therefore been interpreted by Gibbs[11] as a decrease in volume associated with the specific expansion of the interface.

At the same time, one should note that, since the signs of Γ_1 and Γ_2 are not known beforehand, one cannot say whether the interfacial tension σ_0 will increase or decrease with increase in P. This applies also to the specific change in the volume of the interface.

The experimental results obtained from measurements of the $\sigma_0(P)$ relation are contradictory: a negative value $(\partial\sigma_0/\partial P)_T = -0.07$ Å has been obtained[39] for the benzene–water systems; a positive value $(\partial\sigma_0/\partial P)_T \simeq +0.025$ Å has been found[38,40–42] for the hexane–water system, and this decreased to +0.01 Å after the addition of tetradecanol to the system.[35] It follows from Eqn. (23) that, with increase in pressure, the interfacial tension should not change if the interfacial layer is liquid-like. In this case, an increase in hydrostatic pressure is transmitted in all directions without change, i.e. P and $P_T(z)$ increase by the same amount, and the integral (23) does not change.

On the other hand, if the structure of the layer is such that it exhibits 'solid-like' properties, the increase in σ_0 with increase in the pressure P is induced by the 'shielding' effect. Indeed, if it is assumed that the increase in pressure dP is not transmitted at all to the narrow transitional interfacial layer (Fig. 4), then the depth of the minimum in the $P_T(z)$ curve does not change and the external force acting on the mobile wall from the right increases. In this case, the derivative $(\partial\sigma_0/\partial P)_T$ has the physical significance of the thickness of the interfacial layer. If the interfacial layer is structured but not so much that it can be regarded as 'solid-like', then its effective thickness

$$h_f = \left(\frac{\partial\sigma_0}{\partial P} \right)_T, \tag{27}$$

is less than δ.

In connection with the proposed interpretation of the influence of hydrostatic pressure P on the interfacial tension σ_0 we may note that the results of Motomura and coworkers[35,40–42] agree with the conclusion that σ_0 should increase with increase in P for a two-component system. It has been shown[42] that in the water–hexane–octadecanol system the interfacial tension σ_0 decreases with increase in P and the decrease is fairly considerable $[(\partial\sigma_0/\partial P)_T = -2$ Å] in the phase transition from extended octadecanol monolayers to condensed (i.e. 'solid-like') monolayers. This result conflicts with the proposed interpretation of the influence of P on σ_0.

b. The method based on a layer with a finite thickness

This method[6,18,19] is based on the replacement of a real system with a volume V, containing a planar interface, by an idealised system incorporating two phases, α and β, with volumes $V_\alpha^f = l_\alpha A$ and $V_\beta^f = l_\beta A$ respectively (Fig. 5*a*) and a layer with a thickness h_f and a volume $V_f = h_f A$ dividing them, i.e.

$$V = V_\alpha + V_\beta + V_f. \tag{28}$$

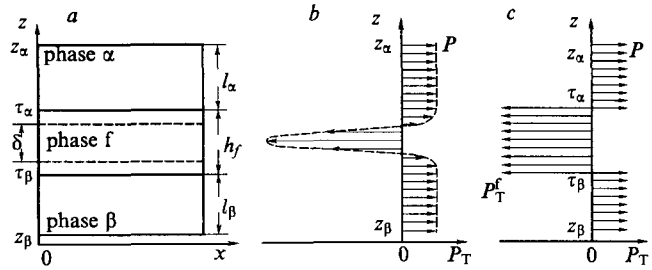

Figure 5. Illustration of the method of the finite thickness layer method in the thermodynamics of a planar free interface: (*a*) open system containing an interface; (*b*) dependence of the component P_T of the hydrostatic pressure tensor on z; (*c*) result of the replacement of the interface by a layer of finite thickness.

The extensive parameters S, N_i, and Ω are also represented by sums of the corresponding bulk-phase components referring to the reference phases α and β and of the excess amounts S_f, N_{if}, and Ω_f referring to the volume V_f of a layer having a finite thickness, i.e.

$$S = S_\alpha + S_\beta + S_f, \tag{29}$$

$$N_i = N_{i\alpha} + N_{i\beta} + N_{if}, \tag{30}$$

$$\Omega = \Omega_\alpha + \Omega_\beta + \Omega_f. \tag{31}$$

Fundamental equation of a layer with a finite thickness. Having substituted Eqns. (28)–(31) in the fundamental equation for the system [Eqn. (6)], we obtain

$$d\Omega = d\Omega_\alpha + d\Omega_\beta + d\Omega_f, \tag{32}$$

where

$$d\Omega_\alpha = -S_\alpha dT - \sum_i N_{i\alpha} d\mu_i - P dV_\alpha, \tag{33}$$

$$d\Omega_\beta = -S_\beta dT - \sum_i N_{i\beta} d\mu_i - P dV_\beta, \tag{34}$$

$$d\Omega_f = -S_f dT - \sum_i N_{if} d\mu_i - P dV_f + \sigma_0 dA. \tag{35}$$

Eqns. (33)–(35) are fundamental for the reference phases α and β and the layer with a finite thickness, respectively.

Hydrostatic description of the layer with a finite thickness. The force f with which the real system acts on the mobile wall is described by Eqn. (21). For the description of the force f^{id} with which the idealised system, containing a layer with a finite thickness h_f, acts on the same surface element of the wall, one has to refine the concept of the layer. If the layer is assumed to be a formation uniform along its thickness and characterised by constant volume densities of the thermodynamic quantities, for example, the entropy

$$s_f = \frac{S_f}{V_f}, \tag{36}$$

and the number of moles of the ith component

$$n_i = \frac{N_{if}}{V_f}, \tag{37}$$

but anisotropic as regards mechanical properties [for example, the layer is extended by the operation of the pressure $P_T^f = P_{xx} = P_{yy}$ (Fig. 5*c*)], then the force f^{id} can be formulated thus:

$$f^{id} = \int_{z_\beta}^{\tau_\beta} P dz + \int_{\tau_\beta}^{\tau_\alpha} P_T^f dz + \int_{\tau_\alpha}^{z_\alpha} P dz, \tag{38}$$

where τ_α and τ_β are the coordinates of the upper and lower surfaces of the layer with $h_f = \tau_\alpha - \tau_\beta$. Taking into account Eqn. (23), we obtain from the condition for the mechanical equivalence of the systems $f = f^{id}$

$$P_T^f h_f = P h_f - \sigma_0. \tag{39}$$

Having substituted Eqn. (39) in Eqn. (35), we find the fundamental equation for a layer of finite thickness:

$$d\Omega_f = -S_f dT - \sum_i N_{if} d\mu_i - PA\, dh_f - P_T^f h_f dA. \tag{40}$$

If it is assumed that a layer uniform with respect to its thickness and having a volume V_f is a liquid phase, then the hypothesis that its properties are anisotropic is unjustified (an isotropic pressure P operates in the liquid phase). In this case, we are forced to consider two dividing surfaces[43] to which the excess pressure P_T^f is referred, assuming that the pressure in the layer is isotropic and equal to P. We may note that the excess amounts of the other thermodynamic quantities are referred to a layer with a thickness h_f, i.e. only the excess pressure, which we shall call the interfacial tension σ_0, is referred to two dividing surfaces.

For this representation of a layer of finite thickness, the force acting on a surface element of the mobile wall is

$$f^{id} = \int_{z_\alpha}^{z_\beta} P dz - \sigma_0. \tag{41}$$

From the condition for the mechanical equivalence of the systems $f = f^{id}$, we obtain an expression for σ_0 which agrees in form with Eqn. (23). However, in this case it is implied that both dividing surfaces are equivalent as regards mechanical properties (unless the difference between them is specially stipulated), i.e. it is assumed that

$$\sigma_0 = \sigma_{0\alpha} + \sigma_{0\beta}, \tag{42}$$

where $\sigma_{0\alpha}$ and $\sigma_{0\beta}$ are the interfacial tensions of the dividing surfaces of finite thickness.

Hansen's method. Hansen[34] proposed a modified finite thickness layer method for the description of systems with a planar interface. He used the model of a layer containing a liquid phase and two dividing surfaces which are placed in such a way that the degrees of adsorption Γ_1 and Γ_2 of the components, which are solvents for phases α and β respectively, are zero. The distance between such dividing surfaces with the coordinates τ_α^H and τ_β^H is

$$\tau^H = \tau_\alpha^H - \tau_\beta^H. \tag{43}$$

By applying to Eqns. (33)–(35) the procedure used to obtain equations of the Gibbs–Duhem type, we obtain

$$s_\alpha dT + n_{1\alpha} d\mu_1 + n_{2\alpha} d\mu_2 + \sum_{i=3}^{N} n_{i\alpha} d\mu_i = dP, \tag{44}$$

$$s_\beta dT + n_{1\beta} d\mu_1 + n_{2\beta} d\mu_2 + \sum_{i=3}^{N} n_{i\beta} d\mu_i = dP, \tag{45}$$

$$-d\sigma_0 = \frac{S_f}{A} dT + \tau^H n_{1f} d\mu_1 + \tau^H n_{2f} d\mu_2 + \sum_{i=3}^{N} \frac{N_{if}}{A} d\mu_i - \tau^H dP, \tag{46}$$

where $n_{1\alpha} = N_{i\alpha}/V_\alpha$, $n_{i\beta} = N_{i\beta}/V_\beta$, $n_{if} = N_{if}/V_f$, $V_f = A\tau^H$, and $s_{\alpha,\beta} = S_{\alpha,\beta}/V_{\alpha,\beta}$.

Assuming that $n_{1f} = n_{1\beta}$ and $n_{2f} = n_{2\alpha}$, which is equivalent to the conditions $\Gamma_1 = 0$, $\Gamma_2 = 0$, and $\varphi_1 = n_{1\beta}/n_{1\alpha}$, $\varphi_2 = n_{2\alpha}/n_{2\beta}$, we obtain from Eqns. (44)–(46)

$$d\sigma_0 = -s_f dT + \frac{(1-\varphi_1)(1-\varphi_2)}{1-\varphi_1\varphi_2}\tau^H dP - \sum_{i=3}^{N}\left[\Gamma_i - \frac{\varphi_1(n_{i\alpha}-\varphi_2 n_{i\beta}) + \varphi_2(n_{i\beta}-\varphi_1 n_{i\alpha})}{1-\varphi_1\varphi_2}\right]d\mu_i, \quad (47)$$

where $\Gamma_i = N_{if}/A$, and $s_f = S_f/A$.

In the case of a two-component system, the following relation follows from Eqn. (47):

$$d\sigma_0 = -s_f dT + \frac{(1-\varphi_1)(1-\varphi_2)}{1-\varphi_1\varphi_2}\tau^H dP, \quad (48)$$

For immiscible components (for example, for component 1, forming phase α, and component 2, forming phase β) and when account is taken of the conditions $\varphi_1 = \varphi_2 = 0$, Eqn. (48) is converted into

$$d\sigma_0 = -s_f dT + \tau^H dP. \quad (49)$$

In this case,[34,35] the distance between the dividing surfaces, for which $\Gamma_1 = 0$ and $\Gamma_2 = 0$, is

$$\tau^H = \left.\frac{\partial\sigma_0}{\partial P}\right|_T, \quad (50)$$

which agrees with the result obtained by Good and Buff.[38] The expression obtained agrees with the conclusion reached by Gibbs,[11] who noted that the derivative $(\partial\sigma_0/\partial P)_T$ characterises the distance between the two equimolecular surfaces. Having compared Eqn. (50) with Eqn. (26), we obtain

$$\tau^H = -\left.\frac{\Gamma_2}{n_{2\beta}}\right|_{\Gamma_1=0} = -\left.\frac{\Gamma_1}{n_{1\alpha}}\right|_{\Gamma_2=0}. \quad (51)$$

In the case of a three-component system (for example, water–oil–surfactant) subject to the additional condition that the oil and water are immiscible, Eqn. (47) gives rise to the following relation:[34,35]

$$d\sigma_0 = -s_f dT - \Gamma_3 d\mu_3 + \tau^H dP. \quad (52)$$

In this representation, a layer with a thickness τ^H is filled solely with component 3 (i.e. the surfactant) and can be regarded as a phase. Attention must be drawn to the fact that the quantity τ^H, defined by Eqn. (43), may be negative (even in the absence of a surfactant or for a constant μ_3), whereupon the concept of a layer with a finite thickness τ^H and filled with the surfactant is not quite so clear. In particular, it has been found[42] for the water–hexane–octadecanol system that σ_0 diminishes from 35 to 25 mJ m^{-2} with increase in P from 0.1 to 50 MPa for a constant mole fraction of the surfactant in the oil $x_3 = 2.21 \times 10^{-3}$. Since the chemical potential μ_3 changes with increase in pressure, Motomura[35] suggested that one goes over to the variables T, P, and x_3 (the mole fraction of component 3 in one of the phases) by replacing μ_3 in Eqn. (52) by x_3 in accordance with the relation

$$d\mu_3 = \frac{\partial\mu_3}{\partial T}dT + \frac{\partial\mu_3}{\partial P}dP + \frac{\partial\mu_3}{\partial x_3}dx_3. \quad (53)$$

Then instead of Eqn. (52), we obtain at a constant temperature T

$$d\sigma_0 = \left(\tau^H - \Gamma_3\frac{\partial\mu_3}{\partial P}\right)dP - \Gamma_3\frac{\partial\mu_3}{\partial x_3}dx_3. \quad (54)$$

If the solvent is ideal in relation to the surfactant, one can write[35]

$$\mu_3 = \mu_3^0(T,P) + RT\ln x_3, \quad (55)$$

and instead of Eqn. (54) we have

$$d\sigma_0 = \left(\tau^H - \Gamma_3\frac{\partial\mu_3^0}{\partial P}\right)dP - RT\Gamma_3 d\ln x_3, \quad (56)$$

where μ_3^0 is the standard value of the chemical potential μ_3, i.e. its value at $x_3 = 1$. Since $\partial\mu_3^0/\partial P$ can be interpreted as the volume of one surfactant molecule $v_3 \simeq 10^{-29}$ m^3 and the adsorption Γ_3 is $\sim 10^{-6}$ mol m^{-2}, the product $\Gamma_3(\partial\mu_3^0/\partial P)$ in Eqn. (56) increases from 0 to ~ 1 Å with increase in x_3 from 0 to the value corresponding to a surfactant monolayer on the interface.

If the thickness of the layer τ^H does not change as x_3 increases, then the quantity

$$\tau_*^H = \tau^H - \Gamma_3\frac{\partial\mu_3}{\partial P} = \left.\frac{\partial\sigma_0}{\partial P}\right|_{T,x_3} \quad (57)$$

should diminish with increase in x_3, which was observed by Motomura and coworkers[35,40–42] for tetradecanol and octadecanol. However, for a water-soluble surfactant (NaDDS) τ_*^H does not vary with increase in x_3,[41] which may indicate the simultaneous increase in τ^H in Eqn. (57). Furthermore, an abrupt decrease in τ_*^H from positive ($\sim +0.2$) to negative (~ -0.2) values at a certain critical pressure P has been observed for octadecanol, which has been attributed[35–41] to a phase transition within the surfactant adsorption layer.

Thus the finite thickness layer method, in particular Hansen's method improved by Motomura,[35] permits certain definite conclusions concerning the structure of interfacial (adsorption) layers. On the other hand, the mechanism of the influence of hydrostatic pressure P on the interfacial tension σ_0 is not entirely clear. For example, it follows from Eqn. (49) that a layer with a thickness τ^H is 'solid-like' (if one uses the ideas of local thermodynamics), i.e. an increase in pressure in the bulk phase is not transmitted to the mobile wall in contact with this layer (Fig. 2). The interfacial layer with a thickness τ^H as it were shields the wall from the external pressure and an increase in pressure dP leads to an increase in interfacial tension by $d\sigma_0 = \tau^H dP$. The decrease in σ_0 with increase in P proves to be difficult to express in terms of local thermodynamics, since it is not clear why an increase in pressure leads in this instance to a marked decrease in the depth of the minimum on the $P_T(z)$ curve (Fig. 3), which is greater than the increase in P in the system.

III. Thermodynamics of plane-parallel thin liquid films

1. Definition of a thermodynamic system incorporating a thin liquid film

We shall consider a system (Fig. 6) incorporating a plane-parallel liquid film with an area A fixed on a rigid frame which can be moved without friction by an external force f_e.[10,13,44] The film is in mechanical equilibrium with the flowing (liquid or gaseous) phase β surrounding it and the liquid phase α from which it is formed. The chemical potentials μ_i of the ith components are equal in all the phases of the system and in the film. The external force f_e is balanced by the tension of the film γ. A force f_α is applied to the left-hand piston. With its aid, the pressure P_α within phase α in this piston is controlled. The chemical potentials (the numbers of moles of the components) can be varied with the aid of a material source ν_i.

An open subsystem with a volume V (Fig. 6) (containing phase β and the film element) in thermal, material, and mechanical equilibrium with the system considered above is examined simultaneously.

2. Fundamental equation of a system containing a thin liquid film

If the variable parameters of the system are the temperature T, the volume of the system V, the area of the film A, and the number of moles N_i of the ith component, then the fundamental equation for such a system can be written in the form[4,9,10,13,45]

$$dF = -S dT - P_\beta dV + \sum_i \mu_i dN_i + \gamma dA.$$

In terms of the variables T, V, μ_i, and A, the fundamental equation for the system becomes[13, 16, 46, 47]

$$d\Omega = -S\,dT - P_\beta\,dV - \sum_i N_i\,d\mu_i + \gamma\,dA, \tag{58}$$

where $\Omega = F - \sum \mu_i N_i$ is the grand thermodynamic potential and F is the Helmholtz free energy of the system.

3. Membrane model of a thin liquid film

By analogy with Gibb's approach[11] to the thermodynamic description of free interfaces, Deryagin and coworkers[1,2] developed the thermodynamics of thin liquid films using a membrane of zero thickness as the reference thermodynamic model of the film. They determined the excess thermodynamic quantities relative to this membrane.

Within the framework of this model, the volume of the system V is equal to the volume of the reference phase β, i.e. $V_\beta = V$, and one assumes arbitrarily that

$$N_i = N_{i\beta} + \tilde{N}_{if}, \tag{59}$$

$$S = S_\beta + \tilde{S}_f, \tag{60}$$

where $N_{i\beta}$ and S_β are the number of moles of the ith component and the entropy of the reference phase β, and $\tilde{N}_{if}$ and $\tilde{S}_f$ are the corresponding excess values of these quantities for the reference phase referred to the membrane. The free energy of the system Ω is also expressed by the sum

$$\Omega = \Omega_\beta + \tilde{\Omega}_f, \tag{61}$$

where Ω_β and $\tilde{\Omega}_f$ are the free energy of the reference phase β and the excess free energy referred to the membrane, respectively.

The fundamental equation (58) for the system is written in the form

$$d\Omega = d\Omega_\beta + d\tilde{\Omega}_f, \tag{62}$$

where

$$d\Omega_\beta = -S_\beta\,dT - P_\beta\,dV_\beta - \sum_i N_{i\beta}\,d\mu_i \tag{63}$$

is the fundamental equation of the reference phase β and

$$d\tilde{\Omega}_f = -\tilde{S}_f\,dT - \sum_i \tilde{N}_{if}\,d\mu_i + \gamma\,dA \tag{64}$$

is the fundamental equation for the membrane.

a. Hydrostatic pressure in a thin liquid film

A thin liquid film cannot be regarded as a phase because, as within the transition region of the interface, intensive thermodynamic parameters (such as the pressure and the densities of matter, internal energy, entropy, etc.) change sharply within it perpendicular to its plane. Within the framework of local thermodynamics,[26–29, 47, 48] thin liquid films are represented as an anisotropic medium in each microscopic volume of which the fulfillment of the principal thermodynamic relations is postulated. In particular, the fulfillment of the condition for mechanical equilibrium [condition (1)] is postulated, whereas in an isotropic medium the tangential components of the hydrostatic pressure tensor $\boldsymbol{P}$ are zero, while the normal components P_{xx}, P_{yy}, and P_{zz} are equal to the hydrostatic pressure P in the isotropic medium. As in interfaces (Fig. 3), the tangential components within the liquid film are zero, while the normal components (Fig. 7*a*) are

$$P_{xx} = P_{yy} = P_T(z), \tag{65}$$

$$P_{zz} = P_N = P. \tag{66}$$

In the case of a plane-parallel thin liquid film, the pressure tensor component P_N is independent of the coordinate z. Within curved thin liquid films of constant thickness, the pressure P_N varies, remaining nevertheless compressive (positive).

b. Film tension

In the membrane approach, the film tension γ is understood as the specific excess pressure $P_T(z)$ (per unit length) relative to the isotropic hydrostatic pressure P_β in the reference phase β acting in the direction tending to reduce the film area:[7, 9, 26–29, 45, 47, 48]

$$\gamma = -\int_{-\infty}^{+\infty} [P_T(z) - P_\beta]dz = -\int_{-\infty}^{+\infty} [P_T(z) - P_N]dz, \tag{67}$$

where the integration with respect to z is carried out in the region of the inhomogeneity of the film and the minus sign before the integral is selected in conformity with the definition of the film tension as the force tending to reduce the length of the film.

Fig. 7*b* shows that in the membrane approach the plane bounding the system on the right is acted upon by the pressure P_β directed to the right and the film tension γ directed to the left. These forces are balanced by the force of the pressure P_β acting on the plane from the right and by the external force f_e directed to the right. Thus the specific force (per unit length of the film) is equal in magnitude to the film tension γ.

The following definition of the film tension follows from the fundamental equation (64):

$$\gamma = \left.\frac{\partial \tilde{\Omega}_f}{\partial A}\right|_{\mu_i, T}, \tag{68}$$

$$\gamma = \left.\frac{\partial \Omega}{\partial A}\right|_{\mu_i, T, V_\beta}. \tag{69}$$

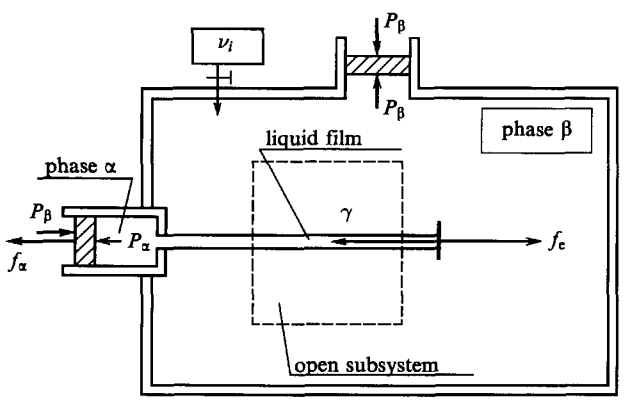

Figure 6. A closed system incorporating a flowing (liquid or gaseous) phase β and a plane-parallel liquid film formed from the liquid phase α.

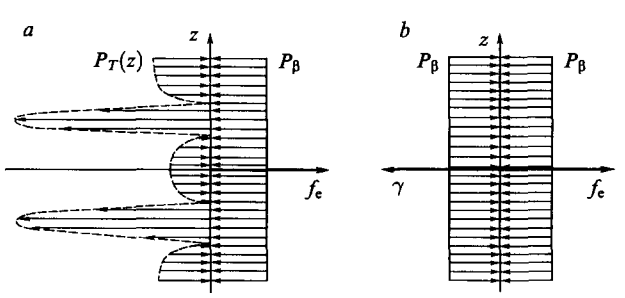

Figure 7. The membrane model of a liquid film: (*a*) equilibrium in a section of the vertical plane of the film holder acted upon by an external force f_e and the hydrostatic pressure P_β from the right and by the local pressure $P_T(z)$ from the direction of the film on the left; (*b*) result of the replacement of the film by a membrane of zero thickness.

This actually means that the film is stretched when the piston comprising the cylinder containing phase α is stationary (the volume of phase β is then also kept constant).

4. The model of the film based on the concept of two dividing surfaces

The thermodynamics of thin liquid films, based on this idea, was first worked out by Rusanov[3-5,8] and was subsequently developed in a number of other studies.[6,7,9,16,17,44-47]

In this model, the thin liquid film is represented by a thin layer of the reference phase α with a finite thickness H, separated from the external reference phase β by the dividing surfaces (as defined by Gibbs) (Fig. 8). The volume of the open subsystem V is equal to the sum of the volumes of the reference phase β and phase α from which the film has been obtained:

$$V = V_\beta + V_\alpha. \tag{70}$$

Under these conditions, $V_\alpha = V_f$, and $dV_\alpha = -dV_\beta$ (if V = const.) and the following relation also holds:

$$dV_f = dV_\alpha = A\,dH + H\,dA. \tag{71}$$

The grand thermodynamic potential of the system Ω is now formulated as the sum

$$\Omega = \Omega_\beta + \Omega_\alpha + \tilde{\Omega}_s, \tag{72}$$

where Ω_β and Ω_α are the free energies of the reference phases β and α respectively and $\tilde{\Omega}_s$ is the excess grand thermodynamic potential for the reference phases β and α referred to the two dividing surfaces.

The fundamental equation for the system is written in the form

$$d\Omega = d\Omega_\beta + d\Omega_\alpha + d\tilde{\Omega}_\sigma, \tag{73}$$

where the fundamental equations for phases β and α are respectively

$$d\Omega_\beta = -S_\beta\,dT - \sum_i N_{i\beta}\,d\mu_i - P_\beta\,dV_\beta, \tag{74}$$

$$d\Omega_\alpha = -S_\alpha\,dT - \sum_i N_{i\alpha}\,d\mu_i - P_\alpha\,dV_\alpha, \tag{75}$$

where P_α is the pressure in phase α, which is the reference phase for the film:

$$S = S_\beta + S_\alpha + \tilde{S}_s, \tag{76}$$

$$N_i = N_{i\beta} + N_{i\alpha} + \tilde{N}_{is}. \tag{77}$$

Here $\tilde{S}_s$ and $\tilde{N}_{is}$ are the excess entropy and the excess number of moles of the ith component respectively for the reference phases β and α relative to the two dividing surfaces.

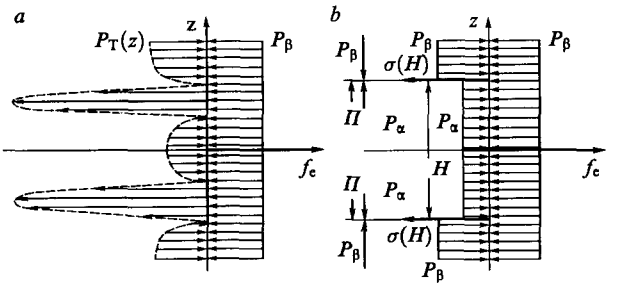

Figure 8. Illustration of the model of the liquid film based on the concept of two dividing surfaces in the film: (*a*) equilibrium in the film holder acted upon by $P_T(z)$, P_β, and f_e; (*b*) result of the replacement of the film by an idealised model comprising two interacting dividing surfaces and a layer of phase α having a thickness H.

The fundamental equations for two interacting dividing film surfaces is obtained from Eqns (58), (70), and (73)–(77):[13,16,47]

$$d\tilde{\Omega}_s = -\tilde{S}_s\,dT - \sum_i \tilde{N}_{is}\,d\mu_i - (P_\beta - P_\alpha)\,dV_\alpha + \gamma\,dA. \tag{78}$$

Taking into account Eqn. (71) as well as the definition of the disjoining pressure[28,29]

$$\Pi = P_\beta - P_\alpha, \tag{79}$$

and the definition[5,8,17,44] of the interfacial tension $\sigma(H)$ in a film with a thickness H, i.e.

$$\gamma = 2\sigma + \Pi H, \tag{80}$$

the fundamental equation for interacting dividing surfaces was obtained:[16]

$$d\tilde{\Omega}_s = -\tilde{S}_s\,dT - \sum_i \tilde{N}_{is}\,d\mu_i - \Pi A\,dH + 2\sigma\,dA. \tag{81}$$

a. The disjoining pressure in a liquid film

According to the formal definition, the disjoining pressure Π in a film[28,29] is equal to the difference between the hydrostatic pressures in the two reference phases β and α under the conditions of the equilibrium between the film and these phases. Since, as shown above [see Eqn. (66)], the normal component of the pressure $P_{zz} = P_N$ in the film is equal to the pressure P_β in phase β, Eqn. (79) can be rewritten in the following form:

$$\Pi = P_N - P_\alpha, \tag{82}$$

which corresponds best, according to a number of workers,[6,7,8,20,28,29] to the physical significance of the disjoining pressure.

There exist two points of view on the interpretation of the physical significance of the disjoining pressure Π. One group of workers[9,28,29,45,49,50] understand the disjoining pressure as the manifestation of forces of the 'second kind',[28,29,51] which arise in the region of the mutual overlap of the "surface forces of the first kind", i.e. two interfacial discontinuity surfaces (dividing surfaces according to Gibbs). The disjoining pressure is then represented as a pressure acting within the bulk of the film and existing, as it were, independently of the dividing surfaces of the film. The dividing surfaces are assumed not to interact with one another, so that the interfacial tension remains constant in magnitude as the film thickness diminishes and is equal to σ_0 (i.e. to the interfacial tension of the boundary of the bulk phases). The reference pressure in the film (the Gibbs reference pressure) chosen in some investigations[9,45,50] is not the hydrostatic pressure P_α but the hydrostatic pressure P_β. It has been shown[16] that this choice of reference pressure leads to the appearance of a pressure gradient in the transition region of the film and to difficulties in the determination of the disjoining pressure in this region.

The second group of workers[10,13,14,16,17,44,52-54] use the concept of the disjoining pressure as a specific force (per unit area) of the interaction between the dividing surfaces in the film. The chosen reference phase and pressure in the film are α and P_α respectively, so that a pressure gradient does not arise in the transition region of the film.[16]

The interfacial tension $\sigma(H)$ corresponding to this concept of the pressure is a function of the film thickness H. The following expression for the disjoining pressure arises from the fundamental Eqn. (81):

$$\Pi = -\frac{1}{A}\left.\frac{\partial\tilde{\Omega}_s}{\partial H}\right|_{T,\mu_i,A}, \tag{83}$$

where $\tilde{\Omega}_s$ has the significance of the excess free energy of the interacting dividing surfaces in a film with a thickness H. The function $\Pi(H)$ is called the isotherm of the disjoining pressure in the film. Despite the fact that the film thickness was chosen arbitrarily, the disjoining pressure is independent of the choice of the parameter H, i.e. is invariant for a fixed physical state of the film (is determined by the parameters T, μ_i, P_α, and P_β).

b. The interfacial tension in a thin liquid film

According to the definition, the interfacial tension σ [Eqn. (80)] depends on the choice of the positions of the dividing surfaces in the film (i.e. on the parameter H) for a fixed physical state of the film. If the film tension γ and the disjoining pressure Π are invariant and independent of the parameter H for the constant T, μ_i, P_α, and P_β, then σ depends linearly on H:

$$2\{\sigma\} = \gamma - \Pi\{H\}, \tag{84}$$

(the braces denote that the parameter H varies virtually for a fixed physical state of the system).

The interfacial tension σ is by definition the specific (referred to unit length) excess pressure $P_T(z)$ from the reference phases β and α compared with the isotropic pressures P_β and P_α in the reference phases relative to the dividing surfaces[6,9,10,16] (Fig. 8):

$$2\sigma(H) = -\int_{-\infty}^{-H/2} [P_T(z) - P_\beta]\,dz - \int_{-H/2}^{+H/2} [P_T(z) - P_\alpha]\,dz - \int_{+H/2}^{+\infty} [P_T(z) - P_\beta]\,dz. \tag{85}$$

If the film thickness really increases, which may be indicated by a decrease in the difference between the hydrostatic pressures $\Pi = P_\beta - P_\alpha$ (for $P_\beta \geqslant P_\alpha$), then it follows from Eqn. (67) that the film tension γ also varies and tends to γ_0, corresponding to the condition $\Pi = 0$. Then, according to Eqn. (80), the interfacial tension also tends to its limiting value σ_0 corresponding to the absence of interaction between the dividing surfaces and we have $\gamma_0 = 2\sigma_0$. As was to be expected, under these conditions the interfacial tension in such a thick liquid film is independent of the position of the dividing surfaces.

c. The specific free energy of the interaction in the film

For a real increase in film thickness from a certain value H to infinity for constant parameters T, μ_i, and A, the disjoining pressure executes an amount of work which is given by the following expression according to the fundamental Eqn. (81):

$$\tilde{\Omega}_s(\infty) - \tilde{\Omega}_s(H) = -A\int_H^\infty \Pi(H)\,dH. \tag{86}$$

Having put

$$\Delta\Omega(H) = \frac{\tilde{\Omega}_s(H) - \tilde{\Omega}_s(\infty)}{A}, \tag{87}$$

where $\Delta\Omega(H)$ is the specific (referred to unit surface area) free energy (grand thermodynamic potential) of the interaction between the dividing surfaces in a film with a thickness H, we obtain a relation which is valid for constant T, μ_i, and A:

$$\Delta\Omega(H) = \int_H^\infty \Pi(H)\,dH. \tag{88}$$

By putting

$$\tilde{S}_s = 2As_s, \tag{89}$$

$$\tilde{N}_{is} = 2A\Gamma_i, \tag{90}$$

we can rewrite the fundamental Eqn. (81) in the form

$$d\tilde{\Omega}_s = -2As_s\,dT - 2A\sum_i \Gamma_i\,d\mu_i - \Pi A\,dH + 2\sigma\,dA, \tag{91}$$

where s_s and Γ_i are the specific (referred to one of the dividing surfaces of a film with a thickness H) excess entropy and number of moles of the ith component respectively and Γ_i is referred to as the adsorption of the ith component on the film surface.

When the surfaces in the film are really moved apart an infinitely great distance, the disjoining pressure Π tends to zero and we obtain the following expression for free non-interacting surfaces in a plane-parallel film when account is taken of Eqn. (91):

$$d\Omega_s^0 = -2As_s^0\,dT - 2A\sum_i \Gamma_i^0\,d\mu_i + 2\sigma_o\,dA, \tag{92}$$

where the superscript 0 means that the corresponding quantity refers to a free planar surface.

By integrating the fundamental Eqn. (91) with respect to the film area A for constant T, μ_i, and H, we obtain[16]

$$\tilde{\Omega}_s(H) = 2\sigma(H)A. \tag{93}$$

If the film thickness is infinte in such integration (the case of non-interacting planar dividing surfaces), we have from Eqn. (92)

$$\tilde{\Omega}_s(\infty) = 2\sigma_o A. \tag{94}$$

An important relation of the thermodynamics of plane-parallel thin liquid films arises from Eqns. (86)–(88), (92)–(94):[16]

$$\Delta\Omega(H) = 2\Delta\sigma = 2\sigma(H) - 2\sigma_0 = \int_H^\infty \Pi(H)\,dH. \tag{95}$$

We recall that the definition (95) is valid for constant parameters T, μ_i, and A. Taking into account the relation between the grand thermodynamic potential Ω and the Helmholtz free energy F, i.e. $\Omega = F - \sum N_i\mu_i$, we obtain the following relation for the constant parameters indicated above:

$$\Delta F(H) = \Delta\sigma(H) - 2\sum_i \Delta\Gamma_i(H)\mu_i, \tag{96}$$

where

$$\Delta F(H) = \frac{F_s(H) - F_s(\infty)}{A}, \tag{97}$$

and

$$\Delta\Gamma_i(H) = \Gamma_i(H) - \Gamma_i(\infty), \tag{98}$$

Here $\Gamma_i(\infty)$ and $F_s(\infty)$ are the adsorption and the Helmholtz free energy of the non-interacting surfaces. Furthermore, the following relation holds:[16]

$$\Delta F(H) = \int_H^\infty \Pi(H)\,dA - 2\sum_i \Delta\Gamma_i(H)\mu_i. \tag{99}$$

d. The Gibbs–Duhem equation for a plane-parallel thin liquid film

On differentiating Eqn. (93) and combining the result with Eqn. (91), we obtain[13,16] the Gibbs–Duhem equation for interacting dividing surfaces in a thin liquid film with a thickness H:

$$2d\sigma = -2s_s\,dT - 2\sum_i \Gamma_i\,d\mu_i - \Pi\,dH, \tag{100}$$

which is converted into the familiar Gibbs–Duhem equation for free (non-interacting) planar surfaces:[11,23]

$$d\sigma_0 = -s_s^0\,dT - \sum_i \Gamma_i^0\,d\mu_i. \tag{101}$$

Evidently the disjoining pressure $\Pi(H)$ and the interfacial tension $\sigma(H)$ are linked by the relation

$$\Pi(H) = -2\frac{\partial\sigma(H)}{\partial H}\bigg|_{T,\mu_i}, \tag{102}$$

which follows from Eqn. (100) and is also known as the Gibbs–Duhem equation for a plane-parallel film.

In thermodynamics based on the membrane approach, the Gibbs–Duhem equation

$$d\gamma = -s_f\,dT - \sum_i \Gamma_{if}\,d\mu_i, \tag{103}$$

is obtained from the fundamental Eqn. (64) in the same way as Eqn. (100), i.e. by integrating Eqn. (64) with respect to A for constant T and μ_i as well as P_α and P_β and subsequent differentiation and simultaneous solution with Eqn. (64). Here

$$s_f = \frac{\tilde{S}_f}{A}; \quad \Gamma_{if} = \frac{\tilde{N}_{if}}{A}, \tag{104}$$

are the specific (referred to unit area of a membrane of zero thickness) excess entropy and number of moles of the ith component.

We may note that s_f and Γ_{if} differ from the corresponding excess amounts s_s and Γ_i defined by Eqns. (89) and (90).

5. The film model based on the concept of a membrane of finite thickness

In the approach based on the concept of the film as a membrane of zero thickness, the film thickness naturally cannot be regarded as a thermodynamic parameter of the system. This approach can be used for the description of those experiments in which the film thickness H is not measured and the pressure in the reference phase α is also unknown.

If the change in the volume of the system dV can be measured experimentally with adequate accuracy (Fig. 6), then, for a known film area A, it is possible to determine the effective film thickness H^*. When the temperature T and the chemical potential μ_i of the ith components are kept constant, it is of interest to examine two situations.

1. If the hydrostatic pressure in phase β as well as the external force f_α are kept constant then, following an increase in the film area A by dA when the film is acted upon by f_e, the volume of the system increases by dV, while the effective film thickness can be determined from the relation

$$H^* = dV\,dA \quad .$$

The volume of the system then changes largely as regards the volume of phase α from which the film has been formed.

2. If the force f_α is constant (i.e. the pressure in phase α is constant although unknown) and the film area is likewise constant, then an increase in the pressure in phase β can lead to a measurable decrease in the volume of the system by an amount dV. This makes it possible to determine the change in the effective film thickness dH^* from the relation $dH^* = dV/A$. Furthermore, in the latter case it is possible to determine the change in the film tension γ, which is interpreted as the influence of the external pressure on the mechanical (energy) properties of the film.

We may note that in both cases it is assumed that the composition of phase α within the film and the constant pressure P_α are assumed to be unknown and the variable parameters are the pressure P_β, the temperature T, the chemical potentials μ_i of the ith components, and the film tension γ which is equal to the force f_e.

The film thermodynamics, based on the model of a membrane with a finite thickness, is constructed on the basis of the fundamental Eqn. (58) and the volume V of the open subsystem is represented by the sum

$$V = V_\beta + V_f, \tag{105}$$

where V_β is the volume of the reference phase β and V_f is the volume of the film which can be found by varying the volume of the reference phase β during the formation of a film having an area A for constant parameters T, μ_i, P_β, and P_α.

a. Fundamental equation for a membrane with a finite thickness

Having put the fundamental Eqn. (58) for an open subsystem containing a plane-parallel thin liquid film in the form

$$d\Omega = d\Omega_\beta + d\tilde{\Omega}_f^*,$$

having retained the previous form of the fundamental equation [Eqn. (63)] for the reference phase β, and using for the membrane the expression

$$d\tilde{\Omega}_f^* = -\tilde{S}_f^*\,dT - \sum_i \tilde{N}_{if}^*\,d\mu_i - P_\beta\,dV_f + \gamma\,dA, \tag{106}$$

($\tilde{S}_f^*$ and $\tilde{N}_{if}^*$ are the excess entropy and the number of moles of the ith component of the reference phase β on a membrane of finite thickness), we obtain the following equation defining the tension of a film of finite thickness:

$$\gamma = \left.\frac{\partial \tilde{\Omega}_f^*}{\partial A}\right|_{T,\mu_i,V_f}. \tag{107}$$

We may note that the excess entropy and the excess numbers of moles of components in Eqn. (106) differ from the corresponding excess amounts which enter into Eqn. (64) because the volumes of the reference phases β are different in the two cases.

b. The Gibbs–Duhem equation for a membrane of finite thickness

Having integrated the fundamental equation for a membrane of finite thickness [Eqn. (106)] with respect to the extensive parameters V_f and A for constant intensive parameters T and μ_i, we obtain

$$\tilde{\Omega}_f^* = -P_f V_f + \gamma A.$$

After differentiating the resulting equation and combining the result with Eqn. (106), we have

$$A\,d\gamma = -\tilde{S}_f^*\,dT - \sum_i \tilde{N}_{if}^*\,d\mu_i + V_f\,dP_\beta. \tag{108}$$

Introducing the effective film thickness

$$H^* = \frac{V_f}{A}, \tag{109}$$

and also the effective specific surface excess entropy and excess number of moles of the ith component, i.e.

$$s_f^* = \frac{\tilde{S}_f^*}{A} \qquad \Gamma_i^* = \frac{\tilde{N}_{if}^*}{A}, \tag{110}$$

which differ from the corresponding values defined by Eqn. (104), we obtain the Gibbs–Duhem equation for this case in the form

$$d\gamma = -s_f^*\,dT - \sum_i \Gamma_i^*\,d\mu_i + H^*\,dP_\beta. \tag{111}$$

c. Frumkin's equation

We may note that the effective film thickness H^*, defined by Eqn. (109), can be obtained from Eqn. (111):

$$H^* = \left.\frac{\partial \gamma}{\partial P_\beta}\right|_{T,\mu_i}. \tag{112}$$

It differs from the film thickness defined as the distance between two equimolecular (as defined by Gibbs) surfaces for which $\Gamma_1 = 0$ (Γ_1 is the adsorption of the solvent on the film interface) or in other ways (for example, as the distance between two tension surfaces, etc.).

Using the definitions of the disjoining pressure [see Eqns. (79) and (82)] and taking into account the fact that for a constant pressure P_α the relation $dP_\beta = d\Pi$ holds, one can rewrite Eqn. (112) as follows:[55]

$$H^* = \left.\frac{\partial \gamma}{\partial \Pi}\right|_{T,\mu_i}. \tag{113}$$

The relation obtained is known as Frumkin's equation in a differential form.[10, 45]

Integrating Eqn. (111) with respect to Π for constant T and μ_i, we find (in terms of our notation)

$$\gamma = \gamma^0 + H^*\Pi + \int_{H^*}^{\infty} \Pi \, dH. \tag{114}$$

Assuming that γ^0, the film tension at $\Pi = 0$ (i.e. in the case of an infinitely large H^*), can be replaced by $2\sigma_0$ (where σ_0 is the interfacial tension of a free planar surface), Eqn. (114) can be rewritten thus:[45, 55]

$$\gamma = 2\sigma_0 + H^*\Pi + \int_{H^*}^{\infty} \Pi \, dH. \tag{115}$$

This expression is known as the integral form of Frumkin's equation.

We may note that Eqn. (115) was derived for the special case corresponding to the special selection of the film thickness defined by Eqn. (190). In contrast to this, on taking into account Eqn. (95), Eqn. (80) can be written in the form

$$\gamma = 2\sigma_0 + H\Pi + \int_{H}^{\infty} \Pi \, dH, \tag{116}$$

and is valid for any choice of the positions of the dividing surfaces in the film and it is therefore more general than Eqn. (115).

The introduction into consideration of the disjoining pressure Π in the approach based on the concept of the film as a membrane of finite thickness is equivalent to the formal replacement of the pressure P_β by Π in the fundamental Eqn. (106) for the membrane. Such replacement was natural in the approach based on the concept of two dividing surfaces in the film [see Eqn. (78)], because the reference phase α with a pressure P_α was introduced into consideration in order to calculate the excess thermodynamic parameters relative to the dividing surfaces. On the other hand, in the case of a membrane of finite thickness, where the excess thermodynamic parameters are calculated relative to the entire membrane, the pressure P_α is assumed to be unknown (although it is kept constant with the aid of an external force f_α—see Fig. 6). The disjoining pressure Π in Eqn. (115) is also unknown because it was determined with an accuracy to within a constant quantity.

Thus the replacement of P_β by the disjoining pressure Π in Eqn. (106)[9, 45] is, strictly speaking, illegitimate. On the other hand, the Gibbs–Duhem equation, derived on the basis of a weaker condition, namely that $dP_\beta = d\Pi$, is more rigorous, like Frumkin's equation in the differential form (113), which follows from Eqn. (111) written in the form[45]

$$d\gamma = -s_f^* \, dT - \sum_i \Gamma_i^* \, d\mu_i + H^* \, d\Pi. \tag{117}$$

The discussion concerning the definition of the disjoining pressure in thermodynamics, based on the concept of a film as a membrane of finite thickness, was taken up by a number of workers.[9, 31, 44, 45] One of the considerations was the problem of the choice of the reference pressure for the film: de Feijter et al.[44] used P_α as the reference pressure, Toshev and Ivanov[6, 45] chose P_β. Whereas for plane-parallel films the choice of the reference pressure is insignificant, since it leads formally to the same Gibbs–Duhem equation for the film, it has been shown[16] that in the case of the transition region the second approach leads to difficulties associated with the need to take into account the hydrostatic pressure gradient in this region of the film.

IV. Conclusion

The above analysis of studies in the thermodynamics of plane-parallel liquid thick and thin films showed that three main approaches to the construction of such thermodynamics have now been developed.

The first approach, based on the thermodynamic film model as a membrane of zero thickness, developed by Deryagin and coworkers,[1,2] relates the excess free energy (grand thermodynamic potential) of the system $\tilde{\Omega}_f$, referred to the membrane, to variable thermodynamic parameters: the temperature T, the chemical potentials μ_i of the ith components, and the film area A:

$$d\tilde{\Omega}_f = -\tilde{S}_f \, dT - \sum_i \tilde{N}_{if} \, d\mu_i + \gamma \, dA,$$

where $\tilde{S}_f$ and $\tilde{N}_{if}$ are the excess entropy and the excess number of moles of the ith component of the reference phase β (Fig. 7), referred to the membrane, and γ is the film tension.

The Gibbs–Duhem equation for constant T, μ_i, and P_β assumes the form

$$d\gamma = -s_f \, dT - \sum_i \Gamma_{if} \, d\mu_i,$$

where s_f and Γ_{if} are the specific (referred to unit area of the membrane) excess entropy and excess numbers of moles of the ith components.

The membrane approach is convenient when a description of the mechanical and energy behaviour of thin liquid films, whose thickness is not measured experimentally, is required.

The second approach is based on the concept of the film as a membrane of finite thickness[6, 7, 9, 45, 56] and relates the excess free energy $\tilde{\Omega}_f^*$ to the variable parameters T, μ_i, and A and also to the film volume V_f, which is assumed equal to the apparent change in the volume of the system (Fig. 7) on formation of a film with an area A for constant T, μ_i, P_β, and P_α [see Eqn. (106)]:

$$d\tilde{\Omega}_f^* = -\tilde{S}_f^* \, dT - \sum_i \tilde{N}_{if}^* \, d\mu_i + H^* \, dP_\beta,$$

where the excess amounts $\tilde{S}_f^*$ and $\tilde{N}_{if}^*$ differ from the corresponding excess amounts in Eqn. (64).

The Gibbs–Duhem equation is written in this case in the form

$$d\gamma = -s_f^* \, dT - \sum_i \Gamma_{if}^* \, d\mu_i + H^* \, dP_\beta,$$

or, if $P_\alpha = \text{const.}$, then, taking into account that $dP_\beta = d\Pi$, it is formulated as follows:

$$d\gamma = -s_f^* \, dT - \sum_i \Gamma_{if}^* \, d\mu_i + H^* \, d\Pi,$$

where $H^* = V_f/A$ is the effective film thickness.

This approach is convenient when the experimental determination of the mechanical properties of a liquid film is accompanied by the measurement of the volume of the system containing the given film.

The third approach is based on the concept of two dividing surfaces in the film[3–5, 6] and relates the excess grand thermodynamic potential of the film $\tilde{\Omega}_s$ to the variable parameters T, μ_i, A, and the film thickness by the equation

$$d\tilde{\Omega}_s = -\tilde{S}_s \, dT - \sum_i \tilde{N}_{is} \, d\mu_i - \Pi A \, dH + 2\sigma \, dA,$$

in which the interfacial tension σ in a film having a thickness H is related to the tension γ by the expression

$$2\sigma = \gamma - \Pi H.$$

The corresponding Gibbs–Duhem equation is

$$2d\sigma = -2s_s \, dT - 2\sum_i \Gamma_i \, d\mu_i - \Pi \, dH.$$

The specific excess amounts s_s and Γ_i are referred to one of the dividing surfaces of the film.

This approach is convenient when the experimental measurement of the mechanical properties of the film is accompanied by the simultaneous measurement of its thickness at a known pressure P_α in phase α.

Thus the use of a specific approach to the description of the thermodynamic and mechanical behaviour of plane-parallel liquid (emulsion and foam) films is determined and limited by the possibility of the experimental measurement of the liquid film thickness and the pressure in the reference phase α from which the film has been formed. The approach based on the concept of two dividing surfaces in the film is optimum when it is extended to the transition region in liquid films within the limits of which the disjoining pressure varies sharply both in magnitude and in sign.

Abstract. The correlations between the retention parameters and the physicochemical properties of sorbates are examined and the possibility of their use for the identification of compounds in gas–liquid chromatography is discussed. It is shown that the chromatographic retention can be most accurately fitted by multifactorial equations based on structural and topological parameters. The bibliography includes 256 references.

I. Introduction

A number of reviews and monographs have been devoted to the problem of the preliminary calculation of retention parameters and the identification of substances in gas–liquid chromatography (GLC).[1–4] At the present time, this topic continues to interest investigators, particularly in connection with the universal chemical analysis system being developed.[5, 6] The methodology underlying such a system involves using a computerised standard reference data bank to derive individual retention parameters and functional relations between the retention parameters and the physicochemical properties of the substances analysed.

Considerable advances have been achieved in qualitative analysis with the aid of so called standard-free identification methods[7, 8] based on the correlations between retention parameters and various physicochemical characteristics of the substances being separated. An advantage of these methods is that they do not require the availability of the postulated components of the test mixture.

The interaction in the sorbate–sorbent system, which determines the chromatographic retention of a substance, is a result of the structural units of the molecule being brought into contact. The mathematical modelling of the retention, which reflects the characteristics of such interactions, gives rise to the possibility of not only identifying the compound but also of predicting the chromatographic behaviour of its molecule as a whole, i.e. of achieving a predictive calculation of retention parameters on the basis of the postulated structural formula.[9–12]

The correlations between the structure of substances and chromatographic parameters frequently assume the form of linear equations, although other types of functions are also possible: fractional-linear, third degree, etc.[13, 14] The retention parameters used in correlation equations are proportional to the free energy change associated with the chromatographic distribution process. The relations between the structures of the substances separated and their chromatographic parameters can be regarded as an example of the linear free energy relations (LFER).[15]

The correlations between the physicochemical properties of sorbates, obtained mainly on non-polar and weakly polar stationary phases, for which adsorption effects do not exert a significant influence on the retention parameters, are analysed in this review.

II. Dependence of retention parameters on the number of carbon atoms and the molecular mass

A relation of the following type is frequently used in practice for chromatographic identification:

$$R = an + b, \qquad (1)$$

where R are logarithms of the corrected retention time or volume, the specific or relative retention volume, or the retention index, a is a constant characterising the contribution of the interaction energy of a CH_2 group with the stationary phase, b is a constant reflecting the contribution of the interaction of the functional groups with the sorbent to the retention energy, and n is the number of carbon atoms. The validity of Eqn. (1) for homologous series of different compounds has been confirmed in both early[7, 16–18] and later[19–23] studies. A relation of type (1) is characteristic of a wide range of organic substances (Table 1).

A linear relation holds more accurately for non-polar stationary phases, the retention on which is determined by dispersion forces. However, it has been noted[2] that the first members of a homologous series do not obey a linear correlation. This effect is apparently due to the fact that the properties of the methyl (or methylene) group located close to a functional group change under the influence of the latter. It has come to be assumed that the linear relation (1) holds rigorously starting from the third or fourth member of a homologous series, but there have been frequent instances of the breakdown of the linear relation up to the fifth to eighth members[40] and above.[41] Rohrschneider[42] noted the breakdown of linearity in the series of n-alkanes up to C_9,

Table 1. Homologous series of compounds for which the linear relation (1) has been established.

Homologous series	R	Stationary phase	Refs.
C_9-C_{19} *n*-alkanes	$\lg t'_R$	Squalane, phases with cyano-groups	24
C_5-C_8 *n*-alkanes, alkenes	$\lg V_R$	Porapak Q, Polysorbate-2, Polysorb	25

Methyl esters of $C_{12}-C_{24}$ aliphatic acids	I	SE-30, OV-225, Silar 5CP	37
Methyl ethers of C_7-C_{17} phenols	$\lg V_g$	Apiezon L, poly(ethylene glycol succinate)	38
C_5-C_{14} esters	I	Squalane, Carbowax 1540	39

while Grigor'eva and Golovnya[43] showed that Eqn. (1) does not hold for any sequence of homologues containing more than 7–8 members. As regards the prediction of retention parameters, the above limitations extend over the interpolation range, the expansion of which leads to an increase in the error of the determination.[44]

The distortion of the linear relation is influenced by the parity of the number of carbon atoms: the free energy of solution increment for the methylene group in n-alkanes with an even number of carbon atoms is greater than in those with an odd number.[3]

The inaccurate determination of the 'dead' volume, the use of methane as the non-sorbable component, and the assumption that its retention volume is zero may also cause deviations from linearity. Reviews[45,46] have been devoted to these questions and to comparing the characteristics of the computational methods for the determination of the 'dead' volume.

In order to take into account the non-linear variation of retention parameters as a function of the number of carbon atoms, various equations have been proposed (Table 2). The majority of them describe the gas-chromatographic parameters of *n*-alkanes. Comparison of the retention parameters calculated by Eqns. (2)–(9) and determined experimentally showed that the highest accuracy of the calculation is achieved on the basis of Eqns. (4) and (8).[53] At the same time the error of the determination of retention indices by Eqn. (8), which is 3–6 units, restricts its application in identification with the use of a computer.[43]

The universal equation (10), describing the gas-chromatographic behaviour of all the members of any homologous series R_nX on stationary liquid phases of different polarity with an accuracy sufficient for the identification of homologues, including the first members, is free from this disadvantage.

It is easy to show that the change in the length of the hydrocarbon chain of the molecule by one CH_2 group (or another group or atom) leads to the corresponding change in the molecular weight of the compound, so that

$$R = aM_S + b, \tag{11}$$

where M_S is the molecular weight of the sorbate.

Eqn. (11), which was already noted by James,[56] has been confirmed in relation to various classes of compounds.[8,21,35,57] It is based on the enhancement of the dispersion interaction with increase in the volume and mass of the molecule and holds most rigorously for homologous series.[58,59] For non-polar systems, this relation is linear[60] and standard deviations of the calculated retention indices are 4–7 units[59] but can be also higher. They can be reduced with the aid of multifactorial equations. Thus the retention indices of 1-haloalkanes calculated by the equation $I = f(n, M_S)$ differ from the experimental values by 1–2 units.[61]

In polar systems, the correlation coefficient for Eqn. (11) is appreciably smaller[62] or this relation does not hold at all.[63]

Table 2. Non-linear equations for the calculation of the retention parameters in GLC as a function of the number of carbon atoms.

Homologous series	Equation	No. of equation	Refs.

n-Alkanes,, amines, alcohols, aldehydes, ketones, sulphides, carbamates, alkylbenzenes	$I = an + b(\lg n)/n + c/[(n-2)^2 + 0.1] + d$	(10)	43, 53–55

III. Correlation between the retention, the vapour pressure, and the boiling point

A linear relation between the retention and the vapour pressure of the sorbate is valid for homologous series:

$$\lg V_g = a \lg p^0 + b. \quad (12)$$

It can be obtained from the fundamental Herington equation and the dependences of the vapour pressure and the activity coefficient on the number of carbon atoms in the molecule.[64]

Eqn. (12) holds over a wide temperature range up to a pressure of several atmospheres and can be used for identification.[3] The correlation improves if a term incorporating the activity coefficients of substances analysed is introduced into Eqn. (12).[4,64]

Dimov and Shopov[11] proposed a more accurate equation for the calculation of the retention indices of hydrocarbons on non-polar phases:

$$I_{p^0,v^0} = 100\frac{\lg(p_n^0 v_n^0/p_x^0 v_x^0)}{\lg(p_n^0 v_n^0/p_{n+1}^0 v_{n+1}^0)} + 100n, \quad (13)$$

where v_x^0, v_n^0, v_{n+1}^0 are the molar volumes of substances x and of n-hydrocarbons containing n and $n+1$ carbon atoms. Since the retention indices calculated by Eqn. (3) differ from the experimental Kovats indices, corrections must be applied in order to convert I_{p^0}, v^0 into I. The error of the calculation for isoalkanes in squalane is then reduced to 1.4 units, but the number of empirical corrections becomes as much as five, which renders the calculation extremely complex and cumbersome.

Relations similar to Eqn. (12) have been found for isoalkanes and cycloalkanes,[65] aromatic hydrocarbons,[32] and the hydrocarbons in petrol [gasoline] fractions.[66]

The linear dependence of retention parameters on the vapour pressure on non-polar phases has been widely used for the solution of the converse problem: the determination of the vapour pressure from GLC data.[13] The boiling points of compounds are most often used for the determination of correlations with chromatographic retention parameters. The simultaneous solution of Eqn. (12) and

$$\lg p^0 = b - aT_b$$

yields

$$R = aT_b + b. \quad (14)$$

Eqn. (14) does not hold rigorously even for homologous series, since the dependence of the boiling point on the number of carbon atoms is non-linear.[3] In homologous series, an increase in the boiling point per methylene group is approximately constant. However, in reality this difference between the boiling points diminishes with increase in the number of carbon atoms, i.e. it depends on the type of homologous series and M_S. Thus the difference between the boiling points for successive C_9-C_{16} n-alkanes decreases from 23.5 to 17.0 °C.[67]

Over a wide range of boiling points, deviations from linearity are observed even for hydrocarbons, especially for the lower members of this series.[3,68] These deviations are most notable in series of polar compounds such as phenols,[69] pyridines, quinolines,[60,70] etc.[71] Table 3 presents a list of homologous series for which Eqn. (14) is valid.

When a two-parameter relation $I = f(T_b, n)$ is used, the linear correlation improves and the predictive power of the computational method for the determination of retention indices increases.[34,84] A similar equation for esters may include the numbers of carbon atoms in the acid and alcohol fragments.[19]

The generalised dimensionless parameter φ, called the retention number, is used for the identification of related compounds:[3,13]

$$\varphi = \frac{\lg V_{g_x} - \lg V_{g_1}}{\lg V_{g_2} - \lg V_{g_1}} = \frac{T_{b(x)} - T_{b(1)}}{T_{b(2)} - T_{b(1)}},$$

where V_{g_x}, V_{g_1}, V_{g_2}, $T_{b(x)}$, $T_{b(1)}$, and $T_{b(2)}$ are respectively the retention volumes and boiling points of the related substances: the unknown substance x and the known substances 1 and 2. In the calculation of φ, it is essential to use standard compounds belonging to the same homologous series as the test substance. When n-alkanes are used as reference substances, the parameter φ acquires the functions of the temperature retention index, which is unambiguously related to the Kovats index. The index φ is independent of the temperature of the analysis and the stationary phase.

It has been established[85] that the relation between the retention indices and boiling points is most accurately described by an expression similar to the Antoine equation:

$$T_b = A - \frac{B}{I + C}$$

The standard deviations of the boiling points calculated from the retention indices of polar compounds are 3.3 °C on polar stationary phases, 2.3 °C on non-polar phases, and less than 1.1 °C for hydrocarbons.

Using the principle of linear free energy relations, Sojak[86] obtained a modified Hammett equation for the relation between the retention indices of alkylbenzenes and their boiling points:

$$\lg T_{b(a)} = \lg T_{b(t)} - \frac{1}{\rho}\left(\lg \frac{I_t}{I_a} - b\right), \quad (15)$$

where $T_{b(a)}$ and $T_{b(t)}$ are respectively the boiling points of the alkylbenzene and toluene (adopted as the standard), I_a and I_t are the retention indices of the alkylbenzene and toluene respectively, and ρ and b are constants. The maximum deviations of the boiling points calculated by Eqn. (15) do not exceed 0.6 °C and those of the retention index do not exceed 0.6 unit.

The use of the universal equation (10) made it possible to achieve the predictive calculation of the boiling points of members of homologous series of polar organic compounds (such as amines, alcohols, carboxylic acids, and their nitriles) with a high accuracy: the standard deviation of the calculated boiling points T_b did not exceed 2 °C.[87]

The widely used second Kovats rule,[88] based on the similarity of properties, reflects a linear correlation between I and T_b for isomeric compounds on non-polar stationary phases:

$$\delta I = k\,\delta T_b,$$

where δI and δT_b are respectively the differences between the retention indices and boiling points for two isomers and $k = 5$ is a proportionality coefficient.

Further studies showed that k differs from 5 for certain isoalkanes and isoalkenes.[3] Wide ranges of values of k have been found for alkylbenzenes (1.7–8.2)[31, 89] and alkylpyridines (0.8–6.4).[60] For isomeric C_{10}–C_{11} alkylquinolines, k = 3.9–4.2 on OV-101 and increases with increasing polarity of the stationary phases.[57, 90]

An important characteristic is the temperature coefficient of the retention indices dI/dT, which is frequently used for the identification of components.[91] The identification is based on the dependence of the temperature coefficients on the molecular structures of the substances analysed: on the degree of saturation and branching,[92] on the number of carbon atoms,[93] and on the position of the multiple bond.[27, 28] Sojak and coworkers have shown[86, 94] that the temperature coefficients for alkylbenzene vary within comparatively wide limits and reflect the fine structure differences between the hydrocarbons: they are directly proportional to the polarity of the stationary phases and inversely proportional to the symmetry of the molecules and the number of their alkyl substituents.

Relations have been established between the quantities dI/dT and the molecular structures of amines,[8, 35] alkylpyridines,[60] alkylquinolines,[57, 90] alkylphenols,[38] alcohols and ethers,[34] and hydrocarbons.[31, 32, 89, 95]

IV. Dependence of the retention on the molecular refraction and the dipole moment

In systems formed by polar and weakly polar phases, the chromatographic retention is determined by the strength of the dispersion forces, which is proportional to the polarisability of the substances interacting, i.e. to their refractions. It has been shown[96] that the dependence of the logarithms of the retention volumes of substances in a homologous series on the molar refraction is expressed by a linear function:

$$\lg V_g = aR_M + b. \quad (16)$$

Numerous publications indicate that Eqn. (16) is valid for different homologous series of organic substances.[60, 97–99] Thus the correlation coefficient for the equation

$$I = aR_M + b$$

reaches 0.999–1.000 for the homologous series of hydrocarbons on non-polar and weakly polar phases with a standard deviation of 0.5–2.0 units. For cycloalkanes, the analogous data are 0.990–0.997 and 3.4–4.4 units respectively.[98] The impairment of linearity for cycloalkanes is apparently associated with the manifestation of the effect of intramolecular shielding.

In order to improve the correlation, the specific and molar refractions are frequently used in two-parameter equations in combination with T_b,[76, 77, 99, 100] the dipole moment,[101] or the Hammet constant.[102]

Multiple correlation equations including the molar refraction and the refractive index as independent variables are used for the description of various mechanisms of the intermolecular interaction.[74, 76, 103]

Equations of type (16) make it possible to determine the molar refractions from GLC data with a high accuracy.[104, 105] Thus the average value of R_M for *n*-pentylbenzene, calculated from five equations for different polyester phases, is 50.00, while the value found from familiar formulae using the experimental densities and refractive indices is 49.96.[98]

According to the theory of intermolecular interactions, the dipole moments of substances exert a direct influence on their retention in GLC.[56] The retention indices of alkyl halides are related to the dipole moments as follows:[106]

$$\Delta I_{130} = 6\Delta R_M + 50\mu_{C-X},$$

where ΔI_{130} is the difference between the retention indices on polar and non-polar stationary phases at 130 °C, ΔR_M is the difference between the refractions of the C–X and C–H bonds (X = halogen), and μ is the dipole moment of the C–X bonds.

Franc[107] established a linear relation between the relative retention times and the dipole moments of isomeric alkylphenols, aromatic amines, and nitro-compounds:

$$\lg V^{rel} = a\mu + b. \quad (17)$$

It is noteworthy that the dipole moment enters into Eqn. (17) with an exponent of unity. This conflicts with the equation for the orientation interaction energy.[108] At the same time, the majority of compounds are characterised by having a quadrupole moment as well as the dipole moment.[109] The factors listed are the cause of the appreciable deviations from linearity when Eqn. (17) is used.[62, 109, 110] Therefore Eqn. (17) holds only for a limited number of compounds belonging to separate homologous series.[71, 78] The replacement of μ by μ^2 in Eqn. (17) makes this relation valid for the estimation of the orientation and inductive interaction energies.

Sakharov[111] suggested that the difference between the retention parameters of two substances having equal molar refractions be determined as follows:

$$RT\Delta \lg V_g = \frac{2}{9}\frac{\Delta\mu^2}{r^3}\left(1 - \frac{1}{\varepsilon}\right), \quad (18)$$

where $\Delta\mu^2$ is the difference between the squares of the dipole moments of the sorbates, r is the molecular radius, and ε the dielectric constant of the solvent. The requirement that the molar refractions are equal is stipulated to eliminate the effect of the electronic polarisability.

Eqn. (18) makes it possible to estimate the dipole moments of substances from GLC data with a greater accuracy than Eqn. (17). In the derivation of Eqn. (18), a simplified model of the interaction of the sorbates and the stationary phase, which does not take into

account the mutual polarisation of two molecules, was used. According to Onsager,[112] when account is taken of such polarisation, the following relation should hold:[113]

$$RT \lg V_g = \frac{\Delta\mu^2}{r^3} \frac{\varepsilon - 1}{2\varepsilon + 1}. \quad (19)$$

It is widely used to characterise the intermolecular interaction in various systems.[113-115]

In the multiple regression equations employed, the dipole moment functions as a descriptor of the polarity of the solute.[35,62] Apart from the dipole moment, such equations include the molecular weight, the sum of the steric factors,[62] the molar refraction,[116] the number of carbon atoms, the ionisation potential, the sum of the steric factors,[35] the molecular connectivity index,[117,118] and topological, electronic, and quantum-chemical parameters.[119,120] the correlation coefficients for the proposed equations are fairly high, amounting to 0.740–0.975 on polar phases and to 0.940–0.999 on non-polar phases.

At the same time, the use of the dipole moment of the molecule for the description of the intermolecular interaction does not correspond to the real nature of the orientation interaction.[121] It is known that specific interactions between the molecules of sorbates and the stationary phase depend to a greater extent on the local polarity of these molecules than on the overall dipole moment.[119-122] The electronic topological index (ETI) has been proposed for the quantitative description of the differences between the polar properties of sorbates.[123] It is calculated by the summation of the absolute differences between the excess charges on all the atomic pairs of the given molecule divided by the squares of the corresponding interatomic distances. The correlation equations based on the ETI have a high level of statistical significance for chromatographic parameters obtained on both non-polar and polar stationary phases.

Among other parameters associated with the energy characteristics of sorbates and used in correlations, mention should be made of the electronic polarisability,[13,124] the ionisation potential,[60,98,125,126] the diamagnetic susceptibility,[98] the electron density in molecules,[127] and the resonance energy of the π-electron system.[128]

V. Relation between the retention and the molar volume of the sorbate

The dependence of the retention indices on the molar volume follows from Eqn. (13), which has been used to predict the retention indices of different hydrocarbons.[129] It has been shown[64,131] in relation to alkylsilanes,[130] alcohols, hydrocarbons, and their derivatives that the relation between the retention parameters and the molar volumes of sorbates is linear:

$$I \text{ (or } \lg V_g) = aV_M + b. \quad (20)$$

The validity of Eqn. (20) has been confirmed for short homologous series of aromatic hydrocarbons (r = 0.999 and above) but for the series of C_6–C_{11} alkylbenzenes the correlation coefficient was found to be only 0.88 on squalane and 0.77 on PEG-20M.[99] The correlations considered can be improved with the aid of two- and three-parameter equations including the boiling point and the specific refraction together with V_M as independent parameters.[76,77] The correlation coefficient for such an equation reaches 0.998 on polar stationary phases and more than 0.999 on non-polar ones.

Other physical properties of sorbates which have found applications in correlations include the heat and energy of formation,[13] surface tension,[64] density,[64,68,97,132] viscosity,[133] and heats of crystallisation, evaporation, and combustion.[134,135] Since such characteristics have been determined for a small number of compounds, the possibility of predicting the retention parameters on their basis is extremely limited.

VI. The retention parameters and the principle of linear free energy relations

The interaction of a substance with the stationary phase, determined by the free energy change, can be described by the Hammett equation:[136]

$$\lg \frac{R}{R_0} = \rho\sigma, \quad (21)$$

where R and R_0 are the retention parameters of the given and standard compounds, their ratio being a measure of the free energy change on passing from the standard component to the given component within the limits of the homologous series investigated, σ is the inductive constant of the substituent which serves as a quantitative characteristic of the effect of the substituent on the electron density at the given centre, and ρ is a constant characterising the stationary phase.

The linear relation between the retention parameters of aromatic hydrocarbons and the Hammett constants of stationary phases was first noted by Araki and coworkers and by Nabivach and coworkers[137-140] and was then discovered for a whole series of similar systems.[141,142] This relation was subsequently used to characterise the selectivity of solvents—with the aid of the ratio of the activity coefficients of the sorbates.[143]

The application of the Hammett constants proved to be extremely useful when there is a significant contribution by the specific interaction forces (for example, by the donor–acceptor bond) to the overall intermolecular interaction energy. The series of correlations

$$\lg \frac{R}{R_0} = a\sigma + b$$

(σ is the Hammett constant for the corresponding substituent in the sorbate molecules) have been established for derivatives of phenol, aniline,[144-147] methyl benzoates,[145] alkylbenzenes,[148,149] and nitrobenzenes.[150]

The Taft equation has come to be widely used for the description of the characteristics of intermolecular interactions:[151]

$$\lg \frac{R}{R_0} = \rho^*\sigma^*, \quad (22)$$

in which the parameters R_0, ρ^*, and σ^* are analogous to the corresponding quantities in Eqn. (21). It is assumed that the constant σ^* characterises the purely inductive polar effect of substituents. The linear relation based on Eqn. (22) has been demonstrated for series of alkylbenzenes,[98,149] haloalkanes, halo-derivatives of epoxy-compounds, ethers,[115,152] ethoxyalkanes, amines, alcohols,[153] and alkylquinolines.[57,90]

A method has been proposed for the determination of the induction constant of the methyl group (arbitrarily assumed to be zero) for which the principle of the additivity of the change in the quantity σ^* corresponding to a change in the length of the alkyl group of alkylbenzenes per methylene group holds under GLC conditions.[98] An experimental test confirmed the legitimacy of such calculation of σ^* for the methyl group based on the correlation with the retention indices for different series of alkylbenzenes.

A complex equation has been proposed for the calculation of the retention indices of aniline, phenol, and pyridine derivatives:[154]

$$\Delta \lg V_N = \rho_I\sigma_I + \rho_R\sigma_R + \rho_E\sigma_E,$$

where σ_I, σ_R, and σ_E were derived from literature data with the aid of factorial analysis and were found to be close to the corresponding Taft induction and resonance constants.

The Taft equation for the estimation of the steric effect of substituents[151]

$$\lg \frac{R}{R_0} = \delta E_S, \quad (23)$$

where E_S are the steric constants of the substituents, can be used to characterise the quantitative measures of the steric effects of individual groups in the vicinity of the reaction centres of molecules, in the separation of polar compounds on polar stationary phases. Experimental data have shown that the Taft[57,90,149] and Palm[57,90,155] steric constants as well as their sum[62,102] can be used with equal success in equations of type (23).

In order to increase the correlation coefficient for Eqn. (23) for a series of aromatic hydrocarbons containing branched substituents (for example, butylbenzene isomers), a corrected Palm constant has been proposed:[98]

$$E^0_{S_{cor}} = E^0_S - \varphi,$$

where E^0_S is the Palm steric constant and φ is the contribution of the φ-interaction arising between the groups of the substituent linked directly.[15] The use of $E^0_{S_{cor}}$ instead of E^0_S increases the correlation coefficient of Eqn. (23) for butylbenzene isomers from 0.87 to 0.99.

By combining Eqns (22) and (23), we obtain the Hammett–Taft equation, which makes it possible to describe more complex types of intermolecular interaction[156,157] and to estimate quantitatively the role of each effect.

The Hammett–Taft equation has been improved by French investigators,[153,158] who proposed the following relation:

$$\lg t'_R = \rho^*\delta^* + \delta E_S + h(n_H - 3),$$

where n_H is the number of hydrogen atoms at the carbon atom in the α-position relative to oxygen. Assessment of the resulting coefficients showed that the contribution of E_S is much smaller than the contributions of the remaining terms of the equation, which can be rewritten in the form

$$\lg t'_R = \rho^*\delta^* + h(n_H - 3).$$

The application of this equation to a series of oxygen-containing compounds yielded satisfactory results.

VII. The use of the principle of the additivity of properties for the prediction of retention parameters

A general relation for the calculation of the chromatographic retention, based on the additivity of the contributions by structural fragments, has been proposed by Berezkin and coworkers:[159,160]

$$R = \sum_{ij}^{K} n_{ij}C_{ij} + C_0, \qquad (24)$$

where C_{ij} is the contribution of a particular structural fragment (atoms, a group of atoms, bonds) to R, and n_{ij} is the number of structural fragments in the molecule. Bonds were selected as the computational structural fragments taking into account the immediate environment. If more distant environment is also taken into account, it is possible to obtain more accurate results.

The simplest expression for the additivity rule—Eqn. (1)—is a special case of Eqn. (24). Eqns (11), (14), and (20) are also special cases of this kind.

The principles formulated by Berezkin have found applications in the predictive calculation of retention parameters in accordance with an additive scheme by the summation of increments corresponding to subtypes of bonds between carbon atoms[3,161] or functional groups.[162]

The additivity of the retention characteristics considered logically presupposes also the additivity of the retention indices,[162] whose calculation is based on the principle of the additivity of the intermolecular interaction energies for individual groups of molecules.[106]

The increments in the differences between the retention indices, measured on stationary phases of different polarity and reflecting the specific interaction between the test molecules and the stationary phase, are also additive.[163–166]

The functional retention index proposed by Swoboda[167] reflects the dispersion and specific interactions of the functional group of the sorbate with the sorbent:

$$H_X = I_{R-X} - I_{R-H},$$

where X is the functional group and R–H the homomorphic n-alkane with the same number of carbon atoms. The functional group is understood not only as a group containing a heteroatom but also as any structural group differing in its multiple or aromatic bond or in the arrangement of carbon atoms in space.

Schomburg[9] proposed that the quantity H be called the homomorphy factor and showed that it is extremely sensitive to the characteristics of the fine structure of the molecule.[168]

Andersons and coworkers[8,35] introduced the concept of two homomorphy factors: H_H describes the effect of the substitution of a hydrogen atom by a functional group and H_C describes the effect of the substitution of a carbon atom by a heteroatom or a group of atoms.

Among compounds for which the values of H have been determined and the corresponding correlations with the structure have been established, mention should be made of cycloalkanes, cycloalkenes, cycloalkadienes,[93] alkylbenzenes,[20,89,169] alkylnaphthalenes,[170] alkylpyridines,[60] amines, alcohols, and ethers.[8,35]

Extensive experimental data on the increments for various functional groups or individual fragments, used in accordance with Eqn. (24) for the predictive calculation of retention indices and for the identification of components of complex mixtures, are available in the literature.[171–173]

The principle of additivity breaks down when the structural fragments of the molecule are close to one another, on passing from unbranched to branched compounds, and with increase in the polarity of stationary phase and in the capacity of the functional group for specific interactions.

The non-additivity of the retention indices and their increments in homologous series is also indicated by data in numerous publications.[174,175] Correction coefficients are usually introduced in such cases or one calculates second-order increments, taking into account the positions and interaction of functional groups, the nature of the bonds in the molecule, steric factors, and other effects of substitution and the environment.

The causes of non-additivity and procedures for the reliable prediction of retention indices based on allowance for the non-identity of the energy contributions of identical alkyl groups have been described in detail.[179–185]

One of the causes of the breakdown of additivity is the presence in the molecule of a heteroatom or a functional group, the degree of shielding of which by neighbouring alkyl groups affects appreciably the specific forces of the interaction of the test substance with the stationary phase. Linear relations for such compounds (alkylphenols, alkylpyridines, alkylquinolines, alkylanilines, etc.) are therefore characterised by a low correlation coefficient. In order to take into account the shielding effect, the entire set of compounds (for example, alkylpyridines) can be usefully divided into three groups: alkylpyridines with a non-shielded nitrogen atom, i.e. with alkyl groups in the 3-, 4-, and 5-positions, alkylpyridines with one alkyl group in the *o*-position relative to the nitrogen atom, and alkylpyridines with two alkyl groups in the 2- and 6-positions.[165] Such subdivision is based on the change in the π-electronic charges on the reaction centre under the influence of the alkyl groups introduced into the molecule. This factor is responsible for the linear variation of the basicity of alkylpyridines as a function of the groups indicated, which makes it possible to represent the dependence of the retention indices on the dissociation constants of alkylpyridines by three equations, whose correlation coefficient is 0.995.

The system for the predictive calculation of retention indices developed by Takacs and coworkers[186-188] provides for the use of not only the properties of the pure sorbates but also of the characteristics of their interaction with the stationary phase:

$$I = I_a + I_b + I_i,$$

where I_a is the contribution of atoms, I_b the contribution of bonds, and I_i the contribution of the interaction in the sorbate and the stationary phase.

The Takacs system is based on the separate determination of all the factors responsible for the chromatographic retention of the test substance; its undoubted advantage is the use of molecular constants instead of empirical characteristics or sorbates such as the boiling point, the vapour pressure, and the molar refraction. At the same time, the semiempirical nature of the determination of the components of the index and the need to calculate a large number of empirical parameters give rise to considerable difficulties in the practical application of this system.[189]

VIII. Calculation of retention parameters with the aid of structural and topological parameters

The effect of molecular size on chromatographic retention was first noted by Hively and Hinton,[92] who concluded that the quantity dI/dT increases with increase in the cross-sectional area of the isoalkane molecule.

Similar results were obtained by Littlewood[190] for *n*-alkanes and their derivatives, whose retention is proportional to the surface area of the molecules calculated with the aid of a computer.

Altenburg[3,191] developed a method for the determination of the retention indices of hydrocarbons and their derivatives based on the correlation with the square of the molecular radius:

$$I = I_0 + bM_S d + \frac{c\overline{R^2}}{a_1^2},$$

where d is the density of the hydrocarbon, I_0 a constant which depends on M_S, $\overline{R^2}$ the mean square molecular radius, a_1 the length of a carbon–carbon single bond, and b and c are constants of the equation.

More accurate results were obtained by using equations including, together with $\overline{R^2}/a_1^2$, the boiling point:[3,68]

$$I = a + b(T_b - 273.15) + \frac{c\overline{R^2}}{a_1^2},$$

$$I = a + b(T_b - 273.15) + C(T_b - 273.15)^2 + \frac{D\overline{R^2}}{a_1^2} + E\left(\frac{\overline{R^2}}{a_1^2}\right) + Fd + Gd^2.$$

The error of the calculated retention indices of isoalkanes varies in the range 0.3–5.5 units. For example, equations of the following type are valid for the homologous series of alkylbenzenes:

$$I = f\left(\frac{\overline{R^2}}{a_1^2}\right)$$

with a correlation coefficient of 0.994 and above.[192,193]

Correlation equations relating the retention index to the shape parameters of the molecules, which have been calculated on the basis of the van der Waals radii of the hydrogen atom for polycyclic aromatic hydrocarbons[194] or the van der Waals surface areas for polychlorinated dibenzofurans,[195] have been proposed.

Correlations based on the van der Waals volumes of sorbate molecules V_W have come to be widely used. Hammers and De Ligny[196] already showed that the thermodynamic functions of solution in squalane, calculated from the retention volumes, are linearly related to V_W for hydrocarbons in different homologous series.

Linear relations between retention indices and the van der Waals volume have been observed for the homologous series of alcohols, ketones, aldehydes, ethers,[197] *n*-alkanes and isoalkanes,[198] ketone derivatives,[21] alkylbenzenes[99,105,199] and alkylphenols.[200] The correlation coefficients of such equations are 0.999–1.000 for hydrocarbons on non-polar phases and 0.994–1.00 for other compounds. When the above relation is applied not to short homologous series but to the entire set of isomeric compounds (for example, alkylbenzenes), the correlation coefficient falls as a function of the polarity of the stationary phases to 0.88–0.98. The level of correlation can be improved by combining V_W with characteristics of sorbate such as the boiling point, the refractive index, and the specific refaction within the framework of three- and five parameter equations.[76,79,99,197]

When correlations in the structure–retention system are considered, various methods for the conversion of molecular structures into unique characteristic structural descriptions, expressed by numerical indices, are very promising. For this purpose, one uses chemical graph theory, according to which the chemical structural formula of a compound is expressed by a mathematical graph. The mathematical graph describes abstract vertices connected by faces. Each molecular graph can be represented either by a matrix, or by a polynomial, or by numerical index (topological index).[201] The topological index contains information about the size and shape of the molecule, about the connections between atoms and structural groups, and about their mutual disposition.[202]

More than 40 different topological indices are known at the present time. An approximate classification, the characteristic principles of the derivation of topological indices, and their realistic possibilities as a means of describing chemical structures when correlations of the structure–property type are considered have been described in detail in a number of reviews.[201-208a]

The topological index W proposed by Wiener[209] for the comparison of carbon skeletons is defined as the sum of the C–C bonds between all the pairs of carbon atoms in the molecular graph:

$$W = \frac{1}{2}\sum_{ij} D_{ij}.$$

The smaller this number, the more compact the corresponding structure.

Correlations between the Wiener index and the chromatographic retention parameters of various hydrocarbons have been described.[105,199,210-212] A disadvantage of the Wiener index is the fact that part of the information contained in the distances matrix is lost during the summation of its elements. This explains the finding that the values of W referring to different isomers frequently overlap. It has been established that, compared with W, a higher level of correlation is ensured by the molecular connectivity index.[105,199,212]

The concept of the connectivity index, which is one of the most popular topological indices in theoretical chemistry, was introduced by Randic.[213] Later this method of topological analysis was used as a basis of the molecular connectivity system.[214]

Molecular connectivity constitutes a topological description of the molecular structure and represents mathematically coded information about the size of the molecule, the degree of its branching, cyclisation, and unsaturation, and about its content of heteroatoms. The first-order connectivity index is most common:[214]

$$^1\chi = \sum_{q=1}^{K} (\delta_i \delta_j)^{-1/2}, \qquad (25)$$

where δ is the difference between the numer of valence electrons and the number of hydrogen atoms connected to the given atom, i and j are the atoms of the molecule formally connected by the bond under consideration, δ_i and δ_j are the values of δ for two

atoms involved in a bond q, and K is the total number of bonds in the molecule.

The second-order to fourth-order and higher-order connectivity indices are calculated similarly. These take into account the numbers of two, three, four, and more of neighbouring bonds respectively. In Eqn. (25), the first-order connectivity index takes into account the pair interactions of neighbouring atoms in the molecule. A disadvantage is that it does not distinguish the *m*- and *p*-isomers of aromatic compounds. Higher-order connectivity indices, taking into account not only the nearest pair interactions but also remote interactions between atoms in the molecule, ensure a more complete description of the structural features of the test compounds.

Thus molecular connectivity is a fundamental parameter and expresses structural information in the form of a weighted sum of all the types of bonds in the molecule. Compared with other indices, the molecular connectivity model is more flexible, since it makes it possible to relate both general and local structural properties of molecules.

The application of connectivity indices in GLC in order to establish the sorption-structural correlations for different compounds has proved especially fruitful.[77,100,215–221] Table 4 presents data on the correlations based on connectivity indices. A significant advantage of this index compared with the Wiener index is the possibility of describing a compound with polar functional groups. Although a high level of correlation is observed mainly on non-polar phases, it does not reduce the practical value of the proposed equations.[76,239–242]

The application of multiparameter equations, including, apart from the connectivity indices of different orders, also other physicochemical constants of sorbates (the number of carbon atoms, the boiling point, the molar refraction, the dipole moment) makes it possible to increase the correlation coefficient of the equations and to reduce the standard deviation.[241,243] It has been concluded that satisfactory results for compounds of different classes are obtained when a multiparameter equation of the following type is used:[105,199,200]

$$I = f(V_w, {}^1\chi \ldots {}^n\chi_m), \qquad (26)$$

where n is the order of the connectivity index and m the designation of the chain or branching index. In Eqn. (26) the van der Waals volume describes the size of the solute and the connectivity indices of different orders characterise the fine structure features of its form. A close relation has been noted[244] between the indices obtained in accordance with graph theory and by quantum-chemical methods.

Eqn. (26) has been successfully tested for alkylbenzenes and alkylarylcarbamates,[105,199,245] alkylphenols,[200,246] alkylquinolines,[247] aliphatic alcohols,[248] and alkylanilines.[249] The correlation coefficients of the above equations are 0.996–1.000 and the standard deviations are 0.5–8.0 units.

The program packs developed for the calculation of connectivity indices[250–252] and also the combined program for the determination of sorption–structure correlations on the basis of topological indices[253] greatly facilitate chromatographic identification and permit its automation using computers.[2,254]

Another topological system (DARC)[255] involves the arbitrary specification in each molecule of a focus (the given functional group) and its environment—the first, second, third, and subsequent spheres. The reliability and accuracy of the calculations increase with increase in the number of surrounding spheres taken into account. This leads to an increase of the prespecified empirical parameters for the calculation, whose number can reach 2000 and more.[256]

Despite the complexity of the calculations and the large amount of the information used, the accuracy attained in the determination of the retention indices varies within wide limits (3–48 units). Comparison with other computational methods showed that the DARC system has no special advantages and its use for the prediction of the retention parameters involves considerable difficulties.[2]

Analysis of the studies examined shows that the simplest correlations between chromatographic retention and the physicochemical properties of sorbates can be used for a homologous series of compounds in order to characterise their retention on non-polar stationary phases. However, the prediction of the retention parameters is then rather difficult, since physicochemical properties have been determined for a limited number of substances.

Table 4. Characteristics of the correlation equations based on connectivity indices.

Compound	Equation	Stationary phase	Correlation coefficient	Standard deviation	Refs.
n-Alkanes, isoalkanes	$I = a^1\chi + b$	Squalane	0.994	17.3	198
	$\lg t_R^{rel} = a^1\chi + b$	Dimethylsulpholan	0.996	0.1	222
Alkylbenzenes	$I = a^1\chi + b$	Squalane, SE-30	0.999–1.000	–	223
Alkylnaphthalenes	$I = f({}^1\chi \ldots {}^5\chi_p)$	Hepta(phenyl ether)	0.998	4.8	224
Polycyclic aromatic	$I = a^1\chi + b$	SE-52	0.996	8.8	225
hydrocarbons (PAC)	$I = a^1\chi + b$	0V-101	0.998	36.9	226
Nitro-derivatives of PAC	$I = f({}^0\chi \ldots {}^5\chi_p)$	SE-52	0.999	2.3	227
Chloroalkanes	$I = f({}^1\chi, {}^5\chi_p, {}^5\chi_{pc}, {}^6\chi_p)$	PEG-20M	1.000	–	228
Chlorobenzenes	$I = f({}^1\chi, {}^4\chi_{pc})$	SE-30	0.988	–	229
Chlorobiphenyls	$\lg t_R^{rel} = f({}^1\chi, {}^4\chi_{pc}, {}^5\chi_p)$	SE-54	0.999	0.006	230
Alkylpyridines	$I = f({}^0\chi \ldots {}^5\chi_{pc})$	0V-1	0.996–0.999	3.6–8.4	231
Nitrogen-containing heterocycles	$I = f({}^1\chi, {}^4\chi_{pc}, {}^5\chi_p, {}^6\chi_p, {}^6\chi_{pc})$	0V-1	0.960	54.0	232
Alkylpyrimidinone derivatives	$I = a^1\chi + b$	0V-1	0.970	–	233
Cyclic methyl esters and alcohols	$I = a^1\chi + b$	SE-30	0.952	32.2	234
Aliphatic alcohols	$I = a^1\chi + b$	Squalane	0.950	–	235
	$I = a^0\chi + b^1\chi + c$	Squalane	0.994	–	236
Esters	$I = a^1\chi + b^4\chi_p + c$	Squalane	0.996–0.998	–	237
Ethers	$I = a^1\chi + b$	Squalane	0.968	–	236
5,5-Disubstituted barbiturates	$I = a^1\chi_N + b$	SE-30	0.996	–	238

Correlation equations taking into account the deviations from additivity in the intermolecular interaction energy [in particular the universal equation (10)] as well as equations based on the structural and topological parameters of compounds (for example, the van der Waals volume and the connectivity indices) are more reliable and promising. Such sorption–structure correlations can be used in schemes for the automatic identification of complex mixtures with the aid of computers.

Abstract. Processes bringing about amplification of the primary photoeffect in polymer layers through complex formation, autocatalysis, autosensitisation, and acid catalysis are discussed and their practical applications are considered. Attention is concentrated on highly sensitive photoresists for the photolithographic process used in advanced technologies. The bibliography includes 114 references.

I. Introduction

The problem of the amplification of the primary photoeffects on polymer systems is of cardinal importance because it is based on fundamental phenomena such as spectral and chemical sensitisation, complex formation, and electronic excitation energy and charge transfer. Furthermore, the use of amplification processes makes it possible to create highly sensitive polymer layers for the optical recording of information and highly sensitive photoresists and electronic resists and also to achieve directed far-reaching modification of polymer layers.

Systems in which the amplification processes occur with participation of components present in the polymer layers and do not require additional treatment of these layers in liquid or gaseous media, in contrast to, for example, well known photographic materials with chemical or physical development of the latent image in developer solutions, are considered below. The amplification coefficient of the primary photoeffect is equal to the ratio η_{ef}/η_0, where η_0 is the quantum yield of the formation (consumption) of the products of the primary action of light and η_{ef} is the effective quantum yield measured after the amplification of the primary effect.

These systems can be used in fields such as highly sensitive optical recording of information, detection of weak optical signals, photomodification of spectral and physicochemical properties of polymer layers, and selective photosynthesis of a series of chemical compounds in polymer matrices.

In the present communication, attention is concentrated on processes involving the amplification of the primary photoeffects in polymer layers in order to create on their basis highly sensitive photoresists for use in photolithography. In the first stage of the photolithographic process, photochemical reactions in polymer layers result in a change in the physicochemical properties of the exposed sections such as solubility, thermal stability, light transmittance, etc. On subsequent heating, treatment in solvents, or plasmachemical etching, the exposed (positive) or unexposed (negative) sections are fully removed from the support. The next stage of the photolithographic process is the treatment of the support (a plate made of silicon, a metal, or another material) through apertures obtained in the polymer layer (resistor) by etching or in some other way.[1–3] We emphasise that photolithography based on the use of photoresists has in fact made it possible to achieve a qualitative major advance in electronics—the introduction of the manufacture of integrated circuits.

The high sensitivity of polymer compositions to the action of light, X-rays, and electron irradiation is ensured by the electron donor – acceptor (EDA) interactions, the formation of aggregates from chromophoric groups, as well as autocatalytic,[4] chemical,[5,6] and optical[4,7] processes amplifying the primary photoeffects. In the systems considered below, catalysts are formed directly during the photochemical reaction or in the reaction of photoproduct with a compound introduced additionally—a chemical sensitiser. The mechanism of the optical amplification in the resist-free photoetching of metallic films by halogen-containing radicals, formed and deposited on these films of polymeric EDA compositions as a result of the dissociative addition of an electron to the halogen-containing acceptor, is also discussed.

A photoinitiated autocatalytic free-radical process is characteristic of the well known class of photoresists based on aromatic azides.[8] In order to create highly sensitive photoresists for use in microelectronics, detailed studies have been made in recent years, in connection with the manufacture and copying of optical [compact] discs, of the photoinitiated cross-linking of polyfunctional oligomeric acrylates in which $10^4 - 10^5$ cross-links arise as a result of a single photochemical act.[9]

The primary chemical stage of the photoprocess in polymeric EDA systems is electron transfer from the donor (D) to the acceptor (A). Compounds which dissociate into free radicals when acted upon by light, for example, ketones [R – C(O) – R'], are used as photoinitiators of the cross-linking of acrylates. This results in the formation of radical-ion pairs $[D^{\cdot+}...A^{\cdot-}]$ or radical pairs $[\dot{R}-\dot{C}(O)...\dot{R}']$. The spin – orbit and hyperfine interactions of the unpaired electrons determine the efficiency and mode of the subsequent reactions. Examples of reactions in which magnetic interactions exert an appreciable influence on the characteristics of the photoprocess are examined below.

II. The influence of spin–orbit and hyperfine interactions on the efficiency and mode of the photochemical reaction

The efficiency and mode of the photochemical reaction depend on the multiplicity of the radical-ion or radical pair formed as a result of the action of light. Indeed, the reverse electron transfer or recombination of radicals are allowed only for the singlet orientation of the radical-ion spins in the geminal pair $[D^{\cdot+}...A^{\cdot-}]$ or the radicals in the pair $[R-\dot{X}...\dot{R}']$ respectively:

$$\begin{array}{c} D+A \rightleftharpoons D\cdot A \\ D\cdot A \xrightarrow{h\nu} {}^1(D\cdot A)_1 \longrightarrow {}^1[D^{\cdot+}\ldots A^{\cdot-}] \longrightarrow [D\ldots A] \\ \downarrow \qquad\qquad \Updownarrow \\ {}^3(D\cdot A)_1 \longrightarrow {}^3[D^{\cdot+}\ldots A^{\cdot-}] \longrightarrow (D^{\cdot+}+A^{\cdot-}) \end{array} \tag{1}$$

$$\begin{array}{c} R-X-R' \xrightarrow{h\nu} {}^1[R-\dot{X}-R']_1 \longrightarrow {}^1[R-\dot{X}\ldots\dot{R}'] \longrightarrow R-X-R' \\ \downarrow \qquad\qquad \Updownarrow \\ {}^3[R-\dot{X}-R']_1 \longrightarrow {}^3[R-\dot{X}\ldots\dot{R}'] \xrightarrow{RH} R-XH+ \\ +R-R'. \end{array}$$

The spin forbiddenness of these reactions in triplet pairs increases the probability of the liberation of radical-ions from the pair and is also responsible for the preferential interaction of radicals with the compounds (RH) present in the composition. For this reason, the quantum yield of the free radical-ions or the mode of the photochemical reaction depend on the rate of intersystem crossing in the pair (i.e. on the rate of change of the spin of the unpaired electron in one of the radicals as a consequence of either spin–orbit interaction (SOI)[10] or hyperfine interaction (HFI)[11]. These interactions ensure an admixture of the singlet (triplet) configuration in the triplet (singlet) state of the pair:

$$\varphi^T[D^{\cdot+}\ldots A^{\cdot-}] = \varphi^3[D^{\cdot+}\ldots A^{\cdot-}] + \alpha\varphi^1[D^{\cdot+}\ldots A^{\cdot-}],$$

or

$$\varphi^S[D^{\cdot+}\ldots A^{\cdot-}] = \varphi^1[D^{\cdot+}\ldots A^{\cdot-}] + \alpha\varphi^3[D^{\cdot+}\ldots A^{\cdot-}].$$

The probability of intersystem crossing in the radical-ion pair is determined by the contribution of the singlet (triplet) state α^2, where

$$\alpha = \frac{1}{{}^1E - {}^3E}\int \varphi^1[D^{\cdot+}\ldots A^{\cdot-}]H_n\varphi^3[D^{\cdot+}\ldots A^{\cdot-}]. \tag{2}$$

Here ${}^1E-{}^3E$ is the distance between the the energy levels of the 'pure' S and T states in the radical-ion pair and $H_n = H_{SOI}$ and H_{HFI}, where H_{SOI} and H_{HFI} are the operators of the spin–orbit and hyperfine interactions respectively:

$$H_{SOI} = \sum_i \xi_i\rho_i\bar{l}_i\bar{S}_i\ ,$$

$$H_{HFI} = \sum_i a_i\bar{S}_i\bar{I}_i\ ,$$

where ξ_i is the SOI constant for the ith atom, $\bar{l}_i$ is the azimuthal quantum number of the atom, $\bar{\rho}_i$ and $\bar{S}_i$ are the density and spin of the unpaired electron on the ith atom, a_i is the HFI constant, and I_i is the spin of the ith nucleus. According to Buchachenko et al.,[11]

$${}^1E - {}^3E = 2J_0\exp[-(R-R_0)],$$

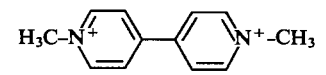
where $J_0\exp(-R_0) \simeq 1.5$ eV is the energy of the exchange interaction between the radical-ions separated by the van der Waals distance R_0. R is the distance between the radical-ions in the pair (Å).

It follows from Eqn. (2) that intersystem crossing occurs for distances between the radical-ions such that the following relation holds:

$${}^1E - {}^3E \leq \int \varphi^1[D^{\cdot+}\ldots A^{\cdot-}]H_n\varphi^3[D^{\cdot+}\ldots A^{\cdot-}].$$

Thus for SOI and HFI, intersystem crossing takes place with the greatest probability under the following conditions:

$$\begin{aligned} 2J_0\exp[-(R-R_0)] &\simeq \sum_i \xi_i\rho_i\ , \\ 2J_0\exp[-(R-R_0)] &\simeq \sum_i \alpha_i\ . \end{aligned} \tag{3}$$



In polymeric media, where the separation of the radical-ion components may be difficult, the probability of the S → T or T → S conversion increases with increase in ξ_i and α_i.

1. Spin–orbit interaction

The spin–orbit interaction constant ξ_i increases with increase in the charge on the nucleus (Z_i) with which the unpaired electron interacts:

$$\xi_i = \sum_i \frac{Z_i^4}{n_i^3}\ ,$$

where n_i is the principal quantum number of the ith atom. In liquid-phase donor–acceptor–sensitiser systems, where the donor is an amine (Am), the acceptor is Methyl Viologen (MV^{2+})

and the sensitisers are the organometallic complexes $M(L)_3^{2+}[M^{2+} = Ru^{2+}, Os^{2+}$; L = bipyridyl (bipy) or other ligands], electron transfer takes place with participation of the triplet-excited sensitiser. The equilibrium reduction potential of MV^{2+} is $E_{1/2}(MV^+/MV^{2+}) = -0.44$ V relative to the potential of the normal hydrogen electrode (n.h.e.).[12] Depending on the oxidation potential of the donor $E_{1/2}(Am/Am^{\cdot+})$, two types of electron transfer are possible. In one of them, the primary reaction is

$$\begin{array}{c} Am + {}^3[M(L)_3^{2+}]_1 \longrightarrow {}^3[Am^{\cdot+}\ldots M(L)_3^{1+}] \longrightarrow \\ \longrightarrow Am^{\cdot+} + M(L)_3^{1+}, \end{array} \tag{4}$$

while the second reaction is

$$M(L)_3^{1+} + MV^{2+} \longrightarrow M(L)_3^{2+} + M^{\cdot+}. \tag{5}$$

In the other type of electron transfer, the primary reaction is

$${}^3[M(L)_3^{2+}]_1 + MV^{2+} \longrightarrow {}^3[M(L)_3^{3+}\ldots MV^{\cdot+}] \longrightarrow M(L)_3^{3+} + MV^{\cdot+} \tag{6}$$

while the second reaction is

$$M(L)_3^{3+} + Am \longrightarrow M(L)_3^{2+} + Am^{\cdot+}. \tag{7}$$

The free energies of reactions (4)–(7) can be calculated from the following formulae respectively:

$$\Delta G(4) = eE_{1/2}\left(\frac{Am}{Am^{\cdot+}}\right) - eE_{1/2}\left(\frac{M(L)_3^{1+}}{{}^3[M(L)_3^{2+}]_1}\right),$$

$$\Delta G(5) = eE_{1/2}\left(\frac{M(L)_3^{1+}}{M(L)_3^{2+}}\right) - eE_{1/2}\left(\frac{MV^{\cdot+}}{MV^{2+}}\right),$$

$$\Delta G(6) = eE_{1/2}\left(\frac{{}^3[M(L)_3^{2+}]_1}{M(L)_3^{3+}}\right) - eE_{1/2}\left(\frac{MV^{\cdot+}}{MV^{2+}}\right),$$

$$\Delta G(7) = eE_{1/2}\left(\frac{Am}{Am^{\cdot+}}\right) - eE_{1/2}\left(\frac{M(L)_3^{2+}}{M(L)_3^{3+}}\right).$$

We shall consider as an example a system where the sensitiser is a bipyridyl complex of ruthenium. The corresponding reduction and oxidation potentials of the triplet-excited ruthenium complex $^3[Ru(bipy)_3^{2+}]_1$ are

$$E_{1/2}\left(\frac{Ru(bipy)_3^{1+}}{^3[Ru(bipy)_3^{2+}]_1}\right) = E_{1/2}\left(\frac{Ru(bipy)_3^{1+}}{Ru(bipy)_3^{2+}}\right) + \frac{E(^3[Ru(bipy)_3^{2+}]_1)}{e} = -1.27 + 2.1 = 0.83 \text{ V (n.h.e.)} \quad (8a)$$

and

$$E_{1/2}\left(\frac{^3[Ru(bipy)_3^{2+}]_1}{Ru(bipy)_3^{3+}}\right) = E_{1/2}\left(\frac{Ru(bipy)_3^{2+}}{Ru(bipy)_3^{3+}}\right) - \frac{E(^3[Ru(bipy)_3^{2+}]_1)}{e} = 1.27 - 2.1 = -0.83 \text{ V (n.h.e.)}; \quad (8b)$$

$E_{1/2}[Ru(bipy)_3^{1+}/Ru(bipy)_3^{2+}]$ and $E_{1/2}[Ru(bipy)_3^{2+}/Ru(bipy)_3^{3+}]$ are the equilibrium reduction and oxidation potentials of $Ru(bipy)_3^{2+}$ in the ground state respectively and $E(^3[Ru(bipy)_3^{2+}]_1)$ is the distance from the ground to the excited triplet level of the sensitiser.

Reactions (4) and (5) are more favourable on energy grounds only in the case where one uses as the donors compounds with equilibrium oxidation potentials $E_{1/2}(D/D^{\cdot+}) < 0.83$ (n.h.e.) [see Eqn. (8a)] for which the free energies $\Delta G(4)$ and $\Delta G(5)$ are negative. The aromatic amines tetramethyl-*p*-phenylenediamine [$E_{1/2}(Am/Am^{\cdot+}) = 0.16$ V], diphenyl-*p*-phenylenediamine (0.36 V), tetramethylbenzidine (0.49 V), phenothiazine (0.53 V), β-naphthylamine (0.64 V),[13] as well as anthracene, 9-methylanthracene, and 9-bromoanthracene are classified as donors of this kind.[12] If compounds such as ethylenediaminetetraacetic acid (EDTA) or triethanolamine (TEOA), having $E_{1/2}(D/D^{\cdot+}) = 1.0$ or 0.9 V (n.h.e.), are used as the donors, then reaction (4) has a positive free energy: $\Delta G(4) = +0.16$ and $+0.06$ eV respectively. In this case, reactions (6) and (7) are energetically more favourable, because in both of them ΔG is negative [see Eqn. (8b)]:

$$\Delta G(6) = -0.83 - eE_{1/2}\left(\frac{MV^{\cdot+}}{MV^{2+}}\right) = -0.83 + 0.44 = -0.39 \text{ eV}$$

and

$$\Delta G(7) = eE_{1/2}\left(\frac{D}{D^{\cdot+}}\right) - 1.27 = \begin{cases} 1.0 - 1.27 = -0.27 \text{ eV (for EDTA)}, \\ 0.9 - 1.27 = -0.37 \text{ eV (for TEOA)}. \end{cases}$$

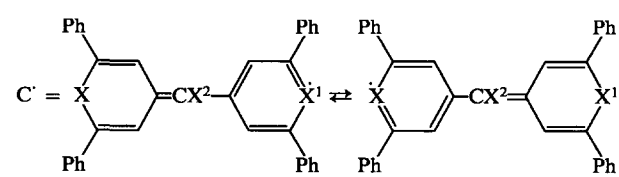
The quantum yield of the free radical-cations $D^{\cdot+}$, which avoided recombination in pairs, depends on a number of factors: the reaction pathway and the chemical structures of the sensitiser and donor. A number of systems can be quoted as examples.

(1) In systems comprising the donors Am sensitising $M(L)_3^{2+}$ (where $M^{2+} = Ru^{2+}$ or Os^{2+}) and the acceptor MV^{2+}, the quantum yield reaches 1, if the primary reaction (4) takes place, and is 0.2 ± 0.07 for the primary reaction (6).[12,13] According to the concepts developed, such decrease in the quantum yield is caused by the increase in the probability of the T → S intersystem crossing in the radical-ion pair and hence by the increase in the rate of the reverse reaction in the transition from the $^3[Am^{\cdot+}...M(L)_3^{1+}]$ pairs [see reaction (4)], where the electron transferred from Am to the metal complex is concentrated on the ligands and the spin–orbit interaction constant does not exceed $\xi = 76$ cm^{-1}, to the $^3[M(L)_3^{3+}...MV^{\cdot+}]$ pairs. In the latter case, the unpaired electron interacts with the orbitals of the central heavy atom, which has a spin–orbit constant $\xi = 1100-1350$ cm^{-1} (Ru^{2+}) or 3000 cm^{-1} (Os^{2+}).[14]

(2) The T → S intersystem crossing in the radical-ion pairs is responsible for the low quantum yield (~0.01) of the free radical-cations $MV^{\cdot+}$ and $D^{\cdot+}$ in systems containing a set of xanthen dyes, incorporating heavy iodine atoms ($\xi = 5060$ cm^{-1}) as sensitiser.[15,16]

(3) The quantum yield of the free radical-cations $D^{\cdot+}$ and $MV^{\cdot+}$ in reactions (4) and (5) is reduced from 1 to 0.74 when donors such as anthracene or 9-methylanthracene are replaced by 9-bromoanthracene and to 0.3 on subsequent addition of CH_3I to the solvent (a mixture of CH_3CN and CH_2Cl_2).[12] The authors explained this decrease by the effect of the heavy bromine ($\xi = 2640$ cm^{-1}) and iodine ($\xi = 5060$ cm^{-1}) atoms.

(4) In systems containing EDTA or TEOA as donors, Methyl Viologen as the acceptor, and Ru^{2+}, Os^{2+}, and Cu^+ complexes or the set of xanthen dyes as sensitisers,[15,16] an increase in the quantum yield of the radical-ion $D^{\cdot+}$ (which avoided recombination within the pairs) by a factor of 3–80 was attained by introducing species such as the anthracene-9-carboxylate anion (AA^-) or 9-methyl-anthracene.[12,15–17] These species are effective acceptors of the triplet energy of the photoexcited sensitiser and participate in the excited triplet state in the subsequent redox reactions (6) and (7) with formation of the triplet pairs $^3[AA^{\cdot}...MV^{\cdot+}]$, which do not contain heavy atoms.



(5) In the photosensitive EDA composition consisting of a poly(vinyl ethylal) (PVE) matrix, in which are dissolved diphenylbenzylamine (DPBA) [$E_{1/2}(DPBA/DPBA^{\cdot+}) = 0.98$ V relative to the saturated calomel electrode (s.c.e.) or 0.74 V (n.h.e.)] as the donor and di(tribromomethyl) sulphone (DTBMS) as the acceptor, the dye (S^+)-sensitised formation of the coloured product (CP^+) takes place in accordance with the reaction[18]

$$S^+ \xrightarrow{h\nu, S\to T} {}^3(S^+)_1 \xrightarrow{DPBA} {}^3(DPBA^{\cdot+}...S^{\cdot-})_1 \longrightarrow$$

$$\longrightarrow {}^3[DPBA^{\cdot+}...S^{\cdot}] \xrightarrow{DTBMS} S^+ + {}^3[DPBA^{\cdot+}...DTBMS^{\cdot-}] \longrightarrow$$

$$\longrightarrow CP^+Br^- + HR \text{ (or } CP^+R^- + HBr). \quad (9)$$

Here $Cp^+Br^- = N,N$-diphenyl(phenylmethyleneiminium) bromide $(C_6H_5)_2N^+=CH-C_6H_5Br^-$ with $\lambda_{max} = 665$ and $HR = H[CBr_2=S(O_2)-CBr_3]$.[19] In the case of the dyes listed in Table 1, the pair $^3[DPBA^{\cdot+}...S^{\cdot}]$ is formed during reaction (9), the unpaired electron in the radical $S^{\cdot}$ being concentrated on the X^1 and X atoms. The decrease in the quantum yield in the formation of CP^+ via reaction (19) on passing from oxygen- to sulphur-containing dyes, indicated in Table 1, was explained[20] by the corresponding increase in the rate of the reverse reaction owing to the acceleration of T → S intersystem crossing in the pair $^3[DPBA^{\cdot+}...S^{\cdot}]$ with increase in the spin–orbit interaction constant from 113–130 cm^{-1} for the O atom to 382 cm^{-1} for the S atom. The unpaired electron interacts weakly under these conditions with a H atom or the heavy bromine atom in the central methine group of the dye:

2. Hyperfine interaction

Those S → T and T → S transitions in which the overall magnetic quantum number M_z of the electronic-nuclear system does not change become allowed as a result of hyperfine interaction:

$$M_z = M_s(1) + M_s(2) + \sum_i m_i(1) + \sum_k m_k(2),$$

Table 1. Equilibrium redox potentials $E_{1/2}$(Ox) and $E_{1/2}$(Red) (measured relative to the saturated calomel electrode) and the maxima positions in the optical spectra (λ_{max}) of the sensitising dyes (S^+), the quantum yield η_0 of *N,N*-diphenyl(phenylmethyleneiminium) bromide [formed by reaction (9)] in the composition consisting of PVE, DPBA, DTBMS, and S^+.

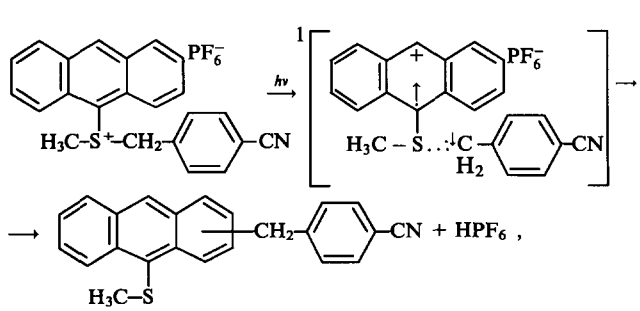
where $M_s(1)$ and $M_s(2)$ are the magnetic quantum numbers of the unpaired electrons 1 and 2 in the pair, and $m_i(1)$ and $m_k(2)$ are the magnetic quantum numbers of the nuclei over which the electron densities of the unpaired electrons 1 and 2 extend.

We shall consider how hyperfine interaction affects the rate of recombination of the components of the triplet pair in relation to dibenzyl ketone (DBK).[11] This influence is manifested by the photochemical enrichment of dibenzyl ketone in the ^{13}C isotope. The process is due to the fact that dibenzyl ketone dissociates in the excited triplet state into radicals, which form the radical pair $^3[R-\dot{C}(O)...\dot{R}]$, where $\dot{R} = \dot{C}H_2C_6H_5$. The triplet pairs decompose preferentially with formation of the dibenzyl ketone cleavage product if they contain the ^{12}C isotope in the $R-\dot{C}(O)$ group, but recombine with reformation of the initial ketone if the group contains the ^{13}C isotope. The effect is caused by the fact that, in contrast to the ^{12}C isotope, the ^{13}C isotope (the natural abundance of which is 1.1%) has a magnetic moment ($I = 1/2$) and the T → S transitions become allowed as a consequence of the hyperfine interaction:

$$-\overset{O}{\overset{\|}{C}}\cdot^{\uparrow}(m_i = -1/2)\ldots R\cdot^{\uparrow} \xrightarrow{T_{+1}\to S} -\overset{O}{\overset{\|}{C}}\cdot^{\downarrow}(m_i = +1/2)\ldots R\cdot^{\uparrow}$$

$$-\overset{O}{\overset{\|}{C}}\cdot^{\downarrow}(m_i = +1/2)\ldots R\cdot^{\downarrow} \xrightarrow{T_{-1}\to S} -\overset{O}{\overset{\|}{C}}\cdot^{\uparrow}(m_i = -1/2)\ldots R\cdot^{\downarrow}$$

$$-\overset{O}{\overset{\|}{C}}\cdot^{-}(m_i = \pm 1/2)\ldots R\cdot^{-} \xrightarrow{T_0\to S} -\overset{O}{\overset{\|}{C}}\cdot^{\downarrow}(m_i = \pm 1/2)\ldots R\cdot^{\uparrow}\ .$$



This permits the recombination of the radical pair. (The direction of the electron spin is indicated in the above formulae by arrows.)

In the general case the probability of the T → S transitions is determined by the sum of the hyperfine interaction constants:[11]

$$a^2 = \left[\sum_i a_i^2(1) + \sum_k a_k^2(2)\right] t\ ,$$

where t is the hyperfine interaction time.

In order to devise photoresists whose operation is based on acid photocatalysis, a large number of onium salts, such as arenediazonium salts ($ArN_2^+\ MX_n^-$), aryliodonium salts ($Ar_2I^+\ MX_n^-$), arylsulphonium salts ($Ar_3S^+\ MX_n^-$), and arylammonium salts, arylphosphonium salts, and arylarsonium salts ($Ar_4M'^+\ MX_n^-$; M' = N, P, and As respectively) were synthesised; $MX_n^- = PF_6^-$, AsF_6^-, BF_4^-, etc. On photoexcitation of the onium salt, the spectral sensitiser, or the charge-transfer complex between the additional organic donor (RH) and acceptor (onium salt), a reaction accompanied by the appearance of a Lewis (MX_{n-1}) or Brønsted (HMX_n) acid takes place. The acids induce the degradation of the chains or the cross-linking of the polyesters. The mode of such photochemical reactions is determined by the hyperfine interaction,[22,23] because S → T intersystem crossing in the singlet radical pair formed in the primary step competes with the reaction between the radicals. Thus the photolysis of sulphonium, arsonium, and phosphonium salts proceeds in different ways,[22] which is associated with the increase in the hyperfine interaction constant on passing from sulphonium [$a(^{32}S) = 0$ Oe] to arsonium [$a(^{75}As) = 4.65$ Oe], and further to phosphonium [$a(^{31}P) = 306$ Oe]. Whereas the products of the photolysis of sulphonium salts are formed as a result of an intramolecular rearrangement via the singlet state of the pair,[22,23] the photolysis of arsonium salts takes place both via the singlet and triplet states of the pair,[22] while the ammonium and phosphonium salts are photolysed solely via the triplet state, because in this case S → T intersystem crossing predominates and results in the formation of a triplet radical pair. In this case, the intramolecular rearrangement becomes spin-forbidden and the formation of HMX_n requires the involvement of a molecule of the solvent. For example, in the case of the salt 9-anthrylmethyl-*p*-cyano-benzylsulphonium hexafluorophosphate the photoexcitation of the 9-anthryl chromophore entails charge transfer from the sulphonium fragment and subsequent rearrangement within the pair[23]

whereas in arsonium salts the following reactions takes place.

$$(C_6H_5)_3As^+ - CH_2 - C_6H_4 - CN \xrightarrow{h\nu}$$
$$\rightarrow\ {}^1[(C_6H_5)_3As^{\cdot+}\ldots\dot{C}H_2C_6H_4 - CN\ MX_n^-] \rightarrow (C_6H_5)_2As - C_6H_4 - CH_2 - C_6H_4CN + HMX_n\ ,$$
$$\rightarrow\ {}^3[(C_6H_5)_3As^{\cdot+}\ldots\dot{C}H_2C_6H_4 - CN\ MX_n^-] \xrightarrow{H_2O} (C_6H_5)_3AsO + (CH_3 - C_6H_4CN) + HMX_n\ . \qquad (10)$$

A high rate of S → T intersystem crossing is to be expected in the radical pairs of iodonium salts via both spin–orbit and hyperfine interaction mechanisms as well as the predominance of reaction (10), because high spin–orbit and hyperfine interaction constants are characteristic of the iodine atom.

III. Processes amplifying the latent image

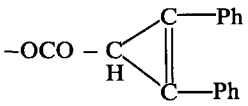
1. Highly sensitive photoresists based on [2 + 2] photoaddition

In the familiar photoresists consisting of poly(vinyl cinnamates) (PVCI) and related compounds $-CH_2-CHR-$, the chromophore R incorporates the $-CH=CH-$ group, which is responsible for the photoinduced cross-linking of the polymer chain via the [2 + 2] photocycloaddition mechanism:[2]

$$2(-CH=CH-) \xrightarrow{h\nu} \begin{matrix} -CH-CH- \\ | \quad | \\ -CH-CH- \end{matrix} \qquad (11)$$

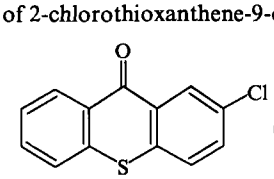
As a result of this reaction, the exposed polymer film is not removed from the support throughout the period of the dissolution of the unexposed sections in organic solvents.

[2 + 2] Photocycloaddition involving PVCI proceeds via the excited singlet and triplet states of the chromophores R when the latter are themselves photoexcited. The process proceeds with a much higher efficiency under the conditions of triplet energy transfer to R from the photoexcited spectral sensitiser. For a random relative distribution of the chromophores in neighbouring PVCI chains ($R = -OCO-C=CH-C_6H_5$), the quantum yield of the cyclobutane rings formed via reaction (11) is $\eta_0 \simeq 0.045$ and the exposure corresponding to the onset of gel formation is $H_g \simeq 700$ mJ cm^{-2}. In order to increase the photosensitivity of photoresists, much attention has been devoted in recent years to the synthesis of new polymers with an increased triplet energy migration distance[24] and also the synthesis of compounds in which the cinnamoyl groups form aggregates.[7,25,26]



The lifetimes of the triplet excitation (τ), the quantum yield of the cyclobutane ring (η_0), and the photosensitivities $S = 1/H_g$ (estimated relative to S for PVCI) have been compared[24] for PVCI and the polymers **1–3**

$$(-CHR-CH_2-)_{0.9}-(-CHOH-CH_2-)_{0.1};$$



1–3

1: R = $-OCO-CH=CH-C_6H_4-COOC_2H_5$;

2: R = $-OCO-CH=CH-C_{10}H_8$

3: R =

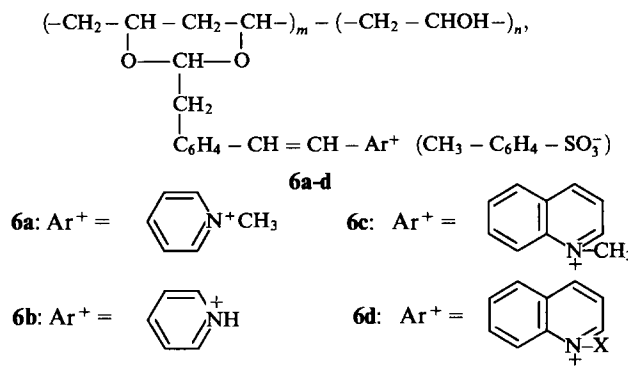
4

or 3,3′-carbonylbiscoumarin **5**

(E_T = 56.2 kcal mol^{-1})

5

as the sensitiser (Table 2). The table shows that, on passing from PVCI to the polymer **3**, the lifetime of the triplet excitation increases by more than four orders of magnitude. This is responsible for the increase in S by a factor of 17.5, i.e. a decrease in H_g to 40 mJ cm^{-2}.



In order to obtain intermolecularly bound chromophoric groups, poly(vinyl cinnamates) $-CH_2-CH(RX)-$ were synthesised with chromophoric groups (RX) containing a fragment X with electron-donating (PVCI–D) or electron-accepting (PVCI–A) properties:[25,26]

$$-CH_2-\underset{|}{CH}-O-CO-CH=CH-C_6H_4-D \quad \text{(PVCI-D)}$$

$$-CH_2-\underset{|}{CH}-O-CO-CH=CH-C_6H_4-A \quad \text{(PVCI-A)}$$

Table 3 presents the quantum yields of the overall consumption of the double bonds (η') and the intermolecular cross-links (η'') and the values of H_g for different combinations of PVCI-D and PVCI-A in the absence of a sensitiser and on photoexcitation of 3,3-carbonylbiscoumarin as the sensitiser.[25,26] Table 3 shows that the relative efficiency of the gel formation, which can be estimated from the ratio η''/η', increases with enhancement of the donor–acceptor interaction from 0.18 for pure PVCI to 0.82 for the PVCI–OCH_3/PVCI–Cl (50 : 50) pairs. As a consequence of this, on passing from the homopolymer PVCI to the equimolar mixture of polymers PVCI–OCH_3/PVCI–Cl, there is also a decrease in H_g from 700 to 152 and 62 mJ cm^{-2} in the non-sensitised and sensitised systems respectively.

The highly sensitive water-soluble photoresists

6a-d

6a: Ar^+ = **6c**: Ar^+ =

6b: Ar^+ = **6d**: Ar^+ =

whose operation is based on [2 + 2] photocycloaddition, have been proposed.[27,28] The capacity of these photoresists to form aggregates is responsible for their high sensitivity even at a low concentration of chromophoric groups:

Polymer	(m/n)/%	H_g/ mJ cm^{-2}
6a	2.2	~12
6b	2.5	~10

It has been shown in relation to the polymer **6c** [27,28] that the deprotonation of the quinoline group by treatment in an organic solvent containing amines, i.e. its transformation from an electron-accepting into an electron-donating group, leads to a 100-fold increase in H_g and also to a shift of the long-wavelength optical absorption maximum from 420 nm to 360 nm. It was therefore suggested that a polymer with a low sensitivity be employed and that it be sensitised directly before exposure by treatment in acid-containing solvents. The photosensitivity obtained under these conditions depends on the nature of

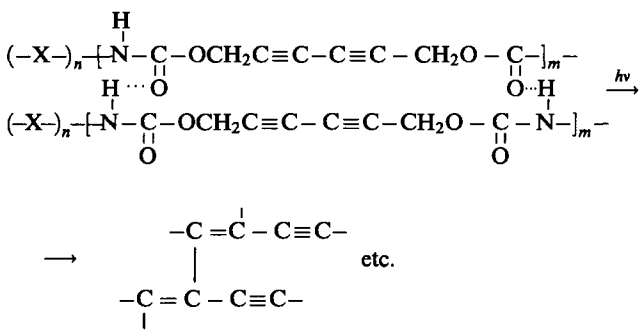


Table 2. The lifetimes of the triplet excitation (τ), the quantum yield in the formation of the cyclobutane ring (η_0), and the photosensitivity ($S = 1/H_g$) relative to S for PVCI) of PVCI and the polymers **1–3**.[24]

Polymer	τ/ μs	η_0	S/ cm^2 mJ^{-1}
PVCI	0.01	0.045	1
1	6.9	0.073	2.5
2	10	0.12	3.3
3	360	0.53	17.5

the acid[28] and increases in the sequence corresponding to the ratios HCl : HPO_3 : $HClO_4$: H_2SO_4 : p-$CH_3C_6H_4SO_3H$ = = 1 : 21 : 71 : 100 : 101.

The intermolecular interactions in the linear polyesters $-CO-C(CN)=CH-CH=CHC_6H_4CH=C(CN)-CO-O-[(-CH_2-)_2-O-]_3-$ in the ground state ensure their high photosensitivity[29] with H_g = 1.6 mJ m^{-2}.

It has been suggested[30,31] that the hydrogen bonds in the block-copolymers of diacetylene with polyurethanes, polyesters, and polyamides are responsible for the formation of stacks of chains containing diacetylene fragments. Light at the wavelength corresponding to the absorption bands of diacetylene ($\leqslant$400 nm) initiates the chain reaction involving the cross-linking of neighbouring acetylene groups with formation of a branched system of conjugate bonds. This reaction proceeds effectively when an exposed film is heated (80 °C, 10 min):

The highest sensitivity (H_g = 0.5 mJ cm^{-2} when the content of diacetylene groups is 30 wt%) is shown by copolymers based on aliphatic polyurethanes, which is associated with the flexibility of the chains promoting the formation of stacks of rigid diacetylene fragments and also with the absence of groups which absorb light in the same region as the diacetylene chromophore.

2. Autocatalysis

A typical example of compositions in which the catalyst is formed as a result of a photochemical reaction directly from the photosensitive components is the system incorporating a polymer matrix and an electron donor [$(C_5H_5)_2Fe$] and acceptor (CBr_4) dissolved in it. The donor–acceptor complex $(C_5H_5)_2Fe \cdot CBr_4$, the optical absorption maximum of which is in the range 370–400 nm, is responsible for the photosensitivity of the composition. Photoexcitation of the complex leads to its dissociative decomposition:[5,32,33]

$$(C_5H_5)_2Fe \cdot CBr_4 \xrightarrow{h\nu}$$
$$\longrightarrow (C_5H_5)_2Fe^+ \ldots Br^- \ldots \dot{C}Br_3 \text{ (or } Br^{\cdot} \ldots CBr_3^-) \longrightarrow$$
$$\longrightarrow [Fe^{3+}Br_4]^- + \text{products} \qquad (12)$$

with formation of the ferrocenium cation $(C_5H_5)_2Fe^+$, which is converted by interaction with the free radical $\dot{C}Br_3$ into the tetrabromoferrate(III) anion $[Fe^{3+}Br_4]^-$ with characteristic optical absorption bands at λ_{max} = 397 and 472 nm, which are responsible for the brown colour.

It has been noted[34] that heating of the exposed layer at 70–100 °C ensures the development of the latent image. It has been established[5,34,35] that the key factor in this process is the formation of trivalent iron which enters into the thermal reaction[36]

$$Fe^{3+} + (C_5H_5)_2Fe \longrightarrow Fe^{2+} + (C_5H_5)_2Fe^+.$$

This is followed by charge transfer:

$$Fe^{2+} + CBr_4 \longrightarrow Fe^{3+} + Br^- \ldots CBr_3^{\cdot} \text{ (or } Br^{\cdot} \ldots CBr_3^-).$$

Thus the Fe^{3+}/Fe^{2+} pair, arising as a result of illumination, catalyses the thermal electron transfer between the donor and acceptor components. The overall process can be formulated as follows:

$$(C_5H_5)_2Fe + CBr_4 \xrightarrow{Fe^{3+}/Fe^{2+}}$$
$$\longrightarrow (C_5H_5)_2Fe^+ + Br^- \ldots CBr_3^{\cdot} \text{ (or } Br^{\cdot} \ldots CBr_3^-). \qquad (13)$$

The thermal stages of the photochemical reaction (12) are then repeated.

The factors limiting the amplification coefficient as a consequence of the parallel occurrence of the photoinitiated autocatalytic reaction (13) and the dark thermal electron transfer in the complex $(C_5H_5)_2Fe \cdot A$, where A = CBr_4 or halo-derivatives of organic compounds of different structure, have been analysed.[37] It was established that the principal stages of the autocatalytic process (13) include diffusion-controlled reactions, so that the decisive factors are the size of the acceptor and the segmental mobility of the polymer chains at elevated temperatures. The primary quantum yield of the coloured product [formed via reaction (12)] is η_0 = 0.05–0.1 regardless of the nature of the acceptor. It has been shown that, when a polystyrene matrix is used, the highest

Table 3. The influence of the donor–acceptor interaction on the principal characteristics of PVCI-based photoresists.

amplification coefficient (~6000) is attained in the case of CBr_4. When CBr_4 is replaced by $O_2N-C_6H_4-SO_2-CBr_3$, the amplification coefficient is reduced to 450.

Compositions containing, in addition to the ferrocene donor, also aromatic amines (Am), namely diphenylamine (DPA), DPBA, and dibenzylaniline (DBA), have been investigated.[38-41] It was established that the photoexcitation of the complex $(C_5H_5)_2Fe \cdot CBr_4$ and subsequent heating of the composition to 60–100 °C results in the autocatalytic accumulation not only of the ferrocene decomposition products but also of the triphenylmethane dye (TPM D) derived from the aromatic amine, the dye being responsible for the absorption at λ_{max} = 605 nm. It has been suggested[40,41] that the charge transfer

$$(C_5H_5)_2Fe^+ + Am \longrightarrow (C_5H_5)_2Fe + Am^{\cdot+} \qquad (14)$$

and subsequent thermal reactions of the radical cation $Am^{\cdot+}$ and of $Br^-...CBr_3^{\cdot}$, i.e.

$$Am^{\cdot+}...Br^- \ ...CBr_3^{\cdot} \xrightarrow[HBr]{2Am}$$

$$\longrightarrow R^1R^2N^+ = C_6H_4 = C(C_6H_4NR^1R^2)_2Br^- \qquad (15)$$

(TPM D)

take place.

Under the conditions of the photoexcitation of the complex $(C_5H_5)_2Fe \cdot CBr_4$ in the presence of amines it was established[38] that DPA inhibits the autocatalytic accumulation of $[Fe^{3+}Br_4]^-$ to a much greater extent than do DPBA and DBA. It is most likely that the inhibition is due to the charge-transfer process (14), the rate of which is determined by the nature of the aromatic amine. Indeed, the ionisation potentials of ferrocene (I_D = 6.88 eV[42]), DPA (7.2 eV[43]), DPBA (~7.5 eV[20]), and DBA (7.55 eV[20]) correspond to the following free energies of activation for reaction (14): ΔG_1 = 7.2–6.88 = 0.32 eV for DPA, ΔG_2 = = 7.5–6.88 = 0.62 eV for DBA. Hence it follows that the rate constants for reaction (14) with participation of the tertiary amines DPBA and DBA are smaller by the factor $\exp[(\Delta G_2 - \Delta G_1)/kT]$, i.e. by approximately five orders of magnitude, than in the case of DPA. However, it has been established experimentally that the rate of formation of the coloured products from the tertiary amines DPBA and DBA is the same as the rate measured for the secondary amine DPA. It is most likely that the coloured products derived from the tertiary amines DPBA and DBA and the secondary amine DPA are formed via different pathways.

It is known that the photoexcitation of complexes between DPA and CBr_4 involves electron transfer from the donor to the acceptor component with formation of the radical-ions $CBr_3^{\cdot}...Br^-$ and $DPA^{\cdot+}$ and the products of their interaction:[44]

$$DPA^{\cdot+} + + CBr_3^{\cdot} \ ...(Br^-) \longrightarrow p\text{-DPA} - CBr_3 + HBr\,.$$

It has been suggested[45,46] that the free radical chain process

$$\begin{array}{l} DPA + \dot{C}Br_3\ (Br^{\cdot}) \longrightarrow DPA^{\cdot} + CHBr_3\ (HBr) \\ \quad\uparrow\qquad\qquad\qquad\qquad\quad\downarrow \\ DPA^{\cdot} + CBr_4 \longrightarrow p\text{-DPA}-CBr_3 + Br^{\cdot} \end{array} \qquad (16)$$

takes place and leads to the amplification of the latent image. The interaction of DPA – CBr_3 with DPA ensures the formation of the triphenylmethane dye.

The interaction of tertiary amines with $\dot{C}Br_3$ radicals involves the abstraction of a hydrogen atom from the α-position relative to the nitrogen atom:[47]

$$C_6H_5(R)N - CH_2 - C_6H_5 + CBr_3^{\cdot} \longrightarrow$$

$$\longrightarrow C_6H_5(R)N - \dot{C}H - C_6H_5 + HCBr_3\,. \qquad (17)$$

The α-radicals $R_2N-\dot{C}H-R$ exhibit powerful electron-donating properties and transfer an electron to the acceptor in dark reactions.[46,49] On this basis, one may postulate the occurrence of a chain process involving the formation of the coloured products CP^+Br^- [see Eqn. (9)]:

$$C_6H_5(R)N - \dot{C}H - C_6H_5 + CBr_4 \longrightarrow$$

$$\longrightarrow C_6H_5(R)N^+ = CH - C_6H_5\ Br^- ...\dot{C}Br_3 \qquad (18)$$

and its subsequent accumulation via reactions (17) and (18). On heating, the product CP^+Br^- reacts with the amine and other components of the layer with formation of compounds of the type of triphenylmethane dyes.[19,50,51]

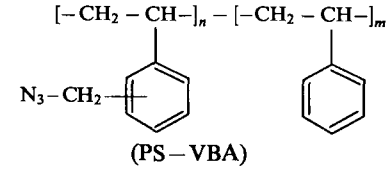
Molecular oxygen lowers the rate of autocatalytic accumulation of the coloured species $[Fe^{3+}Br_4]^-$ due to its consumption via the reaction

$$Fe^{3+} \xrightarrow{O_2} Fe_2O_3 + Fe(OH)_3\ \text{, etc.}$$

It has been shown[40,41] that the autocatalytic amplification of the latent image occurs also at room temperature when the content of molecular oxygen has been reduced appreciably in the polymeric photosensitive layer by placing it between two protecting films of poly(vinyl alcohol) (PVA). It is known[52,53] that PVA prevents the penetration of O_2 from the atmosphere and also adsorbs the oxygen dissolved in the polymer layer. The autocatalytic formation of coloured products ceases completely when the upper protective PVA film is removed from the photosensitive layer. The high amplification coefficients (~10^4 in the absence of oxygen), characteristic of these compositions, are responsible for their maximum photosensitivity (~0.01 $lx^{-1}\ s^{-1}$) among non-silver photographic systems.

Exposure to laser radiation at 441 or 488 nm, acting in the region corresponding to absorption by the complex $(C_5H_5)_2Fe \cdot CBr_4$, and subsequent heating at 70–90 °C results in the formation of ester bonds in the copolymer of vinyl acetate and crotonic acid $[-CH_2-C(COOH)H-]_n-[-CH_2-C(OCOCH_3)H-]_m$ containing $(C_5H_5)_2Fe$ and CBr_4, which leads to an appreciable decrease in the solubility of the polymer composition in aqueous alkaline solution.[54] It has been shown[54,55] that the divalent iron formed via reactions (12) and (13) catalyses the processes:

$$Fe(II) + (-CH_2 - \underset{\displaystyle O - COCH_3}{\underset{|}{CH}}-) \longrightarrow - CH_2 - \underset{\displaystyle O^- ...\dot{C}OCH_3}{\underset{|}{CH}} - + Fe(III) \xrightarrow{H_2O}$$



$$\longrightarrow - CH_2 - \underset{\displaystyle OH}{\underset{|}{CH}} - + CH_3COOH + Fe(II)$$

and further

$$- CH_2 - \underset{\displaystyle COOH}{\underset{|}{CH}} - + - CH_2 - \underset{\displaystyle OH}{\underset{|}{CH}} - \longrightarrow \underset{\displaystyle HC-CO-O-CH}{\underset{|}{H_2C}} \quad \underset{|}{CH_2} + H_2O.$$

After the exposed film has been placed in a 2.5% aqueous solution of $(CH_3)_4NOH$ for 5 min, the non-exposed sections are fully dissolved, while the thickness of the sections which receives an exposure $H_g \geqslant 10$ mJ cm^{-2} (λ = 488 nm) remains unchanged.

Photoinitiated autocatalytic decomposition is characteristic also of aromatic azides, a very familiar class of photoresists. The branched chain decomposition has been investigated in relation to low-molecular-weight azides[8,56-59] as well as layers made up the styrene–vinylbenzyl azide (PS–VBA) copolymer:[60-62]

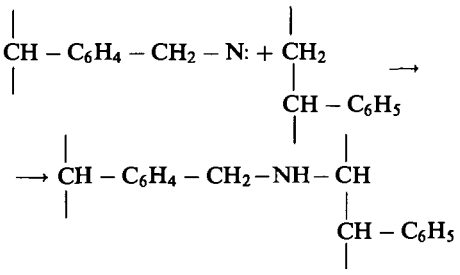
(PS–VBA)

The chain mechanism of the decomposition of phenyl azide in liquid media has been established:[8,56]

(a) chain initiation

$$C_6H_5-N_3 \xrightarrow{\lambda=254\ nm} C_6H_5-N: + N_2,$$

(b) chain propagation



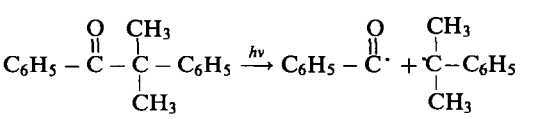
$$C_6H_5-N: + C_6H_5-N_3 \longrightarrow 2C_6H_5-N: + N_2,$$

(c) chain termination

$$C_6H_5-N: + C_6H_5-N_3 \longrightarrow C_6H_5-N=N-C_6H_5+N_2,$$

$$2C_6H_5-N: \longrightarrow C_6H_5-N=N-C_6H_5.$$

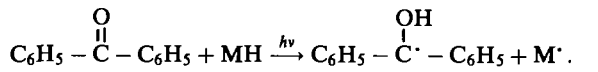
The initial quantum yield of $C_6H_5-N:$, measured either in diluted (to 10^{-4} M) solutions at room temperature or in organic glasses frozen at 77 K, is ~0.58. At high $C_6H_5-N_3$ concentrations (~0.08–0.72 M) at room temperature, the amplification coefficient reaches 10^3-10^4.[8] The efficiency of the chain decomposition of PS–VBA layers increases under the conditions of the photoexcitation of additional triplet energy donors (thioxanthone, anthracene, and their derivatives).[60,61] The azide-containing compositions are negative photoresists, their reduced solubility in organic media being caused by the cross-linking of the



polymer chains with participation of the nitrene formed under the inluence of light:

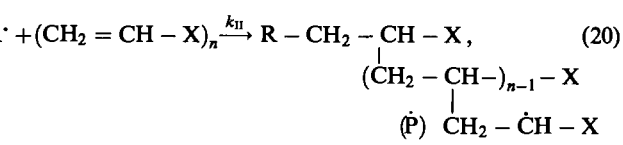
In compositions comprising PS–VBA (m/n = 14.9%) and 2,4-diisopentylthioxanthone (sensitiser), the onset of gel formation corresponds to the exposure H_g = 45 mJ cm^{-2}.[62]

3. Photochemically induced cross-linking of polyfunctional acrylates



In recent years, much attention has been devoted to the photoinitiated cross-linking of polyfunctional oligomeric acrylates (compounds containing two and more $-O-CO-CH=CH_2$ groups). Studies on this subject have been recently discussed in detail in review publications[63–66] and only compositions proposed as highly sensitive photoresists for use in micro-electronics, in the manufacture and copying of compact discs,[9,67–69] and also in the manufacture of microencapsulated photographic material[70] will therefore be considered below.

Diacrylates of aliphatic polyurethanes, the diacrylates of polyepoxybisphenol A, and the triacrylate of trimethylpropane [trimethylpropanetriol?] have been used as polyfunctional acrylates. The photoinitiators (I) were ketones of different structure: dimethylphenylacetophenone, isobutyl ether of benzoin or benzophenone, phenanthrenequinone, etc. Depending on the structure of the initiator, either direct photodissociation



(19)

or (in the presence of added MH) a photoredox process with the transfer of an electron and a proton)

Free radicals formed in sections (19) and (19a) give rise to polymerisation

(20)

and chain termination

$$P^{\cdot} + P^{\cdot} \xrightarrow{k_0} 2P, \quad (21)$$

$$P^{\cdot} + R^{\cdot} \longrightarrow PR. \quad (21a)$$

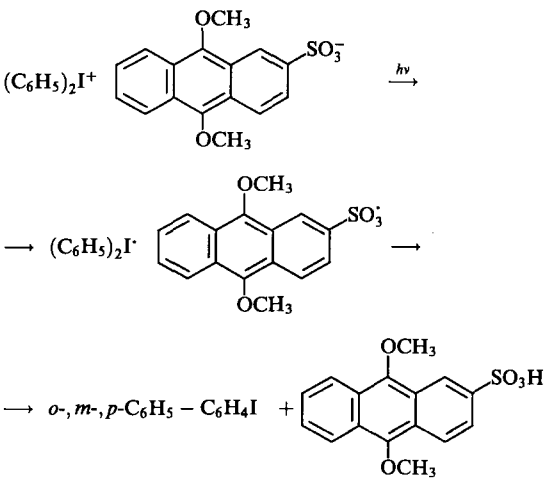
The influence of hyperfine interaction on the rate of recombination of radicals in the pair formed via reactions (19) and (19a) was discussed above (see sub-section II.2).

The quantum yield of radicals formed by reactions (19) and (19a) is ~0.1 both in dilute liquid solutions and in viscous media.[67] The chain termination corresponds to the second-order reaction (21) in the polymerisation of monofunctional acrylates in any condensed media. The chain termination in the polymerisation of monomers in microcapsules has been shown to be a first-order process,[70] where the consumption of radicals mainly as a result of their preferential reaction with the walls of the capsule predominates. The first-order process of destruction of the radical $\dot{P}$ has also been observed on exposure to intense pulsed laser radiation.[9] On the basis of the analysis of the kinetics of photopolymerisation with the use of photoinitiators of different kinds, it has been suggested[77] that, in the photoredox reaction (19a), the radicals formed serve simultaneously as initiators and inhibitors of polymerisation and are responsible for the first order of the consumption of $\dot{P}$ via reaction (21a).

The polymerisation of a polyfunctional molecule involves simultaneously several groups and the polymer network is formed already in the early stages of the reactions. The mutual approach of the radicals grafted to the network is sterically hindered. In the case of the diacrylate of polyepoxybisphenol A, the kinetic chain of reaction (20) included 10^4-10^5 links,[9,69] which is the reason for the high photosensitivity of the system[9] corresponding to $H_g \simeq 3$ mJ cm^{-2}. Molecular oxygen greatly reduces the rate of polymerisation and the length of the kinetic chain when low-intensity light sources are used.[69]

4. Chemical amplification of the latent image

Nowadays much attention is devoted to photoresists whose action is based on the photochemical formation of acids and subsequent occurrence of chain processes (chemical amplification) involving the polymerisation of vinyl monomers or epoxides,[6,7,72–74] cationic polycondensation and cross-linking of polymer chains (for example novolac resin and hexamethoxymethylenemelamine),[75,76] and cationic depolymerisation [degradation of poly(phthalic aldehyde) to gaseous products].[77–79] The creation of photoresists based on polymers with protecting groups, which are abstracted by a photochemically generated acid, thus altering the polarity and hence the solubility of the polymers, has found wide application.[80–84] Specific photoresist systems of this type have been discussed in detail in recent years in the review literature[6,7,55] and only fundamental questions referring to chemical amplification will therefore be considered below.



As stated above (see sub-section II.2), acids are generated photochemically from onium salts via reaction (10). Iodonium

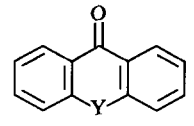
[a] Equilibrium potentials of the reduction the ionium salts are shown in brackets.

salts have been synthesised in which the photosensitivity is due to the optical absorption of the counteranion.[85] The acid is formed as a result of the electron phototransfer via the reaction

The decomposition of ionium salts under the conditions of the photoexcitation of organic sensitisers (dyes or aromatic hydrocarbons ArH) has been investigated in detail.[86–90] Electron transfer takes place via a stage involving the formation of an exciplex, for example, we have for a diphenyliodonium salt

$$\mathrm{ArH} \xrightarrow{h\nu} {}^{1,3}(\mathrm{ArH})_1 \xrightarrow{(C_6H_5)_2I^+X^-} {}^{1,3}(\mathrm{ArH})_1\cdot(C_6H_5)_2I^+X^- \longrightarrow$$

$$\longrightarrow {}^{1,3}[\mathrm{ArH}^{\cdot+}\ldots(C_6H_5)_2I^{\cdot}\,X^-] \longrightarrow$$



$$\longrightarrow \mathrm{Ar}-C_6H_5 + C_6H_5I + HX. \qquad (22)$$

It has been established experimentally that for onium salts the reaction proceeds effectively only when the free energy change on electron transfer is $\Delta G(22) \leqslant -0.43$ eV:[86–89]

$$\Delta G(22) = e\left[E_{1/2}\left(\frac{^{1,3}(\mathrm{ArH})_1}{\mathrm{ArH}^{\cdot+}}\right) - E_{1/2}\left(\frac{\mathrm{On}^{\cdot}\mathrm{X}^-}{\mathrm{On}^+\mathrm{X}^-}\right)\right]\mathrm{eV}\ ,$$

where $E_{1/2}[^{1,3}(\mathrm{ArH})_1/\mathrm{ArH}^{\cdot+}] = E_{1/2}(\mathrm{ArH}/\mathrm{ArH}^{\cdot+}) - {}^{1,3}E_{00}$ and $E_{1/2}(\mathrm{ArH}/\mathrm{ArH}^{\cdot+})$ are equilibrium potentials of the oxidation of the sensitiser in the excited singlet and triplet ground states respectively [via the reactions $^{1,3}(\mathrm{ArH})_1 \rightleftarrows \mathrm{ArH}^{\cdot+} + e$ and $\mathrm{ArH} \rightleftarrows \mathrm{ArH}^{\cdot+} + e$], $^{1,3}E_{00}$ is the distance from the ground to the reactive singlet or triplet level of the sensitiser, and $E_{1/2}(\mathrm{On}^{\cdot}\mathrm{X}^-/\mathrm{On}^+\mathrm{X}^-)$ are the equilibrium potentials of the reduction of the onium salts by the reaction $\mathrm{On}^{\cdot}\mathrm{X}^- = \mathrm{On}^+\mathrm{X}^- + e$ (listed in brackets in Table 4).

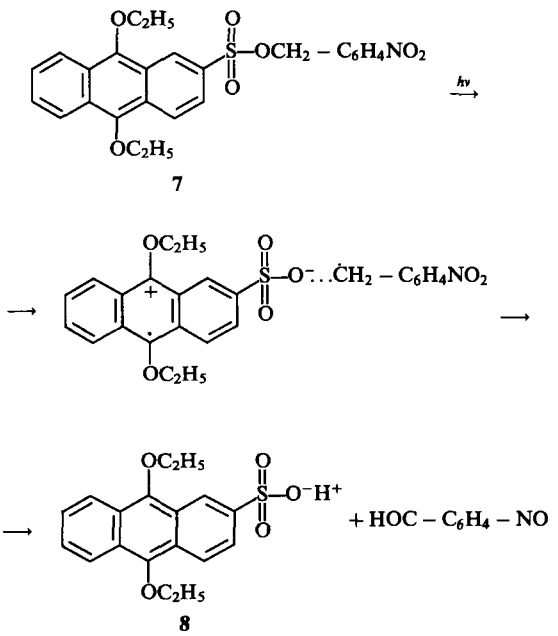


Table 4 also includes the values of ΔG_{22} ($^{S}\Delta G$ and $^{T}\Delta G$, the free energies of electron transfer to the onium salt from the acridine dye in the excited singlet and triplet states respectively).[87,89]

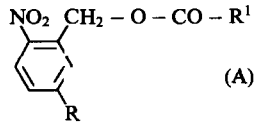

Y = O	xanthone

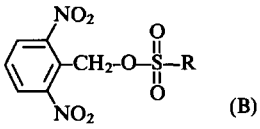
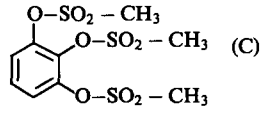
NCH_3	10-methylacridone

It follows from the tabulated data that the diazonium and iodonium salts can be sensitised by any of the dyes considered in the excited singlet or triplet state. The effective electron phototransfer to the sulphonium salt is possible only from the singlet-excited xanthone. As a rule, the sensitisers used for sulphonium salts are aromatic hydrocarbons, for example, perylene (Pe),[87,91] the equilibrium oxidation potential of which in the excited singlet state is $E_{1/2}(^1\mathrm{Pe}_1/\mathrm{Pe}^{\cdot+}) = -1.86$ V, since $E_{1/2}(^1\mathrm{Pe}_1/\mathrm{Pe}^{\cdot+}) = 1$ V and $^1E_{00} = 2.86$ eV. Owing to the high reduction potentials, it has not been possible to sensitise phosphonium and ammonium salts.

Special interest attaches to organic acid-forming compounds such as *p*-nitrobenzyl 9,10-diethoxyanthracene-2-sulphonate **7**,[91–93] in which dissociative intramolecular electron transfer takes place under the influence of light (250–300 nm) with the subsequent formation of the strong 9,10-diethoxyanthracene-2-sulphonic acid **8**:

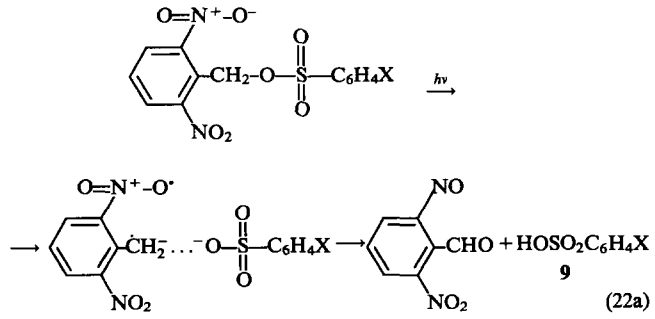


Esters having the structures (A),[94] (B),[80,84,95] and (C),[81,96] also belong to the acid-forming class:



where R = H, NO_2; $R^1 = CH_3$, C_2H_5;

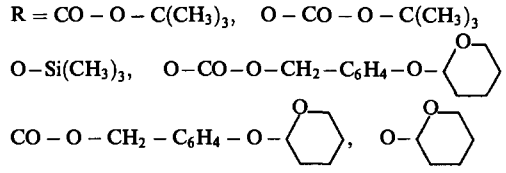
(A)



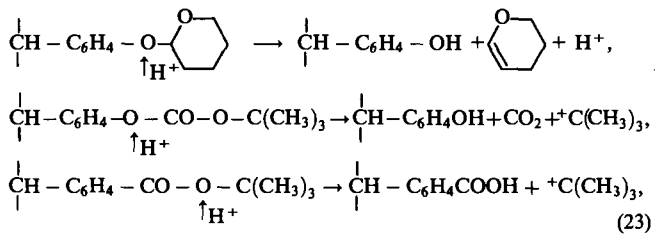
where R = CH_3, *p*-C_6H_4–CH_3, C_6H_5, *p*-C_6H_4–NO_2 etc.

(B)

(C)



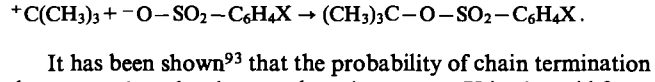
Acids are formed from these esters as a result of the dissociative intramolecular electron phototransfer, for example by the reaction



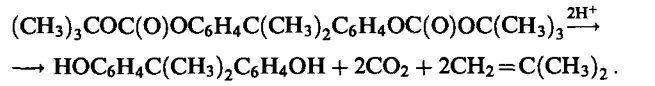
(22a)

The quantum yield of the acid **9** diminishes when the electron-donating substituent X is replaced by an electron-accepting one and its values are 0.16 (X = CH_3), 0.14 (X = H), and 0.1 (X = NO_2).

Photochemically generated acids deblock polymers which contain protecting groups[6,7,82,84,91,96,97] such as $-C(p\text{-}C_6H_4R)H-CH_2-$, $-C(p\text{-}C_6H_4R)(CH_3)-CH_2-$, and $-C(p\text{-}C_6H_4R)H-CH_2-)_2-SO_2-$, where



i.e. they transform them in accordance with the schemes presented below[6,82,93,96,97] into polymers which readily dissolve in 1–2% aqueous solution of $(CH_3)_4NOH$:



(23)

It has been shown[93] that the probability of chain termination decreases when the electron-donating groups X in the acid **9** are replaced by electron-accepting groups which withdraw the negative charge from the oxygen atom in the direction of the phenyl fragment. As a result, following the replacement of CH_3 by NO_2, the chain length, i.e. the chemical amplification coefficient (holding at 120 °C for 4 min), increases from 200 to 800.

Processes based on the inhibition of the dissolution of the novolak resin $[-C_6H_2(OH)(CH_3)-CH_2-]_n$ following the addition to the solvent of compounds with protecting groups have been widely investigated in recent years.[7] As an example, one may quote the composition of the novolak resin, the acid-forming ester, and an inhibitor—bisphenol A with *tert*-butoxycarbonyl groups.[81] As a result of the formation of acids on photoexcitation of the acid-forming ester, the inhibitor is transformed into bisphenol A via the reaction

It has been shown[81] that the initial quantum yield of the acid is 0.205 and the kinetic length of this chain, i.e. the amplification coefficient, is 76–123.

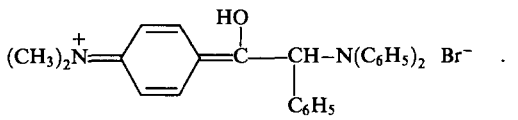
The working exposures in photoresists with chemical amplification are in the range $H = 2-10$ mJ cm^{-2}.

5. Chemical sensitisation of photosensitive systems

Chemical sensitisation is understood as the increase in the effectiveness of the chemical amplification by the introduction of an additional compound—a chemical sensitiser.

The mechanisms of the chemical sensitisation have been examined[55,98–100] as a function of the nature of the donor in photoresists based on charge-transfer complexes. Systems consisting of a poly(vinyl ethylal) matrix containing DTBS as the acceptor and tertiary amines—diphenylbenzylamine and triphenylamine (TPA)—as the donor have been investigated.

Dimethylaminobenzaldehyde (DMABA) was used as the chemical sensitiser. Under the influence of light at the wavelength corresponding to absorption by the complex Am · DTBMS, the latter dissociates into radical-ions with subsequent formation of coloured products and an acid, for example:



$$\text{DPBA}\cdot\text{DTBMS} \xrightarrow{h\nu} \text{DPBA}^{\cdot+} + \text{Br}^- \ldots \text{R}^\cdot \text{ (or } \text{R}^- \ldots \text{Br}^\cdot) \longrightarrow$$

$$\longrightarrow \text{CP}^+\text{Br}^- + \text{HR} \text{ (or } \text{CP}^+\text{R}^- + \text{HBr}) , \quad (24)$$

$$\text{DPBA}^{\cdot+} = (\text{C}_6\text{H}_5)_2\text{N}^{\cdot+} - \text{CH}_2 - \text{C}_6\text{H}_5,$$

$$\text{R}^\cdot = [\text{CBr}_2 - \text{SO}_2 - \text{CBr}_3]^\cdot .$$

The structures of CP^+Br^- and HR are given in Scheme (9). The quantum yield of CP^+Br^- and hence of the acids HR and HBr is ~0.05. The coloured product reacts with DMABA and forms a compound whose absorption has a maximum at 450 nm:[99,100]

(CP'^+Br^-)

It has been established[98–100] that the main chemical sensitisation reaction involves the protonation of DMABA by the acids HR and HBr, formed by the photochemical reaction (24), and the conversion of part of the keto-form $(CH_3)_2N^+H-C_6H_4-CHO\ R^-$ (and Br^-) into the enolic tautomer $(CH_3)_2N^+=C_6H_4=CHOH\ R^-$, the low oxidation potential of which $E_{1/2}$ = 0.49 V (s.c.e.) is responsible for the thermal electron transfer to DTBMS:

$$(\text{CH}_3)_2\text{N} - \text{C}_6\text{H}_4 - \text{CHO} \xrightarrow{\text{HR}} (\text{CH}_3)_2\text{N}^+\text{H} - \text{C}_6\text{H}_4 - \text{CHO} \rightleftarrows$$

$$\rightleftarrows (\text{CH}_3)_2\text{N}^+ = \text{C}_6\text{H}_4 = \text{CH(OH)R}^- \xrightarrow{\text{DTBMS}}$$

$$\longrightarrow (\text{CH}_3)_2\text{N}^+ = \text{C}_6\text{H}_4 = \text{C}^\cdot\text{OH} \ldots \text{Br}^- \ldots \text{R}^\cdot + \text{HR} . \quad (25)$$

$$(\text{DMABA}^+)$$

As shown in Scheme (25), the electron transfer from the enolic tautomer is followed by the abstraction of a proton, which leads to the formation of the radical-cation $DMABA^{\cdot+}$, the equilibrium reduction potential of which (via the reaction $DMABA \rightleftarrows DMABA^{\cdot-} + e$) is 1.1 (s.c.e.).[101] The mechanisms of the subsequent reactions depend on the ionisation potential of the tertiary amine.

In the case of compositions containing donors with high ionisation potentials $I_D \geqslant 7.3$ eV, such as DPBA (I_D = 7.5 eV) and DMABA itself (I_D = 7.36 eV),[102] new coloured products are formed via the reactions[99]

$$\text{DMABA}^{\cdot+} + \text{Br}^- \ldots \text{R}^\cdot \longrightarrow$$

$$\xrightarrow[-\text{HR}]{\text{DPBA}} (\text{CH}_3)_2\text{N}^+ = \text{C}_6\text{H}_4 = \text{C(OH)HC}(\text{C}_6\text{H}_5)\text{N}(\text{C}_6\text{H}_5)_2\text{Br}^- \quad (\text{CP}'^+\text{Br}^-)$$

$$\xrightarrow[-\text{HR}]{\text{DMABA}} (\text{CH}_3)_2\text{N}^+ = \text{C}_6\text{H}_4 = \text{C(OH)C(O)C}_6\text{H}_4\text{N}(\text{CH}_3)_2\text{Br}^- \quad (\lambda_{max} = 430 \text{ nm})$$

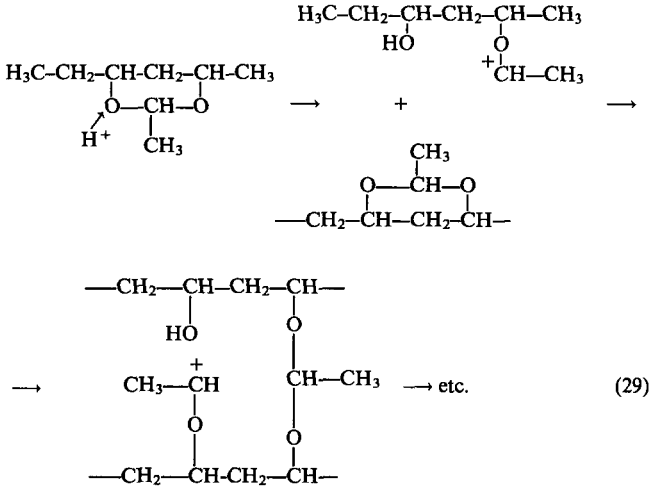
$$\xrightarrow[-\text{HR}]{} (\text{CH}_3)_2\text{N}^+ = \text{C}_6\text{H}_4 = \text{C} = \text{O}\ \text{Br}^- \quad (26)$$

The acid HR (or HBr) formed in addition enters into reaction (25) and ensures the further occurrence of reaction (26). The chemical amplification coefficient in the formation of the product CP'^+Br^- and hence of the acid HR via the upper pathway of reaction (26) is $\eta_{ef}/\eta_0 \simeq 50$.

In layers containing donors with low ionisation potentials, for example TPA (I_D = 6.8 eV),[102] the nature of the coloured product does not change during the chemical amplification process. In contrast to DPBA, a cyclic process takes place in these layers, where the photochemical formation of the acid, i.e.

$$\text{TPA}\cdot\text{DTBMS} \xrightarrow{h\nu} \text{TPA}^{\cdot-} \ldots \text{Br}^- \ldots \text{R}^\cdot$$

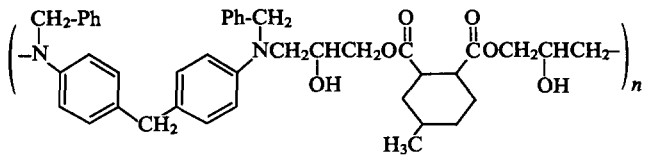
$$\text{TPA}^{\cdot+} \ldots \text{Br}^- \ldots \text{R}^\cdot \begin{cases} \longrightarrow \text{BPDPA} + \text{HR}^\cdot \\ \longrightarrow \text{CP}''^+\text{Br}^- + \text{HR} \end{cases} \quad (27)$$



[BPDPA = 4-bromophenyl(diphenyl)amine] is followed by reaction (25) and charge transfer:

$$\text{TPA} \xrightarrow{\text{DMABA}^+ \ldots \text{Br}^- \ldots \text{R}^\cdot} \text{TPA}^+ \ldots \text{Br}^- \ldots \text{R}^\cdot + \text{DMABA} . \quad (28)$$

where CP''^+Br^- is the coloured product obtained from TPA (with λ_{max} = 610 nm).

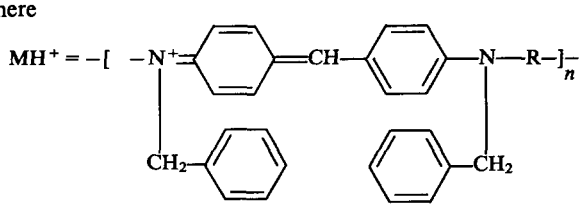


The formation of BPDPA as a result of the reaction between $TPA^{\cdot+}$ and Br^- in the presence of the anthracene radical has been established.[103] Reaction (27) is then repeated. The chemical amplification coefficient, determined from the product CP''^+Br^-, reaches ~600.

The acid ensures the effective cross-linking of the PVE chains by the reaction[55,97,99]
and a decrease in the solubility of the exposed section of the layer in the developer—a mixture of water and alcohol.

It is seen from the schemes presented above that, under the conditions of the chemical sensitisation of compositions based on tertiary aromatic amines, the photochemical formation of coloured products and the acids HR and HBr [reactions (24) and (27)] is followed by the thermal stages (25), (26), and (28) involving the additional formation of coloured products and the acids HR and HBr, in contrast to the systems based on onium salts and other compounds in which the acid is formed only under the influence of light [see reaction (23)].

Polymers containing electron-donating groups in the main chain, for example polyhydroxyaminoester (PHAE)[104]



are especially interesting. Polymers of this type are photosemiconductors[105] and, after the addition of halogen-containing acceptors (for example DTBMS) acquire the properties of photoresists. In principle, this makes it possible to use photolithography for the manufacture of microcircuits based on organic photosemiconductors. The photosensitivity is due to the formation of a charge-transfer complex between the donor fragment of the macromolecule and the acceptor. The complex has its intrinsic optical absorption in the visible region (300–550 nm) and its ionic photodissociation leads to the formation of coloured polycationic products of the type of Michler's hydrol (MH^+) (λ_{max} = 630 nm) and the acids HR:

$$PHAE \cdot DTBMS \xrightarrow{h\nu} PHAE^{\cdot+} \ldots Br^- \ldots R^{\cdot} \longrightarrow$$

$$\longrightarrow MH^+Br^- + HR \ , \qquad (30)$$

where

The polyhydroxyaminoester has a low ionisaion potential ($I_D \simeq 7.0$ eV). The addition of DMABA to the layer does not alter the nature of the coloured product but increases its quantum yield from η_0 = 0.12 to 1.2.[106] Thus, as in the case of TPA, in layers based on PHAE the photochemical formation of the acid via reaction (30) is followed by a cyclic process involving reaction (25), charge transfer with formation of $PHAE^{\cdot+}...Br^-...R^{\cdot}$ [a reaction of type (28)], and the repetition of the thermal stage of reaction (30). The different solubilities of the polycationic products and of the initial PHAE in polar and non-polar solvents are used in development.

In contrast to tertiary amines and PHAE, in compositions containing the secondary amine DPA as the donor, the Mannich reaction between $(CH_3)_2N^+H-C_6H_4-CHO$ and DPA takes place effectively in the presence of DMABA without the participation of DTBMS and with retention of the concentration of the acid formed on photolysis. The quantum yield of the triphenylmethane dye is 0.07 in the primary photochemical reaction. The ratio $\eta_{ef}/\eta_0 \simeq 35$ and 54 after the films have been maintained at 22 °C and 70 °C respectively.[99] The preferential occurrence of the Mannich reaction restricts the involvement of the acid in the cross-linking of the polymer chains via reaction (29).

6. Optical amplification of the latent image

Processes leading to the optical amplification of the latent image in non-silver photographic layers have been frequently discussed in the review literature.[5,20,43,107–110] Optical amplification (autosensitisation) was first established by Fotland.[107] In this process, the entire film carrying the latent image is acted upon by light in the spectral range where only the coloured products of the photochemical reaction [the auto-sensitiser, for example the product CP^+ formed by reactions (9) and (24)] absorbs, while the remaining components of the layer do not. In polymer systems containing donors such as the leuco-form of the triphenylmethane dye (LTD),[107] styryl derivatives,[108] heterocyclic aromatic compounds,[109] and the CBr_4 acceptor, the photoexcited coloured product transmits the energy absorbed to the complex via a triplet–triplet mechanism, ensuring the additional formation of the coloured product via a reaction of type (24). It has been demonstrated for LTD·CBr_4 that such transfer is possible by virtue of the low position of the triplet level of the complex.[107] In this complex, the triplet level ($E_T \simeq 1.8$ eV) lies appreciably below the excited singlet level ($E_S \simeq 3.2$ eV) and is close to the triplet level formed as a result of the action of light on the triphenylmethane dye (E_T = 1.7 eV).[107]

In compositions containing benzylanilines (DPBA and DBA) as donors and CBr_4 or DTBMS as acceptors, optical amplification occurs as a result of the transfer of triplet energy to the complex from the two-quantum-excited (with light at $\lambda \geqslant 650$ nm) coloured product CP^+. The subsequent ionic dissociation of the excited triplet complex via reaction (24) is responsible for the additional formation of CP^+ on the exposed sections.[5,110,111] This two-quantum process requires the use of powerful light sources. It has been established[19,97,112] that, when a pyrylium dye (Table 1, 2,2′,6,6′-tetraphenylpyrylomethinecyanine perchlorate) is introduced into the system consisting of PVE, DPBA, and DTBMS, the optical amplification changes from a two-quantum process to a low-energy one-quantum process. It has been shown that the above dye does not quench the fluorescence of the CP^+ but it does quench its phosphorescence. The unfavourable relative positions of the oxidation-reduction potentials of the reacting components are responsible for the low probability of quenching via electron transfer.[19] The coincidence of the upper limit of the spectral range corresponding to the emission of the triplet energy of CP^+ (1.77–1.41 eV) with the position of the triplet level of the pyrylium dye (1.77 eV) ensures that the autosensitisation reaction takes place via the triplet energy transfer mechanism:

$$CP^+ \xrightarrow{h\nu,\ S-T} {}^3(CP^+)_1 + Dy \longrightarrow CP^+ + {}^3(Dy)_1. \qquad (31)$$

Next $^3(Dy)_1$ induces the additional formation of CP^+ via reaction (9), as in the direct photoexcitation. Thus the pyrylium dye fulfills two functions in the photosensitive composition: it is a

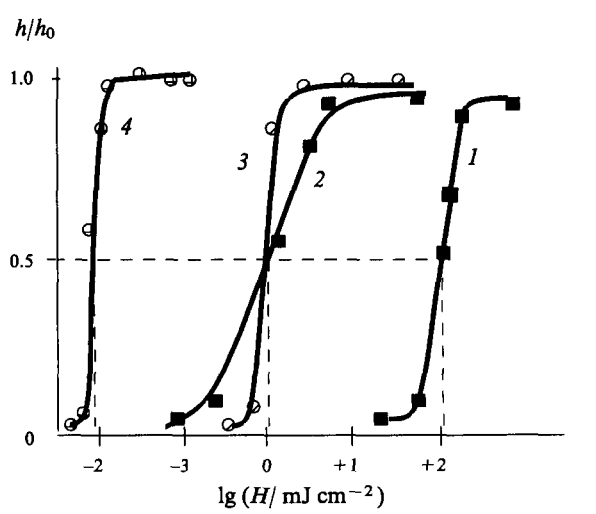


Fig.1 Dependence of the relative height of the relief h/h_0 on the exposure at λ = 576 ± 5 nm: (*1*) and (*3*) without amplification; (*2*) and (*4*) with optical amplification, the energy of the amplifying light being 0.1 J cm^{-2} (λ = 690–720 nm). h is the thickness of the layer retained on the exposed sections after the complete removal of the unexposed sections by dissolution in a mixture of water and alcohol; h_0 is the thickness of the initial layers. Concentrations employed (mol dm^{-3}): [DPA] = [DTBMS] = 0.8; [DMABA] = 0 (curves *1* and *2*) and 0.8 (curves *3* and *4*). The optical density of the dye at λ_{max} is 0.08. After exposure and optical amplification, the layers were maintained for 2.5 min at 100 °C.

Table 5. The photolithographic sensitivities ($H_{0.5}$ and H_{20}) and the photosensitivities ($S_{0.2}$) of layers comprising PHAE and DTBMS.

Optical amplification	$H_{0.5}$/ mJ cm^{-2}	H_{20}/mJ cm^{-2}	$S_{0.2}$/cm^2 J^{-1}
	Layer without DMABA		
Absent	180	180	16.3
Present	–	–	270
	DMABA introduced into layer		
Absent	28	12	163
Present	~0.4	~0.2	2.5×10^4

spectral sensitiser (S^+) in reaction (9) and ensures the formation of CP^+ on photoexcitation with a quantum yield $\eta_0 = 0.12$ (Table 1). Furthermore, it alters the mechanism of the optical amplification of the latent image by entering into reaction (31).

The transformation of the two-quantum process into a one-quantum process in these compositions is also achieved by adding indole. On interaction with the intermediate products of the photochemical reaction (24), the latter forms a new indole-containing coloured compound (ICC, λ_{max} = 550 nm, long-wavelength limit 700 nm), which is an autosensitiser of the oxidation–reduction type and ensures (in the photoexcited state) the occurrence of the one-quantum reaction (9) (in this case S^+ = ICC).[18] It is noteworthy that in compositions based on the DPA donor and the DTBS or CBr_4 acceptor the primary coloured product (λ_{max} = 665 nm) formed on photoexcitation is not an autosensitiser and the optical amplification becomes possible solely by virtue of the addition of indole.[18]

In photoresist systems, optical amplification has been achieved in layers based on charge-transfer complexes between the DPBA or PHAE donor and the DTBMS acceptor.[55,98,99,106] Fig. 1 illustrates the characteristic curves for the photoresists consisting of PVE, DPBA, DTBMS, and the dye 2,2',6,6'-tetraphenylpyrylomethinecyanine perchlorate (Table 1) in the absence or presence of DMABA on photoexcitation of the dye by light at a wavelength of ~576 nm. Fig. 1 shows that, in the absence of DMABA, the exposure giving the relative height of the relief is $h/h_0 = 0.5$, $H_{0.5}$ = 100 mJ cm^{-2}. Optical amplification makes it possible to increase $H_{0.5}$ to ~1 mJ cm^{-2}. Fig. 1 shows that this value of $H_{0.5}$ can be obtained also without optical amplification as a result of the addition of DMABA to the layer. Evidently, under the conditions of chemical and optical amplification of the latent image, a working exposure $H_{0.5}$ = 0.01 mJ cm^{-2} is attained.[98,99] Such low working exposures (high sensitivities) had not been obtained previously.

In layers based on PHAE, Michler's hydrol [formed via reaction (30) on exposure] is an autosensitiser of the oxidation–reduction type and ensures the optical amplification of the latent image [via a reaction of type (9), where $S^+ = MH^+$] on illumination of the entire layer with red light, which acts solely on MH^+, since the remaining components do not absorb in this region. The quantum yield of the additionally formed MH^+ under the conditions of its intrinsic photoexcitation is 0.9×10^{-2} and 0.24 in the absence and with addition of DMABA respectively. Analysis led to the conclusion[106] that in the presence of DMABA optical amplification proceeds in accordance with the mechanism

$$MH^+ \xrightarrow{h\nu,\ S-T} {}^3(MH^+)_1 + DMABA \longrightarrow MH^\cdot + DMABA^{\cdot+},$$

$$MH^\cdot + DTBMS \longrightarrow MH^+ + Br^- \ldots R^\cdot \ (\text{or } R^- \ldots Br^\cdot),$$

which is followed by the charge-transfer process

$$DMABA^{\cdot+} + PHAE \longrightarrow DMABA + PHAE^{\cdot+}$$

and the additional formation of MH^+ as a result of the occurrence of the thermal stages of reaction (30).

Table 5 presents the principal characteristics of the layers based on PHAE and DTBMS, namely $H_{0.5}$ and H_{20}, where H_{20} is the exposure for which the selectivity of the development is $U = t_e/t_u = 20$, where t_e and t_u are the times required for the dissolution of the exposed and unexposed sections, as well as $S_{0.2} = 1/H_{0.2}$, where $H_{0.2}$ is the exposure for which the optical density at the MH^+ absorption maximum (at 630 nm) reaches 0.2. Table 5 shows that the use of chemical and optical amplification of the latent image makes it possible to increase by approximately three orders of magnitude the photosensitivity of the recording layers based on polyhydroxyaminoesters and to obtain $H_{0.5} \simeq 0.4$ and $H_{20} \simeq 0.2$ mJ cm^{-2}, and $S_{0.2} = 2.5 \times \times 10^4$ cm^2 J^{-1}.

IV. Photochemical etching of bismuth films

The processes amplifying the primary effects of light in recording layers and in the photoresists examined above are universal and can be used for the sharp increase of the efficiency of any photochemical processes occurring in polymer systems. As an example, the non-resist photoetching of metallic films with the aid of polymer layers is examined below.

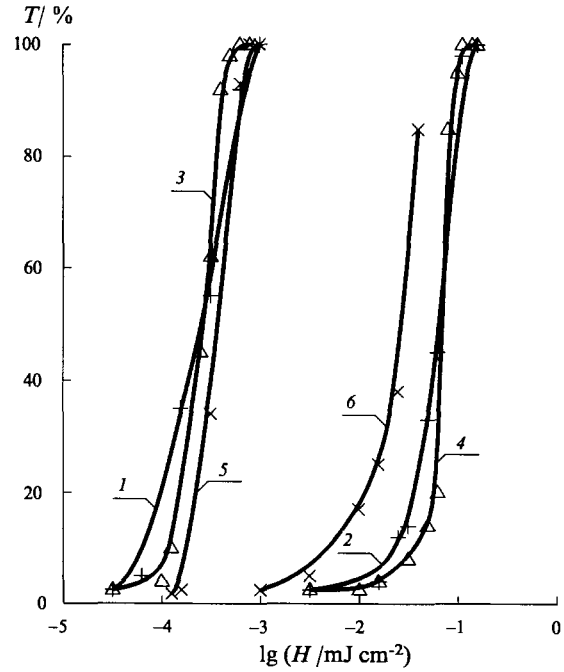

Fig. 2. Dependence of the transmittance of light (T) by a Bi film on the exposure: (*1*), (*3*), (*5*), and (*6*) with optical amplification; (*2*) and (*4*) without amplification; energy of amplifying light 0.06 J cm^{-2}; λ = 650–700 nm. Exposure: λ = 436 nm (curves *1*–*5*) and 633 nm (curve *6*). Composition of the photosensitive layer:
(*1*) and (*2*) PVC–DPA–indole–DTBMS;
(*3*) and (*4*) PVC–DPBA–indole–DTBMS;
(*5*) and (*6*) PVC–DBA–indole–DTBMS.

A new highly sensitive non-resist process for the photoetching of metallic bismuth films has been developed on the basis of polymer compositions incorporating DPBA, DPA, or DBA donors, the DTBMS acceptor, and indole.[113,114] The photosensitive polymer composition was deposited on a bismuth film (film thickness 0.2 μm) sputtered onto a support. It was established that metallic bismuth dissolves in the exposed sections of the polymer layer as a result of a two-stage reaction. In the first stage, bismuth reacts with the radical product Br$^{\cdot}$ (or R$^{\cdot}$) formed on illumination by reaction (24):

$$Bi \xrightarrow{Br^{\cdot}(R^{\cdot})} BiBr_{3-n}R_n ,$$

where $n = 0, 1, 2, 3$. In the second stage, after prolonged storage or on heating to 80–105 °C, the compound $BiBr_{3-n}R_n$ dissolves in the polymer composition as a result of the reaction with the photochemically generated acid HR(HBr). The degree of photoetching was inferred from the transmittance (T) in the range 750–800 nm, where only the metallic film absorbs and the polymer layer does not, or from the transmittance in the range 560–600 nm after the removal of the entire polymer layer by dissolution, for example, in acetone. Fig. 2 illustrates the dependence of the transmittance by the bismuth film on the exposure obtained under conditions with optical amplification of the latent image and without such intensification. Evidently the increase in transmittance from 1.56 to 50% under the influence of light at $\lambda = 436$ nm is attained for exposures $H_{50} \simeq 0.07$ J cm^{-2} in the absence of amplification, but the etching process is characterised by a high photosensitivity: $H_{50} \simeq 3 \times 10^{-4}$ J cm^{-2} for optical amplification of the latent image. For exposure in the region of the long-wavelength absorption limit of the complex DBA · DTBMS at $\lambda = 633$ nm, the photosensitivity is $H_{50} \simeq 2 \times 10^{-2}$ J cm^{-2}, as shown in Fig. 2.

***

Thus, a common feature of all the methods of amplifying the primary effects of light is the formation of photoproducts whose physicochemical properties differ significantly from those of the initial components and the accumulation of these photoproducts as a result of the subsequent occurrence of autocatalytic reactions with their participation, the selective action of light on them, etc.

A distinctive property of the systems considered is the fact that only components present in polymer layers participate in the amplification process and there is therefore no need for their additional treatment in liquid or gaseous media.

The fields where these systems are used, determined by the characteristic features of their functioning, are, in particular, the highly sensitive optical recording of information, the detection of weak optical signals, the photomodification of spectroscopic and physicochemical properties of polymer layers, and the selective photosynthesis of a number of chemical compounds in polymer matrices.

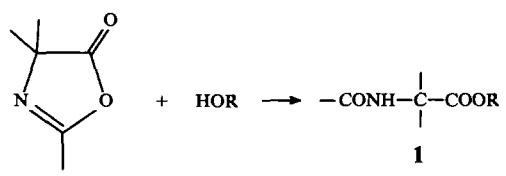
VI.	Intramolecular reactions of 5(4*H*)-oxazolones containing a hydroxy-group	61

Abstract. The literature data on the interaction of 4,5-dihydro-5-oxo-1,3-oxazoles with alkyl and aryl alcohols as well as aminoalcohols are surveyed. The intramolecular reactions of the oxazoles containing a hydroxy-group are examined. The bibliography includes 141 references.



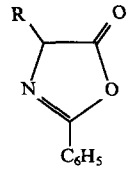
I. Introduction

Several reviews have been published since 1946 on the synthesis and chemical properties of 4,5-dihydro-5-oxo-1,3-oxazoles [(5(4*H*)-oxazolones)].[1–5] However, the reactions of 5(4*H*)-oxazolones with oxygen-containing nucleophiles are inadequately described in all these publications. Nevertheless, these reactions afford various compounds which are of both theoretical and practical interest.

At the present time, numerous studies devoted to the interaction of 5(4*H*)-oxazolones with oxygen-containing nucleophiles have accumulated in the literature. The aim of the present review is to survey the literature data on the interaction of both saturated and unsaturated 5(4*H*)-oxazolones with alcohols, phenols, aminoalcohols, and hydroxylamine derivatives. The intramolecular reactions of oxazolones containing a hydroxy-group are also discussed.

II. Reactions with alcohols and phenols

The reactions of 5(4*H*)-oxazolones with alkyl alcohols and aromatic alcohols proceed mainly with the cleavage of the 1,5-bond of the heterocycle, forming the corresponding esters of *N*-substituted aminoacids **1**:



1

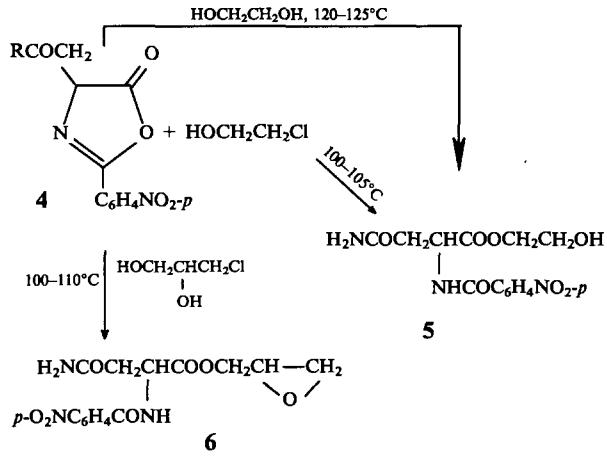
In this process, saturated and unsaturated 5(4*H*)-oxazolones exhibit different reactivities. As a rule, saturated 5(4*H*)-oxazolones are more reactive than their unsaturated analogues. 4-Benzyl-2-phenyl-5-oxazolone **2** (R = $C_6H_5CH_2$ reacts smoothly at room temperature with methanol, forming the methyl ester of *N*-benzoylphenylalanine, whereas 4-benzylidene-2-phenyl-5-oxazolone **3** remains unchanged under similar conditions.[2]

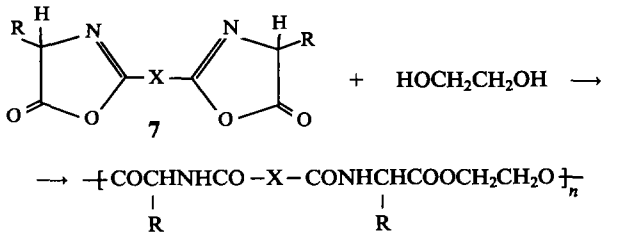
2



3

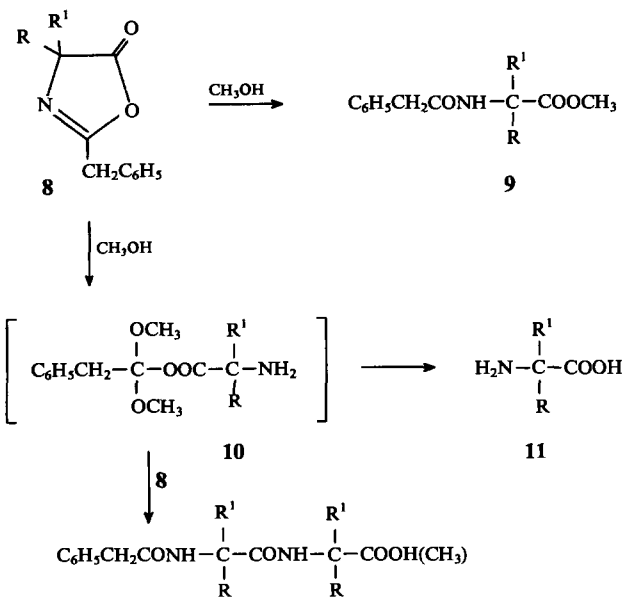
The inertness of unsaturated 5(4*H*)-oxazolones in relation to alcohols is indicated by their recrystallisation from ethanol, which has been described in most studies devoted to the synthesis of these compounds.

The rate of alcoholysis is also affected by the nature of the substituent in the 4-position in saturated 5(4*H*)-oxazolones. It has been noted[2] that the oxazolone **2** (R = $C_6H_5CH_2$) reacts with alcohols faster than 2-phenyl-5-oxazolones **2** (R = H), while 4-methyl-2-phenyl-5-oxazolone **2** (R = CH_3) reacts more slowly than the latter.



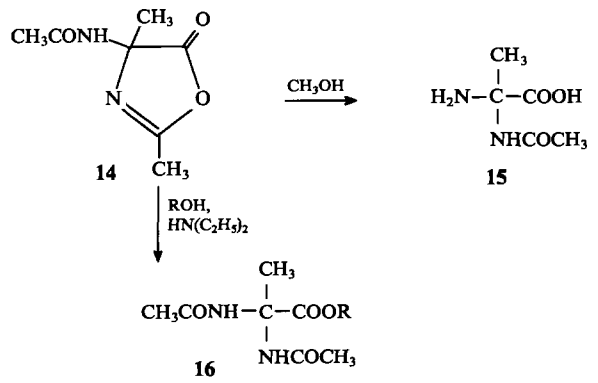
The alcoholysis also depends on the nature of the alcohol. Certain oxazolones react with methanol but are inert with respect to ethanol.[6] Secondary alcohols react with 5(4*H*)-oxazolones with difficulty, whilst tertiary alcohols frequently do not react at all.[4]

4-Carboxymethyl-2-(*p*-nitrophenyl-5-oxazolone **4** (R = OH) reacts with ethylenechlorohydrin at high temperatures (110–120 °C) to form the α-2-chloroethyl ester of *N*-*p*-nitrobenzoyl-DL-asparagine.[7,8] It is of interest to note that 4-aminomethyl-2-(*p*-nitrophenyl)-5-oxazolone **4** (R = NH_2) forms the 2-hydroxyethyl ester of the corresponding acid **5** under analogous conditions. The latter compound was also obtained by the reaction of the oxazolone **4** (R = NH_2) with 1,2-ethylene glycol.[7]

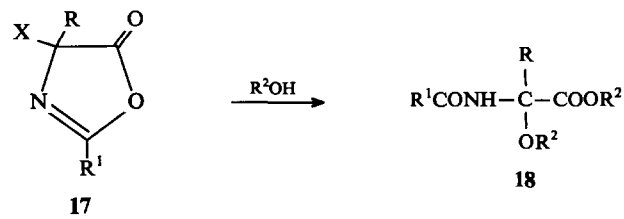


When the ratio of oxazolone **4** to ethylene glycol is 2 : 1 at 85–95 °C, the product of the reaction in dioxane is the bis-*O*-acylated glycol.[7] It was noted in the same communication that the oxazolone **4** (R = NH_2) reacts with glycerol-α-chlorohydrin [1-chloropropane-2,3-diol?] at high temperatures to form 2,3-epoxypropyl ether **6**.

The interaction of 2,2-bisoxazolones **7** with ethylene glycol at a temperature not exceeding 60 °C for 146 h leads to the formation of polymers:[9]

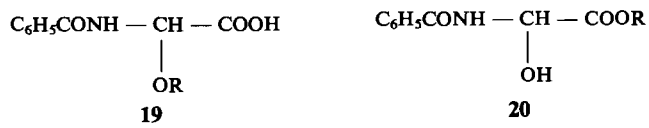


The reaction of unsaturated 5(4*H*)-oxazolones with ethylene glycol takes place at a higher temperature (150 °C).[10] Heating of glycerol containing 1–2% of an unsaturated 5(4*H*)-oxazolone to 200 °C leads to the formation of the monoglyceryl ester of a *N*-substituted aminoacid.[11,12]

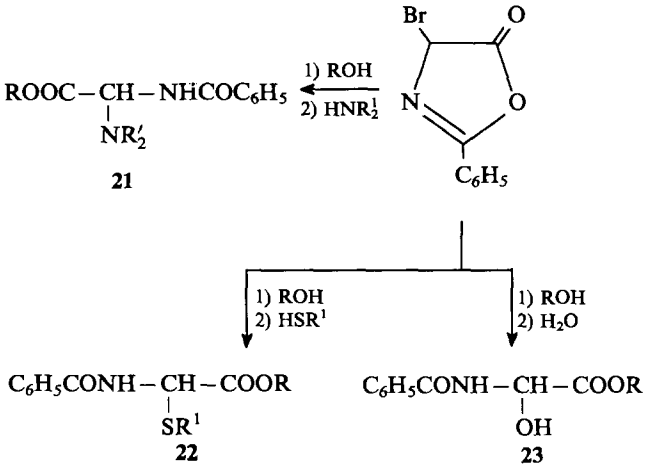


Certain saturated 5(4*H*)-oxazolones containing the benzyl substituent in the 2-position in the heterocycle behave in a non-standard manner on alcoholysis. Treatment of 2-benzyl-4-methyl-5-oxazolone **8** (R = H, R^1 = CH_3) or 2-benzyl-4,4-dimethyl-5-oxazolone **8** (R = R^1 = CH_3) with absolute alcohol does not, against expectation, lead to the formation of ester **9**. Under similar conditions, 2-benzyl-4-(*p*-methoxy-benzyl)-5-oxazolone **8** (R = H, R^1 = $CH_2C_6H_4OCH_3$-*p*) and 2-benzyl-4-isobutyl-5-oxazolone **8** [R = H, R = $CH_2CH\cdot(CH_3)_2$] not only undergo cleavage of the 1,5-bond with formation of the expected esters **9** but also react with the oxazolones as aminoalcohols with formation of the intermediate **10**. The latter can either decompose to the aminoacid **11** or its reaction with the oxazolone **8** can lead to the *N*-substituted dipeptide **12** or its ester **13**.[2]

The appearance of α-acetamidoalanine **15** in the methanolysis of 4-acetamido-2,4-dimethyl-5-oxazolone **14** is also explained by the formation of an intermediate analogous to compound **10**.[13] According to Nicolet,[14] the alcoholysis (methanolysis, ethanolysis) of the oxazolone **14** in the presence of diethylamine proceeds normally with formation of the ester **16**.

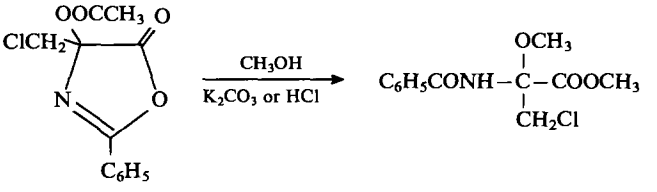


4-Halooxazolones **17** react smoothly with different alcohols.[15–20] The reaction with an excess of alcohol leads to the formation of *N*-substituted α-alkoxyaminoacids **18**. Under identical conditions the process proceeds with participation of both primary and secondary alkyl, arylalkyl, and alicyclic alcohols.[17]



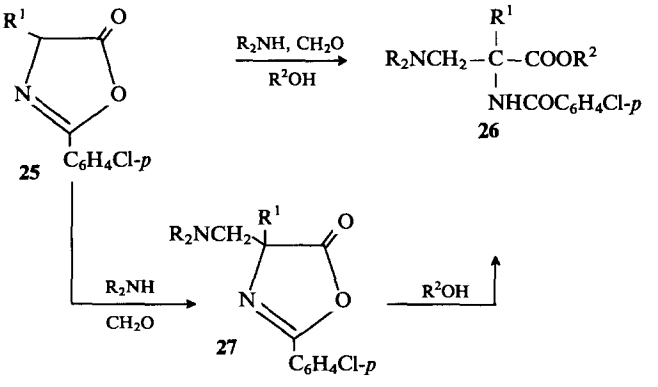
In the reaction of *tert*-butyl alcohol with 4-bromo-2-phenyl-5-oxazolone **17** (X = Br, R = H, R^1 = C_6H_5), *N*-benzoyl-α-*tert*-butoxyglycine **19** [R = $C(CH_{33}]$ and the *tert*-butyl ester of *N*-benzoyl-α-hydroxyglycine **20** [R = $C(CH_3)_3$] were obtained together with the *tert*-butyl ester of *N*-benzoyl-α-*tert*-butoxyglycine **18** [R = H, R^1 = C_6H_5, R^2 = $C(CH_3)_3$].

The analogous reaction with phenol leads to the formation of the phenyl ester of the aminoacid **20** (R = C_6H_5).[17] According to



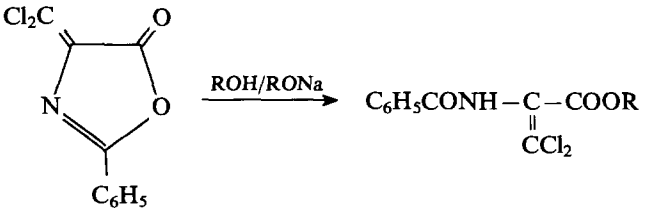
Chaman and co-workers,[15,17] the process under consideration, involving the alkoxides derived from alkyl alcohols, proceeds with greater difficulty than the reaction with the alcohols.

The study of the reaction of 4-halo-5(4*H*)-oxazolones with alcohols established[16,17] that opening of the oxazolone ring is proceeds faster than the substitution of the halogen atom by the alkoxy-group. This difference in reactivity has been used for the synthesis of esters of *N*-benzoylglycine with various substituents in the α-position compounds **21**–**23** (cf. Shemyakin and co-workers[17–20]).



An α-alkoxyaminoacid ester is also formed in the reaction of 4-acetoxy-4-chloromethyl-2-phenyl-5-oxazolone **24** with methanol:[16]

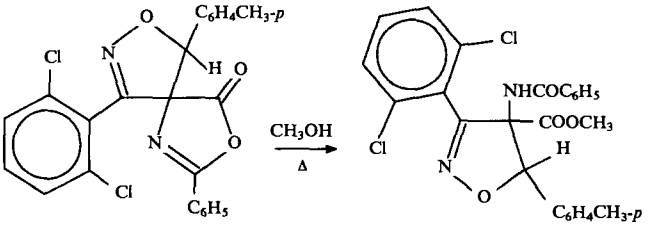
24



In the methanolysis of the oxazolone **24** in the presence of 10% potassium carbonate, the yield of the ester is 70%, whereas in the presence of hydrogen chloride the methanolysis proceeds with 50% yield. In the latter case, the corresponding α-methoxy-acid was also isolated from the reaction mixture in 15% yield.

The dialkylaminomethyl group in the 4-position of the saturated 5(4*H*)-oxazolone promotes alcoholysis. Under the conditions of the Mannich reaction,[21,22] carried out in methanol or ethanol, the oxazolone **25** gives rise to the formation of esters of 2-*N*-acylamino-3-dialkylaminopropionic acid **26**:

It was established that the product of the Mannich reaction — the oxazolone **27** — undergoes the ring opening reaction,[22] whereas according to other data[21] 2-*p*-chlorophenyl-5-oxazolones **25** are inert in relation to ethanol.



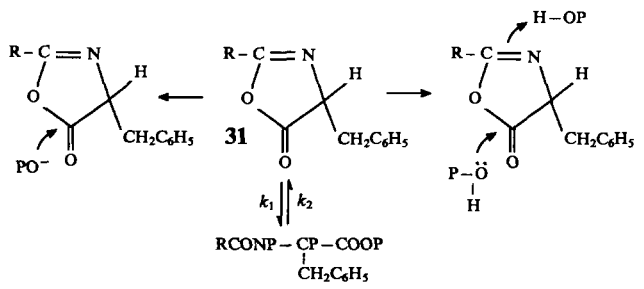
The alcoholysis of 4-dichloromethylene-2-phenyl-5-oxazolone **28** takes place on refluxing for up to 30 h with aliphatic alcohols (methanol, ethanol, isopropyl alcohol).[23] The process is accelerated in the presence of sodium alkoxides[24] but the substitution of halogen atoms is not then observed:

28

This phenomenon has been explained with the aid of Pearson's principle of hard and soft acids and bases (HSAB). Evidently the electrophilic centres in the oxazalone **28** — the carbon atoms of the dichloromethylene group and the carbon atom of the carbonyl group — clearly differ in their 'hardness'. The hard nucleophile — the alkoxide anion — therefore prefers to interact with the hard electrophilic centre located on the carbonyl group.[24]

4-Hydroxymethylene-2-phenyl-5-oxazolone readily undergoes alcoholysis by *p*-methoxybenzyl and 2,2,2-trichloroethyl alcohols when a benzene solution of the oxazolone and the corresponding alcohol are refluxed.[25] The spiro-oxazolones **29** also exhibit properties characteristic of 5(4*H*)-oxazolones; on refluxing, they react with methanol, affording the corresponding esters **30**:[26]

29 **30**



Among phenols, phenol itself and β-naphthol interact readily with 5(4*H*)-oxazolones.[27]

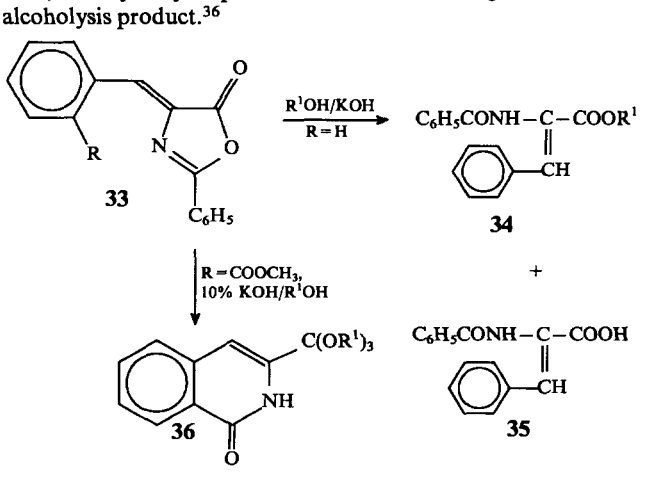
The reaction of saturated 5(4*H*)-oxazolones with phenols, especially *p*-nitrophenol, is also of theoretical importance in the study of the stereospecificity of peptide synthesis by the method of activated esters. One of the pathways leading to the racemisation of *N*-acylaminoacids in the formation of a peptide bond involves the intermediate formation of 5(4*H*)-oxazolones.[28] The question of both the formation of 5(4*H*)-oxazolones and of the opening of the oxazolone rings under the conditions of peptide synthesis has therefore become important. A number of studies have been devoted to such questions.[29–31]

The relative reactivities of 4-benzyl-2-benzyloxycarbonylaminomethyl-5-oxazolone **31** (R = $C_6H_5CH_2OCONHCH_2$) in relation to *p*-nitrophenol, dinitrophenol, and pentafluorophenol have been investigated.[29,30] According to Kovacs, et al.,[30] the above phenols can be arranged in the following sequence in terms of descending rate of opening of the oxazolone **31** ring: dinitrophenol, pentachlorophenol, *p*-nitrophenol. In all cases the rate of reaction depends on the phenol concentration. In the presence of triethylamine the series becomes *p*-nitrophenol, pentachlorophenol, dinitrophenol. Whereas in the absence of a tertiary amine the reactivity of phenols increases with enhancement of their acid properties, in the presence of triethylamine the opposite behaviour is observed. On this basis, one may conclude that the mechanisms of the opening of the oxazolone **31** ring by phenols and phenoxide anions differ.[29,30]

Thus the acidity of the phenols affects both the rate and the mode of the alcoholysis of 5(4*H*)-oxazolone. The comparatively less acid *p*-nitrophenol reacts slowly with the oxazolone **31**, as a result of which the resulting ester is racemic.[30]

Similar results were obtained in a study of the reaction of 4-benzyl-2-phenyl-5-oxazolone **31** (R = C_6H_5) with *p*-nitrophenol in the presence of tributylamine.[31] The determination of the rate constants for the forward (k_1) and reverse (k_2) reactions in the formation of the ester **32** (P = *p*-$NO_2C_6H_4$) for oxazolone : phenol : amine ratios of 1 : 10 : 10 shows that the equilibrium is displaced towards the formation of the ester.[31]

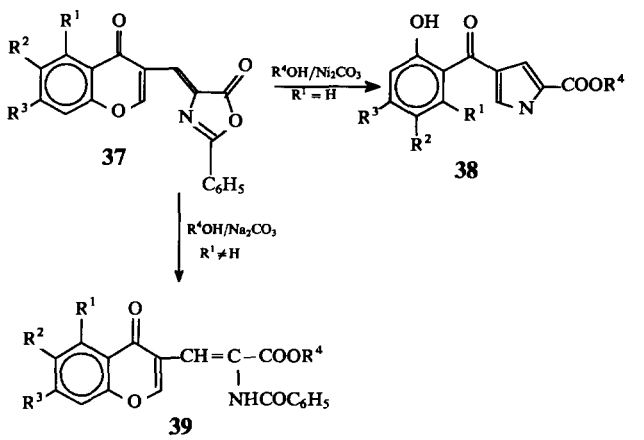
32



The kinetics of the reactions of 2-phenyl-5-oxazolone with substituted phenoxide anions have been investigated.[32]

p-Nitrophenyl *N*-benzamidoisobutyrate was obtained by the reaction of 4,4-dimethyl-2-phenyl-5-oxazolone with *p*-nitrophenol in the presence of triethylamine.[33] According to Suh et al.,[34] phenol reacts smoothly at pH 7 with unsaturated 5(4*H*)-oxazolones.

The reactions of oxazolones with alcohols and phenols are catalysed by both bases and acids.



Potassium[10, 35–38] or sodium[10, 39–44] hydroxides have been used to catalyse the alcoholysis of unsaturated 5(4*H*)-oxazolones. There have also been studies where alkali metal salts were used for this purpose: potassium[45] and sodium[42, 46–48] carbonates and also sodium acetate[49, 50] and tetrahydroborate.[51] Evidently in all cases the reaction is accelerated by the alkoxide ion generated under these conditions, which leads to the cleavage of the 1,5-bond of the oxazolone ring. According to Tripathy and Mikerjee,[36] in the case of unsaturated 5(4*H*)-azlactones the addition of the alkoxide anion to the exocyclic double bond is not observed.

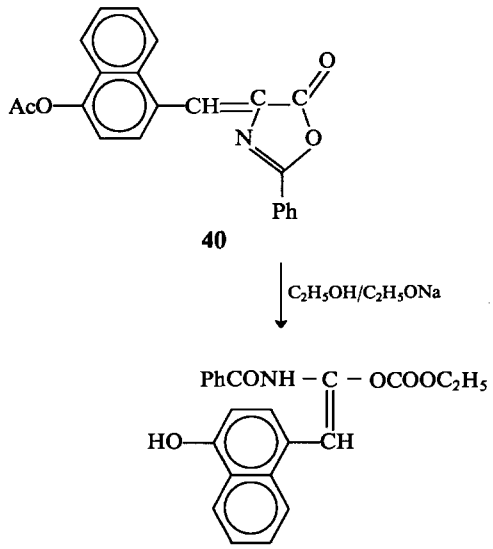
Analysis of the literature data shows that the amount of alkali used can affect the nature of the final products. The reaction of 4-benzylidene-2-phenyl-5-oxazolone **33** (R = H) with ethanol in the presence of catalytic amounts of potassium hydroxide leads to the formation of the ethyl ester of *N*-benzoyl-α,β-dehydrophenylalanine **34** (R^1 = C_2H_5 in a high yield. When an equivalent amount (in relation to the oxazolone) of alkali is used, the hydrolysis product **35** is detected together with the alcoholysis product.[36]

According to Stiller's data[35] the formation of only the acid **35** is observed in the reaction of the same oxazolone **33** (R = H) with a 10% alcoholic solution of potassium hydroxide. Evidently an increase in the amount of potassium hydroxide increases the concentration of hydroxide anions, increasing thereby the possibility of the competing reaction — the hydrolysis of the oxazolone. The formation of the ester **34** (R^1 = CH_3) and the acid **35** is also observed in the methanolysis of the oxazolone **33** (R = H) in a methanol – 1 M sodium hydroxide solution at room temperature.[43]

It is of interest to note that, in the presence of 10% potassium hydroxide in methanol or ethanol, 4-(*o*-methoxycarbonylbenzylidene)-2-phenyl-5-oxazolone **33** (R = $COOCH_3$) gives rise to the orthoformate **36** (R = CH_3 or C_2H_5).[35] The effect of the nature of the substituent in the 4-position on the product of the alcoholysis of 5(4*H*)-oxazolone is also observed in the reactions of unsaturated oxazolones **37** with alcohols (methanol, ethanol) in the presence of sodium carbonate.[46] Depending on R^1 in the benzene ring of the chromone residue of the oxazolone **37**, the reaction product can be the pyrrole **38** or the ester of the corresponding acid **39**:

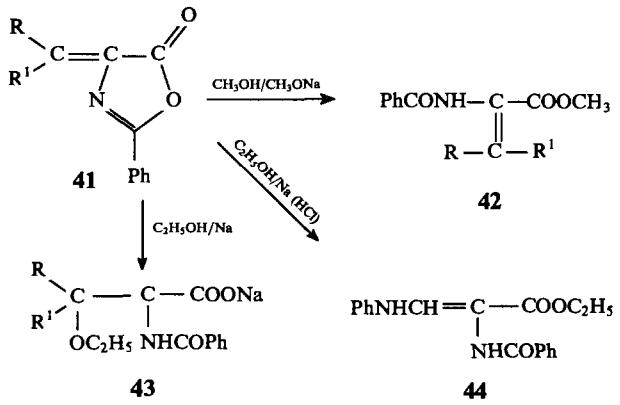
It has been noted[46] that both the oxazolone **37** and the ester **39** are converted into the pyrrole **38** on refluxing in the presence of sodium methoxide regardless of R^1.

The results of a study carried out to determine the optimum conditions for the alcoholysis of a series of unsaturated 5(4*H*)-oxazolones in the presence of ethylene chlorohydrin and ethylene glycol have been published.[10] It was established that in the case of ethylene chlorohydrin it is necessary to avoid a high concentration of the hydroxide anion (a 5% KOH solution is optimal), while in the case of ethylene glycol base catalysis can be replaced by the corresponding increase in temperature.



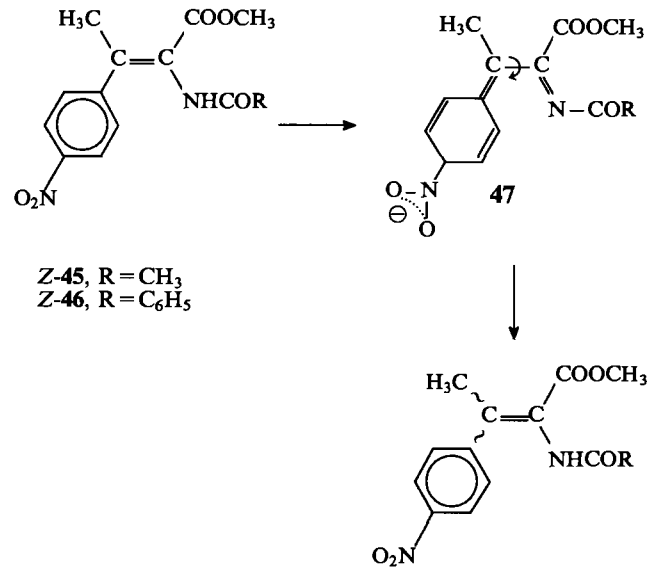
The influence of the electronic effects of the substituent in the 4-position in unsaturated 5(4*H*)-oxazolones on the rate of base-catalysed alcoholysis has been investigated.[39]

One of the common ways of catalysing the reactions of unsaturated 5(4*H*)-oxazolones with aliphatic alcohols is the method involving the use of the alkoxides derived from the same alcohols. The reaction proceeds mainly with the formation of the alkyl esters of *N*-substituted α,β-dehydroaminoacids with satisfactory results.[2, 24, 42, 46, 52–74]



The ethanolysis of 4-[(4-acetoxy-1-naphthyl)methylene]-2-phenyl-5-oxazolone **40** in the presence of sodium ethoxide proceeds with simultaneous deacylation.[72]

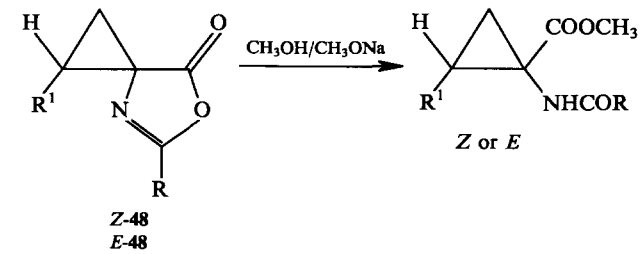
It has been established[56] that the reaction of 4-isopropylidene-2-phenyl-5-oxazolone **41** (R = R^1 = CH_3) with methanol in the presence of sodium methoxide at pH 8.5 at room temperature is completed quantitatively after 4 h, whereas at 80 °C it leads to the formation of the methyl ester **42** (R = R^1 = CH_3) in 60% yield after 0.5 h. According to Zubareva et al.,[57] the methanolysis of the same oxazolone in the presence of comparatively small amounts



of sodium alkoxide leads to the expected ester **42** in 60% yield at room temperature after 20–25 h.

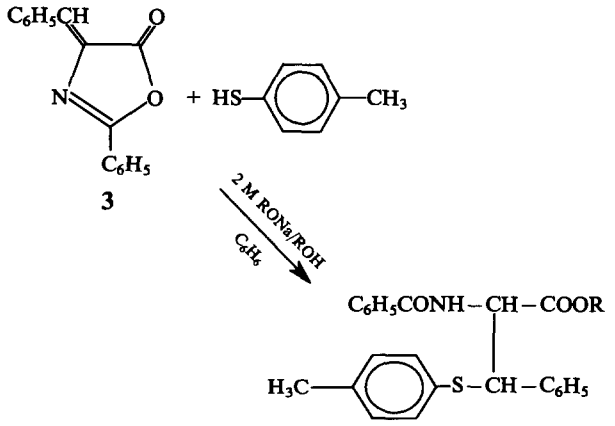
Cases are known where in the presence of sodium alkoxide the alcohol not only cleaves the 1,5-bond of the unsaturated 5(4*H*)-oxazolone but also adds to the exocyclic double bond of the heterocycle.[2, 4] 4-Ethylidene-2-phenyl-5-oxazolone **41** (R = H, R^1 = CH_3) is stable in boiling ethanol for 88 h. However, in the presence of sodium ethoxide the product was ethyl α-benzamido-β-ethoxybutyrate **43** (R = H, R^1 = CH_3).[2] The alkoxy-group in the 4-position increases the stability of the oxazolone ring in relation to alcohols.[4] However, according to the data quoted by Conforth,[2] the 2-phenyl-4-phenyl-4-phenylaminomethylene derivative **41** (R = H, R^1 = C_6H_5NH) reacts readily with ethanol in the presence of sodium ethoxide, giving rise to the ester of α-benzamido-β-phenylaminoacrylic acid **44**.[55]

One of the important questions concerning the alcoholysis of unsaturated 5(4*H*)-oxazolones is that of the configuration of the double bond in the reaction products. The study of this problem established[62] that reactions of *Z*- and *E*-4-arylethylidene-2-phenyl-5-oxazolones **41** (R = Ar, R^1 = CH_3) with sodium methoxide in methanol involve the stereospecific opening of the oxazolone ring with formation of the methyl esters of the corresponding *Z*- and *E*-acids. The same effect has been observed for 4-isobutylidene-2-phenyl-5-oxazolone **41** (R = C_2H_5, R^1 = CH_3) [56, 57] or 2-methyl(phenyl)-4-thienylmethylene-5-oxazolone **41** (R = thienyl, R^1 = H).[58, 68] However, in the case of *Z*-4-(α-*p*-nitrophenylethylidene)-2-phenyl-5-oxazolone **41** (R = 4-$NO_2C_6H_4$, R^1 = CH_3) the initial oxazolone isomer isomerises to form a mixture of the *Z*- and *E*-isomers of the expected ester with the *E*-isomer predominating.[62] The isomerisation of the *p*-nitrophenyl derivatives **45** and **46** can be explained by the fact that under alkaline reaction conditions the quinonoid compound **47**, in which rotation about the C–C bond becomes possible, may be formed:



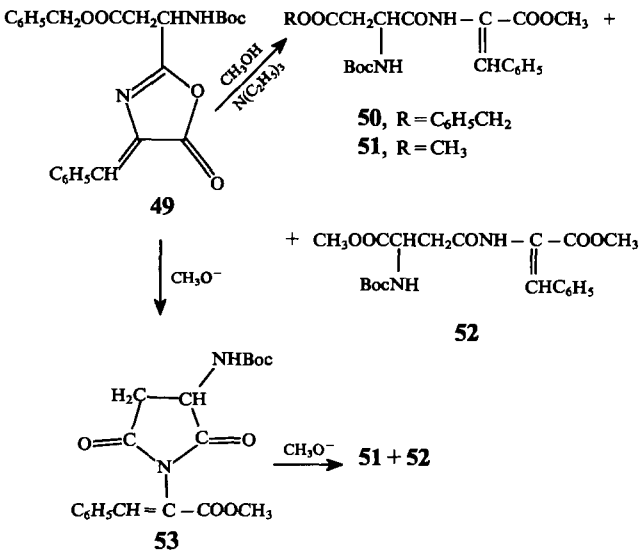
This conclusion is confirmed by the finding that the alcoholysis of the oxazolone *Z*-**46** in the presence of catalytic amounts of sulphuric acid proceeds without isomerisation.[62]

It is of interest to note that *Z*-4-benzylidene-2-phenyl-(methyl)-5-oxazolone **41** (R = H, R^1 = C_6H_5) undergoes alcoholysis in the presence of sodium alkoxide without change in the conformation of the double bond. However, the *E*-isomer leads to the formation of a mixture of the *Z*- and *E*-alkyl esters of *N*-substituted α,β-dehydrophenylalanine **42** (R = C_6H_5, R^1 = H) under the same conditions with the *Z*-isomer predominating.[53, 62]



The alcoholysis of 4-(*p*-dimethylaminobenzylidene)-2-phenyl-5-oxazolone **41** [R = H, R^1 = 4-$(CH_3)_2NC_6H_4$] in the presence of alkali (NaOH) proceeds stereoselectively, while acid alcoholysis leads to the formation of a mixture of two geometrical isomers of the unsaturated ester **42** [R = H, R^1 = 4-$(CH_3)_2NC_6H_4$].[44]

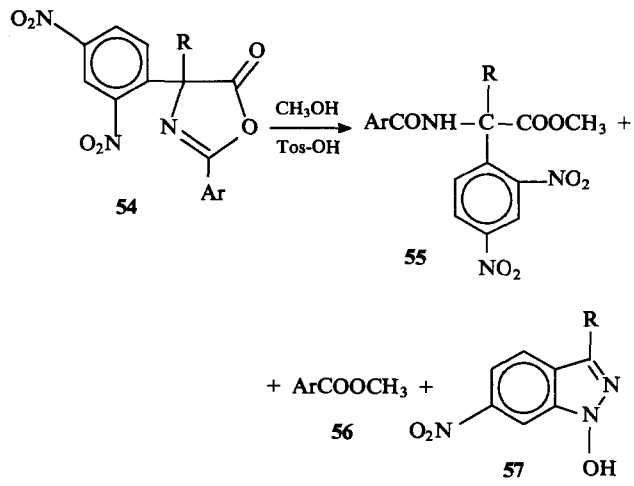
The spiro-oxazolones **48** having both the *E*- and *Z*-conformations readily react with absolute methanol in the presence of catalytic amounts of sodium methoxides, being converted into the corresponding esters:[66, 67]



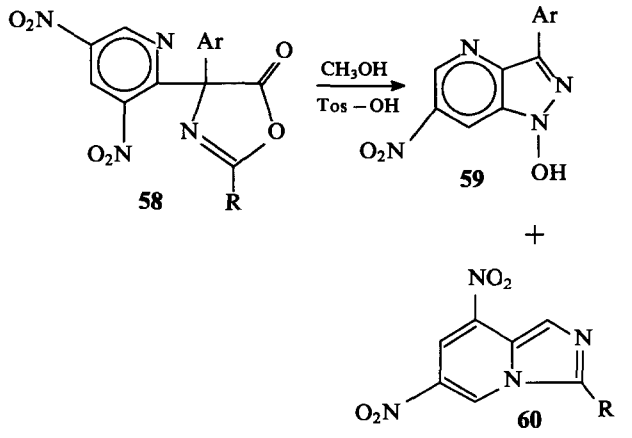
Z-48
E-48

It has been shown[2, 53] that the reaction of the oxazolone **3** with tolylmercaptan in the presence of sodium methoxide proceeds with formation of the corresponding ester of α-benzamido-β-phenyl-β-(*p*-tolylthio)propionic acids (see over):

The alcoholysis of 5(4*H*)-oxazolones also occurs in the presence of organic bases—amines. Both secondary[13] and tertiary[75–78] amines have been used for this purpose.



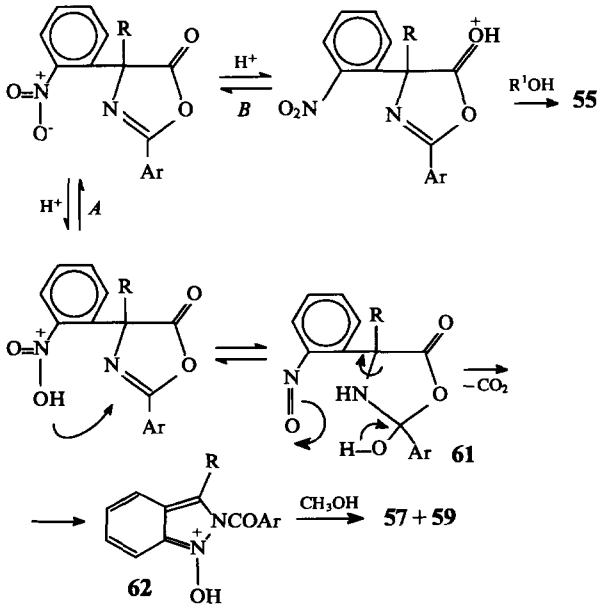
The methanolysis of the oxazolone **49** in the presence of triethylamine does not proceed unambiguously.[76] It affords a mixture of three compounds—the benzyl ester **50** and the methyl esters **51** and **52**. Evidently when the oxazolone ring is opened at the 1,5-bond on treatment with the nucleophile, the succinimide **53** is formed and leads to the formation of the unexpected methyl esters **51** and **52**.



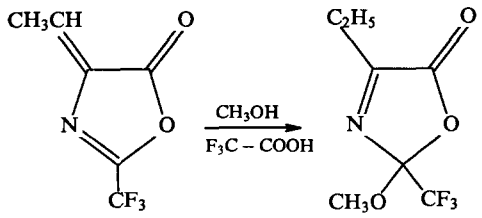
It has been noted[76] that the methanolysis of the oxazolone **49** in the presence of equimolar amounts of 4-dimethylaminopyridine leads unambiguously to the desired ester **50** without side products.

The opening of the oxazolone ring by alcohols is also catalysed by acids. Sulphuric acid,[79, 80] hydrochloric acid,[75, 81, 82] and toluene-*p*-sulphonic acid[83] have been used. In all cases the main reaction product is the alkyl ester of a *N*-substituted aminoacid.

According to D'Anello et al.,[83] on refluxing in methanol in the presence of catalytic amounts of toluene-*p*-sulphonic acid, 2-aryl-4-(*o*-nitrophenyl)-5-oxazolones **54** afford mixtures of methyl benzoate **56** and derivatives of 1-hydroxy-1*H*-indazole **57**. This reaction proceeds similarly also in ethanol and 1,2-ethylene glycol. However, in 2-propanol or *tert*-butyl alcohol, the main product is compound **57**. It is of interest to note that, both in the presence and absence of toluene-*p*-sulphonic acid in methanol, the oxazolone **54** (R = *iso*-C_3H_7) gives rise to the methyl ester of the corresponding acid **55** (R = *iso*-C_3H_7).

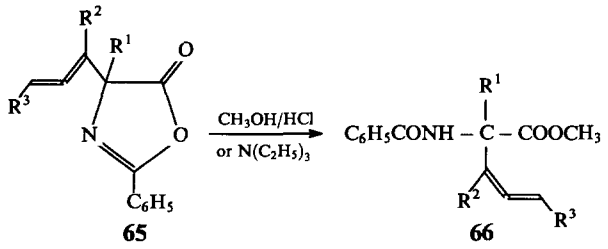


The reaction of 4-(β-nitropyridyl)oxazolones **58** with methanol in the presence of toluene-*p*-sulphonic acid has also been investigated.[83] It was established that the main reaction products are the indazole **59** and the imidazo[1,5-a]pyridine **60**:

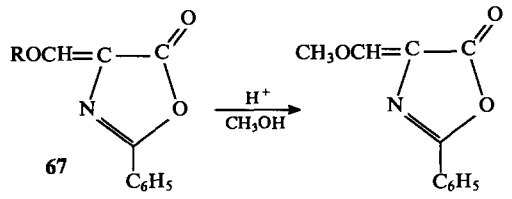


An ester analogous to compound **55** is formed in small amounts in this process.

The formation of compounds **57** and **59** can be explained by the nucleophilic attack by the oxazolone nitrogen atom on the protonated nitro-group (pathway *A*) with subsequent migration



of the hydroxy-group to C(2) — an oxazolone carbon atom. After the evolution of carbon dioxide, the intermediate **61** formed in this process is converted into compound **62**, in which deacylation by the alcohol takes place with formation of compound **57** or **59**. The competing reaction — the catalytic opening of the oxazolone ring with formation of the aminoacid ester **55** (pathway *B*) — takes place simultaneously.



In the presence of trifluoroacetic acid, the reaction of a mixture of the *Z*- and *E*-isomers of 4-ethylidine-2-trifluoro-methyl-5-oxa-zolone **63** with methanol gives rise to the 1,4-adduct **64**:[84]

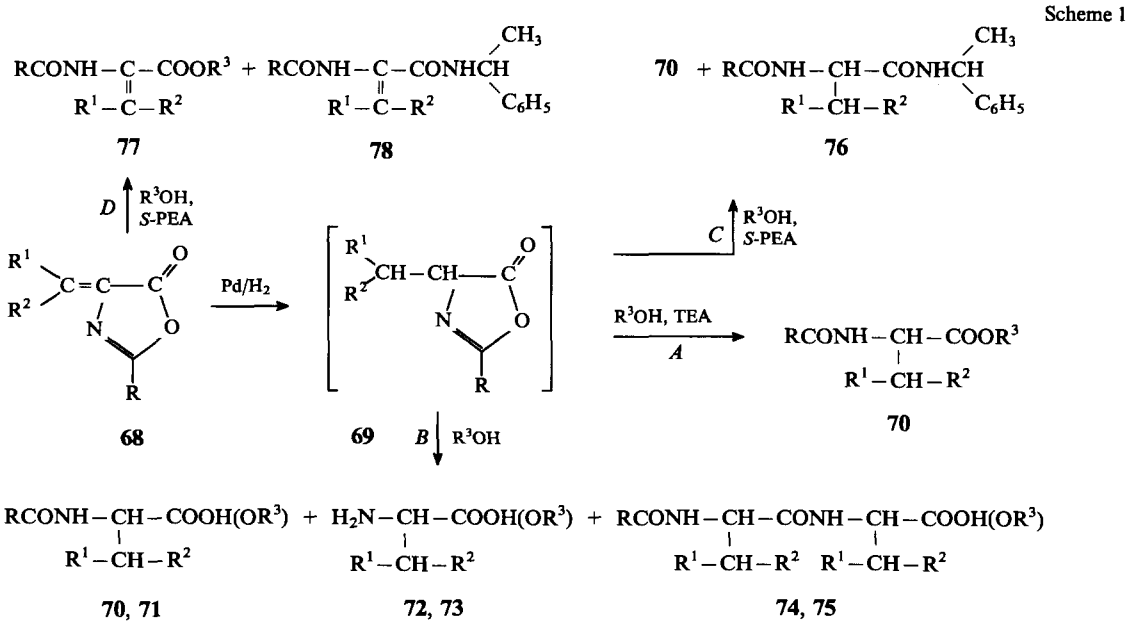
Methanolysis of the oxazolone **65** in the presence of hydrogen chloride leads to the formation of the corresponding ester **66** in a quantitative yield over a period of 15 min at room temperature. A similar result was obtained when the alcoholysis was carried out in the presence of triethylamine.[75]

In the presence of catalytic amounts of acid in methanol, the alkoxy-group of the alkoxymethyleneoxazolone **67** is substituted by the methoxy-group.[2]

The transalkylation of the alkoxy-group in compound **67** also proceeds in the presence of a platinum catalyst on heating with various alcohols.[85, 86]

The reactions of 5(4*H*)-oxazolones with epoxide resins proceed with ring opening.[87] The main products are the amidoesters containing the $-OOC-\overset{|}{C}-N-CO-$ fragment. The reaction in the absence of a catalyst is carried out at 190 °C. On the other hand the employment of catalysts usual for epoxide compositions makes it possible to reduce the reaction temperature to 140 – 150 °C. Both in the reactions with alcohols and in the case of the epoxide resins the chemical reactivity of 5(4*H*)-oxazolones depends on the polarity of the substituents in the 2- and 4-positions. Saturated 5(4*H*)-oxazolones react comparatively readily, while their unsaturated analogues require severe conditions.[87]

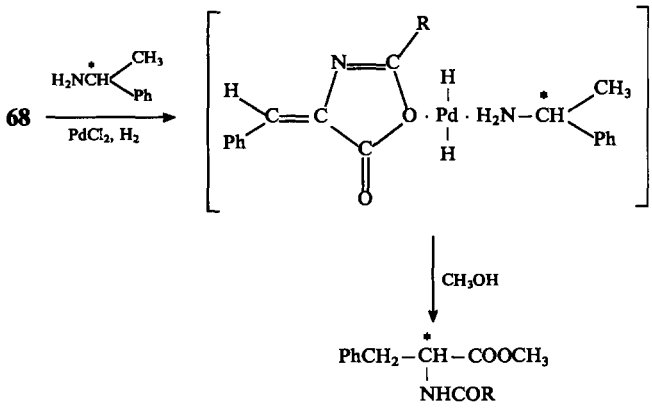
It has been shown[88, 89] that the reaction of saturated 5(4*H*)-oxazolones with hydroxylated polymers is catalysed by acids.



III. Reductive alcoholysis of unsaturated 5(4*H*)-oxazolones

A group of workers[90–97] achieved a very successful catalytic hydrogenation of unsaturated 5(4*H*)-oxazolones in alcohols. The catalyst is palladium obtained by reducing $PdCl_2$ in situ. The hydrogenation is carried out in the presence of triethylamine (TEA),[91] (*S*-(–)-α-phenylethylamine (*S*-PEA),[90–96] and (*S*)-(–)-*N*,*N*-dimethyl-α-phenylethylamine (*S*MPA).[94] According to Neupokoeva et al.,[91] the reductive alcoholysis of unsaturated 5(4*H*)-oxazolones can proceed in accordance with Scheme (1).

The unsaturated oxazolone **69** is obtained during hydrogenation, leading to a mixture of products **70** – **75** in the absence of a base (pathway *B*). The formation of the diacylated aminoacids **72** and **73** and their condensation products **74** and **75** can be explained by the interaction of the alcohol with the C(2) atom of the oxazolone **69** [the analogous process with 5(4*H*)-oxazolones was described above]. With decrease in the acidity of the alcohol (CH_3OH > C_2H_5OH > *iso*-C_3H_7OH), the cleavage of the 1,5-bond of the oxazolone **69** intensifies and leads to the formation of aminoacid esters **70**. In the presence of tertiary amines (TEA, *S*-MPA) the alcoholysis with formation of the ester **70** becomes the main reaction pathway (pathway *A*).

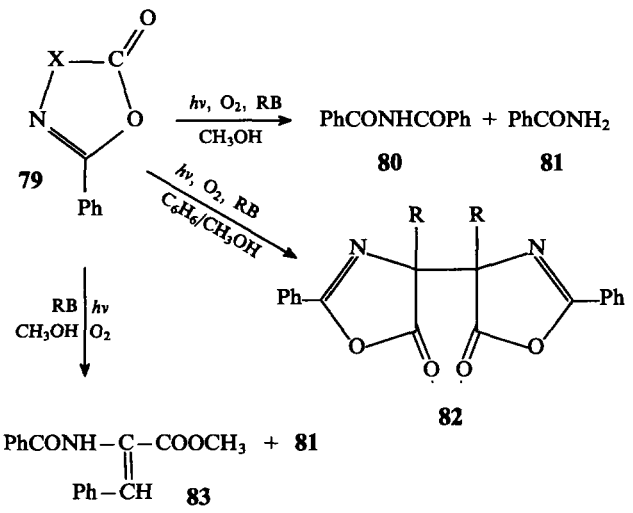


In the presence of *S*-PEA, the opening of the saturated [compound **69**] and unsaturated [compound **68**] oxazolones can

Scheme 1

take place under the influence of both the primary amine and the solvent (pathways *C* and *D*). Under these conditions, mainly the acylaminoacid ester[70] forms in methanol (pathway *C*).[91, 93-95, 97] On passing to alcohols with a higher molecular weight and a greater degree of branching of the molecule (C_2H_5OH, C_3H_7OH, *iso*-C_3H_7OH, C_4H_9OH, *sec*-C_4H_9OH, *tert*-C_4H_9OH), the content of the amide **76** increases.[93, 94] Furthermore, in connection with the decrease in the rates of hydrogenation of the unsaturated oxazolone **68** in the presence of *S*-PEA, unsaturated reaction products—the ester **77** and the amide **78**—are detected in the catalytic reaction mixture (pathway *D*).[91]

Reductive alcoholysis in the presence of the chiral amine *S*-PEA leads to the (*R*)-configuration of the ester **70** in the case of 2-alkyl(aryl)-4-benzylidene-5-oxazolone **68** (R^1 = H, R^2 = C_6H_5)[90] and to the (*S*-enantiometer in the case of 4-benzylidene-2-phenyl-5-oxazolone **68** (R = C_6H_5, R^1 = H, R^2 = C_6H_5).[97] The formation of the optically active methyl esters **70**) in the reductive methanolysis shows that in alcohols there is a possibility of the interaction of the oxazolone **68** with the hydrogen on the surface of the palladium catalysts modified by the chiral amine *S*-PEA without the migration of the reaction into the bulk phase.[90, 91] It has been suggested[93] that, in the enantioselective reductive methanolysis of unsaturated 5(4*H*)-oxazolones, the oxazolone **68** initially assumes a definite orientation in relation to the hydrogenating centre under the steric control of the chiral *S*-PEA coordinated to the catalytic palladium complex. This is followed by the formation of a coordinate bond between palladium and compound **68** and then by the saturation of the double bond and the opening of the oxazolone ring, which takes place within the complex without the elimination of the intermediate compounds.



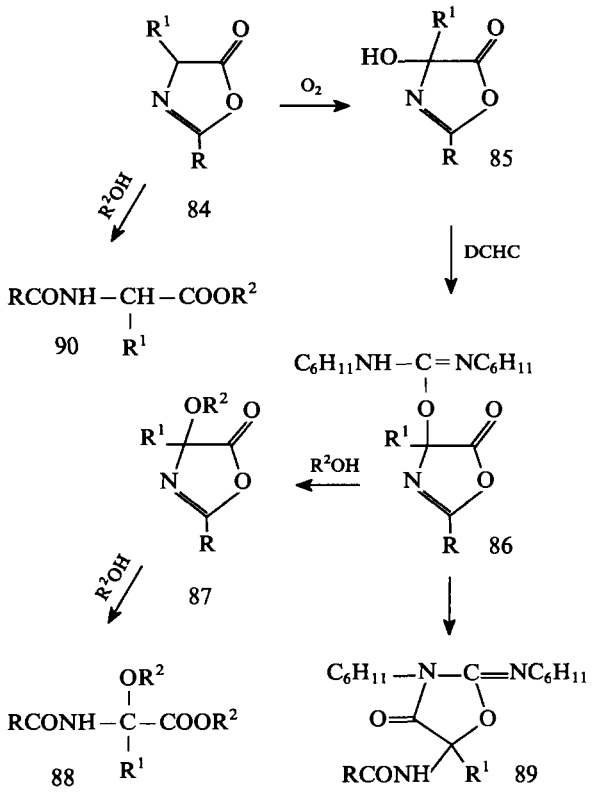
According to Khatskevich et al.,[94] the reductive methanolysis by the *Z*- and *E*-isomers of 4-*sec*-butylidene-5-oxazolones **68** (R^1 = CH_3, R^2 = C_2H_5) gives rise to the same diastereoisomeric composition of the aminoacid esters **70**. It follows from this that the *Z* – *E* isomerisation of the oxazolone **68** takes place in this process and that an identical mixture of isomers undergoes reduction. This is demonstrated by the finding that 4-*sec*-butylidene-5-oxazolone is not reduced in *tert*-butyl alcohol in the absence of a base and that the *Z*- and *E*-unsaturated oxazolones isomerise regardless of the initial compound **68**. In this case, the formation of *N*-substituted aminoacid esters takes place with a lower enantioselectivity than for 4-benzylidene-2-methyl-5-oxazolone **68** (R = CH_3, R^1 = H, R^2 = C_6H_5).[91] The reduction of both the *Z*- and *E*-isomers of 4-*sec*-butylidene-5-oxazolone in the presence of *S*-MPE leads to the optically active methyl ester **70** with a *threo* : *erythro* ratio of 63 : 67.[94]

When chiral phosphonic acid complexes of palladium are used as the catalyst, the double bond of the oxazolone **68** is hydrogenated initially and this is followed by the alcoholysis of the saturated oxazolone **69**.[97]

The reductive alcoholysis of unsaturated 5(4*H*)-oxazolones also proceeds in methanol in the presence of magnesium[98] or Raney nickel and sodium methoxide,[99] which leads to racemic methyl esters of *N*-substituted aminoacids.

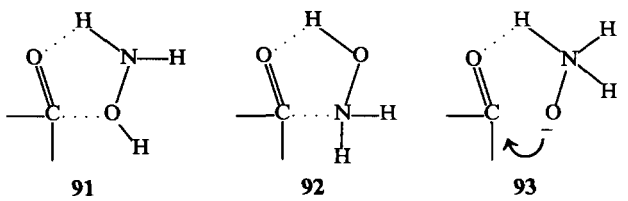
IV. Oxidative alcoholysis of 5(4*H*)-oxazolones

Saturated and unsaturated 5(4*H*)-oxazolones react with alcohols in different ways in the presence of oxygen. The sensitised photochemical oxidation of 2,4-diphenyl-5-oxazolone **79** (X = CHC_6H_5) in methanol and in the presence of Rose Bengal (RB) for 0.5 h leads to the formation of 40% of the dibenzamide **80** (R = C_6H_5) and 49% of the benzamide **81**:



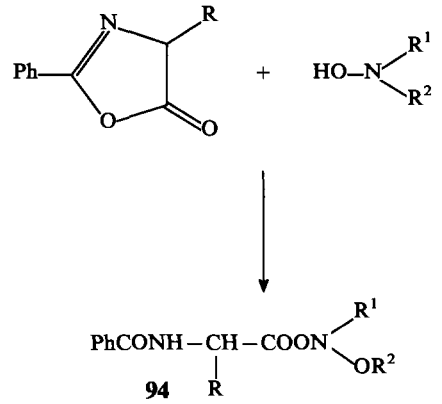
PhCONH–C(=CH–Ph)–COOCH3 + **81**

83



In a benzene–methanol mixture, the photochemical oxidation in the course of 0.25 h leads mainly to the formation of the dimer **82**.[100] Similar results were also obtained for 4-benzyl-2-phenyl-5-oxazolone **79** (X = $CHCH_2C_6H_5$), while, as in the case of its unsaturated analogue **79** (X = $C{=}CHC_6H_5$), the photochemical oxidation in the course of 0.25 h leads to the formation of a mixture consisting of 53% of the methyl ester **83** and 29% of the benzamide **81**.[100] When the photochemical oxidation of the unsaturated oxazolone **79** is prolonged to 0.75 h, the only product isolated from the reaction mixture is benzoic acid (yield 45%).

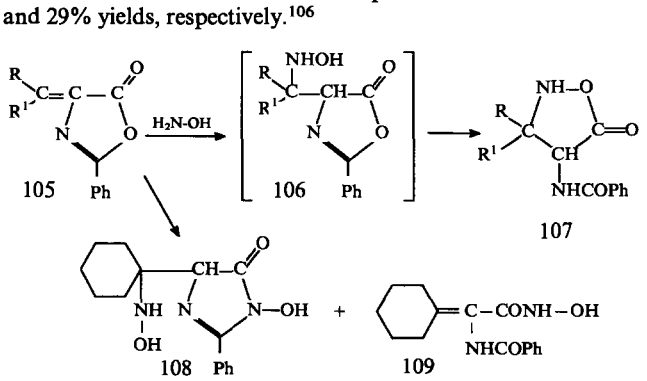
The interaction of the saturated oxazolones **84** with *N*,*N*-dicyclohexylcarbodiimide (DCHC) in methanol or ethanol and under an oxygen atmosphere also leads to the formation of a mixture of products.[101, 102] In the case of 2-benzyl-4-phenyl-5-oxazolone **84** (R = $CH_2C_6H_5$, R^1 = C_6H_5), the alkyl ester of α-alkoxy-*N*-phenylacetylphenylglycine **88** [R = $CH_2C_6H_5$, R^1 = C_6H_5, R^2 = CH_3 or C_2H_5 (37 and 27% respectively)], the alkyl ester of *N*-phenylacetylglycine **90** [R = $CH_2C_6H_5$, R^1 = C_6H_5, R^2 = CH_3 (7%)], and the oxazolone **89** [R = $CH_2C_6H_5$, R^1 = C_6H_5 (10% in methanol and 32% in ethanol)] were isolated from the reaction mixture.[102] It is suggested that the reaction proceeds via the oxidation of the oxazolone **84** to 4-hydroxy-oxazolone **85**, which interacts with DCHC to form the intermediate **86**. As a consequence of the attack by the alcohol, the latter gives rise to the ester **88** via compound **87** or undergoes an intramolecular rearrangement to compound **89**. When this reaction is carried out in 2,2,2-trichloroethanol, it leads to the formation of only the corresponding ester **90** (R = $CH_2C_6H_5$, R^1 = C_6H_5, R^2 = CH_2CCl_3). In the case of 2-benzyl-4-methyl-5-oxazolone **84** (R = $CH_2C_6H_5$, R^1 = CH_3), the oxidative alkoxylation product **88** is not detected, whereas in the case of 4-methyl-2-phenyl-5-oxazolone **84** (R = C_6H_5, R^1 = CH_3) compounds **88** and **90** (R = C_6H_5, R^1 = R^2 = CH_3) were isolated from the reaction mixture in 9% and 44% yields, respectively.[102]



V. Reactions with hydroxylamine derivatives and aminoalcohols

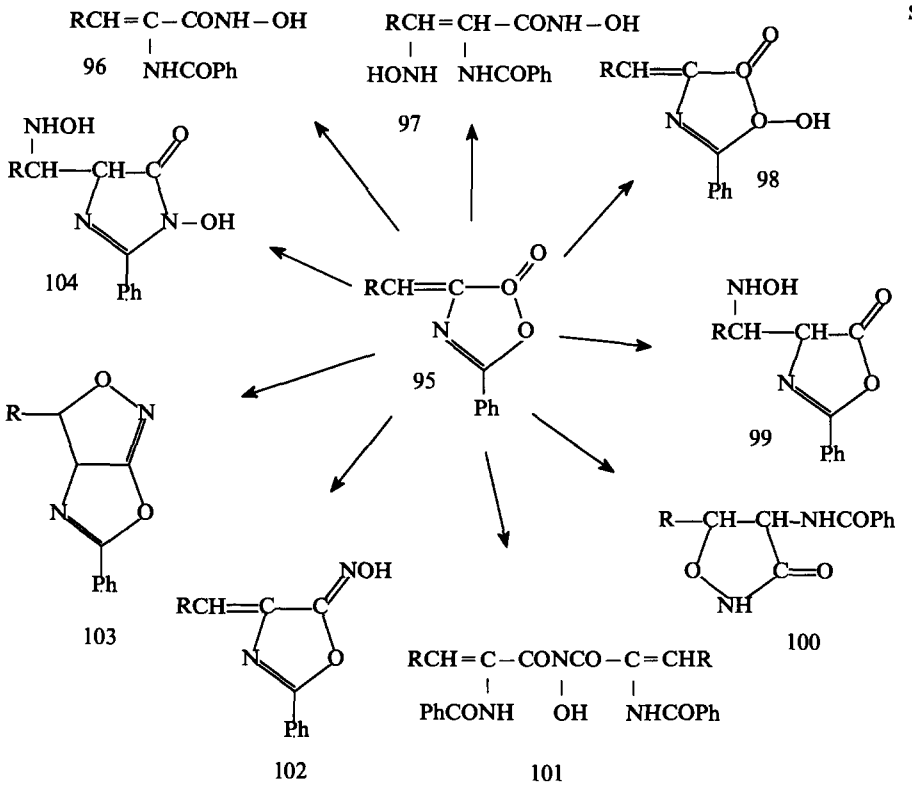
Studies on the interaction of 5(4*H*)-oxazolones with hydroxylamine and its derivatives occupy a special place in the literature. The composition of reaction products is affected not only by the nature of the oxazolone but also by the reaction temperature and the solvent. Unsaturated 5(4*H*)-oxazolones react with hydroxylamine to form two products.[103] Evidently this entails the *N*- and *O*-acylation of hydroxylamine. In the presence of an excess of the latter, one product (the *O*-acyl derivative) vanishes. According to Goodman and Glaser,[103] hydroxylamine can attack 5(4*H*)-oxazolone along one of two pathways with the formation of products **91** and **92**. In addition, hydroxylamine can attack the 5(4*H*)-oxazolone in the form of the zwitter-ion **93**.

In the reaction of saturated 5(4*H*)-oxazolones with *N,N*-disubstituted hydroxylamine derivatives, the reaction product is an ester of the *N*-substituted aminoacid **94**.[103–105] According to the authors,[103] in the latter case a zwitter-ionic reaction mechanism takes place. Evidently, by virtue of the bifunctional attack by hydroxylamine and its derivatives, the opening of the oxazolone ring without racemisation becomes possible, particularly in the case of strong nucleophiles such as *N*-hydroxysuccinimide or 1-hydroxybenzotriazole, which have the properties of weak bases.[103–105]



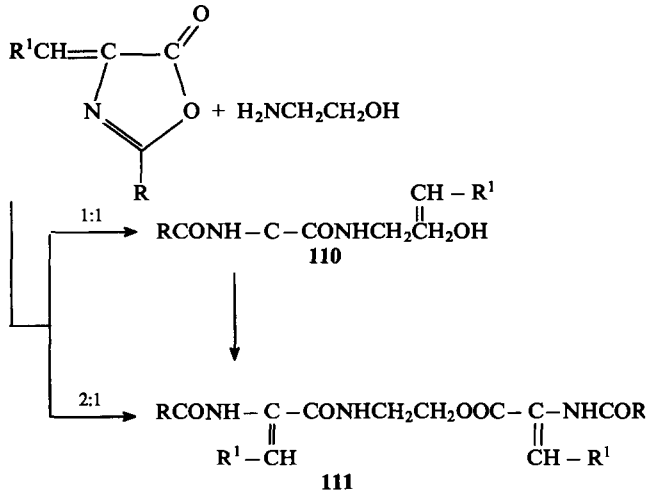
The reaction of hydroxylamine with unsaturated 5(4*H*)-oxazolones leads to different products. The reaction has been very effectively investigated by Ali and Khan.[106] Depending on the pH of the medium, the reactant ratio, the nature of the solvent, and temperature, different products are then obtained.

The hydroxamic acids **96** (26%) and **97** (51%) are obtained in the reaction of compound **95** (R = C_6H_5) with hydroxylamine at room temperature. When there is an excess of hydroxylamine, one obtains in the presence of sodium methoxide 20% of bis-(α-benzamidocinnamoyl)hydroxamic acid **101**, 4-(α-hydroxyaminobenzyl)-2-phenyl-5-oxazolone **99** (28%), 1-hydroxy-4-(α-hydroxyaminobenzyl)-2-phenyl-5-imidazolone **104** (35%), and 4-benzylidene-1-hydroxy-2-phenyl-5-imidazolone **98** (15%). The yield of the last product **98** increases sharply (to 58%) when pyridine is used instead of methanol. On heating hydroxylamine hydrochloride with the oxazolone **95** (R = C_6H_5) in acetic acid, compound **102** is obtained in 77% yield,[106] whereas in the presence of sodium hydroperoxide compound **100** is formed in 66% yield.[107] 4-Benzamido-4,5-dehydro-5-phenyl-5-isoxazolone **100** is formed in a high yield (76%) on exposure to light.[106] (see over)



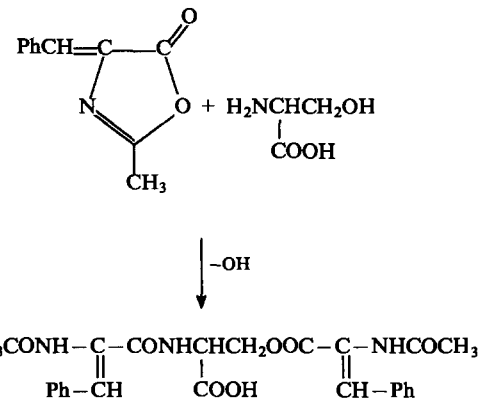
The reaction of hydroxylamine with 4-alkylidene-5-oxazolones **105** [107] proceeds, in contrast to 4-arylidene-5-oxazolones,[38] with formation of 3-alkyl-4-benzamido-5-oxo-1,2-oxazolidine **107**. The mechanism of this reaction involves[107] the addition, in weakly alkaline or neutral media, of a hydroxylamine molecule to the exocyclic double bond of the oxazolone, after which the resulting saturated oxazolone **106** undergoes intramolecular ring opening with formation of the isoxazolidine derivative.

The reaction involving 4-cyclohexylidene-2-phenyl-5-oxazolone **105** (R = R^1 = C_5H_{10}) in the presence of sodium methoxide in methanol affords a mixture of compounds **108** and **109** in 40% and 29% yields, respectively.[106]



No studies on the reaction of unsaturated 5(4*H*)-oxazolones with *N,N*-di-substituted hydroxylamine derivatives have been described in the literature. However, there are communications devoted to the study of the reactions of these oxazolones with ethanolamine[108] and its derivatives.[109–121]

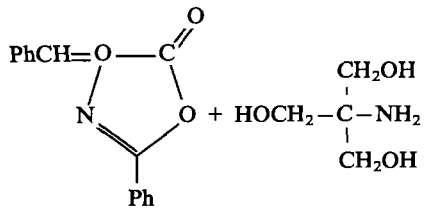
Scheme 2



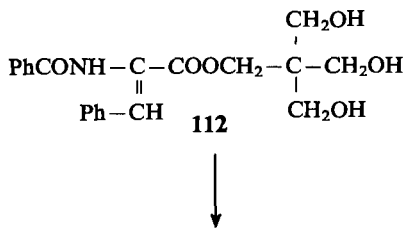
According to Lupsa,[108] owing to the comparatively high nucleophilicity of the amino-group, the interaction of equimolar amounts of monoethanolamine and an unsaturated 5(4*H*)-oxazolone leads to the formation of the 2-hydroxyethylamide **110**. On the other hand, when the oxazolone : aminoalcohol ratio is 2 : 1, the reaction product in the presence of 1–2% of a base (NaOH) is the *N,O*-diacylated aminoethanol **111**. Lupsa[108] also achieved the opening of the oxazolone ring by the 2-hydroxyethylamides **110** to give compound **111**.

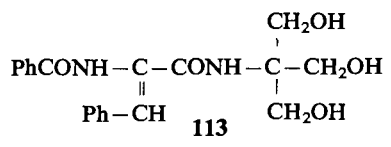
The products of *N,O*-diacylation are also formed on reaction of 4-benzylidene-2-methyl-5-oxazolone with serine in the presence of alkali.[110, 111]

According to Botvinnik et al.,[110] saturated 5(4*H*)-oxazolones react with the hydroxy-group of *N*-benzoylserine or the ethyl ester of *N*-benzoylserine without ring opening.

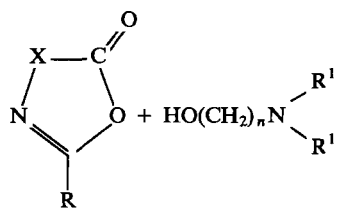


In the reactions of saturated 2,2-bis-5(4*H*)-oxazolones with ethanolamine, polymers with a regular structure have been obtained.[9]

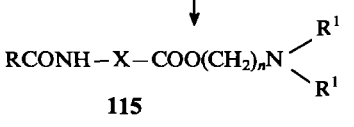




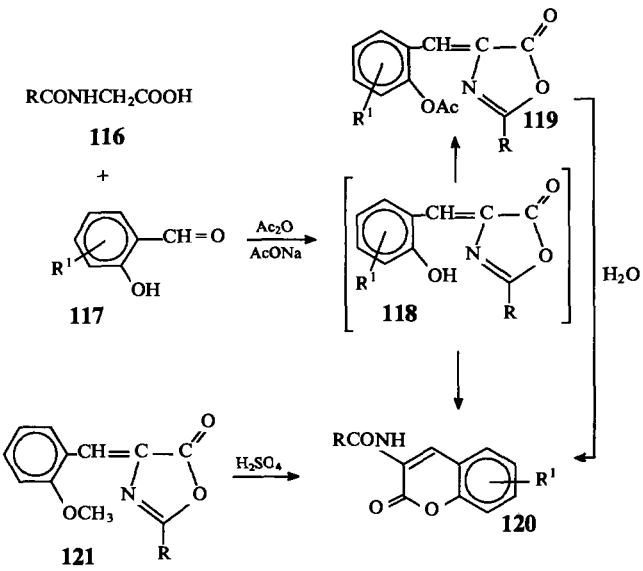
De Jersey and co-workers[112, 113] succeeded in isolating an ester of the α,β-dehydroaminoacid **112** in the reaction of the *Z*-isomer of 4-benzylidene-2-phenyl-5-oxazolone with tris-(hydroxymethyl)aminomethane in acetonitrile.It has been noted that the ester **112** is unstable, especially under alkaline conditions, and can be converted into the corresponding amide **113** as a consequence of an intramolecular rearrangement and an intermolecular interaction. The formation of an ester can be accounted for by the steric hindrance generated by the hydroxymethyl groups, on the one hand, and by the intramolecular hydrogen bond between the amino- and hydroxy-groups (which increases the nucleophilicity of the hydroxy-group), on the other.



The interaction of dialkylaminoalkyl alcohols with both saturated,[114, 115] and unsaturated[115–118] 5(4*H*)-oxazolones leads to the formation of the corresponding esters of *N*-substituted aminoacids **115**.

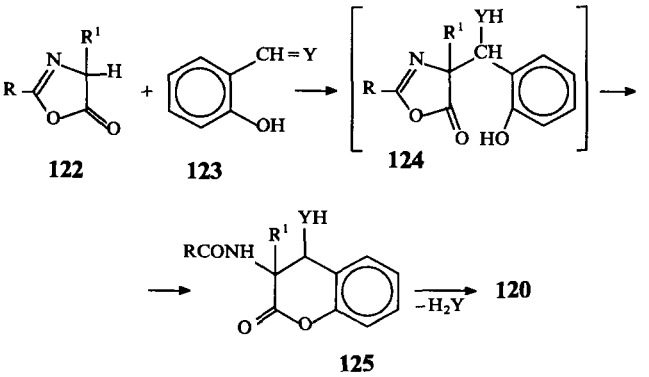


According to the data of Topuzyan et al.,[115] the reaction of the saturated oxazolone **114** (X = $CHCH_2C_6H_5$) with 2-dimethylaminoethanol takes place under milder conditions than the reaction with the unsaturated analogue **114** (X = $C=CHC_6H_5$). When *Z*-unsaturated 5(4*H*)-oxazolones are used, the heterocycle is opened stereoselectively by this aminoalcohol.[119]

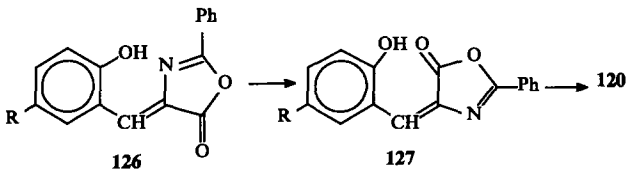


It has been established that the interaction of 2-dimethylaminoethanol with 4-benzylidene-2-phenyl-5-oxazolone involves general base catalysis.[120] The influence of the solvent[120] and certain additives (1-hydroxybenzotriazole, *N*-hydroxysuccinimide, imidazole, and *p*-nitrophenol)[121] on this reaction has been investigated. According to a patent,[118] the opening of the unsaturated oxazolone ring by dialkylaminoalkyl alcohols is accelerated in the presence of the alkoxides derived from the same aminoalcohols.

VI. Intramolecular reactions of 5(4*H*)-oxazolones containing a hydroxy-group

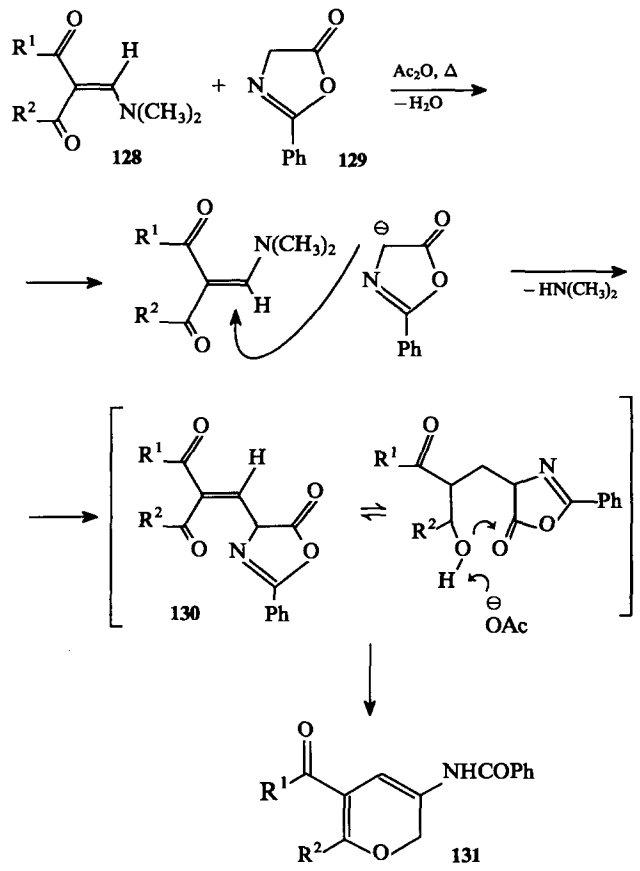


The synthesis of unsaturated 5(4*H*)-oxazolones from *N*-acylglycine **116** and derivatives of salicylaldehyde **117** involves the formation, under the conditions of the Erlenmeyer reaction, of a mixture of products consisting of the target oxazolone **119** and 3-*N*-acylcoumarin **120**.[122–124] Evidently this entails the intermediate formation of 2-aryl(alkyl)-4-(2-hydroxybenzylidene)-5-oxazolone **118**. The intramolecular hydrophilic attack by the hydroxy group of the latter on the carbon atom of the carbonyl group leads to the formation of the coumarin **120**. This hypothesis is confirmed by data indicating the formation of



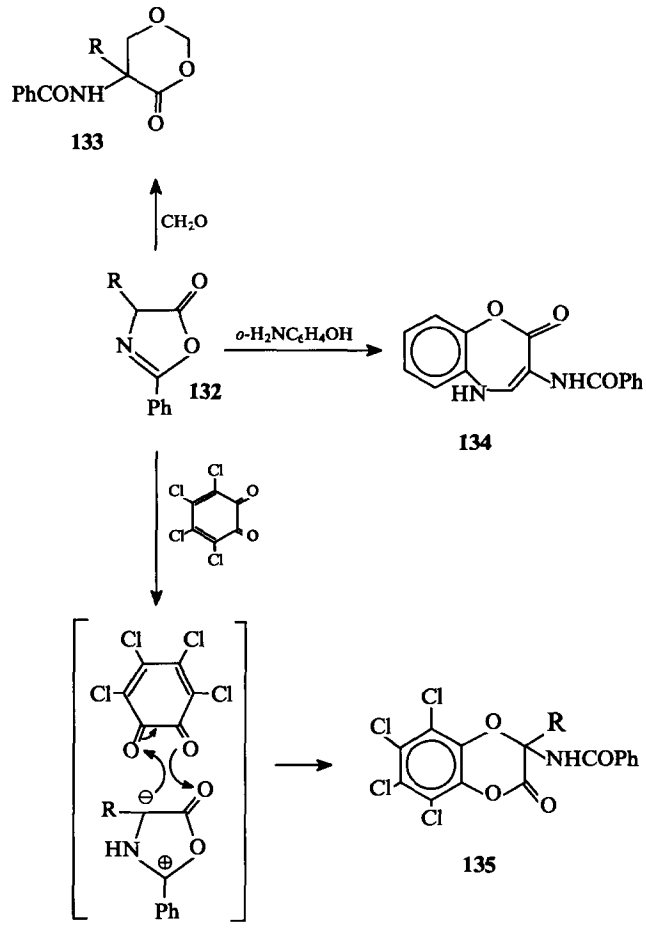
3-benzamidocoumarin **120** (R = C_6H_5, R^1 = H) from 4-(2-acetoxybenzylidene)-2-phenyl-5-oxazolone **119** (R = C_6H_5, R^1 = H)[125] and 4-(2-methoxy-benzylidene)-2-phenyl-5-oxazolone **121**[126] under the conditions involving the removal of the O-protecting groups in these compounds.

The formation of 3-acylaminocoumarins **120** is observed also in the reaction of the saturated oxazolones **122** with salicylaldehyde or its derivatives **123**.[127–129] The course of this reaction is appreciably influenced both by the substituent in the 2-position in the heterocycle **122** and by the substituent R in the second component **123**. According to Kumar and Mukerjee,[127] the use of salicylideneaniline **123** (Y = NC_6H_5) instead of salicylaldehyde leads to a decrease in the yield of acylaminocoumarins **120**. In the case of the oxazolone **122** (R = H), the corresponding coumarin **120** (R = R^1 = H) is obtained only when salicylaldehyde is used. The yield of the coumarin **120** increases in the following sequence of R: H < H < CH_3 < C_6H_5 < C_6H_5CH = CH.

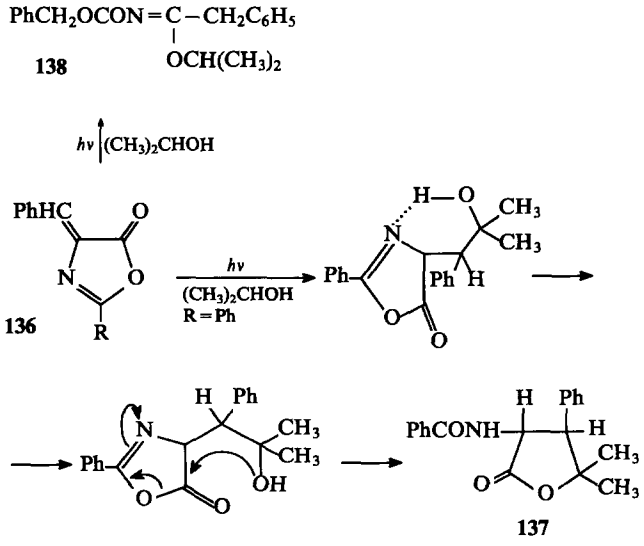


The study of the mechanism of the formation of acylaminocoumarins **120** showed[128] that the process proceeds via the formation of the dihydrocoumarin **125**. In the case of compound **122** (R = H), this intermediate **125** undergoes β-elimination, which leads to the coumarin **120**. In the reaction of 2,4-dimethyl-5-oxazolone **122** (R = R^1 = CH_3) with salicylaldehyde **123** (Y = O) or salicylideneaniline **123** (Y = NC_6H_5), the corresponding hydrocoumarin **125** (Y = O or NC_6H_5) was isolated, since under these conditions the β-elimination of the YH_2 group does not take place.

The acylcoumarins **120** have also been synthesised under the conditions of the photochemical[130] or electrochemical[131] conversion of the *Z*-oxazolone **126** into the *E*-isomer **127**:

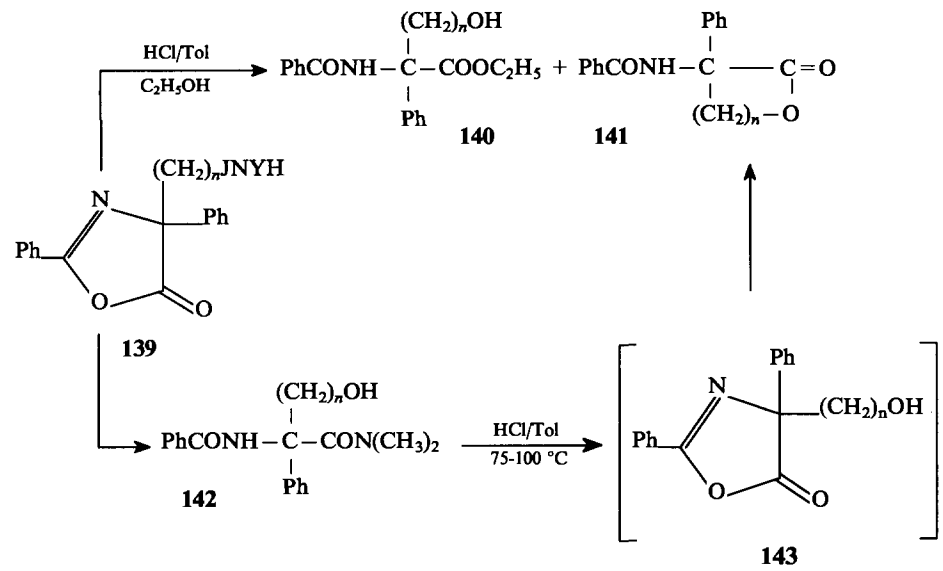


A method for the synthesis of 3-benzamido-2*H*-pyranones **131** via the reaction of esters of 2-acyl-3-dimethylaminoacrylic acids **128** ($R^1 = C_2H_5O$, $R^2 = CH_3$, C_6H_5) or 2-dimethylaminomethylene-1,3-diketones **128** ($R^1 = R^2 = CH_3$, C_6H_5) with 2-phenyl-5-oxazolone **129** has been described:[132]

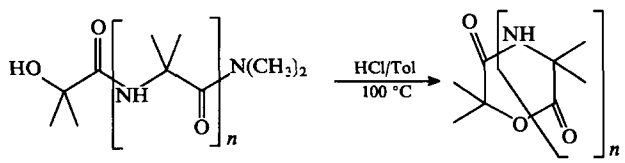


The reaction leads to nucleophilic substitution of the protonated dimethylamino-group in compound **128** and subsequent intramolecular attack by the carbonyl group of the oxazolone **130** on the alcoholic graph of the side substituent, which is completed by cyclisation to the pyran **131**.

The intramolecular opening of the ring in the saturated oxazolone **132** (R = H, alkyl) in the presence of alcohols is observed also in the hydroxymethylation of the heterocycle.[133–135] The reaction products are then 1,3-dioxan-4-ones **133**.



It has been found that the reaction of 4-ethoxycarbonyl-2-phenyl-5-oxazolone **132** (R = $COOC_2H_5$) with *o*-aminophenol leads to the formation of the benzoxazepin **134**,[136] while the reaction of the oxazolone **132** (R = H, alkyl, aryl) with chloranil affords benzodioxanes **135**.[137]



On irradiation with light in solution in 2-propanol, the unsaturated oxazolone **136** (R = C_6H_5) gives rise to the lactone **137** in 17% yield,[138, 139] while 4-benzylidene-2-benzyloxy-5-oxazolone **136** (R = $C_6H_5CH_2O$) affords compound **138** in 92% yield under analogous conditions.[140]

Under the conditions where the O-protecting group is removed from the saturated oxazolone **139** a mixture of the ethyl ester of the *N*-benzamidoacid **140** and the lactone **141** was obtained in the presence of ethanol.[141] It was noted in the same study that the lactonisation can occur when the dimethylamide of the *N*-substituted aminoacid **142** is heated in the presence of hydrogen chloride in toluene (tol.). This reaction proceeds via the intermediate formation of the oxazolone **143**.

Morpholinediones and more bulky cyclic compounds **144** (n = 1 – 4) are formed similarly:[142, 143]

Thus it is readily seen that the study of reactions of 5(4*H*)-oxazolones with oxygen-containing nucleophiles is important for the determination of the chemical properties of these heterocyclic systems and for the synthesis of organic compounds belonging to a wide variety of classes.

IV. Oxidation of the carbohydrate fragments in nucleic acids 75
V. Conclusion 84

Abstract. The chemical mechanisms of the oxidative degradation of nucleic acids are surveyed and described systematically. The bibliography includes 141 references.

I. Introduction

The oxidative degradation of nucleic acids, induced by active forms of oxygen, is of interest from several points of view.

Firstly, in aerobic organisms biochemical processes and various physical and chemical influences (ionising radiation, UV light, etc.) result in the formation of free radicals and activated oxygen species: the superoxide radical-ion $O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), and the free hydroxyl radical ($^{\cdot}OH$).[1–4] The damage to DNA induced by them plays an important role in mutagenic, carcinogenic, ageing, and other processes.

Secondly, many oxygen-dependent antitumour preparations (bleomycin) and low-molecular-weight complexes of variable-valence metal ions (Cu-1,10-phenanthroline, Fe-EDTA, Fe- and Mn-porphyrins, etc.) catalyse effectively the cleavage of nucleic acids with participation of active forms of oxygen.[5–9]

Thirdly, investigators have devoted increasing attention recently to designing synthetic molecules capable of binding specifically to DNA and cleaving the sugar phosphate skeleton like natural antibiotics of the type of bleomycin. Such compounds might find applications in the creation of the so called "chemical restrictases", i.e. reagents which, like restriction endonucleases, cleave nucleic acids in the vicinity of definite sequences, and of chemotherapeutic preparations which cause selective damage to nucleic acids.[10]

II. Activated oxygen species

Molecular oxygen is a four-electron oxidant and its stepwise reduction to water may be represented schematically as follows:[11–13]

$$E^0_{O_2/O_2^{\cdot-}} = -0.16\,V;\quad E^0_{HO_2^{\cdot}/HO_2^-} = 0.74\,V;$$

$$E^0_{HO^{\cdot}/HO^-} = 1.9\,V;$$

$$E^0_{O_2/HO_2^{\cdot}} = 0.13\,V;\quad E^0_{HO_2^{\cdot}/H_2O_2} = 1.43\,V;$$

$$O_2 \xrightarrow{e^-,H^+} HO_2^{\cdot}(H^+ + O_2^{\cdot-}) \xrightarrow{e^-,H^+} H_2O_2(H^+ + HO_2^-) \xrightarrow{e^-} HO^{\cdot} + OH^-$$

$$(E^0)'' = 0.3\ V \qquad e^-, H^+$$

$$(E^0)' = 0.815\ V \qquad 2H_2O$$

In reduction to both H_2O and to H_2O_2, molecular oxygen in aqueous solution is a powerful oxidant—the values of $(E^0)'$ are respectively 0.815 and 0.3 V. However, direct oxidation by oxygen, both two-electron and four-electron oxidation, hardly occurs. This is associated primarily with the fact that the O_2 molecule has a triplet ground state whereas the majority of organic substrates and their oxidation products have singlet ground states. The direct reaction of triplet O_2 with the substrate molecule is therefore spin-forbidden.

Several ways of overcoming this limitation are known: (1) successive one-electron reduction of the oxygen molecule to H_2O in conformity with a scheme such that each individual elementary reaction is spin-allowed; (2) activation of oxygen by enzymes or by the formation of complexes with transition metal ions; (3) transition of O_2 molecules to the excited singlet state.

The successive one-electron reduction of O_2 can be most simply achieved using variable-valence metal ions. Iron and copper ions are usually employed for this purpose. The process can be described by the following scheme:

$$M^{(n-1)+} + O_2 \rightarrow M^{n+} + O_2^{\cdot-}(HO_2^{\cdot}) \quad (1)$$

$$M^{(n-1)+} + O_2^{\cdot-}(HO_2^{\cdot}) \rightarrow M^{n+} + HO_2^-(H_2O_2) \quad (2)$$

$$M^{(n-1)+} + H_2O_2 \rightarrow M^{n+} + HO^{\cdot} + OH^- \quad (3)$$

$$M^{(n-1)+} + HO^{\cdot} \rightarrow M^{n+} + OH^- \quad (4)$$

The involvement of the metal ion is particularly significant in the first stage, because the reduction of O_2 to $O_2^{\cdot-}$ is characterised by a low oxidation–reduction potential $E^0 = -0.16$ V, i.e. is thermodynamically unfavourable.[11] Since the use of small amounts of metal ions is preferable, the occurrence of these reactions requires the presence of a coupled, readily oxidisable substrate H_2A (ascorbic acid, thiols, etc.) for the reduction of the metal ion to the lowest oxidation state:

$$M^{n+} + H_2A \text{ (or } HA^{\cdot}) \rightarrow M^{(n-1)+} + HA^{\cdot} \text{ (or } A + H^+) \quad (5)$$

Reaction (1) is reversible and $M^{(n-1)+}$ can be partly regenerated by the reaction

$$M^{n+} + O_2^{\cdot-} \rightarrow M^{(n-1)+} + O_2 \quad (6)$$

The rate constants for the competing reactions (2) and (6) are as a rule similar and are determined to a large extent[14] by the values of E^0 for the $M^{n+}/M^{(n-1)+}$ couple. Apart from reaction (2), the superoxide radical can be converted into hydrogen peroxide also via the disproportionation reaction (7) or via a reaction with an auxiliary reductant [reaction (8)]:

$$2O_2^{\cdot-} + 2H^+ \rightarrow O_2 + H_2O_2 \quad (7)$$

$$O_2^{\cdot-}(HO_2^{\cdot}) + H_2A \rightarrow HO_2^-(H_2O_2) + HA^{\cdot} \quad (8)$$

The hydrogen peroxide formed subsequently enters into reaction (5). The OH radical is the strongest oxidant among all the oxygen species examined and not only can it be reduced by metal ions [reaction (4)] but it can also accept an electron or can abstract a hydrogen atom from many organic substrates:

$$HO^{\cdot} + HX \rightarrow OH^- + H^+ + X^{\cdot} \quad (9)$$

Molecular oxygen reduction processes with participation of variable-valence metal ions have been described in greater detail in various other reviews, for example, those of Aust et al.[15] and Halliwell and Gutteridge.[16]

The one- and two-electron reduction of molecular oxygen in living organisms takes place in the course of various biochemical processes.[4] The formation of the superoxide radical is catalysed by the majority of NAD(P)H-dependent oxidases functioning within the composition of membrane complexes[17] and by flavin-dependent oxidases such as xanthine oxidase.[18] In the normal functioning of the mitochondrial respiratory chain, $O_2^{\cdot-}$ is formed in small amounts, but under the conditions of various disturbances in the operation of mitochondria the generation of $O_2^{\cdot-}$ as well as other active oxygen species increases sharply.[19]

Oxygen can be reduced to $O_2^{\cdot-}$ also by certain long-lived organic radicals (for example, semiquinone radicals) formed in the enzymic or photochemical reduction of anthraquinone antibiotics, riboflavin, and certain other compounds.[20]

Hydrogen peroxide can be formed via the disproportionation reaction (7), which can be both spontaneous or can be catalysed by special enzymes—superoxide dismutases. The direct enzymic reduction of O_2 to H_2O_2 without the intermediate formation of $O_2^{\cdot-}$ is characteristic of metabolic processes occurring in neutrophils and peroxisomes[21] and occurs, for example, in reactions catalysed by aminooxidases.[22]

The generation of hydroxyl radicals *in vivo* is apparently due primarily to the reduction of O_2 or H_2O_2 by transition metal ions.[6, 23, 24]

Active oxygen species are also formed under various external influences on living organisms, for example when the latter are acted upon by ionising radiation. The radiolysis of water[25–27] results in the formation of the following products:[27]

$H_2O \rightarrow$	$HO^{\cdot}$,	e_{aq}^-,	$H^{\cdot}$,	H_2O_2,	H_2	$H^+(H_3O^+)$
G	2.7	2.7	0.55	0.7	0.45	2.7

where G is the radiation-chemical yield (in dilute solutions) equal to the number of species formed per 100 eV of absorbed energy.

In aerated aqueous solutions, the solvated electron e_{aq}^- and $H^{\cdot}$ interact very rapidly with O_2, affording the superoxide radicals $O_2^{\cdot-}$ or $HO_2^{\cdot}$. Both H_2O_2 and $O_2^{\cdot-}$ can be reduced subsequently by the transition metal ions to OH radicals.

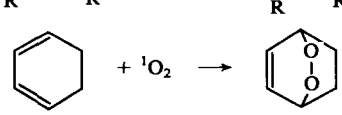
As a result of all these factors, the principal species in aerated solutions responsible for the oxidation of various substrates under the action of ionising radiation are OH radicals (>90%). In the study of reactions with participation of OH radicals, solutions are radiolysed in the presence of nitrous oxide N_2O, which promotes the conversion of e_{aq}^- into the OH radical.

Among the intermediates in the reduction of O_2 examined, OH radicals play the main role in the oxidative degradation of DNA. Under physiological conditions, the superoxide radical-ion is incapable of oxidising organic substrates. With the use of various systems for the generation of $O_2^{\cdot-}$, it has been shown that[28] it does not participate in the oxidative degradation of nucleic acids. Likewise H_2O_2 does not oxidise DNA under physiological conditions.[29–32] However, the introduction into the same systems of transition metal ions, which catalyse the reduction to the OH radicals of both the superoxide radical-ion and hydrogen peroxide via reactions (2), (3), and (7), leads to the degradation of nucleic acids.[28–30]

The OH radical is a powerful oxidant and is highly reactive. Under physiological conditions, it is able to abstract the hydrogen atom from the C–H bonds [reaction (10)] or it adds to unsaturated C=C double bonds [reaction (11)]:

$$R\text{-}H + \dot{O}H \longrightarrow \dot{R} + H_2O \quad (10)$$

$$\text{>C=C<} + \dot{O}H \longrightarrow \text{>}\dot{C}\text{–}C(OH)\text{<} \quad (11)$$



The rates of addition to the double bonds are usually higher than the rates of abstraction of the hydrogen atom from C–H bonds.[33]

The OH radicals interact with nucleic acids and model compounds such as nucleosides and nucleotides, the rate constant for the corresponding reactions being close to the diffusion-controlled values (Table 1).[25, 26, 33]

The dominant processes are addition to the double bonds of the heterocycles and the abstraction of hydrogen atoms from the C–H bonds of the pentose with formation of the corresponding free radicals. In aerated solutions, these radicals interact rapidly with oxygen O_2 to form peroxyl radicals. The subsequent reactions, leading ultimately to the modification of the heterocycles or to the cleavage of the pentose phosphate skeleton, will be examined in the later sections of this review.

Singlet oxygen can be formed as a result of photosensitisation and also as a side product in many biological oxidation processes.[34] Despite its considerable reactivity, singlet oxygen cannot react with alkanes and many aromatic systems. Interaction with alkenes to form allyl peroxides [reaction (12)] or endoperoxides [reaction (13)] is most characteristic of this species:[35]

$$R\text{–}C(R)=C(CHR_2)\text{–}R + {}^1O_2 \longrightarrow R\text{–}C(R)(OOH)\text{–}C(CR_2)\text{–}R \quad (12)$$

(13)

It has been shown that singlet oxygen does not oxidise the sugar phosphate skeleton in nucleic acids,[36, 37] but does react selectively with guanine residues, forming as a result modified fragments in which the sugar phosphate skeleton may be cleaved on treatment under alkaline conditions.[28]

The reduction of oxygen by variable-valence metal ions can occur with preliminary coordination of O_2 or species corresponding to its partial reduction. This results in the formation of oxo-complexes of metals, which are in high-valence states (Fe or Mn in the +4 or +5 oxidation states, Cu in the +3 state, etc.).[38] Such complexes can behave directly as oxidants or can generate OH radicals with transition of the metal to a lower oxidation state. The latter version has been postulated, for example, for the Fe·ATP complexes:[39]

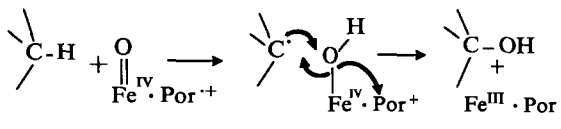
$$Fe^{II} \cdot ATP + H_2O_2 \rightarrow \overset{O}{\underset{\|}{Fe^{IV}}} \cdot ATP + H_2O \quad (14)$$

$$\overset{O}{\underset{\|}{Fe^{IV}}} \cdot ATP + H^+ \rightarrow Fe^{III} \cdot ATP + {}^{\cdot}OH \quad (15)$$

Such oxo-complexes have been isolated and characterised by various chemical and physical methods for iron-porphyrins.[40-46] It has been shown that they can be obtained by the two-electron oxidation of iron(III)-porphyrins by peracids, hydroperoxides, or iodosobenzene (Por = porphyrin):

$$Fe^{III} \cdot Por + PhIO \rightarrow \overset{O}{\underset{\|}{Fe^{IV}}} \cdot Por^{\cdot +} + PhI$$

(RCO$_3$H, ROOH) (RCOOH, ROH)



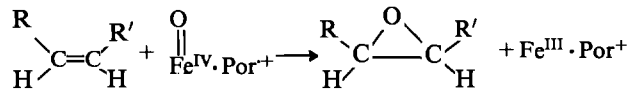
The structure of the oxo-complex containing iron in the +4 oxidation state and a porphyrin radical-cation stabilised by delocalisation in the π-system of the macrocycle has been generally accepted for iron-porphyrins.[42, 46]

The formation of high-valence metal oxo-species has been observed also for the porphyrin complexes of other transition metals. However, in the manganese and chromium complexes[47] the macrocyclic ligand does not participate in the oxidation and the metal is in the +5 oxidation state:

$$Mn^{III} \cdot Por + PhIO \rightarrow \overset{O}{\|}Mn^{V} \cdot Por + PhI$$

(RCO$_3$H, ROOH) (RCOOH, ROH)

Such oxo-complexes of high-valence metals are apparently weaker oxidants than OH radicals.[48] The following types of reactions are characteristic of them: the insertion of an oxygen atom in C–H bonds (hydroxylation) or addition to C=C bonds (epoxidation). It is believed that the first stage of the hydroxylation of alkanes involves the abstraction of the H atom from a C–H bond with subsequent transfer of the OH radical from the oxo-complex to the alkyl radical via the following mechanism:[49-51]



The selectivity of the reaction is achieved mainly as a result of the orientation of the oxygen atom in the complex relative to particular C–H bonds in the molecule being oxidised.[52] The hydroxylation of aldehydes with formation of carboxylic acids takes place in accordance with the same mechanisms.[53, 54]

DNA	0.3–0.8

The epoxidation of alkenes is achieved by the insertion of an oxygen atom in the C=C double bond:[47]

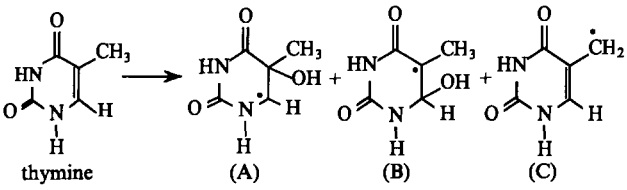
The oxidative degradation of DNA constitutes the basis of the action of the group of antibiotics of the class of bleomycin (Blm). It has been suggested[7, 55-56] that species of the type Blm·Fe^{V}=O participate in this process.

The hydrogen peroxide–Cu-1,10-phenanthroline complex system has found extensive applications in the oxidative degradation of DNA. There are two points of view on the mechanism of the oxidative cleavage of DNA in this system. According to one of them, a species bound to the metal and equivalent to the OH radical is responsible for the oxidation.[57, 58] According to the other, more widely adopted point of view, the Cu-1,10-phenanthroline complex is bound to DNA and interacts with H_2O_2 in the presence of reductants, generating OH radicals[8, 59, 60] via a mechanism analogous to that described by reactions (14) and (15) for the Fe·ATP complexes.[39] As a result, both free OH radicals and such radicals bound to the metal function in the system.

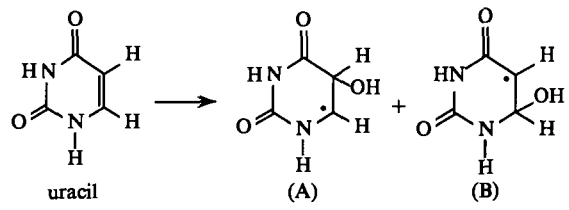
Thus, summarising all the factors described above, one may say that the free hydroxyl radicals, which are the products of the three-electron reduction of molecular oxygen, and, in certain systems, coordinated oxygen species in the form of oxo-complexes of metals in the highest oxidation states are primarily responsible for the degradation of nucleic acids under various oxidative conditions.

III. Oxidation of the heterocycles in nucleic acids

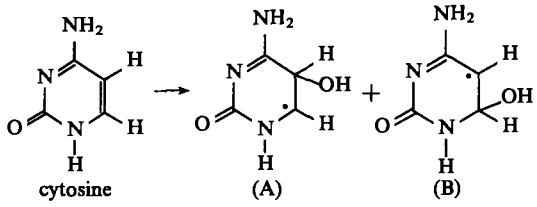
The oxidative modification of nucleic acid heterocycles by hydroxyl radicals has been studied in greatest detail under the conditions of γ-radiolysis, because this method of generation of OH radicals makes it possible to eliminate the involvement of other active species. These studies led to the isolation of a large number of products of the modification of the heterocycles and the mechanisms of the formation of some of them have been established. These investigations were carried out mainly on the free heterocycles and nucleosides. Further studies on nucleic acids showed that the data obtained on model compounds can be to a large extent transferred to the oxidation of polymeric molecules. The greatest progress has been achieved in the study of the oxidation of pyrimidine heterocycles.[25, 26, 61]



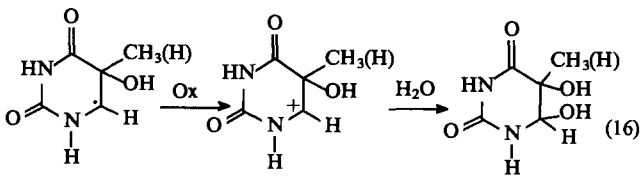
1. Anaerobic oxidation of pyrimidine heterocycles



Hydroxyl radicals are electrophiles and attack preferentially sites with a high electron density, forming free radicals derived from the heterocycles. The structures of these radicals have been largely characterised on the basis of the structures of the products formed on γ-radiolysis in the presence of spin trapping agents—2-methyl-2-nitrosopropane or α-(1-hydroxy-4-pyridyl)-*N*-*tert*-butyl nitrone.[62-66] It was established that, as a result of the reaction with pyrimidines, the OH radicals add to the C(5) or C(6) carbon atoms, forming type (A) and type (B) radicals, while for thymine the abstraction of a H atom from the methyl group at the C(5) atom with formation of a type (C) radical is also observed.

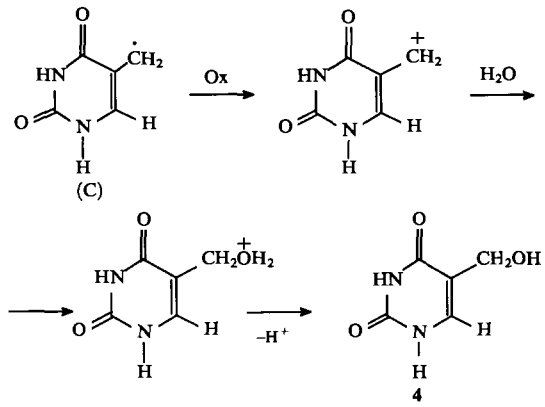


The three types of free radicals formed differ in their oxidation–reduction properties. The type (A) radicals, which are α-aminoalkyl derivatives, have the properties of reductants and can be determined quantitatively by reaction with oxidants such as benzoquinone, tetranitromethane, and tetracyanoferrate(III). The type (C) radical of thymine is also a reductant, although a weaker one, but it can be determined by reactions with strong oxidants. On the other hand, the type (B) radicals have oxidising properties by virtue of the presence of the mesomeric form—the oxyl radical—and can be determined with the aid of reductants such as *N,N,N′,N′*-tetramethylphenylenediamine and ascorbic acid. Such differences in the oxidation–reduction properties of the radicals formed made it possible to devise a method for their quantitative determination based on pulse radiolysis in the presence of the corresponding oxidants and reductants with the subsequent determination of their consumption.[67] It has been established with the aid of this method[68-70] that the preferential addition of the OH radicals to the C(5) position in the heterocycles is characteristic of all pyrimidines: to the extent of 87% for cytosine, 80% for uracil, and 56% for thymine. This is due to the greater electron density on the C(5) carbon atom. Only 10% of the OH radicals add to C(6) in the case of cytosine, 20% for uracil, and 35% for thymine. Less than 9% of the OH radicals participate in the abstraction of a hydrogen atom from the methyl group of thymine (Table 2).



In the oxidation of type (A) radicals of thymine or uracil, the carbonium ion **1** is formed, the rapid solvolysis of which leads to the quantitative formation of glycols, namely the *cis*- or *trans*-form of 5,6-dihydroxy-5,6-dihydrothymine **2** or 5,6-dihydroxy-5,6-dihydroxyuracil **3**, by the following reaction:

The equality of the amount of type (A) radicals, estimated by the method of pulse radiolysis, and of the amount of the corresponding thymine or cytosine glycols, isolated chromatographically (Table 2), permitted the conclusion that the pyrimidine glycols are formed exclusively by the reaction involving the oxidation of type (A) radicals [reaction (16)].[68]



(16)

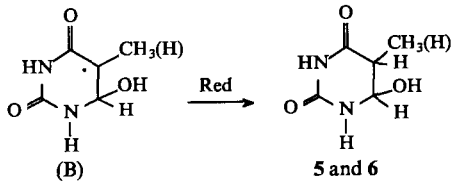


Table 2. The yields and oxidation-reduction properties of free radicals of the pyrimidines formed on reaction with hydroxyl radicals.[67-69]

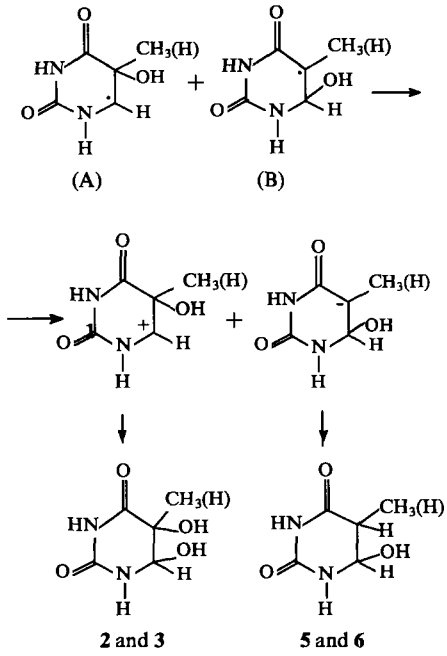
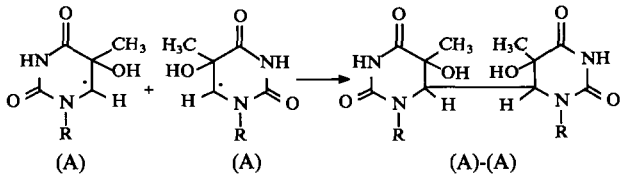
Heterocycle	Radical	Oxidation–reduction properties	Yield/(%[OH])	
			pulse radiolysis	analysis of products
Thymine	(A)	reductant	56	57
	(B)	oxidant	35	–
	(C)	weak reductant	9	–
Uracil	(A)	reductant	80	77
	(B)	oxidant	20	–
Cytosine	(A)	reductant	87	–
	(B)	oxidant	10	–



The oxidation of the type (C) thymine radical leads to the formation of 5-hydroxymethyluracil **4**.[71, 72]

The reduction of the type (B) thymine or uracil radicals leads to the formation of 6-hydroxy-5,6-dihydrothymine **5** or 6-hydroxy-5,6-dihydrouracil **6** respectively:



Since the oxidation–reduction properties of the radicals differ, it follows that, in the absence of exogenic oxidants or reductants, a type (A) radical may be oxidised by type (B) radicals to a carbonium ion with the subsequent formation of the glycols **2** or **3** and the 6-hydroxy-derivatives **5** or **6**.

Under these conditions, the yield of glycols is appreciably lower and amounts to one third of the yield of type (B) radicals, which are consumed also in the dimer formation reaction. The dimerisation reaction is likewise characteristic of other types of radicals [type (A) and type (C) radicals]:[73]

(B) + (B) → dimer (B),
(A) + (A) → dimer (A),
(C) + (C) → dimer (C),

The cytosine radicals behave similarly.[68] The *cis*- and *trans*-glycols of cytosine **7**, C–C cytosine dimers, 5-hydroxycytosine **8**, and, to a lesser extent, 6-hydroxycytosine **9** are formed in the course of further reactions of the cytosine radicals. Furthermore, the deamination of cytosine is observed, which results in the formation of uracil and the uracil glycols **3**.

Thus the main products of the oxidation of pyrimidines are glycols, hydroxyhydrates, and dimers, while in the oxidation of thymine 5-hydroxymethyluracil is also formed. The formation of these products in the γ-radiolysis of deaerated solutions of pyrimidines has been noted in studies by different investigators, although with some differences in their estimated amounts (Tables 3–5).[74–80]

Apart from these products, the radiolysis of pyrimidines in deaerated solutions (particularly for high doses) involves the formation of various urea derivatives: N^1-formyl-N^2-pyruvylurea **10**, *N*-formylurea **11**, and urea **12**. Their formation can be accounted for by the further oxidative degradation of the glycols.[78]

2. Aerobic oxidation of pyrimidine heterocycles

Under aerobic conditions, the type (A), (B), and (C) radicals combine with oxygen, the reaction having a diffusion-controlled rate constant ($k \approx 2 \times 10^9$ litre mol^{-1} s^{-1}), forming the corresponding peroxyl radicals [reaction (17)], the decomposition of which leads to the formation of stable products.[25, 26]

Studies carried out in recent years on simple model compounds made it possible to formulate general principles governing the decomposition of organic peroxy-radicals.[25, 26] It usually takes place via a bimolecular mechanism with formation of a short-lived intermediate—a tetroxide, which can redissociate at low temperatures into two peroxy-radicals, while at room temperature it decomposes rapidly to stable products. The number of reactions involved in the decomposition of the tetroxide is small. Four main processes have been distinguished:

(1) the formation of an alcohol molecule, a carbonyl compound, and an oxygen molecule [reaction (18)]—Russell's concerted mechanism;

(2) the formation of two molecules of a carbonyl compound and a H_2O_2 molecule [reaction (19)];

(3) dissociation into two molecules of a carbonyl compound with a carbon atom having a lower degree of substitution, one oxygen molecule, and two alkyl radicals, which recombine with O_2 to form peroxy-radicals [reaction (20)];

(4) the products of all these reactions can be obtained also via a free-radical pathway through the formation of alkoxyl radicals [reaction (21)].

Tertiary peroxyl radicals do not undergo concerted decomposition via reactions of type (18)–(20), but do decompose via reaction (21), forming O_2 and tertiary alkoxyl radicals, which rapidly undergo β-elimination:

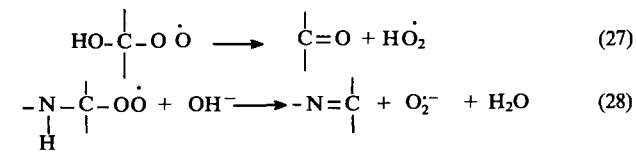
Scheme 1



The rates of reaction of various peroxyl radicals, leading to the formation of tetroxides, differ greatly. Certain peroxyl radicals interact with rate constants close to the diffusion-controlled values, whilst others, particularly tertiary peroxyl radicals can have rate constants several orders of magnitude smaller.[33] However, usually more than one type of peroxyl radical is formed and tertiary peroxyl radicals, which interact with one another very slowly, are involved in reactions with primary or secondary peroxyl radicals. A similar situation occurs also with superoxide radical-ions. Owing to their comparatively low rate of disproportionation, they probably interact with other peroxyl radicals present [reaction (26)].

The resulting hydrotetroxide can decompose to an alkoxyl radical, molecular oxygen, and a OH radical via a reaction of type (21) or to a carbonyl compound, molecular oxygen, and water via a reaction of type (18).

If the peroxyl radical contains a OH or NH group in the α-position, then there is a possibility in this case of unimolecular decomposition with formation of the superoxide radical-ion. In the presence of the OH substituent, $O_2^{\cdot-}$ is formed spontaneously [reaction (27)], while in the presence of the substituent NH base catalysis is necessary [reaction (28)]:

On the basis of the mechanisms described, one may predict the pathways leading to the formation of the majority of the products identified in the γ-radiolysis of uracil in a N_2O/O_2-saturated aqueous solution (Table 6).

Since the OH radical adds preferentially to the C(5) position in uracil (80%), the main peroxyl radical is 5-hydroxy-6-peroxy-5,6-dihydrouracil **13**. The unimolecular reaction (28), involving the decomposition of the peroxyl radical **13** accompanied by the evolution of O_2 and requiring catalysis by OH^- ions, leads to the formation of 5-hydroxyisouracil **14** which can afford the *cis*- or *trans*-glycol **3** on interaction with H_2O and at pH 7 it can rearrange to isobarbituric acid **15**. In conformity with the foregoing, four mechanisms are possible for the bimolecular reaction (17) involving the decomposition of the peroxy-radical **13**. The first [mechanism (18)] leads to the formation of the *cis*- or *trans*-glycol **3** and dialuric acid **16** and is accompanied by the evolution of O_2. Two molecules of dialuric acid **16** and H_2O_2 are obtained via the second pathway [mechanism (19)]. In the third case [mechanism (20)], the C(5)–C(6) bond is ruptured

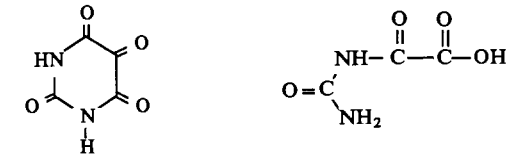
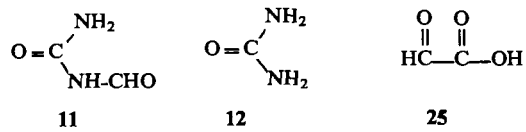
and the radical formed recombines with a O_2 molecule and, after the formation of HO_2^-, N^1-formyl-N^2-glyoxylurea **17** or its cyclic isomer N^1-formyl-5-hydroxyhydantoin **18** is produced. The latter readily loses the formaldehyde group and is converted into 5-hydroxyhydantoin **19**. The fourth pathway [mechanism (21)] leads to the formation of two alkoxyl radicals **20**, which are subsequently converted into dialuric acid **16** via pathway (23) or into N^1-formyl-5-hydroxyhydantoin **18** via pathway (24) [Scheme 2].



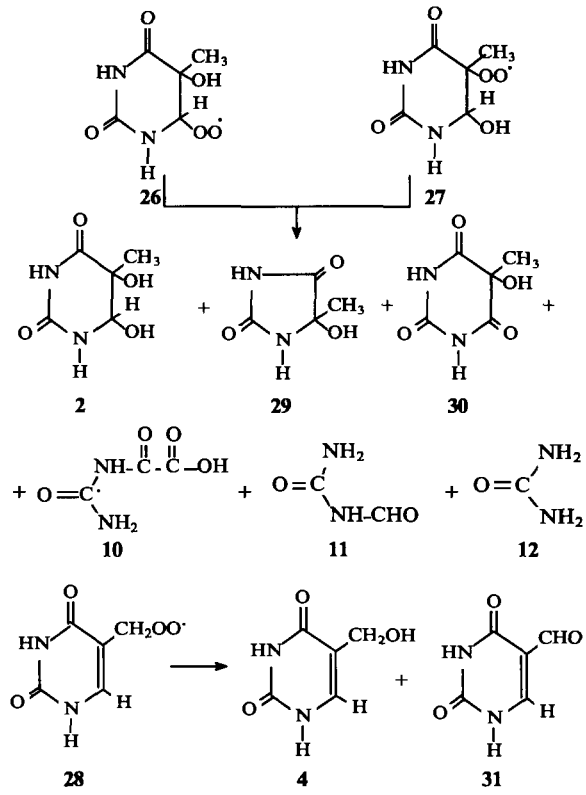
The unimolecular reaction (28) and the bimolecular reaction (17) compete. As shown in Table 6, the composition of the product varies with the pH of the medium and the power of the radiation.[81] At high pH, base catalysis renders the unimolecular reaction preferable, which results in isobarbituric acid (**15**) becoming the main product together with the glycols **3**, while the amount of N^1-formyl-5-hydroxyhydantoin **18** and dialuric acid **16** which are the main products of the bimolecular reaction, diminishes appreciably. At acid pH, there is a sharp change in the proportions of the product involving their inversion: N^1-formyl-5-hydroxyhydantoin and dialuric acid become the main products, while isobarbituric acid is not detected at all.

Evidently, only the bimolecular decomposition reaction is characteristic of the minor 6-hydroxy-5-peroxy-5,6-dihydrouracil **21** peroxyl radical. The main products are in this case the glycols **3** and N^1-formyl-5-hydroxyhydantoin **18**, as for the C(6)-peroxyl radical, and isodialuric acid **22** is formed instead of dialuric acid (Table 6).



21 **22** **3** **18**

For high irradiation dose rates and doses,[82] alloxan **23**, *N*-formyl-urea **11**, urea **12**, oxalic acid and its ureide **24**, and glyoxalic acid **25** are detected to the products listed above. These compounds are the products of more far-reaching oxidation of uracil and become the main ones for high irradiation doses.



23 **24**

11 **12** **25**

In aerated aqueous thymine solutions, type (A), (B), and (C) radicals combine with O_2 and form respectively three types of peroxyl radicals: 5-hydroxy-6-peroxy-5,6-dihydrothymine **26** and 6-hydroxy-5-peroxy-5,6-dihydrothymine **27**, which are analogous to the uracil peroxyl radicals **13** and **21**, as well as 5-peroxymethyluracil **28**.

Overall, the mechanisms of the decomposition of the peroxyl radicals **26** and **27** do not differ from those described above for uracil peroxyl radicals. Table 7 presents the yields of different products of the anaerobic γ-radiolysis of thymine.[25, 79, 83–85] As in the γ-radiolysis of uracil, the oxidation of thymine entails the formation of the *cis*- and *trans*-glycols of thymine **2**, 5-hydroxy-5-methylhydantoin **29**, 5-hydroxy-5-methylbarbituric acid **30**,

N^1-formyl-N^2-pyruvylurea **10**, *N*-formylurea **11**, and urea **12**. The decomposition of 5-peroxymethyluracil **28** leads to two main products: 5-hydroxymethyluracil **4** and 5-formyluracil **31**.

In addition, thymine hydroperoxides, obtained by the reduction of the peroxyl radicals, were isolated and characterised (Table 7).[86] The half-reaction time of the thymine hydroperoxides in aqueous solutions can reach 5 days at 37 °C.[25, 26] Four possible isomeric forms were isolated: the *trans*- and *cis*-forms of 6(5)-hydroxy-5(6)-peroxy-5,6-dihydrothymine and derivatives of type (A) and (B) radicals, the *trans*-isomers of the latter being formed preferentially. Hydroperoxymethyluracil—a derivative of the radical (C)—was also isolated.

Estimation of the products of the γ-radiolysis of cytosine in aerated aqueous solutions showed that 40% of the products isolated are the same as in the radiolysis of uracil (Table 8).[87, 88] This is apparently associated with the fact that the free-radical product formed from cytosine undergoes deamination in one of the first stages of the radiolysis. The free-radical products derived from uracil obtained as a result react via the mechanisms described for them above. The mechanism of the deamination has not yet been finally established.

In the decomposition of the peroxyl radicals derived from cytosine **32** and **33** which have not yet undergone deamination, the main products formed are *trans*-1-carbamoyl-2-oxoimidazolidine-4,5-diol **35** and 4-amino-N^1-formyl-5-hydroxy-2-oxo-Δ^3-imidazoline **36**. Compound **36** is apparently obtained via a mechanism similar to that of the formation of 5-hydroxyhydantoin and is subsequently converted on deamination into parabanic acid **37**. The formation of compound **35** can be explained by the dissociation of the C(4)–C(5) bond with formation of compound **34** which subsequently either cyclises to form compound **35** or undergoes further degradation to the biuret **38**. It is of interest to note that glycols are not formed in the radiolysis of cytosine in the presence of O_2 (Table 8). However, 5-hydroxycytosine, which may be a product of the dehydrogenation of the glycols, has been detected (Scheme 3):

3. Oxidation of purine heterocycles

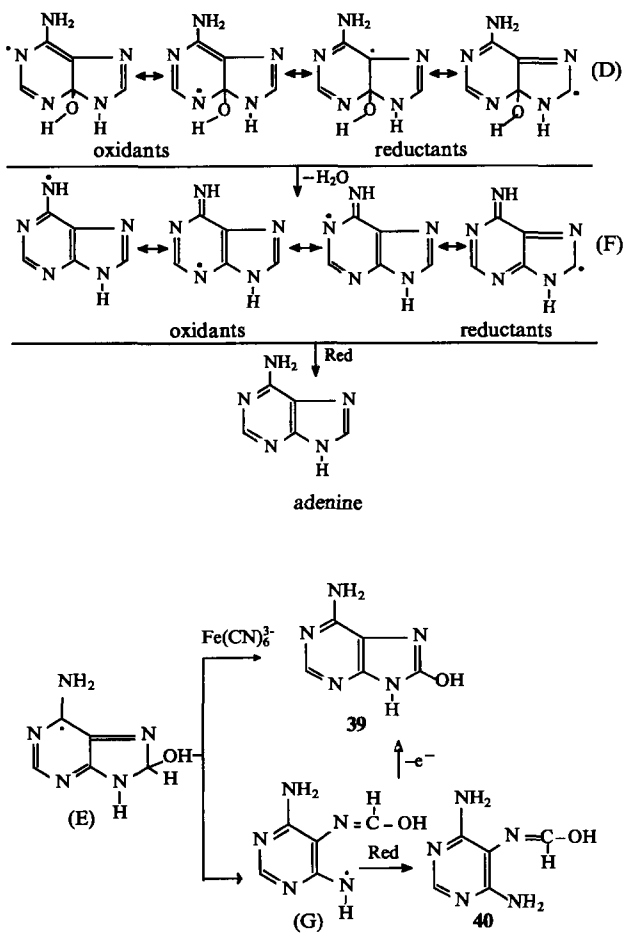
The advances in the study of the oxidation of purines by OH radicals on γ-radiolysis are not quite so considerable. This is because the methods for the investigation of the reactions of OH radicals, which have proved very useful in studies involving pyrimidines, encounter certain difficulties when applied to purine heterocycles. The use of EPR methods in combination with spin-trapping agents did not permit the unambiguous identification of the purine radicals formed on interaction with OH radicals.[89] Pulse radiolysis experiments combined with the study of the oxidation-reduction properties of the radicals obtained yield much information but their interpretation is also difficult. This is associated with the fact that the radicals formed in the reaction between free hydroxyls and purine heterocycles undergo rapid intramolecular rearrangements such as ring opening, dehydration, or dehydrogenation with formation of secondary radicals.

By means of pulse radiolytic methods it has been established[90–93] that, in its reaction with adenine, the OH radical adds preferentially to the C(4) carbon atom of the C(4)=C(5) double bond and to a lesser extent to the C(8) atom of the N(7)=C(8) double bond, forming respectively type (D) and (E)

radicals.

The type (D) radical is a weak oxidant, but as a result of dehydration it is converted into a type (F) radical, which is a powerful oxidant. The amount of radicals (F), determined by reaction with a reductant, was 81% for free adenine (Table 9). The reduction of the radical (F) leads to the formation of the initial adenine, which explains the observed low level of its degradation (30% relative to the amount of OH radicals).[93]

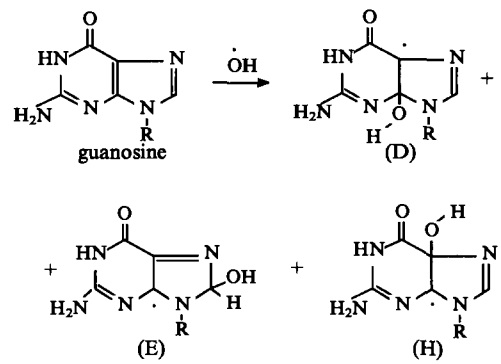
The type (E) radical is a reductant. Its yield, determined by reaction with an oxidant (Methyl Viologen), is 15% (Table 9). The oxidation of the radical (E) leads to the formation of 8-hydroxy-adenine **39**. When the γ-radiolysis was carried out in the presence of the oxidant $Fe(CN)_6^{3-}$, the yield of 8-hydroxyadenine was 18%, which agrees with the amount of the radical (E). However, the intramolecular reaction involving the opening of the imidazole ring with formation of the radical (G), which is an oxidant, is also characteristic of the radical (E). The reduction of the radical (G) leads to the formation of 4,6-diamino-5-formamidopyrimidine **40**.



In the absence of exogenic oxidants, the yield of 8-hydroxyadenine **39** exceeds that of the derivative of **40** by a factor of 3. This confirms that the oxidation reaction is the main reaction pathway to the radical (E), which can be oxidised in this instance

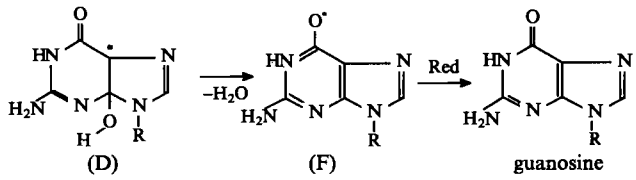
Table 9. The yields and oxidation – reduction properties of the free radicals of purines formed by reaction with hydroxyl radicals.

Heterocycle	Radical	Oxidation–reduction properties	Yield, %[OH]$^{-1}$	Method of estimation
Adenine	(D)	oxidant	81	by reaction with TMPD
	(E)	reductant	15	by reaction with MV
	(E)	reductant	18	yield of 8-hydroxyadenine
Guanosine	(D)	oxidant	50	by reaction with TMPD
	(E)	reductant	25	yield of 8-hydroxyguanosine
	(H)	reductant	25	difference between the overall yield of the radicals formed by reaction with MV and the yield of the radical (E)

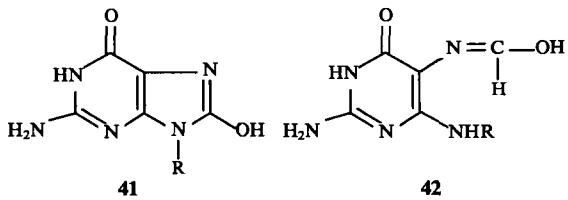


Notation: MV = Methyl Viologen;
TMPD = *N,N,N',N'*-tetramethylphenylenediamine.

by the radical (F) with formation of 8-hydroxyadenine and adenine. Compound **40** is apparently formed only as a result of the disproportionation of the radical (G).



The addition of the OH radical to the C(5) carbon atom of adenine has been detected only in the case of *N*(6)-methyladenine and its contribution does not exceed 10–15%. Further reaction pathways for the radicals formed have not been characterised.



As a result of the interaction of OH radicals with guanosine or its 9-substituted analogues, the formation of approximately equal amounts of radicals of two types has been detected. One of these radicals has oxidising properties and the other has reducing properties (Table 9).[92] As in the case of adenine derivatives, OH radicals add to the C(4), C(8), and also, with appreciable yields, C(5) carbon atoms of guanosine, forming type (D), (E), and (H) radicals respectively:

Like the adenine radical (D), the type (D) guanosine radical is rapidly converted as a result of dehydration into a type (F) radical, which is a powerful oxidant. The yield of the radical (D) was determined by reaction with a powerful reductant and was found to be 50%. The reduction of the radical (F) leads to the formation of the initial guanosine,[93] lowering thereby the overall yield in the degradation of guanosine.

The radicals (E) and (H) have reducing properties. The same reaction pathways as for the adenine radical (E) are characteristic of the type (E) guanosine radical. Its oxidation and the reduction of its radical product (F), in which the imidazole ring has been opened, lead to the formation of 8-hydroxyguanosine **41** and 6-*N*-(2'-deoxy-D-*erythro*-pentofuranosyl)-2,6-diamino-5-formamido-4-hydroxypyrimidine **42** respectively. The amount of the radical (E), estimated from the yield of 8-hydroxyguanosine, was 25% (Table 9). The remaining 25% of radical products derived from guanosine were assumed to comprise a type (H) radical, the subsequent reaction pathways of which have not yet been established.

The interaction of purine radicals with molecular oxygen has been investigated very poorly. The rates of these reactions are lower than for the pyrimidine radicals. Furthermore, the type (D) radical is rapidly converted into a type (F) radical, which does not react with oxygen. The reactions of purine peroxyl radicals have not been characterised.

The 8-hydroxy-derivatives **39** and **41** and compounds **40** and **42**, in which the imidazole ring has been opened, have been detected as the main products of the oxidation of nucleic acid purines in different oxidation systems (Tables 10 and 11).[26, 94–98] Furthermore, in the oxidation of the dinucleotide d(CG) by the Cu-1,10-phenanthroline complex, the formation of *N*-(2′-deoxy-D-*erythro*-pentofuranosyl)formamide was detected. This compound is apparently the product of more far reaching oxidation of guanosine.[99]

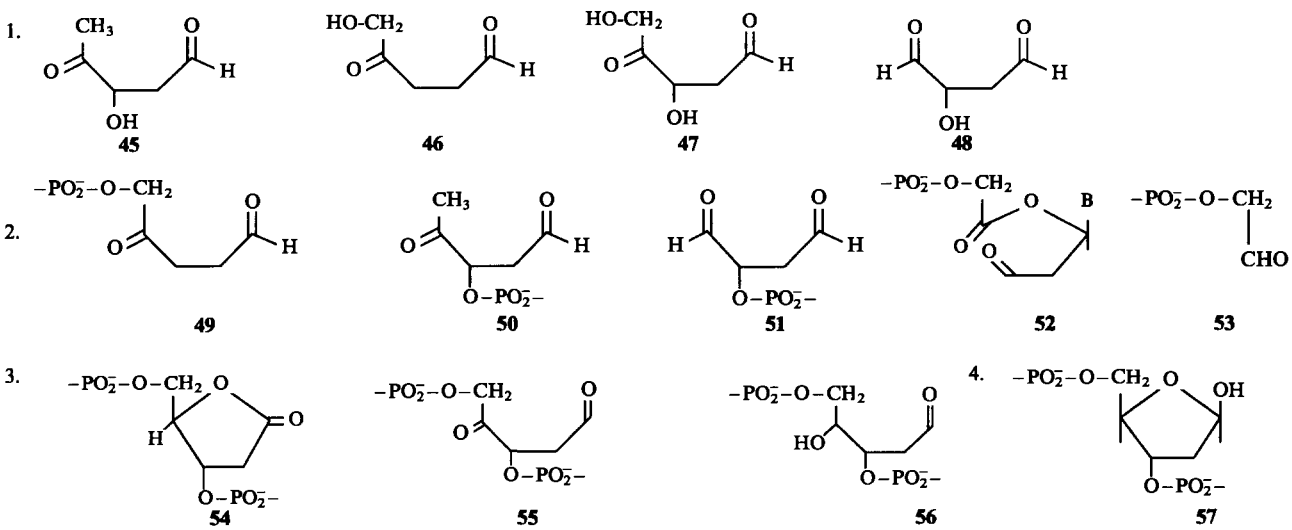
The majority of the products of the oxidation of heterocycles, characterised in terms of model compounds, have been detected also in the oxidation of DNA both *in vitro* and *in vivo* in different oxidation systems, namely on γ-radiolysis[100, 101] in the hydrogen peroxide–(Fe-EDTA)[31] or the superoxide radical ion–(Fe-EDTA)[29, 30] systems and also on oxidation by Cu-1,10-phenanthroline or Fe-bleomycin.[60, 102]

IV. Oxidation of the carbohydrate fragments in nucleic acids

1. General characteristics of the oxidation of the carbohydrate fragments of nucleic acids

The rate of reaction of hydroxyl radicals with ribose and 2′-deoxyribose is several times lower than for the heterocycles (Table 1). The reaction involves the abstraction of a H atom from all five carbon atoms in the pentose residue with not very different probabilities: approximately 25% each from the C(1′) and C(2′) carbon atoms, 20% each from the C(3′) and C(4′) atoms, and only 10% from C(5′).[103] This leads to the formation of a large number of modification products, which hinders the determination of the reaction pathways for particular primary radicals.

The use of spin-trapping agents made it possible to detect some of the ribose and deoxyribose free radicals formed in nucleic acids and their model compounds.[62, 63, 65] The stable products of the interaction of the C(4′), C(5′), and C(1′) radicals with 2-methyl-2-nitrosopropane have been isolated and characterised on γ-radiolysis of aqueous solutions of derivatives of uracil (uridine 3′-monophosphate and polyuridylic acid) and thymine (thymidine 5′-monophosphate). For cytosine derivatives (cytidine, deoxycytidine, cytidine 5′-monophosphate, cytidine 3′-monophosphate, and deoxycytidine 5′-monophosphate), it has been possible to detect by the reaction with 2-methyl-2-nitrosopropane only the C(4′) radical **43** and the radical product resulting from the further reaction of the C(5′) radical **44**:



For purine nucleosides (deoxyadenosine, adenosine, guanosine, deoxyguanosine inosine) and their homopolymers poly(A) and poly(G), only the product derived from the C(4′) radical was identified.[58]

All the final products of the modification of the sugar residue which have been established (Table 12), formed on γ-radiolysis of aqueous DNA solutions, have been arbitrarily divided into 4 types:[25, 26, 61] (1) the pentose oxidation products **45–48** obtained on dissociation of both phosphoester bonds and on splitting off the unmodified heterocycles; (2) modification of the pentose residues linked to only one terminal phosphate group and containing or not containing the heterocycles **49–53**; (3) products in which both phosphate bonds are retained but the heterocyclic base has been split off and the pentose has been modified [compounds **54–56**]; (4) the product **57** with a non-purine/non-pyrimidine site formed as a result of the modification of the heterocycles leading to the cleavage of the glycosidic bond. The formation of type (1) and (2) products is accompanied by the rupture of the sugar phosphate skeleton of DNA and the isolation of intact heterocycles. Products of types (3) and (4) represent the so called alkali-labile sites, giving rise to breaks in the DNA chain after heating in an alkaline medium. Their formation is not always accompanied by the simultaneous splitting off of intact heterocycles, for example in the case of the product **52**.

Table 12. Products of the modification of the hydrocarbon residue on γ-radiolysis of aqueous solutions of DNA.

Studies on the mechanisms of the oxidation of the simplest DNA analogues made it possible to establish certain characteristic features in the reactions of the free radicals derived from sugar phosphate esters, on the basis of which the mechanisms of the OH-radical-induced oxidation of ribose and deoxyribose in nucleic acids to known final products were postulated. The principal features are listed briefly below. They were described in greater detail in other reviews.[25, 26, 61]

(1) α-Alcoholic and α-alkoxyalkyl radicals, containing a phosphate group in the β-position, are capable of splitting off the latter rapidly:

$$R\dot{C}OH-CH_2-O-PO_2^- \longrightarrow R-CO-\dot{C}H_2 + H^+ + PO_3^{2-} \quad (29)$$

$$RO\dot{C}H-CH_2-O-PO_2^- \longrightarrow \left[R-O-\overset{+}{\dot{C}}H-CH_2 \leftrightarrow R-O-CH-\overset{+}{\dot{C}}H_2\right] + PO_3^{2-} \quad (30)$$

$$\left[\quad\right] \xrightarrow{OH^-} RO-\dot{C}H-CH_2OH + RO-\underset{OH}{CH}-\dot{C}H_2$$

(2) Radicals of the type $RCHOH-\dot{C}O$ rapidly split off a CO molecule:

$$R-CH(OH)-C\dot{O} \rightarrow R-\dot{C}H-OH + CO \quad (31)$$

(3) The oxidation of the radicals by various oxidants leads to the formation of carbonium ions:

$$R\dot{H} + Ox \rightarrow R^+H + Ox^-, \quad (32)$$

(4) In the presence of oxygen, alkyl radicals rapidly combine with an oxygen molecule to form peroxyl radicals:

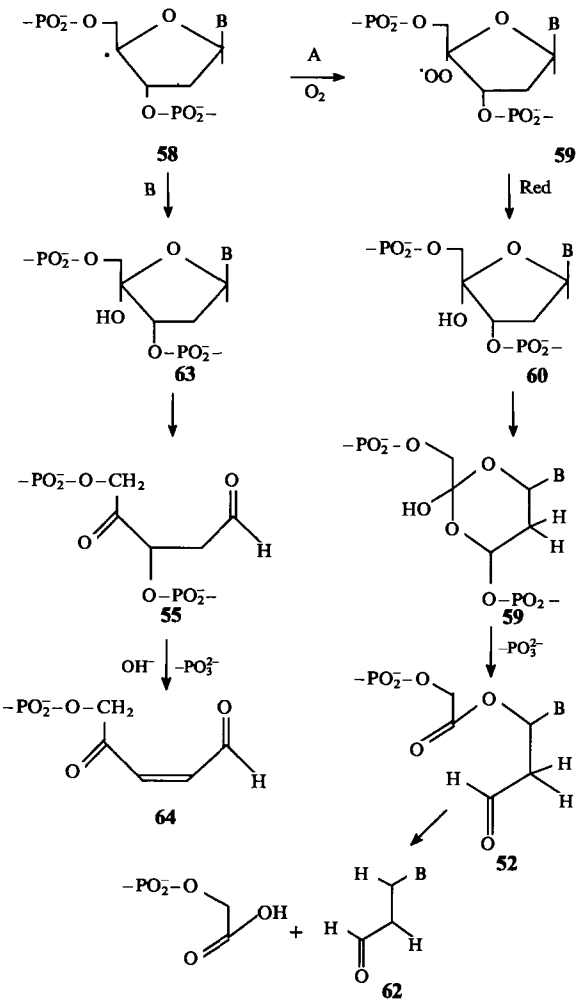
$$RR'R''C^{\cdot} + O_2 \rightarrow RR'R''C-OO^{\cdot} \quad (33)$$

(5) The peroxyl radicals decompose via the unimolecular or bimolecular mechanisms, described in the previous section.

A series of important data on the mechanism of the oxidation of the carbohydrate fragments have been obtained with the use of antitumour antibiotics (bleomycin, neocarzinostatin) and metal complexes (Cu-1,10-phenanthroline, Mn-porphyrin) which bind to DNA and oxidise pentose selectively in a specific position (subsections 2, 4, and 5 of the present section).

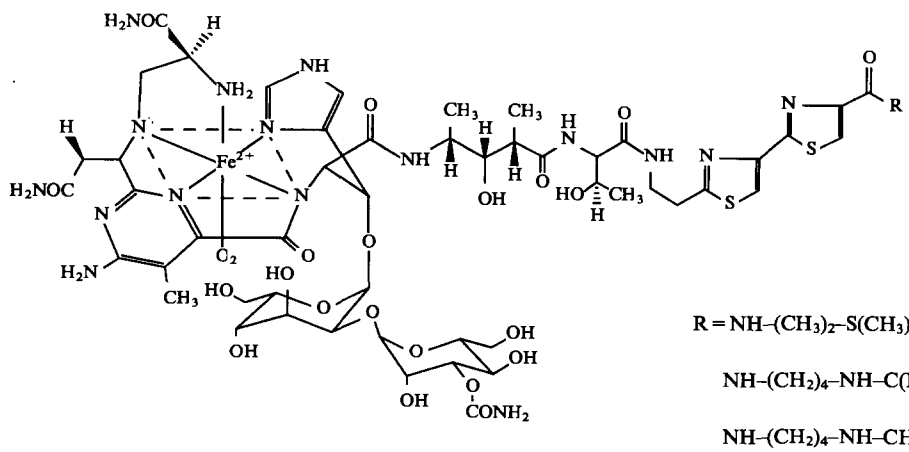
The oxidation of pentoses in the C(4') position has been studied in greatest detail. This is due to two causes. Firstly, the oxidation in the C(4') position is the main pathway leading to the degradation of nucleic acids by the antitumour antibiotics of the bleomycin group.[7] Secondly, the dominant formation of the ribose C(4') radical on γ-radiolysis in aqueous solutions as a result of the additional abstraction of a H atom from the C(4') position

in the sugar by the free radical of a heterocycle in a neighbouring monomer unit is characteristic of certain homopolynucleotides—poly(U) and poly(dT).[104] The known pathways leading to the oxidation of the sugars in nucleic acids in different positions in ribose or deoxyribose by both free OH radicals and certain antibiotics and metal complexes are described below.



2. Oxidation of deoxyribose in the C(4′) position in the presence of bleomycin

Bleomycins are a group of glycopeptide antitumour antiobiotics inducing the degradation of DNA in the presence of Fe^{2+} ions and molecular oxygen.[7, 55, 105, 106]

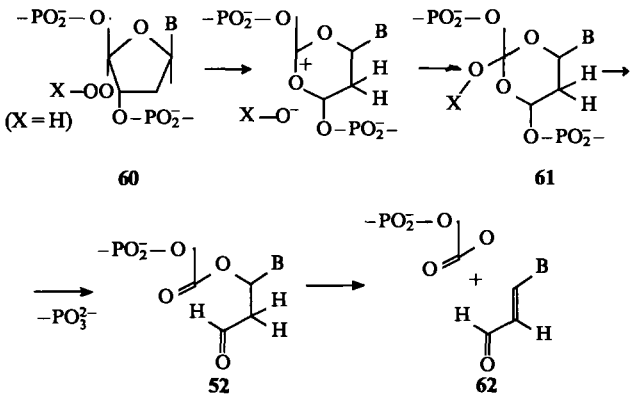


The oxidising unit is the so called 'activated bleomycin', which is a product of the two-electron reduction of the ternary complex Blm · Fe^{2+} · O_2, as already noted in Section II of this review, which is an oxo-complex of iron[50]. As a result of the degradation of DNA by the activated bleomycin, two types of monomeric products are detected: *trans*-propenals derived from the heterocycles (pathway A) and free heterocycles (pathway B). The formation of propenals requires the involvement of yet another oxygen molecule in addition to that used to activate bleomycin. This process is accompanied by the cleavage of DNA into two fragments, one of which contains a 5′-terminal phosphate and the other a 3′-terminal phosphoglycolate. The splitting off of the heterocycles does not require an additional oxygen molecule and leads to the formation of non-pyrimidine/non-purine sites in the oxidised deoxyribose residue, at which cleavage takes place only under alkaline conditions. At the normal oxygen pressure, the amount of the free heterocycles formed is virtually equal to the amount of heterocycle propenals. When the oxygen pressure is raised, reaction A takes place preferentially; under anaerobic conditions [Fe(III) and H_2O_2], pathway B is observed exclusively.[7, 55, 105, 106]

Experiments with different DNA containing tritium in the 4′-positions showed that the liberation of tritiated water is correlated with the formation of the sum of both monomeric products—propenals and free heterocycles.[55, 107] This shows that the first stage in both pathways is the abstraction of a hydrogen atom from the 4′-carbon atom of deoxyribose. The considerable isotope effect associated with the replacement of 4′-H by tritium or deuterium (by a factor of 7–11 and 4–5 respectively) permits the conclusion that the abstraction of a H atom from the C(4′) position in the pentose is the rate-limiting stage in both reactions.

Under aerobic conditions, the 4′-radical **58** rapidly interacts with oxygen, forming the 4′-peroxyl radical **59**. In order to demonstrate directly the occurrence of this process a series of experiments were carried out[108], in which the ^{16}O and ^{18}O oxygen isotopes were used. When $^{18}O_2$ was incorporated in the activated bleomycin and DNA was oxidised directly in the presence of $^{16}O_2$, no incorporation of the label in the product was detected. In the opposite situation, where the reaction medium contained $^{18}O_2$, the label was found to be incorporated in one of the oxidation products—3′-phosphoglycolate. Under these conditions, only one ^{18}O atom was incorporated in 3′-phosphoglycolate, while the other oxygen atom in this product originated from deoxyribose. The second oxygen atom of the peroxide group should apparently be included in the heterocycle propenal. However, so far it has not been possible to demonstrate this.

The subsequent stages, leading to the dissociation of the C(3′)–C(4′) bond, the cleavage of the sugar phosphate residue, and the formation of heterocycle propenals cannot yet be regarded as finally established. It appears that the 4′-peroxyl radical **59**

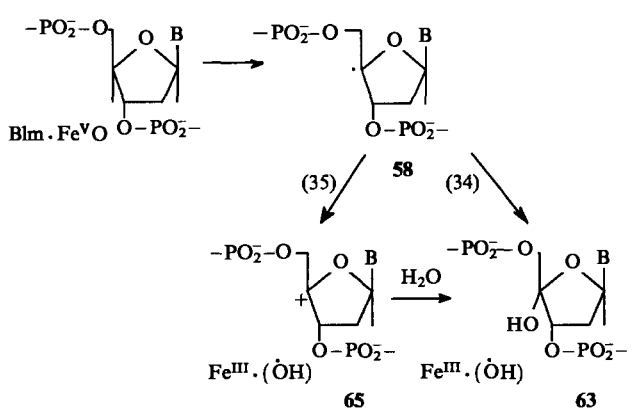


R = $NH-(CH_3)_2-S(CH_3)_2X^-$

$NH-(CH_2)_4-NH-C(NH_2)=NH$

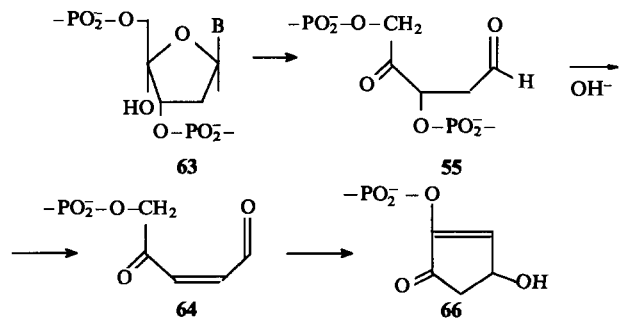
$NH-(CH_2)_4-NH-CH(CH_3)-Ph$

subsequently accepts yet another electron from the reductant present and is converted into the fairly unstable 4′-peroxide **60**. It has been suggested that the peroxide **60** subsequently undergoes the Criegee rearrangement. During this rearrangement, the C(3′) atom migrates from the C(4′) atom to the O atom of the peroxide with the simultaneous heterolytic dissociation of the O–O bond. The C(2′) atom, activated by the appearance of the carbonyl group in the C(3′) positon in the intermediate **52**, can be deprotonated, initiating elimination via the C(2′)–C(1′) bond and the formation of the heterocycle propenal **62** and the phosphoglycolate product. In this mechanism, the appearance of the label in the phosphoglycolate product should be observed when DNA is oxidised in the presence of $^{18}O_2$, which has in fact been done:[108]



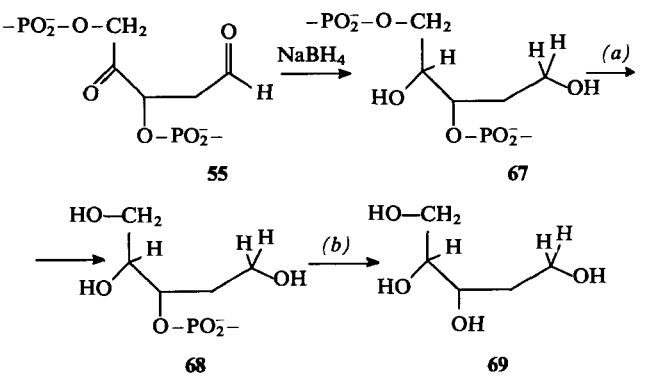
Confirmation has been obtained for this mechanism in a study[109] where it was shown, with 3′-^{18}O-labelled poly(dA-dT) as the substrate, that the 5′-phosphate products obtained on degradation by bleomycin contain the ^{18}O-label in the phosphate group. This indicates that the reaction proceeds via the pathway accompanied by the cleavage of the C(3′)–O(3′) bond.

Data in support of the existence of a precursor of the propenals **52** have been obtained.[110] The existence of a long-lived precursor of the heterocycle propenal, coprecipitated with DNA, was detected. This made it possible to demonstrate that the rate of formation of the propenals is an order of magnitude lower than the rate of appearance of single-strand breaks: $t_{1/2} \simeq 40$ min and $t_{1/2} \simeq 2.5-5$ min, respectively.



In a more detailed study of the rupture of the C(2′)–H bond, DNA selectively labelled with tritium was used:[111] poly(dA-[2′-proS-^{3}H]dU) and poly(dA-[2′-proR-^{3}H]dU). It was shown that the rigorously stereospecific elimination of 2′-proR-H takes place via anti-elimination with the exclusive formation of *trans*-propenals.

As noted previously, in the presence of a low O_2 content the oxidation of DNA proceeds via pathway B. After the abstraction of hydrogen from the C(4′) position, the splitting off of the heterocycles requires the addition of some kind of analogue of the OH radical. Two C(4′) hydroxylation mechanisms can be postulated.



In the first case [reaction (34)], the C(4′) radical recombines with the hydroxyl radical bound to the antibiotic, resembling the mechanism proposed for cytochrome P-450 and metalloporphyrins.[111] In the second case [reaction (35)], the C(4′) radical can be oxidised by a second equivalent of the activated antibiotic, affording a carbonium ion, which rapidly interacts with water. The results of experiments using oxygen isotopes, which will be discussed below, support the second pathway.

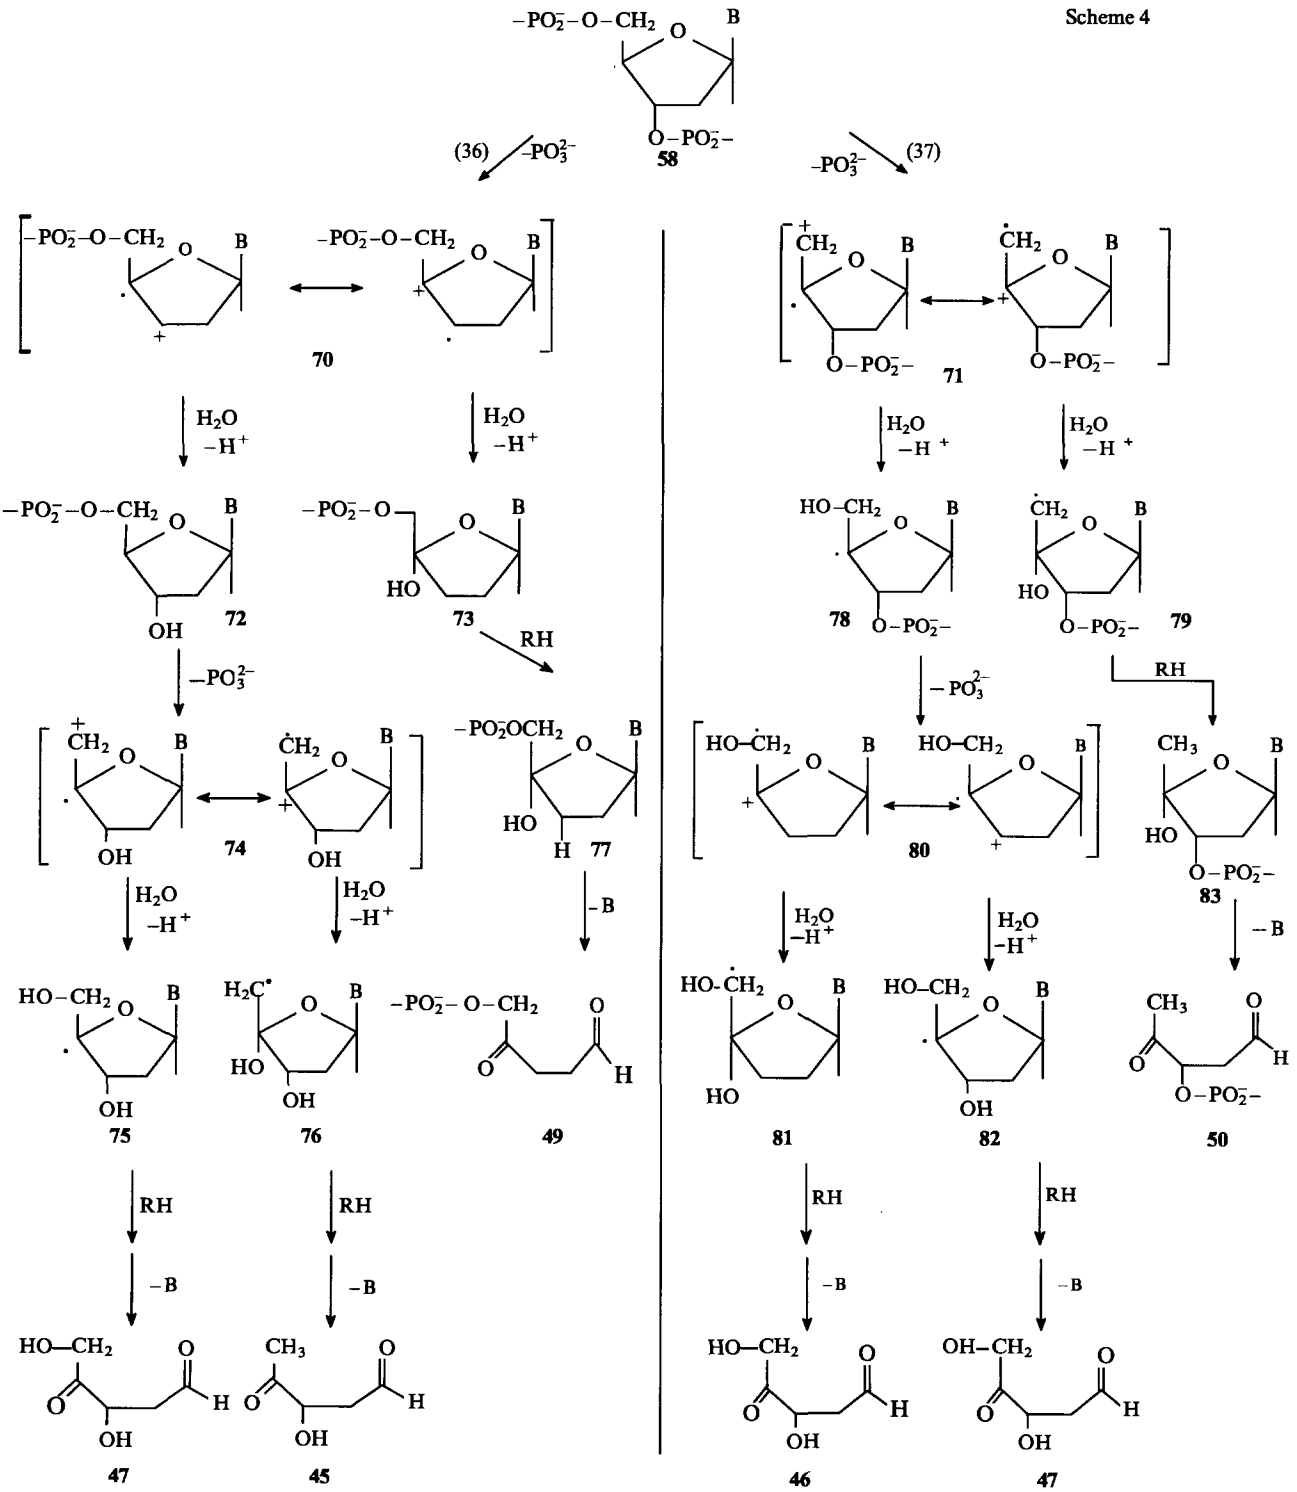
The compound **63** formed is cleaved, giving rise to the free heterocycles. Under physiological conditions, the oxidised deoxyribose residue **55** remains bound to the DNA chain. Under alkaline conditions, the 3′-terminal fragment is split off in the form of a phosphomonoester. In the second fragment, the sugar oxidation product—3-hydroxyl-5-oxo-1-cyclopentenyl **66**— remains at the 3′-phosphate end:

Certain aspects of this mechanism have been confirmed experimentally. Sugiyama et al.,[112] using the model substrate d(CGCTTTAAAGCG) containing a single site in the third deoxycytidine, which is cleaved by bleomycin, isolated the product CpGpx and determined its structure by direct comparison with synthetic analogues. This compound corresponded to the product **66** postulated in the mechanism. However, a correlation was not traced in the above study between the amount of heterocycles isolated and the amount of alkali-labile products of the modification of deoxyribose.

An alternative approach to the identification of the product **55** has been proposed.[113, 114] After incubating the model substrate d(CGCGCG) under anaerobic conditions with Fe(III)·Blm and H_2O_2, the product of the oxidation of compound **55** was stabilised by reduction with $NaBH_4$. After the enzymic degradation of the polymer, the deoxyribose residue **69** was identified with the aid of chromatograph-linked mass spectrometry by comparison with synthetic analogues of 2-deoxy-D-*erythro*-pentitol and 2-deoxy-D-*threo*-pentitol:

(*a*) treatment with P1-nuclease and alkaline phosphatase;
(*b*) treatment with phosphodiesterase I and alkaline phosphatase.

The product **69** isolated corresponded to a mixture of diastereoisomers and its amount was correlated to the amount of heterocycles formed.



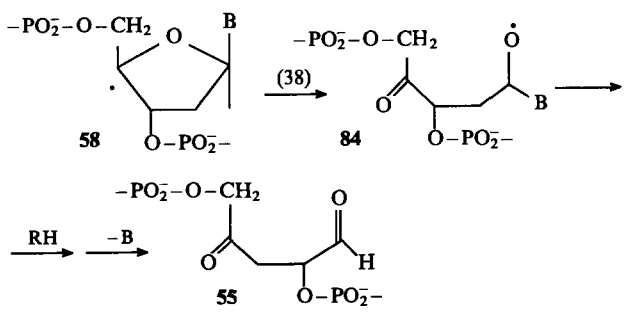
Using the approach described, the same workers[114] established the mechanism of the hydroxylation of the C(4') position. Using ^{18}O-labelled O_2 or H_2O, they showed that the source of oxygen in the 4'-keto-group of compound **64** is the solvent H_2O and the C(4') position is therefore hydroxylated via the second of the proposed pathways.

Thus wide scale investigations carried out in various laboratories made it possible to establish the mechanism of the oxidative fragmentation of DNA by bleomycin *in vivo*, although individual stages require further evidence.

3. Oxidation of pentose in the C(4') position by free OH radicals (according to γ-radiolytic data)

By analogy with bleomycin, the abstraction of a H atom by the OH radical from the C(4') carbon atom on γ-radiolysis leads to the splitting off of the free heterocycles and different modifications of the pentose. However, whereas the chain rupture under anaerobic conditions occurs only after treatment with alkali during oxidation with bleomycin, the splitting off of the heterocycle on γ-radiolysis is accompanied by rapid chain rupture.[25, 26]

Scheme 4

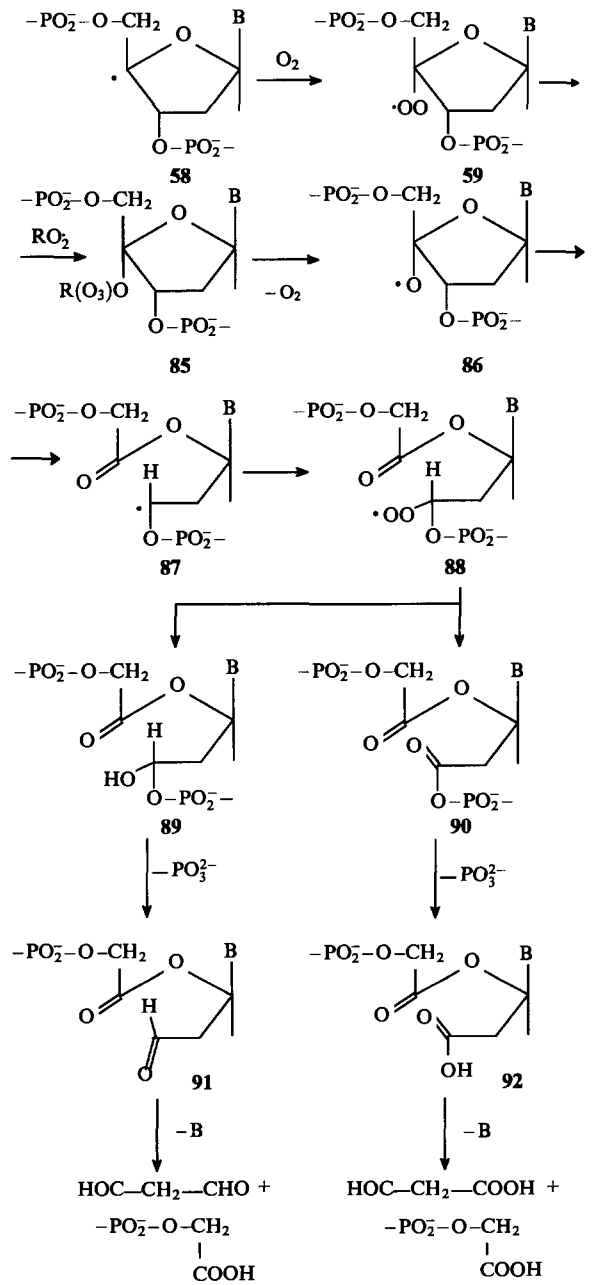


Consequently, the reactions of the C(4′) radicals leading to the final products are different in γ-radiolysis and in oxidation by bleomycin.

The C(4′) radical is a β-phospho-α-alkoxyalkyl radical, a characteristic feature of which has been shown, in simple models,[26] to involve the rapid elimination of the phosphate group. Since the ribose and deoxyribose C(4′) radicals contain two phosphate groups in the β-positions relative to the free valence, two competing reactions should be observed for them: the elimination of the phosphate group from the C(3′) atom [reaction (36)] and the C(5′) atom [reaction (37)]. It follows from the results of the study of model compounds that the elimination from the C(3′) atom should be faster, which is in fact reflected in the ratio of the final products (Table 12).

The postulated main reaction pathway for the deoxyribose C(4′) radical is presented in scheme 4. The radical-cation **70**, obtained when the phosphate group is split off from the C(3′) carbon atom [reaction (36)], can exist in two mesomeric forms with the positive charge located on the C(3′) or C(5′) atom. This radical-cation combines rapidly with a water molecule at one of the positively charged centres, forming respectively the C(4′)-β-phospho-α-alkoxyalkyl radical **72** again or the C(3′)-alkyl radical **73**. The radical **72** eliminates a second phosphate group and is converted into the radical-cation **74**. One nucleoside unit is fully eliminated from DNA at this stage. The intermediate **74** rapidly combines with a water molecule at the C(4′) or C(5′) position. The resulting alkyl radicals **75** and **76** are converted into the identified final products **45** and **47** respectively after reduction via a disproportionation reaction with any other radical and after the elimination of the intact heterocycle. The C(5′) radical is converted similarly via a disproportionation reaction into the unstable compound **77**, which is converted, after the heterocycle has been split off, into the detected product **49**. Although DNA is in fact cleaved at this stage, the oxidised nucleoside residue remains bound to the 3′-phosphate end of one of the DNA fragments.

The radical-cation **71** formed via the minor pathway (37) undergoes similar reactions, which result in the formation of the products **46**, **47**, and **50** (Table 12). They have also been detected as the final products of anaerobic γ-radiolysis of nucleic acids.[115]



The isomerisation of the C(4′) radical to the C(1′) radical **84** [reaction (38)], accompanied by the opening of the furanose ring, may compete with the elimination reactions (36) and (37).[116] Reaction (38) prevents the cleavage of DNA. The alkyl radical **84** formed eliminates the heterocycle after reduction and is converted into the product **55**, analogous to the product of the anaerobic oxidation by bleomycin.

In the aerobic γ-radiolysis, the reactions of the C(4′) radical are much more complex than in the oxidation by bleomycin despite the fact that certain products are identical in both cases. Molecular oxygen, which adds to the C(4′) radical with a diffusion-controlled rate constant $k = 10^9$ litre mol^{-1} s^{-1}, fully suppresses the phosphate group elimination reactions (36) and (37). The peroxyl radicals formed were detected by EPR. They have an unusually long lifetime[117] (~0.2–3.3 s). The subsequent decomposition of the C(4′) peroxyl radicals leads to the cleavage of nucleic acids. The main products detected were fragments of nucleic acids containing the phosphate group at the 5′-end and fragments containing either the phosphate or the phosphoglycolate group at the 3′-end. In addition, heterocycle propenals and unidentified products, undergoing a reaction with thiobarbituric acid characteristic of malonaldehyde, were also detected.

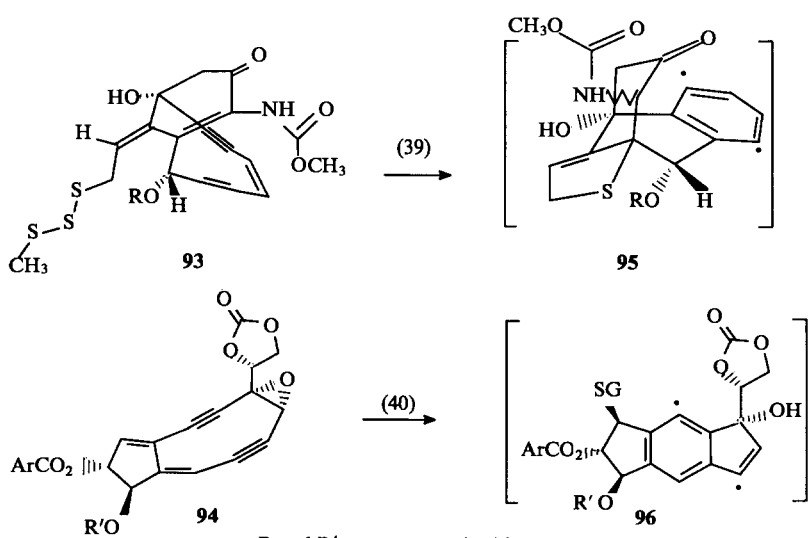
The mechanism of the decomposition of the peroxyl radical **59** on γ-radiolysis most consistent with the experimental data has been proposed by Schulte-Frohlinde and Bothe.[104] According to this mechanism, the peroxyl radical decomposes via a bimolecular reaction with formation of the tetroxide **85**. The intermediate **59** is a tertiary peroxyl radical and, in conformity with the foregoing, decomposes solely via the radical mechanism (21) with formation of two oxyl radicals and an oxygen molecule. The rearrangement with selective cleavage of the C(3′)–C(4′) bond and the formation of the radical **87**, which again interacts with O_2, is characteristic of such oxyl radicals **86**. Being a secondary peroxyl radical, the radical **88** decomposes via the formation of a tetroxide intermediate in accordance with Russell's concerted bimolecular

Scheme 5

mechanism (18) described above. An hydroxy- or carbonyl group (compounds **89** and **90** respectively) appears with equal probability at the C(3') carbon atom as a result of this reaction. The phosphoester bond in the C(3') position undergoes rapid hydrolysis in the compounds **89** and **90** formed, which leads to the rupture of the sugar phosphate skeleton and the formation of the fragments **91** and **92**. The subsequent decomposition of these fragments is accelerated in an acid medium or on heating and leads to the formation of the intact heterocycle and the 5'-phosphoglycolate end group. According to some hypotheses, the hydrolysis of compound **91** can involve the formation of heterocycle propenals (see scheme 5).

As noted above, free OH radicals are formed also during the reduction of molecular oxygen by transition metal ion complexes, for example, Fe-EDTA. One might expect that nucleic acids are oxidised in such systems via the same mechanisms as in γ-radiolysis. The products of the degradation of DNA by the iron complex of methidiumpropyl-EDTA (MPE) in the presence of O_2 and a reductant or H_2O_2 have been most thoroughly characterised.[118] It was shown that the pentose phosphate skeleton is cleaved. For each break, one heterocycle is split off with formation of 5'-phosphate end groups and of 3'-phosphates and 3'-phosphoglycolates in approximately equal amounts. The mechanism of the degradation of DNA was not discussed in the above study.[118] Nevertheless, the formation of the products is consistent with the sequence of the reactions of the pentose C(4') radical proposed for γ-radiolysis, where the heterocycle is liberated in the presence of a deficiency of oxygen together with free 5'- and 3'-phosphate end groups, while in the presence of oxygen the 5'-phosphate and 3'-phosphoglycolate end groups and the heterocycle are formed. Indeed, if MPE · Fe(III) · H_2O_2 is used instead of MPE · Fe(II) · O_2, then 3'-phosphoglycolates are formed in significantly smaller amounts.

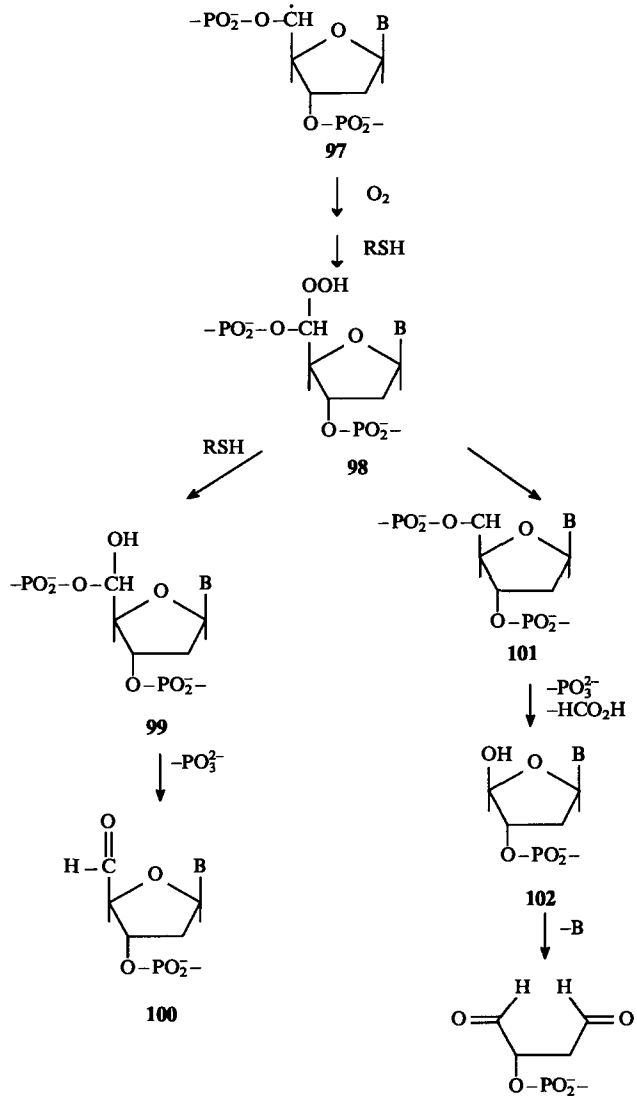
4. Oxidation in the C(5') position in the pentose



The preferential oxidation in the C(5') position in deoxyribose has been observed when DNA was cleaved by antibiotics of the diene-ene type such as neocarzinostatin **93** and calcomycin **94**.[119, 120] These antibiotics contain a bicyclodiene-ene structure, capable of being converted via reactions (39) and (40) into the biradicals **95** and **96**, which attack deoxyribose and abstract a H atom preferentially from the C(5') carbon atom.

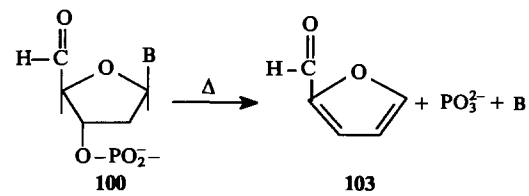
The mechanism and the cleavage of DNA by neocarzinostatin has been investigated in greatest detail.[121–124] The neocarzinostatin biradical **95**, formed as a result of reduction by thiols, abstracts as a rule an H atom from the C(5') position in the pentose, which has been demonstrated in experiments with nucleic acids containing atoms of the ^2H or ^3H hydrogen isotope in different positions in deoxyribose. When the H atom at the C(5') atom was replaced, both covalent incorporation of a deuterium or tritium atom in the antibiotic molecule and an isotope effect in the DNA cleavage reaction were observed.[122, 125] The abstraction of a H atom from the C(4') or C(1') position is observed to a much lesser extent. The specificity of the reaction in relation to a particular position in deoxyribose is apparently due to the different accessibility of the H atoms of deoxyribose in different sections of DNA.

In the next stage, only covalent adducts between DNA and the antibiotics are formed under anaerobic conditions. On the other hand, under aerobic conditions, DNA is cleaved and the formation of two sets of cleavage products is observed. The main product (80%) involves single-strand breaks (T > A ≫ C > G) with formation at the cleavage site of a fragment with the 5'-phosphate end group and a fragment containing a nucleoside-5'-aldehyde at the 3'-end. Less than 20% of the breaks occur in one nucleoside with phosphates at both the 5'- and 3'-ends and accompanied by the spontaneous liberation of the heterocycles.

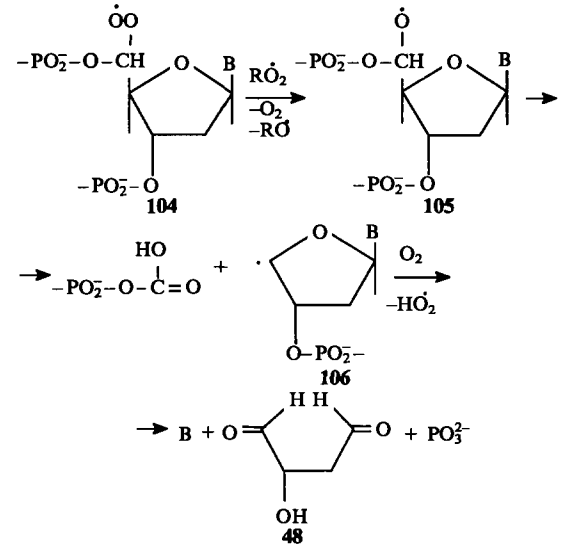


It has been shown [126] that under aerobic conditions the activation of the antibiotic is followed by the rapid absorption of an oxygen molecule via each antibiotic molecule and the subsequent utilisation of at least yet another reductant molecule. These results agree with the reaction in which the oxygen molecule adds to the radical **97**, generating a peroxyl radical, which is rapidly reduced by thiols to the hydroperoxide **98**. The use of $^{18}O_2$ made it possible to detect the incorporation of the oxygen isotope in one of the end products of the oxidation—nucleoside-5'-aldehyde.[127] The formation of the 5'-aldehyde end group has been demonstrated[124, 125] by reaction with $NaBH_4$, which leads to the reduction of the aldehyde group to the alcoholic group, and this was in its turn detected by phosphorylation catalysed by the T4 polynucleotidekinase. The use of a self-complementary short oligonucleotide,[124] having one site for oxidation by neocarzinostatin, made it possible to isolate all the final oxidation products and to establish their structures.

Two pathways leading to the decomposition of the hydroperoxide **98** have been postulated on the basis of the sum total of the results. Since the system contains a reductant (thiols), the peroxide group in the hydroperoxide **98** can be reduced to the hydroxy-group. The resulting compound **99** eliminates the phosphate group from the 5'-end, which ultimately leads to the rupture of the DNA chain and the formation of the 3'-phosphate and 5'-aldehyde (compound **100**) end groups. In addition, the hydroperoxide **98** can apparently undergo the Criegee rearrangement, which results in the formation of compound **101**. Compound **101** eliminates from the 5'-end a fragment containing the 3'-formyl

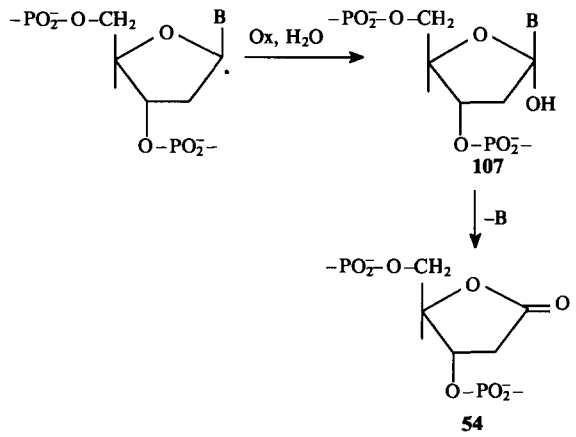


R and R' are monosaccharides



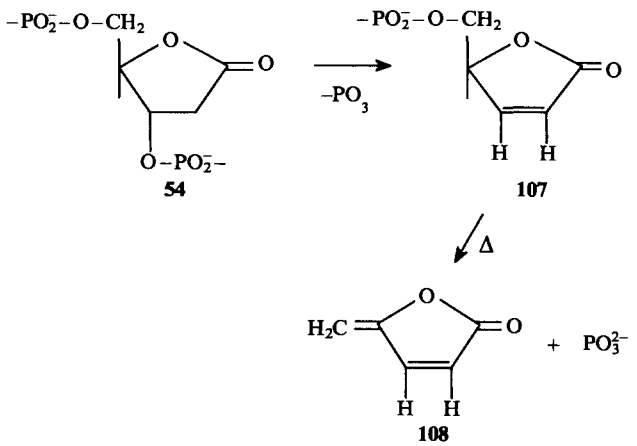
phosphate group, which hydrolyses spontaneously with the formation of the free 5′-phosphate end group. The second fragment contains the unstable compound **102**, which decomposes to compound **51**, liberating the heterocycle. It has been shown[127] that the amount of the nucleoside-5′-aldehyde increases with increase in the concentration of thiols, while the liberation of the free heterocycle diminishes. This confirms that the pathways leading to the formation of these products do indeed start from a single precursor—the hydroperoxide **98**—and that they compete with one another.

The selective oxidation of deoxyribose in the C(5′) position has been observed also for cationic metalloporphyrins.[128] However, as mentioned previously, in the case of metalloporphyrins the active oxidising species is apparently a high-valence metal oxocomplex, the most characteristic reaction of which is hydroxylation. Therefore, in the oxidation of DNA by metalloporphyrins, the first stage most probably involves the hydroxylation of the C(5′) carbon atom of the deoxyribose with the immediate formation of compound **99**. After the elimination of the phosphoester fragment from the C(5′) position, the nucleoside-5′-aldehyde fragment **100** is also formed. On further heating, it eliminates furfural **103**, splitting off the 5′-phosphate group.



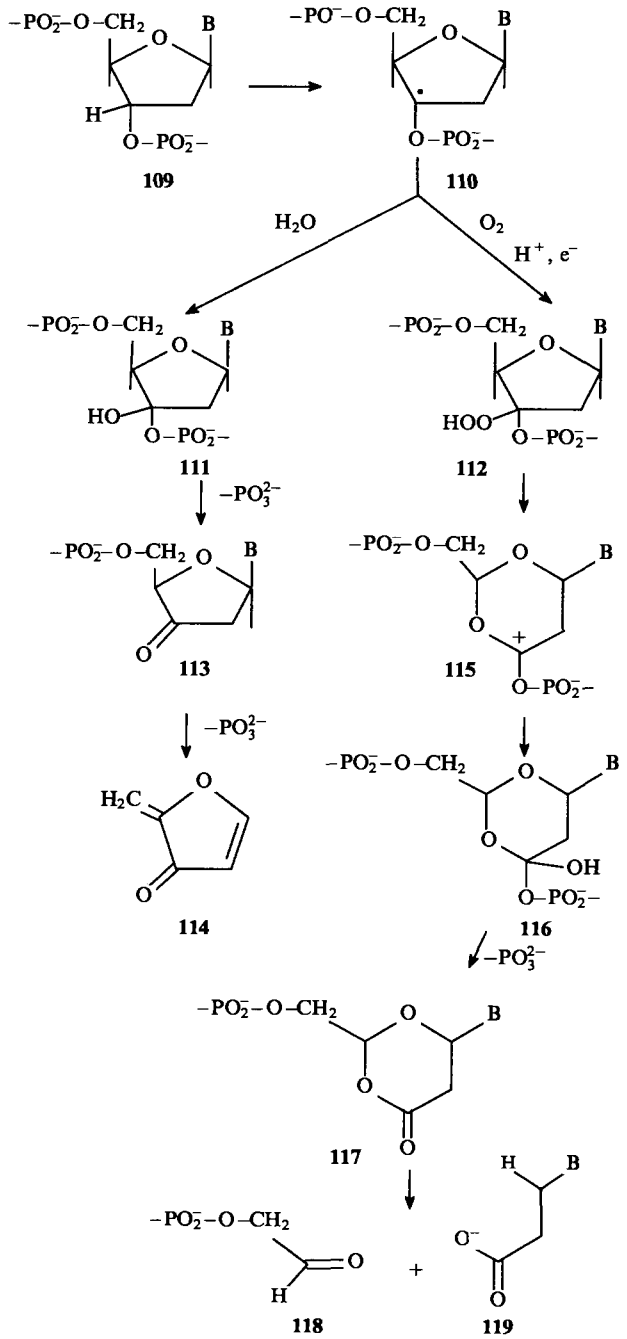
The formation of nucleoside-5′-aldehyde, accompanied by the splitting off of the phosphate, has been observed in the γ-radiolysis of aqueous solutions of D-ribose-5′-phosphate and guanosine 5′-phosphate under both anaerobic and aerobic conditions.[129] However, on γ-irradiation of aqueous DNA solutions, the formation of the nucleoside-5′-aldehyde was not observed. As regards the four-carbon fragment of deoxyribose of type **51**, linked to the 5′-phosphate end group of DNA, under aerobic conditions an analogous 2′-deoxytetradialdose is formed, but it is either linked to the 3′-phosphate end groups, as in **49**, or is present in the free state **96**.[30] The formation of such tetradialdose can be represented as a result of the conversion of the 5′-peroxyl radical **104**. The latter, being a secondary radical, can decompose via Russell's mechanism with formation of the oxyl radical **105**, which undergoes β-fragmentation, affording one DNA fragment with a 3′-formyl phosphate end group and another with the radical **106** linked to the 5′-phosphate group. At this stage, the DNA chain is cleaved betweren the C(4′) and C(5′) carbon atoms of deoxyribose. The radical **106**, which is a β-phospho-α-alkoxyl-akyl radical, rapidly eliminates the phosphate group from C(3′), recombines with an oxygen molecule, and the resulting peroxyl radical decomposes via a unimolecular mechanism with formation of the tetradialdose **48** and the liberation of the intact heterocycle.

5. Oxidation in the C(1′) position of the pentose



The oxidation in the C(1′) position leads to the formation of only one final product both on γ-radiolysis (under aerobic and anaerobic conditions) and on selective oxidation by certain 'chemical nucleases' (Cu-1,10-phenanthroline, Mn-porphyrins) although apparently via different mechanisms.

On γ-radiolysis under anaerobic conditions, the C(1′) radical can be oxidised with formation of a carbonium ion, the rapid solvolysis of which leads to the formation of compound **107**. The latter is unstable and rapidly splits off the heterocycle. The resulting lactone **54** remains bound to the sugar phosphate skeleton of DNA, as shown by Urata et al.[131] The presence of such a site can lead to the cleavage of DNA on heating or under acid conditions.



In the presence of molecular oxygen, the C(1′) radical should rapidly combine with oxygen to form a peroxyl radical, the subsequent reaction of which, apparently via Russell's mechanism, also leads to the formation of the lactone **54** bound to DNA.

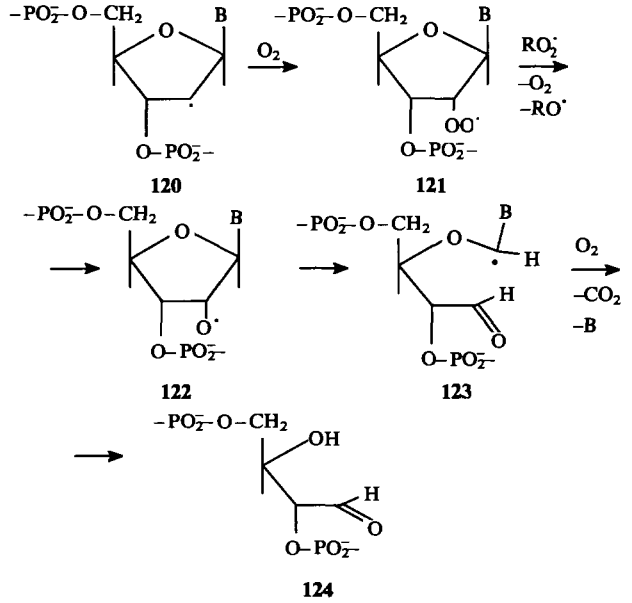
The selective oxidation of DNA in the C(1′) position in deoxyribose is characteristic of certain metal complexes with affinity for DNA. This applies in the first place to Cu-1,10-phenanthroline[8, 132, 133] and Mn-tetra(4-methylpyridinium)porphyrin.[128, 134–136] The formation of coordinated active forms of oxygen is characteristic of such complexes and nucleic acids are oxidised via the hydroxylated C(1′) positions of deoxyribose, also with formation of compound **107**, which decomposes to the lactone **54**. However, it has been shown that compound **54** is unstable, so that its decomposition is also accompanied by the rupture of the DNA chain with liberation of the 3′-phosphate fragment and the 5′-intermediate. The latter gives rise to 5-methylene-2-5*H*-furanone **108** on heating with liberation of the 5′-phosphate end group. This difference between the stabilities of compound **54** in various oxidation systems has not so far been explained. It may be associated with the catalysis of the elimination of the phosphate group from the C(3′) position in the vicinity of the site where modification by metal complexes takes place. Such complexes may behave as Lewis acids.

6. Oxidation in the C(3′) position of the pentose

The oxidation in the C(3′) and C(2′) positions of the pentose has been investigated to a lesser extent because the majority of compounds catalysing the oxidative cleavage of DNA are bound to a small groove, whilst the C(3′) and C(2′) atoms are located in a large groove. Compounds have been discovered quite recently, which, on binding to DNA, are located in a large groove and catalyse the photochemical oxidative cleavage of DNA. These are mixed rhodium(III) complexes with two 9,10-phenanthrenequinone diimine molecules and one 2,2′-bipyridyl molecule or with two 1,10-phenanthroline molecules and one 9,10-phenanthrenequinone diimine molecule.[137] These complexes bind to DNA from the side of the large groove as a result of the intercalation of the 9,10-phenanthrenequinone diimine ligand. On irradiation, the latter is converted into a radical-cation,[138] which is capable of abstracting a hydrogen atom from deoxyribose. In conformity with crystallographic studies, on

intercalation from the side of the large groove the intercalator comes close to the C(3′)–H bond.[139]

The products of the oxidation of a short oligonucleotide duplex by such rhodium complexes have been isolated and characterised.[140] The mechanism of the oxidation of DNA in the C(3′)-position under both aerobic and anaerobic conditions has been proposed on the basis of the results. The radical **110** obtained is apparently oxidised by the rhodium(II) ion and then combines with water molecule. The compound **111** formed is unstable and as a result of several β-elimination processes splits off the 3′- and 5′-phosphate end groups and the free heterocycle. The oxidised deoxyribose residue is isolated in the form of 2-methylene-3-2*H*-furanone **114**.



An alternative pathway is observed under aerobic conditions. In the first stage, an oxygen molecule adds rapidly to the C(3′) position and the resulting peroxyl radical is reduced. The hydroperoxide **112** undergoes the Criegee rearrangement, which leads to the rupture of the DNA chain with formation of 5′-phosphate and 3′-phosphoglycolaldehyde and groups (compound **118**). The heterocycles liberated contain a deoxyribose residue—propionic acid **119**.

Among the products of the γ-radiolysis of nucleic acids, products which might be formed as a result of the oxidation in the C(3′) position of the pentose were not identified. Only in the oxidation of deoxycytidine 5′-monophosphate was a product of the reaction of the C(3′) radical characterised,[117] but these results cannot be transferred to nucleic acids because the 3′-phosphate is absent in the given instance.

7. Oxidation in the C(2′) position of the pentose

Among the DNA oxidation products under aerobic conditions, only one compound was isolated for which a mechanism involving its formation from the C(2′) radicals may be postulated.[141]

Like other deoxyribose radicals, the radical **120** rapidly combines with an oxygen molecule and is converted into the peroxyl radical **121**, which decomposes via Russell's mechanism with formation of the oxyl radical **122**. The oxyl radical **122** undergoes fragmentation with rupture of the C(1′)–C(2′) bond and the resulting radical **123** can again combine with an oxygen molecule, which is followed by the elimination of the heterocycle and a CO_2 molecule. The ultimate formation of the four-carbon deoxyribose fragment (erythrose) **124** is not accompanied by the cleavage of the nucleic acid under physiological conditions.

V. Conclusion

Thus the main species responsible for the degradation of nucleic acids in various oxidising systems are usually free OH radicals. Hydroxyl radicals interact with nucleic acids and model compounds the rate constants of which are close to diffusion-controlled values and generate organic free radicals either by adding to the unsaturated bonds of the heterocycles or by abstracting a hydrogen atom from the pentose. The OH radicals interact preferentially with the heterocycles: in nucleotides and single-stranded nucleic acids, the ratio of the radicals formed from the heterocycles to the pentose radicals is 10–15. For double-stranded DNA, in which the heterocycles become less accessible, this ratio reaches 5–7. In a number of instances, the heterocycle radical may abstract a hydrogen atom from the C(4′)-position in the pentose of the preceding monomer unit, inducing the formation of this radical. In this case, the yield of the pentose radical reaches 40%.

In the oxidation of nucleic acids by a number of antibiotics or transition metal complexes, the oxidising species is a bound analogue of the OH radical—the oxo-complex of a high-valence metal. In this case, a selective interaction with the pentose takes place and its radicals become the main primary product of the oxidation reaction.

The pentose radicals obtained induce in the course of further reactions either direct cleavage of nucleic acids or modifications of pentose which lead to cleavage after treatment with alkali. In the presence of oxygen, only oxidation in the C(3′)-, C(4′)-, and C(5′)-positions in the pentose leads to the rupture of the nucleic acid target. In the absence of oxygen, only oxidation in the C(3′)- and C(5′)-positions is accompanied by the cleavage of the pentose phosphate skeleton. Oxidation in the C(1′)-position can induce the cleavage of nucleic acids only under the conditions of catalysis by transition metal complexes.

The appearance of radicals derived from heterocycles usually leads to irreversible modifications of the heterocycle in the course of further reactions. Some of these modifications may weaken the glycosidic linkage and may induce the formation of non-pyridine/non-purine sites, which is accompanied by the cleavage of the pentose phosphate skeleton under alkaline conditions. The stable modifications of the heterocycles, remaining bound to DNA, can have intrinsic coding properties different from those of the initial nucleoside, inducing mutations.

VIII.	Summary	103

Abstract. The theory of the synthesis of diamond by the polycondensation of light carbon-containing molecules is examined, and the optimum stoichiometric, thermodynamic, and kinetic conditions for diamond and graphite polycondensation and the reverse conversion of diamond and graphite by water vapour and carbon dioxide are described. The formation of critical nuclei of diamond shows no specific restrictions, and can take place under static conditions. The growth of these nuclei and their transformation into macrocrystals require specific macrokinetic conditions, which can be produced only in non-equilibrium open catalytic systems. The conclusions from the theory are confirmed by analysis of the conditions of experiments on the growth of diamond crystals and the synthesis of diamond films on various supports, and of the formation and growth of diamond meta-crystals in nature. The bibliography contains 74 references.

I. Introduction

It is now becoming increasingly evident that diamond can be formed not only at high pressures and temperatures by the polymorphic transformation of graphite but also at medium and low pressures by the transformation of simple carbon-containing molecules. The extension of ideas about possible conditions of diamond formation applies not only to artificial synthesis but also to natural deposits. Until recently the formation of diamonds under natural conditions was assumed to be explained by the pallial (mantle) hypothesis [super-high pressure (SHP) conditions]. An important contribution to the establishment of the polygenetic hypothesis of diamond formation was made by work on the epitaxial growth of single crystals and the synthesis of diamond films from the gas phase at low pressures,[1-7] and also by facts revealed by the study of kimberlite[55-57] and non-kimberlite[66-70] diamond deposits. From the viewpoint of the polygenetic approach to diamond formation, which takes account of not only physical factors but also, and primarily, chemical factors, both the polycondensation of light carbon-containing species without SHP, and the polymorphic transformation of graphite into diamond by the action of SHP, but not without the involvement of certain chemical factors, are possible.

The possible high-pressure formation of diamond is confirmed by the present industrial production of diamonds by static synthesis at 1300 – 1400 K and 45 – 50 kbar, and also by the production of diamonds by explosion (detonation) at pressures up to 150 kbar, containing as the principal phase the hexagonal polytype of diamond — lonsdaleite. This is consistent with the discovery of lonsdaleite-containing polycrystalline diamonds in meteoric impact products with distinct traces of the action of SHP, and with the discovery of minerals formed at high pressures as inclusions in kimberlite diamonds. SHP was not critical, however, for the formation of kimberlite and more particularly non-kimberlite diamond deposits, similar to the Kokchetav deposit. The conservatism of various workers who consider that the high-pressure route is the only path to diamond formation is related to the neglect of chemical factors in diamond synthesis. Thus the solution to the problem of the genesis of natural diamonds lies not in the search for new evidence of their pallial (mantle) origin but in the accurate discrimination of the conditions for possible routes to the formation of diamond.

The present review provides a theoretical justification of the conditions of the chemical synthesis of diamond from small carbon-containing molecules without the use of high pressure. This synthesis is being successfully reproduced in laboratories, and is undoubtedly a source of diamonds in various types of natural deposit.

II. The chemical synthesis of diamond from light carbon-containing molecules

The general concept of the chemical synthesis of diamond from the gas phase at atmospheric pressure has been discussed.[8] The analysis of experimental data on the synthesis of diamond films by different authors has established the optimum conditions for the formation of diamond in relation to the atomic composition (H, C, O) of the original gas phase, its temperature, and the temperature of the support on which the diamond film is deposited.

A P Rudenko, I I Kulakova, V L Skvortsova Department of Petroleum Chemistry and Organic Catalysis, Faculty of Chemistry, Lomonosov Moscow State University, Leninskie Gory, 119899 GSP-3, Moscow V-234. Fax (7-095) 939 01 26

Received 29th October 1992
Uspekhi Khimii **62** (2) 99 – 117 (1993); translated by D A Paterson

The optimum range of diamond formation corresponds to a definite atomic ratio H : C : O. With increase in the temperature of the gas mixture there is a significant increase in the rate of diamond formation and a decrease in the influence of the nature of the original molecules. The deposition of diamond on the support, which may be practically any solid material, takes place at 700–1600 K; increasing the temperature of the support or going beyond the stoichiometric boundary of the diamond range (at H : C : O ratios characteristic of reducing conditions) gives 'non-diamond carbon'. All points of the H–C–O diagram corresponding to the syntheses carried out lie in a narrow diamond range close to the CO–H line, with rare exceptions, observed in experiments with mixtures enriched in oxygen or hydrogen and in experiments in which the influence of the nature of the original molecules and the support is appreciable.

In most of the studies analysed in the work cited,[8] increase in the temperature of the source of carbon (gas mixture or plasma) was the chief factor giving a high rate of formation of diamond films. Thus in addition to thermal heating, use was made of various methods of preparing the gas mixtures (high-frequency heating at low pressure, oxygen–acetylene flames, a high-voltage glow discharge, microwave or laser heating of plasma), which made possible a 10^2-10^3-fold increase in the rate of diamond formation, compared with thermal heating.

Naturally, increase in the temperature of the gas mixture from 400–800 K to 7000 K, leading to degradation of the molecules and levelling of the composition of the gas–plasma mixture, fully explains the fact that the position of the diamond range on the H–C–O diagram at high temperatures of preparation of the gas mixture is determined mainly by the H : C : O ratio in it, and not by the nature of the component molecules. This can be regarded as corresponding to a decrease in the role of chemical factors and an increase in the importance of physical factors in the formation of diamond films. This view is far from the truth, however, for the decisive role of chemical factors, even in experiments with a hot plasma, is related to the fact that the diamond range corresponds to a definite stoichiometric H : C : O ratio, and the formation of each new C–C bond in the diamond lattice is a chemical polycondensation process, taking place on the support at a comparatively low temperature and independent of the temperature of the plasma and the nature of the light carbon-containing species involved in the process.

Of course, with change in temperature the composition of the gas–plasma mixture changes, from that corresponding to the original mixture of components to some equilibrium composition, which is the same for all isostoichiometric mixtures. The specific mechanisms of formation of the new C–C bonds will differ in their elementary stages, but in all cases the process remains a chemical process. It is influenced strongly not only by stoichiometric but also by thermodynamic and kinetic conditions, and also by effects related to the non-equilibrium nature of open catalytic systems.

In the work cited,[8] most attention was paid to the stochiometric conditions of the synthesis of diamond from the gas phase, and no consideration was given to the other conditions of this chemical process, which are of no less importance for ensuring its stability. In the present review we have tried to fill this gap and to show the influence of various factors on the chemistry of the transformations of light carbon-containing molecules leading to the formation of diamond and non-diamond carbon and their conversion into gaseous products in the processes of chemical synthesis at low and medium pressures. Most attention is paid not to the formation of diamond films from the components of a high-temperature plasma[8] but to the heterogeneous-catalytic processes taking place under isothermal conditions with identical temperatures of the gas phase and the support or the nucleus of the diamond crystal. The last case reveals most fully and clearly the essential chemical nature of the diamond synthesis, which differs from the synthesis from a high-temperature plasma only in the details of the mechanism.

At low temperatures of the gas phase, the diamond material is formed by the polycondensation of the original molecules by a molecular mechanism. In a high-temperature plasma, the polycondensation involves both the undissociated original molecules and small molecules formed by the decomposition of the original molecules, and also ions and radical species. Thus the mechanism of the process may be to a large extent ionic and radical. In both cases, however, all the stages of the process take place at the temperature of the support, and diamond formation involves the polycondensation of light species with the necessary participation of the support and the diamond film growing on it. In other words, this is a heterogeneous-catalytic process. The catalysts may be the support, the diamond material formed on it, and various non-stoichiometric components of the gas phase.

The examination of the chemical aspect of the general theory of the synthesis of diamond from light carbon-containing molecules cannot be restricted to the question of diamond synthesis, without considering the polycondensation synthesis of graphite, graphite-like materials, and other condensation products (CP), often called 'non-diamond carbon'. The processes of diamond and graphite polycondensation are related chemical processes having the same stoichiometry and similar thermodynamics and differing only in the kinetic conditions and mechanisms. Thus the determination of the optimum kinetic conditions of diamond polycondensation compared with the conditions of graphite polycondensation is acquiring decisive importance in the development of the general theory of the chemical synthesis of diamond.

A basis for the discussion of the specific features of the kinetic conditions of diamond synthesis is provided by the results of systematic studies over many years in the following directions.

1. Work on the chemical synthesis of diamond at atmospheric pressure; the study of the chemistry of the surface of diamond crystals and the catalytic transformation of diamond in its reactions with gaseous and liquid media; the study of the mechanism of the oxidation of diamond material in its reaction with CO_2, H_2O, and other oxidants, and the conditions of the selective oxidation of graphite and other forms of non-diamond carbon in the presence of diamond; and the determination of the influence of various factors on the prevention of the oxidation of graphite under oxidising conditions.[9–14]

2. Work on the study of the nature and mechanism of formation of the polycondensation products of organic substances on heterogeneous catalysts, accompanying almost any organic catalytic reaction; the determination of the role of condensation products in stationary and non-stationary open catalytic systems; and the study of the influence of various factors on the polycondensation process, the degree of molecular condensation, the extent of aromatic condensation, the ratio of volatile and non-volatile condensation products, and the discrimination between the conditions for diamond and aromatic polycondensation.[15–18]

3. Work on the investigation of the conditions of diamond formation, the characteristics of the distribution of diamonds in deposits, and their mineral and geochemical associations with the surrounding medium; the establishment of correlations between the diamond-bearing character of various kimberlite pipes of Yakutia, the catalytic properties of the rock (in the oxidation of diamond by water vapour and carbon dioxide), and the oxidation potential and concentration of non-diamond carbon and bitumens[19–23] to develop a physicochemical criterion of diamond-bearing character; and the study of the properties of diamonds and the conditions of diamond formation in deposits of other types — metasomatic (Kokchetav), impact (Popigay), etc.

4. Work on the creation of models of the growth of diamond crystals and the abiogenic synthesis of hydrocarbons, bitumens, and graphite-like substances in the polycondensation of CO with H_2 and other light molecules in open catalytic systems,[19,24] and the development of the theory of non-equilibrium open catalytic systems[25,26] and evolution chemistry.[27]

III. The stoichiometric and thermodynamic conditions of diamond and graphite polycondensation

Published data[15-22,24,25] show that at the same temperatures at atmospheric or low pressures with the participation of heterogeneous catalysts (K), polycondensation of carbon-containing molecules A can take place with the formation of various solid products and the removal of various light molecules L:

$$nA \overset{K}{\rightleftharpoons} A_nK \rightarrow \{A_n - mL\}K + mL ,$$

$$A + \{A_n - mL\}K \rightleftharpoons \{A_{n+1} - mL\}K \rightarrow$$

$$\rightarrow \{A_{n+1} - (m+1)L\}K + L , \quad (i)$$

where $\{A_n - mL\}$, $\{A_{n+1} - (m+1)L\}$ represent the solid polyconden-sation products and other forms of non-diamond carbon or diamond.

Graphite (aromatic) and diamond polycondensation processes take place under their own specific kinetic conditions, but have the same or similar stoichiometric and thermodynamic parameters. Thus to distinguish the diamond range it is not sufficient to take as a basis the stoichiometric atomic ratio H : C : O, as was done in the work cited,[8] since in the same range the diamond and graphite polycondensation processes are equally probable.

In the work cited,[8] it was possible to distinguish the diamond range only because the diamond film syntheses examined were characterised by specific kinetic conditions which ensured that the experimental points lay in this range. Other factors were not examined. A definite role in the neglect of the kinetic conditions of the processes was also played by the observed[8] levelling of the influence of the nature of the molecules in equiatomic mixtures with increase in the temperature of the plasma. Although this is not inconsistent with the chemical nature of diamond synthesis, it reduces the stoichiometric conditions to the same equilibrium composition of the dissociation products of any isostoichiometric mixture, which is the case only for the highest-temperature plasma. If, however, the gas–plasma mixture contains undissociated molecules, or if an undissociated gas mixture heated to the temperature of the support is used, then it is obvious that the conditions of the polycondensation (1) for a definite atomic ratio H : C : O will differ not only in the kinetic factors but also in the stoichiometry and thermodynamics of the transformations of each of the equiatomic mixtures taken, according to each possible transformation direction.

This can be seen by examining the stoichiometry and thermodynamics of the reactions on which the polycondensation process (1) is based. We can take the series of simplest reactions giving graphite and diamond[15,19,24,25]

$$2CO \rightleftarrows C(\text{diamond}) + CO_2 , \quad (2)$$

$$2CO \rightleftarrows C(\text{graphite}) + CO_2 , \quad (2')$$

$$CO + H_2 \rightleftarrows C(\text{diamond}) + H_2O , \quad (3)$$

$$CO + H_2 \rightleftarrows C(\text{graphite}) + H_2O , \quad (3')$$

$$CH_4 + CO_2 \rightleftarrows 2C(\text{diamond}) + 2H_2O , \quad (4)$$

$$CH_4 + CO_2 \rightleftarrows 2C(\text{graphite}) + 2H_2O . \quad (4')$$

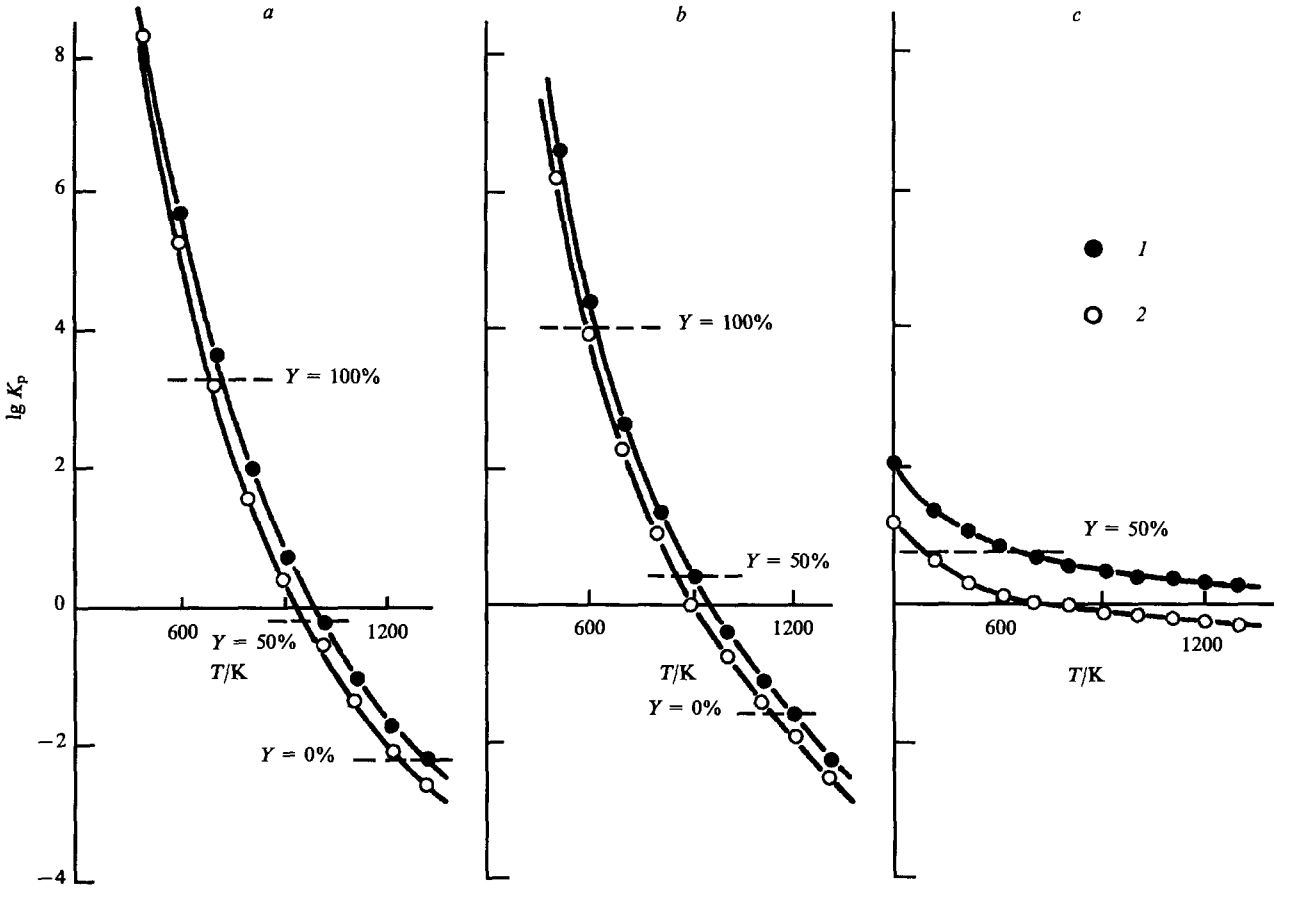

Figure 1. Thermodynamic conditions of the synthesis of graphite (*1*) and diamond (*2*) at P = 1 atm (Y is the degree of transformation); synthesis by the reactions: *a*, (2), (2′); *b*, (3), (3′); *c*, (4), (4′).

There are many analogous processes, for example

$$CH_3OH \rightleftarrows C(\text{diamond}) + H_2O + H_2 , \quad (5)$$

$$CH_3OH \rightleftarrows C(\text{graphite}) + H_2O + H_2 , \quad (5')$$

and also reactions involving solid components

$$CO + 2FeO \rightleftarrows C(\text{diamond}) + Fe_2O_3 , \quad (6)$$

$$CO_2 + 4FeO \rightleftarrows C(\text{diamond}) + 2Fe_2O_3 . \quad (7)$$

All these processes are thermodynamically possible, and the thermodynamic conditions for the diamond or graphite polycondensation processes to take place, although not the same, are nevertheless fairly similar (Fig. 1).

The thermodynamic conditions of different versions of the polycondensation (1) within a given type also differ from one another. For example, for the diamond polycondensation of methanol, in addition to version (5), it is possible to suggest at least another three:

$$2CH_3OH = C(\text{diamond}) + CO_2 + 4H_2 , \quad (8)$$

$$2CH_3OH = C(\text{diamond}) + CO + H_2O + 3H_2 , \quad (9)$$

$$2CH_3OH = C(\text{diamond}) + CH_2O + H_2O + 2H_2, \quad (10)$$

having different stoichiometries and thermodynamics (Fig. 2).

For diamond polycondensation from mixtures of different substances equiatomic with methanol we again have different thermodynamics for all four versions with different stoichiometries (Table 1).

There will be similar differences in the thermodynamic conditions for the processes of aromatic (graphite) polycondensation from the same original substances and mixtures. The calculations given were carried out for the formation of diamond and graphite, which are the products of the limiting stages of the polycondensation (1). The genealogical series of products of the diamond and graphite polycondensation processes (Tables 2 and 3 and Fig. 3), however, may also include the products of an intermediate stage of the polycondensation.

$$\left.\begin{array}{l} CH_3OH \\ C_2H_5OH + H_2O \\ C_2H_4 + 2H_2O \\ CH_2O + H_2 \end{array}\right\} \rightarrow \left\{\begin{array}{l} C(\text{diamond}) + H_2O + H_2 \\ C(\text{diamond}) + CO_2 + 4H_2 \\ C(\text{diamond}) + CO + H_2O + 3H_2 \\ C(\text{diamond}) + CH_2O + H_2O + 2H_2 \end{array}\right. \quad (11)$$

The extent of the polycondensation in these series is characterised by the ratio of the number of functional groups or hydrogen atoms on the peripheral parts of the polycyclic molecules of the condensation product to the total number of carbon atoms in the rings.[15,16] For example, for the hydrocarbon monomers A in the genealogical series of condensation products of the graphite series the atomic ratio H : C decreases from 1 to 0 on going from the simplest products (A = C_2H_2) to polycyclic aromatic hydrocarbons (PAH) and graphite, with a simultaneous increase in the specific (per monomer unit) decrease in the thermodynamic potential of process (1) (Fig. 4). In large crystals of diamond or graphite, or in carbon fibres, in which the polycyclic network of the PAH is coiled to form a tube, the H : C ratio approaches zero, but does not reach it. In the fullerenes[28] (C_{60} and others), however, the polycyclic carbon network is coiled into a closed sphere, leading to the limiting degree of aromatic polycondensation and a ratio H : C = 0.

The degree of aromatic polycondensation is related to the equilibrium degrees of transformation of A into different condensation products, which have their maximum values for the formation of the end member of this series, namely graphite. The degree of the transformation of A into diamond in all the parallel

reactions (2) and (2'), (3) and (3'), etc. is lower than the degree of transformation into graphite, and much higher than the equilibrium degree of transformation of CO + H_2 into PAH (see Fig. 4).

None of these differences, however, is significant for the polycondensation (1) taking place to give diamond or graphite, since the calculated thermodynamically equilibrium degrees of transformation characterise only the possibility that the reactions will take place spontaneously, and the question of whether they actually take place is determined by the kinetic conditions, which are different for each reaction.

The kinetic conditions include not only the actual characteristics of the interaction of the molecules and the mechanism of the reaction but also the effects of catalysts, other

non-stoichiometric components, and factors determining material exchange, the level of non-equilibrium character in the open system, etc. When favourable kinetic conditions are created, some of the thermodynamically possible reactions will take place, while others may be completely eliminated or largely suppressed, and in some cases this leads to diamond polycondensation under thermodynamic conditions favourable for graphite polycondensation.

IV. The kinetic conditions of diamond and graphite polycondensation

The most important factor creating favourable kinetic conditions for diamond polycondensation and the preservation and accumulation of diamond material with unfavourable conditions for the formation and preservation of graphite condensation products (non-diamond carbon) is the selection of catalysts and conditions for which the rate of formation of diamond (v_{di}) by reactions (2)–(5) is greater than the rate of formation of graphite (v_{gr}) by reactions (2′)–(5′) and, which is most important, the rate of oxidation of graphite $v_{o(gr)}$ is much greater than the rate of oxidation of diamond $v_{o(di)}$:

$$C(\text{diamond})[C(\text{graphite})] + H_2O(CO_2, O_2) \xrightarrow{v_o} CO + H_2. \quad (12)$$

The conditions

$$v_{di} > v_{gr}\,;\; v_{o(di)} \ll v_{o(gr)} \quad (13)$$

can obviously be produced in systems with a sufficiently high initial oxidation potential, in which reactions which are the reverse of reactions (2)–(5) or (2′)–(5′) and other polycondensation processes leading to the formation of diamond or graphite are possible. Thus the hatched diamond range established[8] on the H–C–O atomic diagram (Fig. 5) lies between a range with a high reduction potential (the range corresponding to hydrocarbons, whose polycondensation gives mainly graphite and other forms of non-diamond carbon) and a range with a high oxidation potential [the range corresponding to H_2O, CO_2, O_2, in which neither diamond nor graphite can be formed and preserved, since they undergo complete conversion according to Eqn. (12)].

This range should also be restricted in the direction corresponding to mixtures very rich in hydrogen, where hydrogenolysis of diamond and graphite with the rupture of C–C bonds is possible

$$C(\text{diamond})[C(\text{graphite})] + 2H_2 \rightarrow CH_4\,. \quad (14)$$

This process can take place, however, only when specific hydrogenolysis catalysts are present. The fact that diamond films have been synthesised in mixtures with a large excess of molecular hydrogen[8] is apparently due to the absence of these catalysts and the greater ease of hydrogenolysis of graphite compared with diamond.

The range very rich in carbon on the atomic diagram can be represented essentially by different types of solid polycondensation products. These products cannot be transferred to the vapour phase without degradation, and the possible synthesis of diamond from them reduces to the polymorphic transformation of graphite, for which the thermodynamic conditions are unfavourable without super-high pressure even with allowance for intermediate gasification

$$C(\text{graphite}) + CO_2 \rightarrow [2CO] \rightarrow C(\text{diamond}) + CO_2\,. \quad (15)$$

A number of experimental studies[9–12,15,16,19,20,24] have proved the existence of ranges with different oxidation potentials, in which it is possible to have polycondensation of hydrocarbons and other organic substances with the formation of condensation products of the graphite series and polycondensation of CO, H_2, CO_2, CH_4, H_2O mixtures with the predominant formation of diamond, and also complete conversion of diamond, graphite, and other condensation products by the action of water vapour, carbon dioxide, and certain other oxidants.

The hydrogenolysis of C–C bonds has been studied in the work[30,31] on the gasification of coals and on the hydrogenation of diamond in the presence of metallic catalysts.

It was established that: it is easy to find kinetic conditions favourable for graphite polycondensation, and much more difficult to find kinetic conditions favourable for diamond polycondensation;[15,16,19] there exist kinetic conditions under which graphite is oxidised, and diamond is not oxidised[11,12] or is oxidised much more slowly;[32] the nature of the catalysts has a strong influence on the rate of oxidation of diamond, and a mutual influence of different catalysts and substances in the vapour phase on the kinetics of the oxidation is observed, as far as its complete inhibition.[10,11] The formation of different functional groups on the diamond surface in its chemical reactions with the gas and liquid phases,[13,14] and the influence of the functional covering on the physical and chemical properties of diamond,[14] were established.

The data obtained brought us closer to an understanding of the mechanism of the oxidation of diamond by carbon dioxide and water vapour at 900–1300 K and of the reverse process, that is the synthesis of diamond by reactions (2)–(5). They made it possible to determine the necessary synthesis conditions and catalysts [since under conditions close to the equilibrium for

reactions (2)–(5) the catalysts of the forward and reverse reactions are the same]. The catalysts chosen for these processes were the ions of the alkali, alkaline earth, lanthanide, and heavy elements present in kimberlites.[9–11] The most active were potassium among the alkali metals, strontium among the alkaline earth elements, lanthanum among the lanthanides, and chromium, nickel, cobalt, and iron among the heavy elements.

The above catalysts and conditions have been used repeatedly for the synthesis of diamond at 1073–1233 K and atmospheric pressure under isothermal conditions by growing diamond material on the faces of diamond crystals (seed crystals) and diamond powders by reactions (2)–(4). Since the conditions and results of these syntheses have not been described, they are given in the present review. Fig. 5 shows points corresponding to the stoichiometry of the original substances and mixtures in the diamond syntheses which we have carried out.

The results of some of the experiments on the synthesis of diamond can be considered.

Since the rate of growth of the diamond material under isothermal conditions at 1150 K was found to be very low (~ 1 μm d^{-1}) along the normal to the {111} face, the experiments were carried out not only on single crystals (in this case it is possible to monitor both the change in mass and the surface) but also on natural diamond powders with a particle size of 3–5 μm (in this case it is possible to monitor only the change in mass). The following gases and gas mixtures were used as the sources of carbon: CO, $CO + H_2$, $CO + H_2O$, $CO_2 + CH_4$. In the last case the influence of change in the composition of the mixture (from pure CO_2 to pure CH_4) on the course of the reaction was studied. The experiments with single crystals were carried out using KOH melts and solutions of manganese oxide in molten KOH, and also molten boron glasses containing the ions of chromium, copper, manganese, etc. The studies were carried out in platinum reactors at 700–1200 K. Typical results of the experiments are given in Fig. 6 for the single crystals, and in Fig. 7 for the diamond powders.

Fig. 6*a* shows that the growth of the diamond material on a diamond crystal takes place only in a narrow range of compositions of the $CH_4 + CO_2$ mixture, with a maximum rate at 30 vol.% CH_4 and 1180 K (with increase in temperature to 1230 K the height of the maximum decreases, and its position is displaced to 42 vol.% CH_4). In the ranges richer in CO_2 or CH_4, the diamond support shows a mass loss, taking place as a result of the graphitisation of diamond, accelerated by CO_2, and as a result of the direct oxidation of diamond by carbon dioxide. The mass characteristics of the diamond product, given in Fig. 6*a*, correspond to pure diamond, since after the experiments all the graphite obtained by the graphitisation, and the other non-diamond carbon deposited on the surface of the diamond crystals by the polycondensation of methane in the range of high CH_4 concentrations, were completely removed using Moissan mixture and perchloric acid.

The fact that the synthesis of diamond material takes place not only in the narrow zone where the weight increases but also in the graphitisation zones adjoining it is confirmed by the appearance on the {111} diamond faces of specific growth formations — reversed-parallel triangular and hexagonal indentations. In the oxidative solution of diamond by the action of CO_2, H_2O, and other oxidants, only directly-oriented triangular indentations are formed.[33] These facts indicate not only growth in the zone indicated but also recrystallisation of the diamond material.

The characteristics of the thermodynamics of the transformation of $CH_4 + CO_2$ mixtures with different compositions at different temperatures are hardly reflected in any way in the kinetics of the processes of growth, recrystallisation, and graphitisation of the diamond material (see Fig. 6*b*). This proves again that favourable thermodynamic conditions are not sufficient for diamond polycondensation to take place, and that the kinetic conditions are of the greatest importance.

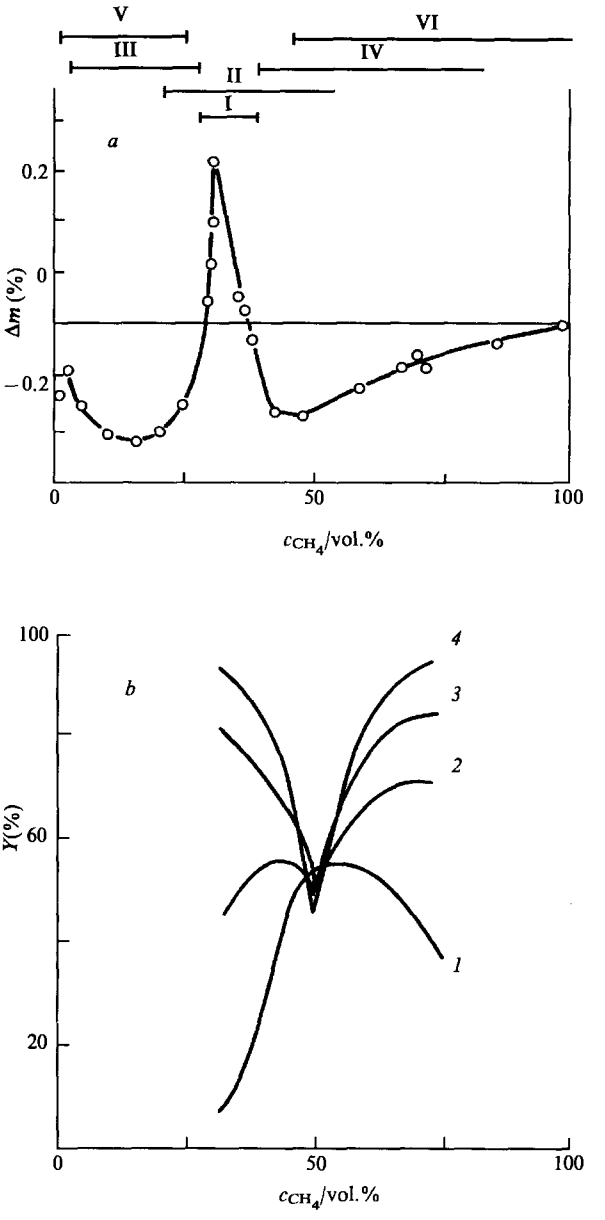

Figure 6. The results of experiments on the growth of diamond material on the {111} face of a diamond support by reaction (4) in a melt of the catalyst KOH (K_2CO_3); *a*, influence of the composition of the reaction mixture $CH_4 + CO_2$ on the change in the mass of the diamond support (T = 1180 K); ranges: *I*, growth of diamond; *II*, recrystallisation of diamond; *III*, *IV*, oxidation of diamond by CO_2; *V*, formation of condensation products of the graphite series from CH_4; *b*, equilibrium degree of transformation of $CH_4 + CO_2$ mixtures with different compositions into diamond at 673 (*1*), 873 (*2*), 1073 (*3*), and 1273 K (*4*).

The rate of growth of the diamond material on the powder in the polycondensation of CO depends markedly on the composition of the gas mixture, and is increased by small quantities of hydrogen (Fig. 7).

The data obtained indicate that at 1200 K the rate of growth of the diamond material corresponds to 0.8–1.5 carbon monolayers per hour; with decrease in temperature to 700 K it decreases to 0.06 monolayer per hour. This observation is consistent with published data,[34] according to which the rate of growth of diamond powders from CO at 1273 K has the values 0.0025 mass% per hour and 0.1 mass% per hour on powders with particle sizes of 53 μm and 1 μm respectively.

Fig. 5 shows that not all the points corresponding to diamond syntheses lie within the stoichiometric boundaries of the "diamond range" established by Bachmann and coworkers,[8] and that some are displaced considerably into the selective-oxidation zone. It is true that they do not lie in the complete-oxidation zone (the H_2O-CO_2-O triangle), but they lie below the lower boundary of Bachmann's diamond zone. The points corresponding to the formation of diamond films, established by Carrington and coworkers[35] and noted as exceptions by Bachmann,[8] also lie below this boundary. All these deviations are evidently not accidental, and are related to the fact that in the zone below the boundary indicated by Bachmann[8] as far as the upper boundary of the zone corresponding to the complete oxidation of diamond by water vapour and carbon dioxide (the line H_2O-CO_2), the formation of diamond is possible under certain kinetic conditions, while under other conditions it will be oxidised. These conditions are characteristic of non-equilibrium states of open catalytic systems, and they are extremely favourable for the recrystallisation and growth of crystals of the highest quality.

Thus in addition to Bachmann's diamond range, in which diamond and graphite may be formed under constant-growth conditions, it is also necessary to distinguish the recrystallisation diamond range $H-C_2O_3-CO_2-H_2O-H$ (Fig. 5), in which diamond may be formed mainly under growth–solution conditions. In this range and on its boundary with the Bachmann range, conditions are created for the formation of the purest diamond material without non-diamond carbon impurities. For example, to obtain a polycrystalline diamond film completely free from non-diamond carbon impurity (synthesis from microwave plasma) it is sufficient to add only 2.2 vol.% O_2 to the $CO+H_2$ mixture.[36]

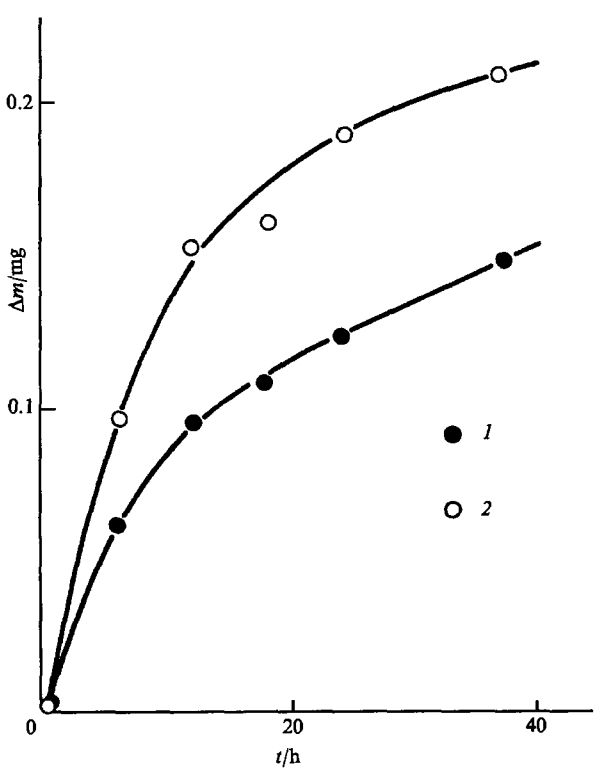

Figure 7. The growth of diamond material in the polycondensation of CO by reactions (2) and (3) on AP 3/5 natural diamond powder (T = 1123 K): *1*, input CO saturated with water vapour (32 mmHg); *2*, input CO saturated with water vapour (32 mmHg) after the establishment of the equilibrium $CO+H_2O \rightleftharpoons CO_2+H_2$; weight of powder in each series of experiments 6 mg; rate of supply of CO 0.5 litre h^{-1}; an increase in mass of 0.1 mg corresponds to the growth of 25 carbon monolayers.

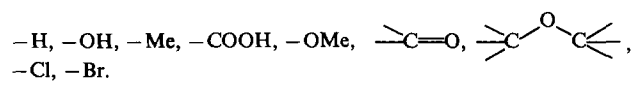
The zones corresponding to the graphitisation of the diamond support by the action of CO_2 in experiments with CH_4+CO_2 mixtures extend both into the recrystallisation zone at high concentrations of CO_2 in the mixture and into the Bachmann diamond range and beyond it into the zone corresponding to the formation of non-diamond carbon with a high reduction potential, where graphitisation is accompanied by the additional formation of condensation products from the excess of methane (Figs. 5 and 6*a*). However, judging from studies of the nature and mechanism of formation of condensation products from individual organic substances,[15,16] the formation of condensation products of the graphite series by the polycondensation of various monomers A takes place readily throughout the entire $CH_4-C_2H_2-CO-C_2O_3-H_3O^+-CH_4$ zone (Fig. 5), including the Bachmann diamond range. This proves again that carrying out the polycondensation (1) under the stoichiometric conditions of the diamond range does not necessarily lead to the formation of diamond, which requires the creation of favourable kinetic conditions (13) for diamond polycondensation.

V. The polycondensation mechanism of the formation of diamond and non-diamond carbon

1. Polycondensation mechanism and genealogical series of condensation products

Without dwelling on the familiar facts that diamond and graphite are allotropic forms of carbon, crystallising in two different forms, we shall concentrate attention on the chemical and genetic aspects of the polymorphism and allotropy of carbon in diamond and graphite directly related to the chemical and genetic problems of their formation.

Formally, crystals of diamond and graphite are macromolecules; a single crystal of diamond is a three-dimensional macromolecule, and a single crystal of graphite is a stack of planar macromolecules. This approach leads to the recognition of the existence of a carbon ring and peripheral functional groups localising the free valences of the carbon atoms on the surfaces of the diamond crystal and the edges of the polycyclic graphite macromolecule emerging on to the faces of the graphite crystal prism.

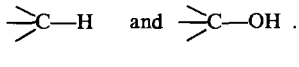


The introduction of each new carbon atom into the diamond or graphite lattice and the formation of the corresponding chemical bonds result from the processes of the polycondensation (1) of the original light carbon-containing molecules A with the reactive groups of the condensation product $\{A_n-mL\}$, which may be elements of the diamond or graphite lattice on the surface of the crystals. There are differences, however, in the details of the mechanism of the polycondensation giving the diamond or graphite material. There are also differences in the composition and structure of the condensation products which are the genealogical precursors of diamond and graphite, and the two directions of the polycondensation (1) have their own genealogical series (Tables 2 and 3 and Fig. 3). It is only in the lower stages of the polycondensation, involving the formation of linear and branched carbon–carbon chains and non-aromatic rings, that the compositions and structures of the condensation products are identical in the diamond and aromatic polycondensation series, with sp^3-configuration of the carbon atoms. The series differ completely, however, even at the stage corresponding to the formation of adamantane and its derivatives in the case of diamond polycondensation and to the formation of aromatic polycyclic compounds with sp^2-hybridisation of the carbon atoms in the case of graphite polycondensation.

The extent of the aromatic and diamond polycondensation in the genealogical series increases with decrease in the ratio of the number of surface functional groups to the number of carbon atoms in the ring of the macromolecule (Table 2).

Both the diamond and the graphite series may contain surface functional groups of different kinds, depending on the composition of the original monomers A, the conditions of the

polycondensation (1), and the subsequent chemical treatment of the condensation product. Thus for a monofunctional covering, the entire genealogical series of condensation products can be related to the corresponding class of organic substances, for example hydrocarbons, monohydric alcohols, etc. Thus the products of the diamond condensation of the original carbon-containing substances may contain series of diamond-hydrocarbons, diamond-alcohols, and diamond-ketones, differing chemically in their surface properties and even in their crystal habits (Tables 2 and 3).



A particular functional covering can be produced on diamond not only by diamond polycondensation but also by special modifying chemical treatment of diamond crystals and powder. In particular, a hydrogen covering can be completely replaced by a hydroxyl covering, or vice versa, by treating diamond with water vapour or hydrogen respectively at 1073 K. This is reflected in the changes in the infrared spectra and the contact angles of wetting by water (in the range 0–90°). For different treatment conditions, the following groups have been detected on a diamond surface:[13,14,37,38]

Similar results have been obtained for graphites and coals. Thus the carbon material obtained by the polycondensation of benzene or ethylene contains the groups

and that obtained from acetone contains the alternating groups[15]

Many publications (for example by Rudenko and coworkers[15,16]) describe the mechanisms of the polycondensation (1) as series of simple repeatedly alternating reactions (addition of the monomer A, removal of different light molecules L, cyclisation, isomerisation, etc.) leading to the successive formation of all the more complex condensation products of the corresponding genealogical series. A particularly large number of studies have been devoted to the aromatic condensation of organic substances. The complexity of the mechanism of diamond polycondensation is indicated by the mechanism of the reverse processes of the oxidation of diamond by water vapour and carbon dioxide.[9,11]

2. Macrostructural forms of graphite and diamond polycondensation products

The formation of the diamond and graphite material is influenced considerably by the mechanism of formation of their macrostructural supermolecular forms. Additional macrokinetic conditions must be established, which when combined with the molecular mechanism of the polycondensation (1) lead to the production of a particular macrostructural form of the diamond or graphite material. For one combination this will be a polycrystalline diamond film, for another a three-dimensional polycrystalline aggregate, and for a third a single crystal of diamond, and the formation of a particular macrostructure will be determined not by the conditions of the polycondensation (1) but by the factors facilitating or preventing the formation of new crystallisation nuclei and determining the intensity and form of the reagent fluxes and the ratios of their rates to the rate of reaction (1), by factors related to the equilibrium in the open catalytic systems, etc.

It is well known that these macrokinetic factors influence the production of various macrostructural forms of graphite (carbonaceous) material,[15] which can be obtained as anisotropic films, polycrystalline or vitreous graphite, carbon spirals, dendrites, hollow carbon fibres, or spherical fullerene molecules.[28] For the production of particular macrostructures, specific additional conditions must be established. For example, the formation of graphite spirals and dendrites, which have an internal spiral structure, takes place during the polycondensation of n-hexanol only in the regions where screw dislocations emerge on the single crystals of nickel, and does not take place on defect-free regions of the face of cubic nickel.[39] Catalytic corrosion of the nickel crystal at the base of the carbon dendrite is observed, and nickel is transferred to the carbon material, in which the nickel is not present in the dispersed state but forms a spiral of crystalline hexagonal nickel, analogous to the graphite spiral (the concentration of nickel in the carbon dendrite reaches 6 mass%). These data indicate that the carbon spirals grow from the base.

Completely different conditions must be established in the formation of carbon fibres having the form of tubes with a constant diameter of ~500 Å and consisting of a polycyclic graphite macromolecule coiled coaxially with the axis of the fibre. The carbon fibres grow from the tip, and a necessary condition for their growth is the presence on the tip of the fibre of a catalyst crystal which is commensurate with the diameter of the fibre and which acts as the 'operator' for its growth.[40]

Fibres and spirals are also formed in the chemical synthesis of diamond. Filamentary acicular crystals of diamond with lengths up to 400 μm grow on diamond seed crystals in the presence of metallic catalysts (Fe, Ni, Mn, etc.) both at low pressures from the vapour phase[41,42] and under SHP conditions from solutions of carbon in the metals.[43,44] Diamond filaments and needles with a diameter : length ratio of 1 : 20 usually grow along the normal to the {110} face of the diamond seed crystal[42,43] at a rate of up to 200 μm h^{-1};[41] this is much greater than the rate of growth of diamond powders. These macrostructural forms are present at the tip of the metal catalyst crystal.[41,42]

Au does not bring about the formation of diamond filaments at low pressures,[42] but brings about the production of different skeletal forms of diamond and its dendrites under SHP conditions.[44] The production of diamond fibres in the form of spirals has been observed in the regions where screw dislocations emerge on a diamond seed crystal.[45] The growth of filamentary crystals of diamond has been observed[46] on the projections and edges of seed crystals on different supports (diamond, garnet, mica) by the action of the electron beam directly in an electron microscope in a high vacuum. The source of carbon was the residual vapour of the oil in a vacuum of 10^{-4}–10^{-6} mmHg. Thus the growth of diamond as single-crystal filaments is brought about by a number of specific factors, and pressure does not play a significant role.

Diamond spirals of filaments with a thickness of 0.6 μm with a step and diameter of 2.5 μm and a length of up to 75 μm were found by us in AP 5/3 diamond powder after experiments on its further growth by reaction (2) at 1220 K in the presence of a melt of MnO in B_2O_3. The diamond spirals were joined to the diamond seed crystal, and in one case the formation of two spirals joined by one seed particle and lying at an angle to one another was observed. In this case the growth of the diamond spirals apparently takes place on the diamond particles at regions corresponding to the emergence of screw dislocations, which have an increased ability to bring about diamond polycondensation. This is confirmed by the fact that the calculated rate of formation of diamond by the growth of the diamond spiral is greater by several powers of ten than the average rate of the layer growth of diamond material on the {111} face.

A unique theoretically possible macrostructural form of diamond material that can be distinguished corresponds to macrocrystals (molecular species) with dimensions of 100–1000 Å, having a high ratio of the number of surface carbon atoms, and hence number of functional groups, to the number of internal carbon atoms in the particle, and exhibiting colloidal

properties as a consequence of the polarity of the functional groups (Table 2). Colloidal diamonds should have unique physical and chemical properties, differing from those of diamond micro-powders and the organic substances formed by diamond polycondensation. In particular, colloidal diamonds should not have abrasive properties, and on the contrary may be good lubricants. Some parameters of detonation diamonds, produced by the explosion of chemical substances, are close to those corresponding to a colloidal form of diamond material.[47]

A unique position among the macrostructural forms of diamond material is occupied by epitaxial molecular films (several carbon atom layers) with a regular single-crystal structure. They may be formed by a chemical mechanism analogous to crystallisation, for example in any of the reactions (2)–(4), in the presence of non-equilibrium concentrations of the starting materials when the crystal faces of the support show a two-dimensional crystal-structural similarity (crystal-chemical correspondence) to the arrangement of the carbon atoms on one of the faces of diamond. The existence of this crystal-structural correspondence with a low value of the coefficient of surface tension with respect to diamond leads to the production of a strong field in the crystalline support, capable of initiating on it the growth of an isomorphous diamond lattice, which as it were extends the lattice of the support.

3. The formation of equilibrium epitaxial films of diamond and the non-equilibrium growth of macroscopic crystals of diamond

According to the model of the growth of diamond crystals in open catalytic systems,[19] two-dimensional diamond films may be the nuclei for the growth of diamond crystals. The growth of a microscopic diamond crystal requires a constant displacement of the equilibrium of reactions (2)–(4) to the right under the conditions of non-equilibrium of an open catalytic system, whereas the formation of macroscopic epitaxial film–nuclei can also take place in a closed system before its equilibrium is established.

When equilibrium is established in reactions (2)–(4) and the kinetic conditions of diamond polycondensation are established in the presence of a suitable matrix–crystal face, an equilibrium epitaxial diamond film of several carbon atom layers is necessarily formed, and will be stable under these conditions.

The possibility of the formation of two-dimensional equilibrium nuclei of a new phase on a support with the properties indicated is established by de Wolff's theory, and also by the principle of minimum Gibbs–Curie surface free energy and the crystal-growth theorems of Gibbs, Volmer, and others. Using these theories it is possible to calculate the work of formation of a two-dimensional critical (equilibrium) nucleus with allowance for its parameters, the specific inter-phase free energies at the nucleus–crystal–medium boundaries (ΔG), and also the critical size (l) and the rate of formation of a nucleus with super-critical perimeter (J)

$$\Delta G = -\frac{\varepsilon^2}{4\gamma h \Delta G_v}; \quad l = -\frac{\varepsilon}{2\gamma h \Delta G_v}; \quad J = la \exp\left(-\frac{\Delta G}{kT}\right),$$

where ε is the specific boundary free energy; γ a coefficient which makes it possible to calculate the area of the nucleus; γl^2 the area of the nucleus; h the height of the nucleus; ΔG_v the free energy of the medium,

$$\Delta G_v = \frac{kT}{\Omega} \ln \frac{p}{p_{equil}},$$

p the partial pressure of the gas; p_{equil} the equilibrium pressure of the gas; Ω the volume of one carbon atom in the crystal; and a a coefficient which depends on the frequency of the molecular collisions and on pressure.

Without knowing the values of a, γ, and ε it is impossible to calculate the specific parameters of the nuclei (for example the number of atomic layers in the epitaxial film). The above expressions have been used successfully[1] to determine the ratio of the rates and work of formation of epitaxial nuclei of diamond and graphite on the {111} face of a diamond support. It was shown that the equilibrium gas pressures for the formation of the diamond nuclei are twice those for the formation of graphite, and that the ratio of the rates of formation of the nuclei has a maximum value at a definite ratio of the partial and equilibrium pressures. Thus the most favourable range for the epitaxial growth of diamond will correspond to p/p_{equil}(graphite) = $2^{2.7}$.

From our viewpoint, however, this calculation, which is based on thermodynamic data, is of no significance for determining the most favourable range for the epitaxial synthesis of diamond, since this is determined entirely by the differences between the kinetic conditions for the synthesis of diamond and graphite.

At the same time it would be useful to know the specific parameters of the diamond critical nuclei obtained as equilibrium epitaxial films on the faces of minerals with the properties required for epitaxy.

It can readily be shown that there is a relationship between the thickness of the epitaxial diamond film, expressed as the number of carbon atomic layers (δ), and its two-dimensional size ($d = 2r$) and the equilibrium degree of transformation (Y) into diamond by reactions (2)–(4) at a definite temperature and pressure. A corresponding relationship should naturally exist for epitaxial films of graphite. The differences between the ratios of these parameters for diamond and graphite should not be of particular interest to us, since the formation of a particular epitaxial film is determined entirely by the kinetic conditions, and we are considering cases with kinetic conditions favourable for the synthesis of diamond.

For a microscopic volume with local equilibrium of the reactions, the quantities indicated are related to one another as follows:

$$\delta = \frac{c_{loc}}{c_1} Y\beta,$$

where c_{loc} is the number of carbon atoms in the volume of the local equilibrium, in a hemisphere with a volume of $(\frac{2}{3})\pi r^3$; c_1 the number of carbon atoms in one monolayer with an area of πr^2; and β the relative volume concentration of the substance A in the volume of the local equilibrium (if the volume is occupied by a gas, $\beta = 1$; if it is occupied by a solution of A in a melt or by a solid, $\beta \neq 1$). A model of the region of local equilibrium on the surface of the support is shown in Fig. 8.

Having determined the values of c_{loc} and c_1 with allowance for the fact that only half of the starting materials A in reactions (2) and (3) corresponds to the number of carbon atoms taken in the calculation,

$$c_{loc} = \frac{1}{3}\pi r^3 \frac{N_A}{V_0},$$

(V_0 is the volume of a mole of gas under normal conditions, and N_A is Avogadro's number) and

$$c_1 = \frac{\pi r^2}{\gamma},$$

(γ is the area occupied by one carbon atom on the {111} face of diamond, equal to 5.5 Å^2), we obtain

$$\delta = \frac{1}{3}\frac{\beta\gamma r Y N_A P_0}{273R}. \quad (16)$$

The results of the calculation of δ for different values of r and different temperatures of the equilibrium of reactions (2) and (3) for $\beta = 1$ and $P_0 = 1$ atm are given in Table 4. The value of δ is

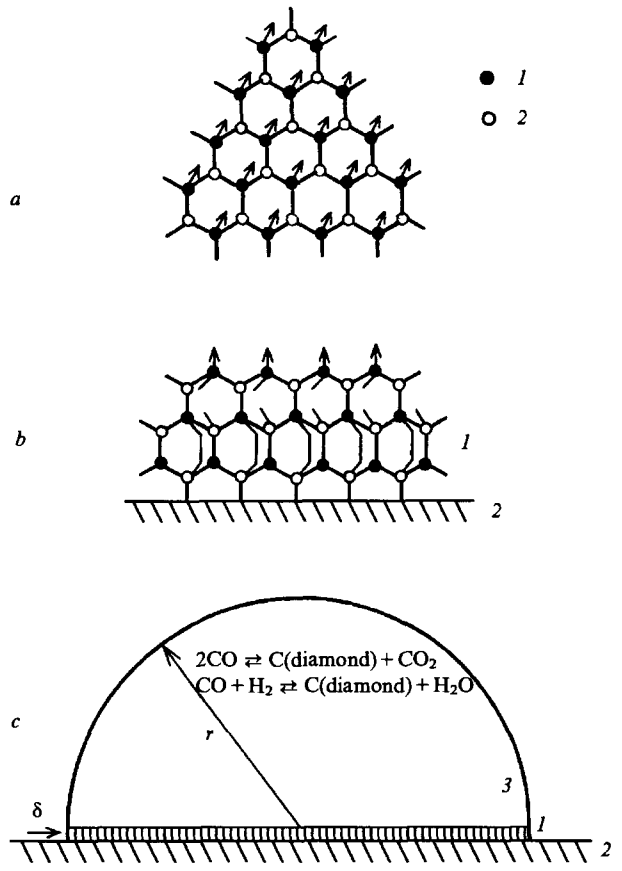


Figure 8. The formation of an equilibrium epitaxial film of diamond on supports showing a crystal-structural correspondence with the arrangement of the carbon atoms on the {111} face of diamond; *a*, view of a critical nucleus from above; the arrows indicate the free valences of carbon, lying at an angle of 90° to the {111} surface and localised by the functional groups; *1*, *2*, carbon atoms of the upper and lower sheets respectively; *b*, view of a critical nucleus from the side; *1*, three-layer epitaxial film of diamond; *2*, face of the mineral support; *c*, model of the region of local equilibrium on the surface of the support, bringing about the epitaxial growth of the diamond film; *1*, epitaxial film (nucleus) with thickness δ and diameter $d = 2r$; *2*, support; *3*, hemisphere bounding the range of local equilibrium of reactions (2) and (3).

proportional to the pressure (P) as it increases from the normal value (P_0) to the critical value (P_{cr}), and is independent of pressure for $P_0 > P_{cr}$.

Table 4 shows that the thickness of the epitaxial film in the critical nuclei of diamond may be greater, the greater the size of the nucleus and the volume of the local equilibrium in which the film is formed, and the lower the temperature of the synthesis. The increase in δ and δ/d with decrease in temperature reaches a limiting value at 400–600 K. The ratio of the thickness of the film to the diameter δ/d in the limit is independent of the diameter of the nucleus and is equal to 3300.

Thus the formation and preservation of the equilibrium epitaxial diamond films which are the critical nuclei for the crystallisation of diamond do not require exotic conditions, and can take place in a static closed system. The only factors making possible the formation of these films are the presence of the starting materials A for the diamond polycondensation in the local volume and the establishment of favourable kinetic conditions, including the presence of suitable matrix–minerals for the epitaxial growth of the diamond material.

In some cases the factor of epitaxial growth of critical diamond nuclei may be particularly favourable. This is indicated by the accelerating action of fullerenes on the synthesis of

Table 4. Number of atomic layers of carbon (δ) in the equilibrium epitaxial film of diamond for different nucleus diameters and reaction temperatures, calculated with the use of Eqn. (16).

diamond films on a silicon support.[47] The deposition of C_{60} on silicon increases the rate of growth of the film by a factor of 10^4, and the deposition of C_{70} increases it by a factor of 10^{10}. Thus the presence on silicon of spherical fullerene molecules, whose surface consists of a 'parquet' of six-membered and five-membered carbon rings, increases the rate of diamond formation by a factor of at least 10^4, and the presence of the pyrene structural elements in the C_{70} molecule leads to a further increase in the rate of growth of the diamond film by a factor of 10^6. This case evidently shows not only the more favourable crystal-structural correspondence between the structural elements of the fullerenes and diamond, compared with the silicon lattice, but also the accelerating action of the spherical deformations of the pyrene and triphenylene structural elements of the fullerenes.

Pressure is not a decisive factor, since epitaxial films may be formed at low, high, and super-high pressures. Thus since minerals capable of bringing about the epitaxial growth of diamond are widely distributed, it may be concluded that the appearance of nuclei for the crystallisation of diamond has never been the limiting stage of the formation of diamond deposits in nature. In nature, an excess of diamond nuclei should evidently exist. At the same time, when all other favourable conditions for diamond polycondensation are established, the formation of natural deposits containing diamond macro-crystals might have been limited by a range of additional macroscopic conditions required to bring about the growth of crystals under the non-equilibrium conditions of an open catalytic system functioning for a prolonged period.

The macrokinetic conditions for the formation of diamond nuclei and for their growth to give macro-crystals differ considerably, despite the same optimum conditions of competition between the processes of formation and conversion of diamond and graphite materials (13). It is possible to have combinations of conditions leading to competition between the processes of the formation of nuclei (n) and the growth of crystals (c), between the processes of the formation and the oxidative solution of the diamond material of nuclei and crystals (o), and also between the processes of the formation of small and large crystals. The ratio of the degrees of transformation (Y_n, Y_c, Y_o) of the substance in these processes with the formation and oxidation of the diamond material, and the conditions for movement into

the recrystallisation zone shown in Fig. 5, are given by the diagram in Fig. 9. The vertices of the diagram correspond to 100% transformation in the formation of the diamond material as nuclei, the growth of crystals, and the oxidation of diamond material. The diagram contains zones corresponding to the complete oxidation of the diamond material (Y_oAOC), the preferential formation of the diamond material as nuclei (Y_nAOB), and the growth of diamond crystals (Y_cBOC).

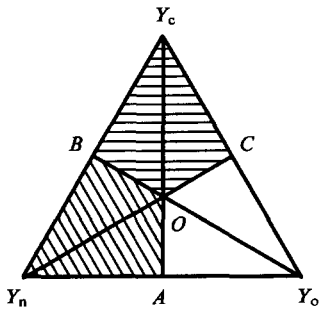

Figure 9. Diagram showing the degrees of transformation of the material in the competing processes of diamond formation and the oxidation of the diamond material (the vertices correspond to 100% degrees of transformation); Y_nAOB is the zone of nucleus formation; Y_cBOC the zone of crystal growth; Y_oAOC the zone of complete oxidative solution of the diamond material; the AOC the recrystallisation line.

Under the conditions of diamond polycondensation corresponding to the vertex Y_n, only the formation of nuclei takes place, and under the conditions corresponding to the apex Y_c, all the diamond material formed grows into crystals; on going from Y_n to Y_c, the number of nuclei (crystals) formed decreases sharply from infinitely large to 1. Under growth conditions without competition between the processes of nucleus formation and crystal growth and the processes of oxidation of the diamond material, however, the quality of the diamond crystals will be poor, because of various inclusions, dislocations, and polycrystalline aggregates.

Under conditions bringing about the dynamic process of growth and oxidation of diamond in the recrystallisation zone, corresponding to the line AOC in Fig. 9,

$$Y_{di} = Y_l = Y_o = 50\%;\ V_c = V_o;\ Y_{di} = Y_n + Y_c;\ Y_n \to 0,$$

the formation of large defect-free crystals of the highest quality is possible. The formation of new nuclei is almost completely suppressed

$$V_c \geqslant V_o;\quad V_n = 0.$$

These conditions were created in an experiment on the further growth of single crystals of diamond from $CH_4 + CO_2$ mixtures in alkaline melts. Fig. 6*a* shows that the recrystallisation zone includes the range of observed increase in the weight of the diamond material, and is appreciably broader than this range, that is recrystallisation changes in the diamond crystal are observed, corresponding both to an increase in its mass as a result of the formation of new diamond material and to a mass loss as a result of oxidation. Other examples of recrystallisation changes in single crystals of diamond and powders are known.[10, 23, 49]

For example, excellent photographs have been obtained[49] of successive recrystallisation changes on the surface of single crystals of diamond under the catalytic action of molten NaOH containing Ni^{2+} ions at 1100 K in a gaseous medium containing air.

Moving from the vertex Y_c to the point C in Fig. 9 corresponds to the change from reducing conditions of diamond polycondensation to oxidising conditions. According to the results of studies[10, 23] of the change in the habit of diamond crystals during partial oxidative solution and data[36, 50] on the relationship between the habit of diamond crystals and the oxidation potential of the growth medium, this is reflected in a change in the morphology of the diamond crystals formed. Thus under reducing conditions a $CO + H_2$ mixture gives cubic crystals; when traces of O_2 are added to the mixture, cubo-octahedral crystals are formed; and at an O_2 concentration of 2.2%, only octahedral diamond crystals are formed.[36] Increase in the oxidation potential of a kimberlite deposit, characterised by the change in the ratio Fe^{III}/Fe^{II}, leads to a change from octahedral diamond crystals with smooth faces to rhombododecahedral and rounded forms as a result of oxidative solution.[50] With further increase in the oxidation potential, however, when $v_o > v_c$, combustion of the finer diamond crystals with preservation of the large crystals will take place, and the size of distribution of the diamond crystals will change, as confirmed by the displacement of the maximum of this distribution towards large diamonds and the absence of fine diamonds in a number of kimberlite pipes of Yakutia.[51]

VI. A model of the non-equilibrium growth of diamond crystals in a macroscopic open catalytic system

When the polycondensation process (1) takes place in a macroscopic open catalytic system (a flow reactor) with the constant supply of the original light carbon-containing molecules A or their mixtures with the product A + L at a rate w_f and the removal of the light reaction products L, non-stationary conditions may be established

$$A \to \left\{ \frac{nA_n \to \{A - mL\} + mL}{\sum\{A_n - mL\}_i K} \right\} \to L, \qquad (17)$$

when the condensation product $\{A_n - mL\}$ formed by the reactions (2)–(4), (2′)–(4′), etc. remains in the constitution sphere of the system on the catalyst K and gradually accumulates as the diamond or graphite material $\sum\{A_n - mL\}_i$. The removal of the products L = CO_2, H_2O, etc. capable of oxidising the condensation product, and the displacement of the equilibrium in the system, lead to the establishment of a stationary (stable) non-equilibrium, and continuous growth of the diamond or graphite material takes place. When the products of reactions (2)–(4) and (2′)–(4′) enter the system (17) together with the starting materials, however, the rate of exchange of the materials and the effect of non-equilibrium growth of the condensation products decrease. We have used this model to describe the growth of diamond crystals in kimberlite deposits[19] and the abiogenic synthesis of hydrocarbons,[24] and also to describe non-stationary polymolecular processes involving the condensation products.[17]

As noted above, the direction of process (1) towards the formation of diamond material requires favourable kinetic conditions. If these conditions are observed, then a definite decrease in the intensity of material exchange and in the non-equilibrium character of the system (17) as a result of the retarding action of the products is favourable for the formation of large diamond crystals of good quality, since it moves the process into the dynamic conditions of growth and oxidation characteristic of the recrystallisation zone. This corresponds to the zone situated between the lower boundary of Bachmann's diamond range and the line $H_2O - CO_2$ in Fig. 5 or the lines AO and OC in Fig. 9.

At the same time, the continuous growth of diamond crystals on top of the initially formed equilibrium epitaxial films is possible only under non-equilibrium conditions. The apparent contradiction arises because the growth of the crystals, as well as the formation of epitaxial films, can take place at different degrees of non-equilibrium, but when equilibrium is reached, only the epitaxial film can be formed and exist.

The macroscopic open catalytic system (17), in which favourable kinetic conditions are created for diamond polycondensation by reactions (2)–(4), can exist for wide variations in the specific kinetic and macrokinetic conditions: from limiting non-equilibrium to close to equilibrium; from reactions taking place in the kinetic range to reactions taking place in the diffusion range; from conditions leading to the formation of only epitaxial films (nuclei) to conditions leading to the growth of single crystals; and from conditions leading to an increase in the number of nuclei to conditions preventing the formation of new nuclei and bringing about the growth of large crystals. A diagram of such a macroscopic open catalytic system with allowance for varied local conditions of diamond synthesis is given in Fig. 10. These conditions are characterised by different combinations of the rate of flow of the materials

$$w_f = w_{lf} + w_{diff},$$

(where w_{lf} is the rate of linear flow along the gas-transport channels, pores, and cracks, and w_{diff} the rate of diffusion through the pores) and the rate of formation and accumulation of the diamond material in the crystallisation centres

$$v_c = \frac{d[\{A_n - mL\}]}{dt},$$

which is a function of temperature, the rate of flow of the materials, and the composition of the mixture A + L, that is

$$v_c = \varphi[T, w_f, (A + L)].$$

In Fig. 10, *A* is the gas-transport channel through which the reacting mixture A + L moves under the influence of a pressure gradient at a rate w_{lf}; *B* the porous environment of the gas-transport channel, in which the reacting mixture diffuses under the influence of a pressure gradient at a rate w_{diff}; the total rate of flow through the non-equilibrium zone is $w_f = w_{ef} + w_{diff}$; *C* is the boundary of the non-equilibrium zone, at which $v_c = 0$ at $(A + L)_{equil}$; within the zone $v_c > 0$; $v_c < w_f$; *I* is the kinetic range in which diamond polycondensation takes place, including the extrakinetic range (*I'*) on the walls of the gas-transport channel ($v_c > v_{diff}$; $v_c < w_{lf}$; $w_{diff} < w_{lf}$) and the intrakinetic range (*I''*) in the porous wall ($v_c < w_{diff}$); and *II* the diffusion range in which diamond polycondensation takes place ($v_c > w_{diff}$).

With allowance for possible gradients in the pressure and in the concentrations of the starting materials A at the inlet and outlet of the system (Fig. 10), the model can be used to describe diamond polycondensation in the preparation of polycrystalline diamond films on supports by the reaction of the latter with a gas–plasma flux of original carbon-containing substances, for processes in ordinary catalytic flow reactors, and in the natural open catalytic systems produced in the fractures, cracks, and other gas-transport channels in the degassing paths in the earth's minerals.

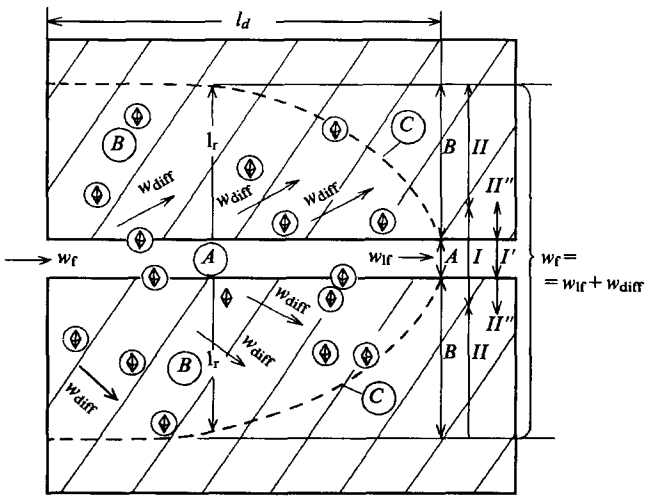

Figure 10. Model of the non-equilibrium zone in the macroscopic open system (17), bounded by the longitudinal and transverse ranges corresponding to the conditions for the growth of diamond crystals.

In the last cases the model makes it possible to describe not only the processes of diamond synthesis taking place at

$$v_c < w_f,$$

in the kinetic range but also syntheses in the diffusion paths, when

$$v_c > w_{diff}.$$

These conditions are ensured by the porosity of the catalysts in experimental flow reactors or by the porosity and diffusion gas-permeability of the rocks surrounding the fluid-transport channels in natural diamond deposits.

For constant values of *T*, w_f, and w_{diff}, the rate of growth of the diamond crystal will depend only on the composition of the mixture of carbon-containing starting materials and products passing into the system and into each local zone in which individual crystals grow

$$v_c = \varphi(A + L),$$

and for the equilibrium composition of the mixture, $v_c = 0$ ($v_c > 0$ only for a non-equilibrium composition).

Thus the growth of diamond crystals in the polycondensation reactions (2)–(4) etc. will be determined entirely by the macroscopic conditions maintaining non-equilibrium in the system (17).

According to the theory of open catalytic systems,[25,26] the extent to which a macroscopic open system deviates from equilibrium (ρ) is directly related to the potential degree of transformation $\tilde{Y}$ of the original mixture A + L in the system. The relationship between these parameters and the composition of the gas mixture entering the system (17) is shown in Fig. 11*a*. The figure shows that the maximum degree of non-equilibrium character $\rho = 1$ and the maximum value of the potential degree of transformation for the forward reactions (2)–(4), determined from the equation

$$\tilde{Y} = \frac{M_A(c) - M_A(equil.)}{M_A(c)}.$$

[$M_A(c)$ and $M_A(equil.)$ are the mole fractions of the substance A in mixtures with the current and equilibrium compositions respectively], are reached when the pure starting material A is supplied, and that these quantities are equal to zero when the equilibrium mixture is supplied. The same applies to the back reactions (2)–(4) when super-equilibrium quantities of oxidising products (CO_2, H_2O) are supplied to the system (17), if $\tilde{Y}$ is determined in terms of the mole fractions of L in the mixtures A + L.

By taking account of the fact that the composition A + L will change, approaching the equilibrium composition $(A + L)_{equil}$, along the direction of flow of the reaction mixture in the system as a result of reaction (1), it is possible to determine the longitudinal distance to which the polycondensation process will extend, l_d. This distance will be greater, the greater the difference between the composition of the entering mixture $(A + L)_{current}$ and the equilibrium composition (Fig. 11*b*). In the same way it is possible to estimate the transverse distance l_r to which non-equilibrium conditions of diamond polycondensation will extend in a macroscopic reactor (Fig. 10). In both cases the boundary of the non-equilibrium range in which the growth of diamond crystals is possible is determined by the approach of the composition of the mixture to the equilibrium composition, that is the actual range is finite.

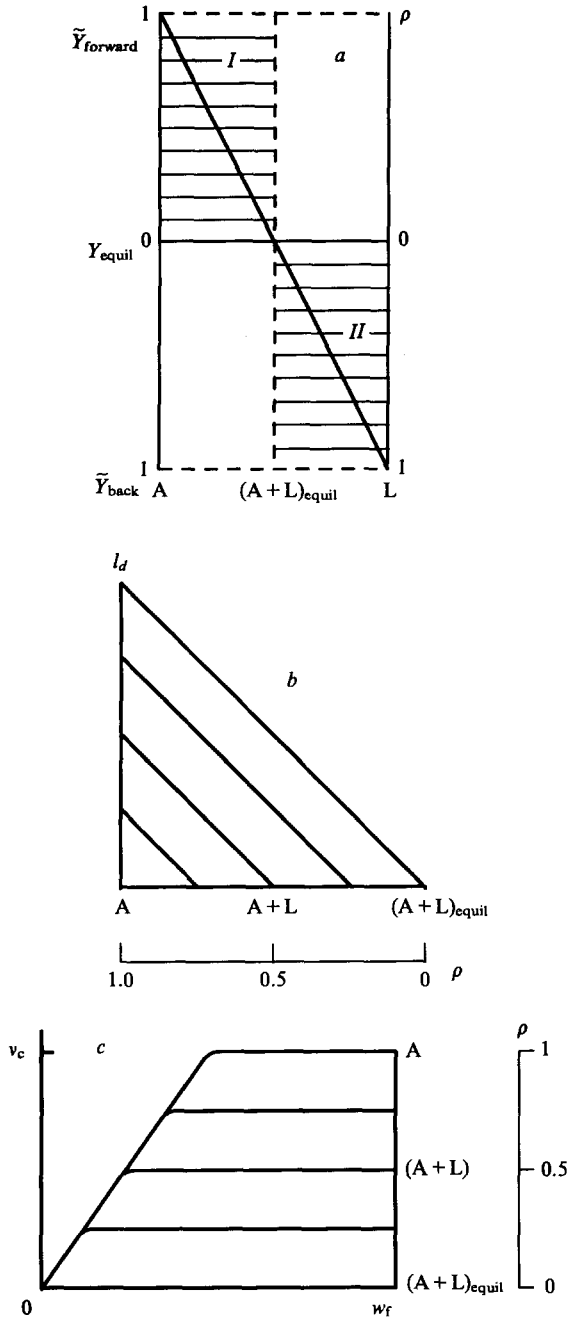

Figure 11. Relationship between the potential degree of transformation (*a*), the longitudinal distance to which the non-equilibrium conditions extend (*b*), and the rate of growth of diamond crystals (*c*) on the one hand and the rate of flow and the extent to which the composition of the reaction mixture entering the open catalytic system deviates from the equilibrium composition on the other; *a*: *I*, diamond polycondensation by reaction (1); *II*, conversion by reaction (12).

The non-equilibrium of system (17) as a whole and in each local zone in it, however, will be determined not only by the composition of the reaction mixture entering the system and the changes which it undergoes in reaction (1) but also by the ratio of the rate of polycondensation v_c and the rate of flow w_f and by the actual value of w_f (Fig. 11*c*). Non-equilibrium conditions in the open system are established with the condition that, essentially, reaction (1) is of zeroth order with respect to A, and there is a decrease in the value of v_c as the composition of the entering mixture approaches the equilibrium composition $(A+L)_{equil}$ and in the value of w_f at which the change to the non-equilibrium range takes place.

The last feature acquires great importance in the establishment of recrystallisation conditions (Fig. 9) at the boundary between the growth and the oxidative solution of diamond. These conditions are favourable for the prevention of the formation of new nuclei, for the oxidative solution of excess nuclei and fine crystals, and for the growth of the largest crystals of highest quality.

VII. An analysis of the conditions of formation of diamond in experiments and in various natural deposits

1 Experiments on the growth of polycrystalline diamond films from plasma on different supports and the epitaxial growth of single crystals

All known facts in the chemical synthesis of diamond at low pressures, both as polycrystalline films on different supports and in the growth of the diamond lattice in epitaxial films and single crystals, are consistent with the proposed model of the polycondensation growth of diamond material under the non-equilibrium conditions of open catalytic systems. In all observed cases of the formation and accumulation of diamond material in macroquantities, kinetic conditions have always been observed for the diamond condensation of the original light molecules [by reactions (2)–(4) etc.] in the non-equilibrium zones of the open catalytic systems, including primarily the macrokinetic conditions ensuring stationary non-equilibrium in the diamond crystal growth zones.

The slight differences between the kinetic and macrokinetic parameters in observed cases of diamond synthesis at low pressures do not go beyond the range of optimum conditions. Thus in the growth of polycrystalline diamond films on supports in a gas–plasma stream, the observed ratio of the rate of formation of the diamond material to the rate of flow is

$$v_c \ll w_f,$$

ensuring stable zeroth order of reaction (1) with respect to the original carbon-forming material and the maximum degree of non-equilibrium character. The process of diamond material formation takes place in the kinetic range (range *I* in Fig. 10), or more precisely in the extra-kinetic range (*I'*) on the wall of the gas-transport channel A.

In the case of the growth of a single-crystal lattice on a diamond seed crystal (in a solution of metal oxides in a molten alkali metal hydroxide), studied by us (Fig. 6), however, reaction (1) took place in the diffusion zone (zone *B* in Fig. 10), in which the transport of the reacting material to the growing diamond crystal took place from the gas-transport range A by diffusion through the melt, and

$$w_{diff} \ll w_f.$$

Reaction (1) in the diffusion zone was dependent on the thickness of the catalyst layer and took place either in the intra-kinetic range (range *II'* in Fig. 10), when

$$v_c < w_{diff},$$

or in the intra-diffusion range (range *II* in Fig. 10), when

$$v_c > w_{diff}.$$

The two sets of conditions are equally favourable for the growth of the diamond crystal, since they lie within the range of non-equilibrium of the open catalytic system. The boundaries of the non-equilibrium zone for constant values of w_f and w_{diff}, however, are determined only by the depletion of the reaction mixture in the direction of the fluxes of w_f and w_{diff} and by the approach of its composition to the equilibrium composition (range *C* in Fig. 10).

2. Facts indicating the growth of diamond metacrystals in the solid phase of kimberlite deposits

The optimum conditions for the growth of diamond crystals according to the model(17) can readily be established in kimberlite pipes, which are the funnels of characteristic volcanoes with an explosive action, filled with breccia, that is a porous rock with a large number of gas-transport channels, through which the degassing of the minerals of the earth took place (and in some cases is still taking place) from deep fractures, to which the pipes are confined. The gases liberated contain all the starting materials and products of reactions (2)–(4), and the kimberlites contain all known active catalysts of the formation of epitaxial nuclei and the synthesis of diamonds, from heavy metal ions to alkali metal ions.

In different parts of the pipe there may arise local regions with the properties of the non-equilibrium open catalytic system (17), having favourable micro- and macro-kinetic conditions for diamond polycondensation (1), corresponding to the model given in Fig. 10. The growth of diamond crystals will take place with ideal exchange of the materials in the system (17), when $v_c \ll w_f$ and the gas mixture A + L has a non-equilibrium composition. These conditions are established in the gas-transport channels.

The growth of diamond crystals will also take place in the diffusion zones (range *B* in Fig. 10), where $w_{diff} \ll w_f$: in the intra-kinetic range for $v_c < w_{diff}$ or in the intra-diffusion range for $v_c > w_{diff}$. In the diffusion zones of the porous solid filling the pipe, the rate of growth v_c will decrease in the radial direction relative to the transport channel as the composition of the mixture approaches the equilibrium composition $(A + L)_{equil}$; at the boundary of the non-equilibrium zone (range *C* in Fig. 10), reaction (1) necessarily moves into the intra-kinetic range as a result of the decrease in v_c to $v_c < w_{diff}$, and at the boundary of the non-equilibrium zone the reaction stops ($v_c = 0$). The growth of the diamond crystals also stops with decrease in the flow rate ($w_{diff} \to 0$).

In any case—when the composition A + L approaches the equilibrium composition or when the open system becomes static—the growth of the diamond crystals stops. The absence of direct removal of CO_2 and H_2O from the growing crystal under the specific conditions of a kimberlite deposit may be replaced by another mechanism of displacement of the equilibrium in reactions (2)–(4), leading to further growth.

This mechanism may be the accumulation of CO_2 and H_2O by the surrounding solid material, accompanied by allochemical changes in it

$$2CO \rightleftarrows C(\text{diamond}) + CO_2;\ CO_2 + M = MCO_3\ , \qquad (18)$$

$$CO + H_2 \rightleftarrows C(\text{diamond}) + H_2O\ ;$$

$$4H_2O + 3Mg_2SiO_4 = Mg_6[Si_4O_{10}](OH)_8\ . \qquad (19)$$

Carbonate and serpentine coatings, which do not oxidise diamond, should be formed round the diamond crystals. Special experiments have shown that at 1073–1273 K an oxidising action is shown only by free CO_2, and not by molten carbonates,[8,9] and that diamond does not dissolve in silicate melts.[9]

The carbonate and serpentine coatings detected round kimberlite diamonds and various characteristics of their composition and structure confirm that reactions (18) and (19) take place.[19,22,53] In kimberlite pipes of Yakutia, the primary contacts of diamonds with kimberlites and eclogites in fact indicate allochemical changes in the surrounding rock, revealed not only by the formation of layer mineral coatings but also by aureoles of chemical changes in the surrounding rock.[19,22] Cataclastic changes in the surrounding rock have also been revealed[19] by the formation of oriented micro-cracks and micro-displacements as a result of the increase in the volume of the diamond meta-crystal growing in the solid medium; this should be observed if reactions (18) and (19) take place with a constant supply of the starting materials of reactions (2) and (3) to the growing crystal.

The secondary contacts of diamond crystals with kimberlite breccia, taken by Rudenko and coworkers[53] as a typical case, are not accompanied by allochemical or cataclastic changes in the surrounding rock, and in this case the diamonds are xenocrysts. In the primary contacts, the growth of diamond as a meta-crystal in the solid medium is confirmed by the observed fractionation of carbon isotopes in reaction (18). For example, according to published data,[54] the carbonate carbon of the coating is lighter ($\delta^{13}C$ from −6.7‰ to −7.6‰) than the carbon of the carbonates in the surrounding kimberlite ($\delta^{13}C$ from −6.9‰ to −8.2‰) situated outside the zone of chemical changes.

These facts not only confirm the model of the growth of diamond crystals in the catalytic system (17) as a whole but also make it possible to deduce its details with allowance for the chemical and metasomatic processes (18) and (19), which maintain the disequilibrium in the system and ensure favourable conditions for diamond polycondensation.

The favourable kinetic conditions for diamond polycondensation, created in the formation of kimberlite deposits, are extended by the possible inclusion in the synthesis of reactions (6) and (7), which also take place under conditions corresponding to the constant displacement of the equilibrium as a result of the binding of the products with oxidising properties by surrounding solid minerals. Minerals containing divalent iron are converted into minerals containing trivalent iron, and the thermodynamic equilibrium of reactions (6) and (7) is displaced completely to the right ($\lg K_p$ at 1000 K has the values 35.6 and 71.1 respectively).

The duration of the preservation of the stationary non-equilibrium in reactions (6), (7), (18), and (19) ensuring the growth of the diamond crystal in the solid phase will naturally be determined by the concentration of the appropriate minerals in the local volume accessible for allochemical changes. For reactions (6) and (7) these are minerals containing Fe^{II}, for reaction (18) they are alkaline earth metal oxides and silicates, and for reaction (19) they are olivine and other silicates. Reactions (6), (7), (18), and (19), which extend the favourable conditions for diamond polycondensation, have undoubtedly been of considerable importance in the formation of kimberlite deposits.

The model of the growth of diamond crystals in non-equilibrium open catalytic systems is consistent with many other facts established during the exploration and exploitation of kimberlite deposits:[55,56] the existence of diamond-bearing and non-diamond-bearing kimberlite pipes with similar chemical compositions and locations,and a decrease in diamond-bearing character with depth;[55,57,61] the non-equilibrium nature of the distribution of diamonds along horizons and the correlation of the distribution with the characteristics of the morphology of the crystals;[54,56,57,60,62] and the correlation of the diamond-bearing character of individual sections of the pipes with the catalytic activity of the kimberlites in the reactions which are the reverse of reactions (2) and (3), and with the concentration of juvenile bitumens and the oxidation potential. This is also confirmed by the presence in the pipes of xenoliths of diamond-bearing and non-diamond-bearing eclogites with identical compositions,[63,64] the rare occurrence of diamond-bearing eclogites and the very high concentration of diamonds in them, the uniformity of the morphological characteristics and dimensions of eclogite diamonds, and the non-uniformity of the distribution of diamond crystals in the xenolith of eclogite, which are confined to the surface of the xenolith or to cracks intersecting the xenolith.[64–66] For example, in a xenolith of a diamond-bearing eclogite intersected by a serpentine vein, found in the Mir pipe in Yakutia, all the diamonds were confined to this vein.[66]

All these facts can be explained using the model of the chemical synthesis and growth of diamond crystals in open catalytic systems under non-equilibrium conditions. This model may be established under crustal conditions in the formation of kimberlite pipes or veins in degassing paths in the interior of the earth, and are not associated with super-high pressures.

The same facts cannot be explained, however, by assuming that diamonds are formed in the mantle at super-high pressures and removed from it.

The pallial (mantle) hypothesis is not consistent with the kinetic conditions of the formation and preservation of diamonds examined above. In the equilibrium magma of the mantle, only equilibrium epitaxial films of diamond on the faces of various minerals can be formed independently of the pressure by reactions (2)–(4) and exist for an unlimited time. Diamond crystals formed in the mantle at super-high pressure as a result of the polymorphic transformation of graphite under reducing conditions can exist for a long time only in the absence of CO_2 and H_2O, which is unlikely. Under non-equilibrium conditions in the mantle when open catalytic systems are produced, diamond crystals can be formed by reactions (2)–(4), etc., as in the crust, without super-high pressures. They will exist, however, so long as the non-equilibrium of system (17) is preserved and the exchange of materials continues, but will undergo combustion by the reverse reactions (2) and (3), or graphitisation, when these conditions break down {for example if there is a change in the composition of the mixture of light molecules A + L passing through the system (17) and super-equilibrium concentrations $[CO_2]$ and $[H_2O]$ appear in it as a result of the removal of the magma into the crust or on to the surface and as a result of a decrease in pressure}.

3. Facts relating to the growth of diamond crystals under the metasomatic conditions of the earth's crust without super-high pressure

Certain specific conditions of the formation of kimberlite pipes and paragenetic associations of diamond with high-pressure minerals have led a number of workers to assume that a leading role is played by the mantle production of kimberlite diamonds, that is by high pressures and temperatures. The recently established existence of non-kimberlite diamonds,[67–71] which eliminates completely high-pressure conditions for their formation, however, not only makes it necessary to doubt again the universal mantle hypothesis but also provides convincing confirmation of the model of the growth of diamond crystals in non-equilibrium open systems.

Metasomatic diamonds of the Kokchetav deposit. In the eighties, the Kokchetav (Kumdykul'skoe) deposit of fine diamonds with a cubic habit was discovered in Kazakhstan, occurring together with flaky graphite formations as a vein, localised in an old fracture, and formed as a result of metasomatic changes in the surrounding rocks by the reaction of the latter with products of the earth's degassing, passing along the fracture.[67–69] Diamonds with dimensions of 0.02–0.07 mm are present in very high concentrations in garnet–mica gneiss, garnet pyroxenites, marbles, and skarns. These minerals were formed as a result of metasomatic changes by the reaction of all types of rock intersected by the diamond-containing vein with gaseous fluids at 1000–1300 K and pressures not exceeding 6–9 kbar. At the same time, diamonds have not been found at a distance from the vein in corresponding surrounding rocks which have not undergone metasomatic changes. In the diamond-containing rocks the diamonds are found as inclusions in crystals of practically all the minerals (almandite, pyroxene, mica, quartz, etc.), and are often localised in micro-cracks and in the contacts between granules of other minerals.† In the axial zone of the deposit, richest in diamonds, there are very fine crystals (0.02–0.07 mm), and the less rich peripheral zones contain the largest crystals (up to 0.1–0.5 mm), and also contain pseudomorphs of graphite after diamond, not found in the other zones. In addition to diamonds, the diamond-containing rocks contain flaky graphite, formed at the same time as the diamond. The concentration of this graphite is 10^2 times the diamond concentration.

All this indicates the polycondensation of juvenile carbon-containing gases in the non-equilibrium open catalytic system (17), taking place in the diamond and graphite directions simultaneously and accompanied by the metasomatic transformation of the rocks surrounding the fluid-transport channels. The polycondensation has taken place under strongly reducing conditions with the predominant formation of graphite material, as shown not only by the higher yields of graphite material compared with diamond but also by the predominance of the cubic habit of the diamond crystals.[67] In this case the diamond material has been obtained under conditions leading to the preferential growth of nuclei (zone Y_nAOB in Fig. 9), as confirmed by the very high concentration of fine crystals in the rock and by the abundance of negative skeletal forms.

The model (17) is also consistent with the observed[69] distribution of diamonds relative to the axis of the diamond-containing ore vein. In the peripheral regions of the vein with a high oxidation potential and diffusion flow conditions, situated at the boundary of the non-equilibrium zone under conditions with $v_c < w_{diff}$, close to the conditions of the recrystallisation zone (COA in Fig. 9), the formation of nuclei has been retarded, and the diamond material has been deposited as larger crystals. This model is also consistent with the formation of paramorphs of graphite after diamond in the peripheral regions of the vein at the boundary of the non-equilibrium zone (range C in Fig. 10). The graphitisation of diamond

$$C(\text{diamond}) \rightarrow C(\text{graphite}),$$

accelerated by CO_2, will have favourable conditions as the composition of the diffusing gases (CO, H_2, CO_2) approaches the equilibrium composition and with the corresponding increase in the CO_2 concentration after the completion of the metasomatic changes, and also after the weakening or complete cessation of degassing, which gives non-equilibrium concentrations of the starting materials of reactions (2), (3), etc. The non-equilibrium character of the open catalytic system (17), which ensures favourable conditions for the synthesis of diamond and prevents graphitisation, disappears.

Pseudomorphs of graphite after diamond in the Beni Bouchera deposit (Morocco). Equally convincing confirmation of the model being considered is provided by the discovery of pseudomorphs of graphite after octahedral crystals of diamond[70, 71] in the laminated pluton of the ultrabasic rocks of the Beni Bouchera deposit, formed at temperatures of 770–1070 K and pressures not exceeding 5 kbar. In this deposit, between layers of flaky graphite, there is a lens of clinopyroxenites, in which all the graphite is present as pseudomorphs after graphite crystals with dimensions of 0.2–8 mm. The paramorphs constitute up to 15% of the volume of the rock. The concentration and size of the pseudomorphs are greatest at the centre of the lens.

In contrast to the metasomatic diamonds of the Kokchetav deposit, all the primary diamonds of the diamond-containing layer of the Beni Bouchera deposit have been completely converted into graphite pseudomorphs. The formation of the primary diamonds in this case has been associated with metamorphic changes in the cupola section of the pluton during its degassing and the movement of the carbon-containing fluids, and diffusion processes have predominated in the flux of fluids directed along the pressure gradient, that is

$$w_{diff} > w_f.$$

As a result of this last feature, the metamorphised part of the pluton has been formed as rhythmic layers. The production of this rhythmic diffusion stratification of the pluton indicates the prolonged action of the fluxes of the directed exchange of materials in this macroscopic open system and the development of self-organisation processes characteristic of these non-equilibrium systems.[72]

† The concentration of diamond granules is so high that it has been possible to study the distribution of their inclusions in the crystals of other minerals, in microcracks, and in the space between the granules from micrographs.[67–69]

The existence of the macroscopic open system (17) in the pluton degassing flux, which has given a mixture

$$\text{C(diamond)} + \overset{\downarrow}{\overline{\text{CO}_2 \rightarrow [2\text{CO}] \rightarrow \text{C(graphite)} + \text{CO}_2}} ,$$

of carbon-containing light molecules and other substances which bring about metasomatic changes in part of the pluton and the enclosing sedimentary rocks, has led to the development of all forms of the polycondensation process (1) and to the appearance of a zone most favourable for diamond polycondensation, together with zones in which ordinary flaky graphite has been formed. The conversion of diamond into graphite, irreversible at low pressures, has taken place, however, after the completion of the production of the pluton and the formation of the diamond and graphite deposits.

As in the case of the Kokchetav deposits, the start of graphitisation has been due mainly to a decrease in the non-equilibrium character of system (17) of diamond polycondensation as a result of a change in the composition of the entering gases, since only diamond polycondensation can oppose graphitisation under the same temperature conditions. The more favourable nature of the kinetic conditions for diamond polycondensation compared with graphite polycondensation reduces to the appropriate ratio of the rates (13). The graphitisation of diamond will become possible if a change in the composition of the gas-forming components or the cessation of the material exchange flux through the system (17) bring the conditions for reactions (2) and (2′) close to the equilibrium conditions and the reverse reactions (2) and (2′) take place to an insignificant extent in the presence of prepared crystals of diamond and graphite at a CO_2 concentration slightly greater than its equilibrium value.

The mechanism of this topochemical process may be the intermediate local conversion of diamond with the participation of CO_2 as catalyst, and the driving force may be the decrease in the thermodynamic potential in the polymorphic transformation of the diamond lattice into the graphite lattice. At super-high pressures, the reverse reaction (15) may take place with the same catalyst.

VIII. Summary

A large number of experimental facts and observations of natural phenomena confirm the model of the polycondensation synthesis of diamond from light-carbon-containing molecules by reactions of the type

$$2\text{CO} \rightleftarrows \text{C(diamond)} + \text{CO}_2 ,$$

$$\text{CO} + \text{H}_2 \rightleftarrows \text{C(diamond)} + \text{H}_2\text{O} ,$$

$$\text{CH}_4 + \text{CO}_2 \rightleftarrows 2\text{C(diamond)} + 2\text{H}_2\text{O} ,$$

at low pressures (not corresponding to the super-high pressures of the graphite $\rightleftharpoons$ diamond phase transformation). The chemical synthesis of diamond crystals has been observed in various open non-equilibrium catalytic systems differing in the scale of the observations.

The theory of this synthesis takes account of the stoichiometric, thermodynamic, and kinetic conditions of diamond polycondensation and the growth of diamond films and crystals. It defines the boundary and optimum conditions for the establishment of this complex process against a background of the aromatic polycondensation of the same original carbon-containing molecules leading to the production of graphite and other forms of non-diamond carbon. The general level of the oxidation potential and the difference between the kinetic conditions of diamond and graphite polycondensation is of considerable importance for determining the optimum conditions.

In addition to the conditions of the formation of new C–C bonds in the growth of the diamond lattice, the proposed theory examines the kinetic and macrokinetic conditions of formation of equilibrium epitaxial diamond films on crystal faces showing a crystal-structural correspondence with the arrangement of the carbon atoms on the faces of diamond, and also the conditions of the growth of macroscopic diamond crystals. It has been shown that equilibrium epitaxial films on appropriate supports (diamond critical nuclei) should be formed easily under static conditions. Their thickness, expressed as the number of carbon atomic layers, depends on the temperature and the size of the region of local equilibrium containing the original molecules of the polycondensation, but the ratio of the thickness of the film to the diameter is always constant and equal to 3×10^{-4}. At the same time the growth of the critical nuclei to give diamond macro-crystals requires special and rare (compared with those for the formation of the nuclei themselves) macrokinetic conditions. The growth of diamond macro-crystals by successive chemical synthesis is possible only in an open catalytic system operating in stationary fashion and ensuring a constant supply of the original carbon-containing molecules and the removal of product (CO_2 and H_2O) capable of displacing the equilibrium in the reverse direction.

The theory of the chemical synthesis of diamond essentially substantiates the possibility of the so-called metastable crystallisation of diamonds from the fluid or gas phase without super-high pressure, postulated by various authors in the formation of natural[73] and synthetic[2,74] diamonds. From the viewpoint of this theory, however, the actual term "metastable crystallisation of diamond" does not correspond to reality, since in it, metastability is defined with respect to the range of thermodynamic stability of diamond in the graphite $\rightleftharpoons$ diamond process, previously assumed to be the only possible route for the formation of diamond. We are dealing, however, with other processes of diamond synthesis with different thermodynamics, having its own ranges of stability of the diamond material under both equilibrium and non-equilibrium conditions.

Abstract. Experimental data on the use of IR spectra to identify compounds formed on the surface of various supports during the deposition of heteropoly compounds are reviewed. The spectral properties of the heteropoly compounds are analysed according to their type, to the character of the central ion, and to the form of the support. The first attempts to study the acidic properties of systems of this type are reported. The prospects of identifying the compounds formed on the surface of the carriers during the preparation of supported catalysts containing molybdenum or tungsten are examined. The bibliography includes 124 references.

I. Introduction

Heteropoly compounds (HPC) [heteropoly acids (HPA) and their salts] are now widely used in heterogeneous catalysis. They are effective catalysts of important chemical processes,[1–4] and they are also convenient as model catalytic systems, offering a useful combination of acid and oxidation–reduction properties which allows the composition and structure of the catalytically active centre to be strictly determined. Furthermore the HPC allow controlled variations of both the acidic and the oxidation–reduction function of the catalytic system, and in this sense they are superior to the zeolites.

The heteropoly compounds of molybdenum are good starting compounds for the preparation of multicomponent catalysts containing molybdenum, which includes most of the heterogeneous catalysts used in a variety of chemical processes such as partial oxidation.[4,5] Indeed, these compounds make possible the preparation of previously stipulated and exactly defined catalyst compositions with good mixing and complete interaction of the components, which allow the function of each of the components to be clearly displayed.

The role of HPC as precursors of active and selective catalysts has been pointed out more than once[5,6] in published work. the composition of many well known (including industrial) catalysts containing molybdenum probably included compounds of the HPC type. These can be formed in the course of the catalytic reaction (at least, on the surface of the heterogeneous system, where they cannot be observed by traditional methods such as X-ray diffraction analysis).

Supported catalysts offer several advantages,[7] of which the most important for HPC are probably a high mechanical strength and a developed specific surface. Furthermore a great saving in the expensive molybdenum compounds can be achieved by using supported catalysts. It has been shown[8] that in oxide catalysts the carrier can experience strong chemical interactions with the supported compound.

Published data on the character of the interaction of supported heteropoly compounds with the surface of the carrier are few.[8] It has been shown that when ammonium paramolybdate (APM) $(NH_4)_6Mo_7O_{24}$ is supported on carriers such as SiO_2, TiO_2, and Al_2O_3 the Si–Mo,[9] Ti–Mo,[10] and Al–Mo heteropoly compounds[11,12] can be synthesised on the surface of the catalysts under the influence of the cations of the support. These compounds are stable up to high temperatures. We may therefore assume that compounds of this type containing molybdenum as the active component will find extensive application as catalysts for the partial oxidation of hydrocarbons.[7] Therefore a more general formulation of the published information, a critical assessment of the reliability with which these compounds have been identified, and a determination of their properties are currently important problems.

II. Molybdenum heteropoly compounds

Traditional phase analysis methods, including X-ray phase analysis (XPA), have not been applied to HPC because of the dehydration of these materials and of the small content of the active component in supported catalysts. Vibrational spectroscopy offers some important advantages in these systems.[8–11,13] However, one of the difficulties in the study of supported systems is that the spectrum of the support usually overlaps the spectral region of the active component, making the latter difficult to resolve. Therefore the spectrum of the active component is often revealed by a procedure based on compensation for the spectrum of the support.[8–11,14]

1. IR spectra of massive heteropoly compounds

The IR spectra of HPC have been studied in detail. They adequately characterise HPC belonging to different structure types. In Fig. 1 we show the IR spectra of massive HPC containing 6 and 12 Mo atoms (Mo_6-HPC and Mo_{12}-HPC). In the spectra of Mo_6-HPC (spectra *4–6*) at 400–700 cm^{-1} we find strong absorption bands near 650 (ν_{as}) and 450 cm^{-1} (ν_s), assigned to the vibrations of the Mo–O–Mo bridging bonds.[15–17]

A A Davydov, O I Goncharova Institute of Catalysis, Siberian Division of the Russian Academy of Sciences, 5 prosp. akad. Lavrent'eva, 630 090 Novosibirsk, Fax (7-383-2) 35 57 66

Furthermore the vibrations of the Mo=O multiple bonds[15-17] can be seen at 880–950 cm^{-1}. We should stress the difference between the spectra of the Mo_6-HPC in which the central atoms are triply charged (Fe^{3+} or Al^{3+}) ions (spectra *5* and *6*) or doubly charged ions (Cu^{2+}, Co^{2+}, spectrum *4*).† In the latter case the absorption bands assigned to $\nu_{Mo=O}$ and $\nu_{Mo-O-Mo}$ are shifted towards lower frequencies (925 and 635 cm^{-1} respectively) in comparison to the Al–Mo–HPC (945 and 665 cm^{-1}) and Fe–Mo–HPC spectra (945 and 645 cm^{-1}).

In the IR spectra of Mo_{12}- and $Mo_{11}Co$-HPC (Fig. 1, spectra *1–3*)‡ strong absorption bands are not found at 400–700 cm^{-1}, in contrast to the spectra of Mo_6-HPC. According to generally accepted suggestions[15-17] the IR absorption spectra of Mo_{12}-HPC in the 900–1000 cm^{-1} region correspond to the vibrations of the Mo=O end bonds (for example, the 965 cm^{-1} band in the spectra of P–Mo-HPC, spectrum *2*), whereas at 700–900 cm^{-1} we observe the stretching vibrations of the Mo–O–Mo bonds (absorption band at 780 cm^{-1} in the spectrum of Si–Mo-HPC, spectrum *1*). We note that the replacement of one molybdenum cation in the $SiMo_{12}O_{40}$ heteropoly anion by a different transition metal ion (mixed HPC, spectrum *3*) shifts the absorption band at 900–1000 cm^{-1} towards lower frequencies by 20–30 cm^{-1}. We also observe the appearance of an absorption at 720–730 cm^{-1}, which is not seen in the spectra of the Si–Mo-HPC.[18-20]

Thus the IR spectra of Mo_6-HPC in the region of 400–700 cm^{-1} differ markedly from those of Mo_{12}-HPC, whereas the IR spectra of mixed HPC at 700–1000 cm^{-1} differ from those of Si–Mo_{12}-HPC. These differences in the IR spectra of HPC belonging to different structure types allow the behaviour of the HPC supported on oxide carriers to be studied by IR spectroscopy.

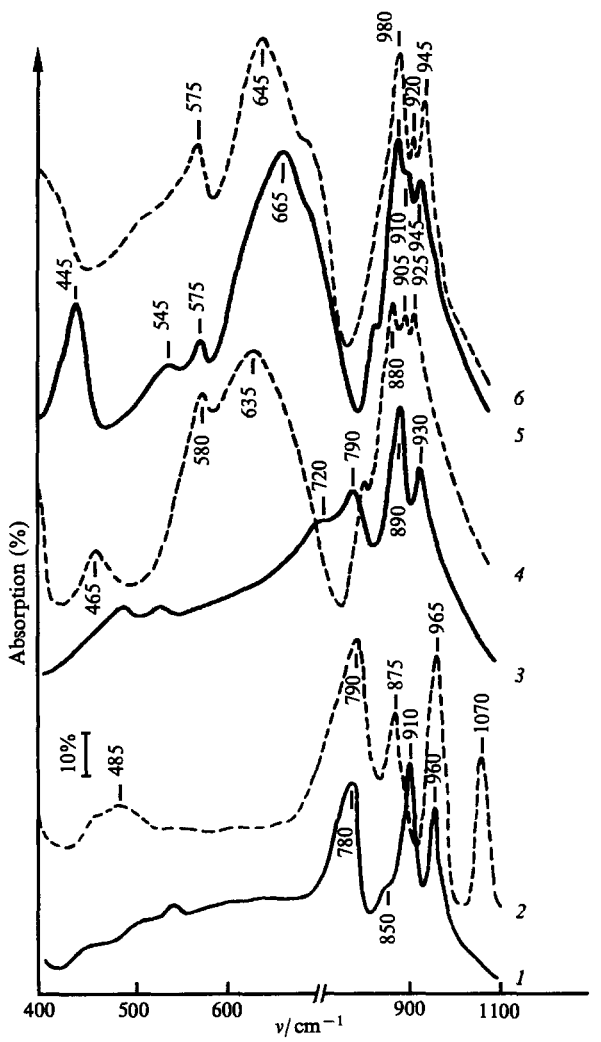

Figure 1. IR spectra of massive HPC dried at 373 K:
1) Cu_2SiMo_{12}, *2*) $Cu_{2/3}PMo_{12}$, *3*) $(NH_4)_6SiMo_{11}Co$, *4*) $(NH_4)_4CoMo_6$, *5*) $(NH_4)_3AlMo_6$, *6*) $(NH_4)_3FeMo_6$.

2. IR spectra of supported heteropoly compounds and effect of the support on their structure

The IR spectra of catalysts prepared by depositing the HPC $(NH_4)_{6-n}M^{n+}Mo_6$ (M = Cu^{2+}, Co^{2+}, Fe^{3+}) on SiO_2 are almost identical (spectra *3–5* of Fig. 2), but they differ markedly from the spectra of the unsupported (bulk) Mo_6-HPC of the transition metals (spectra *4–6* of Fig. 1): the strong absorption bands at 400–700 cm^{-1} are replaced by strong bands at 730–970 cm^{-1}, which are not found in the spectra of bulk Mo_6-HPC. As was stated above, these spectral features are also found in Mo_{12}-HPC and in mixed HPC. Comparing the spectra of Mo_6-HPC supported on SiO_2 (spectra *3–5* of Fig. 2) with the spectra of Mo_{12}- and $Mo_{11}Co$-HPC shows an analogy with the IR spectrum of the mixed $Mo_{11}Co$-HPC (spectrum *3* of Fig. 1). This suggests that when the Mo_6-HPC of copper, cobalt, and iron are supported on SiO_2 they become rearranged into mixed Si–Mo–M-HPC, i.e. molybdenum ions are replaced by transition metal cations.

The IR spectra of samples prepared by supporting $(NH_4)_4CuMo_6$ (spectrum *7* of Fig. 2) and $(NH_4)_4CoMo_6$ (spectrum *8* of Fig. 2) on Al_2O_3 are almost identical, and differ significantly from the spectrum of unsupported $(NH_4)_4CoMo_6$ (spectrum *4* of Fig. 1): for example, their $\nu_{Mo=O}$ and $\nu_{Mo-O-Mo}$ frequencies are shifted (by 20 and 30 cm^{-1} respectively) towards longer wavelengths as compared with the absorption bands at 925 and 635 cm^{-1} observed for the bulk compounds. These shifts in the position of the IR absorption bands can be used to distinguish the Mo_6-HPC of doubly charged cations from the HPC of triply charged cations. Comparing the spectra of these catalysts (Fig. 2, spectra *7* and *8*) with the spectrum of the NH_4 salt of the Al–Mo-HPA (where HPA is a heteropoly acid) supported on Al_2O_3 (Fig. 2, spectrum *6*) shows marked similarities, with coinciding maxima of the most characteristic absorption bands. This suggests that the deposition of the molybdenum heteropoly compounds of Cu and Co on Al_2O_3 causes the formation of Al compounds, involving the Al surface atoms of the support. Under these conditions the copper and cobalt cations usually continue to be the salt formers. The change in colour of the samples (from blue to green for the copper HPC and from light brown to lilac for the cobalt HPC) confirms the change in state of the Mo_6-HPC of copper and cobalt when supported on Al_2O_3.

An analysis of the IR results for samples prepared by supporting $(NH_4)_3FeMo_6$ on Al_2O_3 shows that in this case $FeMo_6O_{24}H_6^{3-}$ is converted into $AlMo_6O_{24}H_6^{3-}$. In the IR spectra of these catalysts in the $\nu_{Mo-O-Mo}$ region (spectrum *9* of Fig. 2) the characteristic absorption of the Fe–Mo-HPC at 645 cm^{-1} (spectrum *6* of Fig. 1) is replaced by an absorption band at 665 cm^{-1}, proper to the spectrum of the Al–Mo-HPC (spectrum *5* of Fig. 1), and furthermore an absorption at 445 cm^{-1} (belonging to the spectrum of Al–Mo-HPC, spectrum *5* of Fig. 1) is also seen. However, at 880–950 cm^{-1} these two compounds behave identically.

Thus the MMo_6-HPC (where M = Cu, Co, Fe) are unstable. When supported they react with the oxide carrier, and they decompose even at the drying stage. On an SiO_2 surface the silicon ions of the carrier form mixed Si–Mo–M-HPC in which transition metal cations replace molybdenum ions:

$$(NH_4)_{6-n}M^{n+}Mo_6O_{24}H_6 + SiO_2 \xrightarrow{373\ K} \longrightarrow (NH_4)_{8-n}SiMo_{11}M^{n+}O_{40}H_2/SiO_2 .$$

† The IR spectra of the Mo_6-HPC of copper and cobalt are identical.
‡ The IR spectra of the Cu and Co salts of Si–Mo- and P–Mo-HPC are similar to those of the corresponding heteropoly acids.

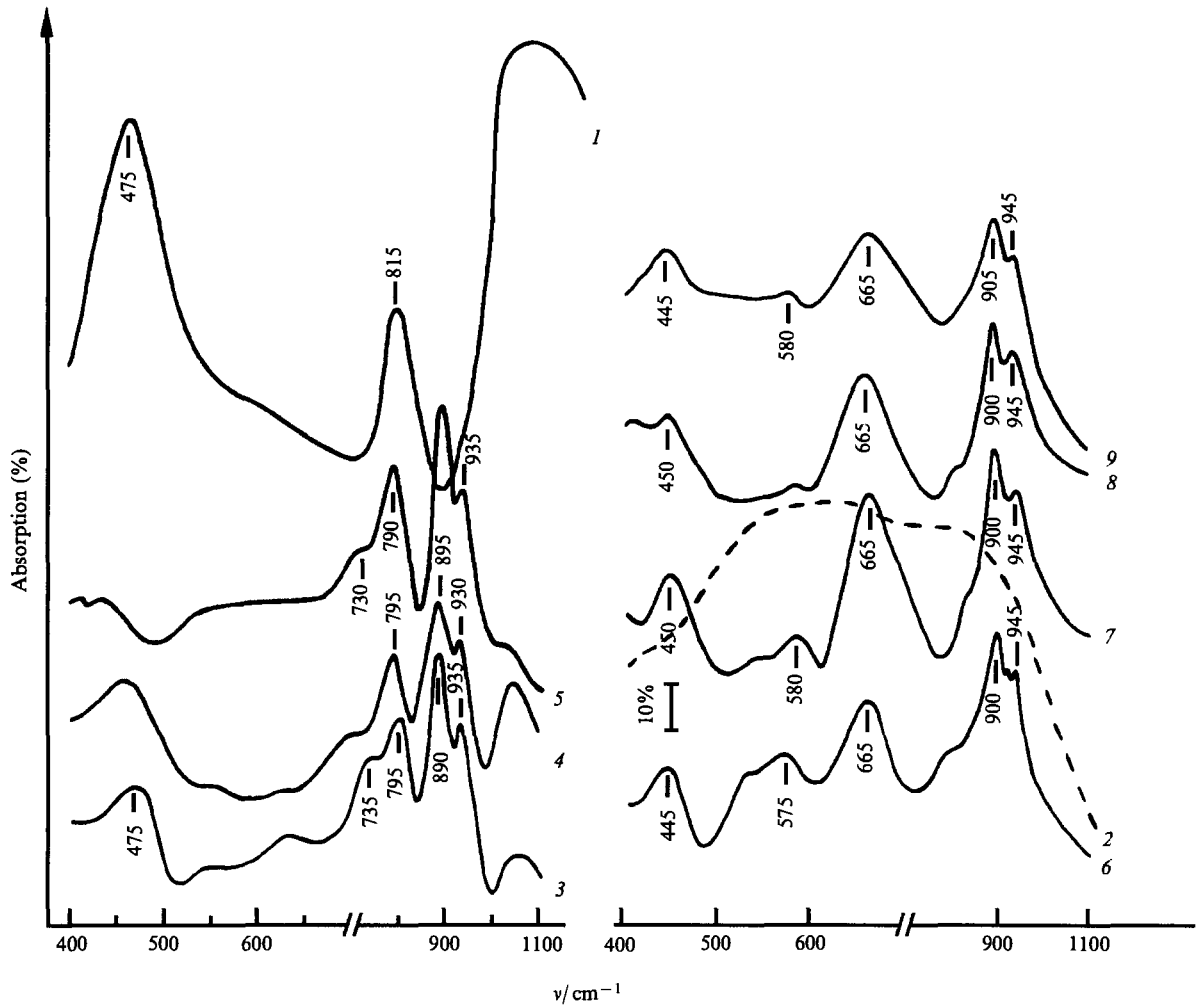

Figure 2. IR spectra of the carriers SiO_2 (*1*) and Al_2O_3 (*2*) and of the samples prepared by supporting Mo_6-HPC on these carriers: *3*) $(NH_4)_4CoMo_6/SiO_2$ (16.5% Mo), *4*) $(NH_4)_4CuMo_6/SiO_2$ (16% Mo), *5*) $(NH_4)_3FeMo_6/SiO_2$ (15% Mo), *6*) $(NH_4)_3AlMo_6/Al_2O_3$ (16.1% Mo), *7*) $(NH_4)_4CuMo_6/Al_2O_3$ (17.6% Mo), *8*) $(NH_4)_4CoMo_6/Al_2O_3$ (16% Mo), *9*) $(NH_4)_3FeMo_6/Al_2O_3$ (16.5% Mo).

When supported on Al_2O_3 the M–Mo_6-HPC (M = Cu, Co, Fe) are converted into Al–Mo_6-HPC with the participation of Al atoms from the carrier surface:

$$(NH_4)_{6-n}M^{n+}Mo_6O_{24}H_6 + Al_2O_3 \xrightarrow{373\ K} \longrightarrow (NH_4)_xM_{(3-x)/n}AlMo_6O_{24}H_6/Al_2O_3 .$$

These processes are of interest from the standpoint of the chemistry of HPC, but they have only very recently begun to be discussed in published work. Results so far available suggest that the tendency of surface atoms to form complexes with molybdenum depends on their nature, and in particular that this property is more clearly developed in Si and Al atoms than in Cu^{2+}, Co^{2+}, and Fe^{3+}. As a result the aluminium and silicon atoms on the carrier surface can displace copper, cobalt, and iron from the central ion position in the mixed HPC.

The IR spectra of Si–Mo_{12}- and P–Mo_{12}-HPC supported on SiO_2 or TiO_2 are identical to the spectra of their copper and cobalt salts on the same supports. The form of the spectra is independent of the content of HPC on the support (5–25 wt.% Mo). In the spectra of P–Mo_{12}-HPA on SiO_2 and TiO_2, we find absorption bands at 790, 875, and 965 cm^{-1} which are also seen in the spectra of massive P–Mo_{12}-HPA (spectrum *2* of Fig. 1). We note that the absorption band at 1065 cm^{-1} seen in the spectra of massive P–Mo-HPC cannot be reliably resolved in the IR spectra of these compounds supported on SiO_2 because of the strong absorption of the carrier in this region (spectrum *1* of Fig. 2). In the spectra of Si–Mo_{12}-HPC supported on SiO_2 and TiO_2 absorption bands can be seen at 780, 865, 910, and 960 cm^{-1}: these are characteristic of the heteropoly anion (HPAn) $SiMo_{12}O_{40}^{4-}$ (spectrum *1* of Fig. 1).

On the whole the good agreement between the IR spectra of bulk P–Mo_{12}- and Si–Mo_{12}-HPA (and their salts) and of the samples supported on SiO_2 and TiO_2 suggests that the structure of the anion of Mo_{12}-HPA is preserved when the material is supported on these carriers.[9,10]

A different state of affairs is found for Mo_{12}-HPC supported on Al_2O_3. The IR spectra of samples prepared by depositing the Cu and Co salts of Si–Mo_{12}-HPA on Al_2O_3 (~15% Mo) are similar. Fig. 3 (spectrum *2*) shows as an example the spectrum of Co_2SiMo_{12}/Al_2O_3, which differs markedly from the characteristic spectrum of the $SiMo_{12}O_{40}^{4-}$ HPA (spectrum *1* of Fig. 1), and is almost identical to the IR spectrum of the NH_4 salt of the Al–Mo-HPA supported on Al_2O_3 (spectrum *6* of Fig. 2). These results indicate the decomposition of $SiMo_{12}O_{40}^{4-}$ when the Cu and Co salts of Si–Mo_{12}-HPA are supported on Al_2O_3 in concentrations of ~15% Mo. Under these conditions Al–Mo_6-HPC are formed on the support. Unlike its salts, the Si–Mo_{12}-HPA itself is preserved when supported on Al_2O_3: the IR spectrum of the Si–Mo_{12}-HPA/Al_2O_3 sample (16.8% Mo) (spectrum *1* of Fig. 3) is similar to that of the massive heteropoly acid (spectrum *1* of Fig. 1).

The IR spectra of the catalysts prepared by supporting the P–Mo-HPA and its Cu and Co salts on Al_2O_3 (concentration of HPC ~15% Mo) are similar (spectra *3* and *4* of Fig. 3), and almost indistinguishable from the spectrum of $(NH_4)_3AlMo_6/Al_2O_3$

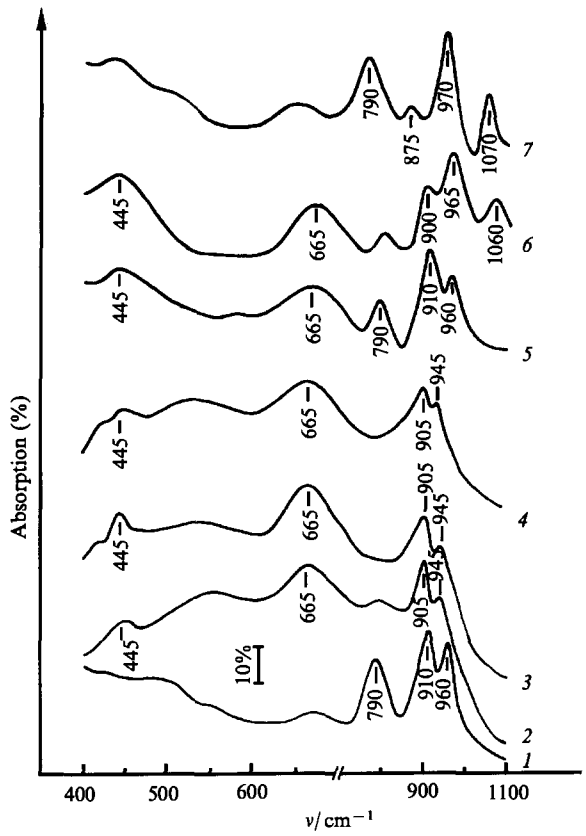

Figure 3. IR spectra of samples prepared by supporting Mo_{12}-HPC on Al_2O_3 and drying at 373 K:
1) H_4SiMo_{12} (16.8% Mo) *2*) Co_2SiMo_{12} (15.5% Mo)
3) $Cu_{3/2}PMo_{12}$ (14.6% Mo) *4*) H_3PMo_{12} (13.3% Mo)
5) Co_2SiMo_{12} (27.3% Mo) *6*) $Co_{3/2}PMo_{12}$ (21.5% Mo)
7) H_3PMo_{12} (23.4% Mo).

(spectrum *6* of Fig. 2). Absorption bands characteristic of the P–Mo_{12}-HPC are not observed in the spectra of these samples.

The totality of these results convincingly shows that at low concentrations (~15% Mo) on the surface of an Al_2O_3 support Mo_{12}-HPC (like Si–Mo_{12}-HPA) is decomposed with formation of Al–Mo_6-HPC by reacting with the aluminium atoms of the Al_2O_3 surface, whereas copper and cobalt cations tend to behave as salt formers:

$$M_xAMo_{12}O_{40} + Al_2O_3 \xrightarrow{373\ K} M_yAlMo_6O_{24}H_6/Al_2O_3 .$$

Fig. 3 also shows the IR spectra of catalysts with large concentrations of Mo_{12}-HPC on Al_2O_3 (23–27 wt.% Mo, spectra *5*–*7*). It can be seen that increasing the concentration of P–Mo_{12}-HPA and its salts (or of the salts of Si–Mo_{12}-HPA) on the support produces, in addition to a weak band at 665 cm^{-1}, characteristic of Al–Mo_6-HPC, absorption bands typical of $SiMo_{12}O_{40}^{4-}$ (780, 860, 910, and 960 cm^{-1}, spectrum *5* of Fig. 3) and of $PMo_{12}O_{40}^{3-}$ (790, 875, 965, and 1065 cm^{-1}, spectra *6* and *7* of Fig. 3). This suggests that at high concentrations the main part of the Mo_{12}-HPC is retained unchanged on the Al_2O_3 surface.

Thus the Mo_{12}-HPC are preserved (irrespectively of their concentration on the surface) when deposited on SiO_2 or TiO_2, whereas on the surface of Al_2O_3 the P–Mo_{12}-HPA and its salts, as well as the salts of Si–Mo_{12}-HPA, decompose at low concentrations with formation of Al–Mo_6-HPC.

These results have been explained[8] in terms of the acid–based properties of the substrates and of the pH stability range of the supported HPC.

As reported,[21,22] the substrates can be arranged in the following order of decreasing acidity: $SiO_2 > TiO_2 > Al_2O_3$. We know that P–Mo-HPA is stable over a very narrow range of pH (0.8–1.5), whereas for Si–Mo-HPA the range is much wider (from 1 to 4).[23,24] Solutions of the Cu and Co salts of Si–Mo- and P–Mo-HPA are also acidic: pH ~2 for $M_{3/2}PMo_{12}$ and pH ~4 for M_2SiMo_{12}.[23] The Mo_6-HPC are stable at higher pH values (2–5.5), and in particular the $AlMo_6O_{24}H_6^{3-}$ anion is preserved up to pH 5.5.[23]

The stability of the structure of Mo_6-HPC when supported on SiO_2 and TiO_2, even at low concentrations of Mo, is probably due to the relatively high acidity of these supports. With a more basic support (such as Al_2O_3) and at low concentrations of Mo_{12}-HPC on the support the heteropoly compound decomposes, lowering the acidity of the medium. As we have shown,[11] under these conditions we observe the formation of Al–Mo_6-HPC, whose anion is stable in less acidic media. At higher concentrations of the HPC on the Al_2O_3 (up to 20–25 wt.% of Mo) the structure of the supported material is retained, probably as a result of the increased acidity of the medium.

Si–Mo-HPA (unlike P–Mo, see above) does not decompose when supported on Al_2O_3, even at low concentrations on the carrier. This is probably due to the wider stability range of Si–Mo-HPA as compared with P–Mo-HPA. On the other hand the salts of the Si–Mo-HPA decompose under these conditions, probably because of the lower acidity of their solutions.

We could therefore have expected that the creation of a strongly acid medium on the surface of samples with a low concentration of HPC on the Al_2O_3 would regenerate the Mo_{12}-HPC after this compound had been decomposed with formation of Al–Mo_6-HPC. To test this hypothesis samples prepared by depositing P–Mo- and Si–Mo-HPC on Al_2O_3 (~15% Mo) were treated with a solution of hydrochloric acid (1 : 1). In the IR spectra of these samples (see Fig. 4, spectra *2*, *4*, and *6*) we found, in contrast to the spectra of the initial catalysts (spectra *1*, *3*, and *5*), absorption bands at 790, 875, 965, and 1065 cm^{-1}, characteristic of P–Mo_{12}-HPA (spectra *2* and *4*) and at 790, 910, and 960 cm^{-1}, characteristic of Si–Mo_{12}-HPA (spectrum *6*), i.e. the increased acidity of the medium induces the reverse conversion of Al–Mo_6-HPC into Si–Mo_{12}- and P–Mo_{12}-HPC.

Thus a study of the interactions of the Mo_6- and Mo_{12}-HPC with the oxide supports leads to the following conclusions. The M–Mo_6 molybdenum heteropoly compounds containing copper, cobalt, or iron as the central atom M are unstable. When supported they interact with the carrier, and as a result mixed Si–Mo–M heteropoly compounds are formed on the SiO_2 surface. On a γ-Al_2O_3 surface the Mo_6-HPC of the transition metals decompose with formation of salts of the Al–Mo_6-HPA. The phase composition of catalysts prepared by depositing Mo_{12}-HPC on supports depends on the acid–base properties of the support and on the pH stability range of the supported HPC. Whereas the structure of P–Mo_{12}- and Si–Mo_{12}-HPC is retained when the compounds are supported on SiO_2 and TiO_2, irrespective of their concentration on the carrier, deposition on Al_2O_3 causes decomposition of the compounds (when present at low concentrations) and the formation of Al–Mo_6-HPC. Thus the composition of the compounds on the surface of basic carriers can be controlled either by varying the concentration of the supported heteropoly compounds or by treating the carriers with solutions of mineral acids.

3. Acidic properties of molybdenum heteropoly compounds

The number of publications dealing with the acidic properties of supported HPC is small. We have described[25] a study of the acidic properties of P–Mo-HPA supported on various oxide carriers (SiO_2, TiO_2, Al_2O_3), and also of Si–Mo-HPA and the salts of P–Mo-HPA on SiO_2. The adsorption of molecules of a base (pyridine[25,26] or ammonia[9]) on these HPC was studied by IR spectroscopy.

It was found that the IR spectra of pyridine adsorbed on any of the HPC in the 1300–1650 cm^{-1} region were similar. The presence of an absorption band at 1540 cm^{-1}, assigned to vibrations in the pyridinium ion, was interpreted[25] as evidence of the presence in all the catalysts of Brønsted-acid centres (BAC)

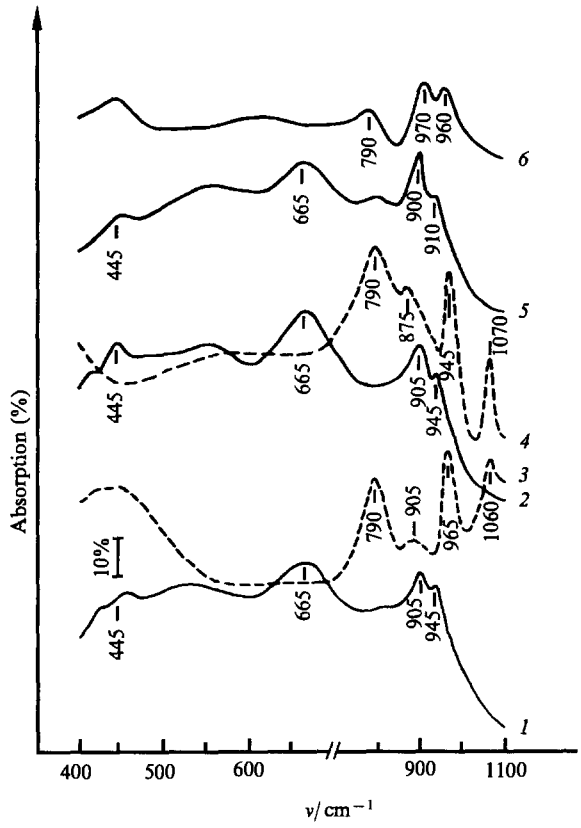

Figure 4. IR spectra of samples prepared by supporting Mo_{12}-HPC on Al_2O_3: *1*) and *2*) H_3PMo_{12} (13.3% Mo), *3*) and *4*) $Co_{3/2}PMo_{12}$ (14.1% Mo), *5*) and *6*) Cu_2SiMo_{12} (16.6% Mo). The spectra *2*, *4*, and *6* were recorded after treating the samples with a solution of HCl.

which protonate the pyridine molecule. The absorption band found at 1450 cm^{-1} denotes the formation of complexes of pyridine with aprotic centres of the catalyst.

Effect of the concentration of HPA. We studied the dependence of the concentration of proton centres (in μmol PyH^+ m^{-2}) on the content of P–Mo- and Si–Mo-HPA on SiO_2 and of P–Mo-HPA on Al_2O_3. All these dependences are of the same type, suggesting that in the region of low concentration of HPA on the carriers (7–15 wt.% of Mo) the amount of BAC increases in proportion to the concentration of HPA. At still higher concentrations of P–Mo- and Si–Mo-HPA on the carrier (up to 20–28 wt.% of Mo) the concentration of mobile protons (in μmol PyH^+ m^{-2}) stays unchanged, but the specific surface decreases.

The increase in the concentration of BAC with increasing content of HPA (in the region of 7–15 wt.% of Mo) was attributed to the increased coverage of the carrier surface by HPA molecules. A further increase in the content of HPA causes agglomeration of the molecules, which lowers the specific surface of the samples while the concentration of the proton centres per m^2 stays constant.

Since according to Okuhara et al.[27] the acidity measured for massive HPA is the bulk value, our results[25] indicate that in the case of supported HPA the main role is played by the surface properties.

The strength of the proton centres (in units of *PA*, or proton affinity[26]) was characterised by the frequency of the stretching vibrations band of the pyridinium ion, which depends on the basic properties of the acidic residue.[25]

The strength of the proton acid centres was unaffected by varying the content of P–Mo- and Si–Mo-HPA on SiO_2 or of P–Mo-HPA on Al_2O_3: the parameter ν^c_{NH} (defined as the position of the centre of gravity of the ν_{NH} band)§ is 2900 cm^{-1} for all the samples of P–Mo- and Si–Mo-HPA on SiO_2, and 2600 cm^{-1} for the HPA supported on Al_2O_3.

The acidic properties of the different HPC were compared at high concentrations of these compounds on the carrier.

Comparing the acidic properties of HPA with P and Si central atoms supported on SiO_2 showed that the concentration of BAC is greater by a factor of 1.4 in H_3PMo_{12}/SiO_2 than in H_4SiMo_{12}/SiO_2 over the whole range of concentrations of the HPA on the carrier. The strength of the proton centres (as previously defined[26]) was the same for P–Mo- and Si–Mo-HPA supported on SiO_2: ν^c_{NH} = 2900 cm^{-1}.

Effect of the type of carrier. It was reported[23] that the concentration of mobile protons in P–Mo-HPA supported on SiO_2 is much higher than in the same compound on Al_2O_3 over a wide range of concentrations of the HPA. The concentration of BAC in P–Mo-HPA supported on TiO_2 (13.7% of Mo) is 0.4 μmol m^{-2}, i.e. three or four times lower than the concentration of BAC in P–Mo-HPA on SiO_2 (13.6% of Mo), for which this quantity is 1.5 μmol m^{-2} (for samples conditioned at the same temperature of 423 K).

By comparing the ν^c_{NH} values obtained for P–Mo-HPA samples on different carriers it was shown that the centres of gravity ν^c_{NH} for HPA/TiO_2 and HPA/Al_2O_3 are strongly shifted towards lower frequencies. Their calculated ν^c_{NH} values were about 2600 cm^{-1}, as compared with 2900 cm^{-1} for HPA/SiO_2. Therefore supporting the P–Mo-HPA on TiO_2 and on Al_2O_3 lowers the strength of the proton centres.

Qualitative results on the change in the number of BAC caused by an increase in the conditioning temperature of Si–Mo-HPA and P–Mo-HPA (and its salts) deposited on SiO_2 were obtained by studying the adsorption of pyridine on these samples. The concentration of mobile protons on all the samples fell when the pretreatment temperature was increased, the effect being most marked following an increase in temperature from 523 to 723 K. The strength of the proton centres (the shift in ν^c_{NH}) was unaffected by increasing the conditioning temperature of the HPC/SiO_2.

Effect of replacing the protons in the HPA by metal cations. This effect was studied[25] for P–Mo-HPA and its sodium and copper salts supported on SiO_2.

Replacing some of the protons in P–Mo-HPA/SiO_2 by Na^+ produces a large change in the proton-donor capacity of the acid centres (as shown by the changes in the contour of ν^c_{NH}). Upon introducing sodium cations the centre of gravity of ν^c_{NH} is shifted towards lower frequencies (the calculated ν^c_{NH} is 2800 cm^{-1} for the salts and 2900 cm^{-1} for the acid). Similar effects were noted in a study[27] of the decrease in the desorption temperature of pyridine from the Na^+ salts of P–W-HPA as compared with its desorption from the acid itself. For the Cu^+ salts of P–Mo-HPA this decrease in the strength of the proton centres was not observed: ν^c_{NH} was the same for H_3PMo_{12}/SiO_2 and $Cu_{3/2}PMo_{12}/SiO_2$.

The change in the concentration of mobile protons caused by the replacement of H^+ by metal cations in P–Mo-HPA showed[25] that for conditioning temperatures between 423 and 723 K the number of BAC (in μmol PyH^+ m^{-2}) decreases monotonically as the concentration of sodium or of copper in the HPC is increased. However, even in the fully substituted salts Na_3PMo_{12}/SiO_2 and $Cu_{3/2}PMo_{12}/SiO_2$ a small number of mobile protons is still detectable.

Lewis-acid centres. As reported[28], the massive HPA and their salts can be classified as proton acids. The concentration of Lewis-acid centres (LAC) in these catalysts is negligibly small (the amplitude of the absorption band due to co-ordinated pyridine is small in comparison with the absorption band of PyH^+).

§ The position of the centre of gravity of the ν_{NH} band of the pyridinium ion was determined from the outline of the ν_{NH} line at 3400–1800 cm^{-1} (see Okuhara et al.[27]).

Studies of the acidic properties of HPC supported on a carrier have shown[9, 25] that the absorption bands which characterise the ions of co-ordinated pyridine and NH_3 are relatively strong. The concentration of LAC in P–Mo-HPA/SiO_2 has been measured, and the dependence of the concentration of LAC on the composition of the HPC and on their heat-treatment temperature was determined.[25]

Thus the results discussed above show that IR spectroscopy can be conveniently used to establish the presence of HPC on carriers (at least, on SiO_2, Al_2O_3, and TiO_2 as carriers). The method can also be used to monitor the formation of similar compounds during the preparation of traditional supported catalysts containing molybdenum. However, it should be noted that in this case the problem is much more complex than the problems considered above. This is due partly to the large number of phases present in the traditional catalysts (as has been repeatedly pointed out in published papers) and partly to the use of very high conditioning temperatures, which cannot fail to cause decomposition of the HPC, even in the case of compounds formed on the carrier surface during the preparation of the catalyst. Nevertheless the possibility of stabilising these compounds by an appropriate choice of support has now been established: in other words, the carrier should be treated as one of the components of the resulting HPC.[9–11]

As was shown by Mastikhin et al.,[29] important information on the changes in acidity of the HPA induced by the support can be obtained by using the PMR method.

III. Supported molybdenum oxide catalysts. Formation, identification, and surface properties of surface compounds

In this section we shall dwell on two aspects of the study of supported molybdenum oxide catalysts: (1) the development of methods of studying supported catalysts, and (2) the analysis of published data on the identification of the compounds formed on the surface of various carriers during their interaction with molybdenum oxide compounds. Of course, equal attention will be paid to the identification of other compounds formed on the surface of the carriers during this interaction. There are recent reports of the formation of HPC on the carrier surface during the deposition of molybdenum and tungsten oxide compounds (including the traditional methods) as a result of the far-reaching interaction of the supported compounds with the carrier.

X-Ray phase analysis is often not suited to the study of oxide systems formed on the surface of carriers, especially when the active component is present at low concentration. In this case IR spectroscopy is the most attractive method, widely used to establish the phase composition of oxide systems including catalysts amorphous to X-rays.[30, 31] To a first approximation the study of supported compounds by IR spectroscopy is similar to the study of adsorbed molecules:[32] in both cases the basic problem is to identify the type of compound formed by the interaction of the supported compound with the surface and to make apparent the changes taking place during this interaction, i.e. in this case IR spectroscopy is used mainly as a method of analytical control, showing the presence of various compounds of interest.¶ This application of IR spectroscopy suffers from the limitations imposed by the use of vibrational spectroscopy in surface chemistry: (1) the inability to provide a complete spectrum of the surface compound, due both to the overlap of the absorption bands of the active component with those of the support, and to the low concentration of the surface compound, and (2) the simultaneous formation on the carrier surface of several compounds and the overlap of the absorption bands belonging to different structures. For supported molybdenum oxide systems these limitations are even more serious because of the need to identify an inorganic surface compound on the surface of an inorganic carrier.

Because of these difficulties spectral compensation methods seem to be the most attractive: they have been reviewed in depth,[14] and are widely used by several workers to establish the nature of the active component,[8–11, 33] including supported molybdenum oxide compounds formed on the surface of carriers.[8–11]

1. Formation and identification of Al–Mo oxide compounds

Aluminium molybdenum oxide catalysts are being intensively studied everywhere because of the extreme importance of hydrodesulphurisation processes in petroleum refining, in which Al–Mo and Al–W systems promoted with cobalt and nickel are the most widely used industrial catalysts. Several reviews[33–36] of the structure and physicochemical properties of Al–Co–Mo hydro-refining catalysts have been published. The study of unpromoted Al–Mo catalysts is also of interest because these materials are active in many hydrocarbon conversion reactions: oxidation, hydrogenation, isomerisation, dehydrogenation, polymerisation, olefin metathesis, and paraffin condensation.

Several methods of preparing Al–Mo catalysts are available: the adsorption of $MoO_2(OH)_2$ on Al_2O_3 from the gas phase,[37] fixing metal-organic complexes on the Al_2O_3 surface,[38, 39] the adsorption of molybdate ions by the carrier from solutions,[40–44] and coprecipitation from solutions of ammonium paramolybdate (APM) and $Al(NO_3)_3$.[45, 46] The simplest and most widely used method relies on impregnation of the formed Al_2O_3 carrier with solutions of ammonium paramolybdate followed by drying and roasting of the catalyst at given temperatures.[37, 47–54]

Depending on the concentration and pH of the APM solution, surface compounds of different composition can be obtained on the carrier.[42, 43, 49–54] This is primarily due to the presence of different associations in the APM solution, depending on the pH and on the concentration.[55, 56] Increasing the pH and lowering the concentration shifts the equilibrium towards the formation of molybdates containing molybdenum ions in a tetrahedral coordination (MoO_4^{2-}). At low pH and high concentrations the dominant species are the isopoly molybdates, in which the molybdenum ions have an octahedral coordination.[50, 54] Furthermore the γ-Al_2O_3 carrier itself has acid–base properties,[22, 50, 54, 57, 58] and therefore an equilibrium determined by the initial pH and concentration of the solution and by the type of carrier is established at the interface with the molybdenum solutions.[42, 43, 50, 54] By using a more acidic carrier (SiO_2) the polymeric compounds can be stabilised at much lower molybdenum concentrations (down to 10%) than on the more basic Al_2O_3. On the strongly basic MgO the formation of octahedral molybdenum polyanions was not detected at any concentration of APM.[54, 59]

The surface OH groups of the carrier can interact with the molybdenum anions with formation of surface compounds. A large decrease (or complete suppression) of the fluorescence background accompanying the Raman spectrum and attributed to the OH groups on the Al_2O_3 surface has been noted[51] after the deposition of APM on the carrier, suggesting a reaction of the APM with the OH groups. A Raman study of Al–Mo catalysts prepared by impregnating Al_2O_3 carriers with APM solutions of pH between 6 and 11 led to the conclusion[50] that at low molybdenum concentrations (1–3 wt.% MoO_3) only MoO_4^{2-} ions are formed on Al_2O_3 even at pH 6, when the impregnating solution contains $Mo_7O_{24}^{6-}$ ions. The dissociation of the $Mo_7O_{24}^{6-}$ ions is attributed[50] to an increase in the pH of the

¶ This does not exclude the use of IR spectroscopy as a structural technique. If the limitations defined below can be overcome the results of IR spectroscopy can be used to establish the structural parameters of the supported compound.

solution due to the increased concentration of OH^- ions in solution produced by the ion-exchange adsorption

$$Al-OH + MoO_4^{2-} \leftrightarrows AlOMoO_3^- + OH^-.$$

The presence of tetrahedral molybdenum ions on the surface of Al–Mo catalysts prepared by adsorption of molybdate ions from dilute solutions APM at a high pH (8.6) has been established.[42, 43] Adsorption from concentrated solutions of APM or at low pH (4.0) results in the stabilisation of octahedral Mo polyanions[42, 43] on the Al_2O_3 surface; these are retained when the sample is dried.

According to Giordano et al.[53] the Al–Mo catalysts (before being heated) contain tetrahedral ions weakly interacting with the OH groups of the Al_2O_3. During the subsequent activation of the catalysts by oxidative high-temperature treatment further interaction of the molybdenum compounds with the carrier surface takes place.

Under these conditions stable monomeric molybdate complexes (MoO_4^{2-}) are formed at low molybdenum concentrations.[52] Experimental confirmation of the formation of a monolayer of tetrahedrally coordinated molybdenum ions has been obtained by different methods, including IR, Raman, and UV spectroscopy, XPS, and others.[37, 50, 52, 53, 60] According to most of the authors at low concentration (5–10 wt.% MoO_3) the whole of the molybdenum in the roasted catalysts is present in a highly dispersed state, and mainly as tetrahedral ions.[52, 53, 61–63] Increasing the concentration of MoO_3 (to 16 wt.%) increases the fraction of the molybdenum in octahedral coordination and forms polymolybdate structures. At even higher molybdenum concentrations the MoO_3 and $Al_2(MoO_4)_3$ phases are formed.[44–46, 50, 52–54, 59, 61, 64]

The degree of crystallinity of the compounds formed in the $MoO_3-Al_2O_3$ system depends on the concentration of molybdenum, and the extent of reaction depends on the heat treatment temperature.[45, 46] An X-ray study of amorphous molybdenum compounds by atomic radial distribution and ESR methods has shown[46] that polymolybdates containing molybdenum in an octahedral coordination are formed, in addition to the MoO_3 and $Al_2(MoO_4)_3$ phases, during the interaction of APM with Al_2O_3. An analysis of aqueous extracts from Al–Mo catalysts led to the same conclusion.[44] According to these results MoO_3 and $Al_2(MoO_4)_3$ are sparingly soluble in water, whereas a large fraction of the supported molybdenum is transferred to the solution when the Al–Mo catalysts are treated with water. The UV spectra of the aqueous extracts suggest the presence of molybdenum isopoly anions. It was therefore concluded[44] that in addition to the MoO_3 and $Al_2(MoO_4)_3$ phases observed by XPA (which are sparingly soluble and cannot pass into the solution) isopoly compounds are also formed on the surface of the Al–Mo catalysts, especially at high molybdenum concentrations. These are apparently responsible for the activity in the hydrogenolysis of thiophen. However, no attempt was made to identify these isopoly compounds directly on the surface of the catalysts.

Shmidt et al.[48] have established the presence in ignited Al–Mo catalysts of three different forms of molybdenum: water-soluble (W), soluble in ammonia (M), and insoluble in either water or ammonia (S). They claim that the water-soluble form is a compound containing molybdenum in an octahedral coordination (and assumed to be active towards the dehydrogenation of cyclohexane), but the nature of this compound was not examined in that study.[48]

In their discussion of the nature of the active centres created on the Al–Mo catalysts and responsible for the oxidation of propene to acetone Giordano et al.[47, 53] assumed that the compounds possessing acidic and oxidising properties and active in the conversion of propene into acetone could be reduced heteropoly acids or compounds of the $Mo_4O_{10}(OH)_2$ type (though the structure and properties of the heteropoly acids were not investigated in that work).

Several studies of the reduction of Al–Mo catalysts have been reported, and some of these have been reviewed in depth.[35, 36] Only a few features of that work call for comment here. The degree of reduction of Al–Mo catalysts increases with the reduction temperature. The reduction of the supported MoO_3 is much less complete than that of the massive compound.[65] It has been shown[53, 66] that the tetrahedral molybdenum ions are more difficult to reduce than the octahedral. On the whole the reduction of Al–Mo catalysts increases the degree of inhomogeneity of the molybdenum because of the different reducibilities of the molybdenum compounds of different composition.[53]

Studies aimed at identifying the molybdenum compounds formed by reduction and at determining their thermal stability and their stability in catalytic reaction[11, 67] have relied mainly on IR spectroscopy.

A special study[11] was made of the sequence of reactions of the molybdenum oxide compounds on the surface of Al_2O_3 during the thermal conditioning of the sample. In particular, in the IR spectrum of the 25% $MoO_3-Al_2O_3$ catalyst dried at 383 K (spectrum *4* of Fig. 5) we find, in addition to the absorption band at 920 cm^{-1}, a group of strong bands at 450, 665, 900, and 945 cm^{-1}, which is characteristic (according to published data) of polymolybdates.[35, 43] The presence of a strong band with a maximum at 945 cm^{-1} indicates the formation of a compound containing molybdenum in an octahedral coordination. By combining these results with those of previous studies by XPA and ESR,[46] and by Raman[50] and by UV and IR spectroscopy,[52] and also with recently formulated propositions,[53, 68] we may conclude that these compounds are polymeric formations consisting of MoO_6 octahedra or heteropoly compounds of molybdenum and aluminium.

In order to identify the resulting polymolybdate we compared[8] the IR spectra of a 25% $MoO_3-Al_2O_3$ catalyst and of ammonium paramolybdate (an isopoly compound), whose molecule consists of seven MoO_6 octahedra (spectrum *8* of Fig. 5), and of the heteropoly Al-Mo compound $(NH_4)_3AlMo_6O_{24}H_6$, whose anion is constructed from six MoO_6 octahedra connected by their edges into a ring (spectrum *9* of Fig. 5).[23, 69–71] In the latter compound the Al atom occupies the central octahedron. As can be seen from Fig. 5 and Table 1 the IR spectroscopic manifestations of the isopoly and the heteropoly compounds are quite different, which allows these compounds to be identified fairly reliably on catalyst surfaces.

By comparing the spectra *4*, *8*, and *9* of Fig. 5 with the spectral data in Table 1 we can see that the spectrum of the 25% $MoO_3-Al_2O_3$ catalyst dried at 383 K is essentially similar to that of the salt of the Al–Mo heteropoly acid: the maxima of the strongest absorption bands in the region of the Mo–O–Mo bridging bonds (445 and 665 cm^{-1}) are in identical positions, and include a triplet in the high-frequency region 880–950 cm^{-1} (Mo=O vibrations).[70] This suggests the formation on the Mo–Al catalyst surface of a compound similar in structure to the Al–Mo-HPA, and disproves the reported[46] formation of an isopoly compound.

It can also be seen from Fig. 5 that the spectrum of the supported HPA salt is more similar to that of the individual salt than is the spectrum of the compound formed on the surface of the 25% $MoO_3-Al_2O_3$ catalyst. This confirms our hypothesis of the effect of the surface aluminium atoms on the spectral characteristics of the heteropoly anion. When the salt of the HPA is deposited on the carrier the heteropoly anion is already formed, whereas during the interaction of ammonium paramolybdate and Al_2O_3 the anion is formed through the participation of aluminium atoms from the carrier surface.

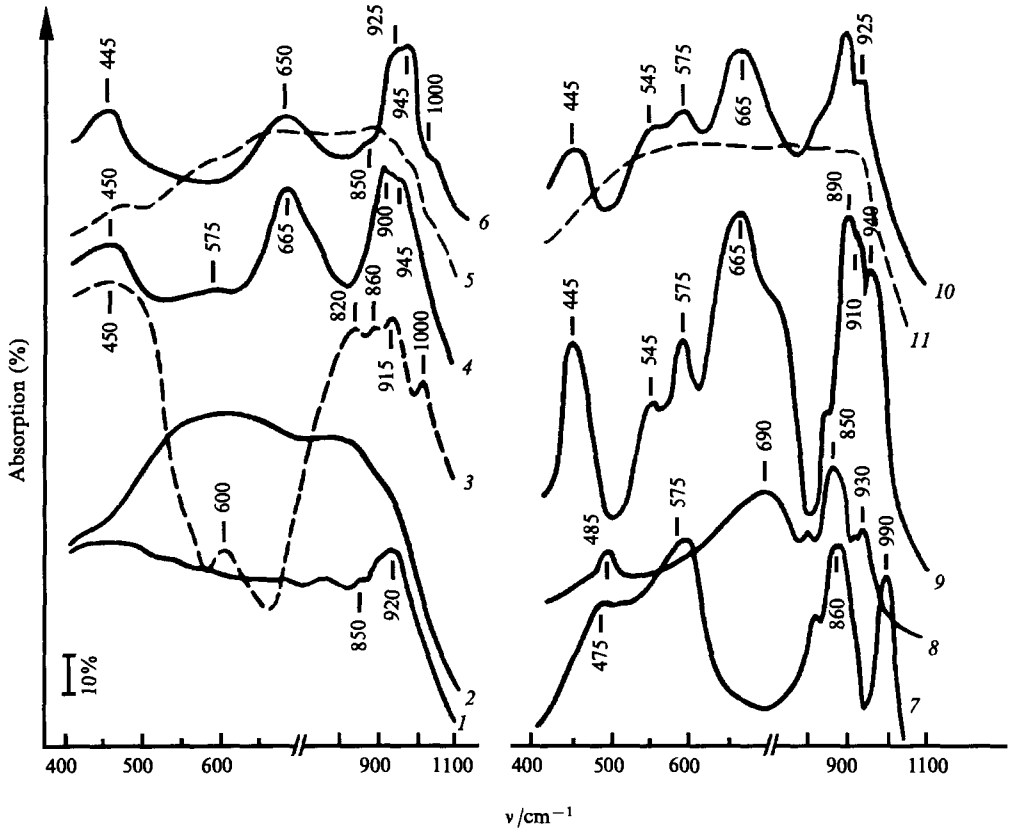

Figure 5. IR spectra of various molybdenum compounds and Mo–Al catalysts: *1*) 10% $MoO_3-Al_2O_3$; *2*) γ-Al_2O_3; *3*) $Al_2(MoO_4)_3$; *4*)–*6*) 25% $MoO_3-Al_2O_3$ at 383 (*4*) and 773 K (*5*), and after treatment with water (*6*); *7*) MoO_3; *8*) $(NH_4)_6Mo_7O_{24}$; *9*) individual $(NH_4)_3AlMo_6O_{24}H_6$; *10*) $(NH_4)_3AlMo_6O_{24}H_6$ supported on Al_2O_3 and dried at 383 K; *11*) ditto, heated at 573 K

In the latter case we can expect the effect of the carrier to be reflected by the IR spectra of the heteropoly anion. Obviously, the same is true of the differences in thermal stability of the heteropoly anions deposited on Al_2O_3 from solutions of their salts or formed by the reaction of ammonium paramolybdate with the carrier. The supported heteropoly compound dissociates even at 573 K (spectrum *11* of Fig. 5), whereas the polymolybdate formations on the surface of the Mo–Al catalysts are not decomposed at 773 K (spectrum *5* of Fig. 5).

Heating the 25% $MoO_3-Al_2O_3$ catalyst to 773 K apparently produces a large perturbation of the octahedral coordination of the molybdenum in the heteropoly compound, which manifests itself in the IR spectrum (spectrum *5* of Fig. 5) as a set of changes in the vibrations of the Mo = O bonds: the absorption band with a maximum at 890 cm^{-1} disappears, and the relative intensities of the bands at 925 and 945 cm^{-1} are increased. However, the character of the spectrum of the catalyst heat treated at 773 K suggests that the polyanion structure of the compound formed during the preparation of the catalyst from ammonium paramolybdate and Al_2O_3 is retained at these quite high temperatures.

Table 1. Position of the absorption bands (cm^{-1}) in the IR of various Mo compounds and Mo–Al catalysts.[14]

Note. Relative intensities of the absorption bands: v.s, very strong; s, strong; av, average; w, weak; v.w, very weak; sh, shoulder.

A comparison of the spectrum of the 25% $MoO_3-Al_2O_3$ catalysts heated at 773 K with the spectra of aluminium molybdate (spectrum *3* of Fig. 5) and of MoO_3 (spectrum *7*) shows that these phases are formed during the heat treatment of the catalyst. The presence of aluminium molybdate is indicated by the higher relative magnitude (as compared with the dried catalyst) of the absorption band at 445 cm^{-1}, and also by the appearance of a band at 920 cm^{-1} (spectrum *3*). The formation of MoO_3 is confirmed by the presence in the spectrum of the heated catalyst of an absorption band at 850 cm^{-1} and a shoulder at 1000 cm^{-1} (spectrum *7*). However, the absorption bands which characterise these phases are relatively weak, i.e. the predominant species on the surface of the heated catalyst are the paramolybdates.

As was pointed out above, one method of establishing the formation of HPC on the surface of carriers is by dissolution, since we know that all the heteropoly acids and many of their salts are readily soluble in water, unlike MoO_3 and aluminium molybdate. It was shown[68] that when these Mo–Al catalysts (with different aluminium contents) are treated with water the amount of molybdenum transferred to the solution is strongly dependent on its concentration in the initial sample. In other words the proportion of water-soluble molybdenum is negligibly small in a 5–10% $MoO_3-Al_2O_3$ sample, but it increases rapidly beyond this point and in a catalyst containing 25% of MoO_3 it amounts to about 50% of the molybdenum added to the sample.

The ^{27}Al NMR spectra of the aqueous extracts indicate the presence of the $AlMo_6O_{24}H_6^{3-}$ anion. It has been shown[11] that, as expected, treating a 25% $MoO_3-Al_2O_3$ catalyst (heated at 773 K) with water, i.e. removing the water-soluble molybdenum from it, produces a marked decrease in the absorption bands which characterise the polymolybdate (spectrum *6* of Fig. 5). This means that the water treatment of the catalyst removes the paramolybdate from the surface of the sample. These results, coupled with the detection of aluminium as well as molybdenum in the aqueous extracts, provide strong additional evidence of the formation of Al–Mo heteropoly compounds on the surface of Mo–Al catalysts with a high molybdenum content.

The presence of polymeric molybdenum compounds in the heat-treated 25% $MoO_3-Al_2O_3$ catalysts is additionally confirmed by the lines at 956, 891, and 345 cm^{-1} seen in the Raman spectra.[72]

Acidic properties. As was pointed out above proton acidity is a special feature of both supported and massive HPC. It should be noted that in order to account for the catalytic properties of Al–Mo catalysts in various reactions[40, 73–76] some workers have postulated the presence of strongly acid centres (including mobile protons) on the surface of these catalysts. Several studies of the acidity of these surfaces have been reported.[75–81] Information on the overall acidity of the catalysts can be obtained from titrations of the molybdenum oxides with *n*-butylamine[76, 77] and from their heats of immersion in pyridine.[75] However, results from different laboratories are usually inconsistent.

According to Parsons and Ternan[76] the acidity of Al–Mo catalysts increases monotonically with the molybdenum content form 2 to 30 wt.% of MoO_3, whereas Ragaini et al.[75] observed a non-monotonic change in the acidity with the content of MoO_3: samples containing 8 and 25 wt.% corresponded to maxima in the acidity. The maximum near 8 wt.% of MoO_3 was attributed[75] to the formation of the protonated $(HMoO_4)^{2-}$ and $(H_2Mo_2O_7)^{2-}$ [or $MoO(OH)^{2+}$] surface structures. At high concentrations (25 wt.% MoO_3) the acidity maximum was interpreted as the formation of $Mo_4O_{10}(OH)_2$ structures,[75] including the Mo^{5+} and Mo^{6+} ions. The decrease in the acidity at low concentrations (up to 4 wt.%) of MoO_3 is explained by the complete neutralisation of the most basic centres in the Al_2O_3 upon the addition of molybdenum. In the catalysts containing more than 27 wt.% of MoO_3 acid centres with H_0 between 6.8 and 3.3 were observed, and in catalysts containing less than 12.5 wt.% of MoO_3 the acid centres had $H_0 < 3.3$ (see Parsons and Ternan[76]).

Spectral studies of the acidity of Al–Mo catalysts by the pyridine adsorption method[78–81] have established the presence of both Lewis and Brønsted acid centres on the surface of these catalysts. The relative concentration of BAC increases with the concentration of molybdenum (from 9 to 25 wt.% of MoO_3),[78] and also when the catalyst is treated with water. Shmidt and coworkers showed[58] that Al–Mo catalysts have two types of BAC, characterised in the IR spectra of adsorbed ammonia by bands at 1450 and 1430 cm^{-1}, the band at the lower frequency being assigned to a compound containing octahedrally coordinated molybdenum ions. Unfortunately the nature of this compound was not established.

We have reported a study[11, 82] aimed at identifying the mutual relationship between the acidity (determined mainly by the BAC) and the formation of postulated molybdenum compounds on the carrier.

In an IR spectroscopic study of the adsorption of ammonia on 25% $MoO_3-Al_2O_3$ catalysts, for which the formation of a heteropoly molybdate had been established, we observed a large number of proton acid centres on the catalyst surface.[82] Kiviat and Petrakis[78] showed that these centres are due to the presence of heteropoly molybdate acidic compounds. Since treating the catalyst with water, which removes the polymolybdate from the surface, greatly lowers the concentration of BAC on the surface of the sample, the proton acidity of the 25% $MoO_3-Al_2O_3$ catalyst can be attributed to the formation of a water-soluble molybdenum compound on the Al_2O_3 surface. As was said above, this acidic compound could be a heteropoly compound of molybdenum and aluminium. The acidic centres (BAC) of these catalysts are relatively strong and can protonate propene, toluene, and ethylene molecules.[82]

Thus an analysis of the extensive published information shows that the formation of various compounds on the Al_2O_3 surface as a result of the deposition of a molybdenum oxide layer is determined by many factors of which the most important are the conditions and the methods used in the preparation of the catalytic system.

The formation on the Al–Mo catalysts of molybdenum ions in the tetrahedral and the octahedral coordination, in relative numbers depending on the composition and on the preparative conditions of the catalysts, is now fairly reliably established. The molybdenum ions in the tetrahedral coordination are present either as isolated MoO_3 units in the monolayer coverage of samples with a low molybdenum content or as aluminium molybdate at high molybdenum concentrations. In samples with a high molybdenum concentration (more than 10 wt.% of Mo) Al–Mo heteropoly compounds are formed on the surface in addition to the MoO_3 phase and to aluminium molybdate: these retain their polyanionic structure up to 773 K as a result of the interaction with the carrier, and are responsible for the strong proton acidity of these catalytic systems.

2. Formation and identification of Si–Mo oxide compounds

We shall assume that the chemical reactions in the Mo/SiO_2 system caused by the deposition of the active component are confined (at least, at low molybdenum concentrations) to the surface, and that bulk phases are not formed.† The state of the molybdenum ions in this system was studied by various methods, (mainly by optical, electronic, and ESR spectroscopy). Most of these studies were aimed at the local suroundings of the molybdenum ions (mainly because of the nature of the chosen methods).

The most important and complex problem seems to be to establish the relationship between the coordination state of the ion

† There are no reports of the formation of silicon molybdates or of solid solutions. The MoO_3 phase is usually observed only for high surface concentrations of molybdenum.

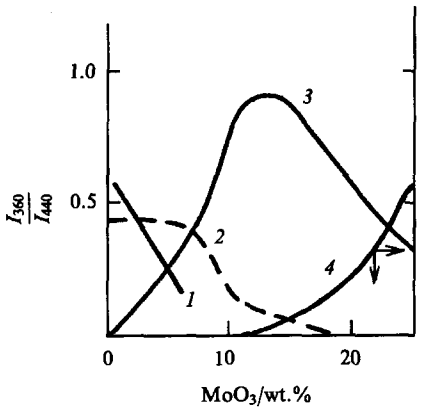

Figure 6. Distribution of the products in MoO_3/SiO_2 as a function of composition, established by titrations of: *1*) dimolybdates (DM), *2*) molybdosilicic acid (MSA), *3*) polymolybdates (PM). The proportion of MoO_3 (in relative units) was determined from the intensity ratio of the IR reflectance bands at 360 and 440 cm^{-1}.

and the type of chemical compound formed on the carrier. XPA is the method traditionally used to solve this problem. However, as in the case of the Mo/Al_2O_3 system, it is applicable only at high concentrations of molybdenum, and therefore vibrational spectroscopy plays an important role[9] in studies of the structure of the molybdenum compounds formed on the surface of SiO_2.

The coordination state of molybdenum at low concentrations was studied by ESR and UV spectroscopy.[83-85] The formation of tetrahedrally and of octahedrally coordinated molybdenum ions was observed. The coordination state of molybdenum was identified from the ESR spectra of Mo^{5+} (used as a paramagnetic probe) on the basis of the correspondence (well established in coordination chemistry) between the structure of the complex and the parameters of the ESR spectra.[86-88] The ESR results agree well with those of diffuse reflectance spectroscopy.[83, 84]

At low molybdenum concentrations tetrahedral molybdenum ions are found on the SiO_2 surface irrespectively of the method of preparing the catalyst. At higher concentrations octahedral molybdenum ions are usually formed as well as tetrahedral ions. However, there also reports of molybdenum ions in the two coordination states in a 1 : 1 ratio at low enough surface concentrations of molybdenum (0.1 Mo atom per 1 nm^2).[85] Whereas the tetrahedrally coordinated molybdenum ions are present as isolated ions in structures of the dimolybdate and MoO_3 type, the nature of the compounds in which the molybdenum is octahedrally coordinated is still problematic.

Castellan et al.[96] studied the Si–Mo system over a wide range of molybdenum concentrations by using a combination of physicochemical methods: XPA, optical spectroscopy, electron microscopy, acidometric titration, etc. From the results they constructed the phase diagram of molybdenum[96] as a function of the molybdenum content of the catalyst (Fig. 6). That work led to the suggestion that the molybdenum is present on the catalyst surface as isopoly and/or heteropoly acids, i.e. that it has a distorted octahedral coordination. In subsequent papers[97, 98] the same workers discussed the catalytic properties of the system towards propene disproportionation and oxidation reactions, and examined a scheme for the formation of products on different active centres.

Mo–Si oxide systems containing between 1 and 20 wt.% of Mo have been studied[9, 88, 89] by ESR and IR spectroscopy. The results were used to correlate the octahedral coordination of molybdenum with the formation of heteropoly compounds. By comparing the results of ESR studies of the state of the molybdenum as a function of the formation temperature of the sample it was concluded[88] that identical changes in the state of the molybdenum take place in the supported Si–Mo-HPA and in the molybdenum oxide catalyst synthesised on the SiO_2 surface (the anisotropic signal denotes stabilisation of the molybdenum in a distorted octahedral coordination of C_{4v} symmetry).

An identification by IR spectroscopy of the types of surface formation on silicon dioxide has been reported.[9] By comparing the IR spectra of SiO_2, MoO_3, and Si–Mo-HPA, and also Si–Mo-HPA supported on SiO_2, it was concluded that the most characteristic absorption bands of these compounds do not overlap (Fig. 7), thus allowing the molybdenum compounds to be identified spectroscopically even at low concentration on the SiO_2 surface. Since the strongest absorption for Mo_{12}-HPA (the Keggin structure) was observed at 700–1100 cm^{-1} and the low-frequency absorption bands are much weaker the absorptions above 700 cm^{-1} were mainly used in the identification of the HPC.

The IR spectrum of the Si–Mo oxide catalyst containing more than 5 wt.% of MoO_3 as the active component, prepared by impregnating SiO_2 with ammonium paramolybdate and drying it at 383 K (spectrum *5* of Fig. 7), was very similar to the spectrum of Si–Mo-HPA supported on SiO_2 (in which the observed absorptions cannot be assigned to ammonium paramolybdate, whose spectrum is also shown in Fig. 7 as spectrum *4*). This suggests the possible formation of Si–Mo-HPA on the SiO_2 surface.[9] Heating this system to 773 K has almost no effect on the form of the spectra (spectrum *6* of Fig. 7), showing that the heteropoly anions are retained on the SiO_2 surface up to quite high temperatures whereas the supported Si–Mo-HPA begins to decompose at 573 K. In the spectrum of the latter sample obtained by compensating for the spectrum of the carrier (spectrum *7* of Fig. 7) weak absorption bands characteristic of trace quantities of the MoO_3 phase are observed in addition to the absorption bands of the HPA. Heating the catalysts at 873 K lowers the intensity of the absorption bands characteristic of HPA and increases that of the MoO_3 bands. After heat treatment at 973 K only the MoO_3 bands can be seen.

Thus an analysis of the spectra of Si–Mo catalysts has shown that the interaction of ammonium paramolybdate with silica produces Si–Mo-HPA, whose thermal stability is higher than that of the heteropoly acid, both individual and supported on SiO_2.[9]

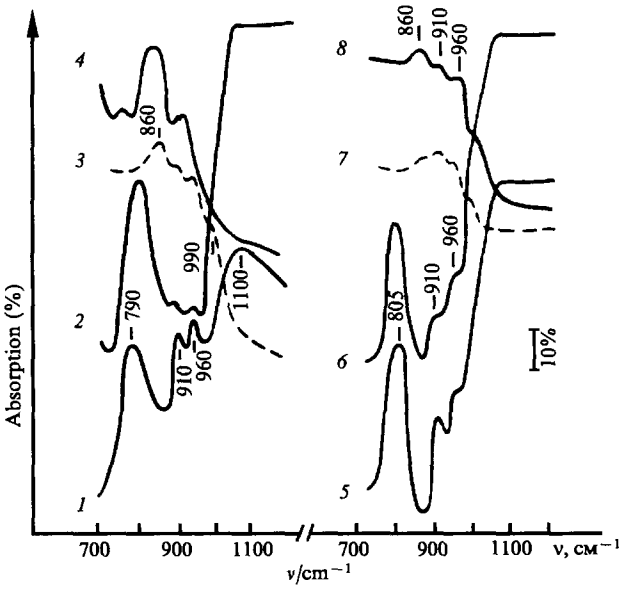

Figure 7. IR spectra of HPA/SiO_2 (spectra *1–3*), ordinary (*1*) and dehydrated at 573 K (*2*) and 673 K (*3*), of ammonium paramolybdate (spectrum *4*) and of a Si–Mo catalyst (spectra *5–8*) dried at 383 K (*5*) and dehydrated at 773 K (*6*, *7*) and 873 K (*8*). The spectra *3*, *7*, and *8* were obtained with compensation of the SiO_2.

Acidic properties. As was pointed out above, a distinguishing feature of the heteropoly acids is their proton acidity. Therefore in order to identify the type of compound formed on the surface of the carrier it is important to establish the nature of the mobile protons.

Studies[9, 91-94] of the acidic properties of Si–Mo oxide catalysts have confirmed the formation of a strong acid.

The IR spectra of ammonia adsorbed on both the HPA/SiO_2 and the Si–Mo catalyst dehydrated at 473 K show the formation of NH_4^+, i.e. the presence of mobile protons on the surface of these samples.[9] Raising the dehydration temperature of the sample from 473 to 573 and 873 K suppresses the intensity of the NH_4^+ absorption bands (as in the case of HPA/SiO_2) by lowering both the number and the strength of the BAC.[9]

The adsorption of ammonia on a Si–Mo catalyst hydrated after being heated to temperatures at which the heteropoly anions are not removed also denotes the presence of BAC. On the other hand after the complete breakdown of the heteropoly acid on the SiO_2 surface after heat treatment at 973 K the ammonium ion is not observed in the spectrum of ammonia adsorbed on the sample rehydrated after decomposition of the polyacid, i.e. in this case the hydration–dehydration processes are irreversible.[9]

Electron defect centres have also been observed on the surface of the Si–Mo system.[95] Thus, the adsorption of aromatic polycyclic hydrocarbon molecules on these catalysts is accompanied by electron transfer from the hydrocarbon to the molybdenum, which forms the corresponding cation radicals and reduces the Mo^{6+} to Mo^{5+}.

It should not be forgotten that an HPA which is thermally stable up to 773 K is formed on the Si–Mo catalysts in addition to MoO_3. This high stability can be attributed to the chemical interaction of the HPA with the carrier (~85–90% of the added molybdenum interacts with the surface according to the chemical analysis results). The thermal stability of this HPA is substantially higher than that of the bulk compound. The presence of mobile protons is associated with the presence of a Si–Mo-HPA on the carrier surface also in this system. The concentration of the protons depends on the degree of hydration of the heteropoly acid.

3. Formation and identification of Ti–Mo compounds

The physicochemical and catalytic properties of Mo/TiO_2 catalysts are largely determined by the method of preparation.[99-102] Catalysts having different phase compositions can be prepared. Thus, in the synthesis of Ti–Mo catalysts by the coprecipitation of molybdenum and titanium oxides, solid solutions based on titanium dioxide are formed. However, the situation is complicated by the formation of two modifications of TiO_2 under these conditions: anatase and rutile.[102, 103] A solid solution of molybdenum oxide in anatase is obtained when ammonium paramolybdate is added to titanium hydroxide paste.[101] The stability of molybdenum is fairly high: up to 25–30 wt.% of MoO_3. The formation of a solid solution is inferred from the abnormally high lattice parameters[104] of the TiO_2 phase, due to the difference in size of Ti^{4+} (r = 0.64 Å), Mo^{6+} (r = 0.66 Å), and Mo^{5+} (r = 0.65 Å). When the Mo–Ti catalyst was prepared by the impregnation of anatase with molybdic acid at low concentrations of Mo only the anatase phase was detected by X-ray diffraction (phases containing Mo could not be detected), and at high concentrations the MoO_3 phase was detected. In the synthesis of a Mo–Ti catalyst from molybdenum tartrate complexes an X-ray amorphous form was obtained.[101]

The effect of the pH used to precipitate the titanium hydroxide on the phase composition of the resulting Mo–Ti catalyst has been studied.[102] However, it was pointed out[89] that the measurements in the region of pH < 1.4 cannot be correct since titanium hydroxide is deposited at pH > 1.4 (see Goroshenko's monograph[103]). A detailed examination[87] of the influence of the method of preparation of the catalyst on the phase composition and on the state of the molybdenum ions showed that the presence of added ions favours the low-temperature formation of rutile and the stabilisation of the molybdenum on the lattice sites and in the interstitial positions of rutile. Molybdenum ions with an octahedral coordination stretched along the tetragonal axis are found in the lattice positions, whereas the interstitial ions are compressed along the same axis. In a catalyst prepared at a high pH without added ions the phase composition was found to depend on the total concentration of added molybdenum.[102]

For molybdenum concentrations up to 25–30 wt.% MoO_3 a solid solution based on TiO_2 is observed by X-ray diffraction. At high molybdenum concentrations MoO_3 is formed in addition to the solid solution. The XPA results were confirmed by IR spectroscopy.[104, 105] It was found that the IR spectrum of the solid solution is almost indistinguishable from the spectrum of titanium dioxide in the region of its characteristic vibrations.

It was also reported[105] that the surface composition of the Ti–Mo oxide catalyst (like that of the Sn–Mo oxide catalyst) differs markedly from the bulk composition by being more enriched in molybdenum. The IR spectrum of this surface layer also differs from the spectrum of the solid solution by the presence of bands characteristic of a compound containing molybdenum. It should be noted that a high proton acidity of the molybdenum compound formed on the surface of the TiO_2 support for concentrations of the active component greater than 5 wt.% of MoO_3 has been reported.[105, 106] This molybdenum compound is the active component (at least, in the oxidation of propene to acetone). However, the compound has not been identified.[105]

By using a combination of different methods (XPA, ESR, and IR spectroscopy) an attempt was made[10] to establish the phase composition of Ti–Mo oxide catalysts prepared by adding ammonium paramolybdate (APM) to a paste of titanium hydroxide and heating the product at 723 K (series A) or by impregnating TiO_2 (anatase) with a solution of APM and heating the product at 723 K (series C). In both cases an anatase phase with lattice parameters identical to those given in the literature was identified by XPA. In the series A catalysts the lattice constants of the anatase increased with the molybdenum content, pointing to the formation of a solid solution. No other phases were observed for Mo concentrations between 1 and 25 wt.% under these conditions. For molybdenum concentrations above 25 wt.% a MoO_3 phase was observed. In the series C catalysts there was no increase in the lattice parameters of anatase when the molybdenum content was increased. Adding 15 wt.% or more of Mo led to the formation of a MoO_3 phase. In this respect the most interesting samples are those of series C containing up to 15 wt.% of Mo, in which phases containing molybdenum are not detected by X-ray diffraction.

A detailed study of the IR and ESR spectral parameters of Ti–Mo oxide systems and of their changes in dehydration–rehydration processes at different temperatures, and a comparison of these spectra with those of Ti–Mo-HPA supported on TiO_2, showed[107, 108] that Ti–Mo-HPA (stable up to 723 K) is formed on the surface during the synthesis of Ti–Mo oxide catalysts. A similar state of affairs exists for the Si–Mo oxide system.

Thus in the Ti–Mo oxide catalysts prepared by adding APM to a paste of titanium hydroxide (series A) several phases are produced, depending on the molybdenum content: a solid solution of molybdenum in TiO_2, Ti–Mo-HPA, and MoO_3. For molybdenum concentrations below 10 wt.% almost the whole of the added molybdenum dissolves in the anatase to give a solid solution. Increasing the concentration of molybdenum in the catalyst results in the formation of new phases on the surface of the solid solution: Ti–Mo-HPA and MoO_3. As the concentration of molybdenum in the catalyst is increased still further the concentration of these phases increases.

In the Ti–Mo catalysts prepared by impregnating anatase with a solution of APM (series C) and heating the sample at 723 K Ti–Mo-HPA is formed for molybdenum concentrations lower

than 15 wt.%, but at higher concentrations MoO_3 is found as well as the HPA. The heteropolymolybdic acid thus obtained has a high thermal stability (up to 723 K).

Acidic properties. The HPA found on the surface of the Ti–Mo oxide catalysts is responsible for their Brønsted acidity.[10] The strong acidity of this type of catalyst and its role in the catalytic reactions have long been recognised,[101, 109–112] even before the formation of a HPA on the catalyst surface had been established.

IV. Thermal stability of molybdenum compounds, decomposition mechanism, role of modifiers

We shall now dwell on two problems directly related to the problems discussed above: the changes induced in the HPC by changes in temperature and the influence of the reaction medium on these changes.

1. Massive and supported heteropoly acids

We shall discuss these problems in terms of the most widely known HPA: molybdophosphoric and molybdosilicic.

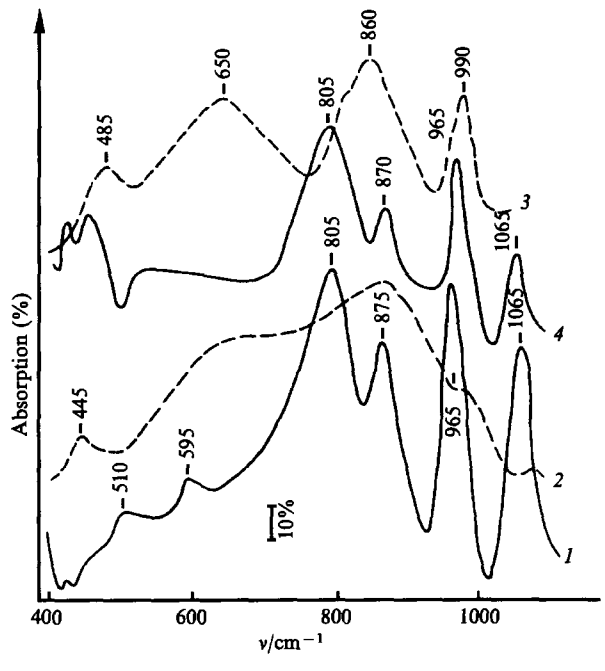

Figure 8. IR spectra of P–Mo-HPA heated at different temperatures: *1*) 673, *2*) 723, *3*) 773 (spectrum *4* relates to hydrated P–Mo-HPA heated at 723 K).

Table 2. Absorption bands in the IR spectra (700–1100 cm^{-1}) of Mo_{12}-HPC (the Keggin structure).

Si–Mo-HPA		P–Mo-HPA		NH_4-salt Ti–Mo-HPA
Ref. 113	Ref. 16	Ref. 113	Ref. 16	Ref. 113
999		1074	1070	1072
960	963	968	972	970
909	915	911		908
859	890	869	882	868
782	782	795	790	790

As was stated above, the IR spectra of Mo_{12}-HPA (the Keggin structure) are typical (Table 2), and those of P–Mo-HPA at 700–1100 cm^{-1} are characterised by strong absorption bands at 805, 875, 965, and 1065 cm^{-1} (Fig. 8). Heating the HPA for 2 h in a stream of air at 673 K does not change the contour of the spectrum, showing that the structure of the Keggin anion is retained. After thermal conditioning of the HPA at 723 K the intensity of the characteristic absorption bands of the HPA decreases rapidly and the shape of the spectrum changes: absorption bands appear at 445 cm^{-1} and in the 700–900 cm^{-1} range, with a maximum at 870 cm^{-1}. Subsequent treatment of the sample with water regenerates the HPA, as shown by the absorption bands at 805, 870, 965, and 1065 cm^{-1} in the spectrum of the hydrated sample (Fig. 8).

According to XPA results the sample heated at 723 K is a mixture of two phases: MoO_3 and a phase with a structure similar to that of Mo_4O_{11}. The MoO_3 phases persists after the treatment with water, but we see a change in the relative intensity of the main diffraction lines on the diffraction pattern of the hydrated sample. The phase with the Mo_4O_{11} structure disappears after the treatment with water.[67]

According to ESR results the state of the molybdenum ions is not markedly affected by heating the sample at 723 K: the molybdenum ions have distorted octahedral surroundings of oxygen atoms, similar to their surroundings in the HPA. In Mo_4O_{11} most of the molybdenum ions also have octahedral surroundings.

In the IR spectrum of the sample heated at 773 K we find absorption bands at 820, 865, and 1000 cm^{-1}, characteristic of MoO_3. After treating the sample with water we find a phase of P–Mo-HPA, and the MoO_3 phase cannot be detected by IR spectroscopy (it can be identified only by XPA).

By comparing the XPA and IR spectroscopy results we reach the following conclusions. After heat treatment of the P–Mo-HPA at temperatures below 623 K the structure of the Keggin anion is retained, whereas heating at 773 K and above causes breakdown of the anion structure and the formation of oxides. In the intermediate temperature region we observe a rearrangement of the Keggin anion with formation of a heteropoly molybdate (poly-oxide) with a structure similar to that of Mo_4O_{11}. We should stress the fact that the similarity between MoO_4 and the poly-oxide (which we shall call a P–Mo-anhydride) lies in their very close structure types, while their chemical natures are quite different. During the hydrolysis the heteropoly molybdate is rearranged into an anion with the Keggin structure, i.e. the process is reversed.

Allowing for these results the process induced by the heat treatment of P–Mo-HPA can be described by the scheme

$$\text{HPA} \leftrightarrows \text{P–Mo-anhydride} \rightarrow MoO_3 + P_2O_5 .$$

It follows from these results that in the region of 723 K the treatment with water produces a reversible rearrangement of the heteropoly anion into a phosphorus–molybdenum anhydride with a structure of the Mo_4O_{11} type. At 773 K this P–Mo-anhydride (poly-oxide) decomposes with formation of MoO_3. The dissociation of the heteropoly anion with an intermediate formation of a compound having the Mo_4O_{11} structure has been reported[18] for several HPA and their salts. It is interesting to note that the addition of water to the anhydride produces the HPA, whence it follows that the poly-oxide is a dehydration product of the HPA, and also that the coordination of the molybdenum ion is not significantly changed in the transition from the heteropoly anion to the poly-oxide: the distorted octahedral coordination is retained. As a result the reducibility of the molybdenum ions is the same in the HPA and in the poly-oxide.

The reduction temperatures of the Mo^{6+} ions to Mo^{5+} by hydrogen (with the corresponding temperatures for the reduction by atomic hydrogen shown in brackets) are listed below for some HPA, for phosphorus–molybdenum poly-oxide, and (for comparison) for MoO_3.

System	T/K
Si–Mo-HPA/SiO_2	373 (300)
Si–Mo-HPA	373 (300)
P–Mo-HPA	373–423
MoO_3	623

As can be seen, the poly-compounds are reduced at the same temperatures, which are much lower than the reduction temperature of MoO_3.

Similar results have been reported for supported systems.[67]

A study by IR spectroscopy and XPA of the change in phase composition as a function of the heating temperature of the P–Mo-HPA supported on SiO_2 showed that after being conditioned at 673 K the sample consists of a mixture of phases: HPA (the principal phase) and anhydride. Increasing the heating temperature to 723 K increases the content of heteropoly molybdate in the sample, and also produces a phase of molybdenum oxide. Therefore the rearrangement of the Keggin anion continues at 723 K. As in the case of massive HPA the heteropoly molybdate phase disappears during the subsequent hydrolysis, and the MoO_3 phase undergoes changes probably due to its texturing by the action of the water. After heat treatment at 773 K the structure of the anion is completely broken down (according to XPA results), and molybdenum oxide is formed: in other words we observe (on the whole) the same stages in the thermal dehydration of P–Mo-HPA supported on SiO_2 as in the dehydration of the massive HPA.

An analysis of the changes in the spectra of supported Si–Mo-HPA during heat treatment shows that above 673 K (or 573 K for the massive HPA) the compound dissociates with formation of MoO_3, as indicated by the appearance of new absorption bands at 860 cm^{-1} ($\nu_{Mo-O-Mo}$) and 990 cm^{-1} ($\nu_{Mo=O}$), which are the most characteristic lines in the MoO_3 spectrum, whereas the appearance of absorption bands in the region of 1100 cm^{-1} denotes the presence of SiO_2 (spectrum 2 of Fig. 7).[29] The complete decomposition of the supported Si–Mo-HPA with formation of MoO_3 and SiO_2 is observed at 773 K: in this case the IR spectrum is a superposition of the spectra of the individual MoO_3 and SiO_2. Thus, in spite of the fact that the deposition of the Si–Mo-HPA increases its thermal stability in comparison with the massive HPA, the nature of the transformations during the thermal conditioning is unchanged.

It should be noted that it has not yet been possible in this case to identify the intermediate compound (anhydride) from the IR spectra (the difficulty being even greater for the Si–Mo oxide catalysts) because of the low intensity of the characteristic absorption bands.[114] However, as in the case discussed above for P–Mo-HPA the spectral changes caused by hydration are reversible up to a dehydration temperature of 773 K for the Si–Mo oxide systems.

Modified catalysts. As has already been pointed out, modifiers are often added to complex catalysts containing molybdenum: for example, phosphorus (in the form of orthophosphoric acid).[115–117] The modifier alters the catalytic properties of the system. However, the role of the phosphorus is still unclear in most cases. There are reports of the formation of surface phases containing phosphorus and molybdenum during the modification by phosphorus,[115–118] i.e. the effect of phosphorus additions can be attributed to chemical changes leading to the formation of P–Mo-HPA and its salts, since the addition of orthophosphoric acid provides an element capable of acting as hetero-atom as well as lowering the pH of the medium.

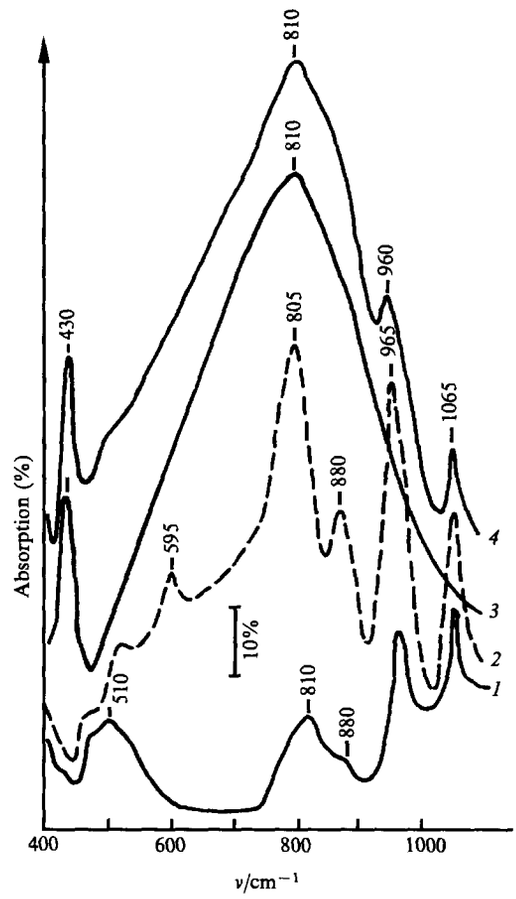

Figure 9. IR spectra of P–Mo-HPA (*1*), $CaMoO_4$ (*2*), and P–Mo-HPA supported on $CaMoO_4$ (*3* and *4*). For comparison we show the spectrum of P–Mo-HPA supported on $CaMoO_4$ taken with compensation for the molybdate absorption.

The possibility of forming P–Mo-HPA by modifying calcium molybdate with orthophosphoric acid has been investigated.[67] Bands at 800–900 cm^{-1}, characteristic of the HPA, were not seen in the IR spectrum of P–Mo-HPA supported on $CaMoO_4$, measured on a background of molybdate absorption (Fig. 9). Only the absorption bands at 960 and 1065 cm^{-1}, characteristic of the Mo = O vibrations and of the vibrations of the central PO_4 tetrahedron in the HPA anion respectively, are clearly seen (spectrum *4* of Fig. 9). The spectrum of supported HPA (with compensation for the absorption of the carrier) is indistinguishable from that of the massive HPA (spectrum *1* of Fig. 9), i.e. these results show that the P–Mo-HPA on the surface of $CaMoO_4$ can be identified reliably from the IR spectra.

The introduction of a superstoichiometric amount of molybdenum into $CaMoO_4$ by treating it with a solution of ammonium paramolybdate and heating the product at 773 K leads to the formation of a MoO_3 phase (Fig. 10). In this case, in addition to an absorption band at 430 cm^{-1} and a strong absorption in the 600–860 cm^{-1} region, characteristic of the molybdate, we find absorption bands at 475, 610, 820, 860, and 995 cm^{-1}, characteristic of molybdenum oxide (spectrum *2* of Fig. 10). By using the compensation procedure we can generate a spectrum for $CaMoO_4$ exactly similar to the initial spectrum, thus confirming that the symmetry of the molybdenum in $CaMoO_4$ is not affected by the addition of a superstoichiometric amount of MoO_3, i.e. indicating the formation of an individual phase of MoO_3. A similar effect has been observed in magnesium molybdate containing superstoichiometric MoO_3.[119]

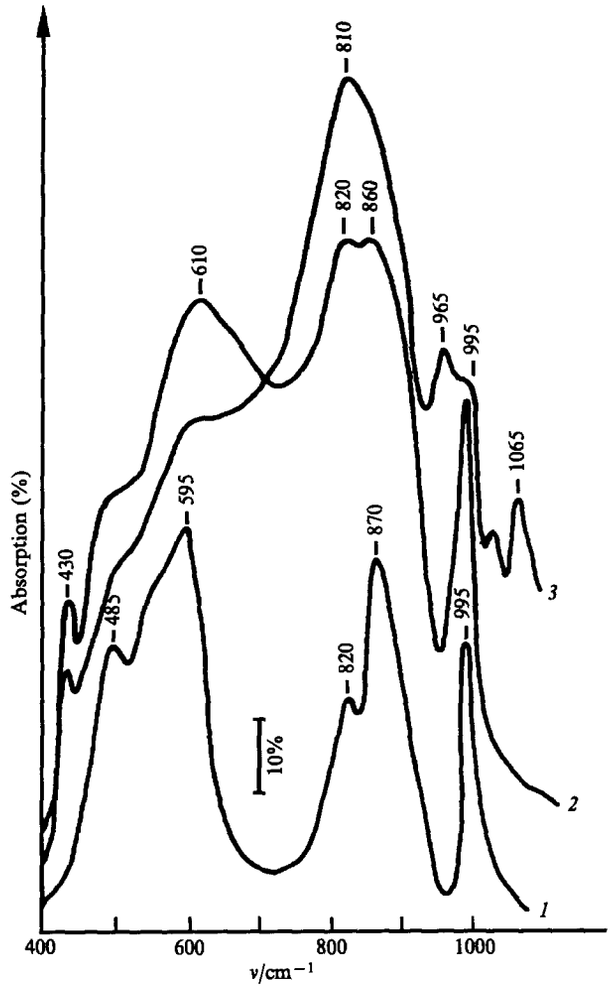

Figure 10. IR spectra of MoO_3 (*1*) and of $CaMoO_4$ modified by 10 wt.% of molybdenum (*2*); *3*) is the spectrum of the same sample after the addition of phosphorus.

Treating a $CaMoO_4-MoO_3$ catalyst with a solution of orthophosphoric acid produces substantial changes in the IR spectrum. The MoO_3 absorption band becomes weaker, and new absorption bands appear at 965 and 1065 cm^{-1} (spectrum *3* of Fig. 10). As was pointed out above, these bands are characteristic of P–Mo-HPA supported on molybdate.

Heating the catalyst at 623 K does not change the shape of the spectrum, confirming that the HPA is stable at this temperature. The absorption bands of the HPA are completely suppressed (i.e. the anion structure is broken down) only after heat treatment of the catalyst at 673 K.

Thus the modification of calcium molybdate with a superstoichiometric molybdenum content by treatment with phosphoric acid produces a P–Mo heteropoly acid stable up to 623 K.

V. Conclusions

The review of published data has shown that vibrational spectroscopy methods, now widely used in studies of the molecular structure of heteropoly compounds, can also be used successfully to identify these compounds when supported on carriers and when forming compounds on the carriers during the preparation of supported catalysts containing molybdenum and tungsten. We have not dwelt in detail on the interpretation of the spectra of HPC because this topic is already adequately reviewed.[13, 15–17, 24] However, it should be noted that in complex molecules a complete analysis of the normal vibrations is too laborious, and the absorption bands are usually assigned in the approximation of group vibrations.[16]

In the Keggin heteropoly anion we identify groups of atoms whose vibrations are not significantly influenced by the vibrations of the other atoms: 12 terminal Mo=O double bonds, 12 almost linear and 12 bridging Mo–O–Mo bonds, and 12 simple M–O bonds in which the oxygen atoms are shared by three molybdenum atoms and by the central hetero-atom.

It is generally accepted[16, 17] that the stretching vibrations of the bridging Mo–O–Mo bonds are observed in the 900–800 cm^{-1} region, and the vibrations of the Mo–O bonds below 600 cm^{-1}. Bands below 300 cm^{-1} are assigned to bending vibrations of the anion skeleton. The vibrations of the central tetrahedron appear at 1100–800 and at 600 cm^{-1}. The vibrations of the Mo=O bond appear at 900–1000 cm^{-1}.

The IR spectra of the Mo_{12}-HPA (the Keggin structure) are characteristic and can be used to identify the molecular structure of the heteropoly compounds.

We have shown that the Mo_6-HPC, in which the central atoms are transition metal ions (copper, cobalt, iron), are unstable. Strong chemical interactions with the carrier take place when these compounds are supported.

The observed influence of the acid–base properties of the carrier on the rearrangement of the heteropoly anion when supported is of great importance. On SiO_2 the Mo_6-HPA are converted into mixed Si–Mo_{12}–M-HPC, in whose coordination sphere the transition-metal cations replace the molybdenum ions. When supported on aluminium oxide the copper, cobalt, and iron heteropoly molybdates are converted into aluminium compounds (by reacting with the surface ions of the carrier).

The Mo_{12}-HPC are stable on SiO_2 and TiO_2 surfaces, but on Al_2O_3 they decompose (when at low concentrations) and they form Al–Mo_6-HPC at high concentrations.

This detailed review of the processes taking place on the surface of TiO_2, SiO_2, Al_2O_3 carriers during the formation of supported molybdenum catalysts has demonstrated the possibility of using vibrational spectroscopy in the identification of the compounds formed on the carrier surface and in establishing their origin.

Spectral criteria for the identification of HPC on carriers (even with inadequate spectral information) have been formulated, and they can be used to obtain reliable information on the resulting compounds. It was established that far-reaching interactions between the active component and the carrier usually take place, leading to the formation of new compounds. We have also examined the formation of different types of HPC on the carrier surface, depending on the acid–base properties of the carrier.

A detailed comparative analysis of published data on the occurrence of acidic properties (at least for the case of proton acidity) in these catalysts and supported HPC has shown that strong proton acidity is a necessary criterion for the formation of HPC on carrier surfaces during the preparation of catalysts.

Extensive evidence is now available of the important role of surface centres of this type (and of the role of the HPC formed on the surface of carriers) in catalytic processes.[3, 54, 67, 89, 106, 110, 120–124] It has been reported[67] that at least in some processes (for example, in the oxidation of propene and of methanol) the HPC are retained on the surface after its interaction with the reaction medium at the temperature and other conditions of the catalytic reaction.

The study of the decomposition of massive and of supported HPA has revealed the formation of acid anhydrides during their dehydration, and their reversible conversion into the initial HPC by hydration.

The possibility of forming HPC on the surface of molybdates with a superstoichiometric molybdenum content during their modification with acids (for example, phosphoric) has been demonstrated.

Electrochemistry of diarenechromium complexes

L P Yur'eva, L N Nekrasov, S M Peregudova

Contents

I. Introduction 121
II. Electrochemical oxidation and reduction processes in the $Arene_2Cr^{+/0}$ and $Arene_2Cr^{2+/+}$ systems 122
III. Cathodic reduction of diarenechromium(0) complexes 131
IV. Characteristic features of the change in the reactivity of arenes under the influence of coordination to a chromium atom in one-electron transfer reactions 138

Abstract. The results of studies on the anodic oxidation and cathodic reduction of diarenechromium complexes are surveyed. The mechanisms of the multistage reactions involving the electrochemical reduction of the complexes are examined. Two aspects of their reactivity are analysed — the nature of the transmission of the electronic effect of substituents in the ligands to the reaction centre and the change in the properties of aromatic compounds as a result of the formation of a complex with a chromium atom. The bibliography includes 133 references.

I. Introduction

A characteristic property of transition metal π-complexes is their ability to enter into oxidation and reduction reactions. Such compounds can exist as neutral molecules and as ions. This is mainly associated with the possible occurrence of different oxidation states of the central metal atom, while the nature of the organic ligands remain unchanged. If the latter are also capable of undergoing oxidation – reduction reactions, the range of redox reactions involving π-complexes is significantly expanded.

The knowledge of the characteristic features of redox processes makes it possible to predict the reactivity of organometallic compounds in different chemical reactions. Electrochemical methods proved to be most effective in the study of redox processes. The high accuracy of the measurement of electrical quantities and the sensitivity of the electrochemical process characteristics to changes in the electronic structure of the molecules ensure a rigorous quantitative level of the investigation.

Received 27th December 1992
Uspekhi Khimii **62** (2) 135 – 156; translated by A K Grzybowski

The problem of the reactivity of transition metal π-complexes of a particular type includes two important tasks: the study of the influence of the nature of organic ligands and of their substituents on the reactivity of the complexes and the determination of the nature of the change in the properties of the organic molecule as a result of its coordination to the metal atom. In relation to redox processes, the first task can be carried out by finding the standard potentials E_0 as a function of the nature and number of substituents in the ligands of the complex. In practice, instead of thermodynamic quantities E_0, use is usually made of the half-wave potentials $E_{1/2}$ of reversible electrochemical reduction or oxidation reactions of the corresponding complexes. The quantities $E_{1/2}$ are determined from polarisation measurements. Different types of polarography, voltammetry at rotating electrodes, cyclic voltammetry, and other methods are used for this purpose. The values of $E_{1/2}$ quoted in the literature do not as a rule include a correction for the interfacial potential jump at the liquid/liquid boundary, arising at the point of contact between solutions of different compositions. The lack of reliable information about the interfacial potential jumps hinders the comparison of the results obtained for the same system in different solvents. The occurrence of interfacial potential jumps as well as the possible differences in the capacities for solvation of the components of the oxidation – reduction system as a function of the nature of the solvent lead to different values of $E_{1/2}$ measured in different solvents relative to the same reference electrode. However, the above effects are not important if all the measurements for the test series of compounds are carried out in the same solvent under identical experimental conditions.

One of the most important problems in the chemistry of transition metal π-complexes is that of the influence of the coordination of the organic molecule to the transition metal atom on the properties of the former. In order to discover the general features of the effect of complex formation on the reactivity of the 'ligand', a comparative study of the electrochemical behaviour of a group of non-coordinated organic compounds and their π-complexes is carried out.

Among transition metal π-complexes, diarenechromium complexes occupy a special place. The discovery of dibenzenechromium and the determination of its sandwich structure[1,2] played an extremely important role in the establishment and development of modern organometallic chemistry. The characteristic features of the structure of complexes of the dibenzenechromium series, namely the presence of ligands of only one type, their aromatic nature, their ability to exist in a non-coordinated state, the formally zero valence of the

central metal atom in the uncharged complexes, as well as the reversibility of the electron transfer stages in the $Arene_2Cr^{+/0}$ and $Arene_2Cr^{0/-}$ systems render diarenechromium complexes exceptionally convenient for the solution of general problems of the reactivity of transition metal π-complexes.

A wide variety of redox processes, occurring both with retention of the sandwich structure and leading to its disruption, are characteristic of diarenechromium complexes:

$$2Arene + Cr^{3+} \overset{-\bar{e}}{\leftarrow} Arene_2Cr^{2+} \overset{-\bar{e}}{\leftrightarrows} Arene_2Cr^{+} \underset{+\bar{e}}{\overset{-\bar{e}}{\rightleftarrows}}$$

$$\leftrightarrows Arene_2Cr \underset{-\bar{e}}{\overset{+\bar{e}}{\rightleftarrows}} Arene_2Cr^{-} \xrightarrow{+m\bar{e}} \text{products.} \qquad (1)$$

Neutral complexes and singly charged paramagnetic cations are stable while the doubly charged cations and the radical-anions are unstable. Their formation in the course of the reaction has been demonstrated by electrochemical methods and EPR.

Chromium complexes are the only ones among the diarene π-complexes of Group VIA metal complexes whose electrochemistry has been investigated in fair detail. The electrochemical behaviour of molybdenum and tungsten analogues has been hardly studied.

The first electrochemical investigations of diarenechromium complexes[3-15] were performed soon after the synthesis of dibenzenechromium by Fischer.[1] In these investigations, a study was made, in relation to dibenzenechromium and its simplest derivatives containing alkyl and aryl groups in the benzene ligand, of redox processes in the $Arene_2Cr^{+/0}$ systems by polarography at the mercury dropping electrode (MDE). Electrochemical reduction reactions of neutral complexes were initially described for only two examples.[15,16] As the methods of synthesis developed, the range of available diarenechromium complexes expanded. This created preconditions for a systematic study of the reactivity of a large series of complexes of this type both in anodic oxidation and in cathodic reduction reactions. The range of electrochemical methods also expanded. Together with polarography at the MDE, cyclic voltammetry (CVA), the rotating disc electrode (RDE) method, and the rotating ring-disc electrode (RRDE) method came to be widely used.

The study of the polarisation characteristics of the oxidation–reduction processes with participation of chromium π-complexes led to the formulation of the characteristic features of the electrode reactions. The mechanism of the transmission of electronic effects of substituents in the complex molecule was established with the aid of correlation analysis. The nature of the changes in the properties of aromatic compounds in the complex formation process was discovered on the basis of comparative data on the reactivity of arenes and their chromium complexes in cathodic reduction reactions. The use of modern electrochemical experimental methods (CVA, RRDE) made it possible to determine the mechanisms of multistage electrochemical reduction reactions, to identify the unstable reaction intermediates, and to investigate their reactions.

A brief description of studies on the electrochemistry of diarenechromium complexes can be found in a number of publications.[17-26] The aim of the present review was to consider as fully as possible the results of studies over the last 10–15 years and also to discuss the characteristics of the electrochemical processes and the conclusions reached on their basis, which are important for the chemistry of transition metal π-complexes.

II. Electrochemical oxidation and reduction processes in the $Arene_2Cr^{+/0}$ and $Arene_2Cr^{2+/+}$ systems

The reversibility of the one-electron transfer stage

$$Arene_2Cr \underset{+\bar{e}}{\overset{-\bar{e}}{\rightleftarrows}} Arene_2Cr^{+} \qquad (2)$$

in protic[3-9,11-13] and aprotic[10,14,27-30] media is characteristic of all the diarenechromium complexes known at the present time. This confirms data obtained by the polarographic, CVA, RDE, and RRDE methods, according to which the half-wave potentials $E_{1/2}^{+/0}$ for the oxidation of the neutral form of the complex and the reduction of the corresponding cation are the same, while the slope of the polarisation curves is 0.06 V, which is close to the theoretical value for a reversible one-electron process. The same value is quoted in most studies for the difference between the potentials of the cathodic (pc) and anodic (pa) peaks on the cyclic voltammogram:

$$\Delta E_p = E_{pa} - E_{pc}$$

for a peak height ratio close to unity:[31] $i_{pc}/i_{pa} \simeq 1$. The polarisation characteristics of the processes, including the values of $E_{1/2}$, are unaffected by the nature of the material of the electrode and the composition and concentration of the supporting electrolyte. The limiting currents on the polarisation curves are diffusional in character.

The data encountered in certain studies which are formally inconsistent with the reversibility of the process, for example the difference between the potentials of the cathodic and anodic peaks on the cyclic voltammograms exceeding appreciably the value for a reversible reaction,[32,33] are in all probability a result of the inadequate accuracy of the experiment and the occurrence of ohmic potential drops in the solution, which has been confirmed convincingly[31] by the comparison of the values of ΔE_p measured with compensation for the ohmic potential drops (ΔE_p = 0.06 V) and without such compensation (ΔE_p = 0.12–0.14 V).

The reversibility of the electrode reactions observed with the aid of the experimental methods mentioned above is a consequence of the high standard exchange current density i_{00} in the test systems or, what amounts to the same thing, the high heterogeneous rate constants for the electron transfer stage at the equilibrium potentials k_s. In such cases, the kinetics of the overall process are wholly determined by the kinetics of the mass transfer stages, while the electrode potentials at each point on the polarisation curve are determined, in conformity with the thermodynamic Nernst formula for the electrode potential, by the logarithm of the ratio of the concentrations (activities) of the oxidised and reduced form of the electrochemically active substance at the electrode. The kinetic parameters of the electron transfer state (i_{00}, k_s, and the transfer coefficients α and β for the cathodic and anodic reactions respectively) can be determined directly using methods making it possible to remove the diffusional limitations and to investigate the kinetics. Thus, according to Gennett et al.,[34] the values of k_s for the bis(biphenyl)chromium$^{+/0}$ system, obtained in the course of impedance measurements by alternating current polarography in seven different solvents, are in the range from 0.3 (benzonitrile) to 4 cm s^{-1} (acetonitrile). Such values correspond to standard exchange current densities into the range 30–400 A cm^{-2} and characterise a very high reversibility of the reaction. The transfer coefficient α for this system proved to be 0.5±0.03.

The results of measurements of the rate constants for homogeneous electron exchange in solutions in hexane and benzene between the oxidised and reduced forms of methyl-substituted dibenzenechromium derivatives ($k_{ex} \sim 3 \times 10^8$ litre mol^{-1} s^{-1}), found by the ^1H NMR and EPR methods, as well as the low activation energies (E_a = 8.6 kJ mol^{-1}) characteristic of

diffusion-controlled reactions are consistent with the data presented above.[35] Similar data have been obtained for other derivatives of dibenzenechromium in dimethyl sulphoxide (DMSO).[28]

A high exchange current density is one of the conditions necessary to permit the use of a particular oxidation-reduction couple as a reference system for the measurement of electrode potentials. This feature as well as the fulfillment of a number of other conditions (closeness of the particles to the spherical shape and their large radius, low ionic charge, stability of both forms of the redox systems and their solubility in different solvents, and the constancy of the geometry of the ligands after electron transfer[36]) enabled the IUPAC Commission on Electrochemistry to recommend the bis(biphenyl)chromium $^{+/0}$ system together with the ferrocene/ferrocenium system for use as a reference electrode (as a portable electrode or as an internal standard) in electrochemical measurements in non-aqueous solvents.[37] Special studies[37,38] have shown that the potential difference between the two systems specified above in 22 organic solvents is virtually constant and the deviation from the average value of 1.124 V is ± 12 mV for an error of the measurements of ± 4 mV. This result indicates the virtually complete absence of effects due to the specific solvation of the cations and an insignificant change in the electrostatic component on passing from one solvent to another. The bis(biphenyl)chromium $^{+/0}$ couple proved to be the best reference system in non-aqueous media. It became possible to compare correctly the parameters of electrode reactions investigated in different organic solvents by potentiometric, voltammetric, and polarographic methods. A table representing a compilation of the half-wave potentials for the electrochemical reduction processes of a large number of metal cations, measured relative to the reference electrode under consideration, in 38 organic solvents has been published.[43] The use of bis(biphenyl)-chromium for similar purposes in aqueous solutions is not indicated in view of the instability of its cationic form, the insolubility of the neutral complex, and the pronounced adsorption phenomena.[39]

The data obtained from electrochemical measurements on the entropies of the electrochemical reduction reactions of bis-(biphenyl)chromium[40] and dibenzenechromium[34] cations in a number of solvents provide information about the temperature variation of the corresponding standard redox potentials. It has been established that the entropies of these reactions decrease linearly with increase in the acceptor number of the solvent.[40]

The change in the charge on the diarenechromium complexes in the course of the one-electron transfer process is accompanied by only a small reorganisation of the inner sphere of this species. Thus, on passing from the reduced to the oxidised form of dibenzene-chromium, the chromium–carbon bond length changes[41,42] by only 0.012 Å, whilst the free energy of the inner-sphere reorganisation ΔG_{is}^{+} is ~ 0.8 kJ mol^{-1}, which is at least 20 times lower than the free energy of the reorganisation of the outer sphere (the solvent). This enabled the authors[34] to use dibenzenechromium as one of the model objects for testing the theory of solvent reorganisation, constituting the basis of modern approaches to the treatment of the elementary electron transfer step in homogeneous oxidation–reduction and electrochemical reactions in condensed systems.[44,45]

Dibenzenechromium and its substituted derivatives are interesting objects for the study of the adsorption of organic cations at the interface. The low solubility of the salts of diarenechromium complexes in water is one of the main causes of the strong adsorption of the cations on the electrodes in aqueous media.[4] The appearance of adsorption waves (Brdicka waves) on the polarograms obtained in aqueous solutions of the iodides of certain alkyl-substituted dibenzenechromium derivatives is associated with this phenomenon.[7–9]

The adsorption of dibenzenechromium and bis(biphenyl)-chromium cations at the aqueous solutions/mercury and solution/air interfaces has been investigated[46,47] by the methods of electrocapillary curves and the maximum air pressure in the bubble. The adsorbability of these species is due to a number of factors: their positive charge, the squeezing effect at the interface owing to the breakdown of the structure of water, the interaction of the π-electrons of the aromatic system with the electrode surface, and the presence of the unpaired electron. The nature of the supporting electrolyte anion also exerts a strong influence on the adsorption. Comparison of the adsorption properties of dibenzenechromium, bis(biphenyl)chromium, and tetraethyl-ammonium cations established that the presence of the unpaired electron and of the π-electron system in the radical-cations of the π-complexes promotes their adsorption on mercury in the absence of the specific interaction of the supporting electrolyte anions with the electrode surface (for sulphate anions), but diminishes the adsorbability somewhat if such interaction does occur (for iodide anions). The appearance of adsorption peaks on the cyclic voltam-mograms of dibenzenechromium, bis(biphenyl)chromium, and dinaphthalenechromium, obtained at a platinum electrode in solutions in tetrahydrofuran (THF), has been noted.[48,49]

The existence of limiting diffusion currents on the electro-chemical reduction or electrochemical oxidation polarisation curves for chromium π-complexes, measured with the aid of the mercury dropping electrode or the rotating disc electrode, makes it possible to determine the diffusion coefficients of these com-pounds. The corresponding data for a series of derivatives of dibenzenechromium in several solvents have been published.[34,39,50]

Diarenechromium complexes are some of the most readily oxidisable transition metal π-complexes. Unsubstituted dibenz-enechromium is oxidised at high negative potentials. The measured value of $E_{1/2}$ (relative to the saturated calomel electrode) depends on the solvent: -0.71 V (DMF), -0.77 V (AN), -0.795 V (BN), -0.93 V (FA),[34] and -0.76 V (DMSO).[29] (The designations of the solvents are indicated in the footnote to Table 1.) Dibenzenemolybdenum is oxidised with somewhat greater difficulty than dibenzenechromium: $\Delta E_{1/2}$ is 0.1 V.[4] There are no literature data on the electrochemical oxidation of dibenzenetungsten.

Comparison[51] of the behaviour of dibenzenechromium, dibenzenevanadium, and cyclopentadienyl(cycloheptatrienyl)-chromium in the electrochemical oxidation reaction showed that the 18-electron dibenzenechromium is oxidised more readily than the 17-electron vanadium complex (the potentials $E_{1/2}$ in DME are -0.72 and -0.35 V respectively) and an asymmetric chromium complex with different ligands ($C_5H_5+C_7H_7$): for the latter, $E_{1/2}^{+/0} = -0.61$ V.

The half-wave potential is strongly influenced by the substituents in the arene ligand. Depending on the nature of the substituents and the number in the complex molecule, the values of $E_{1/2}^{+/0}$ vary from -1 to $+0.4$ V.

The half-wave potentials for the reversible redox transitions $+/0$ and $2+/+$ in the diarenechromium π-complexes are presented in Table 1.

The introduction of alkyl substituents into the dibenzene-chromium molecule shifts $E_{1/2}$ into the region of negative values.[4,6–9,12,27,53] On the other hand, the introduction of phenyl substituents hinders oxidation.[10] The principle of additivity then holds. For example, the shift of $E_{1/2}$ due to the introduction of one alkyl group is the same for the methyl and ethyl groups and amounts to 0.03 V. The validity of the principle of additivity has been indicated also in other studies.[29,31,62] The shift of $E_{1/2}$ after the introduction of one formyl group is 0.27 V, while the shift after the introduction of the cyano-group is 0.3 V (compounds **1**, **44**, **45**, **49**, **56**).† The maintenance of the principle of additivity as the phenyl groups accumulate in the dibenzene-chromium molecule is illustrated in Fig. 1. In a number of

†Here and henceforth the numbers of the compounds in Table 1 are quoted in the text.

Table 1. The potentials $E_{1/2}$ for the $Arene_2Cr^{0/+}$ and $Arene_2Cr^{2+/+}$ redox processes.

Note. The half-wave potentials $E_{1/2}$ were determined either directly from the polarisation curves (MDE, RDE) or were found as half the sum of the potentials of the cathodic (E_{pc}) and anodic (E_{pa}) peaks on the cyclic voltammograms. Unless stipulated otherwise, the electrode potentials listed in Table 1 and in the other tables and also quoted in the text were measured relative to the potential of the aqueous saturated calomel electrode. In the remaining cases, the reference electrode employed is indicated. The table also presents the experimental conditions (the method of measurement, the material of the electrode, the solvent, and the composition of the supporting electrolyte), the most important of which is the nature of the solvent when the process is reversible. The following abbreviations have been adopted in the table and in the text: CG = carbon glass, AN = acetonitrile, BN = benzonitrile, DMSO = dimethylsulphoxide, DMF = dimethylformamide, DME = dimethoxyethane, THF = tetrahydrofuran, FA = formamide, EDA = ethylenediamine.

Reference electrodes: [a] calomel electrode, 0.5 M LiCl, $CH_3-C_6H_6$; [b] $Ag/AgClO_4$; [c] Ag/AgCl/4 M aqueous LiCl; [d] $Ag/AgNO_3$; [e] Ag/AgCl; [f] $Ag/AgBF_4$.

Indeed, the kinetic stabilisation of the cation $Arene_2Cr^{2+}$ is achieved either with the aid of peripheral substitution in a dibenzenechromium molecule or as a result of a decrease in the experimental temperature. Thus, in the oxidation of bis(hexamethylbenzene)chromium in THF[59] and dimethoxyethane[51] at 20 °C and a reduced temperature, it was possible to observe two pairs of reversible peaks corresponding to two one-electron transitions. It was established by low-temperature cyclic voltammetry at a platinum electrode that dibenzenechromium and bis(biphenyl)chromium are also oxidised reversibly in dry THF to doubly charged cations, which are stable in terms of the time scale of the voltamperometric measurements below −80° and −60 °C respectively.[48,95] The anodic oxidation of the cation ({η^{12}-[2.2]paracyclophane}chromium)$^+$ **21** is reversible even at room temperature.[51]

The presence of cathodic peaks due to the electrochemical reduction of the cations $Arene_2Cr^{2+}$ on the cyclic voltammograms constitutes direct proof of the formation of these species during the anodic process. According to Elschenbroich et al.,[51] the lifetime of the doubly charged dibenzenechromium, bis(hexamethylbenzene)chromium, and {η^{12}-[2.2]paracyclophane}chromium cations in dimethoxyethane at −40 °C is several seconds, minutes, and hours respectively.

There are grounds for the assumption that the first stage of the anodic oxidation of the singly charged cations $Arene_2Cr^+$ [reaction (3)] consists as a rule of reversible electron transfer, preceding the chemical reaction with participation of doubly charged species, and determines to a large extent the half-wave potential for the overall irreversible process. We may note that the half-wave potential for the irreversible oxidation of $Arene_2Cr^+$ as well as for the reversible process (2) depends on the nature of the substituent in the arene ligand. Thus, in the presence of two electron-accepting substituents[31] COOR or COR in the dibenzenechromium molecule, the half-wave potential is 1.25 V, while in the presence of two electron-donating groups $N(CH_3)_2$ it amounts to 0.8 V.

During the electrochemical oxidation process, an electron is removed from the HOMO of the complex. In order to solve the problem of the nature of the frontier orbitals in transition metal π-complexes, Vlcek[5] proposed a method based on the comparison of the differences between the half-wave potentials for the reversible oxidation (or reduction) of two structurally similar complexes and the corresponding non-coordinated ligands. The relative contribution of the ligand MO and of the metal AO to the overall MO of the complex was estimated for the dibenzenechromium–bis(biphenyl)chromium system. The highest molecular orbital of the complex, in which electronic changes take place in the course of the electrochemical oxidation process, is a MO localised predominantly on the chromium atom[5,17] (the contribution of the ligand MO does not exceed 15%). Similar conclusions were reached in the study of diarene chromium complexes by quantum-chemical[82–85] and photo-electron spectroscopic (PES)[86,87] methods and also by the EPR of paramagnetic cationic complexes.[88]

The universality and reversibility of the one-electron oxidation of neutral diarenechromium complexes to the cationic form makes this reaction exceptionally convenient for the solution of problems associated with the transmission of the electronic effect of substituents in the dibenzenechromium molecule to the reaction centre (the chromium atom). The reversibility of the process rules out the influence on $E_{1/2}^{+/0}$ of heterogeneous factors associated with the specific features of the electrochemical process — the structure of the electrical double layer, adsorption, etc. For this reason, the value of $E_{1/2}$, which is close to the thermodynamic standard potential E_0, reflects objectively the influence of substituents on the reactivity of the complexes in redox reactions and can serve as its measure.

Table 3. Parameters of the correlation between $E_{1/2}^{+/0}$ and the substituent constants.[61,62]

Substituent constant	No. of points	ρ_π/V	$-b_1$/V	$-\rho$	r	S_{ρ_π}	S_{b_1}
σ_m^0	19	0.513	0.749	8.9	0.992	0.018	0.012
σ_m^+	20	0.520	0.760	9.0	0.990	0.017	0.011
σ_m	25	0.541	0.748	9.3	0.986	0.019	0.012
σ_p^0	17	0.396	0.635	6.8	0.964	0.028	0.019
σ_p	25	0.350	0.602	6.0	0.920	0.031	0.021
σ_I	23	0.456	0.717	7.9	0.814	0.071	0.047
σ_R	21	0.341	0.463	5.9	0.570	0.113	0.042

Note. b_1 and ρ_π are the parameters of the correlation equation; $\rho = \rho_\pi/0.058$; S_{ρ_π} and S_{b_1} are the standard deviations; r is the correlation coefficient; the constants σ were taken from Gordon and Ford[93] and Kochi and Hammond.[94]

In order to estimate quantitatively the electronic influence of substituents in the electrochemical oxidation of diarenechromium complexes, the correlations between $E_{1/2}^{+/0}$ and different σ constants of the substituents were analysed systematically in a number of studies[29,61,62] (Table 3). According to the Hammett–Zuman equation,[89] we have

$$E_{1/2} = b_1 + \rho_\pi \sum \sigma , \qquad (4)$$

where ρ_π is the polarographic reaction constant, b_1 the half-wave potential for the oxidation of dibenzenechromium, and $\Sigma\sigma$ the sum of the substituent constants. When the σ constants corresponding to only the resonance (σ_R) or the inductive (σ_I) mechanisms of the transmission of the influence of substituents are used, a linear relation is not obtained. The best correlation is observed between $E_{1/2}^{+/0}$ and the σ constants to which the main contribution comes from the inductive component: σ_m, σ_m^+, and σ_m^0.

The reversible oxidation of diarenechromium complexes is characterised by high absolute values of ρ, which indicates a high sensitivity of the dibenzenechromium system to the electronic influence of the substituents. High values of ρ are also observed in the series of oxidation–reduction reactions of ferrocene.[90] They are in general characteristic of reactions involving ions.[91] Compared with ferrocene, dibenzenechromium is a less conducting system. This can be inferred from the half-wave potential shift $\Delta E_{1/2}$ after the introduction of the same substituent (for example, CF_3) into the dibenzenechromium and ferrocene molecules. It amounts to 0.26 V in the first case[32,62] and 0.32 V in the second.[92]

The excellent correlation between $E_{1/2}^{+/0}$ and the σ constants of the *meta*-substituents led to the conclusion that the electronic influence of the substituents in the arene ligand on the reaction centre (the chromium atom) is transmitted predominantly via an inductive mechanism; the conjugation in the arene ligand exists only to the extent that this effect is reflected in the constants of the *meta*-substituent.[29,61,62]

The results of other studies carried out with a significantly smaller number of objects are on the whole similar. For example, a linear correlation between $E_{1/2}^{+/0}$ and the σ_m constants has been observed:[28]

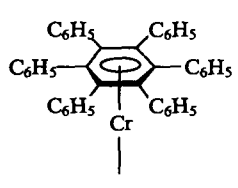
$$E_{1/2}^{+/0} = -0.78 + 0.32 \sum \sigma_m . \qquad (5)$$

Two correlation equations have been obtained by Treichel et al.:[32]

$$E_{1/2}^{+/0} = -0.801 + 0.637\sigma_m , \quad r = 0.986 ; \qquad (6)$$

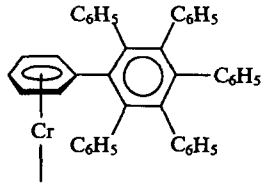
$$E_{1/2}^{+/0} = -0.530 + 0.413\sigma_p , \quad r = 0.976 . \qquad (7)$$

The similarity of the correlation coefficients precluded an ambiguous choice between these equations. It is noteworthy that the experimental data obtained in the above study[32] by cyclic



voltammetry are not quite correct. The potentials of the anodic and cathodic peaks are strongly distorted by the ohmic potential drops in solution, indicated by the difference between the potentials of the anodic and cathodic peaks, which exceeds the theoretical value (0.059 V) by a factor of 1.5–5. The deviation of the value of $E_{1/2}^{+/0}$ for dibenzenechromium from the correlation (7) is also striking: the experimental value is $E_{1/2}^{+/0} = -0.716$ V, while the value obtained from Eqn. (7) is $E_{1/2}^{+/0} = -0.530$ V.

The conclusion that the transmission of the electronic influence of substituents to the chromium atom is inductive was also reached in a study[53] where a correlation was observed between $E_{1/2}^{+/0}$ and the Taft substituent constants for six diarenechromium complexes.



The results of the electrochemical study of the electronic effects in the diarenechromium π-complexes agree with data obtained by other physical methods. A correlation between the first ionisation potentials in the gas phase (IP_1) and the constants σ_m^0 has been established by photoelectron spectroscopy.[87] A correlation has been found between the chemical shift of fluorine and the constants σ_m^+ and σ_m^n (r = 0.958 and 0.952 respectively) with the aid of ^{19}F NMR for a series of heteroannularly disubstituted dibenzenechromium derivatives $(XC_6H_5)Cr(C_6H_5F)$.[96] Hence it follows that the electronic effects of the substituents at one of the arene ligands are exerted across the chromium atom on the indicator fluorine atom in the other ligand also predominantly via an inductive mechanism.

The correlation Eqn. (4) was used to confirm the structure of bis(iodobenzene)chromium.[97] The experimental value $E_{1/2}^{+/0} = -0.38$ V proved to be close to the value −0.40 V calculated by Eqn. (4).

An analogous approach was used to establish the structure of bis(hexaphenylbenzene)chromium obtained by the cyclotrimerisation of diphenylacetylene in the reaction with atomic chromium.[98] The observed[62] half-wave potential for the oxidation of the complex is −0.32 V, which confirms structure A assuming the additive influence of the phenyl ring on the oxidation potential (Fig. 1). If the alternative structure B is obtained, the half-wave potential for the oxidation of the complex would be close to $E_{1/2}^{+/0}$ for bis(biphenyl)chromium (−0.72 V).

A

B

The half-wave potentials $E_{1/2}^{+/0}$ for dibenzenechromium derivatives in DMSO have been compared[62] with the ionisation potentials IP_1 of the same complexes in the gas phase. A satisfactory correlation, described by the equation

$$E_{1/2}^{+/0} = -4.08(\pm 0.16) + 0.62(\pm 0.03)IP_1\,, \quad r = 0.990, \qquad (8)$$

was observed. The coefficient of IP_1 in the equation differs from unity and reflects the contribution of the solvation effects to the energetics of the oxidation reaction in solution in DMSO. The ionisation potentials of various diarenechromium complexes can be calculated using this equation with a fairly high degree of accuracy, which is important, because the experimental determination of the ionisation potentials is difficult compared with the determination of $E_{1/2}^{+/0}$. The existence of a correlation between $E_{1/2}^{+/0}$ and IP_1 shows that the photoelectron processes in the gas phase and the electrochemical oxidation in solution take place with participation of the same molecular orbitals localised predominantly on the chromium atom.

The parallel variation of the redox potentials of a number of sandwich chromium complexes (including three diarene complexes) and the potentials IP_1 of the same compounds in the gas phase was noted previously.[28]

A linear correlation has been observed[51] between the electrochemical potential $E_{1/2}(C_{12}H_{12}M^{+/0})$ for the dibenzene and cyclopentadienylcycloheptatrienyl complexes of chromium and vanadium and their IP_1 obtained from the photoelectron spectra:

$$IP_1 = 6.20 + 0.99E_{1/2}^{+/0}\,, \quad r = 0.995\,. \qquad (9)$$

The half-wave potentials $E_{1/2}$ vary in parallel with the appearance potentials of the molecular ions obtained from the mass spectra.[99]

It has been shown[100,101] that the standard redox potentials of a series of sandwich complexes of transition metals, including diarenechromium and diarenemolybdenum complexes, are linearly correlated with the gas-phase ionisation potentials of the corresponding metals.

III. Cathodic reduction of diarenechromium(0) complexes

Data on the electrochemical reduction of more than 30 diarenechromium complexes have now been published (Table 4).

The main difference between the cathodic reduction reactions and the processes examined in the previous section consists in the fact that they occur with participation of a molecular orbital the main contribution to which comes from the π orbital of the aromatic ligand. This conclusion is justified by the results of quantum-chemical calculations[85,102–106] carried out in different years for dibenzenechromium and dinaphthalenechromium molecules and has been confirmed by numerous experimental data. In particular, this is indicated by the similarity of the polarisation characteristics of the electrochemical reduction of free arenes and the corresponding diarenechromium complexes, including the similarity of the half-wave potentials $E_{1/2}$ for the electrochemical reduction of arenes ($E_{1/2}^{A}$) and the complexes ($E_{1/2}^{C}$)‡ (Table 5).

The application of Vlcek's methods[5,17–19] makes it possible to estimate the contribution of the lowest unoccupied molecular orbitals (LUMO) of the arene ligands in the complex, the results showing that it is the dominant contribution (~90%). This is also indicated by the parallel variation of $E_{1/2}^{A}$ and $E_{1/2}^{C}$ for symmetrical complexes (Table 5). Thus, depending on the nature and number of the substituents in the benzene ring, $E_{1/2}^{A}$ shifts towards positive values in the sequence $C_6H_5 < CF_3 < (C_6H_5)_3 < CN < COCH_3 < (COOC_2H_5)_2 < CHO < CH{=}CHCOOC_2H_5 < CH{=}CHCOC_6H_5$. The ease of the reduction of $Arene_2Cr$ increases in the same sequence. Only the CHO and $CH{=}CHCOOC_2H_5$ groups are an exception. They change places on passing from the arene to the complex.

The electron affinity is determined by the donor–acceptor properties of the substituents in the arene ring and also, and to an even greater degree, by the extent of the conjugated system. Among the compounds investigated,[50,65,107] benzylideneacetophenone and its complex are reduced more readily than the others, since this arene contains the most extensive conjugation system, although, judging from the value of $E_{1/2}^{+/0}$, the substituent $CH = CHCOC_6H_5$ is a moderately strong electron acceptor. A different picture is observed in the anodic oxidation of zerovalent chromium complexes where the electronic changes are localised not on the ligand π-orbitals but on the atomic orbitals of the metal.[62] In terms of their ability to hinder the oxidation of the complex, the above substituents can be arranged in the following sequence: $C_6H_5 < CH{=}CHCOOC_2H_5 < (C_6H_5)_3 < CH{=}CHCOC_6H_5 < COCH_3 < CHO < CF_3 < (COOC_2H_5)_2 < CN$, i.e. in this case the increase in the electron-accepting capacity of the substituent, characterised by the σ constant of the *meta*-substituents, is decisive.

‡Here and henceforth the superscripts A and C denote quantities referring to the free arenes and the chromium complexes respectively.

Table 4. The half-wave potentials $E_{1/2}$ for the cathodic reduction of diarenechromium(0) complexes.

The agreement between the reaction constants ρ in the Hammett equation for the electrochemical reduction of the noncoordinated ketones $4\text{-}XC_6H_4COC_6H_5$ and their asymmetric complexes $(4\text{-}XC_6H_4COC_6H_5)Cr(C_6H_6)$ and the symmetrical complexes $(4\text{-}XC_6H_4COC_6H_5)_2Cr$ [108] as well as the small difference between the rate constants for the dimerisation of the radical-anions of benzylideneacetophenone and bis(benzylidene-acetophenone)-chromium can serve as additional arguments in support of the conclusion that the electronic changes in the course of the electrochemical reduction of the complexes are localised on the π-orbitals of the ligand.[50]

The structure of the radical-anions formed on electrochemical reduction or by chemical generation also confirms this conclusion. According to EPR data, the unpaired electron in the radical-anions of ketones,[108] trimethylsilyl-substituted derivatives of dibenzenechromium[110] and dibenzonitrilechromium,[111] as well as unsubstituted dibenzenechromium[112] and the isoelectronic cyclopentadienyl(cycloheptatrienyl)chromium[106] is localised on the molecular orbital the main contribution to which comes from the ligand π-orbital.

The involvement in the cathodic reduction of the zerovalent chromium π-complexes of the LUMO which has predominantly the character of the ligand π-orbital makes it possible to estimate the changes in the reactivity of the arenes due to the formation of complexes with the chromium atom by comparing the characteristic features of the electrochemical reduction of the chromium π-complexes and the corresponding arenes containing identical electrochemically active groups. This approach is characteristic of the majority of studies (in general not very numerous) of the cathodic reactions of diarenechromium(0) complexes.

Another feature of the electrochemical reduction reactions of diarenechromium complexes distinguishing them from the reversible reaction (2) is the greater complexity of the cathodic processes. The overall processes are as a rule irreversible, consist of many stages, and are characterised by the involvement of several electrons and protons, possible retardation of the electron transfer stages, and the presence of stages involving chemical reactions of the intermediates.

The choice of the potentials $E^{C}_{1/2}$ and $E^{A}_{1/2}$ as the reactivity criteria makes it necessary to justify the comparability of these quantities for complexes of different structure and also for pairs of complex–arene compounds with isotypical electroactive groups. This presupposes in its turn that the preliminary kinetic study of the mechanisms of the electrochemical reduction of the test compounds is carried out and the potential determining stage of the overall process is discovered under identical conditions. This problem, which is of independent interest also for electrochemical

Table 5. Comparative characteristics of the electrochemical reduction of arenes and diarenechromium complexes.[24, 61, 65, 107]

	$(NCC_6H_5)_2Cr$	2.18			

kinetics, has been examined in greatest detail in several studies[50, 61, 65, 107, 109] of the mechanisms of the electrochemical reduction of 17 diarenechromium complexes with different substituents in DMSO.

The complexity of the kinetics of the multistage electrode processes necessitates the use of methods which yield, together with the usual polarisation characteristics, information about the appearance during the reaction of unstable intermediates (including free-radical or radical-ion intermediates), their nature, and properties.

In the study of the electrochemical reduction of chromium π-complexes, such methods were cyclic voltammetry at normal and reduced (cryoelectrochemical measurements) temperatures, EPR with electrochemical or chemical generation of paramagnetic species, and the method of a rotating ring-disc electrode.

The method of a rotation ring-disc electrode (RRDE), proposed by Frumkin and Nekrasov[113, 114] and representing a definite alternative to cyclic voltammetry, is based on the use of a single mechanical system consisting of two concentric electrodes—a disc and a ring—located in a single plane and separated by a thin insulating layer. The electrochemical reaction investigated is carried out at the disc electrode and the resulting unstable intermediate or stable final product of the reaction passes to the layer of solution near the electrode and is supplied by the convective stream of liquid to the ring, with the aid of which it can be detected in terms of its oxidation or reduction current. The comprehensive and in certain respects also unique possibilities of the method have led to its wide scale employment in electro-chemical kinetics, including studies on the electrochemistry of organic compounds.[115–118]

The existence of the reaction involving electrochemical oxidation to the cation, which is universal for the diarenechromium(0) complexes [reaction (2)], makes these compounds convenient objects for the study of their cathodic behaviour by the RRDE method. This reaction makes it possible to detect at the ring electrode all the intermediates of the cathodic process. The yield of the corresponding products can be inferred from the anodic limiting current at the ring and the dependence of the yield of the products on the rate of rotation of the electrode yields information about their stability in further reactions. The values of $E^{C}_{1/2}$ for the wave observed at the ring help to identify the species detected.

The first complex whose cathodic reduction was achieved proved to be benzene(biphenyl)chromium.[15] At the present time, the cathodic reduction reactions have been investigated for a wide range of diarenechromium complexes containing the COR, CN, C=C, C_6H_5, and other groups as substituents (Table 4).

Like benzene, unsubstituted dibenzenechromium has an extremely low electron affinity. The report of the direct electrochemical reduction of benzene to the radical-anion did not appear[119] until 1988 ($E_{1/2}$ = −3.38 V). Despite repeated attempts,[4, 56, 101] dibenzenechromium has not yet been reduced at the electrode, although it has been possible to obtain[112] its radical-anions chemically by treatment with potassium in dimethoxyethane in the presence of a crown-ether at −70 °C.

Compared with dibenzenechromium, its asymmetric analogue cyclopentadienyl(cycloheptatrienyl)chromium has a higher electron affinity:[51] it is reduced at carbon glass, the potential of the cathodic peak being E_{pc} = −2.90 V (DME, −35 °C). Ferrocene, which is isoelectronic with dibenzenechromium, is also reduced[120] at the cathode ($E_{1/2}$ = −2.93 V, DMF, −30 °C).

The introduction into the benzene or dibenzenechromium molecule of groups reducing the electron density in the benzene ring and increasing the extent of the conjugation chain ensures the electrochemical reduction of these compounds in the range of electrochemical potentials accessible to measurements.

The electrochemical reduction reactions of the majority of complexes investigated are usually characterised, like those of the non-coordinated arenes, by the presence of several waves on the polarisation curves corresponding to different macroscopic reaction stages. In the literature, attention is concentrated on the first cathodic waves, while the nature of the subsequent waves has been studied in less detail.

In the analysis of the characteristics of the cathodic process, the test compounds can be usefully divided into several groups. Each of these groups includes a series of π-complexes–corresponding arene systems. The formal criteria of the assignment of substances to a particular group are the number of added electrons n in the range of potentials of the first cathodic wave and the presence or absence of similarity in other process characteristics in this range of potentials in the electrochemical reduction of the π-complex and the arene in aprotic media.

Table 6. Parameters of the electrochemical reduction and oxidation of diarenechromium complexes and of the reduction of the corresponding arenes at an amalgamated gold rotating disc electrode in DMSO.[50,61,65]

[a] Data of Nekrasov and Korotkov.[121]

The mechanisms of the reduction of the π-complexes combined in one group are identical or similar. Different mechanisms of the cathodic processes correspond to different groups of complexes, which constitutes in essence but not formally the basis of the adopted classification. The mechanism of the electrochemical reduction of arenes is in some cases fully identical with that for the π-complexes of the given group (carbonyl compounds, activated olefins), whilst in others, together with the general similarity, there is also an appreciable difference between them (nitriles).

The first group includes aldehydes, ketones, esters, and their vinylogues of the benzene and dibenzenechromium series. The similarity of the electrochemical behaviour under the conditions of the cathodic reaction is characteristic of compounds of this group.[16,50,65,108] In particular, it is manifested by the presence on the polarisation curves of one-electron reduction waves for both the free arenes and their chromium complexes and also by the similarity of the polarisation characteristics of each component of the Arene–$Arene_2Cr$ system (Table 6). In many instances, it has been possible with the aid of the RRDE method,[50,65] cyclic voltammetry, and EPR[108] to observe directly the formation of one-electron transfer products—radical-anions capable of dimerising.

Such similarity was first established[16] on the basis of classical polarographic data, potentiodynamic measurements, coulometry, and preparative electrolysis at a controlled potential and subsequent analysis of the reaction products when the electrochemical reduction reactions of aromatic carbonyl compounds and benzene(benzophenone)chromium were compared in DMF and aqueous alcoholic solutions of different acidity. The polarogram for the reduction of benzene(benzophenone)-chromium in DMF shows two one electron-waves with the potentials $E_{1/2}$ = −1.91 and −2.01 V. The first cathodic wave corresponds to the formation of the radical-anion, while the product of the two electron transfer is a dianion, which is unstable and is rapidly protonated to the alkoxide ion. The latter decomposes slowly in its turn in the bulk of the solution with rupture of the C–C bond and the formation of dibenzene-chromium. It follows from the comparison of the half-wave potentials for the reduction of benzene(benzophenone)chromium ($E_{1/2}$ = −1.91 V) and of the free benzophenone ($E_{1/2}$ = −1.72 V) that the coordination of the benzophenone molecule to the π-C_6H_6Cr fragment hinders the reduction reaction. Comparison of the values of $E_{1/2}$ for a series of ketones C_6H_5COX, where X = CH_3, $C_6H_6CrC_6H_5$, H, or C_6H_5, led the authors to the conclusion that dibenzenechromium resembles the methyl group as a substituent. The Taft substituent constant σ_T for the $C_6H_6CrC_6H_5$ group, found by interpolation, proved to be 0.19.

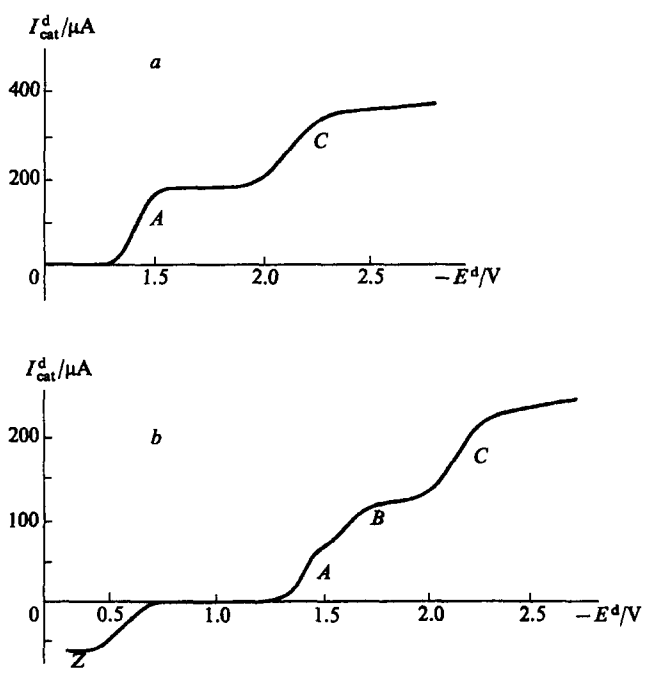

Figure 2. Polarisation curves at the rotating disc electrode in solutions of benzylideneacetophenone ($c = 2\times10^{-3}$ M) (*a*) and bis(benzylidene-acetophenone)chromium ($c = 9.4\times10^{-4}$ M) (*b*) in DMSO in the presence of 0.1 M $N(C_4H_9)_4BF_4$ (ω = 528 s^{-1}).

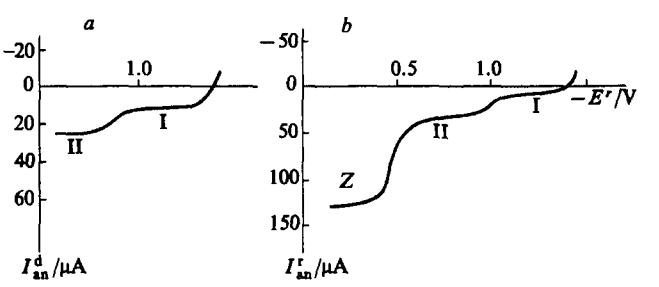

Figure 3. Polarisation curves for the anodic oxidation at the ring electrode of the products of the electrochemical reduction at the disc electrode of benzylideneacetophenone ($c = 4\times10^{-4}$ M) (*a*) and bis(benzylidene-acetophenone)chromium ($c = 2\times10^{-3}$ M) (*b*); E^d = −1.51 V, ω = 214 s^{-1}.

The polarisation characteristics ($E_{1/2}$, the slope b, the number of electrons n participating in the reaction) of all the electrochemical reduction waves (A, B, C) of a series of chromium π-complexes and the non-coordinated arenes, belonging to the first group of compounds, obtained with the aid of an amalgamated gold rotating disc electrode in solutions in DMSO with tributylammonium tetrafluoroborate ($TBABF_4$) as the supporting electrolyte, are presented in Table 6, which also contains analogous data on the Z waves for the electrochemical oxidation of the same complexes.

The kinetics and mechanisms of the electrochemical reduction of benzylideneacetophenone and bis(benzylideneacetophenone)-chromium have been investigated in greatest detail.[50] The polarisation curves for these compounds are presented in Fig. 2, while the corresponding quantitative characteristics are in Table 6. The A waves for the electrochemical reduction of both substances correspond to the reversible addition of one electron and the formation of radical-anions, detected by the RRDE method (I waves in Fig. 3):

$$C_6H_5CH=CHCOC_6H_5 \underset{-\bar{e}}{\overset{+\bar{e}}{\rightleftarrows}} C_6H_5CH=CHCOC_6H_5]^{\cdot-},$$

$$(C_6H_5CH=CHCOC_6H_5)_2Cr \underset{-\bar{e}}{\overset{+\bar{e}}{\rightleftarrows}}$$

$$\leftrightarrows (C_6H_5CH=CHCOC_6H_5)_2Cr]^{\cdot-}.$$

The cathodic B wave for the reduction of the complex can be related to the addition of an electron to the second ligand of the complex radial-anion. This wave is absent from the polarisation curve for the free arene. The C waves correspond to further reduction reactions of the radical species, and the Z waves (Figs. 2*b* and 3*b*) correspond to the electrochemical oxidation of the initial complex. The radical-anions derived from both compounds are unstable and enter into a dimerisation reaction, whose products are also detected at the ring electrode (II waves in Fig. 3).

Thus in the region of the potentials of the A waves, a two-stage reaction takes place: the reversible one-electron transfer stage is followed by the bimolecular chemical dimerisation reaction, which exerts a definite effect on the parameters of the electrode process (EC mechanism), as a consequence of which the A waves acquire a quasi-reversible character.[122]

The potentials $E^A_{1/2}$ and $E^C_{1/2}$, measured by the rotating electrode method under the conditions of the operation of the above electrochemical reduction mechanism, are[123,124] functions of the angular rate of rotation of the electrode ω, the depolariser concentration c, and the dimerisation constant of the radical species k_d:

$$E_{1/2} = E_0 + \frac{2.3RT}{3F}\lg 0.864\left(\frac{\nu}{D}\right)^{1/3} + \frac{2.3RT}{3F}\lg\frac{k_d c}{\omega}, \qquad (10)$$

where F is the Faraday constant, D the diffusion coefficient of the reactant, and ν the kinematic viscosity of the solution.

The experimental[50] dependences of $E^A_{1/2}$ and $E^C_{1/2}$ on $\lg\omega$ at different concentrations c are presented in Fig. 4. They consist of two linear sections—inclined and horizontal. The first reflects the influence of the dimerisation reaction on the half-wave potential. The rates obtained experimentally, $\Delta E^A_{1/2}/\Delta\lg\omega = -0.023$ V, $\Delta E^A_{1/2}/\Delta\lg c = -0.021$ V (for benzylideneacetophenone) and $\Delta E^C_{1/2}/\Delta\lg\omega = -0.021$ V [for bis(benzylideneacetophenone)-chromium] proved to be similar to the values predicted by theory for radical dimerisation ($2.3RT/3F = \pm 0.019$ V). For low concentrations c and high values of ω, the potentials $E^A_{1/2}$ and $E^C_{1/2}$ are independent of further increase in the rate of rotation of the electrode (the horizontal section of the curves in Fig. 4), since the rapid removal of the radical-anions from the layer near the electrode prevents the influence of their dimerisation on the electrode process, which becomes fully reversible under the given conditions. The radical-anions are then detected at the ring electrode with 100% yield, while the II oxidation waves for the dimers are absent. The rate constants for the dimerisation of the benzylideneacetophenone and bis(benzylideneaceto-phenone)-chromium radical-anions were calculated by Eqn. (10) from the experimental data obtained by the rotating disc electrode method:

$$k^A_d = (2.1 \pm 0.2) \times 10^4 \text{ litre mol}^{-1}\text{ s}^{-1},$$

$$k^C_d = (1.5 \pm 0.7) \times 10^4 \text{ litre mol}^{-1}\text{ s}^{-1}.$$

Similar values of k^A_d and k^C_d were also determined by an independent procedure using the RRDE method and a semiempirical calibration curve[125] relating the yield of the radical-anions at the ring electrode to the dimerisation rate constant:

$$k^A_d = (1.5 \pm 0.3) \times 10^4 \text{litre mol}^{-1}\text{ s}^{-1},$$

$$k^C_d = (1.2 \pm 0.5) \times 10^4 \text{ litre mol}^{-1}\text{ s}^{-1}.$$

The small difference between the rate constants for the dimerisation of the radical-anions of the π-complex and the free arene is striking.

A similar EC mechanism of the electrochemical reduction reactions is characteristic also of other classes of substances of the benzene and dibenzenechromium series forming part of the first group of compounds, including those listed in Table 6.

The mechanism is modified somewhat and simplified for benzophenone derivatives. Because of the high stability of the radical-anion of benzophenone itself and apparently also the radical-anions of the π-complexes containing benzophenone and its substituted derivatives as ligands,[108] the chemical stage of the reaction which follows electron transfer, does not occur in the layer near the electrode even when the solution is gently stirred.[126] The only potential-determining stage of the process is the reversible addition of an electron, a situation similar to that observed for the electrochemical reduction of benzylideneacetophenone and its chromium complex at comparatively high rates of rotation of the disc electrode.

The second group of compounds comprises mainly aromatic and complex nitriles (Table 7). An important feature of these substances is that nitriles of the dibenzenechromium series behave

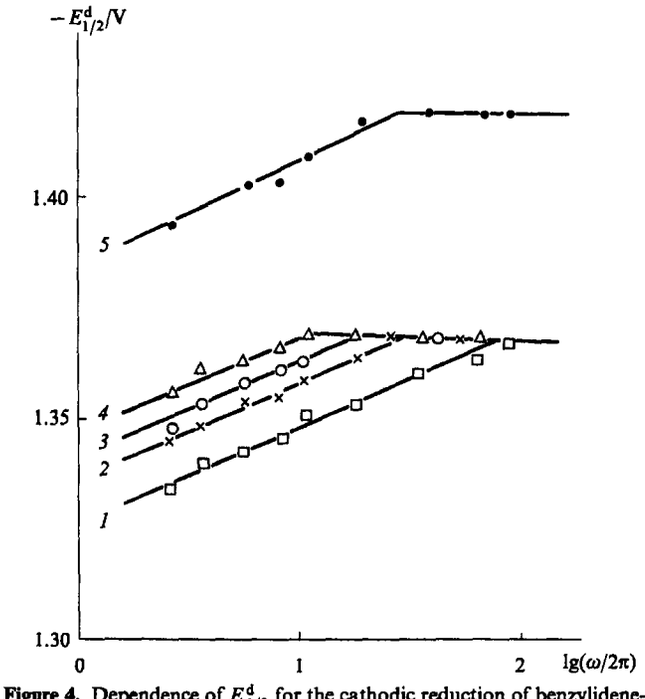

Figure 4. Dependence of $E^d_{1/2}$ for the cathodic reduction of benzylideneacetophenone (lines *1*–*4*) and bis(benzylideneacetophenone)chromium (line *5*) at a rotating disc electrode in solutions in DMSO on the logarithm of the angular rate of rotation of the disc electrode at different molar concentrations of the reactants: (*1*) 2×10^{-3}; (*2*) 8×10^{-4}; (*3*) 4×10^{-4}; (*4*) 2×10^{-4}; (*5*) 5.4×10^{-4}.

differently from the nitriles of the aromatic series under the conditions of cathodic reduction in aprotic media (DMSO, THF).[109] The main difference consists in the absence of reversible one-electron waves from the polarisation curves for the electrochemical reduction of complexes **7–13**§ and their appearance in the reduction of the non-coordinated compounds **1–6**. Instead of the one-electron waves, the polarisation curves for the complex nitriles show one (mononitrile) or two (dinitrile) irreversible two-electron waves. A characteristic feature of the π-complexes, assigned to the second group of compounds, is the occurrence of a rapid chemical reaction with participation of the intermediate products of the one-electron transfer, leading to the elimination of the cyano-group or halogen atoms if the latter form part of the molecule.

In view of the uncertainty in the pathways leading to the reduction of nitriles of different structure, direct comparison of the characteristic features of the reduction of benzonitrile and its π-complexes, necessary for the quantitative comparison of the reactivities, proves insufficient to obtain objective information about the similarities and differences between the mechanisms of the electrochemical reduction of the two types of compounds. The approach based on a comparison of the electrochemical properties of complexes of the type $(NCC_6H_5)Cr(C_6H_5X)$ in a series of cyanobenzenes is more effective. For this reason, Table 7 includes, together with the characteristics of the electrochemical reduction of the π-complexes and free benzonitrile, also the analogous data for the isomers of dicyanobenzene and tetra-cyanobenzene.

In the range of potentials of the *A* wave for the electrochemical reduction of benzonitriles, stable radical-anions can be detected in quantitative yields by the RRDE method. An exception is *m*-dicyanobenzene, whose radical-anions are unstable. The reactivity of the radical-anions depends on the molecular structure. The radical-anions derived from mononitriles and 1,3-dicyanobenzene are not reduced at the electrode in the range of potentials accessible to measurements. A shift of the potential towards negative values by almost 1 V compared with $E^A_{1/2}$ for the formation of the radical-anions (*B* waves) is necessary for the electrochemical reduction of the radical-anions of the *ortho*- and *para*-isomers of dicyanobenzene and 1,2,4,5-tetracyanobenzene.

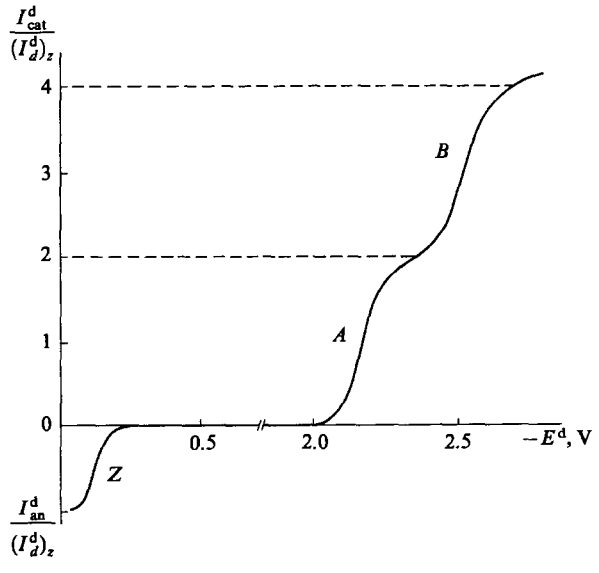

Figure 5. Normalised polarisation curve for the anodic oxidation and cathodic reduction of dibenzonitrilechromium at a rotating disc electrode in DMSO.

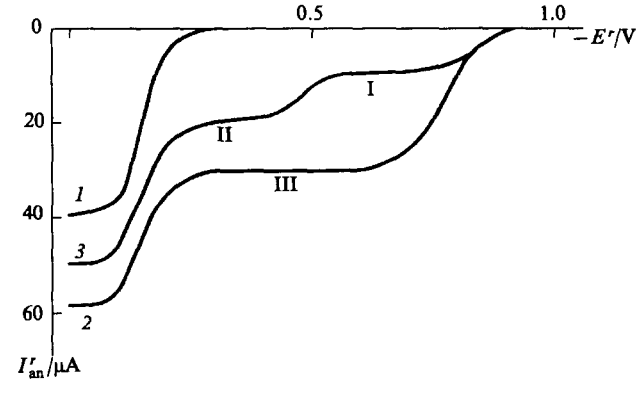

Figure 6. Polarisation curves for the electrochemical oxidation at the ring electrode of the product of the electrochemical reduction of dibenzonitrilechromium at the rotating disc electrode in DMSO at $E^d = -2.4$ V (line *1*) and -2.75 V (line *2*) and for the open circuit of the disc electrode ($I^d = 0$) (line *3*) ($\omega = 250$ s^{-1}). I–III numbers of the waves.

§ Here and henceforth the numbers of compounds in Table 7 are quoted in the text.

The electrochemical reduction of the radical-anions of 1,2- and 1,4-dicyanobenzenes leads to the elimination of one CN group and further reduction of the resulting benzonitrile and its radical-anion.

$$[C_6H_4(CN)_2]^{\cdot-} \xrightarrow[-CN^-,-B^-]{+\bar{e}+BH} C_6H_5CN \overset{+\bar{e}}{\rightleftarrows} [C_6H_5CN]^{\cdot-}$$

The irreversible two-electron *B* wave on the polarisation curves for the reduction of these compounds corresponds to this process. The increase in the number of cyano-groups in the molecule to four is responsible for the reversibility of the electrochemical reduction of the radical-anions of tetracyanobenzene to the dianions, which can be detected with 100% yield.[127]

A completely different picture is observed in the electrochemical reduction of the π-complex nitriles. With the exception of the complex $(NCC_6H_5)Cr(C_6H_5COCH_3)$, whose characteristics in the region of the potentials of the *A* and *B* waves permitted its assignment to the first group of substances, the radical-anions of the complex nitriles could not be detected in any instance by the RRDE method at room temperature, although the formation of the radical-anions of dibenzonitrilechromium as a result of chemical reduction with metallic potassium in dimethoxyethane at −70 °C has been demonstrated by the EPR method.[111] The two-electron *A* waves correspond to the elimination reaction of the CN group (compounds **7**–**10**), the stable products of which, namely the CN^- anion and the complexes $(C_6H_6)Cr(C_6H_5X)$ (X = H, CH_3, OCH_3, CN), can be detected at the amalgamated gold ring electrode.¶ In this respect, the nitriles of the dibenzenechromium series exhibit a greater similarity to the *ortho*- and *para*-isomers of dicyanobenzene than to benzonitrile.

Figure. 5 presents the polarisation curve for the electrochemical oxidation and reduction of the complex $(NCC_6H_5)_2Cr$ at the rotating disc electrode in solution in DMSO normalised with respect to the limiting current of the one-electron anodic oxidation of the complex to the cation (*Z* wave). Each of the cathodic waves (*A* and *B*) is of the two-electron type. Fig. 6 presents voltammograms of the anodic oxidation at the ring electrode of the products of the cathodic reduction of dibenzonitrilechromium at disc potentials E^d corresponding to the limiting currents of the *A* wave (curve *1*) and the *B* wave (curve *2*). In the region of the *A* wave, two products are formed, to which correspond two waves of equal height — the I wave ($E^{I}_{1/2} = -0.82$ V) and the II wave ($E^{II}_{1/2} = -0.46$ V). The current yields for each are 100%. The potentials $E^{I}_{1/2}$ and $E^{II}_{1/2}$ are characteristic of processes involving the formation of mercury cyanide and the oxidation of the complex $(C_6H_6)Cr(C_6H_5CN)$ to the cation respectively. Thus the following reaction takes place in the region of the potential of the *A* wave:

$$(NCC_6H_5)_2Cr \xrightarrow[-CN^-,-B^-]{+2\bar{e}+BH} (C_6H_6)Cr(C_6H_5CN)\ .$$

At the potentials of the *B* wave, a single III wave is observed at the ring electrode, its height exceeding by a factor of 3 that of the I wave on curve *1*. This finding is associated with the simultaneous occurrence of two anodic reactions with similar potentials $E_{1/2}$ — the oxidation of dibenzenechromium ($E^{+/0}_{1/2} = -0.76$ V) and the formation of $Hg_2(CN)_2$ as a result of the elimination of two cyano-groups from this initial complex. Consequently the following overall process takes place in the range of potentials of the *B* wave:

$$(NCC_6H_5)_2Cr \xrightarrow[-2CN^-,-2B^-]{+4\bar{e}+2BH} (C_6H_6)_2Cr\ ,$$

and the *B* wave itself characterises the elimination of the second cyano-group from the intermediate product — benzene(benzonitrile)chromium.

¶ The detection of the CN^- anions is based on the appearance in their presence in the layer near the ring electrode of the mercury oxidation wave with formation of mercury cyanide $Hg_2(CN)_2$ ($E_{1/2} = -0.82$ V).

Analysis of the reaction products by the RRDE method (Table 7) shows that, in the electrochemical reduction of the complex nitriles $(NCC_6H_5)Cr(C_6H_5X)$, where X = F, Cl, CF_3, the elimination of the CN group (*B* wave) is preceded by the elimination of the halogen (*A* wave).

An extremely important factor is the closeness of the slopes of the *A* wave for all the compounds included in Table 7 to 0.06 V regardless of the number of added electrons *n* and the reversible (aromatic nitriles) or irreversible (π-complexes) nature of the wave. This means that the electrochemical reduction of complex nitriles includes a chemical reaction between two electron transfer stages (ECE mechanism) and that the potential determining stage in the overall irreversible process is the reversible addition of the first electron to the initial molecule, which leads to the formation of unstable radical-anions.

The different behaviour at the cathode of free aromatic nitriles and their chromium complexes is due to the marked destabilisation of the radical-anions in the case of coordinated compounds, which diminishes the lifetime of these species compared with the radical-anions of the type $(XC_6H_4CN)^{\cdot-}$ by several orders of magnitude. The instability of the radical-anions of the complex nitriles is not related to their direct reduction at the electrode and is determined by their chemical decomposition via one of two possible pathways: the elimination of the cyano-group (halogen atom) from the radical-anion (a first-order reaction) with subsequent addition of a second electron to the free radical formed or disproportionation of the radical-anion (a second-order reaction) with partial regeneration of the initial complex, which again enters into the electrode reaction, and the formation of a dianion from which the cyano-group is eliminated in the form of the cyanide anion.

The mechanism of the process including the stage involving the reversible transfer of the first electron and the elimination of fluorine atoms operates[61] also in the reduction of trifluoromethylbenzene and its symmetrical chromium complex $(CF_3C_6H_5)_2Cr$. On the polarisation curve for the electrochemical reduction of this complex, it is possible to observe at low depolariser concentrations and for slow rotation of the electrode two waves corresponding to the addition of two (*A* wave) and four (*B* wave) electrons with subsequent formation of the complexes $(CF_3C_6H_5)Cr(C_6H_5CHF_2)$ and $(CF_3C_6H_5)Cr(C_6H_5CH_3)$.

The influence of proton-donating additives (benzoic acid, malonic ester, phenol, water) on the electrochemical reduction of complex nitriles has been investigated.[61] In the presence of additives, the elimination of the cyano-group is replaced by its partial or complete hydrogenation. In the presence of ammonium ions, which are reduced at the electrode more readily than the complex nitriles, the latter limiting current effect occurs[128, 129] — a decrease in the height of the two-electron cathodic waves for the electrochemical reduction of the nitriles to the one-electron level without change in $E_{1/2}$ and in the composition of the products of the cathodic reaction.[61] The cause of this phenomenon is either the interaction of the NH_4^+ ions as proton donor with the intermediate product of the electrochemical reduction of the nitriles (latent limiting current of the second kind) or the replacement of the electrochemical stage involving the addition of a second electron to the initial nitrile molecule by the stage in which the radical-anion is reduced chemically by the ammonium amalgam formed in the course of the reaction (latent limiting current of the first kind).

The third group of compounds includes aromatic hydrocarbons — phenylbenzenes and condensed systems as well as their chromium complexes. The electrochemical reduction reactions of the π-complexes containing naphthalene,[49] phenanthrene,[69] and biphenyl[48] as ligands were investigated by cyclic voltammetry, while the pairs of compounds[24, 61] $(C_6H_5)_2$–$[(C_6H_5)_2]_2Cr$ and $(C_6H_5)_3C_6H_3$–$[(C_6H_5)_3C_6H_3]_2Cr$ were studied by the RRDE method.

The first stage in the electrochemical reduction of aromatic hydrocarbons is known to be the reversible addition of an electron. The radical-anions formed are in many instances fairly stable and can be detected by various methods. Their destruction is attributed to the protonation reaction and subsequent transfer of a second electron either from the electrode or from a second radical-anion to the free radical.[130] The final products of the electrochemical reduction of aromatic hydrocarbons are partly hydrogenated compounds. There is every reason to assume that a similar mechanism, including a radical-anion protonation stage, operates also in the reduction of the corresponding π-complexes. The reversibility of the first electrochemical stage is indicated[61] by the slope of the cathodic wave $b \simeq 0.06$ V and the detection of the radical-anions of diphenanthrenechromium[69] and (naphthalene)-dibenzenedichromium.[49] The stability of the radical-anions of the non-coordinated phenylbenzenes appreciably exceeds that of the radical-anions of their π-complexes. Thus radical-anions have been detected in 50 and 100% yields by the RRDE method at the ring electrode at room temperature in the region of the first one-electron waves for the electrochemical reduction of biphenyl and a mixture of triphenylbenzene isomers respectively. In the electrochemical reduction of the corresponding complexes under the same conditions, the first cathodic waves in DMSO are characterised by $n = 4$ (biphenyl) and $n = 2$ (triphenylbenzene) and the radical-anions cannot be detected. The radical-anions of the π-complexes of condensed hydrocarbons are more stable, as a result of which the electrochemical reduction of diphenanthrene-chromium ($n = 1$) proves to be reversible.

There are incomplete literature data on the quasi-reversible one-electron cathodic reduction reactions of di(arsabenzene)-chromium[54] at 25 °C and bis(triphenylsilylbenzene)chromium[66] at −50 °C. The peaks due to the anodic oxidation of the radical-anions of both complexes were detected by cyclic voltammetry, which provides grounds for extending the conclusion that the first electron addition stage is reversible also to these compounds. As in the anodic oxidation reaction, di(arsabenzene)chromium behaves anomalously, being reduced at the cathode ($E^{C}_{1/2} = -1.36$ V) significantly more readily than free arsa-benzene ($E^{A}_{1/2} = -2.08$ V).

Thus, despite the irreversibility of many processes and the significant differences in the nature of the chemical stages of the reaction (dimerisation or protonation of the radical-anion, elimination of electroactive groups), the principal potential determining stage common to all the compounds of the benzene and dibenzenechromium series examined is the reversible addition of the first electron to the depolariser molecule.

IV. Characteristic features of the change in the reactivity of arenes under the influence of coordination to a chromium atom in one-electron transfer reactions

The establishment of the reversibility of the first electron addition stage in the electrochemical reduction reactions of free arenes and diarenechromium complexes is important from the standpoint of the possibility of using irreversible or quasi-reversible cathodic processes in the study of the reactivities of these compounds. On the one hand, there is a prospect of obtaining quantitative data concerning the influence of substituents in complexes, containing identical electrochemically active groups, on the ease of their reduction. In combination with correlation analysis, this makes it possible to assess the nature of the transmission of the electronic effects of substituents in one of the ligands to the reaction centre in the second ligand. Thus the potentials $E^{C}_{1/2}$ for the electro-chemical reduction of the heteroannularly substituted complex nitriles (compounds **7**–**13** in Table 7) are satisfactorily correlated[109] with the sets of substituent constants $\sigma^0_p, \sigma^0_m, \sigma_m$, and σ^+_m ($r = 0.961-0.972$). This indicates the predominantly inductive mechanism of the transmission of electronic effects in the molecule of the complex and agrees with conclusions reached as a result of the study of the reversible anodic oxidation reactions of the diarenechromium(0) complexes[29,61,62] and the ^{19}F NMR spectra.[96]

On the other hand, a basis appears for a quantitative comparison of the reactivities of the free and metal-coordinated arenes in similar electrochemical reduction reactions. A necessary precondition for the solution of this problem is the identity, noted above, of the reaction centres in the arenes and their π-complexes in cathodic reduction. We may note that the identical type of the main potential determining one-electron stage in the electrochemical reduction of the classes of compounds examined justifies the comparison of the potentials $E^{C}_{1/2}$ and $E^{A}_{1/2}$ of the first cathodic waves regardless of the total number of added electrons, which need not necessarily be identical in reactions involving an arene and its π-complex (electrochemical reduction of aromatic and complex nitriles).

For fully reversible processes, the half-wave potential difference $\Delta E^{CA}_{1/2}$ serves as a measure of the change in the reactivity of the arene as a result of its coordination to a chromium atom:

$$\Delta E^{CA}_{1/2} = E^{C}_{1/2} - E^{A}_{1/2} \simeq E^{C}_{0} - E^{A}_{0} = \frac{2.3RT}{F} \lg \frac{K^{C}}{K^{A}} , \qquad (11)$$

where K^{C} and K^{A} are the equilibrium constants of the corresponding redox processes. The quantity $\Delta E^{CA}_{1/2}$ characterises the overall effect of the change in the reactivities of the reactant in the electrochemical reduction reaction and of the radical-anion in the subsequent chemical reaction. Thus when the rotating disc electrode method is used in the case of the dimerisation of the radical-anions, the potentials $E^{C}_{1/2}$ and $E^{A}_{1/2}$ are defined by Eqn. (10) and their difference for $c = \text{const}$ and $\omega = \text{const}$ is defined by the equation

$$\Delta E^{CA}_{1/2} = \frac{2.3RT}{F} \lg \frac{K^{C}}{K^{A}} + \frac{2.3RT}{3F} \lg \frac{k^{C}_{d}}{k^{A}_{d}} + \frac{2.3RT}{9F} \lg \frac{D^{A}}{D^{C}} . \qquad (12)$$

Estimation of the contributions of the second and third terms on the right-hand side of the equation to $\Delta E^{CA}_{1/2}$ showed[50] that, at least for the first group of compounds, these terms can be neglected to a first approximation and the experimental quantity

$$\Delta E^{CA}_{1/2} \simeq \frac{2.3RT}{F} \lg \frac{K^{C}}{K^{A}} ,$$

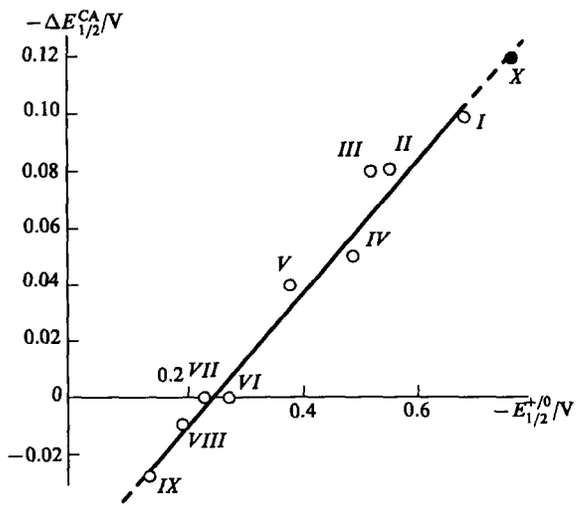

Figure 7. Correlation between $\Delta E^{CA}_{1/2}$ and $E^{+/0}_{1/2}$. The numbering of the points corresponds to the numbering of the Arene–Arene$_2$Cr systems in Table 5; X = calculated value of $\Delta E^{CA}_{1/2}$ for the C_6H_6–$(C_6H_6)_2Cr$ system.

characterises virtually only the change in the reactivity of the arene in the electrochemical reduction reaction as a result of its coordination to the metal atom.

The quantities $\Delta E_{1/2}^{CA}$ and $\lg(K^C/K^A)$ for a series of systems are presented in Table 5. Analysis of the data in the table permits the conclusion that the formation of π-complexes leads as a rule to a shift of the half-wave potential. The most marked difference is observed on passing from the free arene XC_6H_5 to the asymmetric complex $(XC_6H_5)Cr(C_6H_6)$, in which the arene (benzaldehyde, benzonitrile) is coordinated to the benzenechromium fragment. The value $\Delta E_{1/2}^{CA} = -0.31$ V corresponds to a decrease in the equilibrium constant of the electrochemical reduction reaction of the complex K^C by five orders of magnitude compared with K^A for the arene. Thus the fragment π-C_6H_6Cr plays the role of a very powerful donor relative to the arene, inducing an increase in electron density in the aromatic ring. On formation of symmetrical complexes $(XC_6H_5)_2Cr$, the difference $\Delta E_{1/2}^{CA}$ is significantly smaller and, depending on the nature of the substituent X and also on the number of substituents in the ligands, changes both in absolute magnitude and in sign. These results are fully consistent with data[108] for the Arene–(Arene)$Cr(C_6H_6)$–$(Arene)_2Cr$ system.

It has been established in a study of the characteristics of the cathodic processes for nine pairs of Arene–$Arene_2Cr$ compounds (Table 5)[65, 107] that there is a linear relation between the half-wave potential difference for the electrochemical reduction reactions involving each pair of substances $\Delta E_{1/2}^{CA}$ and the half-wave potential $E_{1/2}^{+/0}$ for the reversible anodic oxidation of the neutral form of the π-complex to the singly charged cation (Fig. 7):

$$\Delta E_{1/2}^{CA} = a' + \alpha' E_{1/2}^{+/0}, \quad (13)$$

where $a' = 0.072 \pm 0.007$ V, $\alpha' = 0.25 \pm 0.015$, and $r = 0.991$.

Since $\Delta E_{1/2}^{CA}$ is defined by Eqn. (11) and $E_{1/2}^{+/0}$ is a linear function[24, 61, 62] of the constants of the *meta*-substituents (σ_m, σ_m^0, σ_m^+), Eqn. (13) can be transformed into

$$\Delta E_{1/2}^{CA} = b' + \beta' \sum \sigma, \quad (14)$$

$$\lg \frac{K^C}{K^A} = g' + \gamma' \sum \sigma, \quad (15)$$

where $b' \simeq -0.125$ V, $\beta' = 0.13$, $g' \simeq -2.17$, $\gamma' = 2.2$, and $\sum\sigma$ is the sum of the Hammett constants of the *meta*-substituents.

Eqns. (13)–(15) correspond to the principle of linear free energy relationships and relate the change in the free energy as a result of the coordination of the arene to the metal atom involving the formation of a symmetrical π-complex to the free energy of the redox reaction (2) or other reactions involving the complexes, the logarithms of the equilibrium constants (rate constants) of which are correlated with the constants of the *meta*-substituents in the aromatic ring.

The unusual feature of Eqns. (13)–(15) and the significant difference between them and the Hammett correlation equations consist in the fact that the quantities $\Delta E_{1/2}^{CA}$ characterise pairs of compounds differing from one another in the nature of the reaction centre—in the electrochemically active group. The existence under these conditions of the linear relations (13)–(15) shows that the correlation equations obtained are based on a cause common to all the Arene–$Arene_2Cr$ systems investigated—the transition of the free arene to the state in which it is coordinated to chromium atom, i.e. on complex formation. In relation to this process, the electroactive groups play the role of substituents in the arene and do not participate directly in the process but do influence the distribution of electron density in the molecule. The electrochemical cathodic reduction reaction is in essence an indicator reaction, which makes it possible to determine the free energy change on transition of the arene to the state where it is coordinated to a chromium atom.

It follows from Eqns. (14) and (15) that the overall effect of the coordination of the arene to chromium consists of two components. The first component, characterised by the first term (b', g') is constant for all the symmetrical diarene-chromium complexes investigated and is responsible for the retardation of the cathodic reaction relative to the electrochemical reduction of the free arene. The second component (the $\beta'\sum\sigma$ and $\gamma'\sum\sigma$ terms) is variable and is determined by the nature and number of substituents in the arene ligands. Substituents with electron-accepting properties compensate to some extent for the inhibition of the reaction induced by the constant component of the coordination effect. In the presence of electron-accepting substituents, which give rise to $E_{1/2}^{+/0} > -0.3$ V, the overall effect of complex formation changes sign and the π-complex is reduced more readily than the corresponding free arene.

The relations obtained make it possible to calculate the potentials $E_{1/2}^C$ and hence also E_0^C for the electrochemical reduction reactions of symmetrical chromium π-complexes, provided that the corresponding values for the free arenes are known. This is of special interest in those cases where the cathodic process does not occur in the range of potentials accessible to measurements. Thus, according to Eqn. (14) the half-wave potential for the electrochemical reduction of dibenzene-chromium should be displaced approximately by 0.125 V towards negative values compared with $E_{1/2}^A$ for benzene. Since the potential for the $C_6H_6^{0/-}$ redox transition found experimentally[119] in solution in dimethoxyethane at −90 °C proved to be −3.38 V, the potential $E_{1/2}^C$ for dibenzene-chromium under these conditions should be about −3.5 V, i.e. should be in the range of potentials of the reduction of the solvent or the supporting electrolyte. This has been confirmed by Gavrilov et al.,[48] who were unable to observe the peak due to the electrochemical reduction of dibenzenechromium before the onset of the reduction of the supporting electrolyte under the conditions of the electrochemical reduction of benzene.

The available experimental data permit certain conclusions concerning the influence of coordination to chromium on the stability of the radical-anions—the intermediates in the electrochemical reduction of arenes and their complexes. In the case of compounds of the first group, the coordination of the arene to the metal has comparatively little effect on the stability of the radical-anions, especially in the presence of a double bond in the side chain [benzylideneacetophenone–bis(benzylideneaceto-phenone)-chromium, ethyl cinnamate–bis(ethyl cinnamate)-chromium]. The stability of the radical-anions falls somewhat as a result of the acceleration of the dimerisation reaction in the sequence $[C_6H_5CHO] > [(C_6H_5CHO)Cr(C_6H_6)] > [(C_6H_5CHO)_2Cr]$, which can be inferred from the decrease in the yield of the radical-anions at the ring electrode. The radical-anions of the complexes in the second group (nitriles) are appreciably less stable than the radical-anions of benzonitrile. They rapidly eliminate CN^- anions and are converted into neutral radicals, which are reduced at the electrode.

Table 8.

Compound	G/V
$(C_6H_6)_2Cr$	2.7
$(CF_3C_6H_5)_2Cr$	2.2
$(NCC_6H_5)_2Cr$	2.0
$(C_6H_5$-η^6-$C_6H_5)_2Cr$	1.9
$[(C_6H_5)_3$-η^6-$C_6H_3]_2Cr$	1.8
$[1,2$-$(C_2H_5OCO)_2C_6H_4]_2Cr$	1.7
$(CH_3COC_6H_5)_2Cr$	1.6
$(HCOC_6H_5)_2Cr$	1.5
$(C_2H_5OCOCH=CHC_6H_5)_2Cr$	1.3
$(C_6H_5COCH=CH$-η^6-$C_6H_5)_2Cr$	0.9

The difference in the behaviour of the radical-anions of the π-complexes belonging to the first and second groups of compounds is apparently due to the different nature of the distribution of the electron density.[131,132] In the radical-anions of free benzonitrile, the spin density is localised predominantly in the *para* and *ortho*-positions in the benzene ring and to a lesser extent on the cyano-group. On the other hand, in the presence of carbonyl groups (C=O, CH=CH−C=O), in the benzene ring, an appreciable proportion of the spin density in the radical-anion is on a carbon atom in the side chain. Naturally, the changes in electron density in the benzene ring induced by the coordination to chromium lead in the case of nitriles to a more significant changes in the stability of the radical-anions than in the case of carbonyl and vinyl derivatives.

Yet another aspect of the problem of the reactivity of the diarenechromium complexes is associated with the concept of the electrochemical gap G defined as the difference between the half-wave potentials for the anodic oxidation and cathodic reduction reactions of the complex.[133] The potentials $E_{1/2}$ characterise the relative energies of the frontier orbitals, while G characterises the difference between the energies of the HOMO and LUMO (energy gap).

Compounds of the benzene series are characterised by a wide electrochemical gap. Thus $G > 6$ V for benzene. The complex formation reaction between benzene and chromium leads to a marked narrowing of the gap (to 2.7 V) due to the fact that the HOMO of the complex is localised on the metal and lies appreciably above the HOMO of benzene, whereas the LUMO of the complex and the arene are of the same type and their energies are similar (see Table 8).

As mentioned above, in the diarenechromium complexes, the HOMO is influenced primarily by the electronegativity of the substituents in the ligands, whereas for the LUMO the conjugation effects are of greatest importance. The different character of the influence of substituents on the $E_{1/2}$ for the electrochemical oxidation and reduction processes, established in a number of studies,[24,29,61,62,65] alters the electrochemical gap. The gap is widest in dibenzenechromium and its derivatives containing substituents with a weak mesomeric effect (CN, CF_3) and is narrowest in complexes whose ligands have a long conjugation chain (ethyl cinnamate, benzylideneacetophenone).

The above analysis of studies on the chemistry of diarenechromium complexes demonstrates the interest in these compounds by chemists concerned with different disciplines. This is due to the characteristic features of the structure and chemical properties of dibenzenechromium and its derivatives and also the possibility of using them as convenient model compounds for the elucidation of general problems of the reactivity of transition metal π-complexes. Studies on these lines, to a large extent based on the investigation of the reversible electron transfer reaction in neutral complex/single charged cation systems, are most numerous and are of direct interest for organoelement chemistry and the chemistry of coordination compounds. The above reaction has also proved useful in the solution of certain problems of theoretical electrochemistry (a test of the theory of the reorganisation of the solvent, the creation of new reference electrodes suitable for the comparison of the results of electrochemical measurements in non-aqueous media of different nature). During the last 25 years, undoubted progress has been achieved also in the study of the kinetics and mechanisms of multistage cathodic processes with participation of diarenechromium(0) complexes.

However, one should note that at the present time the literature contains virtually no published study of preparative electrochemistry—not only on the synthesis of chromium complexes but also on the introduction of functional groups into the latter, although the results of the investigation of the kinetics of redox processes open the way in principle to the electrosynthesis of new compounds of the given class.

Abstract. Regioselective methods of synthesis of asymmetrically substituted diazene oxides, in which the diazene oxide group is linked to carbon, oxygen, sulphur, nitrogen, and phosphorus atoms, are examined. Data on the reaction conditions, yields, and structures of azoxy-products are presented. The bibliography includes 232 references.

I. Introduction

The first azoxy-compounds were synthesised almost 150 years ago,[1] but almost up to the middle of the present century these were mainly compounds containing identical structural fragments at the nitrogen atoms of the diazene *N*-oxide group. The vigorous development of the chemistry of the diazene *N*-oxides was stimulated by the isolation from natural sources of compounds of this type exhibiting a high biological activity (carcinogenic,[2-9] antibacterial,[10-16] tuberculostatic,[7-8] fungicidal,[10,16-18] and nematocidal[19,20]) and also of the discovery in the series of asymmetrically substituted *N,N'*-diaryldiazene *N*-oxides of substances exhibiting the properties of liquid crystals.[21-30]

Although a series of reviews has been devoted to the chemistry of azoxy-compounds,[31-35] the regioselective methods of synthesis of asymmetrically substituted compounds of the given series are dealt with in a fragmentary fashion in these publications. Furthermore, since the appearance of the last of the published reviews[34] more than ten years have elapsed, which makes it timely to survey the large amount of synthetic data which have been published during this period.

This review is devoted to the consideration of modern methods of synthesis of asymmetrically substituted diazene *N*-oxides from compounds which do not contain the diazene *N*-oxide group.

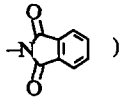
The data are classified in terms of the N→O, C–N, and N=N bonds formed with participation of the nitrogen atoms of the diazene group. The reactions involving the alkylation of anions containing the N_2O_2 structural fragments (salts of *N*-nitrosohydroxylamines, *N*-nitroamines, and hyponitrous acid), accompanied by the formation of a C–O bond separated from the diazene *N*-oxide group and leading to the formation of O-substituted azoxy-compounds which have been actively investigated in recent years (*N'*-alkoxydiazene *N*-oxides, O,N-disubstituted nitroamines) are included in the review as a separate section.

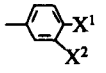
In order to cover more fully the synthetic data and to facilitate the use of the review, a considerable proportion of the information has been arranged systematically in the form of tables containing detailed data on the initial compounds and reagents, the reaction conditions, and the yields and structures of the azoxy-products. Only studies where details of the methods used in carrying out the reactions are given and the structures of the asymmetrically substituted azoxy-compounds have been reliably demonstrated have been included, as a rule, in the sources quoted.

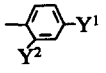
II. Oxidation of asymmetrically substituted azo-compounds

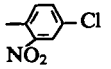
When an azo-compound is treated with oxygen-containing oxidants, a mixture of diazene *N*-oxides with different positions of the oxygen atom in the diazene *N*-oxide group is as a rule formed:[34]

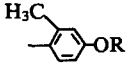
$$R^1-N=N-R^2 \xrightarrow{Ox} \underset{\mathbf{A}}{R^1-\overset{\uparrow}{\underset{O}{N}}=N-R^2} + \underset{\mathbf{B}}{R^1-N=\overset{\uparrow}{\underset{O}{N}}-R^2} \quad (1)$$

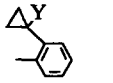


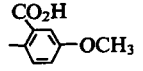












However, in a number of instances, the structural features of the starting substances ensure the preferential or exclusive formation of one of the regioisomeric oxidation products (Table 1).

The influence of the electronic and steric nature of the substituents at the nitrogen atoms of the azo-group on the regiospecificity of the oxidation process is clearly manifested in the series of *N,N'*-diaryldiazenes. The oxidation of *p*-nitro-[38] and *p*-alkoxy-diaryldiazenes[38-40] proceeds fairly selectively, in contrast to the oxidation of the majority of other asymmetric aromatic azo-compounds containing substituents in the *meta*- and *para*-positions in the aromatic ring, and makes it possible to synthesise azoxy-products in which the oxidised nitrogen atom is linked to the unsubstituted aromatic ring[38-40] (Table 1). The phenomenon of the identical directing effect of groups having completely different electronic characteristics has not yet received a satisfactory theoretical explanation,[34,38] but it can be used successfully in synthetic practice.

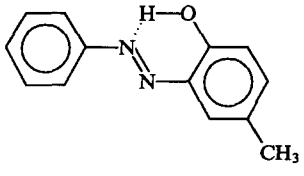
[a] The initial arylazo-compounds may be generated *in situ* by oxidising the corresponding hydrazo-compounds and can be introduced into the process without isolation and purification.



[b] For X ≠ Y, a mixture of the isomers $X-C_6H_4-\overset{\overset{O}{\uparrow}}{N}=N-NH-C_6H_4-Y$ and $X-C_6H_4-NH-N=\overset{\overset{O}{\uparrow}}{N}-C_6H_4-Y$ is formed. The component in which the oxidised nitrogen atom is linked to the aromatic ring containing a substituent with weaker electron-accepting properties predominates.

[c] The initial azo-compounds are generated *in situ* by oxidising the corresponding hydrazones.

In the case of *N,N'*-diaryl(heteroaryl)diazenes[53,54] containing substituents in the *ortho*-position relative to the azo-group, the sterically more accessible nitrogen atom, linked to the unsubstituted aromatic ring, is oxidised preferentially, the regioselectivity of the process reaching 75–100%.[41,47] Alkyl,[41,44] cycloalkyl,[45,46] alkoxy-,[41] ester,[41] carboxy,[42,47] and nitro-groups,[43] as well as halogen atoms[41] can be used as regio-controlling *ortho*-substituents. The *N*-oxide fragment of the heterocycle in the *ortho*-position relative to the azo-group exerts a similar directing effect[48] (Table 1).

The introduction of a second *ortho*-substituent into the aromatic ring as a rule fully inhibits the oxidation of the nitrogen atom of the azo-group linked to this ring.[49–52] The regiospecificity of the oxidation reactions of *N*-tetrafluoro-pyridyl-*N'*-(2,4,6-trimethylphenyl)diazene[53] and *N*-pentafluoro-phenyl-*N'*-phenyldiazene,[54] leading to the formation of azoxy-compounds in which the oxidised nitrogen atom is linked to the aromatic ring containing more bulky substituents in the *ortho*-position, therefore appears anomalous. A possible cause of the unexpected mode of oxidation of the above compounds may be, according to Miller and Furin, the increase in the nucleophilicity of the α-nitrogen atom induced by the decrease in the effectiveness of the interaction between the lone pair of the latter and the π-systems of the perfluoro- and 2,4,6-trimethyl-substituted aromatic rings.[54]

Processes involving the protonation of the reaction centre and the ability of the nitrogen atoms of the azo-group to participate in the formation of intramolecular hydrogen bonds can also exert a significant influence on the mode of oxidation of *N,N'*-diaryldiazenes. Thus, whereas the majority of *ortho*-substituents direct the oxidation of the N=N bond to the most remote nitrogen atom, in the case of *N*-(2-hydroxy-5-methylphenyl)-*N'*-aryldiazenes[41,55] (Table 1) a different mode of oxidation takes place preferentially, which is apparently due to the "blocking" of the lone pair of the β-nitrogen atom by the hydrogen atom of the hydroxy-group.[41]

The important role of the protonation of the reaction centre is confirmed by the different regiospecificities of the oxidation of *N*-(*p*-chlorophenyl)-*N'*-(*p*-alkoxyphenyl)-diazene[40] and *N*-phenyl-*N'*-(*p*-alkoxyphenyl)diazene[38] in media of different acidity (Table 1).

The oxidation reactions of asymmetrical azo-compounds in which one of the atoms is linked to an aromatic or heterocyclic system and the other to alkyl,[56,57] nitrile,[58,60,63] amino-carbonyl,[15,61,62] ester,[58,64] keto-,[58] or amino-group[65] are characterised as a rule by a high regioselectivity (Table 1). The reaction products are in this case usually asymmetrically substituted diazene *N*-oxides in which the oxygen atom is fixed in the α-position relative to the aromatic or heteroaromatic ring. The choice of the oxidant is determined by the stability under reaction conditions of the functional groups present in the molecule. Thus the synthesis of *N'*-cyanodiazene *N*-oxides from the corresponding cyanodiazenes[58–60,63] requires the use of 85% H_2O_2, because a more dilute hydrogen peroxide solution induces the hydrolysis of the nitrile group to the amide group.[15,58]

The oxidation of *N*-aryl-*N'*-(arylamino)diazenes (1,3-diaryltriazenes)[65] proceeds with participation of the nitrogen atom of the amino-group. The reaction results in the formation of a mixture of isomeric oxidation products (triazene oxides) in which the oxidised nitrogen atom is linked to one of the aromatic rings forming part of the molecule (preferentially to the ring containing electron-donating substituents).[65]

Data on the regioselective oxidation reactions of asymmetrically substituted aliphatic azo-compounds are limited to information about the oxidation of *N,N'*-dialkyldiazenes containing the acetoxy-group in the α-position relative to the azo-group[66,67] and about reactions with participation of *N*-alkenyl-[68] and *N*-dimethylaminocarbonyl-*N'*-alkyldiazenes[69] (Table 1).

The mode of reaction depends very greatly on the detailed characteristics of the structure of the initial compounds; slight changes in the structure of the substrates being oxidised (for example, in the number and disposition of the substituents at the double bond) entail a change in the site where the oxygen atom is attached in the azoxy-products formed. In our view, one should adopt a critical attitude to the conclusion[68] that the oxidation products have a regiostructure because it was based only on ^{1}H NMR spectroscopic data and is not supported by other reliable results (^{13}C and ^{14}N NMR and X-ray diffraction).

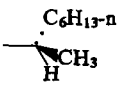
Thus oxidation of asymmetric azo-compounds to diazene *N*-oxides by oxygen-containing oxidants takes place regioselectively only in those cases where the substituents R^1 and R^2, linked to the nitrogen atoms of the azo-group, differ appreciably in their electronic and steric structures. The regiospecificity of the process is frequently unexpected and is not always susceptible to a simple interpretation from the standpoint of the structures of the initial compounds. The complexity of the detailed allowance for all the factors determining the direction of attack by the oxygen atom of the oxidant on a particular atom in the azo-group and the unpredictability of the mode of oxidation associated with this factor greatly reduce the synthetic value of the method and hinder its use for the specific synthesis of asymmetrically substituted diazene *N*-oxides.

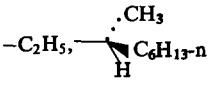
III. Reactions of *syn*-diazotates with alkylating agents

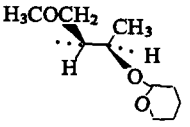
In 1969 Moss and coworkers[70,71] proposed a direct method of synthesis of asymmetrically substituted *N,N'*-dialkyldiazene *N*-oxides and *N*-arylalkyl-*N'*-alkyldiazene *N*-oxides from *syn*-alkyldiazotates and alkylating agents (Table 2).

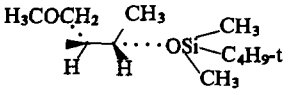
An intramolecular version of the reaction has been described:[79]

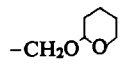
$$R^1-N=N-O^-K^+ + R^2X \rightarrow R^1-\overset{\overset{O}{\uparrow}}{N}=N-R^2 . \qquad (2)$$





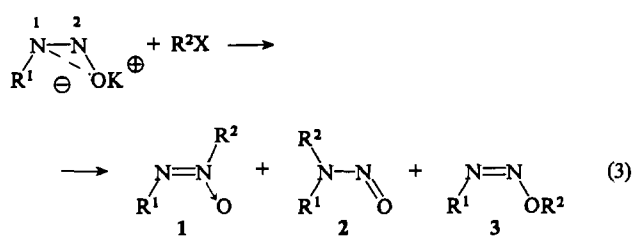






The reaction is regiospecific (the oxidised nitrogen atom in the azoxy-products formed is linked to the substituent R^2, which forms part of the alkylating agent). It involves nucleophilic attack by the N^2 atom of the diazotate anion on the electron-deficient carbon centre of the alkylating agent[80] and leads to complete or partial inversion of the configuration of the latter.[73]

The stereoselectivity of the reaction and the configurational stability of the alkyldiazotates make it possible in a number of instances to construct optically active azoxy-compounds with chiral centres at both nitrogen atoms of the diazene *N*-oxide group[73–75] (Table 2). In particular, the complete synthesis of elaiomycin[75]—a natural diazene *N*-oxide with powerful antibactericidal and carcinogenic properties—was achieved for the first time by the method considered.[7,81]



A serious disadvantage of Moss's method is the formation, together with the target azoxy-compounds **1**, of isomeric dialkylnitrosoamines **2** and diazoesters **3**—the products of alkylation at the N^1 and O atoms of the ambident diazotate anion.[80,82]

The diazoesters **3** are extremely unstable compounds and decompose under the reaction conditions, affording a mixture of nitrogen-free substances.

Table 2. Reaction conditions and the yields of products of the reactions of *syn*-alkyldiazotates with alkylating agents.

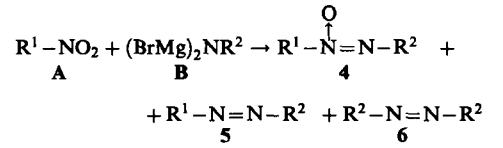
[b] $(C_2H_5)_3OBF_4$ was used as the alkylating agent.
Note. HMPA = hexamethylphosphoramide; THF = tetrahydrofuran (Translator).

(3)



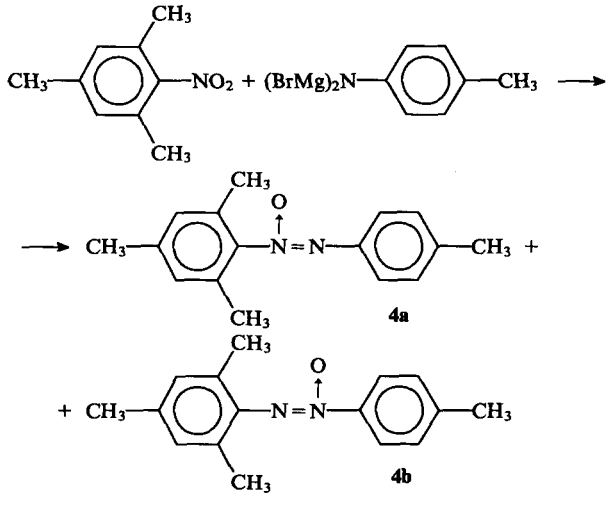
The influence of various factors on the mode of alkylation has been discussed in detail.[35] It is noteworthy that necessary conditions for the preferential formation of azoxy-compounds by Moss's reactions are the use of alkyldiazotates having the *syn*-configuration relative to the N=N bond[82] and the use of highly polar aprotic solvents, such as hexamethylphosphoramide[78] or glyme,[77] as the medium for carrying out the processes. However, even when the above conditions are maintained, it is not always possible to obtain the required azoxy-products.[77] The impossibility of using the more readily available *anti*-alkyldiazotates for the synthesis of diazene *N*-oxides[82] and also the impossibility of obtaining aromatic diazotates,[35] which are alkylated exclusively at the oxygen atom of the diazotate anion, significantly restricts the applications of Moss's reaction.

IV. Reactions of nitro- and nitroso-compounds with amino-derivatives

A more universal approach to the synthesis of asymmetrically substituted diazene *N*-oxides is based on the reactions of nitro- or nitroso-compounds with amino-derivatives. By varying the structures of the initial compounds, this procedure makes it possible to synthesise in one stage a wide range of products with the required combinations of substituents at the nitrogen atoms of the diazene *N*-oxide group.

1. Reactions of nitro-compounds with dimagnesyl derivatives of amines

In 1983 Japanese investigators[83] observed that aromatic nitro-compounds afford diazene *N*-oxides in their reactions with organodimagnesium derivatives of arylamines:



(4)

This reaction served as the basis of a new method of synthesis of asymmetrically substituted *N,N'*-diaryl(heteroaryl)diazene *N*-oxides. Its advantages are the ready availability of the initial compounds and the possibility of obtaining azoxyarenes with a fixed disposition of the oxidised nitrogen atom.

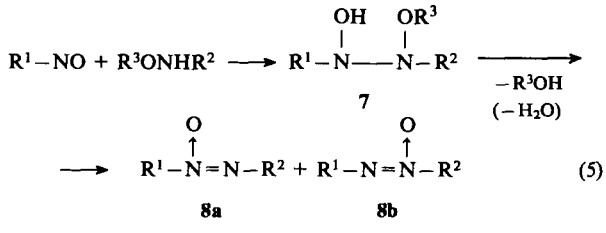
The reaction may be used to synthesise substituted *N,N'*-diaryldiazene *N*-oxides. Nitroarenes and dimagnesyl derivatives of arylamines containing alkyl, alkoxy-, and carbonyl substituents as well as halogen atoms in the aromatic ring enter into this reaction (Table 3). Azoxy-derivatives of naphthalene,[87,88] benzothiazole,[89] pyridine,[90] and ferrocene,[91] as well as polynuclear aromatic polyazoxy-compounds[92,93] have been obtained with its aid (Table 3). The synthesis of asymmetrically substituted azoxy-products from aliphatic nitro-compounds has been described.[94] The yields of diazene *N*-oxides **4** in this reaction reach 20–80% depending on the structure of the initial substances.

Unfortunately, together with the azoxy-compounds **4**, an appreciable amount of side products are formed during the reaction. These include in the first place, the diaryldiazenes **5** and **6**. The formation of the azo-compounds **5** and **6** can be explained[89–91] by the deoxygenation of the azoxyarenes **4** by the excess of the organomagnesium reagent $(BrMg)_2NR^2$ and by the oxidative dimerisation of the latter as a result of electron transfer from the reagent to the substrate. In this instance, the main factors influencing the relative yields of the products are the reactant ratio and the effectiveness of the one-electron transfer estimated from the oxidation-reduction potentials of the initial compounds.[86] Thus the introduction of electron-accepting substituents into the aryliminodimagnesyl reagent leads[83,84] to some increase in the yield of the azoxy-products **4**, while an increase in the ratio [B]/[A] is accompanied as a rule by an increase in the fraction of diaryldiazenes.[90] In a number of instances, the concept of the preliminary association under reaction conditions of the molecules of the initial compounds was used to account for the observed proportions of the products:[86,89]

The interaction of nitro-compounds with dimagnesyl derivatives of arylamines takes place as a rule regiospecifically and leads to the formation of azoxy-products in which the oxidised nitrogen atom is linked to the substituent R^1 forming part of the initial nitro-compound. This factor was used to obtain the isomeric *N,N'*-diaryldiazene *N*-oxides, which cannot be obtained by other methods and which differ in the position of the oxidised nitrogen atom in the diazene *N*-oxide group.[83,85,86,88,92] Substances having the properties of liquid crystals[29] and components of photosensitive compositions[88] have been synthesised in this way.

The only example of the isomerisation of the azoxy-group under the reaction conditions is the formation of isomeric azoxyarenes **4a** and **4b** from the sterically hindered 1-nitro-mesityl and *N,N*-bis(bromomagnesio)toluidine. The fraction of the rearrangement product **4b** increases with increase in the amount of the organometallic reagent, which indicates the involvement in the latter in the isomerisation process.[85]

Thus the interaction of nitro-compounds with dimagnesyl derivatives of arylamines constitutes a promising method of synthesis of asymmetrically substituted *N,N'*-diaryldiazene *N*-oxides of different structure. The wide scale employment of this reaction in synthetic practice has been held back, however, by the appreciable influence of the structure of the starting materials on the mode of this reaction and by the difficulty of isolating the target azoxy-compounds from the multicomponent mixtures of products formed in the course of the process. Furthermore, despite the data of Okubo et al.,[92] it is necessary to assess critically the possibility of synthesising with the aid of this method azoxyarenes carrying, apart from the azoxy-group, other functional group substituents sensitive to the action of bases.



2. Synthesis of asymmetrically substituted diazene *N*-oxides by the reactions of nitroso-compounds with amino-derivatives

In our view, the synthesis of asymmetrically substituted diazene *N*-oxides from organic amino- and nitroso-compounds is the most promising. N-Substituted and O,N-disubstituted hydroxylamines as well as amino-derivatives containing an *N*–halogen bond are used as the amine component. It is noteworthy that reactions of this type were frequently considered in the chemical literature as special methods permitting the synthesis of definite fairly narrowly defined types of azoxy-compounds: triazene *N*-oxides,[95,96] *N'*-alkoxydiazene *N*-oxides,[97,98] *N'*-fluorodiazene *N*-oxides,[99,100,110] etc. In the present review, the processes involving the formation of the diazene *N*-oxide group from nitroso-compounds and amino-derivatives are presented for the first time as a general method of synthesis of carbo- and hetero-substituted azoxy-compounds.

a. Reactions of nitroso-compounds with N-substituted and O,N-disubstituted hydroxyl amines

The traditional method of synthesis of asymmetrically substituted azoxy- compounds involves reactions of aliphatic and aromatic nitroso-compounds with *N*-alkyl- and *N*-aryl-hydroxylamines (Table 4). The reactions are carried out as a rule in organic solvents (C_2H_5OH,[54,56,102] CH_3OH,[103,104] aqueous tetrahydrofuran,[104] and CH_2Cl_2[105]) over a wide temperature range. The use of UV irradiation, promoting the dissociation of dimeric nitrosoalkanes to the monomers, has a favourable effect.[104] Depending on the structure of the compounds involved in the reaction, the yields of the azoxy-products range from 5 to 85%.

A possible reaction mechanism involves the formation of the N=N bond between the nitrogen atoms of the hydroxyamino- and nitroso-groups and the elimination of one of the oxygen-containing substituents from the intermediate **7** with formation of the final reaction products.[104]

(5)

The observed regiospecificity of the process is determined by the structure of the OR^3 fragment and that of the substituents R^1 and R^2. Thus the use of N-substituted *O*-methyl-[104] and *O*-pivaloyl-hydroxylamines,[42] containing the readily removed methoxy- (R^3 = CH_3) and pivaloyl [R^3 = $C(O)C_4H_9$-t] groups, permits the regiospecific synthesis of diazene *N*-oxides in which

the nitrogen atom forming part of the initial nitroso-compound is oxidised. The stabilisation of the adducts **7**, formed from N-monosubstituted hydroxylamines and containing two hydroxy-groups (R^3 = H) is usually achieved as a result of the splitting off of the OH group from the nitrogen atom linked to the least sterically hindered hydrocarbon substituent[104] or the substituent having weaker electron-accepting properties.[54]

However, reactions with participation of N-substituted hydroxylamines most often lead to the formation of both possible regioisomers (Table 4).[104] In certain cases, the reaction proceeds via an alternative rather than the expected pathway.[102,104] Such unpredictability of the regiospecificity of the reaction significantly hinders the use of the method for the synthesis of asymmetrically substituted diazene *N*-oxides with the required structure.

$$Ar^1NO + HONHAr^2 \longrightarrow \underset{\mathbf{9a}}{[Ar^1NHO]^{\bullet}} + \underset{\mathbf{9b}}{[Ar^2NHO]^{\bullet}} \xrightarrow[(-H_2O)]{} \longrightarrow \begin{cases} Ar^1-\overset{\uparrow O}{N}=N-Ar^1 \\ Ar^1-\overset{\uparrow O}{N}=N-Ar^2 \\ Ar^2-\overset{\uparrow O}{N}=N-Ar^1 \\ Ar^2-\overset{\uparrow O}{N}=N-Ar^2 \end{cases} \quad (6)$$

Ar^1, Ar^2 = Ph, *p*-C_6H_4Cl, *p*-$C_6H_4CH_3$.

The reaction of nitroso-compounds with N-monosubstituted hydroxylamines (R^3 = H) is unsuitable for the selective synthesis of asymmetrically substituted aromatic diazene *N*-oxides. In this case, one observes the formation of a mixture of azoxy-arenes — the products of the disproportionation of the aminoxyl radicals **9a** and **9b** detected by the EPR method.[106-109]

The reaction of nitroso-compounds with O,N-disubstituted hydroxylamines (Table 4) has not come to be widely used in synthetic practice owing to the low availability of the initial compounds and the low yields of the azoxy-products.[42,104]

b. The reaction of nitroso-compounds with amino-derivatives containing N–halogen bonds

The method of synthesis of asymmetrically substituted azoxy-compounds based on the reaction of nitroso-compounds with amino-derivatives containing reactive N-halogen bonds has developed appreciably in recent years (Table 5).

$$R^1-NO + XYNR^2 \xrightarrow{Cat} R^1-\overset{\uparrow O}{N}=N-R^2 \quad (7)$$

Derivatives of ammonia,[99,112,118,119,124] aliphatic amines,[105,112-115] the amides of carboxylic[112] and sulphonic[114,116,120-122] acids, urethane,[64,111,112,114,149] urea,[112] tetrafluorohydro-azine,[99,100,121,123,125-128] and 4-(dichloroamino)tetrafluoropyridine[53] are used as the amino-derivatives and aliphatic,[99,100,105,112,113,115,123-132,134,149] aromatic,[53,64,99,105,112-116,118-123,133] and heterocyclic[117,122] *C*-nitroso-compounds are used as the nitroso-derivatives (Table 5). The initial nitrosoalkanes can be introduced into the reaction in a pure state or can be generated *in situ* from olefins,[100,125] *gem*-dinitroalkanes,[126] and oximes[123,132,133] under the reaction conditions.

The reactions occur as a rule at room temperature in organic solvents. Processes with participation of tetrafluorohydrazine,[125,127-131,134] which are frequently carried out by heating the components up to 60–80 °C in the absence of a solvent, are an exception.

A wide variety of asymmetrically substituted azoxy-compounds containing various functional group substituents were synthesised in this way: esters,[64,100,111,112,114-116,121,131,149] carboxy-derivatives,[116,122] sulphoxy-derivatives,[120-122] nitriles,[100,113,114] nitro-derivatives,[64,99,105,115,120,124,126,129] carbonyl derivatives,[111,112] hydroxy-derivatives,[105,123] difluroamino-derivatives,[100,123,125,132] halo-derivatives,[99,112,118,119,121,123-125] etc. The method is applicable to the synthesis of azoxy-compounds in which the diazene *N*-oxide group is linked to a carbon, chlorine, bromine, fluorine, or sulphur atom (Table 5). The involvement of bisnitroso-compounds in the reaction ensures a single-stage synthesis of azoxy-products containing two diazene *N*-oxide groups.[112,113,133]

The reaction is regiospecific. In all cases, its products are asymmetrically substituted diazene *N*-oxides, in which the nitrogen atom of the initial nitroso-compound is oxidised. The chemical nature of the substituent R^2 in the amino-derivative does not affect the mode of reaction.

Whereas the regiospecificity of this process is independent of the nature of the amino-derivative, the reactivity of *N*-haloamines in the given reaction is determined by the type of halogen atom forming part of their composition. *N*-Bromo-derivatives of amines and amides containing the exceptionally reactive N–Br bonds exhibit a high reactivity in reactions with nitroso-compounds.[114] The more stable *N*-chloroamines are distinguished by a greater inertness and interact with nitroso-compounds only in the presence of promoting agents (zerovalent silver,[112] pyridine,[116,118,120-122] alkali metal hydroxides,[113] and Ag^+, K^+, Cu^+, Cu^{2+}, Co^+, Co^{2+}, and Fe^{2+} halides or cyanides[53,64,105,111,112,114]). Among the *N*-fluoroamines, only difluoroammonia and tetrafluorohydrazine, containing N–H and N–N bonds weakened by fluorine atoms and tending as a result to dissociate, have been involved in the reactions with nitroso-compounds (Table 5).

The mechanism of the reaction of nitroso-compounds with *N*-haloamines has not been studied in detail owing to the low stability of the latter. However, it has been suggested that in most cases a radical process mechanism operates and includes the following stages: (1) homolytic dissociation of the N–Y bond in the R^2NXY molecule; (2) the addition of the *N*-haloaminyl radicals **10** formed to the nitroso-compound present in the system; (3) stabilisation of the spin-active adducts **11** as a result of the elimination of the halogen atom.

$$R^2-\overset{X}{\underset{Y}{N}} \xrightarrow[-\dot{Y}]{} R^2-\dot{N}-X \xrightarrow{R^1-NO} \underset{\mathbf{10}}{} \longrightarrow \underset{\mathbf{11}}{R^2-\overset{X}{N}-\overset{O^{\bullet}}{N}-R^1} \xrightarrow[-\dot{X}]{} R^2-\overset{\uparrow O}{N}=N-R^1 \quad (8)$$

X = Cl, Br, F; Y = Cl, Br, H, NF_2.

This mechanism has been confirmed by the EPR detection of the $\dot{N}F_2$ and $R^1-N(\dot{O})-NF_2$ radicals formed in the reaction of nitroso-compounds with tetrafluorohydrazine[128] and by the first order of the reaction of *N*,*N*-dibromoalkylamines with nitrosobenzene.[114] The increase in the reactivity of *N*-haloamines with decrease in the strength of the N–halogen bond and the role of promoting agents, involving the substitution of chlorine atoms in the amino-group by the more reactive bromine

atoms[114] or the initiation of oxidation-reduction reactions of the amine component accompanied by the dissociation of the N–halogen bond therefore become understandable.[112,113]

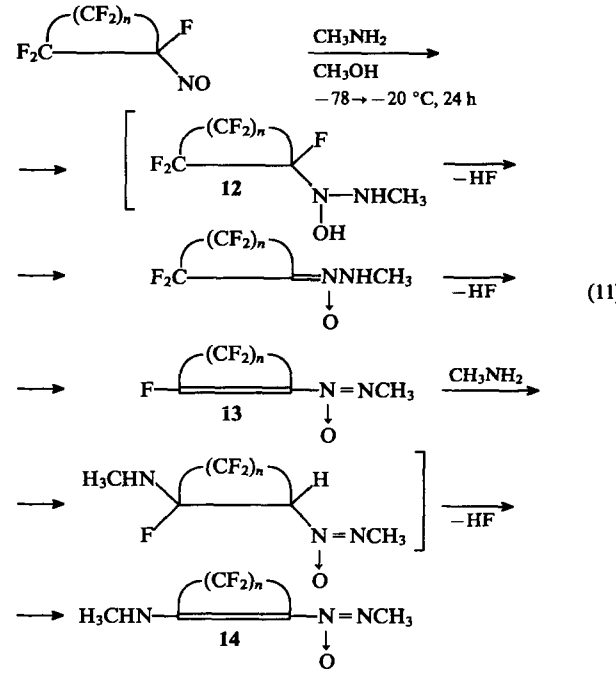
In the reactions involving perfluoronitrosoalkanes, which exhibit an exceptionally high electron affinity,[110] a radical-anion mechanism is more probable. This has been confirmed by the EPR method, with the aid of which the presence of the $R_FNO^{-\cdot}$ radical-anions in the reaction mixture has been detected.[128]

(9)

The ionic mechanism apparently operates in the reaction of nitroso-compounds with the anions of the *N*-chloroamides of sulphonic acids[120–122] and dihaloamine derivatives in the presence of bases.[99,112,113,118]

(10)

X = F, Cl; R^2 = O_2SAr, Cl, F.

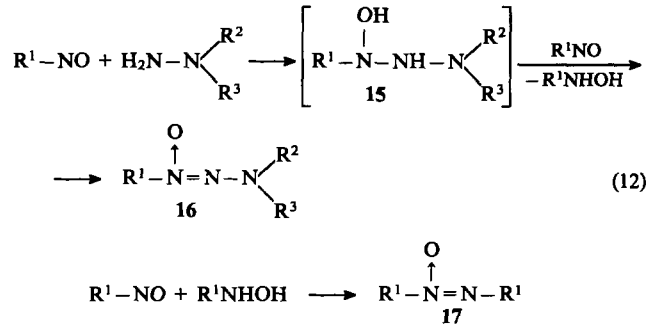


The "nitrene" mechanism of the reactions of nitroso-compounds with *N*-haloamines, *N*-haloamides, and *N*-halohydrazines, involving the formation of the nitrenes $R_2\ddot{N}$ and their addition to the N=O bond, is least probable in view of the absence of the characteristic products of the rearrangement and insertion of the nitrenes in the C–H bonds of the solvent.[113,114]

Thus the reaction of nitroso-compounds with amino-derivatives containing N–halogen bonds constitutes a convenient selective method of synthesis of asymmetrically substituted azoxy-compounds. The principal deficiency of the method is associated with the difficulty of isolation, the low stability, and the risk of explosion of the initial *N*-halo-compounds containing two and more N–halogen bonds. An additional restriction of the application of the reaction is the inability of *N*-haloamines to form the diazene *N*-oxide group in the reaction with *N*- and *O*-nitroso-compounds.[128]

c. Reactions of nitroso-compounds with compounds containing the NH_2 group

In view of the low stability of *N*-hydroxy- and *N*-halo-derivatives of amines, which limits their wide scale application, the direct synthesis of diazene *N*-oxides from nitroso-compounds and amino-derivatives containing an unsubstituted amino-group is extremely attractive. The reaction of nitroso-compounds with mono-substituted amines is known to entail usually the formation of asymmetrically substituted diazenes.[135–139] however, in a number of instances (when use is made of the characteristic features of the structures of certain types of starting compounds or when the reaction is carried out in the presence of oxidants), it is possible to drive the process towards the formation of diazene *N*-oxides.



Thus the products of the reaction of perfluoronitrosocyclobutane and cyclopentane with methylamine are methylazoxyperfluorocycloalkenes **14**. The reaction probably proceeds via the nucleophilic addition of methylamine to the N=O bond. The resulting adduct **12** is stabilised under these conditions by eliminating a HF molecule and by the addition of methylamine to the activated double bond of the azoxyalkene **13**.[140] The dehydrofluorination process is preferred to the usual process involving the dehydration of type **12** intermediates apparently because of the thermodynamic stability of the conjugated π-system forming part of compound **13**.

(11)

n = 2, 3

The reaction of nitroso-compounds with 1,1-dialkyl-,[96,144] 1-alkyl-1-aryl-,[96,141–144] and 1,1-diaryl-hydrazines,[96,142,143] leading to triazene 1-oxides, also takes place with retention of the NO bond (Table 6). Various nitrosoarenes, including those containing substituents in the aromatic ring,[141–144] and tertiary nitrosoalkanes[96] enter into this reaction. The latter probably proceeds via a stage involving the formation of the 1-hydroxy-triazane **15**, which is oxidised to the product **16** by the excess nitroso-compound.[96,144]

(12)

The side products of this oxidation-reduction reaction are hydroxy-aminoderivatives R^1NHOH and the products of their condensation with R^1NO — symmetrically substituted diazene *N*-oxides **17**.[96] The necessity for the use of an appreciable excess of the nitroso-compound (completion of the reaction requires 3 moles of the nitroso-compound per mole of hydrazine) and the marked dependence of the yields of triazene 1-oxides on the structure of the starting materials (Table 6) are serious disadvantages of the method, which lowers its preparative value.

In order to intensify the reactions leading to the formation of the diazene *N*-oxide group, the reactions of nitroso-compounds with primary amino-derivatives are carried out in the presence of compounds capable of oxidising the nitrogen atoms of the amino-groups but inert with respect to the nitroso-compound present in the system (Table 7). Mercury oxide,[96,145] diethyl azodicarboxylate,[144] lead tetraacetate,[96–98,148,150,151] phenyl iodosoacetate,[98,116,146,152,153,155] as well as halogenating agents [sodium hypochlorite,[113] bromine,[156] dibromoisocyanurate (DBI),[157–161]] and the *tert*-butyl hypochlorite–iodine[154] and *tert*-butyl hypochlorite–sodium methoxide[158] systems have been used as

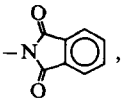
[a] The yield calculated relative to the hydrazine component is quoted.

such substances. The promising nature of the reaction of nitroso-compounds with amino-derivatives in the presence of oxidants is indicated by the finding that it was possible to involve in this reaction aliphatic,[96–98, 146, 148, 150, 152, 157–159, 161] aromatic,[96, 113, 116, 145, 146, 152–154, 156, 158–161] and heterocyclic[98, 152, 153, 155, 158, 161] *C*-nitroso-compounds as well as *N*-nitroso-compounds.[147]

Among amino-derivatives, alkyl- and cycloalkyl-amines,[113, 146, 154, 157] cyanamide,[116, 146, 152, 153, 155, 158, 228–231] urethane,[152, 158] urea,[158] the amides of phosphoric[161] and sulphonic[146, 152] acids, 1,1-disubstituted derivatives of hydrazine,[96, 144–147, 156, 160] and alkoxyamines[97, 98, 148, 150, 151] were used. Such a wide range of substances involved in the given reaction ensures the synthesis with its aid of a wide range of carbo- and hetero-substituted azoxy-compounds whose diazene *N*-oxide group is linked to carbon,[113, 116, 146, 152–154, 157–159] oxygen,[97, 98, 148, 150, 151] nitrogen,[96, 144–147, 156, 160] and sulphur[146, 152] atoms.



$$R^1-NO + H_2N-R^2 \xrightarrow{Ox} R^1-\overset{\overset{O}{\uparrow}}{N}=N-R^2 \qquad (13)$$

The majority of reactions of the given type take place readily under exceptionally mild conditions (at room or lower temperatures in inert organic solvents) and can be used to obtain azoxy-products containing various, including labile, functional groups.

The regiospecificity of the method is valuable. Regardless of the structure of the nitroso- and amino-compounds involved in the process and of the oxidant employed, the nitrogen atom forming part of the initial nitroso-compound is oxidised. The chemistry of the process is determined by the structure of the amine component and by the chemical nature of the oxidant. The mechanism of reaction (13) in the presence of oxidants such as mercury oxide or ethyl azodicarboxylate (a three-component reaction) is apparently similar to that of the corresponding two-component reaction (12) with the sole difference that in the given instance the intermediate **15** is dehydrogenated to the corresponding triazene 1-oxide by the oxidant present in the system.[96, 144] The synthetic result of the use of the oxidant is an increase in the effectiveness of the process, which can be carried out in the absence of an excess of the nitroso-compound.

When $Pb(OAc)_4$ and $C_6H_5I(OAc)_2$ are used as oxidants, the reaction of nitroso-compounds with amino-derivatives probably proceeds via a different pathway. Here the role of the oxidant consists in the formation of an electron-deficient centre of the nitrene type at the nitrogen atom of the amino-group, which subsequently interacts with the nitroso-compound to form the required diazene *N*-oxides.[96, 97, 147, 148, 151, 152]

$$R^2NH_2 \xrightarrow[\text{or } C_6H_5I(OAc)_2]{Pb(OAc)_4} [R^2N:] \xrightarrow{R^1NO} R^2-\overset{\overset{O}{\uparrow}}{N}=N-R^1 \qquad (14)$$

$R^2 =$  , $-OAlk$, $-CN$, $-CO_2C_2H_5$, $-SO_2C_6H_5$.

In the case of $C_6H_5I(OAc)_2$, a coordination process mechanism involving the formation and dissociation of the bond between the nitrogen atom of the amine component and the hypervalent iodine atom, has also been proposed.[146] When $Pb(OAc)_4$ and $C_6H_5I(OAc)_2$ are used, it is useful to involve in the reaction amino-derivatives capable of forming fairly stable nitrenes on treatment with oxidants: *N*-aminophthalimide, alkoxyamines, and cyanamide.[162, 163] Reactions with participation of the amides of arenesulphonic acids and urethane, whose nitrene derivatives are less stable, are characterised by a lower effectiveness.[152] The use of 1,1-dialkylhydrazines, incapable of forming stable nitrenoids in neutral media,[164] as amino-derivatives leads to the formation of 1,1,4,4-tetraalkyltetrazenes — the products of the oxidative dimerisation of the initial amino-compounds — instead of the expected triazene *N*-oxides.[96]

$$PhNO + H_2N-N(CH_3)_2 \xrightarrow{Pb(OAc)_4} \begin{cases} Ph-\overset{\overset{O}{\uparrow}}{N}=N-N(CH_3)_2 \\ (H_3C)_2NN=NN(CH_3)_2 \end{cases} \qquad (15)$$

Finally, in the presence of halogenating agents,[113, 154] the reactions of nitroso-compounds with amino-derivatives probably proceed via a stage involving the formation of *N*-halo-derivatives

[a] The nitroso-compound was obtained *in situ* by oxidising $H_2NOCHPh_2$.

[b] The nitroso-compound is formed *in situ* from acetone oxime.

[c] The nitroso-compound was obtained *in situ* by brominating a salt of ethanenitrolic acid.

of amines[157,158,161] or hydrazines,[160] which interact with nitroso-compounds via one of the pathways examined in section I.3 [via a radical pathway[154] — reaction (8), with participation of diazenium cations[156] — reaction (9), or with participation of the anions of *N*-haloamines[158] — reaction (10)].

Reaction (16) is superior to reaction (7) since in this case there is no necessity to isolate and purify the intermediates with the N–halogen bond, generated *in situ*, which makes it possible to involve successfully in the reaction amino-compounds whose halo-derivatives are distinguished by an extremely low stability (cyanamide,[158] 1,1-disubstituted hydrazines,[156,160] ethers of amidoximes,[159] etc.).

$$AlkNH_2 \xrightarrow[X = Hal]{X^+} \begin{bmatrix} AlkNHX \\ AlkNX_2 \end{bmatrix} \xrightarrow{R^1NO} AlkN{=}\overset{\overset{O}{\uparrow}}{N}R^1 \qquad (16)$$

Overall, the oxidative condensation of nitroso-compounds with substances containing a primary amino-group constitutes one of the most promising approaches to the formation of C-, N-, P-, and O-substituted diazene *N*-oxides of different structure.

V. Interaction of anions containing the N_2O_2 structural fragment with electrophiles

A specific method of synthesis of asymmetrically substituted azoxy-compounds in which the nitrogen atoms of the diazene *N*-oxide group are linked to two oxygen atoms involves the reaction of anions containing the N_2O_2 structural fragment (salts of N-substituted *N*-nitrosohydroxylamines, primary *N*-nitroamines, *N*-nitroamides of hyponitrous acid) with electrophiles. This reaction is accompanied by the formation of the C–O bond the elements of which do not form part of the diazene *N*-oxide group and is therefore considered separately from the chemically related reaction involving the alkylation of *syn*-diazotates [see section III, reaction (2)]. The early studies of reaction (17) and the general principles governing the alkylation of ambient anions with N–N bonds were described in another review.[35] This review deals with the present state of the problem and considers primarily studies carried out in recent years which have greatly expanded the applications and preparative possibilities of the method.

$$R^1{-}N{-}\overset{\ominus}{N}{-}\dot{O}\,Cat^{\oplus} + XR^2 \longrightarrow \underset{\mathbf{18}}{R^1{-}\overset{\overset{O}{\uparrow}}{N}{=}N{-}OR^2} + \underset{\mathbf{19}}{R^1{-}\overset{N=O}{\overset{|}{N}}{-}OR^2} \qquad (17)$$

The alkylation (sulphonylation, stannylation) of salts of N-substituted *N*-nitrosohydroxylamines, which makes it possible to synthesise regiospecifically azoxy-products in which the alkoxy-substituent is linked to the distal nitrogen atom of the diazene *N*-oxide group, has come to be most widely used in synthetic practice among reactions of the type considered (Table 8). The range of *N*-nitrosohydroxylamine salts involved in this reaction is fairly wide: these are the salts of aliphatic and aromatic *N*-nitrosohydroxylamines, including those containing different functional group substituents in the molecule. The cations of alkali[166,167,172,173,176,178–182] and alkaline earth metals,[170] silver,[165,166,168,169,185] ammonia,[165–167,181,182,184] and organic bases[174] were used as counterions. The electrophiles were alkyl halides, dialkyl sulphates, oxirans, toluene-*p*-sulphonyl chloride, and anhydrides of trifluoromethanesulphonic acid, and compounds with the Sn–Cl bond (Table 8).

The reactions are carried out in hydroxylated solvents,[165–167,170–173,175–177,179,181,183] dimethyl sulphoxide,[166,175,176,178–180,186] chlorohydrocarbons,[182] ether,[166,168,169,185] acetonitrile,[174] and sulphur dioxide[184] at −10 to +80 °C.

A favourable effect is achieved by carrying out the reaction in the presence of a base, which neutralises the products of the side processes. An important advantage of the reaction is the possibility of synthesising with its aid *N'*-alkoxydiazene *N*-oxides containing different functional groups in the hydrocarbon fragments of the molecule. Thus alkylation of salts of *N*-nitrosohydroxylamines containing carbonyl[175–177] or ester[178,180] groups proceeds with retention of the above substituents and makes it possible to synthesise in one stage the corresponding *N*-alkyl-*N'*-alkoxydiazene *N*-oxides. Further-more, the formation of the diazene *N*-oxide fragment proceeds smoothly also in the presence in the anion being alkylated of a carboxy-group, which is transformed into an alkoxycarbonyl group under the reaction conditions.[179,180]

N'-Alkoxydiazene *N*-oxides containing functional groups in the alkoxy-component of the molecule are formed in the reaction of salts of *N*-nitrosohydroxylamines with alkylating agents containing functional groups.[166,168,172–174] The involvement of oxirans in the reaction is accompanied by the regioselective opening of the oxiran ring and the formation of hydroxylated *N'*-alkoxydiazene *N*-oxides, in which the diazene *N*-oxide fragment is linked to the most hydrogenated carbon atom of the given compound.[172,173]

The interaction of salts of *N*-nitrosohydroxylamines with sulphonic acid chlorides[181–184] and tin halides[185,186] makes it possible to synthesise azoxy-products (unavailable by other methods) containing a fragment comprising several directly linked heteroatoms: $-\overset{\overset{O}{\uparrow}}{N}{=}N{-}O{-}E{-}$ (E = S, Sn). The products of the alkylation of nitrosohydroxylamines by tin dihalides have a unique structure. In this case the reaction proceeds with participation of both halogen atoms and leads to the formation of bisdiazene *N*-oxides in which the heteroatomic chain consists of nine heteroatoms (Table 8).[185]

Azoxy-compounds containing two diazene *N*-oxide groups can be obtained also by the reaction of salts of *N*-nitrosohydroxylamines with epibromohydrin[172,173] (Table 8) and by alkylating the dianions of 1,1-bis(*N'*-nitrosohydroxyamine)alkanes (Table 9).[167,187,188] The 1,1-bis(*N'*-alkoxy-*N*-oxodiazeno)-alkanes **20** proved unexpectedly stable. Such compounds can be purified by heating with acids and alkalis.[167,169]

$$R^1{-}CH(N{-}\overset{\ominus}{N}{-}\dot{O})_2 \cdot 2Cat^{\oplus} + XR^2 \longrightarrow \underset{\mathbf{20}}{R^1{-}CH(\overset{\overset{O}{\uparrow}}{N}{=}N{-}OR^2)_2} \qquad (18)$$

Kinetic studies have shown that the alkylation reactions of salts of mono- and bis-(*N*-nitrosohydroxyamino)alkanes with dimethyl sulphate are first order with respect to each component and proceed via a bimolecular nucleophilic substitution mechanism.[171,190] The stringent requirements which must be met by the transition state of the process are confirmed by the high negative entropies of activation for the reaction (−63 to −127 J mol^{-1} K^{-1})[171,190] and by the decrease in the yield of the azoxy-products with increase in the three-dimensional branching of the alkylating agent.[165]

The alkylation reaction is complicated in many instances by the low stability of the salts of the initial *N*-nitrosohydroxylamines and the associated impossibility of isolating them in a pure state. The salts obtained by nitrosating the corresponding hydroxyamino-derivatives,[181] Grignard reagents,[170,181,183] or carbonyl compounds[175–178,180] in an alkaline medium are as a rule highly contaminated by side products, which lower appreciably the yields of the *N'*-alkoxydiazene *N*-oxides synthesised from them. The appreciable influence of the quality

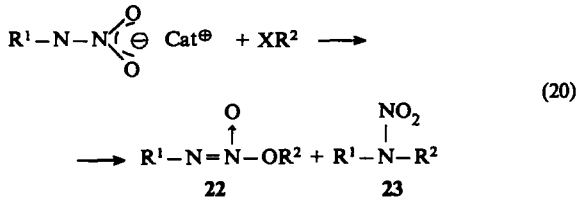
of the initial compounds on the effectiveness of the alkylation reaction is confirmed by the increase in the yields of the azoxy-products when purified salts of *N*-alkyl-*N*-nitrosohydroxylamines are involved in the reaction.[170,181]

Another factor which complicates the alkylation reaction is the ambident nature of the anions of *N*-nitrosohydroxylamines. Both oxygen atoms of the RN_2O_2 group can participate in the process, which leads to the formation, together with the required *N'*-alkoxydiazene *N*-oxides **18**, of isomeric O,N-disubstituted *N*-nitrosohydroxylamines **19** [reaction (17)]. There is virtually no quantitative information in the literature about the ratio of the isomeric products of the alkylation of salts of *N*-nitrosohydroxylamines. This is due to the low chemical and thermal stabilities of compounds **19**, which usually decompose under the reaction conditions. It is only known[174] that the main product of the alkylation of the tetraethylammonium salt of *N*-methyl-*N*-nitrosohydroxylamine with allyl bromide is *O*-allyl-*N*-methyl-*N*-nitrosohydroxylamine **19**, whereas the yield of the required *N*-methyl-*N'*-allyloxydiazene *N*-oxide **18** does not exceed 34% (Table 8). The lack of systematic data precludes the estimation of the influence of the structure of the interacting compounds and the reaction conditions on the mode of alkylation, which hinders deliberate regulation of the process.

On the basis of general considerations, the formation of *N'*-alkoxydiazene N-oxides might have been expected in the reaction of salts of hyponitrous acid, containing the ambident anion $N_2O_2^{2-}$, with alkylating agents. However, only one example of the reactions of hyponitrites accompanied by the formation of the diazene *N*-oxide group has been described in the literature. This involves the alkylation of silver hyponitrite with diphenylmethyl chloride. The reaction is carried out in a benzene–hexane mixture at 20 °C for 3.5 h; the yield of *N*-diphenylmethyl-*N'*-diphenylmethoxydiazene *N*-oxide **21** does not exceed 11%.[191]

$$2Ph_2CHCl + Ag_2N_2O_2 \longrightarrow \underset{\mathbf{21}}{Ph_2CHN(O)=N-OCPh_2} \qquad (19)$$



In the remaining cases the products of the alkylation of the ambident anions $N_2O_2^{2-}$ are unstable esters of *trans*-hyponitrous acids.[192]

Whereas the synthesis of *N'*-alkoxydiazene *N*-oxides is extremely widely represented in the chemical literature, less attention has been devoted to the synthesis of isomeric azoxy-

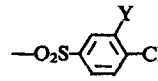
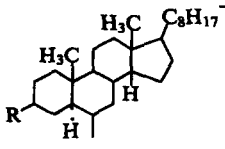
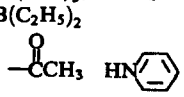
compounds **22** (Table 10), in which one of the nitrogen atoms of the diazene *N*-oxide groups is linked to two oxygen atoms. A general approach to the synthesis of structures of this type involves the interaction of salts of *N*-nitroamines and *N*-nitroamides with alkylating and acylating agents or the interaction of the corresponding CH acids with diazomethane (Table 10).

(20)







Like other reactions involving the alkylation of ambident anions containing the N_2O_2 fragment, the above processes are complicated by the formation, together with the azoxy-compounds **22**, of the isomeric products which in the given instance are secondary nitroamines **23**. The involvement in the reaction of the silver salts of nitroamines[169,193] and nitroamides[197–199] and increase in the size and degree of branching of the groups R^1 and R^2 in the interacting compounds[196,198,200] help to drive the process towards the preferential formation of the diazene *N*-oxide group. A decrease in the polarity of the solvent also promotes an increase in the yield of the *O*-alkylation products.[198]

When the initial compound contains a nitroamino-group and a halogen atom in vicinal positions, the reaction takes place intramolecularly[201] with the selective formation of cyclic azoxy-products **24**.

R^1 = H, CH_3; R^2 = H, CH_3.

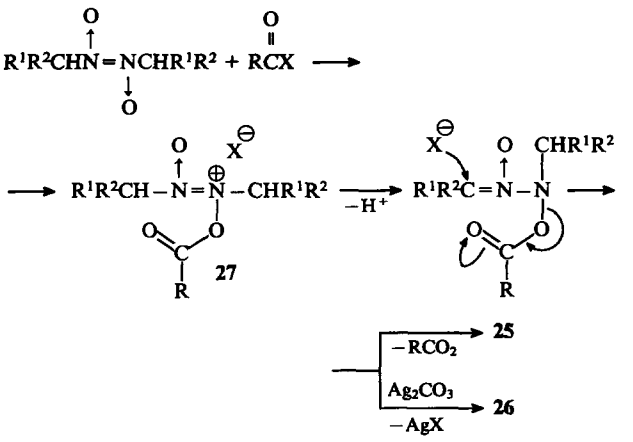
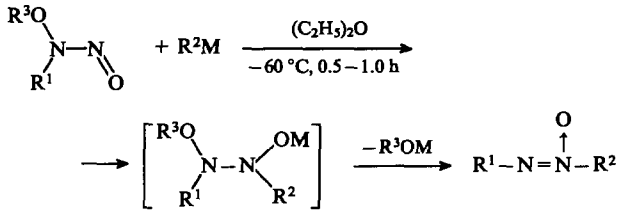
[a] The product was not isolated.
[b] CH_2N_2 was used as the alkylating agent.

Thus the alkylation of ambident anions containing the N_2O_2 structural fragment is a fairly common method of synthesis of asymmetrically substituted azoxy-compounds, in which the diazene *N*-oxide group is linked directly to an oxygen atom. Linear and cyclic azoxy-products, including those with different functional groups, can be obtained by means of this reaction. The principal disadvantage of the method is the uncertainty in the course of the reactions due to the dual reactivity of the alkylated anions and hence the low yields of the target azoxy-compounds.

VI. Other methods of synthesis of asymmetrically substituted diazene *N*-oxides

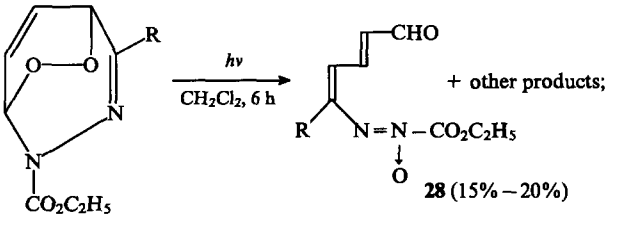
Apart from the alkylation of anions containing the N_2O_2 fragment, a number of other special methods of synthesis of asymmetrically substituted diazene *N*-oxides, used to obtain a narrow range of azoxy-products with specific structures, have been described in the literature. However, these methods have not found extensive applications in synthetic practice because of their limited applicability, low availability of the initial compounds, and also the inconvenient preparative aspect of the process. We shall consider some of these reactions. Thus the reaction of the dimers of primary and secondary nitrosoalkanes with acid halides leads to the formation of α-haloalkyldiazene *N*-oxides **25** containing a halogen atom in the α-position relative to the oxidised nitrogen atom of the diazene *N*-oxide fragment.[202]
When the reaction is carried out in the presence of Ag_2CO_3, its products are the corresponding α-acyloxyalkyldiazene *N*-oxides **26**.



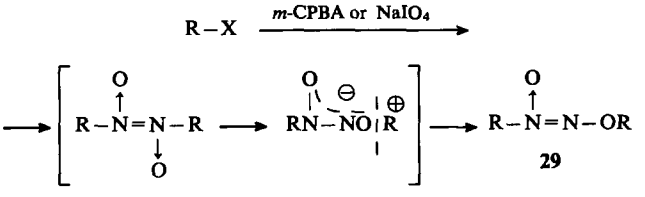


R^1	R^2	X	Yield of **25** (%)
$-C_3H_7$-i	H	Cl	65
$-C_3H_7$-i	H	Br	41
$-(CH_2)_5-$		Cl	25
$-CCl(CH_3)_2$	H	Cl	74

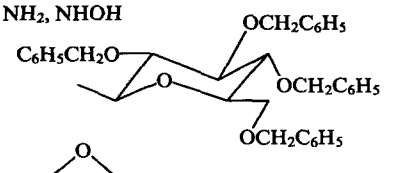
It has been suggested that the process proceeds via a stage involving the formation of *O*-acyl derivatives of diazene *N,N'*-dioxides **27**, which are stabilised by conversion into the final reaction products via the addition of a halide anion or (in the presence of Ag_2CO_3) via a rearrangement.[202]



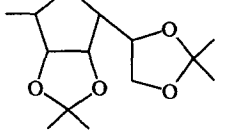
The regiospecific formation of the azoxy-group is observed in the reaction of *N*-nitroso-*O,N*-dialkylhydroxylamines with certain organometallic reagents, but the yields of the asymmetrically substituted azoxyalkanes do not as a rule exceed 20–30% in this case and the reaction has no preparative value.[203]



R = H, CH_3



The photolysis of 1*H*-diazepine 1,2-epidioxides leads to the formation of a mixture of products,[204] one of which is the azoxyalkene **28** with functional group substituents.



R^1, R^3 = Alk; R^2 = Alk, Ar; M = Li, MgBr.

The reaction of the amino- and hydroxyamino-derivatives of glucopyranose and mannose with oxidants results unexpectedly in the formation of the azoxy-derivatives **29** of the corresponding carbohydrates, containing the $-N{=}N(O)-$ structural fragment.[205]

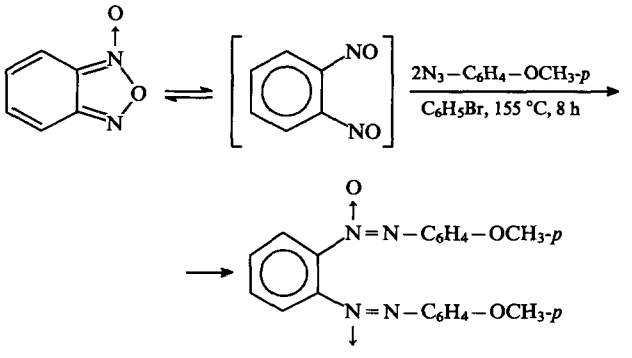
R = 
(yield 32%),

R = 
(yield 44%).

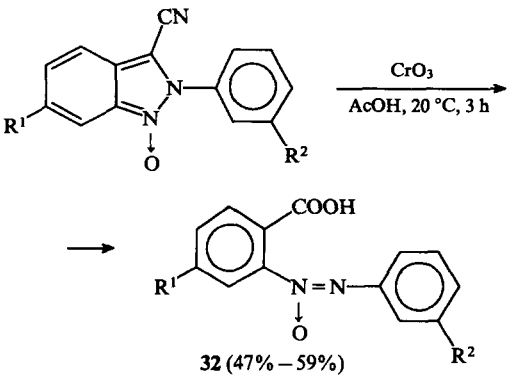
The authors explained this unusual mode of reaction by the heterolytic cleavage of the N–R bond in the dimeric nitroso-compounds (primary oxidation products) and the subsequent recombination of the ion pair, which leads to the product **29**. The driving force of the process is in this case the thermodynamic stability of the anions of the nitrosohydroxylamines and the cyclic oxonium cations.



The formation of the diazene *N*-oxide group has been noted in the reaction of aromatic nitroso-compounds with cyanazides,[59,60] aryl azides,[206] and heteroaryl azides.[53] The most probable reaction pathway involves the addition of cyano-, aryl-, and heteroaryl-nitrenes **30**—the products of the thermal decomposition of the corresponding azide-derivatives—to nitrosoarenes with formation of the final reaction product **31**.

Ar = $-C_6H_4X$ (X = H, NO_2, $N(CH_3)_2$).

Together with nitroso-compounds, benzofuroxan can be made to react with aryl azides. It recyclises under the reaction conditions to *o*-dinitrosobenzene.[207]



In view of the severe conditions in the thermolysis of the azides and the associated risk of explosion in the process as well as the low yields of the azoxy-products, this reaction cannot be regarded as a preparative method of synthesis of asymmetrically substituted diazene *N*-oxides.

A specific method of synthesis of *N,N'*-diaryldiazene *N*-oxides **32** with various substituents in the aromatic rings involves the oxidation of 2-aryl-3-cyanoindazole-1-oxides with chromium trioxide.[208,209]

Despite its regiospecificity, the reaction has not found wide scale application in synthetic practice, apparently owing to the low availability of the initial compounds.

VII. Conclusion

The data examined in this review show that studies designed to expand the applications of the known regioselective methods of synthesis of asymmetrically substituted diazene *N*-oxides and to develop new ones have been actively prosecuted in recent years in both our own and foreign scientific centres. A wide range of asymmetrically substituted azoxy-compounds, whose diazene *N*-oxide group is linked to carbon, oxygen, sulphur, nitrogen, and phosphorus atoms, has become available as a result. The range of the possible practical applications of these substances is extremely wide. Thus many of the newly synthesised asymmetrically substituted diazene *N*-oxides can be regarded as potential medicinal drugs (antibacterial,[7,10,12–16,59–61,63,122,153,214–217] antimicrobial,[218,219] antitumour,[12–16,63,122,153,220] anti-inflammatory,[145,221] immunodepressant,[222–224] anticonvulsive,[225,226] and analgesic[227]) as well as chemical plant protecting agents (nematocides,[19,20] fungicides,[16–18,186,228–231] and insecto-acaricides[161]), as components of liquid crystal compositions,[21–30] as gas-generating substances,[213] and as high-performance phases for gas–liquid chromatography.[30,210–212]

R^1, R^2 = H, NO_2

Bearing in mind the dynamics of the development of the synthetic and applied studies in this field, one may expect the preparation in the next few years of new diazene *N*-oxides which can find wide scale applications in various branches of science, industry, medicine, and agriculture.

The synthesis and properties of unsaturated nitro-compounds of the furan series

R A Karakhanov, V I Kelarev, Yu N Polivin

Contents

I. Introduction	169
II. Methods of synthesis of furylnitroalkenes	169
III. Structure and reactivity of furylnitroalkenes	174
IV. Chemical properties	179
V. Practical applications of furylnitroalkenes	188

Abstract. A systematic account is provided of data in the field of the chemistry of unsaturated nitro-compounds of the furan series. The methods of synthesis of nitroalkenes of the furan series and the characteristic features of the structure and reactivity of furylnitroalkenes are examined. The general characteristics and distinctive features of the chemical reactions of furylnitroalkenes are discussed and their applications are noted. The bibliography includes 212 references.

I. Introduction

The chemistry of unsaturated nitro-compounds is a promising and vigorously developing field in modern organic chemistry. This is associated with the progress achieved in the methods of synthesis of such compounds and their high reactivity.[1-6]

During the last decades, investigators have devoted much attention to unsaturated nitro-compounds of the furan series, since they are used as synthons in the synthesis of physiologically active substances, natural products, and various furan derivatives with a functional group in the side chain and also because of their high biological activity.

Considerable data have now accumulated in the literature on the synthesis, chemical reactions, and practical applications of furylnitroalkenes, which are, however, scattered in numerous article and patent sources. Some general information about furylnitroalkenes has been briefly described in monographs.[1,7,8]

In the present review we attempted to give a systematic account and to examine critically the most significant, from our point of view, aspects of the chemistry of furylnitroalkenes: data on modern methods of synthesis, structure, reactivity, and the synthetic possibilities of these furan derivatives as well as their practical applications.

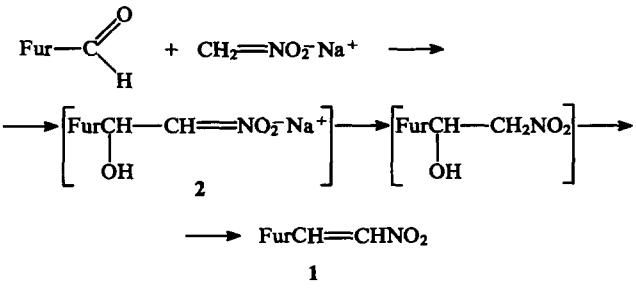
II. Methods of synthesis of furylnitroalkenes

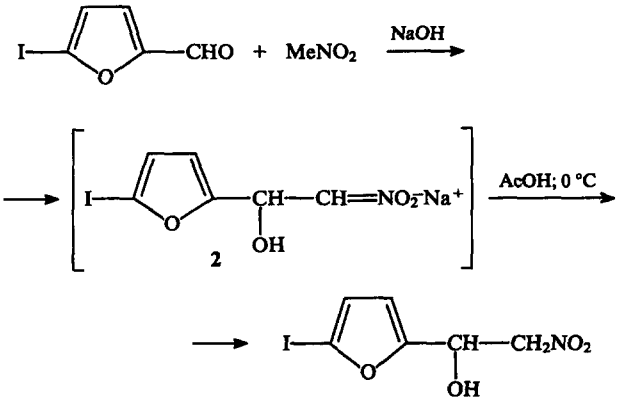
The most thoroughly investigated representatives of unsaturated nitro-compounds in the furan series are conjugated β-(5-R-2-furyl)nitroalkenes. Various methods of synthesis of conjugated heteroarylnitroalkenes have now been developed, among which the most important is the reaction involving the condensation of heteroaromatic aldehydes with primary nitro-compounds in the presence of basic catalysts — solutions of alkalies, alkali metal alkoxides, primary aliphatic amines, ammonium acetate, etc.[1-3]



Numerous β-nitroalkenes, formed as a result of the condensation of furfural or ring-substituted furfurals with nitromethane,[9-35] nitroethane,[13,19,23,28,36-45] 1-nitropropane,[37,39,46] 1-nitrobutane,[37] 2-methyl-1-nitropropane,[46] 1-nitropentane,[39] 3-methyl-1-nitrobutane,[46] phenylnitromethane,[36,47-51] chloronitromethane,[12,52] bromonitromethane,[23,47] and nitroacetic acid derivatives — the methyl ester[53] and the nitrile,[54,55] have been described. It is noteworthy that these reactions (with the exception of the condensation involving methyl nitroacetate) take place stereoselectively and lead to the nitroalkenes **1**, having the (*E*)-configuration, which has been confirmed by spectroscopic methods.

R = H, Me, Cl, Br, I, NO_2, $HOCH_2$, MeOOC, CN, Me_2N, morpholino, PhN(Me), aryl, arylthio, $MeSO_2$, $PhSO_2$, 3-$NO_2C_6H_4O$, heteroarylthio; R^1 = H, 4-Cl, 4-Br, 3-I, 3-NO_2; R^2 = H, Me Et, Pr^n, Pr^i, Bu^n, Bu^i, Ph, 4-ClC_6H_4, Cl, Br, NC, MeOOC, $MeOOCCH_2$.

In the synthesis of β-nitroalkenes of the above type, alkali metal hydroxides or alkoxides as well as primary amines (methylamine, butylamine, 1-aminopentane, etc.) are usually employed as condensing agents. Two main preparative methods of synthesis of β-(5-R-2-furyl)nitroalkenes **1** have been developed accordingly.

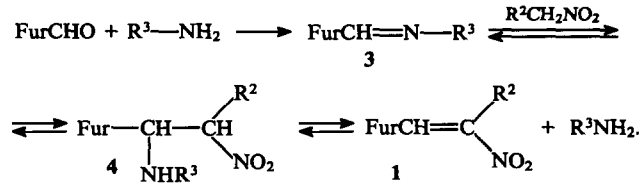


According to the first method, an equimolar mixture of an aldehyde of the furan series and nitromethane in methanol or ethanol is gradually treated, whilst cooling (−15 to −10 °C), with equivalent amounts of an aqueous or alcoholic solution of alkali or a sodium alkoxide solution in the corresponding alcohol. The reaction is accompanied by an appreciable heat change and is completed by the formation of an insoluble salt of the β-nitroalcohol **2**, which is then dissolved by adding water. On subsequent acidification with a dilute solution of an inorganic acid, the β-nitroalkene **1** is isolated in 50%–92% yield (method *A*).[9-23,26-28,30-35,56-58]

Here and henceforth Fur = 2-furyl.

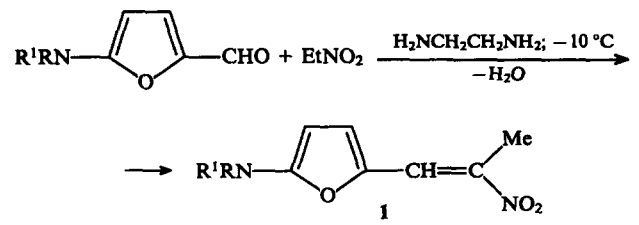
This reaction should be regarded[1,3] as the result of the nucleophilic attack by the nitromethane anion on the electron-deficient carbon atom of the carbonyl group of 5-R-furfural, which leads initially to the aldol condensation product — a salt of the β-nitroalcohol **2**. There are no literature data concerning the mechanism of the dehydration of salts of β-nitroalcohols by inorganic acid solutions.

It has been reported[30] that, when the reaction mixture in the reaction of 5-iodofurfural with nitromethane and NaOH (1 : 1 : 1 molar ratios) is acidified cautiously with acetic acid, it is possible to isolate the unstable 1-(5-iodo-2-furyl)-2-nitroethanol. This finding constitutes confirmation of the formation in the given reaction of the salt **2** as an intermediate.



The study[59] of the kinetics of the condensation of furfural with nitromethane in aqueous alcohol in the presence of KOH also confirmed the intermediate formation of the salt **2**. The kinetic curves for the decrease in the furfural concentration are described by the equation for first-order reversible reactions under pseudo-unimolecular conditions with respect to furfural or by the equation for second-order reactions at comparable concentrations of furfural and nitromethane.

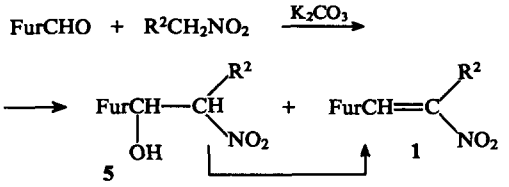
The condensation of furfural with nitromethane,[21] in which a solution of $Ca(OH)_2$ is used as condensing agent, is of interest for industrial application. It is noteworthy that alkalies and alkali metal alkoxides proved to be effective condensing agents in the reactions of furfural and its substituted derivatives not only with nitromethane but also with nitroethane,[19,23,28,36,40,41,43] chloronitromethane,[12,52] and bromonitromethane.[23,47] However, in the case of phenylnitromethane, 1-nitropropane, and 1-nitrobutane, the use of alkaline catalysts leads to appreciable charring of the reaction mixture.



The second method (method *B*) of synthesis of β-(5-R-2-furyl)-nitroalkenes **1** represents a modified Knoevenagel reaction using methylamine, butylamine, 1-aminopentane, ethylenediamine, or piperidine as the catalysts.[13,29,36-38,41,42,44-48] In this method, an equimolar mixture of the furan aldehyde, and nitroalkane in dry ethanol is kept at 20 °C for 3–10 days[47,60] or is refluxed for several hours[13,37,61,62] with 5–10 mol% of a primary amine: under these conditions, the yield of the nitroalkenes **1** is 35–85%.

The mechanism of the catalytic action of primary amines apparently reduces to the formation of the azomethines **3** as intermediates, which react with nitroalkanes to form adducts — unstable β-nitroamines **4**. The latter decompose to the β-nitroalkene **1** and an amine under the influence of the excess nitroalkene:[1,3]

Although a clear cut correlation between the influence of substituents in the furfural ring on the reactivity of the carbonyl group in condensation reactions with nitroalkanes and the yields of β-nitroalkenes **1** are not quoted in the literature, nevertheless certain qualitative features of these reactions can be traced on the basis of the available data. For example, it has been noted[47] that the rate of condensation of 5-R-furfurals with bromonitromethane (method *A*) and phenylnitromethane (method *B*) diminishes in the sequence H > CH_3 > Cl > Br > NO_2 depending on the nature of the substituent R. Thus β-(5-nitro-2-furyl)-α-phenylnitroethylene was obtained in 26% yield only after keeping the reaction mixture at 20 °C for 14 days. On raising the temperature, appreciable charring was observed. The authors[12] were unable to synthesise α-bromo-β-(5-nitro-2-furyl)-nitroethylene by the direct condensation of 5-nitrofurfural with bromonitromethane under the conditions of method *A*; on the other hand, the condensation of 5-nitrofurfural with chloronitromethane and NaOH in aqueous methanol leads to α-chloro-β-(5-nitro-2-furyl)nitroethylene in 41% yield.

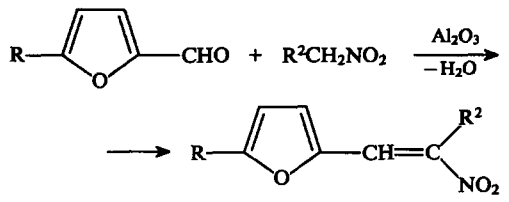


Attempts to obtain β-(5-dimethylamino-2-furyl)nitroethylene by the condensation of 5-dimethylaminofurfural with nitromethane in the presence of alkaline agents proved unsuccessful.[18] However, *N*,*N*-disubstituted 5-aminofurfurals[41,42] react with nitroethane in the presence of catalytic amounts of ethylenediamine at −10 to 0 °C, affording the corresponding β-nitroalkenes **1** in satisfactory yields (50%–80%).

R = R^1 = Me; R = Ph, R^1 = Me; RR^1N = morpholino.

According to patent data,[44] 5-(4-chlorophenyl)-2-(2-nitroprop-1-enyl)furan is formed in 50% yield on refluxing 5-(4-chlorophenyl)furfural in nitroethane in the presence of piperidine.

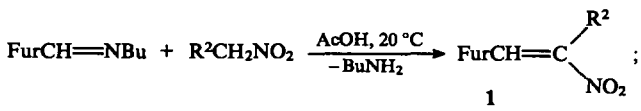
It has been reported[46] that the condensation of furfural with primary nitroalkanes in ethanol in the presence of K_2CO_3 or $KHCO_3$ results in the formation, together with β-(2-furyl)nitroalkenes **1**, also of the corresponding β-nitroalcohols **5**—the products of aldol condensation, their yield reaching 70%.



R^2 = H, Me, Et, Pr, Pr^i, Bu^i.

The dehydration of the β-nitroalcohols **5** leads to the β-nitroalkenes **1**; for example,[63] treatment of 1-(2-furyl)-2-nitroethanol **5** (R^2 = H) with dicyclohexylcarbodiimide in the presence of Cu_2Cl_2 in ether (35 °C, 24 h) affords β-(2-furyl)nitroethylene **1** in 66% yield.

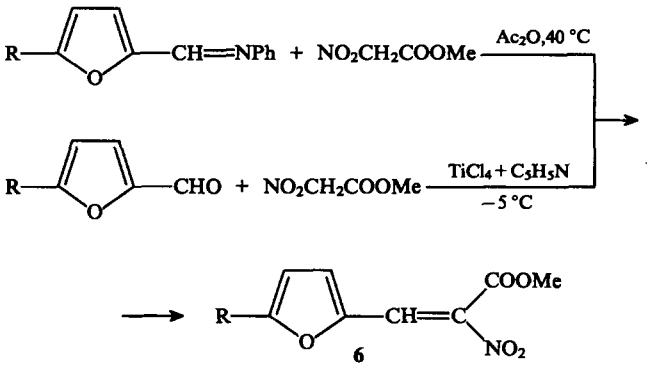
Anion-exchange resins have also been used as catalysts in the condensation of furfural with nitromethane.[64,65] β-(2-Furyl)-nitroethylene was synthesised in 38%–46% yield in the presence of the AN-2F anion-exchange resin. The catalytic activities of various anion-exchange resins have been investigated[65] and it has been established that they decrease in the following sequence: EFE-10P > AN-2F > PE-9 > AN-9F. The strongly basic EFE-10P anion-exchange resin, containing quaternary ammonium groups, proved to be the most active catalyst in the above reaction. When this catalyst was used, the yield of β-(2-furyl)nitroethylene was 78%–86% (40 °C, 5 h).



In 1985, Italian workers[39] proposed an effective method of synthesis of β-nitroalkenes of the furan series in 70%–93% yields by condensing equimolar amounts of 5-R-furfurals with nitroalkanes and carboxylic nitroacid esters on the surface of chromatographic Al_2O_3 without a solvent (20 °C, 30–48 h).

R = H, Me; R^2 = Me, Et, Bu^n, $MeOOCCH_2$, $MeOOC(CH_2)_5$, 2-methyl-1,3-dioxolan-2-ylmethyl.

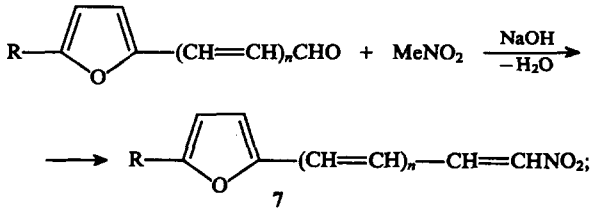
The authors note that this reaction apparently involves the intermediate formation of the corresponding β-nitroalcohols **5**, which are subsequently dehydrated.



Robertson[49,50] used the condensation of phenyl- or 2-chlorophenyl-nitromethane with *N*-furfurylidenebutylamine in order to synthesise β-(2-furyl)-α-arylnitroethylenes (**1**, R = R^1 = H, R^2 = Ph, 2-ClC_6H_4):

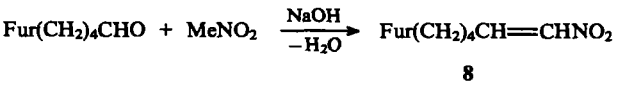
R^2 = Ph, 2-ClC_6H_4.

The reaction was carried out by keeping equimolar amounts of the reactants in glacial acetic acid for several hours at 20 °C.



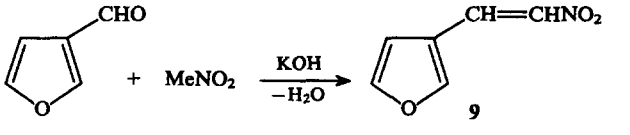
Czechoslovak scientists[53] synthesised the methyl esters of β-(5-R-2-furyl)-α-nitroacrylic acids **6** by condensing methyl nitroacetate with *N*-(5-R-furfurylidene)anilines in acetic anhydride (40–50 °C, 10 h: yield 30%–45%) or with 5-R-furfurals in the presence of $TiCl_4$ and pyridine in CCl_4 (–5 to 0 °C, 24 h; yield 77%–85%). However, the latter method has not come to be widely used for the synthesis of furylnitroalkenes.

R = H, Br, I, Me, MeOOC, NO_2.



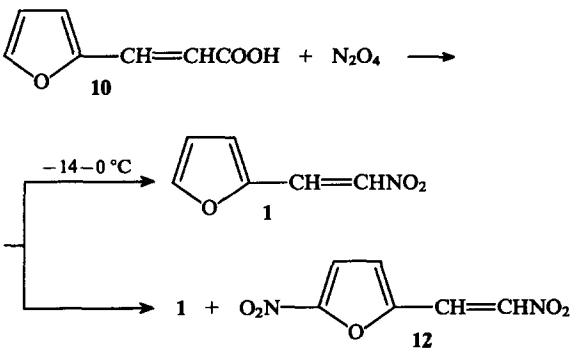
It is noteworthy that the reaction with 5-nitrofurfural takes place stereoselectively[53] to form the (*E*)-isomer of compound **6**. On the other hand, the condensation of other furan aldehydes with nitroacetic acid ester results in the formation of a mixture of (*E*)- and (*Z*)-stereoisomeric nitroalkenes **6** in which the (*Z*)-isomer predominates.

There are isolated literature data[29,66,67] concerning the synthesis of conjugated nitrodienes and nitrotrienes of the furan series **7**. Compounds of this type were synthesised in 70%–75% yield by condensing β-(2-furyl)acroleine or 5-(2-furyl)penta-2,4-dienal with nitromethane in the presence of NaOH (method *A*):



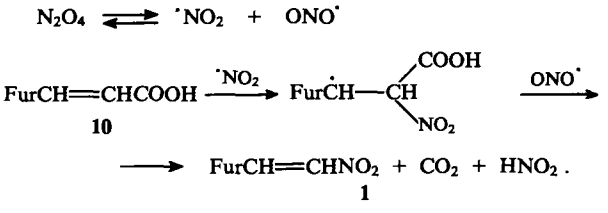
n = 1, 2; R = H, NC.

6-(2-Furyl)-1-nitrohex-1-ene **8** was synthesised in 47% yield by condensing 5-(2-furyl) pentanal with nitromethane and NaOH at 0 °C.[68]



Data concerning the synthesis[69,70] of β-(3-furyl)nitroethylene **9** in 80%–86% yield by the condensation of 3-formylfuran, which is difficult to obtain, with nitromethane in the presence of KOH in methanol appeared in the literature in recent years.

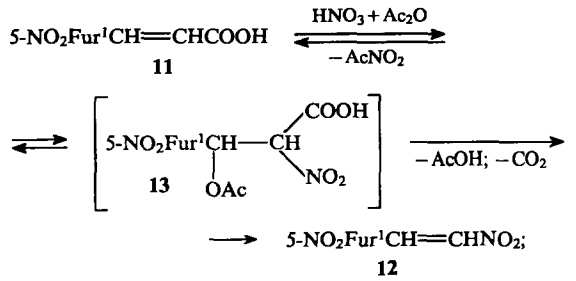
β-Nitroalkenes of the furan series have been obtained using as the starting compounds β-(2-furyl)acrylic acids, which are formed in a high yield on condensation of furfural or substituted furfurals with malonic acid in the presence of piperidine.[7,71]



The nitration of (*E*)-β-(2-furyl)acrylic acid **10** with concentrated nitric acid in acetic anhydride has been described.[8,72–76] (*E*)-β-(5-Nitro-2-furyl)acrylic acid **11** was isolated as the main reaction product in all the investigations. It has been established[77] that (*E*)-β-(2-furyl)nitroethylene (**1**, R = R^1 = R^2 = H) and (*E*)-β-(5-nitro-2-furyl)nitroethylene **12** are formed under these

conditions as side products. The last two substances have also been obtained by passing nitrogen dioxide through a solution of the acid **10** in benzene, acetic acid, or acetic anhydride.[78]

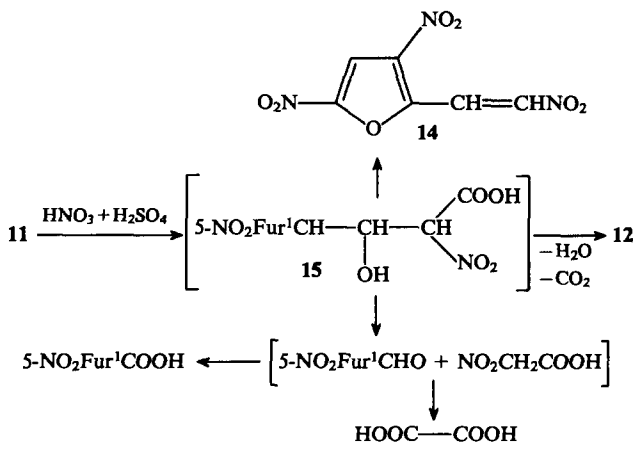
When the acid **10** is nitrated with an equimolecular amount of nitrogen tetroxide in ether[79] at −12 to −14 °C or in benzene and acetic acid[78] at 0 °C, the nitro-group enters preferentially the side chain and the main reaction product is β-(2-furyl)nitroethylene **1** (yield 16%–18%).



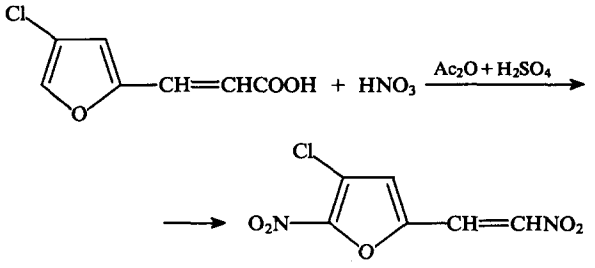
At a higher temperature, the ring is also nitrated;[78] the reaction products contain up to 15% of the β-nitroalkene **12**. According to Sitkin and Klimenko,[79] the synthesis of β-nitroethylene **1** from the acid **10** proceeds at reduced temperatures by a radical mechanism, which can be represented schematically as follows:

Together with the nitroalkene **1**, oxalic acid, formed as a result of the partial oxidation of the nitroalkene **1**, was isolated in the above reaction as a side product; the reaction was accompanied also by the formation of tarry products.

When the acid **10** is acted upon by a large excess of N_2O_4 at −10 °C, products of nitration in the furan ring are obtained[79] — β-(5-nitro-2-furyl)acrylic acid **11** (51.5%) and insignificant amounts of the β-nitroalkene **12**.

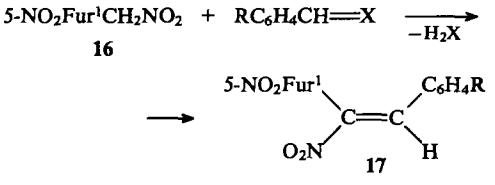


When the acid **11** is nitrated with fuming HNO_3 in acetic anhydride[80] (−20 °C; or 20 °C, 4 h), the nitroalkene **12** is formed in 15% yield:



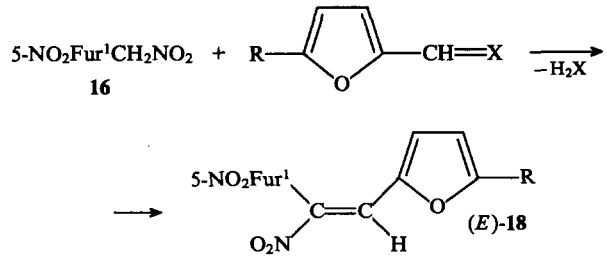
here and henceforth 5-NO_2Fur^1 = 5-nitro-2-furyl.

The unstable adduct **13** — the product of the addition of acetyl nitrate, formed in the mixture of acetic anhydride and fuming HNO_3, is an intermediate in this reaction.



The authors established that the β-nitroalkene **12** is formed in 77% yield when the acid **11** is refluxed with 10% HNO_3; 5-nitrofurfural and 5-nitrofuran-2-carboxylic acid were isolated as side products under these conditions. Treatment of the acid **11** with the nitrating mixture comprising fuming nitric acid and concentrated sulphuric acid[80] at 5 °C affords 13% of β-(3,5-dinitro-2-furyl)nitroethylene **14** together with the β-nitroalkene **12**. The intermediate under these conditions is the unstable adduct **15** — the product of the addition of the elements of HNO_3 to the double bond; 5-nitrofuran-2-carboxylic acid and oxalic acid are formed as side products.

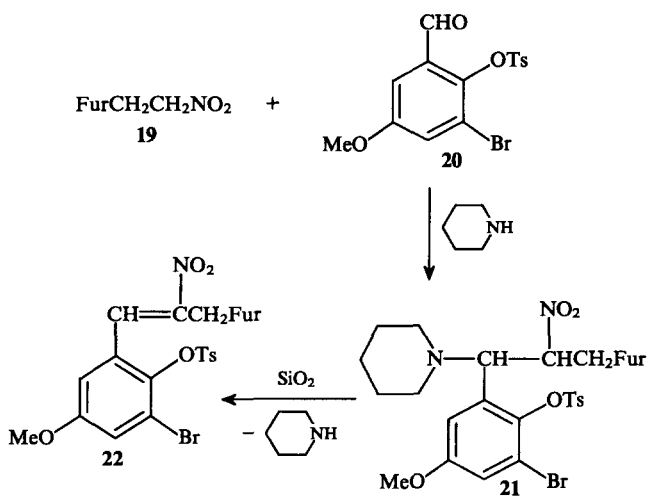
When β-(4-chloro-2-furyl)acrylic acid is nitrated with fuming HNO_3 in acetic anhydride (molar ratios 1 : 4 : 10) in the presence of catalytic amounts of H_2SO_4 at −10 to −5 °C, β-(4-chloro-5-nitro-2-furyl)nitroethylene is obtained in 70% yield.[23]



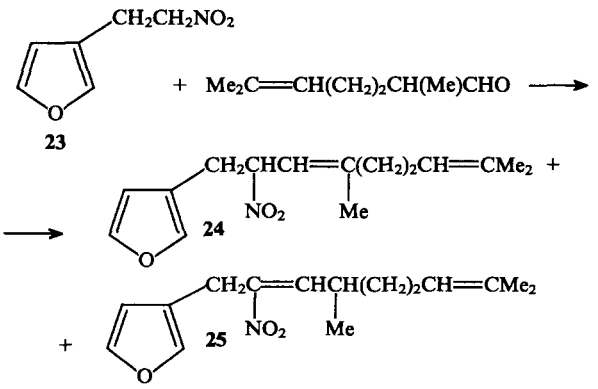
Condensation of 2-nitromethyl-5-nitrofuran **16** with aromatic aldehydes, ammonium acetate, and acetic acid in benzene (refluxing for 3–5 h) or with *N*-benzylidenebutylamines in acetic acid at 20 °C leads to α-nitro-α-(5-nitro-2-furyl)-β-arylethylene **17** having the (*E*)-configuration.[81–83]

X = O, NBu; R = H, 4-Me, 4-MeO, 2-MeO, 4-Me_2N, 2-F, 4-Cl, 4-NC, 2-NO_2, 4-NO_2, 4-AcNH.

The authors note that the first method makes it possible to obtain the β-nitroalkenes **17** in a satisfactory yield (25%–30%) only from benzaldehydes containing electron-donating substituents. The α-nitroalkenes **17** are synthesised by the second method from benzaldehydes with electron-accepting groups (yield 41%–84%).

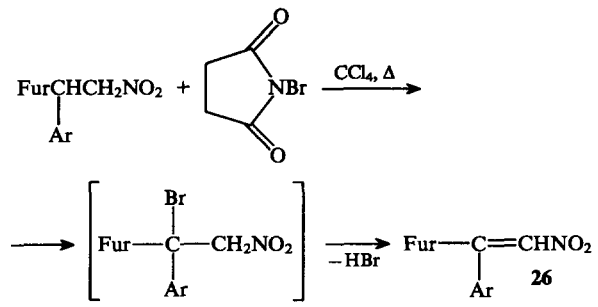


(*E*)-α-nitro-α-(5-nitro-2-furyl)-β-(5-R-2-furyl)ethylenes **18** were obtained in 28%–91% yield under analogous conditions from the nitromethyl derivative **16** and the 5-substituted furfurals or *N*-(5-R-furfurylidene)butylamines.[84]



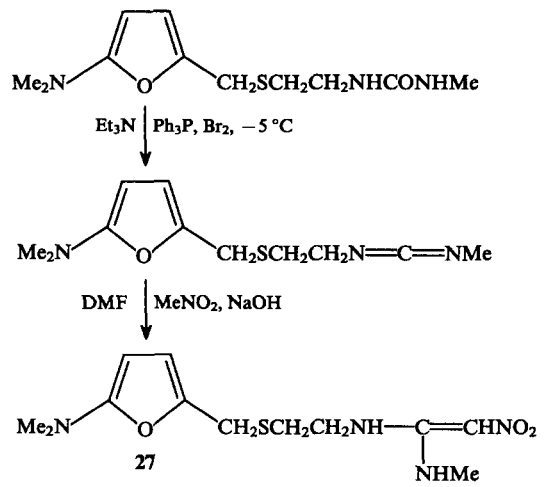
X = O, NBu; R = H, Me, Br, I, Ph, 4-ClC_6H_4, 2-ClC_6H_4, 4-BrC_6H_4, 4-MeC_6H_4, 4-$NO_2C_6H_4$.

However, the condensation of compound **16** with 5-nitrofurfural or with *N*-(5-nitrofurfurylidene)butylamine results in the formation of a 1:2 mixture of (*E*)- and (*Z*)-α,β-di(5-nitro-2-furyl)nitroethylene (**18**, R = NO_2) in 48% yield.

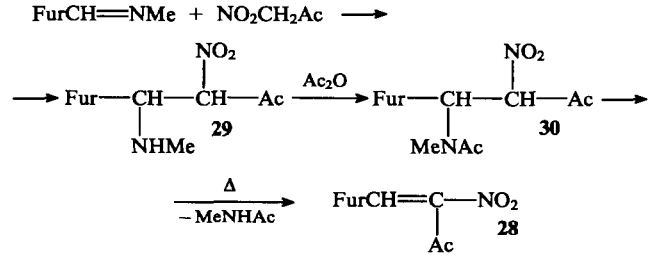


The condensation of 2-(2-furyl)-1-nitroethane **19** with a derivative of salicylaldehyde **20** in the presence of piperidine under the conditions of the Knoevenagel reaction[85] leads to the β-nitroamine **21** (yield 65%), the deamination of which on the surface of silica gel affords the nitroalkene **22** in 65% yield.

2-(3-Furyl)-1-nitroethane **23** reacts with 2,6-dimethylhept-5-enal in the presence of *N*,*N*-dimethylethylenediamine in toluene (refluxing for 2 h) to form a mixture of the allylic nitro-compound **24** (yield 46%) and the conjugated nitroalkene **25** (yield 25%).[70] On refluxing with triethylamine in benzene, the latter isomerises quantitatively to the nitroalkene **24**, which is a key compound in the synthesis of the pheromone dendrolasin.



The bromination of 1-aryl-1-(2-furyl)nitroethanes by treatment with *N*-bromosuccinimide in CCl_4 (refluxing for 1 h) results in the formation of β-aryl-β-(2-furyl)nitroethylenes **26** in the form of a mixture of the (*E*)- and (*Z*)-isomers in 40%–43% yield.[86]



Ar = Ph, 3,4-$(OCH_2O)C_6H_3$.

An effective method of synthesis of the ulcerostatic preparation ranitidine **27**, which is nitrovinyl derivative of the furan series, in accordance with the scheme shown below has been reported.[87]

There exist also isolated data concerning the synthesis of unsaturated nitroketones of the furan series. By condensing furfurylidenemethylamine with nitroacetone in the presence of acetic anhydride, Dornow[88] synthesised 4-(2-furyl)-3-nitrobut-3-en-2-one **28** in 17% yield.

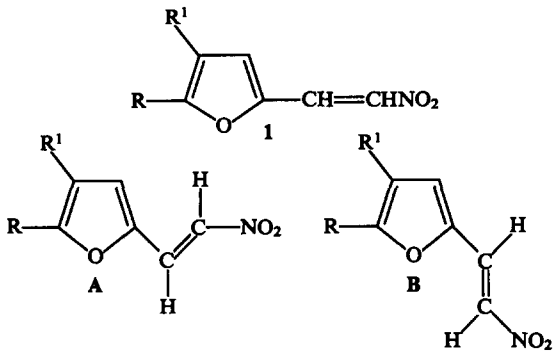
The unstable β-nitroamine **29** is formed initially and reacts with acetic anhydride, affording the *N*-acetyl derivative **30** (yield 67%). After brief heating, the latter splits off *N*-methylacetamide and is converted into the unsaturated ketone **28**. The author notes that, in the absence of acetic anhydride the nitroketone **28**, formed as a result of the deamination of the β-nitroamine **29**, combines with a second acetone molecule, giving rise to an unstable diadduct. This reaction is catalysed by the methylamine liberated; acetic anhydride binds the amine and reduces its basicity, weakening thereby its catalytic effect.

In 1969 German scientists[89] synthesised an unsaturated nitroketone of another type—1-(2-furyl)-4-nitrobut-2-en-1-one **31**, which is an interesting and promising synthon for the preparation of various furan derivatives with functional groups in the side chain. Compound **31** is formed in 80% yield on reaction of

equimolar amounts of 2-acetylfuran and 2-dimethylamino-1-nitroethylene in the presence of potassium ethoxide (60–70 °C) with subsequent hydrolysis (20 °C) of the intermediate potassium salt **32**.

$$\text{FurAc} + \text{Me}_2\text{NCH}{=}\text{CHNO}_2 \xrightarrow[-\text{Me}_2\text{NH}]{\text{EtOK}-\text{EtOH}} \text{FurCOCH}{=}\text{CH}-\text{CHNOO}^-\text{K}^+ \xrightarrow{\text{HOH}} \underset{\mathbf{31}}{\text{FurCOCH}{=}\text{CHCH}_2\text{NO}_2}$$

32



The authors note that this nitroketone is highly reactive and enters into many reactions characteristic of α,β-unsaturated ketones and primary nitrocompounds.

III. Structure and reactivity of furylnitroalkenes

1. The dipole moments of furylnitroalkenes

Important information about the steric structure and reactivity of β-(5-R-2-furyl)nitroalkenes has been obtained by studying their dipole moments.[1,62,90–94] The low aromaticity of furan[95,96] makes it possible to expect a strong π-interaction in the chain between the double bond of the vinyl fragment and the NO_2 group with participation of the furan ring and its substituents in the 5-position.

β-(5-R-4R¹-2-Furyl)nitroethylenes **1** are regarded[49,91] as planar *trans*-isomers which can exist in two forms — *trans*-(*S*)-*trans* (form *A*) and *cis*-(*S*)-*trans* (form *B*), depending on the positions of the double bonds of the furan and the vinyl group relative to the C(2)–Cβ bond.

R = H, Me, Cl, Br, I, NO_2; R¹ = H; R = Br, I; R¹ = Br.

The low aromaticity of the system makes the *trans*-(*S*)-*trans* structure, i.e. structure *A*, energetically more favourable.[41,91] The observed discrepancies between the experimental and calculated dipole moments ($\Delta\mu = \mu_{exp} - \mu_{calc}$) are then attributed to the interaction moment (μ_{int}) arising as a result of the π-conjugation in the molecule.

By analogy with 5-halofurfurals,[93] negative values of μ_{int} should be expected for β-(5-halo-2-furyl)nitroethylenes (**1**; R = Cl, Br, I; R¹ = H, Br) as a consequence of the $-J$ effect of these substituents. However, a higher value of μ_{exp} compared with μ_{calc} is observed for all the compounds of this series (Table 1). This is apparently caused by the stronger electron-accepting properties of the β-nitrovinyl group compared with the aldehyde group.[3,41,94] The electronic interaction of the halogen with the furan ring in the given compound should therefore be expressed by the $+M$ effect. Hence it is of interest to note that an increase in μ_{int} is observed for β-nitroalkenes **1** in the following sequence of substituents 5-R: I < Br < Cl (0.13, 0.30, and 0.76 D).

Table 1. The dipole moments of (*E*)-β-(5R-4R¹-2-furyl)-α-R²-nitroethylenes.[41,90–92,97]

R	R¹	R²	Dipole moments/D		
			μ_{exp}	μ_{calc}	μ_{int}

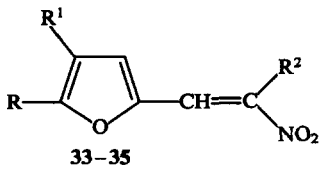
Br	H	Cl	4.32	4.30	0.02
NO_2	H	Cl	3.67	4.52	−0.85

The experimental dipole moments of β-(5-R-4-R¹-2-furyl)-α-methylnitroethylenes **33** are lower by 0.2–0.6 D than the corresponding values for β-(5-R-4-R¹-2-furyl)nitroethylenes **1** (Table 1).[41,92]

The dipole moment probably changes as a result of the breakdown of the planar configuration due to steric hindrance between the methyl group, the nitro-group, and the oxygen of the furan ring. Rotation about the Cα–N and C(2)–Cβ bonds weakens the π-interaction involving the electrons of the substituents in the 5-position in the vinyl group and of the NO_2 group, which decreases the dipole moment. The angle of rotation can then be estimated approximately from the formula



$$\mu = \mu_{int} \cos^2\theta ,$$

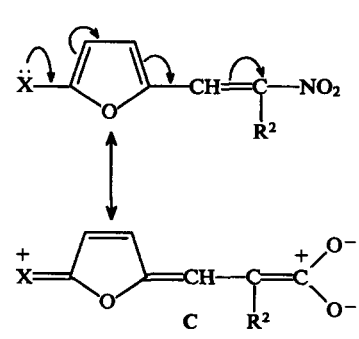
where $\Delta\mu = \mu_{exp} - \mu_{calc}$ for the β-nitroalkene **33**, and θ is the effective angle of rotation.

The angle θ is approximately 60° for β-(5-methyl-2-furyl)-α-methylnitroethylene (**33**, R = Me, R¹ = H, R² = Me), where appreciable changes in the dipole moment of the C(5)–Me bond due to the breakdown of conjugation do not occur because the methyl group has weak electron-donating properties.[41]

The introduction of the phenyl group in the α-position should induce an even greater breakdown of the planar configuration via the rotation of the Cα–N and C(2)–Cβ bonds. However, the values of μ_{exp} for β-(5-R-4-R¹-2-furyl)-α-phenylnitroethylenes **34**

occupy an intermediate position between those for the nitroethylenes **1** and the α-methylnitroethylenes **33**. This is apparently caused by the simultaneous rotation of the phenyl group, which creates conditions for the minimum deviation of the principal fragment of the molecule from the planar structure.[91]

33–35

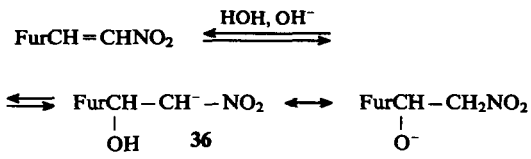


R = H, Me, Cl, Br, I, NO_2, Me_2N, morpholino, PhNMe; R^1 = H;
R = Br, I; R^1 = Br;
33: R^2 = Me; **34**: R^2 = Ph; **35**: R^2 = Cl, Br.

It has been suggested[41] that the $+M$ effect of the halogens predominates in the β-(5-halo-2-furyl)nitroethylenes **1** owing to the strong electron-accepting properties of the nitrovinyl fragment and the planar configuration of these molecules. On the other hand, the decrease in the degree of conjugation in the non-coplanar molecules of β-(5-halo-2-furyl)-α-R^2-nitroethylenes (**33**, **34**; R^2 = Me, Ph) promotes the appearance of the usual electron-accepting properties of the halogen in the 5-position. The latter follows from the appreciably smaller (R = Cl) and even negative (R = Br, I) values of μ_{int}. Evidently this is associated with the fact that the interaction of the electron-accepting nitrovinyl group with the substituent in the furan ring weakens when the planar conformation of the molecules breaks down.[91]

On the other hand, more favourable conditions for the planar molecular structure arise for β-(5-R-4-R^1-2-furyl)-α-halonitroethylenes (**35**; R^2 = Cl, Br).[91] High values of μ_{int}, characteristic of planar-(5,R-4-R^1-2-furyl)nitroethylenes **1**, are typical for these compounds. The high degree of conjugation in these compounds can be accounted for by the operation of two factors: the smaller bulk of the halogens compared with the methyl and phenyl groups and the greater electronegativity of the α-halo-α-nitrovinyl fragment.

2. Electronic absorption spectra of furylnitroalkenes



There are three absorption bands in the UV spectra of β-(5-R-4-R^1-2-furyl)-α-R^2-nitroalkenes **1** and **33–35** in the ranges 205–245, 234–282, and 322–428 nm. The first two bands can be assigned to the $\pi-\pi^*$ and $n-\pi^*$ electronic transitions in the furan, the aryl substituents, and the vinyl group.[18,98] The most intense band in the spectra of the given compounds (322–428 nm; the *K* band) refers to the $\pi-\pi^*$ transition throughout the conjugated polyene system and yields important information about the planarity of the system.[1,18,91,98,99] The observed bathochromic shift compared with 2-vinylfuran (261 nm) is associated with the appearance of the dipolar structure **C** as a consequence of direct polar conjugation:

C

We may note that the corresponding absorption band of β-nitrostyrene (309 nm)[1] lies below that of β-(2-furyl)nitroethylene **1** (346 nm) as a consequence of the stronger electron-donating properties of the furyl group.[95]

It has been reported[59,100] that, when the UV spectrum of the β-nitroethylene **1** is recorded in aqueous ethanol at pH 11.5–12.6, the absorption band at λ_{max} = 346 nm vanishes and a band appears at λ_{max} = 252–255 nm. This finding can be accounted for by the appearance of the stable mesomeric ion **36**.

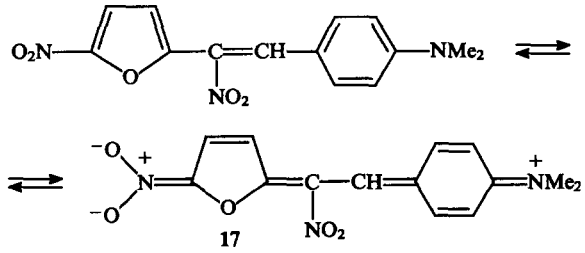
The extinction coefficient ε for this nitroalkene (ε = 24 516) is approximately three times greater than for *cis*-β-(2-furyl)acrylic acid (ε = 9780), which is also evidence in support of the *trans*-conformation of furylnitroethylenes.[100]

In the UV spectra of β-(2-furyl)-α-R^2-nitroethylenes, and absorption *K* band undergoes a bathochromic shift as R^2 is varied in the sequence H (346) < Me (348) < Ph (353) < Cl (358) < Br (365) < CN (371 nm).[18,47,55,59,91,100] The appreciable bathochromic shift and the hyperchromic effect for β-(2-furyl)-α-nitroacrylonitrile (λ_{max} = 371 nm; ε = 21 500) compared with β-(2-furyl)nitroethylene indicates an increased contribution of the dipolar structure **C** to the ground state of the molecule.[55]

A bathochromic shift of the absorption *K* band is observed in the spectra of β-(5-R-2-furyl)nitroethylenes **1**. It increases in the following sequence of substituents R: H (346) < NO_2 (350) < Cl (358) < Br (355) < I (357) < Me (367) < PhS (370) < NMe_2 (428 nm).[18,55,59,80,91,100] The relatively small shift of the absorption maximum for R = NO_2 is associated with the non-coplanarity of this substituent relative to the nitrovinyl fragment.[91] The UV spectrum of β-(3,5-dinitro-2-furyl)nitroethylene **14** exhibits a hypsochromic shift of the *K* band (λ_{max} = 340 nm) as a consequence of the decrease in the mobility of the π-electron system induced by the introduction of the second nitro-group into the furan ring.[80]

The appreciable bathochromic shift of the *K* band in the spectra of β-(5-dimethylamino-2-furyl)-R^2-nitroethylenes (R^2 = H, λ_{max} = 428 nm; R^2 = Me, λ_{max} = 480 nm) can be explained by the possibility of direct polar conjugation in the molecules of these compounds and by the approach to a planar structure.[91]

The absorption maxima of the *K* band in the spectra of different β-(5-halo-2-furyl)-α-R^2-nitroethylenes can be arranged in the following sequence based on increasing wavelengths as a function of the substituents R^2;[18,47,91] Cl < Br < I. This is characteristic also of 4-halonitrobenzenes.[101] This sequence is the reverse of that observed for the changes in the dipole moment μ_{int} in terms of the same substituents, which can be explained by the greater $+M$ effect of the chlorine atom compared with bromine and iodine. The decrease in the C(5)–halogen bond polarity,§ which depends on this factor, is particularly appreciable for chloro-derivatives in view of the insignificant contribution of the π-interaction with the unoccupied *d* orbitals of the halogen atom. The latter feature is most favourable for halogens with a large radius.[102] It is essential to note that both the $+M$ and $-M$ effects of the halogens lead simultaneously to the stabilisation of the ground and excited states, which in fact accounts for the observed order of the bathochromic shifts for the group of furylnitroalkenes examined.



§The decrease in the C(5)–halogen polarity leads to an increase in the resulting molecular dipole moment.[41,91]

As the conjugation chain increases, the UV spectra of nitropolyenes of the furan series $Fur(CH=CH)_nNO_2$ **7** exhibit a bathochromic shift of the absorption *K* band ($n = 0$, $\lambda_{max} = 310$; $n = 1$, $\lambda_{max} = 346$; $n = 2$, $\lambda_{max} = 380$; $n = 3$, $\lambda_{max} = 410$ nm) and an increase in its intensity.[67,103]

R^2	λ_{max}/nm		
	Cl	Br	I
H	352	355	357
Me	353	355	362
Ph	360	363	369
Br	369	375	367

The electronic absorption spectra of α-nitro-α-(5-nitro-2-furyl)-β-(R-phenyl)ethylenes **17** contain two absorption bands in the range 216–275 and 298–318 nm,[81,82] which can be assigned to the electronic transitions in furan[104] and benzene.[99] Apart from the above absorption bands, compounds of this type, containing electron-donating groups in the aryl fragment, have yet another absorption band in the long-wavelength region (R = 4-MeO, λ_{max} = 363; R = 2-MeO, λ_{max} = 362; R = 4-NMe_2, λ_{max} = 370; R = 4-AcNH, λ_{max} = 460 nm).[81,82] This can be explained by the appearance of the corresponding quinnoid structure.

In the spectra of other α-nitroalkenes **17** (R = 2-F, 4-Cl, 4-NC, 4-NO_2, 2-NO_2), there is no absorption in this region, which is an indication of the incomplete coplanarity of the above compounds. Conjugation can also be prevented by the partial displacement of the 5-nitrofuryl and aryl fragments from the plane of the double bond induced by the bulky α-nitro-group.[81]

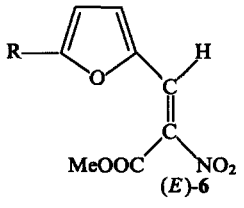
17

The UV spectra of (*E*)-α-nitro-α-(5-nitro-2-furyl)-β-(5-R-2-furyl)ethylenes **18** contain two absorption bands in the ranges 295–345 and 357–440 nm (*K* band).[84] It is noteworthy that, for example, the molecules of α-(5-nitro-2-furyl)-β-phenylethylene and α-(5-nitro-2-furyl)-β-(phenyl-2-furo)ethylene are planar systems and contain in the UV spectra an intense *K* band in the visible region. On the other hand, in the spectra of their α-nitro-analogues, this band has undergone a hypsochromic shift by 15–20 nm, which indicates the non-planarity of the molecules of these compounds.

The hypsochromic shift of the *K* band and the hyperchromic shift in the UV spectrum of (*E*)-α,β-di(5-nitro-2-furyl)ethylene (λ_{max} = 372 nm, $\lg\varepsilon$ = 4.15) relative to the (*Z*)-isomer (λ_{max} = 392 nm, $\lg\varepsilon$ = 4.18)[84] are noteworthy. This is apparently associated with the fact that the steric strain involving the substituents at the double bond in the (*E*)-isomer is greater than that in the (*Z*)-isomer and hence in the former case the system deviates more appreciably from planarity.

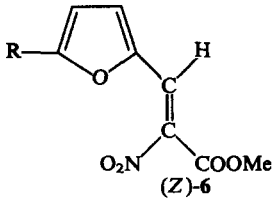
An appreciable hypsochromic shift of the *K* band is observed also in the spectra of the methyl esters of (*Z*)-β-(5-R-2-furyl)-α-nitroacrylic acids **6** (R = H, λ_{max} = 313; R = Br, λ_{max} = 321; R = I, λ_{max} = 333; R = Me, λ_{max} = 325; R = MeOOC, λ_{max} = 320 nm).[53]

3. IR spectra of furylnitroalkenes



In the IR spectra of furylnitroalkenes there are intense absorption bands in the range 1610–1660 cm^{-1}, which are characteristic of conjugated double bonds in the *trans*-isomers of ethylene compounds.[105] The absorption band at 1660–1670 cm^{-1} is associated with the stretching vibrations of the C–C bonds of the furan ring,[100,104] which is typical for furan derivatives with unsaturated substituents in the 2-position. Absorption maxima in the range 1510–1550 and at 1340 cm^{-1} correspond[105,106] to the asymmetric and symmetric stretching vibrations of the NO_2 group.

The IR spectroscopic data confirm the features of the variation of the configurations of β-(5-R-4R^1-2-furyl)-α-R^2-nitroethylenes (**1**, **33**, **34**; R^2 = H, Me, Ph). The most planar molecules (**1**, R^2 = H) are characterised by a low-frequency $\nu_{C=C}$ absorption (1635–1642 cm^{-1}).[91,100] The deviation from the planar configuration on passing from R^2 = Ph (**34**) and specially to R^2 = Me (**33**) increases the $\nu_{C=C}$ absorption frequency (1640–1655 and 1653–1663 cm^{-1}) respectively.

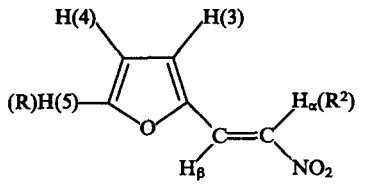


It was noted above that more favourable conditions for a planar molecular structure are created in β-(5-R-4-R′-2-furyl)-α-halonitroethylenes **35**. The high degree of conjugation in these compounds is reflected also in the $\nu_{C=C}$ frequency (1610–1628 cm^{-1}), which is reduced compared with compounds **1**, **33**, and **34**.[47,91]

The appreciable decrease in the $\nu_{C=C}$ absorption frequency in the spectra of N-substituted β-(5-amino-2-furyl)-α-methylnitroethylenes (**33**, R = Me_2N, PhNMe, morpholino) (1638–1645 cm^{-1}) compared with the remaining compounds of the same series (R = H, Me, Cl, Br, NO_2; 1653–1632 cm^{-1}) is noteworthy.[91] This can be explained by the direct polar conjugation in the β-(5-amino-2-furyl)-α-nitroethylene molecules and their approach to a planar structure.

The (*E*)- and (*Z*)-isomers of the methyl esters of β-(5-R-2-furyl)-α-nitroacrylic acids **6** differ in the absorption frequencies ν_{as} and ν_s of the α-nitro-group. The absorption bands due to these vibrations in the spectra of the (*E*)-isomers are at higher frequencies (1540–1542 and 1321–1330 cm^{-1}) than the analogous bands in the structure of the (*Z*)-isomers (1549–1552 and 1373–1375 cm^{-1}).[53]

(*E*)-**6**



(*Z*)-**6**

The vibrations of the C=C valence bonds in the IR spectra of α-nitro-α-(5-nitro-2-furyl)-β-arylethylenes **17** are represented by moderately intense absorption bands in the range 1654–1670 cm^{-1}.[81,82] The introduction of electron-donating substituents (Me, MeO, NMe_2) into the benzene ring induces a bathochromic shift of the bands; electron-accepting substituents (NO_2, CN) induce the opposite shift. In the region of the symmetrical stretching vibrations of the NO_2 group in the spectra of these compounds, two absorption bands are observed at 1310–1340 and 1350–1360 cm^{-1}. The band at the higher frequency corresponds to the vibrations of the nitro-group in the furan ring.[81]

In the spectra of α-nitro-α-(5-nitro-2-furyl)-β-(5-R-2-furyl)-ethylenes **18**, absorption maxima in the range 1640–1655 cm^{-1} (R = H, Me, Br, I, NO_2) or in the range 1650–1662 cm^{-1} (R = aryl) refer to the C=C bond stretching vibrations.[84] The asymmetric stretching vibrations of the NO_2 group are represented by absorption bands at 1540–1560 cm^{-1}, while the

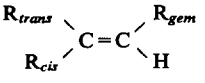
[a] Calculated from Pasqual's equation:[111] δ_{H_α} = 7.65 ppm; δ_{H_β} = 8.10 ppm.
[b] β=(3,5-Dinitro-2-furyl)nitroethylene.



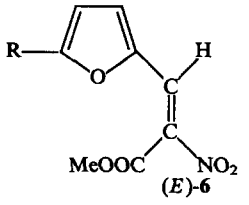
symmetric vibrations are represented by two bands at 1315–1340 cm^{-1} (the α-nitro-group) and 1355–1365 cm^{-1} (the nitro-group in the furan ring).

4. ^{1}H NMR spectra of furylnitroalkenes

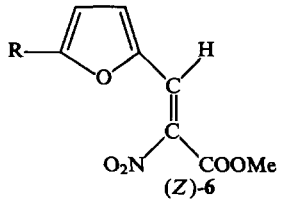
The ^{1}H NMR spectra of β-(5-R-2-furyl)-α-R^2-nitroethylenes **1** and **33–35** contain the resonance bands of three or two protons of the furan ring in the form of doublets with chemical shifts and spin–spin coupling constants usual for these compounds.[104,107,108] Table 2 lists the chemical shifts of the most characteristic protons in the ^{1}H NMR spectra of certain furylnitroalkenes. Depending on the nature of the substituents R in the furan ring and of the solvent, the signals due to the protons of the furan ring are observed in the ranges 5.33–7.16 ppm for H(3), 6.05–7.53 ppm for H(4), and 7.01–7.80 ppm for H(5).

The protons attached to the double bond in β-(5-R-2-furyl)-nitroethylenes **1** give rise to doublet signals in the ranges 6.78–8.20 ppm (H_α) and 6.72–8.46 ppm (H_β) with spin–spin coupling constants of 13.0–14.0 Hz, which is characteristic of protons in the *trans*-position at the double bond.[105] Thus the spin–spin coupling constants ($^3J_{\alpha\beta}$) of the protons in the nitrovinyl group constitute yet another confirmation of the (*E*)-configuration of nitroethylenes of the given type.

It has been shown[110] that the chemical shifts of the vinyl protons in the spectra of β-(2-furyl)nitroethylene **1** are satisfactorily correlated with the values calculated from Pasqual's equation[111] taking into account the additive increments for different protons:



$$\delta_H = 5.25 + \Sigma z_i$$



$z_i^{gem} = 2.00$; $z_i^{trans} = 0.46$; $z_i^{cis} = 1.67$.

Kovac and coworkers[53] noted that the (*E*)- and (*Z*)-isomers of the methyl esters of β-(5-R-2-furyl)-α-nitroacrylic acids **6** may be identified from the difference between the chemical shifts of the β-proton and the protons of the methoxy-group. The signal of the H_β vinyl proton in the spectra of the (*E*)-isomers is located downfield relative to the spectra of the (*Z*)-isomers (Table 3). Thus an appreciable shift of the signal due to this proton is induced by the greater magnetic anisotropy of the nitro-group compared with the carbonyl group. The H_β chemical shifts of the (*E*)- and (*Z*)-isomers of these nitroalkenes have also been calculated from Pasqual's equation using the additive increments:[112] δ_{H_β} is 8.75 ppm for the (*E*)-isomer and 8.10 ppm

Table 3. ^{1}H NMR spectroscopic data[53] for the (*E*)- and (*Z*)-isomeric methyl esters of β-(5-R-2-furyl)-α-nitroacrylic acids **6**.

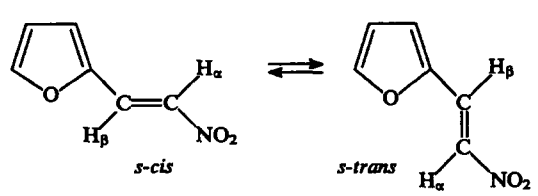
	E	7.77		4.00	
NO_2	*Z*	7.28	0.49	3.86	0.15
	E	7.77		4.01	

[a] Calculated values: δ_{H_β} = 8.10 ppm for the (*Z*)-isomer; δ_{H_β} = 8.75 ppm for the (*E*)-isomer.

for the (*Z*)-isomer. The experimental and calculated H_β chemical shifts differ by approximately 1 ppm, which is an indication of the deviation of the system from planarity.



In the ^1H NMR spectra of the (*E*)-α-nitro-α-(5-nitro-2-furyl)-β-(R-phenyl) ethylenes **17**, the resonance signal of the vinyl proton is observed in the range 8.45–8.81 ppm,[81] which agrees well with the calculated value for the (*E*)-isomer (8.23 ppm). The signals due to the protons of the furan fragments are manifested as doublets at 6.77–7.17 ppm [H(3) and 7.36–7.80 ppm [H(4)] with $J_{3,4}$ = 3.7–3.9 Hz, which is characteristic of 2-substituted 5-nitrofurans.[8] The authors note that the substituent in the phenyl group hardly affects the signal of the vinyl proton. This may be due to the non-planarity of the given systems, where there is no mesomeric influence of the substituents.

The absence of an effect by the substituent R in the furan fragment on the chemical shift of the vinyl proton is also characteristic of (*E*)-α-nitro-α-(5-nitro-2-furyl)-β-(5-R-2-furyl)-ethylenes **18**. The chemical shift is observed in the range 8.44–8.53 ppm.[84] In the case of the (*E*)- and (*Z*)-isomers of α, β-di-(5-nitro-2-furyl)nitroethylene, the chemical shift of the above proton agrees well with the calculated data: 8.58 ppm for the (*E*)-isomer of compound **18** (calculated value 8.23 ppm) and 7.31 ppm for the (*Z*)-isomer (calculated value 7.45 ppm).

It is known[8,113] that the constants for the long-range (across five bonds) spin–spin coupling (^5J) between the β-proton in the side chain and the protons in the heterocyclic ring are highly stereospecific and are used to determine the most preferred configurations of the substituents in the side chain. Table 4 lists the experimental long-range spin–spin coupling constants for β-(2-furyl)nitroethylene as well as their values calculated using different methods of the molecular orbital theory.[114]

The results of the calculations of the populations of the conformational states and of the barriers to internal rotation by the molecular orbital method both at the level of the non-empirical (*ab initio*) and semiempirical (INDO2-MO-FRT, CNDO/2, etc.) approximations and the high stereospecificity show that the *s-trans*-conformer of β-(2-furyl)nitroethylene predominates in polar and non-polar salts. The value of $^6J_{\beta5}$ indicates the existence of an associative bond between H_α and H_β across the heteroatom.[109]

Table 4. The long-range spin–spin coupling constants for the ^1H NMR spectrum of β-(2-furyl)nitroethylene.[109,114]

SSCC	Experimental values for *s-trans*/Hz		Calculated values/Hz			
	CS_2	acetone-d_6	*s-trans* [a]	*s-cis* [a]	*s-trans* [b]	*s-cis* [b]
$^4J_{\alpha3}$	−0.42	−0.40	−1.01	−0.94	−1.23	−0.16
$^5J_{\alpha4}$	0.22	0.29	0.14	0.93	0.04	0.49
$^5J_{\alpha5}$	0.54	0.53	0.67	−0.22	0.56	0.09
$^5J_{\beta3}$	0.58	0.58	0.62	0.41	–	–
$^6J_{\beta4}$	0.06	0.03	−0.22	−0.10	–	–
$^6J_{\beta5}$	0.50	0.48	0.40	0.51	–	–

[a] The INDO-MO-FRT method.
[b] The CNDO-2 method.

The authors[114] concluded that the constant ^5J, incorporating $^5J_{\alpha5}$ and $^5J_{\alpha4}$, is highly stereospecific from the comparison of the experimental spin–spin coupling constants and the values predicted by calculation using the method of finite perturbations. The above constant reflects the transmission of the spin–spin coupling via the σ-electronic mechanism.

5. Quantum-chemical calculations for furylnitroalkene molecules and their reactivity

It was noted above that, among the possible planar structures of the series of β-(R-2-furyl)nitroalkenes **1**, two sterically unhindered forms can be realised: *trans-s-trans* (form **A**) and *cis-s-trans* (form **B**).[41,91]

The planar structures **A** and **B** should be energetically more favourable compared with the analogous structures of the furan aldehydes and ketones owing to the presence in them of a strong intramolecular π–π conjugation between the furan ring and the nitrovinyl fragment, demonstrated by the method of dipole moments and UV spectroscopic data.

Quantum-chemical calculation (EHM method) of the energies of the conformers **A** and **B** of β-(2-furyl)nitroethylene showed that the energy difference between the two planar conformers is comparatively small (ΔE = 0.143 kcal mol^{-1}) and the extent to which the non-planar form with a perpendicular disposition of the molecular fragments (O–C–C–H_β dihedral angle of 90°, *s*-90-conformer[114]) is unfavourable on energy grounds is much greater (E^* ≃ 10 kcal mol^{-1}).[97] The high degree of equalisation of the π-bonds C(2) ⋯ C_β ⋯ C_α ⋯ N in the planar structures of β-(2-furyl)nitroethylene is also consistent with this finding. Thus an appreciable energy barrier to rotation indicates a high stability of the above conformers and a low probability of their spontaneous interconversion.[97,114]

Certain β-(5-R-2-furyl)-α-R^2-nitroethylenes (**1** and **6**; R = H, NO_2; R^2 = H, MeOOC) have been characterised[115] by the Hückel molecular orbital method from the standpoint of their π-electronic structure. The quantum-chemical data obtained by the above investigators were compared with the physical properties (geometry and IR, UV, and ^1H and ^{13}C NMR spectra).

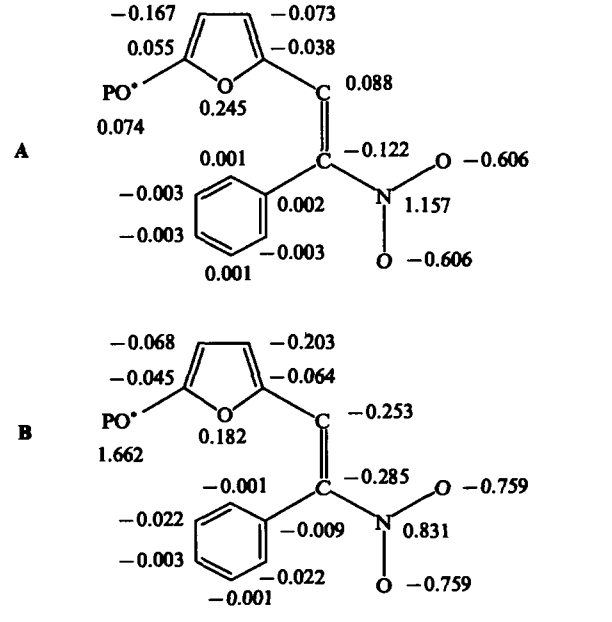


Figure 1. Distribution of the π-electron density of β-(5-chloro-2-furyl)-phenylnitroethylene **34** in the static (**A**) and transition (**B**) states: PO*—pseudo-orbital.

In order to consider the reactivity of furylnitroalkenes relative to nucleophiles, the π-electronic structures and the energies of the molecules in the static and transition (ST) states were calculated by the Hückel molecular orbital method for β-(5-chloro-2-furyl)-α-R^2-nitroethylenes (**1**, **33**, and **34**; R^2 = H, Me, Ph) (Fig. 1).[91,116] It was assumed that in the transition state the nucleophile and the chlorine atom being substituted can be represented in terms of a pseudo-orbital (PO) whose parameters have been published.[116-118]

The data on the distribution of π-electron density in the molecule of β-(5-chloro-2-furyl)-α-phenylnitroethylene **34** in the static and transition states show that nucleophilic substitution of the chlorine atom in the transition state is accompanied by a shift of π-electron density to the NO_2 group, while the phenyl group hardly participates in the electron shifts.[91] As a result of such displacement of π-electron density, the transition state energy is lowered i.e. the nitro group activates the nucleophilic substitution reactions.

Table 5 presents certain reactivity indices for β-(5-chloro-2-furyl)-α-R^2-nitroethylenes. The difference between the π-electron energies of the molecule in the static and transition states in units of the resonance integral $\beta(\Delta E^{\pi/\beta})$ is the π-electronic component of the activation energy and characterises the capacity for the nucleophilic substitution of the chlorine atom.[117] The π-electron density q^7 in the static approximation characterises the capacity for addition to multiple bonds.

The π-electron density at the C_β atom decreases in the sequence H > Ph > M, so that an increase in the capacity of the double bond to combine with nucleophiles in the same sequence should be expected.[91]

It is noteworthy that the above calculated quantities refer to hypothetical planar molecular models. If, on the other hand, account is taken of the breakdown of the planar configuration in compounds **33** (R^2 = Me) and **34** (R^2 = Ph) and of the associated decrease in the delocalisation of the π-electron cloud, then the differences in the capacity for nucleophilic addition in the sequence of R^2 substituents H > Ph > Me should be even more appreciable.

The quantity $\Delta E^{\pi/\beta}$ changes little as a function of the substituent R^2 and such variation is different for the variants of the parameters of the NO_2 group being compared.[117] It has therefore been suggested[91] that the interaction of the substituent R^2 with the NO_2 group alters the degree of its conjugation with the multiple bond and controls the rate of nucleophilic substitution of the chlorine atom. As a result of the electronic effects associated with the nature of the substituent R^2 and the change in configuration, the polarity of the C(5)–Cl bond (and hence also the rate of the nucleophilic substitution of the chlorine atom) diminishes after the introduction of the substituent R^2 in the following sequence: Me > Ph > H > Cl > Br.

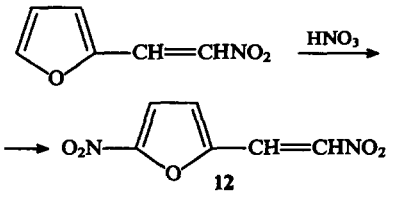
Thus, comparison of the effects of the substituent R^2 on the behaviour in relation to nucleophiles permits the following conclusions.

1. β-(5-Halo-2-furyl)-α-methylnitroethylenes (**33**, R^2 = Me) exhibit the greatest tendency to undergo halogen substitution reactions.

Table 5. The reactivity indices for β-(5-chloro-2-furyl)-α-R^2-nitroethylenes.[91,117]

Variant	Index	R^2		
		H	Me	Ph
1	$\Delta E^{\pi/\beta}$	2.861	2.893 [a]	2.834
	q^7	0.092	0.080 [a]	0.088
2	$\Delta E^{\pi/\beta}$	1.952	1.946	1.958
	q^7	0.192	0.128	0.172

[a] Estimated by the perturbation theory method.[116]



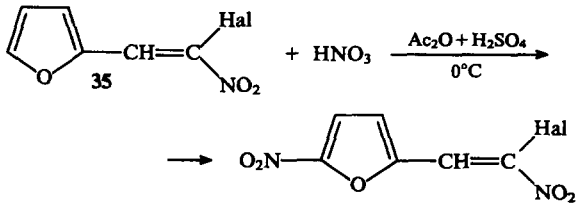
2. Addition reactions are more characteristic of β-(5-halo-2-furyl)nitroethylenes (**1**, R^2 = H) and β(5-halo-2-furyl)-α-halonitroethylenes (**35**; R^2 = Cl, Br).

According to patent data,[119] the interaction of β-(5-halo-2-furyl)-α-R^2-nitroethylenes **1** and **33**–**35** with morpholine leads to the polymerisation of the nitroalkenes when R^2 = H (**1**) and to the substitution of the halogen by morpholine R^2 = Me (**33**); for R^2 = Ph (**34**), products of the substitution and addition of the amine to the double bond were detected in the reaction mixture.

IV. Chemical properties

1. Substitution reactions in the furan ring

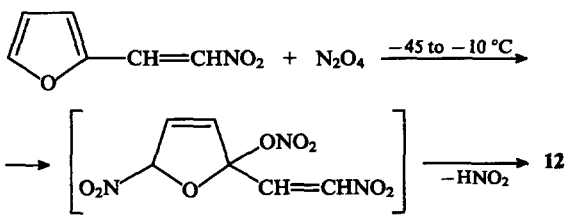
The most thoroughly investigated reaction of this type is the nitration of β-(2-furyl)nitroethylene **1** which leads to β-(5-nitro-2-furyl)nitroethylene **12**.



12

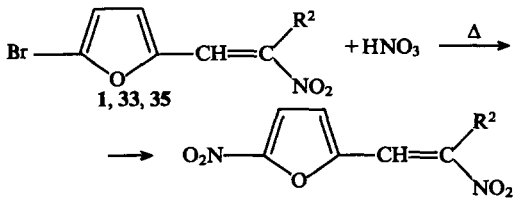
Nazarova[12] carried out the nitration with a tenfold excess of fuming HNO_3 in acetic anhydride at −5 to 0 °C and obtained compound **12** in 60.5% yield. Sasaki[72] used a fivefold excess of concentrated HNO_3 in acetic anhydride for nitration, whereupon the yield of the nitroalkene **12** did not exceed 35%.

The study of the nitration of β-(2-furyl)nitroethylene is of definite theoretical interest from the standpoint of the development of the theory of the nitration of furans. It is known[8] that the first elementary step in the nitration of acidophobic furans is the formation of oxonium compounds, which then either rearrange to 2,5-dihydrofuran derivatives or decompose with the opening of the furan ring to butane-1,4-diol derivatives, which char rapidly.



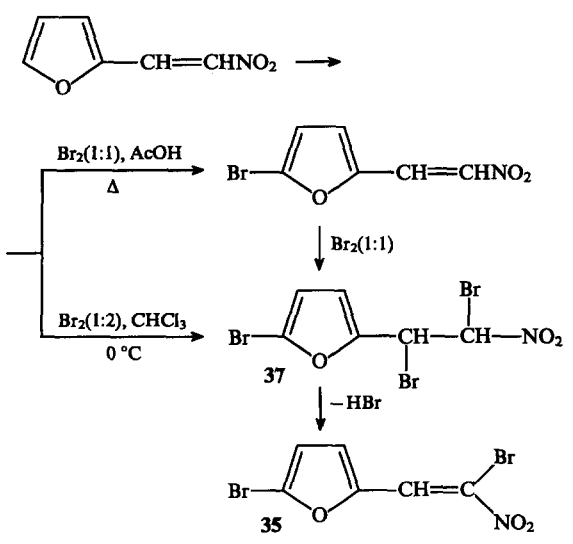
In the nitration of β-(2-furyl)nitroethylene **1**, this reaction pathway is excluded as a consequence of the influence of the electron-accepting NO_2 group, which lowers the tendency of the furan oxygen to be protonated and hence stabilises the entire furan system. Hillers and Nerklava[120] established that the nitration of compound **1** can be most usefully carried out with fuming HNO_3 in acetic anhydride (molar ratios $1:HNO_3:Ac_2O$ = 1:4:10) in the presence of catalytic amounts of H_2SO_4 at −10 to −5 °C; under these conditions, the yield of the nitroalkene **12** is 70%–80%. The authors showed that in this instance the true nitrating agent is the nitronium ion formed in HNO_3 solutions in acetic anhydride, particularly in the presence of H_2SO_4.

Nitration of β-(2-furyl)-α-halonitroethylenes (**35**; R^2 = Cl, Br) under similar conditions results in the formation of β-(5-nitro-2-furyl)-α-halonitroethylenes in 85%–88% yield.[47,52,91]

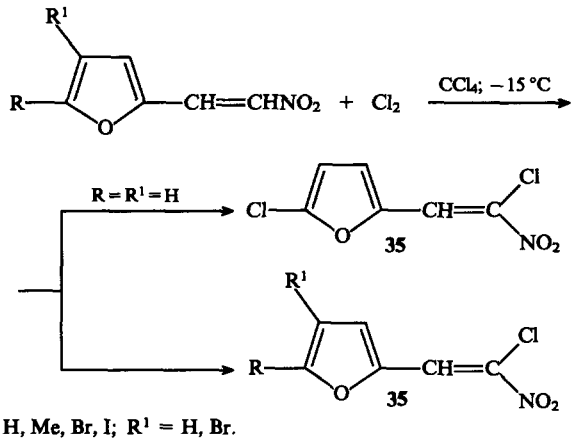


Hal = Cl, Br.

It has been shown[121] that the nitroalkene **12** is formed in 57% yield on treatment of β-(2-furyl)nitroethylene with a 50-fold excess of nitrogen tetroxide at low temperatures in ether.

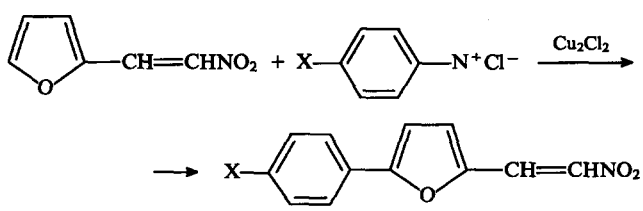


When β-(5-bromo-2-furyl)-α-R^2-nitroethylenes (**1**, **33**, and **35**) are heated with dilute HNO_3, the bromine atoms in the furan ring are substituted with formation of the corresponding 5-nitro-derivatives.[12,41,43,47,52,91] It is noteworthy that 5-bromofurfural does not afford 5-nitrofurfural under these conditions.



R^2 = H, Me, Cl. Br.

When β-(2-furyl)nitroethylene **1** is refluxed with an equimolar amount of bromine in acetic acid, β-(5-bromo-2-furyl)nitro-ethylene (**2**, R = Br) is formed.[12] Under similar conditions, β-(5-bromo-2-furyl)-α-chloronitroethylene (**35**; R = Br, R^2 = Cl) is obtained from β-(2-furyl)-α-chloronitroethylene. On the other hand, the bromination of compound **1** (molar ratio **1** : Br_2 = 1 : 2) in chloroform in the cold or bromination of β-(5-bromo-2-furyl)nitroethylene affords the unstable tribromo-derivative **37**, which decomposes on storage and distillation. Its dehydrobrom-ination with an aqueous solution of alkali at 20 °C leads to the synthesis of β-(5-bromo-2-furyl)-α-bromonitroethylene (**35**; R = R^2 = Br) in 64% yield.[52]



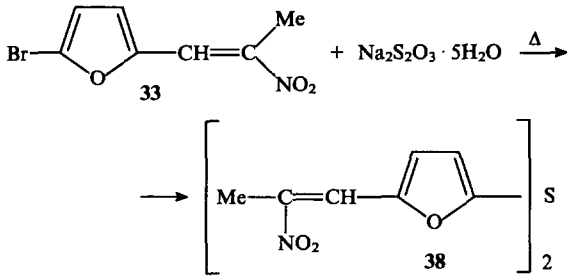
According to patent data,[122] chlorination of the nitroalkene **1** in chloroform or CCl_4 at −15 °C results in the simultaneous substitution of the hydrogen atoms in the 5-position in the furan ring and in the α-position in the vinyl fragment with formation of β-(5-chloro-2-furyl)-α-chloronitroethylene **35**. Chlorination of other β-(5-R-4-R^1-2-furyl)nitroethylenes under analogous conditions leads to the corresponding α-chloronitroalkenes **35** in 61% – 96% yield.

Oleinik and coworkers[98,123,124] reported for the first time the synthesis of (*E*)-β-(5-aryl-2-furyl)nitroethylenes (**1**; R = aryl) in 40% yield by arylating under the conditions of the Meerwein reaction (aqueous acetone, 40 °C) β-(2-furyl)nitroethylene with diazonium salts (molar ratio 1 : 1) containing electron-accepting substituents in the benzene ring.

R = H, Me, Br, I; R^1 = H, Br.

The authors' EPR spectroscopic study of the intermediates in the Meerwein arylation reaction permitted the conclusion that the given process has a radical mechanism.[124]

X = Cl, Br, NO_2.

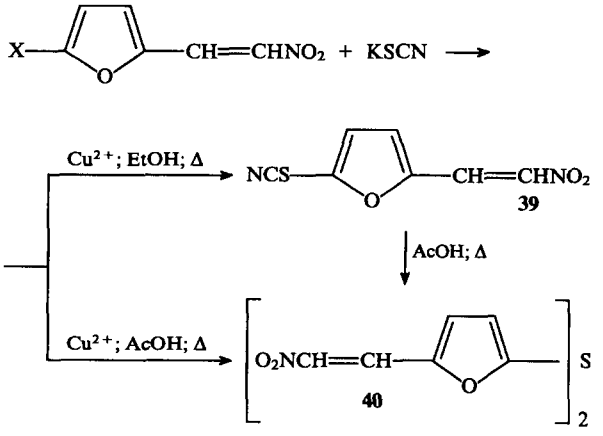


The influence of certain factors on the reactivity of β-(5-halo-2-furyl)-α-R^2-nitroethylenes relative to nucleophiles was examined in Section III.

It is known[93] that mainly the $-J$ effect of the halogens is manifested in 5-halofurfurals, as a result of which the C(5) atom of the furan ring acquires a positive charge, which increases in the sequence I < Br < Cl. The mobility of the halogens relative to the nucleophiles increases in the same sequence. On the other hand, in the case of β-(5-halo-2-furyl)nitroalkene the $n-\pi$ interaction with the furan nucleus is a $+M$ effect, which should diminish the positive charge on the C(5) atom and hinder substitution by nucleophiles compared with halofurfurals. The latter is manifested particularly strongly for β-(5-chloro-2-furyl)-α-R^2-nitroethylenes (**1**, **33**, and **35**; R^2 = H, Me, Ph, Cl, Br), which is indicated by the maximum value of μ_{int} in this instance (Table 1).

It has been shown[43,45] that when β-(5-halo-2-furyl)-α-methyl-nitroethylenes **33** are acted upon by nucleophiles (secondary amines, $Na_2S_2O_3$), the halogen in the 5-position in the furan ring is substituted, whereas in the case of β-(5-halo-2-furyl)nitro-ethylenes **1**, polymerisation or addition to the double bond takes place. These findings can be accounted for as follows. The direct polar conjugation in the planar structure of compound **1** (R^2 = H) leads to the appearance of a high positive charge on the β-atom of the vinyl fragment. The $+M$ interaction of the halogens in the 5-position with the furan ring in these compounds lowers simultaneously the effective positive charge on the C(5) atom of the furan. On the other hand, the introduction of the methyl group in the 5-position disturbs the planar configuration of the molecule and lowers the degree of conjugation, and hence promotes an increase in the positive charge on the C(5) atom of the furan ($-J$ effect of the halogen) and nucleophilic substitution.

The interaction of β-(5-bromo-2-furyl)-α-methylnitroethylene **33** with sodium thiosulphate in aqueous alcohol (refluxing for 2 h) leads to bis[5-(β-nitroprophenyl)-2-furyl] sulphide **38**.[43]

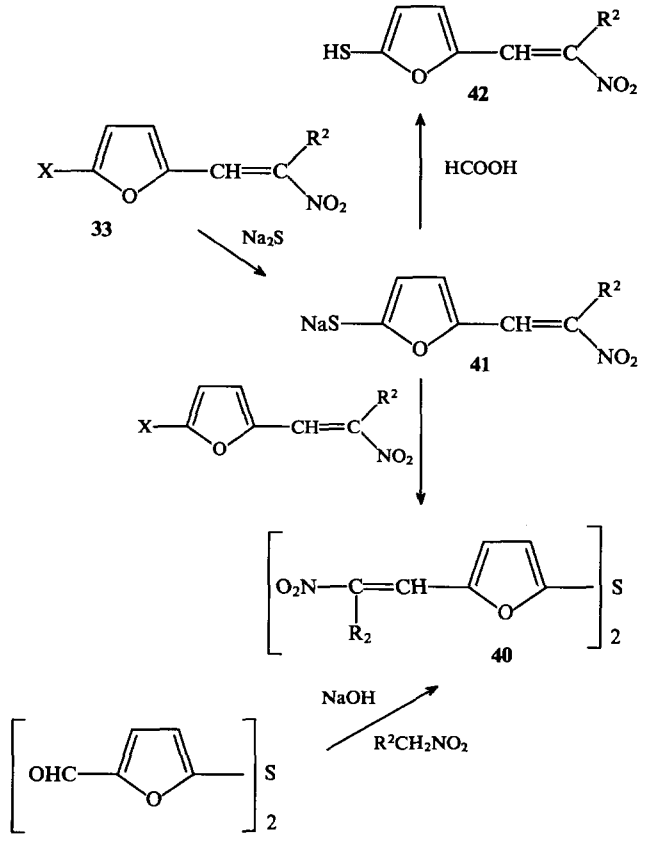


It is noteworthy that β-(2-furyl)-α-methylnitroethylene does not combine with sodium thiosulphate at the double bond, the methyl group apparently reducing the reactivity of the latter.[43]

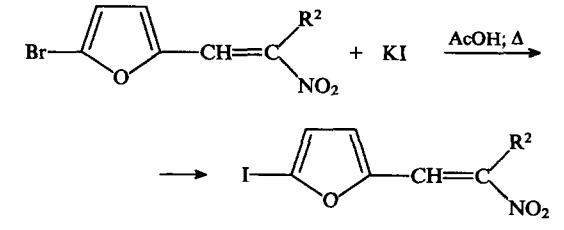
On the other hand, Nazarova and coworkers[125,126] established that, on treatment with potassium thiocyanate or sodium sulphide, β-(5-halo-2-furyl)nitroethylenes form the products of the substitution of the halogen in the furan ring, i.e. in the reaction with the above reagents they behave similarly to the nitroalkenes **33**.

The reaction involving the exchange of bromine for the thiocyanato-group in the nitroalkenes **1** occurs only after prolonged refluxing of the reactants in anhydrous solvents (acetone, methanol, ethanol) in the presence of copper or cobalt salts. Under these conditions, β-(5-thiocyanato-2-furyl)nitroethylene **39** is formed in 78%–85% yield. This compound is more stable than 5-thiocyanatofurfural.[125]

The interaction of compound **1** with potassium or barium thiocyanate in acetic acid in the presence of copper or cobalt salts leads to the sulphide **40**, which is also formed on hydrolysis of the thiocyanate **39** in acetic acid.[126] The reaction of β-(5-halo-2-furyl)-α-R^2-nitroethylenes (compounds **1** and **33**; R^2 = H, Me) with sodium sulphide affords Na derivatives of β-(5-mercapto-2-furyl)-α-R^2-nitroethylenes **41**, whose treatment with formic acid gives rise to the corresponding mercaptans **42**. The sulphides **40** (R^2 = H, Me) are synthesised by the reaction of the Na derivatives **41** with β-(5-halo-2-furyl)nitroethylenes **1** and **33**.[126]



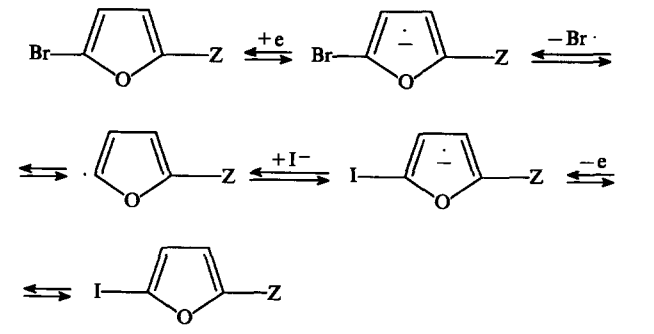
X = Cl, Br, I.



The structures of the sulphides **38** and **40** were confirmed also by unambiguous synthesis — the condensation of bis(5-formyl-2-furyl) sulphide with nitromethane or nitroethane in the presence of alkali.

A preparative method of synthesis of β-(5-iodo-2-furyl)-α-R^2-nitroethylenes (**1**, **33**, and **35**; R^2 = H, Me, Cl, Br) involves the nucleophilic substitution of bromine atoms in the corresponding 5-bromo derivatives.[12,30,43,47] The reaction involving the exchange of bromine for iodine occurs when the substrates are refluxed with potassium iodide in acetic acid for several hours; the target 5-iodo-derivatives are then formed in 50%–82% yield.

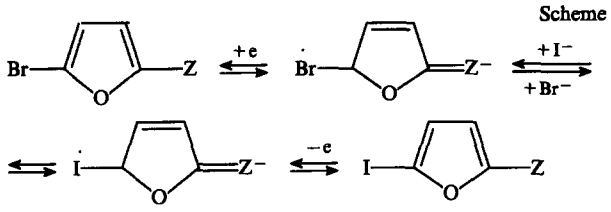
We may note that the chlorine or bromine atoms in the β-(5-nitro-2-furyl)-α-halonitroethylenes do not exchange for iodine under analogous conditions.[30]



X = Br, I; R^2 = H, Me.

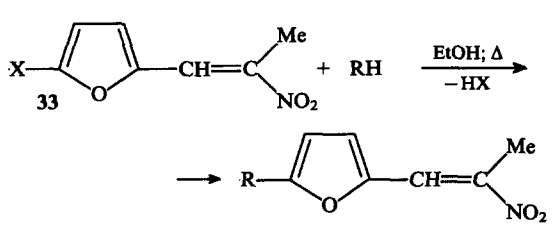
R^2 = H, Me, Cl, Br.

The kinetics of the exchange of bromine for iodine in β-(5-bromo-2-furyl)-nitroethylene have been investigated.[127] It was established that the reaction is reversible and is inhibited by oxidants (atmospheric oxygen, aromatic nitro-compounds, Schiff bases). The authors proposed a cryptoreductive reaction mechanism, which can operate in accordance with two schemes. According to Scheme 1, which includes the reversible electron transfer from the reducing supporting electrolyte generated by



Scheme 1

Z = CH=CHNO$_2$.

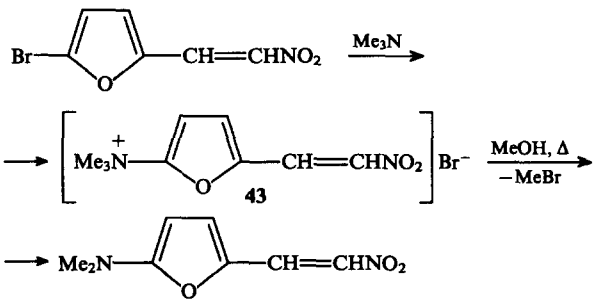


iodide anions to the halofuran molecule, the intermediate formation of a radical-anion with subsequent elimination from the latter of a bromide ion is postulated. The resulting furyl radical reacts with one of the halide ions of the reaction mixture with formation of either the initial or final products. On the other hand, one can assume that the furyl radical is not formed in this reaction as a kinetically independent species: without emerging from the reaction 'cage', it interacts with a second anion, which is also incorporated in the activated complex. In the limiting case, there is a possibility in this instance of a synchronous reaction involving the mutual exchange of the halogens in the radical-anions (illustrated in Scheme 2 in mesomeric form with separation of the radical and ionic fragments)—in terms of Bunnett's terminology,[128] this mechanism can be designated as $S_{RN}2$.

Scheme 2

It is noteworthy that, in terms of the decreasing rate of exchange of bromine for iodine, the substituents Z can be arranged in the following sequence: CH=CHCOPh > CHO > Ac > $CH=CHNO_2$, which is inconsistent with the activating strength of the above groups in reactions proceeding via the classical multistage mechanism of the 'addition–elimination' type.[127] The latter is characteristic, for example, of the reactions of 2-substituted 5-halofurans with secondary amines.[129]

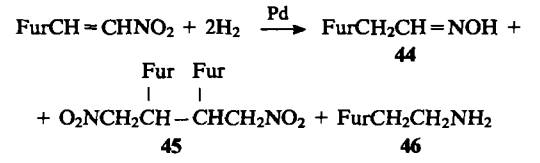
Certain features of the interaction of furylnitroalkenes with secondary amines were noted in Section III. Nazarova and coworkers[45,119] established that the nucleophilic substitution of a halogen by secondary amine residues takes place most smoothly with β-(5-halo-2-furyl)-α-methylnitroethylenes **33**.



X = Br, I; R = morpholino, PhNMe.

The structure of the substitution products was confirmed by unambiguous synthesis from the corresponding N-substituted 5-aminofurfurals. The authors note that, when piperidine, diethylamine, or dimethylamine is introduced into the reaction, the double bond is also subjected to nucleophilic attack. The reaction of β-(5-bromo-2-furyl)nitroethylene with secondary amines proceeds very vigorously and leads to the products of the polymerisation of the initial alkene.

As a result of the study of the kinetics of the interaction of β-(5-halo-2-furyl)nitroethylenes **1** with secondary amines (dimethylamine, piperidine, and morpholine), Novikov and coworkers[130] showed that the halogen exchange reaction takes place against the background of the reversible interaction of the amine with the nitrovinyl group. The latter reaction is then 'asymmetric' as regards mechanism—the addition process takes place as a base-catalysed multistage reaction, while elimination is a synchronous unimolecular process.



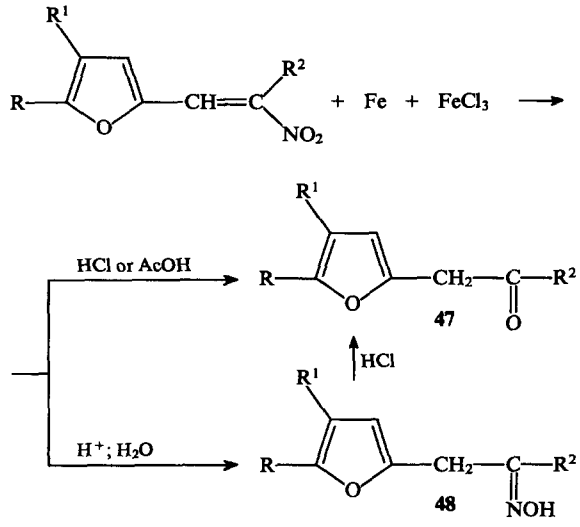
The interaction of the bromo-derivative **1** with trimethylamine in benzene affords the quaternary ammonium salt **43** in quantitative yield. On refluxing in methanol, the salt is converted into β-(5-dimethylamino-2-furyl)nitroethylene in 51% yield.[13]

2. Reduction of furylnitroalkenes

Depending on the chosen reduction method, the nature of the reductant, and the process conditions, the reduction of unsaturated nitro-compounds results in the formation of different classes of organic compounds.[1-3] From this standpoint, furylnitroethylenes are not an exception among other nitroalkenes.

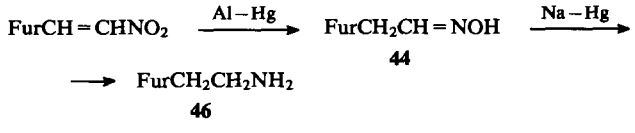
Freidlin and coworkers[31] investigated the hydrogenation of β-(2-furyl)nitroethylene in the presence of palladium black in different solvents at atmospheric pressure and 25 °C. The reaction is zero order with respect to the nitroalkene and the rate of absorption of hydrogen remains constant up to the complete conversion of the initial compound. The main reaction products are furylacetaldehyde oxime **44** and a hydrodimer—2,3-di(2-furyl)-1,4-dinitrobutane **45**. 1-Amino-2-(2-furyl)ethane **46** is formed in very small amounts.

In the hydrogenation of compound **1** in a 1 : 1 ethanol–acetic acid mixture, the yield of the oxime **44** reaches 97%. When the hydrogenation is carried out in ethanol or dioxan, the yield of the oxime **44** reaches 25%–54% together with the hydrodimer **45**; the dimerisation reaction is suppressed in the presence of weak organic acids (HCOOH, CH_3COOH). We may note that under comparable conditions the nitroalkene **1** is hydrogenated at approximately the same rate as β-nitrostyrene; the rate of hydrogenation of the thiophene analogue—β(2-thienyl)nitroethylene—is appreciably lower.[131]



The reduction of β-(2-furyl)nitroethylene **1** with zinc dust in acetic acid results in the formation of the oxime **44** in 60%–70% yield.[16,57]

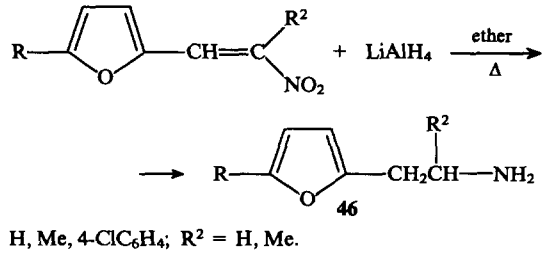
The reduction of β-(5-R-4R^1-2-furyl)-α-R^2-nitroethylenes with iron filings and $FeCl_3$ in hydrochloric acid (85–95 °C, 5–6 h)[37,48,132,133] or in acetic acid (80–100 °C, 1.5 h)[44] leads to ketones of the furan series with the carbonyl group in the 2-position in the side chain (compounds **47**) or to their oximes **48**, which are difficult to obtain by other methods.



It has been established that an increase in the excess of acid promotes the formation of the ketones **47**, whose yield is usually 35%–70%, while a decrease in its amount raises the yield of the ketoximes **48**.

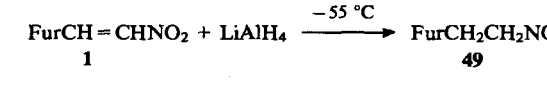
It has been recommended[132] that β-(4-methyl-2-furyl)-α-methylnitroethylene be reduced with an Fe + $FeCl_3$ mixture in 30% HCl, this being followed by treatment of the reaction product with a solution of $TiCl_3$ and ammonium acetate in water.

Japanese workers[14] synthesised 1-amino-2-(2-furyl)ethane **46** by the stepwise reduction of β-(2-furyl)nitroethylene with aluminium amalgam in ether and then with sodium amalgam in an ethanol–acetic acid mixture.



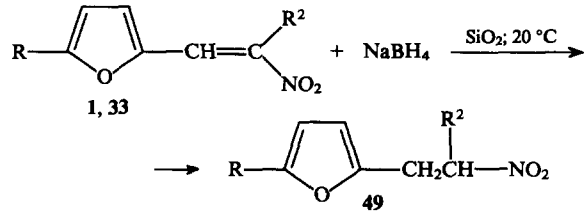
R = H, Me, 4-ClC$_6$H$_4$; R^1 = H, Me; R^2 = Me, Et, Pr, Ph.

The C=C bond, which is inert to the action of lithium tetrahydroaluminate, is readily reduced when it is conjugated with electron-accepting groups.[134] Lithium tetrahydroaluminate has therefore been used successfully for the reduction of a wide variety of nitroalkenes.[1] The structure of the reaction product depends to a large extent on the reduction conditions, primarily on temperature.



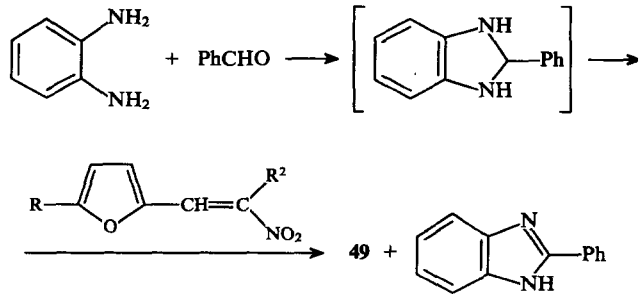
For example, in the reduction of furylnitroalkenes in boiling ether (molar ratio nitroalkene : $LiAlH_4$ = 1 : 2) the reaction is completed by the formation of the corresponding furylethylamines **46** in 52% – 65% yield.[13,25,38,98,135]

R = H, Me, 4-ClC$_6$H$_4$; R^2 = H, Me.



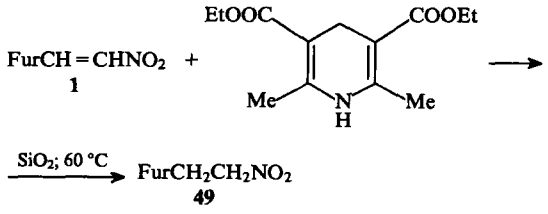
It is noteworthy that this method is the most effective procedure for the synthesis of 2-amino-1-(5-R-2-furyl)propanes (**46**; R = H, Me; R^2 = Me) — non-toxic analogues of the familiar preparation amphetamine.[38]

The reduction of β-(2-furyl)nitroethylene with 0.5 equiv. of $LiAlH_4$ at a low temperature (−55 to −60 °C) does not involve the nitro-group and only the double bond is reduced, the process being completed by the formation of 2-(2-furyl)-1-nitroethane **49**. However, the reaction is accompanied by appreciable charring and the yield[136] of the nitroalkene **49** does not exceed 16%.



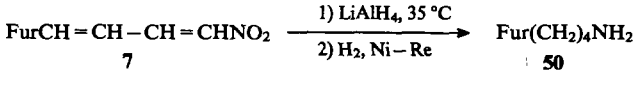
When the nitroalkene **1** is reduced with trimethoxyhydroborate and sodium tetrahydroborate in ether (−40 °C, molar ratios 1 : 1 : 3) or with lithium tetrahydroborate in ether (−73 °C, molar ratio 1 : 0.5),[136] the yield of the nitroalkane **49** can be raised to 28% – 31%.

According to Bogacheva,[137] on reduction of furylnitroalkenes **1** and **33** with sodium tetrahydroborate (molar ratio 1 : 4) in the presence of silica gel in a chloroform – 2-propanol mixture (20 °C, 2 – 4 h), the corresponding 1-nitro-1-R^2-2-(5-R-2-furyl)ethanes **49** can be obtained in 33% – 43% yield.



R = H, Me, NO$_2$; R^2 = H, Me.

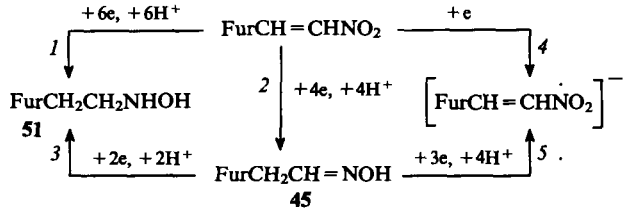
2-Phenylbenzimidazoline, generated *in situ* from *o*-phenylenediamine and benzaldehyde, has been used as the selective reductant for the double bond in the furylnitroalkenes **1** and **33**.[137,138] This method affords the nitroalkanes **49** in 45% – 65% yield when nitroalkenes react with *o*-phenylenediamine and benzaldehyde (molar ratios 1.0 : 1.2 : 1.2) in 1-butanol at 20 °C.



Japanese workers[139,140] proposed an effective method for the selective reduction of the double bond in conjugated nitroalkenes by reaction with the diethyl ester of 2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylic acid (Hantzch's ester) in the presence of silica gel. When β-(2-furyl)nitroalkene is reduced with this reagent in benzene (60 °C, 20 h), the yield of the nitroalkane **49** reaches 93%. The authors note that the reduction does not occur in the absence of silica gel.

The reduction of β-(3-furyl)nitroethylene **9** by this method leads to a 94% yield of 2-(3-furyl)-1-nitroethane,[70] which is a key compound in the synthesis of various limonoid structures[69] and the pheromone dendrolasin.[70]

The reduction of 1-(2-furyl)-4-nitrobutadiene **7** with an excess of lithium tetrahydroaluminate in boiling ether affords, instead of the expected 4-amino-1-(2-furyl)butane **50**, a mixture of four unidentified incomplete reduction products.[141] Without additional purification, this mixture was subjected to catalytic hydrogenation over Raney nickel (methanol, 20 °C, initial hydrogen pressure 120 atm); under these conditions, the amine **50** is formed in 61% yield.

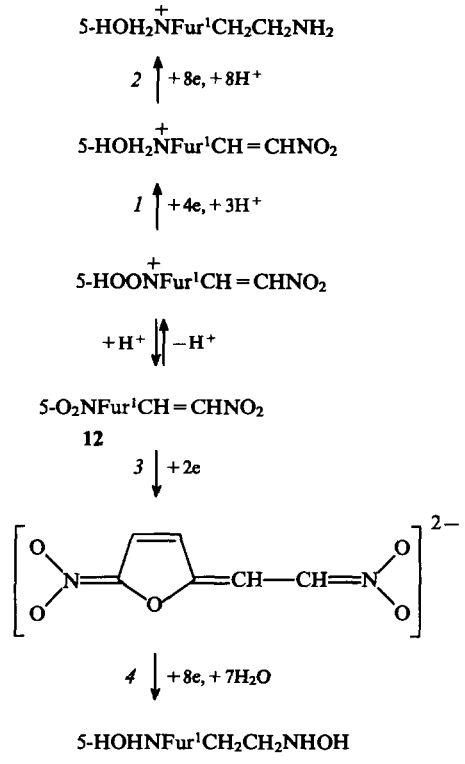


The authors note that the catalytic hydrogenation of the nitrodiene **7** with the aim of obtaining compound **50** in one stage leads to tarry products even under mild conditions.

The reduction of the potassium salt of the aci-form of 1-(2-furyl)-4-nitrobut-2-en-1-one **32** with sodium tetrahydroborate in water at 20 °C results in the formation[89] of the unstable sodium salt of 1-(2-furyl)-4-nitrobut-2-en-1-ol, which is converted into the nitrodiene **7** in 56% yield after acidification.

$$\text{FurCOCH=CHCH=NOO}^-\text{K}^+ \xrightarrow[H_2O]{NaBH_4} \text{FurCHCH=CHCH=NOO}^-\text{Na}^+ \xrightarrow{H^+} \underset{\text{OH}}{\text{FurCHCH=CHCH=NOO}^-\text{Na}^+} \longrightarrow \underset{7}{\text{FurCH=CHCH=CHNO}_2}$$

Takamoto[142] obtained 1-amino-2-(2-furyl)ethane **46** from β-(2-furyl)nitroethylene (yield 91%) by electrochemical reduction using amalgamated nickel as the cathode and a lead plate as the anode (the catholyte was an ethanol–acetic acid mixture and the anolyte was dilute H_2SO_4). The electrolysis was carried out at 30–35 °C at a current of 4–45 A.



Reikhman et al.[143] investigated the mechanism of the polarographic reduction of β-(2-furyl)nitroethylene as a function of the mixture composition as well as the protolytic reactions of the compound. On the basis of the polarographic data recorded in aqueous alcoholic Britton–Robinson buffer solutions in the pH range from 2–12 in the presence of 0.1 M LiCl as the supporting electrolyte, the authors proposed the following mechanism of the polarographic reduction of this nitroalkene:

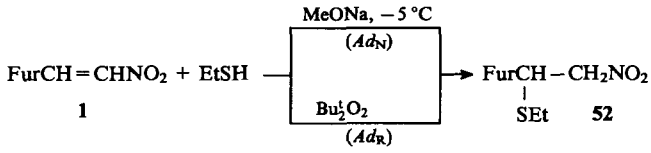
In acid solutions with a low ethanol content, 6-electron reduction to the substituted hydroxylamine **51** (reaction *1*) takes place. In neutral media, there is 4-electron reduction (reaction *2*) to the oxime **45** and the subsequent stage involving the addition of two further electrons (reaction *3*) is displaced towards negative potentials (−0.85 to −1.30 V) and is manifested by separate wave B, the half-wave potential $E_{1/2}$ of which corresponds to the electrochemical reduction potentials of oximes.[8,144,145]

In an alkaline medium, the 4-electron process *2* is split into 1-electron (reaction *4*) and 3-electron (reaction *5*) stages. The waves become clearly separated at pH > 10, where a dimunition of all the waves is observed. The latter is apparently due to the fact that the anionic form of compound **1** is polarographically inactive. in solutions with a high alcohol content at pH < 7, the reduction takes place in two stages (reactions *2* and *3*). In alkaline media and in DMF, distinct processes *4* and *5* take place.

In the electrochemical reduction of β-(5-nitro-2-furyl)-nitroethylene **12**, two reaction centres are reduced simultaneously.[8,145,146] In aqueous and 10% aqueous alcoholic Britton–Robinson buffer solutions in an acid medium (pH ⩽ 3) at potentials in the range 0 to −0.1 V, the 4-electron reduction of the nitro-group, characteristic of derivatives of 5-nitrofuran takes place (stage *1*). At more negative potentials (−0.3 to −0.7 V) the subsequent 8-electron wave, corresponding to the electrochemical reduction of the nitro-group conjugated with a double bond (stage *2*), takes place.

In more alkaline media (pH > 6), the primary step in the electrochemical reduction of this compound is the direct addition of two electrons (stage *3*) to the entire system of conjugated π-bonds of the molecule and is followed at potentials of −1.45 V by the 8-electron process *4* involving the electrochemical reduction of the dianion formed. This somewhat unusual mechanism of the electrochemical reduction is supported by the presence on the polarogram of a distinct 2-electron wave, by the independence of its $E_{1/2}$ of the pH, and also by the similarity to the mechanism of the chemical reduction of *p*-dinitrobenzene.[146]

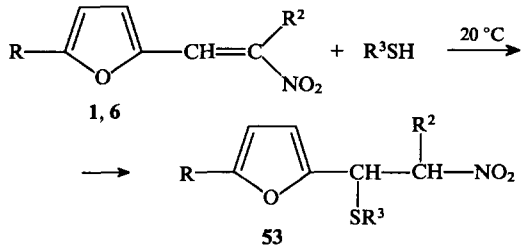
At pH 9, the polarogram shows a sharp decrease in the height of all the waves. Spectrophotometric studies indicate the occurrence in these solutions of irreversible chemical reactions, whose products are polarographically inactive.[146]



It has been shown[147] that β-aryl-α-(5-nitro-2-furyl)-α-nitroethylenes **34** are reduced at a mercury dropping electrode with two or three one-electron waves ($E^1_{1/2} = -0.6$ V, $E^2_{1/2} = 1.25$ V, and $E^3_{1/2} = -1.4$ V relative to 1 M LiCl at a calomel electrode). Unstable radicals with a lifetime of several seconds and with the unpaired electron centred on the nitro-group (according to EPR data) arise under these conditions.

3. Reactions involving addition to the double bond

It was noted in Section III that the tendency of furylnitroalkenes to undergo nucleophilic addition at the activated double bond depends primarily on the structure of the nitroalkenyl fragment.



In considering reactions of this type, account must be taken not only of the appreciable polarity and ready polarisability of the activated double bond but also of the high probability of the delocalisation of the negative charge in the transition state. These factors determine the exceptionally high reactivity of furylnitroalkenes with respect to nucleophiles such as amines, alcohols, phenols, and mercaptans. As a result of the addition of these reagents, with formation of C–S, C–O, and C–N bonds, a wide variety of β-substituted nitroalkyl derivatives of the furan series may be synthesised. However, one should note that in the majority of cases the adducts formed are (in contrast to the analogous adducts in the series of aliphatic, acyclic, and aromatic nitroalkenes[1–3]) thermodynamically unstable, decomposing fairly rapidly and charring.

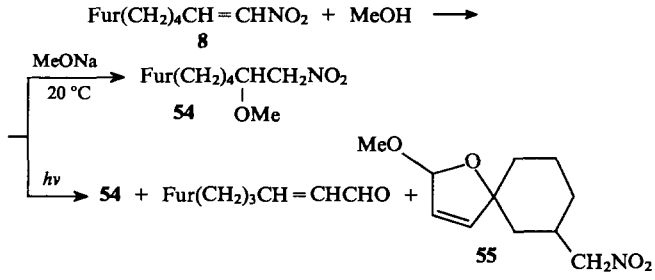
Ethanethiol adds to the double bond of β-(2-furyl)nitroalkene via both nucleophilic and radical mechanisms[148] with formation of the stable 2-ethylthio-2-(2-furyl)-1-nitroethane **52**.

The nucleophilic addition was carried out in the presence of an equimolar amount of sodium methoxide in methanol at −5 to 0 °C, while the radical addition was carried out by heating the reactants in the presence of *tert*-butoxide in sealed tubes, the yield of the adduct being appreciably higher in the latter case (~85%).

In a series of investigations by Czechoslovak workers[149-155] undertaken to investigate the mechanism of the biological activity of furylnitroalkenes **1** and **6** and to establish the structure–reactivity correlation for these compounds, a study was made of the interaction with various mercaptans in methanol at 20 °C, which leads to 1-R²-2-(R³-thio)-2-(5-R-2-furyl)-1-nitroethanes **53**.

R = H, Me, Br, I, MeOOC, NO_2; R^2 = H, MeOOC; R^3 = $PhCH_2$, $HOOCCH_2$, $HOCH_2CH_2$, $H_2NCH_2CH_2$.

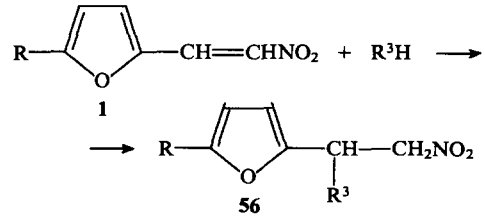
The authors explain the cytotoxic and antimicrobial activities of the vinylfuran derivatives by the action of these biocides on the main processes of the energy metabolism of the cell, primarily on glycolysis. The basis of this interaction is the inhibition of certain enzymes — hexokinase, phosphofructokinase, and glycerol-3-phosphate dehydrogenase. These enzymes are deactivated as a result of the direct chemical modification of their catalytically active HS groups. The capacity of the furylnitroalkenes to undergo the nucleophilic addition of mercapto-derivatives constitutes an index of their antimicrobial and cytotoxic additivities.[156]



Kinetic study of the reactions of furylnitroethylenes with thiols showed that these reactions proceed via a nucleophilic addition mechanism and that the attack of the mercapto-anion is directed to the electron-deficient carbon atom of the double bond. It has been established that in an aqueous buffer system (pH 4.9) the reactions have second-order rate constants; the activity of furylnitroalkenes increases with enhancement of the electron accepting character of the substituent both in the 5-position in the furan ring and in the α-position in the nitrovinyl fragment. Using the Hammett constants, it has been established that this rule is quantitative. for example, in a study[151] of the reaction of the methyl esters of β-(5-R-2-furyl)-α-nitroacrylic acids **6** with mercaptoacetic acid (25 °C, aqueous Clark buffer, pH 4.9), it was found that $\lg K = 1.134\sigma_r + 7.125$ (correlation coefficient $r = 0.971$, $n = 6$).

Depending on the nature of the substituents R and R^2, furylnitroethylenes can be arranged in the following sequence in terms of the decrease in their reactivity in reactions with mercaptans:[151-153] NO_2, COOMe > COOMe, COOMe > I, COOMe > Br, COOMe > H, COOMe > Me, COOMe > NO_2, H > H, H.

The reactivity of mercaptans in the reactions with furylnitroethylenes increases with increase in their basicity. For example, the following sequence has been established for the reactions of mercaptans with β-(5-nitro-2-furyl)nitroethylene (25 °C, pH 4.4) in terms of the variation of the reactivity of the mercaptans:[153] $HSCH_2COOH$ (pK_a = 10.22) ≫ $HSCH_2CH_2OH$ (pK_a = 9.72) > $PhCH_2SH$ (pK_a = 9.43) > glutathione (pK_a = 8.56) > $HSCH_2CH_2NH_2$ (pK_a = 8.35) > $HSCH_2CH\cdot(NH_2)COOH$ (pK_a = 8.15).



However, one should note that in the above investigations the authors carried out only kinetic measurements (mainly spectrophotometrically) and did not isolate or identify the adduct **53** formed.

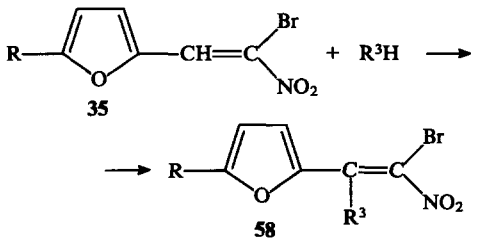
The addition of methanol to the double bond of 6-(2-furyl)-1-nitrohex-1-ene **8** at 20 °C in the presence of calytic amounts of sodium methoxide has been reported.[68] Under these conditions, the yield of the methoxy-derivative **54** was 47%. The authors note that, when a solution of compound **8** in methanol is irradiated with UV light (450 W high-pressure Hg lamp argon-filled), 6-(2-furyl)hex-2-enal and 2-methoxy-6-nitromethyl-1-oxaspiro-[4.5]dec-3-ene **55** are formed together with the methoxy-derivative **54**.

As a result of the nucleophilic addition of amines to the double bond of β-(5-R-2-furyl)nitroethylenes **1**, the β-nitroamines **56** are formed.[18,155,157]

The interaction of β-(5-bromo-2-furyl)- and β-(5-nitro-2-furyl)-nitroethylenes with pyrrolidine and morpholine in ethanol, acetone, DMF, or DMSO leads even at 20 °C to appreciable charring and the formation of unstable adducts. Stable adducts could be obtained[18] only in the reaction of β-(2-furyl)- and β-(5-phenylthio-2-furyl)-nitroethylenes with 4-phenylpiperazine, whereupon the corresponding β-nitroamines **56** (R = H, PhS; R^3 = 4-phenylpiperazino) were isolated in 80%–90% yield.

R = H, Br, NO_2, PhS, $PhSO_2$, 4-$MeC_6H_4SO_2$; R^3 = pyrrolidino, piperidino, morpholino, 4-phenylpiperazine, BuNH, PhNH, $HOOCCH_2NH$

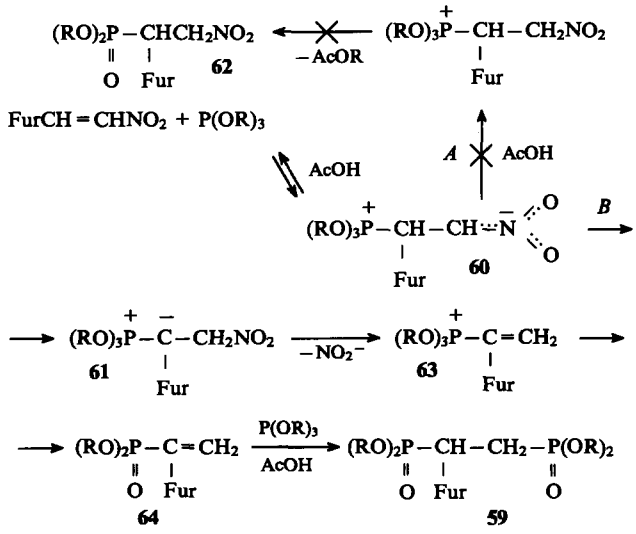
The study of the kinetics of the reaction of β-(2-furyl)nitroethylene with secondary amines showed that the reaction is second-order with respect to the substrate and first-order with respect to the nucleophile.[18,157] The rate of reaction at 25–45 °C increases with increase in the nucleophilicity of the reagents: pyrrolidine > piperidine > morpholine. A high rate constant for the reaction of the nitroalkene **1** with pyrrolidine is observed in non-polar solvents, diminishing with increasing solvent polarity in the sequence heptane > toluene > diethyl ether > DMSO > methanol.[18,157]



In terms of its influence on the rate of addition of secondary amines to the nitroalkenes **1** (MeOH, 25 °C), the substituents R can be arranged in the following sequence: $PhSO_2$ > 4-$MeC_6H_4SO_2$ > PhS ≃ Br > H, i.e. strongly electron-accepting groups induce an increase in the rate of reaction.[18,157]

The kinetics of the interaction of the methyl esters of β-(5-R-2-furyl)-α-nitroacrylic acid esters **6** and β-(5-nitro-2-furyl)nitroethylene with butylamine aniline, and certain aminoacids have been investigated[155,156] and it has been shown that in the case of amines the second-order rate constant is appreciably lower than in the case of mercaptans.

The interaction of the nitroalkene **1** with an equimolar amount of hydroxylamine in methanol leads[158] to the stable 2-hydroxyamino-2-(2-furyl)-1-nitroethane **57** in 80% yield.



$$\underset{\mathbf{1}}{FurCH{=}CHNO_2} + NH_2OH \longrightarrow \underset{\mathbf{57}}{FurCH(NHOH){-}CH_2NO_2}$$

It has been reported[159] that α-bromo-β-(5-R-2-furyl)nitroethylenes **35** react with alcohols and secondary amines via an addition–elimination type of mechanism with formation of β,β-disubstituted nitroethylenes **58**.

Conjugated nitroalkenes can react with trivalent phosphorus acid esters in different ways depending on the nature of the nitroalkene, the groups surrounding the phosphorus atom, and the medium.[160,161]

It has been established that the interaction of β-(2-furyl)nitroethylene with trialkyl phosphites in acetic acid at 40 °C proceeds less vigorously than the reaction with β-nitrostyrene; under these conditions, 4 moles of the phosphite are consumed per mole of the alkene. As a result of the reaction, it was possible to isolate[162,163] 1,2-bis(dialkylphosphinyl)-1-(2-furyl)ethanes **59**. According to the proposed reaction mechanism,[163] the adduct formed initially as a result of addition to the double bond (the betaine **60**) can be either protonated in acetic acid (pathway *A*) or can be converted into the phosphinilide **61** as a result of the migration of the proton from the α- to the β-carbon atom (pathway *B*).

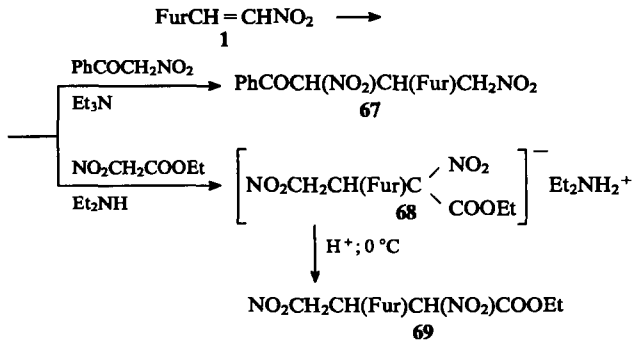
R = Me, Et

The dialkyl esters of 1-(2-furyl)-2-nitroethylphosphonic acid **62**, which should form as a result of the protonation of the intermediate betaine **60**, were not detected in the reaction mixture. This shows that the rate of migration of the protons from the C_α to the C_β atom in the adduct **60** appreciably exceeds the rate of its protonation even in a solvent such as acetic acid.

The phosphinilide **61** is stabilised as a result of the elimination of the nitrite anion with formation of the cation **63**, which is subsequently converted into 1-(dialkoxyphosphinyl)1-(2-furyl)-ethylene **64** in conformity with the second stage of the Arbuzov reaction. However, the latter could not be detected in the reaction mixture, owing to the high rate of addition of trialkyl phosphite to it, which leads to the final product **59**.

According to patent data,[164] the reaction of the nitroalkene **1** with diphenyl(trimethylsilyl)phosphine oxide leads to the corresponding β-nitroethylphosphine oxide **65**, in 80% yield.

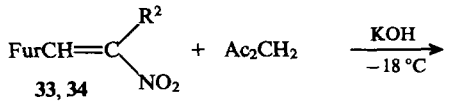
$$\underset{\mathbf{1}}{FurCH{=}CHNO_2} + Ph_2P(O)SiMe_3 \longrightarrow \underset{\mathbf{65}}{Ph_2P(O){-}CH(Fur){-}CH_2NO_2}$$



Reactions involving addition to nitroalkenes of the furan series with formation of new C–C bonds are of considerable theoretical and practical interest. Furylnitroalkenes enter fairly readily into the Michael reaction with a wide variety of CH acids, forming stable β-substituted β-furylnitroalkenes. For example, the interaction of β-(2-furyl)nitroethylene **1** with compounds containing activated methyl groups (2,4,6-trinitrotoluene, 9-methylacridine, and the quinaldine and 2-methylbenzothiazole methiodides) in benzene (20–80 °C, 1–2 h) in the presence of triethylamine, leads to the formation of the monoadducts-[3-R^3-2-(2-furyl)-1-nitropropanes] **66** in 63%–84% yield.[165]

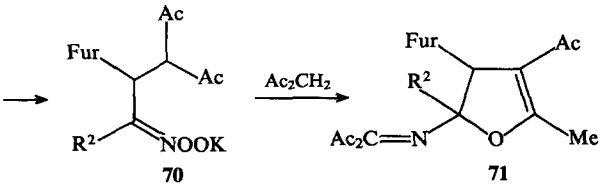
$$\underset{\mathbf{1}}{FurCH{=}CHNO_2} + R^3Me \xrightarrow{Et_3N} \underset{\mathbf{66}}{R^3{-}CH_2{-}CH(Fur){-}CH_2NO}$$

R^3 = 2,4,6-$(NO_2)_3C_6H_2$, 9-acridinyl, 1-methyl-2-quinolinylinium iodide, 3-methyl-2-benzothiazolylinium iodode.



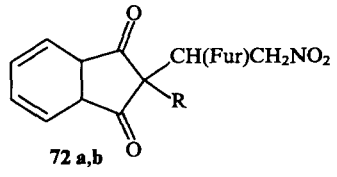
The reaction of the nitroalkene **1** with benzoylnitromethane in the presence of catalytic amounts of triethylamine in benzene (80 °C, 5–10 min) leads to the α,γ-dinitroketone **67** in 50%–54% yield.[166]

The interaction of β-(2-furyl)nitroethylene **1** with ethyl nitroacetate takes place only in the presence of equimolar amounts of diethylamine and leads to the formation of the diethylammonium salt **68**, whose acidification at 0 °C affords ethyl 3-(2-furyl)-2,4-dinitrobutanoate **69** in 25% yield.



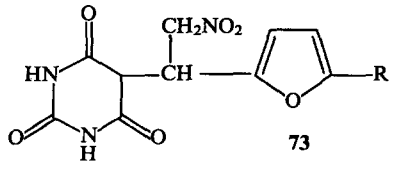
German workers[168,169] reported the reactions of β-(2-furyl)-α-R^2-nitroethylenes (**33** and **34**; R_2 = Me, Ph) with acetylacetone. The interaction of these reagents in aqueous methanol at −18 °C in the presence of equimolar amounts of alkali leads to the salts of 5-acinitro-5-R^2-3-acetyl-4-(2-furyl)pentan-2-ones **70** in 80%–88% yield.[168]

When the reaction is carried out in an excess of the β-diketone,[169] 3-acetyl-5-(diacetylmethylene)amino-4-(2-furyl)-2-methyl-5-R^2-4,5-dihydrofurans **71** are formed in low yields.



33, 34

70 71

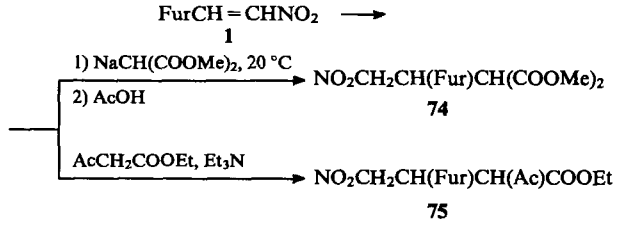


R^2 = Me, Ph.

The interaction of β-(2-furyl)nitroethylene with indan-1,3-dione and 2-phenylindan-1,3-dione (phenylin) in benzene (20 °C) in the presence of triethylamine led to the synthesis of the corresponding diadducts **72a** or the monoadducts **72b** in 50%–56% yield.[170]

72 a,b

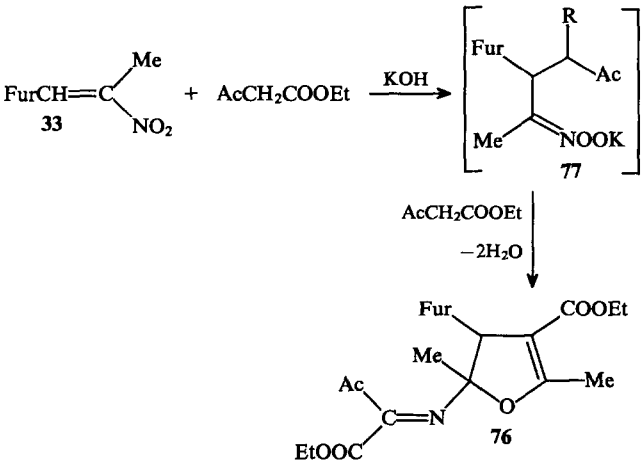
a: R = $NO_2CH_2CH(Fur)$, b: R = Ph.



73

R = H, Me, NO_2.

When equimolar amounts of β-(5-R-2-furyl)nitroethylenes and barbituric acid are refluxed in aqueous ethanol, the monoadducts **73** are obtained in 73%–90% yield.[171] The authors note that the reaction of furylnitroethylenes with barbituric acid proceeds under more severe conditions than the reaction with β-nitrostyrene,[1] which is due to the more pronounced electron-donating influence of the furyl fragment compared with the phenyl group. The reactions could not be carried out at room temperature both in the presence and absence of a basic catalyst. On heating in the presence of alkaline catalysts (i.e. catalysts typical for the Michael reaction), partial or even complete charring takes place.

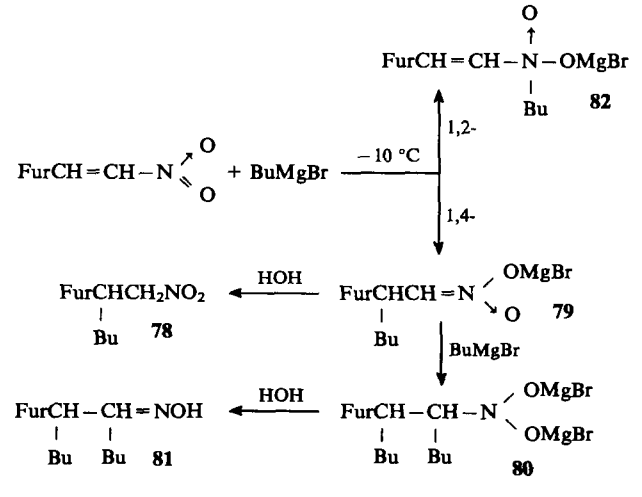


The reaction of sodiomalonic ester with β-(2-furyl)nitroethylene **1** and subsequent treatment with acetic acid lead to an 87% yield of the ester of 3-(2-furyl)-2-methoxycarbonyl-4-nitrobutanoic acid **74**—a valuable intermediate for the synthesis of furyl-containing γ-aminoacids and pyrrolidinones.[172,173]

The mode of interaction of acetoacetic ester with furylnitroalkenes depends primarily on the structure of the latter. For example, the ester of 2-acetyl-3-(2-furyl)-4-nitrobutanoic acid **75** was obtained in 60%–82% yield by the reaction of acetoacetic ester with β-(2-furyl)nitroethylene in the presence of triethylamine (benzene, 20 °C, 48–144 h).[174,175]

On the other hand, the interaction of acetoacetic ester with β-(2-furyl)-α-methylnitroethylene **33** and KOH (in molar proportions of 3 : 1 : 1) in ether led to the isolation of the ester of 5-[acetyl(ethoxycarbonyl)methyleneamino]-4-(2-furyl)-2,5-dimethyl-4,5-dihydrofuran-3-carboxylic acid **76** in 26% yield.[176] The authors believe that the potassium salt **77** of the aci-form of the 1 : 1 adduct is an intermediate in this reaction. It reacts subsequently with a second molecule of acetoacetic ester to form the dihydrofuran **76**.

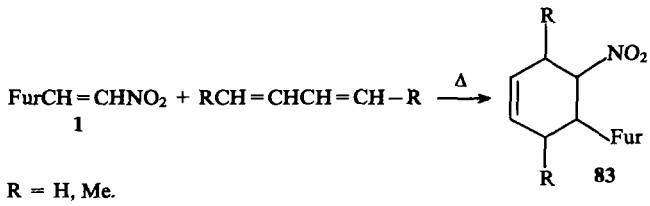
It is noteworthy that there are still no literature data concerning the involvement of furylnitroalkenes in the Michael reaction with reactive CH acids such as nitro- and *gem*-dinitroalkanes, trinitromethane, benzyl cyanide, cyanoacetic ester, dimedone, cyclopentane-1,3-dione, etc.



33 **77** **76**

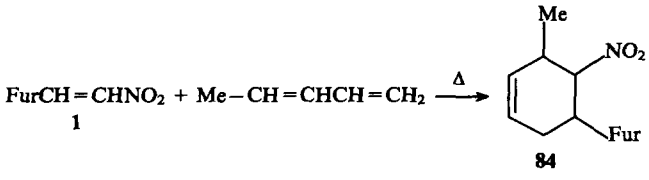
Unsaturated nitro-compounds are capable of reacting with organometallic compounds, forming nitroalkanes derived from isonitroso-compounds, oximes, and hydroxylamine.[1-3] However, there is only one communication in the literature[177] about the reaction of β-(2-furyl)nitroethylene with butylmagnesium bromide, which leads to 2-(2-furyl)-1-nitrohexane **78** in 33% yield.

The 1,4-addition of the Grignard reagent to the conjugated system of the nitroalkene **1** affords predominantly complex **79**, whose hydrolysis leads to the nitroalkene **78**. However, by virtue of the presence of the $-C=N \rightarrow O$ system in complex **79**, it becomes possible to add a second molecule of the Grignard complex and to form complex **80**, which is converted into the oxime **81** on hydrolysis. The Grignard reagent adds partly to the 1,2-positions with formation of complex **82**, whose hydrolysis leads to a *N,N*-disubstituted hydroxylamine.



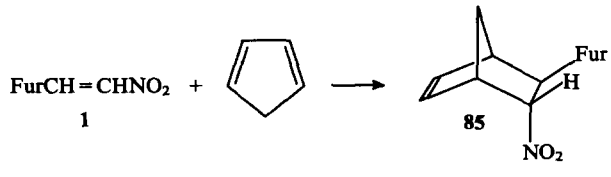
The authors note that, in order to suppress the nitroalkene polymerisation side reaction, it is useful to carry out the process at 10 °C with an excess of the Grignard reagent.

82 **78** **79** **81** **80**

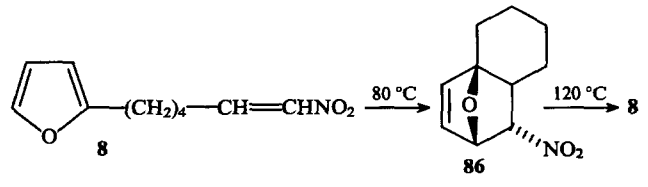


4. The cycloaddition reaction

According to the data of Kataev and Matveeva,[178] heating (150 °C, 10–16 h) of β-(2-furyl)nitroethylene **1** with butadiene and hexa-2,4-diene (molar ratio 1 : 3) in the presence of hydroquinone in a sealed tube affords a 45% yield of 5-(2-furyl)-4-nitrocyclohexenes **83**. The authors note that the reaction is accompanied by appreciable charring.

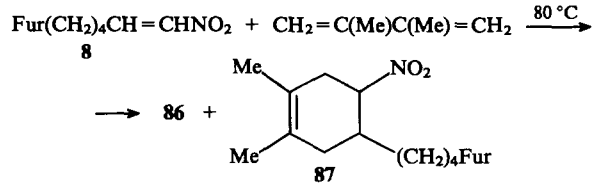


R = H, Me.



The study of the cycloaddition of the nitroalkene **1** to penta-2,4-diene showed that the reaction proceeds regioselectively with formation of only one regioisomer[178] — 5-(2-furyl)-3-methyl-4-nitrocyclohexene **84** in 55% yield.

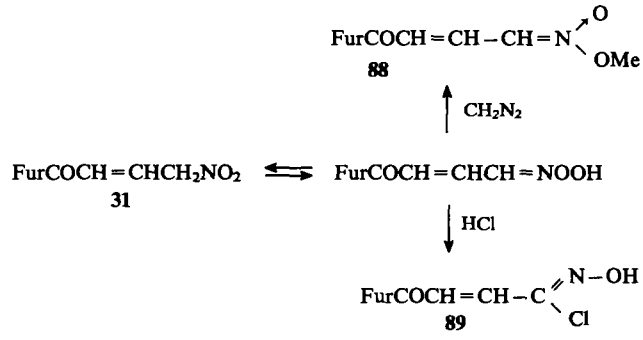
endo-3-(2-Furyl)-2-nitrobicyclo[2.2.1]hept-5-ene **85** can be obtained in 78% yield by the reaction of the nitroalkene **1** with an equimolar amount of cyclopentadiene.[179] The stereochemistry of the process and the relative reactivity of the nitroalkene **1** with respect to cyclopentadiene are correlated with quantum-chemical CNDO/2 calculations.



When 6-(2-furyl)-1-nitrohex-1-ene **8** is refluxed in benzene with catalytic amounts of pyridine, an intramolecular Diels–Alder reaction takes place with formation of the tricyclic adduct **86** in 52% yield.[68] On heating to 120 °C, the latter is reconverted into the initial compound **8**:

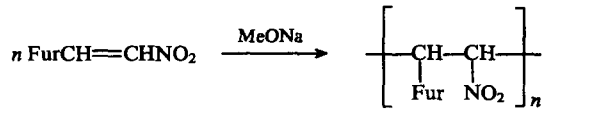
Prolonged (182 h) heating of the nitroalkene **8** with 2,3-dimethylbutadiene (molar ratio 1 : 10) in benzene produces a mixture containing 13.4% of the cyclic adduct **86**, 42.8% of 5-[4-(2-furyl)butyl]-1,2-dimethyl-*p*-nitrocyclohexene **87**, and 22% of compound **8**. Compound **8** is apparently formed as a result of the retroreaction of the adduct **86**.

Heating on compound **86** with 2,3-dimethylbutadiene (molar ratio 1 : 20) in benzene (80 °C, 251 h) affords a mixture containing 36.7% of compound **8**, 25.9% of compound **86**, and 30.8% of cyclohexene **87**.[68]



5. Other reactions of furylnitroalkenes

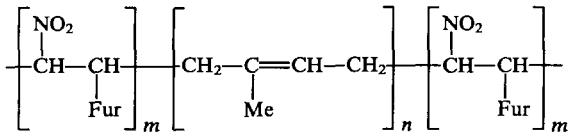
When β-(2-furyl)nitroethylene **1** is heated with concentrated hydrochloric acid, the furan ring is cleaved with formation of 6-nitro-4-oxocaproic acid.[180]



Methylation of 1-(2-furyl)-4-nitrobut-2-en-1-one **31** with diazomethane affords a 50% yield of the *o*-methyl ester of the acinitro-form **90**.[89]

Treatment of a solution of the nitroketone **31** in dioxane with concentrated hydrochloric acid gives rise to the chloride of the corresponding hydroxamic acid **89** in 45% yield.[89]

Studies on the polymerisation of β-(2-furyl)nitroethylene in the presence of anionic initiators (sodium methoxide, sodium ethoxide, etc.) have been reported.[180–182] The reactions were carried out in the temperature range −15 to 20 °C in different solvents — toluene, THF, and DMF. In the presence of cationic and radical initiators, the polymerisation of β-(2-furyl)nitroethylene was not observed.



It has been shown that, with increase in the solvating capacity and polarity of the solvent, the yield of the polymer increases.[181] For example, when the polymerisation is carried out in toluene (0 °C, 150 min) the yield of the polymer is 15%, while in THF and in DMF the yields are 68% and 55% respectively. The polymer formed under these conditions is of the rigid-chain type and has no glass point in the range 20–250 °C.

The rate of polymerisation of β-(2-furyl)nitroethylene increases with increase in temperature and initiator and monomer concentrations; the molecular weight of the polymer rises as the temperature and initiator concentration are reduced and the monomer concentration is increased.[181] The study of the kinetics of the polymerisation reaction showed that the activation energy for the process in THF at temperatures in the range −15 to 20 °C is 2.8 kcal mol^{-1}.

It has been established[181-183] that the rate of anionic polymerisation of nitroalkenes increases in the sequence $FurCH=CHNO_2 < PhCH=CHNO_2 < MeCH=CHNO_2$. As the electron-accepting properties of the substituent in the nitroalkene molecule of the type $R-CH=CHNO_2$ are enhanced (Me < Ph < 2-furyl), the electron density at the double bond increases, which induces a decrease in the reactivity of the nitroalkenes in anionic polymerisation reactions.

Copolymerisation of β-(2-furyl)nitroethylene with isoprene resulted in the synthesis of block-copolymers of the B–A–B type.[183-185]

$m = 5-65$, $n = 400-3200$.

Under static conditions, the copolymers can be synthesised only in the presence of cationic initiators, for example dilithiopolyisoprene or dipotassiopolyisoprene. The reaction was carried out in benzene at temperatures in the range 10–70 °C and the block-copolymers were then obtained in 35%–65% yield. The composition of the copolymers included up to 30 mol% of the nitroalkene.

It has been established[185] that the statistical copolymerisation of isoprene with furylnitroethylene can be achieved also in the presence of $SnCl_4$ in solution in chloroform at temperatures in the range −50 to 50 °C.

It has been noted[181] that 1-(2-furyl)-4-nitrobuta-1,3-diene (**7**, $n = 1$) does not exhibit a tendency to undergo anionic polymerisation owing to the influence of steric effects. In the presence of sodium methoxide, 1-(2-furyl)-6-nitrohexa-1,3,5-triene (**7**, $n = 2$) gives rise to a dimer in yields up to 12%.

V. Practical applications of furylnitroalkenes

Unsaturated nitro-compounds of the furan series are used widely in organic synthesis as starting materials and intermediates of the preparation of various functional derivatives of the furan series, which are difficult to obtain by other methods, and also for the synthesis of biologically active substances and natural products.

Furylnitroalkenes are also of significant interest because of their high physiological activity. For example, β-(5-nitro-2-furyl)-nitroethylenes **12**, used in medical practice under the name nitrofurylene, effectively suppresses the growth of pathogenic fungi.[186,187] In this respect, its activity corresponds to the activity of the most active of the known antifungal antibiotics — nystatin, griseofulvin, etc. Clinical experience gained using this preparation indicates the virtual absence of resistance of the microflora to it and its satisfactory transferability.[188]

β-(5-Chloro-2-furyl)-α-R^2-nitroethylenes (**1** and **33**; R^2 = H, Me) exhibit a powerful lachrymatory activity.[28] This ability diminishes for substituents[23] R in the 5-position in the furan ring in the following sequence: Cl > Br > I > Me > H. The introduction of the nitro- or thiocyanate group in the 5-position weakens the irritant activity and enhances the bacteriostatic properties. For example,[47,125] β-(5-thiocyanato-2-furyl)nitroethylene **39** is capable of arresting the growth of the Siberian ulcer bacillus and of the staphylococcus at dilutions of 1 : 10000.

The introduction of the methyl group in the side chain is not reflected significantly in the nature of the physiological activity,[65] while the presence of a chlorine atom at the double bond of the side chain greatly enhances the bactericidal properties and leads to the appearance of new valuable qualities. For example, α-chloro-β-(5-nitro-2-furyl)nitroethylene **35** exhibits the capacity to inhibit the growth of the blue rot bacillus, but it is fairly toxic.[47]

β-[5-(4-R-phenyl)-2-furyl]-α-R^2-nitroethylenes (R = Cl, NO_2; R^2 = H, Me) have been patented as substances with bactericidal activity.[35]

The antibacterial activity of the methyl esters of β-(5-R-2-furyl)-α-nitroacrylic acids **6** has been reported.[53] The authors note that the 5-nitrofuryl derivative exhibits the highest activity among compounds of this type.

Czechoslovak workers[189-199] carried out a systematic study of the pharmacological activity of substituted vinylfurans, including furylnitroethylenes. It was established that furylnitroalkenes possess antimicrobial,[189-191] cytotoxic,[193] chemotherapeutic,[194,195] carcinogenic,[196-198] and in certain cases mutagenic activities. It was shown that the antimicrobial and cytotoxic activities are associated with the reactivity of the furylnitroalkenes in relation to nucleophiles — mainly low-molecular-weight thiols.[196] The mutagenic activity is associated with the presence of the nitro-group in the 5-position in the furan ring.[191,192,196] Together with the reactivity of furylnitroalkenes, their lipophilic-hydrophilic properties are very important physicochemical parameters which determine the intensity of the biological activity.[189] Attempts to establish quantitative structure–activity correlations in the series of furylnitroalkenes have been reported.[190,191,193,197]

It is noteworthy that β-(5-methanesulphonyl-2-furyl)-nitroethylene exhibits a high antimicrobial activity,[33] while β-(5-cyano-2-furyl)nitroethylene and 4-(5-cyano-2-furyl)-1-nitrobuta-1,3-diene possess only a slight activity.[29]

It has been established that furylnitroalkenes inhibit the activity of alcohol dehydrogenase[195,200-202] and xenobiotic receptors[198] and the fermentation of HS-enzymes[196,200] and are also effective antagonists of histamine.[203]

Furylnitroalkenes exhibit an appreciable fungicidal activity.[31,35,47,204,205] Hillers et al.[206] established that the nitrofurylene **12** is an effective fungicidal preparation. After the introduction of nitrofurylene as an additive to cotton, acetate, or polyester fibres, materials with fungicidal properties are obtained.[207] β-(5-Iodo-2-furyl)nitroethylene[208] and β-(5-aryl-2-furyl)nitroethylenes[209] also exhibit an appreciable fungicidal activity.

β-(2-Furyl)-α-methylnitroethylene **33** has been patented as an effective insecticide.[17] Furylnitroalkenes of different structure have been tested also as repellents.[210,211] It was established that they are excellent agents against rodents. According to patent data,[212] β-(2-furyl)-α-R^2-nitroethylenes (R^2 = alkyl, Ph) can be used as effective nematocides.

Copolymers of isoprene with β-(2-furyl)nitroethylene can be used as multifunctional additives to motor oils, thermoplastic elastomers, emulsifiers in hydrophobic emulsions for drilling in petroleum and gas deposits, and also as components of inhibited thin-film coatings.[181,183-185]

IV. Certain physicochemical properties of organospirocyclosiloxanes	200

Abstract. Monomeric and oligomeric spirocyclic compounds of the siloxane series, the methods of their synthesis, some of their physicochemical properties, and the reactions leading to their conversion into polymers of different structure are examined. The bibliography includes 69 references.

I. Introduction

The term spirocyclic is given to compounds whose molecules consist of two or several cyclic fragments linked to one another via a common atom, which enters simultaneously into the compositions of two neighbouring rings.[1]

In spirocyclic compounds of the siloxane series, either a silicon atom or the atom of any other element whose valence is four may be found in the spiro-position. The silicon atoms at the spiro-nodes of organospirocyclosiloxanes are involved in a fairly rigid tetrahedral coordination.[2] According to X-ray diffraction data, the Si–O bonds in the spiran group are somewhat shortened compared with the Si–O bonds in the cyclic fragment of the molecule, which is usually attributed to the more complete involvement of the central silicon atom in $p_\pi - d_\pi$ conjugation with the four oxygen atoms surrounding it.[2] The cyclic fragments in the molecules of organospirocyclosiloxanes can differ also in their strain. The most strained cyclic fragments play the role of chemically active centres responsible for the conversion of the spirocyclic compounds into oligomers and polymers.

By creating spirocyclic molecules of different composition and by altering the size of the cyclic fragments and their strain, it is possible to obtain three-dimensionally cross-linked polymers with a controllable network density and with different properties.

The fundamental principles of the synthesis of such compounds have already been described.[3] Individual communications concerning the distinctive features of polymeric materials based on spirocyclic oligomers and polymers can also be encountered.[4]

The aim of the present review is the examination of the methods of synthesis of spirocyclic monomers and oligomers and the procedures for their conversion into polymers of different structure.

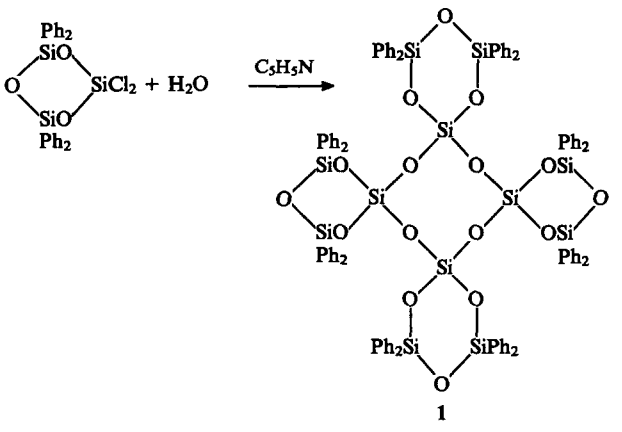
II. Synthesis of organospirocyclosiloxanes

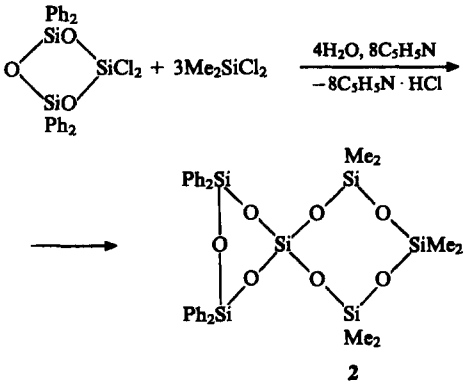
The complexity of the synthesis of organospirocyclosiloxanes consists in the fact that many of them may polymerise during synthesis and isolation owing to the opening of the strained cyclic fragments, forming polymers with three-dimensional structures.



The majority of the traditional methods of synthesis of organosilicon compounds have been tried in order to obtain spirosiloxanes but not all of them proved to be suitable.

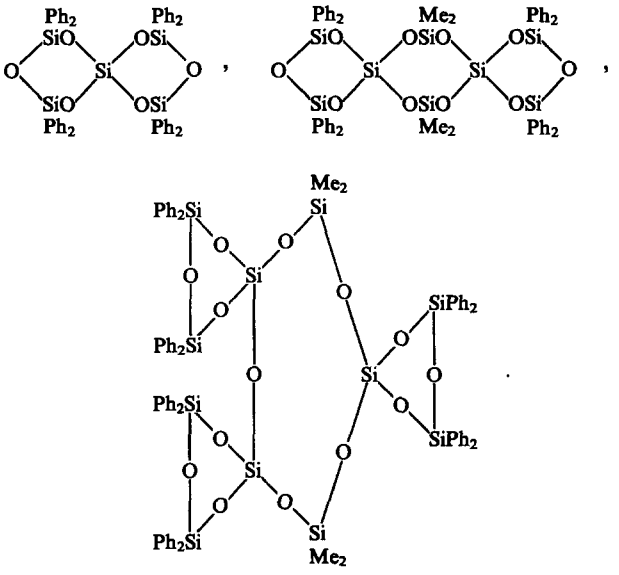
1. Hydrolytic polycondensation

The simplest spirocyclic compounds of the siloxane series (together with other polysiloxanes) were first obtained in very low yields by hydrolytic polycondensation (HPC). Thus octamethylspiro[5.5]pentasiloxane was isolated in 1% yield from a complex mixture produced by the thermal rearrangement of the products of the cohydrolysis of dichlorodimethylsilane and silicon tetrachloride.[5] Subsequently a series of cyclic compounds were isolated in 3%–7% yield from the products of the cohydrolysis of the same monomers and a spirocyclic structure was assigned to them on the basis of elemental analysis and their molecular weights.[6] The authors do not present more rigorous proof of the structures of the compounds synthesised. After the appearance of these studies, the literature contained for a long time no publications devoted to the synthesis of organospiropolysiloxanes by the hydrolytic polycondensation method. This can evidently be explained by the fact that the hydrolytic polycondensation of monomers with different functional groups is very difficult to control. Furthermore, the appreciable difference between the rates of hydrolysis and subsequent condensation of the initial monomers leads in the given instance to a sharp decrease in the yield of the target products and hinders their isolation.[5]



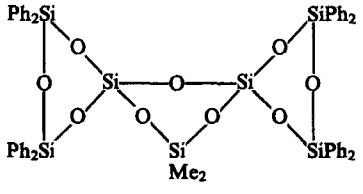
Studies dealing in fair detail with the hydrolytic polycondensation of chlorine-containing organocylcosiloxanes and their copolycondensation with organochlorosilanes have appeared in recent years.[7, 8] It has been established that the products of the hydrolytic polycondensation of these monomers are a mixture of cyclic compounds which cannot always be fully separated.

However, by selecting reaction conditions for each specific case, the authors were able to isolate a series of individual spirocyclic compounds (albeit in low yields) from the complex range of products, whose structure was confirmed by X-ray diffraction and IR and ^{1}H NMR spectroscopy. Thus the spiropentacyclic compound **1** was isolated in a yield reaching 30% from the products of the hydrolytic polycondensation of 2,2-dichlorotetraphenyl-cyclotrisiloxane in ether in the presence of a hydrogen chloride acceptor and a less than stoichiometric amount of water.[8]

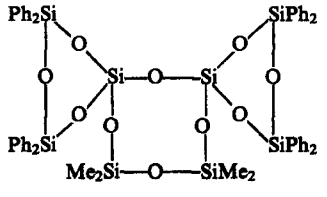


1

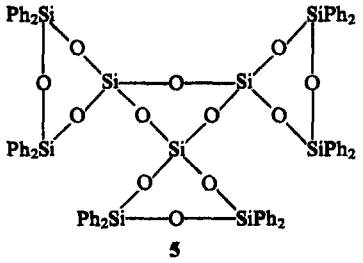
In the hydrolytic cocondensation of 2,2-dichlorotetraphenyl-cyclotrisiloxane with dichlorodimethylsilane, the formation of a mixture of bicyclic, tricyclic, and tetracyclic organospirosiloxanes, containing simultaneously tetraphenylcyclotrisiloxane and dimethyl-siloxane units, is formed only when the cohydrolysis is carried out with an equimolar amount of water in the presence of a hydrogen chloride acceptor.[8] The composition of the mixture formed then depends only slightly on the ratio of the initial reactants. For example, the hydrolytic polycondensation of 2,2-dichlorotetra-phenylcyclotrisiloxane and dichlorodimethylsilane in proportions of 1 : 3 with an equimolar amount of water in the presence of pyridine leads to a mixture of spirocyclic compounds which can be vacuum distilled. The main reaction product[8] is 8,8,10,10,12,12-hexamethyl-2,2,4,4-tetraphenylspiro[5.7]hexasiloxane **2**, which was isolated in 21.4% yield.



2

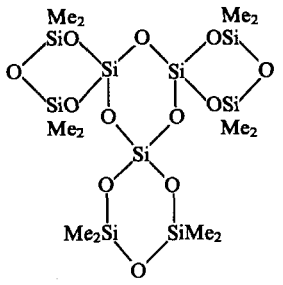


The following compounds are also isolated from the products of this reaction in much lower yield, not exceeding 3%:

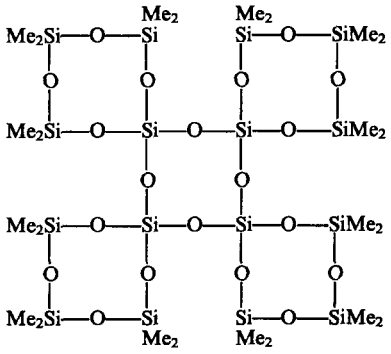


The spirotricyclic and spirotetracyclic compounds **3**–**5** were isolated in 3.5%–9% yield from the mixture of products formed and identified after the cocondensation of 2,2-dichlorotetra-phenylcyclotrisiloxane with dichlorodimethylsiloxane (2 : 1 reactant ratio) and with 1,3-dichlorotetramethyldisiloxane.[8]

3



4

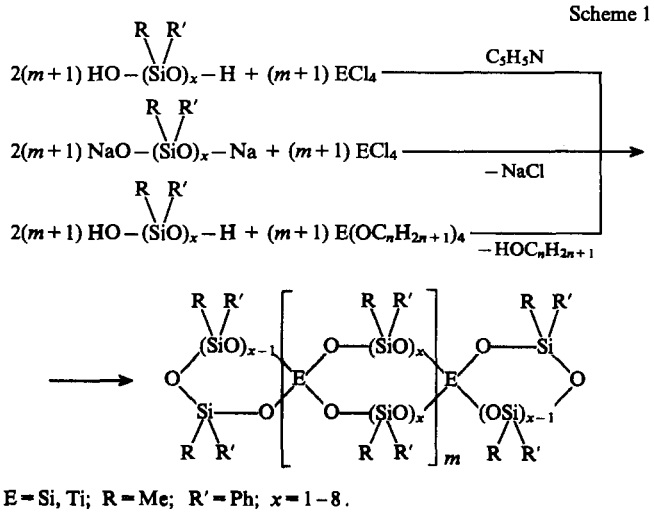


5

The hydrolytic polycondensation of chlorine-containing cyclosiloxanes with methyl groups attached to the silicon atom is no less complex. Thus the hydrolytic polycondensation of 2,2-dichlorotetramethylcyclotrisiloxane with the stoichiometric amount of water in the presence of a hydrogen chloride acceptor leads to a mixture of spirocyclic compounds,[7] from which only one compound, namely the spirotetracyclic compound **6**, was isolated in 22% yield.

6

The spiropentacyclic compound **7**, whose structure was determined by X-ray diffraction, was isolated from the products of the hydrolytic polycondensation of 2,2-dichlorohexamethylcyclotetrasiloxane under conditions similar to those described above.[7, 9]

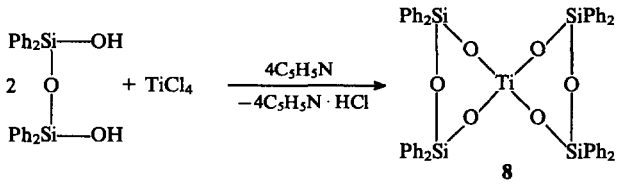


7

Thus the hydrolytic polycondensation of organochlorosiloxanes and organochlorocyclosiloxanes proceeds in a complex manner and leads under the conditions indicated to a mixture of spirocyclic compounds which are difficult to separate and whose yield in each specific case is determined both by the composition and structure of the initial polymers and by the reaction conditions. By virtue of the causes discussed above, it is difficult to obtain by this method organospirocyclosiloxane with a specified disposition and ratio of siloxane units.

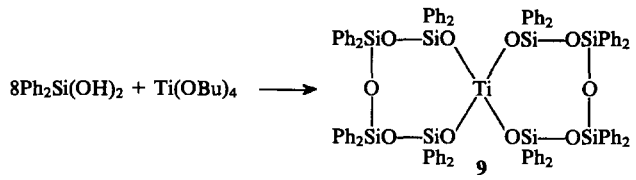
2. Heterofunctional condensation

The method most widely used for the synthesis of organospirocyclosiloxanes is based on the heterofunctional condensation (HFC) reaction of di- and tetra-functional organosilicon compounds. In contrast to hydrolytic polycondensation, this method has been used for the specific synthesis of both the simplest spirobicyclic compounds[10–15] and for the synthesis of polyspirocyclic systems.[7, 16–21] The yield of organospirocyclosiloxanes in these reactions depends on the ratio of the initial reactants, their composition and structure, and the reaction conditions. The heterofunctional condensation of bifunctional organosilanes and linear organosiloxanes with tetrafunctional monomers of the type EX_4 (where E = Si or Ti and X = Cl or OC_nH_{2n+1}) is frequently used for the synthesis of organospirosilosiloxanes.[3, 16–19, 22–24] In this case, the initial reactants are taken in proportions of 2 : 1. α, ω-Dihydroxy- or α, ω-disodio-oxyorganosiloxanes are used as the bifunctional component. In the general case, the reaction can be represented by Scheme 1.



Scheme 1

E = Si, Ti; R = Me; R′ = Ph; $x = 1-8$.

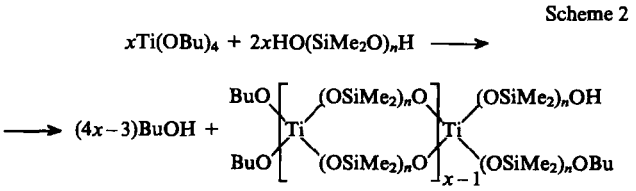


Methylphenylspirocyclosiloxanes, the properties of which have been described,[15, 25, 26] were obtained by means of these reactions. All the compounds synthesised were isolated in 42% to 62% yields and were identified by IR spectroscopy and X-ray diffraction. It is also essential to note that, in the case of the reaction of α, ω-dihydroxyorganosiloxanes with tetrafunctional monomers of the type ECl_4, the reaction proceeds in the direction indicated only in the presence of an acceptor which binds the hydrogen chloride evolved. In the absence of the latter, chlorine-containing cyclosiloxanes, in the molecules of which two chlorine atoms are linked to the silicon atom, are formed preferentially.[14]

Spirobicyclic and polyspirocyclic siloxanes containing titanium as the spiran atom have been obtained by the heterofunctional condensation of linear α, ω-dihydroxyorganosiloxanes with titanium tetrachloride or tetrabutoxytitanium and were identified.[12, 27, 28]

8

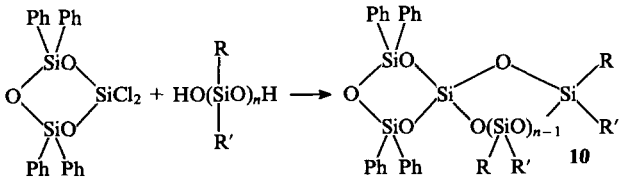
The reactions of α,ω-dihydroxyorganosiloxanes with titanium tetrachloride as well as silicon tetrachloride are carried out in the presence of a hydrogen chloride acceptor in anhydrous organic solvents. Under the conditions indicated,[12] the reaction of 1,3-dihydroxytetraphenyldisiloxane with titanium tetrachloride leads to the formation of octaphenyltetrasiloxyspiro[5.5]titanate **8**, which was isolated from the reaction products in a yield of about 14%. The analogous compound **9** with bulky cyclic fragments have been obtained by the reaction of dihydroxydiphenylsilane with tetrabutoxytitanium.[27]



9

Both compounds were characterised by IR spectroscopy and elemental analysis.

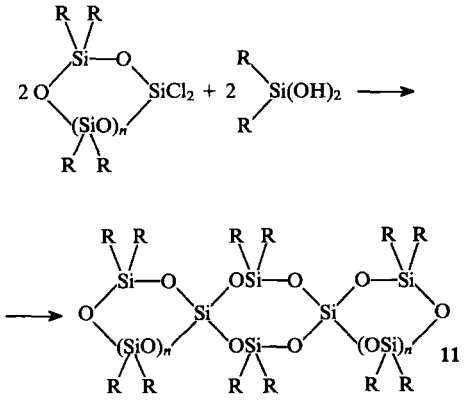
Condensation of tetrabutoxytitanium with α,ω-dihydroxypolydimethylsiloxanes[28] having the general formula $HO(SiMe_2O)_nH$, where n is 2, 3, or 4, takes place in conformity with Scheme 2.



Scheme 2

It has been shown by ^{1}H NMR spectroscopy that the main reaction pathway involves the interaction of the butoxy-groups of tetrabutoxytitanium with the hydroxy-groups of the siloxane. In vacuum at an elevated temperature, the reaction takes place readily with formation of butyl alcohol, the degree of its completion reaching 90%.

One of the versions of the heterofunctional condensation reaction, leading to the formation of organospirocyclosiloxanes, involves the interaction of the bifunctional organosilanes already mentioned and linear organosiloxanes with cyclic di- and tetrafunctional monomers.[7, 10, 11, 29, 30] A series of organodichlorotricyclosiloxanes, organotetrachlorotricyclosiloxanes, and organotetrachlorotetracyclosiloxanes, containing methyl, phenyl, and vinyl substituents at the silicon atom, have now been obtained.[12, 14, 29–31] The study of nucleophilic substitution reactions in organochlorocyclosiloxanes showed that they take place without the cleavage of the siloxane bonds in the rings.[31, 32] This makes it possible to use them as cyclic synthons for the preparation of mixed organospirocyclosiloxanes containing simultaneously different organic substituents in neighbouring rings.[10, 11]



The reactions of organochlorocyclosiloxanes with diorganodihydroxysilanes and α,ω-dihydroxyorganosiloxanes proceed in a complex manner. The yield of organospirocyclosiloxanes depends in this instance to a large extent on the reaction conditions and the organic substituents at the silicon atom. For the equimolar ratio of the initial reactants in the presence of a hydrogen chloride acceptor,[10, 11, 29] the main reaction products are the spirobicyclosiloxanes **10** and spirotricyclosiloxanes **11** having both identical and different sizes of the cyclic fragments in the molecule.[7]

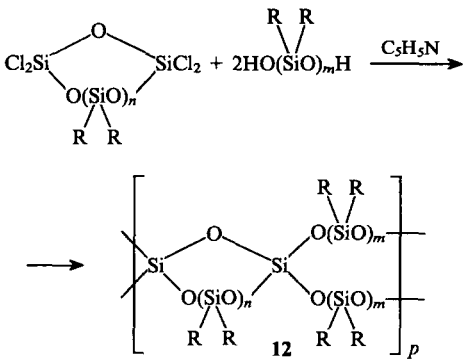
for n = 1:	R = R′ = Me	R = Me	R = Me,
for n = 2:	R = R′ = Me	R′ = Ph	R′ = Bu^i

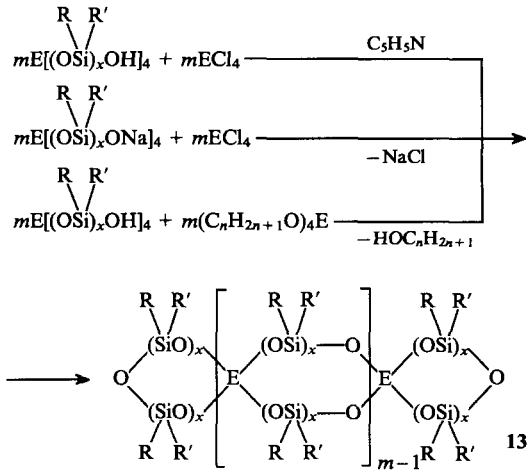
The yield of organospirocyclosiloxanes in these reactions varies from 20% to 48%, the yield of spirobicyclosiloxanes increasing on replacement of the methyl surrounding groups in the diorganodihydroxysiloxane molecule by more bulky substituents, which probably diminish the tendency of diorganodihydroxysiloxanes to enter into homocondensation reactions. The structure of the spirosiloxane thus obtained was confirmed by IR and ^{1}H NMR spectroscopy.



11

R = Me; n = 1, 2.

In contrast to α,ω-dihydroxymethylphenylsiloxanes, the condensation of α,ω-dihydroxyphenylvinylsiloxanes does not lead to the formation of spirocyclic compounds.[12] This is apparently associated with the considerable tendency of compounds in which the silicon atom is surrounded by aliphatic groups to undergo homocondensation.

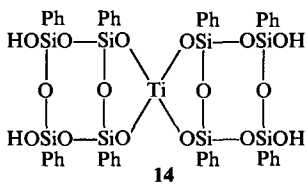


Under conditions analogous to those described above,[30] the oligoorganospirocyclosiloxanes **12** were obtained by the condensation of tetrachlorotetraphenylcyclotetrasiloxane and tetrachlorooctaphenylcyclohexasiloxane with dihydroxydiphenylsilane and 1,3-dihydroxytetraphenyldisiloxane.

12

R = Ph; n = 2, 4; m = 1, 2.

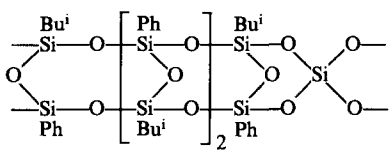
Organospirocyclosiloxanes can also be obtained as a result of the heterofunctional condensation of two tetrafunctional compounds. In this case, a tetrafunctional monomer of the type EX_4 (where E = Si or Ti and X = Cl or OC_nH_{2n+1}) is taken as one of the reactants, while the other is a tetrafunctional compound with a branched or cyclic structure.[3, 16–19, 33–35] Thus the condensation of tetrafunctional compounds having a branched cross-shaped structure with the tetrafunctional monomers indicated above, in proportions of 1 : 1,[3, 16–19] leads to the organospirocylcosiloxanes **13**.



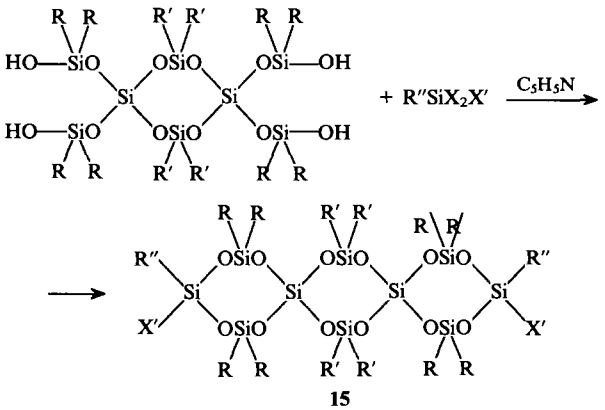
13

E = Si, Ti; R = Me; R′ = Ph; x = 3, 4.

It is noteworthy that the condensation of tetrafunctional monomers with cross-shaped compounds containing a branching titanium atom proceeds readily. The yield of the polycondensation products reaches 63–65% in this case. On passing to compounds with a branching silicon atom, the reaction is retarded and the yield of the reaction product falls to 10%. This mode of reaction is probably due to differences in the steric structure of the above compounds and the influence of the central atom. Nor can one rule out the catalytic action of the titanium atom, which exists in such compounds in a coordinatively unsaturated state.



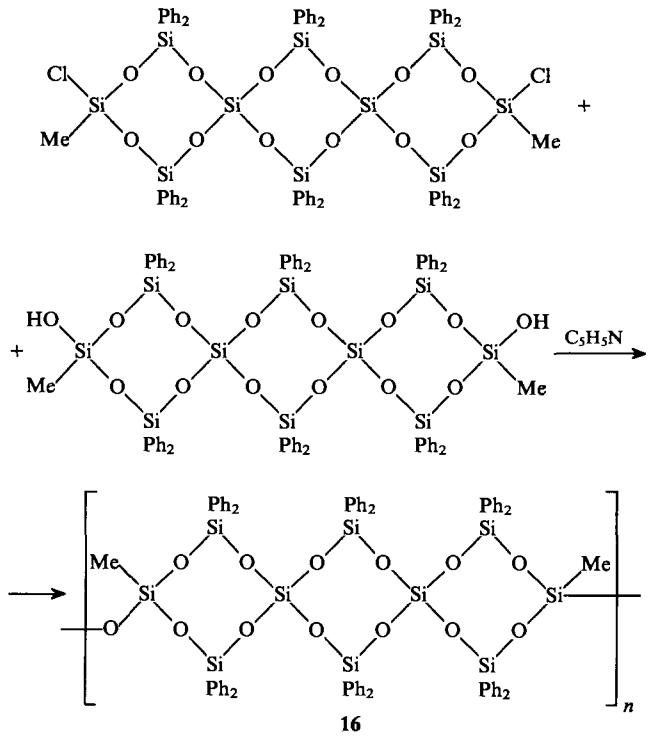
The condensation of tetrafunctional monomers with tetrafunctional cyclic compounds results in the formation of compounds with a spiroladder structure, in contrast to the reaction with tetrafunctional branched organosiloxanes.[33-35] For example, compound **14** was obtained and isolated by the reaction of tetrahydroxytetraphenylcyclotetrasiloxane with tetrabutoxytitanium in proportions of 2 : 1.[34, 35]



14

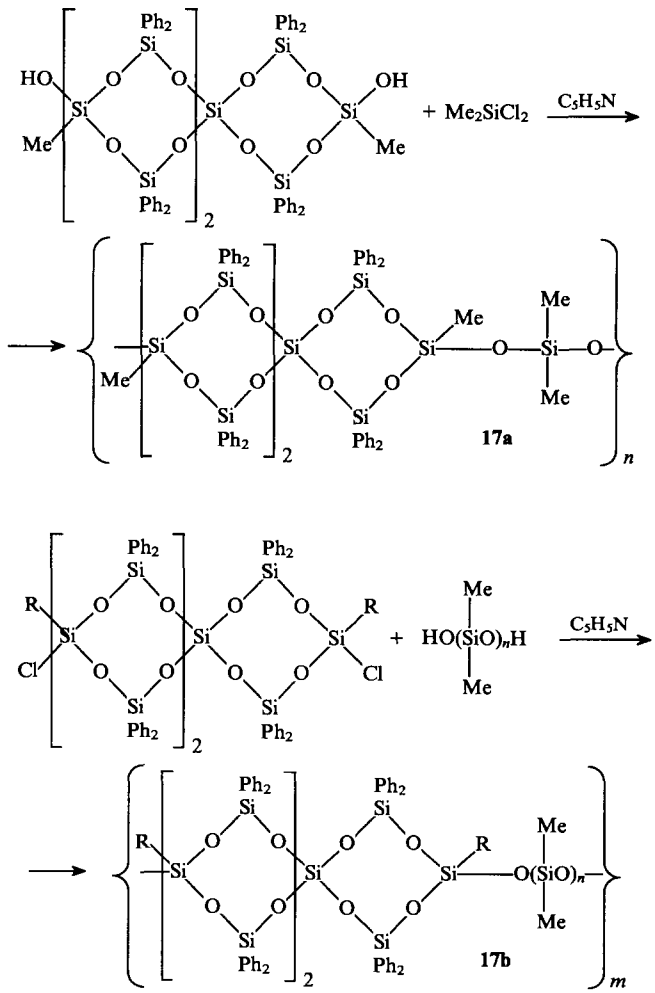
Further condensation of this compound leads to a titanophenylsiloxane oligomer containing spirocyclic fragments.[34]

Polyphenylisobutylsiloxane with a spiroladder molecular structure was obtained by the heterofunctional condensation of tetrafunctional polycyclic compounds with carbon tetrachloride. Its elementary unit has the following structure:[33]



In those cases where the groups surrounding the siloxane chain comprise only phenyl substituents, polymers similar structure are not formed, which is probably due to steric hindrance.[33] Communications describing the synthesis of organospirotricyclic compounds **15** and polymers based on them by the heterofunctional condensation of tetrafunctional branched organocyclosiloxanes and bifunctional organospirocyclosiloxanes with di- and tri-functional organosilicon compounds have been published in recent years.[20, 21, 36-38]

15



R = R′ = Ph; R″ = Me, Ph; X = Cl; X′ = Cl, OEt, CH=CH$_2$;
R = Et; R′ = R″ = Ph; X = Cl; X′ = Ph;
R = Et; R′ = R″ = Ph; X = X′ = Cl;
R = R″ = Me; R′ = Ph; X = X′ = Cl;
R = Me; R′ = R″ = Ph; X = X′ = Cl.

The products of this reaction, carried out in dilute solutions in the presence of pyridine, are bifunctional spirotricyclosiloxanes (yield from 50% to 75%), whose structure has been confirmed by X-ray diffraction and IR and NMR spectroscopy. The bifunctional organospirocyclosiloxanes obtained by this reaction are capable of interacting with various bifunctional organosilicon compounds and with one another, which leads to the formation of spirocyclolinear polyorganosiloxanes **16** and **17**, whose macromolecules contain rigid fragments with a spiran structure joined together either by an oxygen atom[20, 37] or by dimethylsiloxane units.[20, 37]

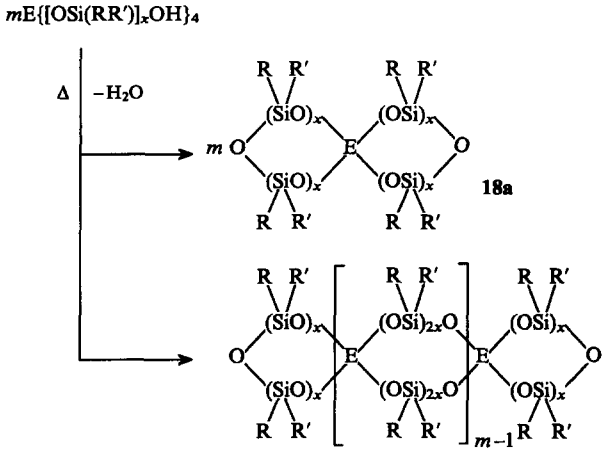
16

As in the previous case, the polycondensation reaction is carried out in organic solvents in the presence of pyridine at 50–150 °C.

R = Me, n = 8;
R = Ph, n = 70, 242;
m = 20–60.

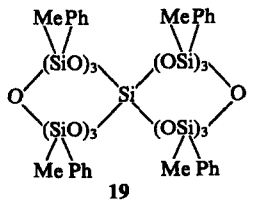
For the equimolar ratio of the initial reactants, the yield of the polymers under the conditions indicated reaches 86–92%.

In conclusion, one should note the extensive synthetic possibilities of the heterofunctional condensation method. Spirocyclic compounds with various organic groups surrounding the silicon atom and with different bulk of the cyclic fragments can be obtained by this method in fairly high yields. Both monomeric and oligomeric and polymeric forms of organospirocyclosiloxanes have been obtained by this method and identified.

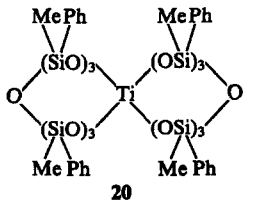


3. Polycondensation of tetrafunctional compounds

The polycondensation of tetrafunctional compounds has been investigated at the present time only for oligomers. The synthesis of organospirocyclosiloxanes by the polycondensation of tetrafunctional cross-shaped oligomers having the general formula



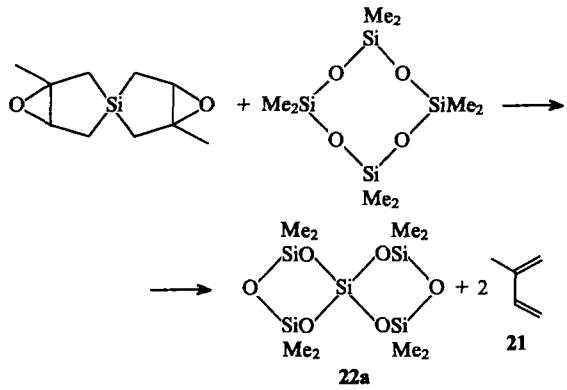
$$E\{[OSi(RR')]_xOH\}_4,$$

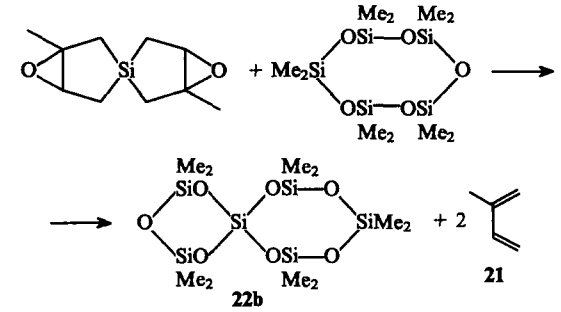


where E = Si, Ti; R = CH_3; R' = C_6H_5, $x = 2-4$, has been described.[3, 15, 16–19]

The block polycondensation of such compounds[15, 39, 40] at 150 °C takes place both intermolecularly and intramolecularly and leads in both cases to the spirocyclic compounds **18**.

The overall yield of the polycondensation products then reaches 70–75%.[15, 40] The spirocyclic structure of the products obtained by this method was demonstrated by isolating the individual compounds and by identifying them by IR spectroscopy and X-ray diffraction. For example, the spirocyclic compounds **19** and **20** were isolated (and identified[15]) in 15 and 10% yields respectively from the products of the polycondensation of tetrakis(3,5,7-trimethyl-3,5,7-triphenylsiloxano-7-hydroxy)silane and tetrakis(3,5,7-trimethyl-3,5,7-triphenylsiloxano-7-hydroxy)-titanium.





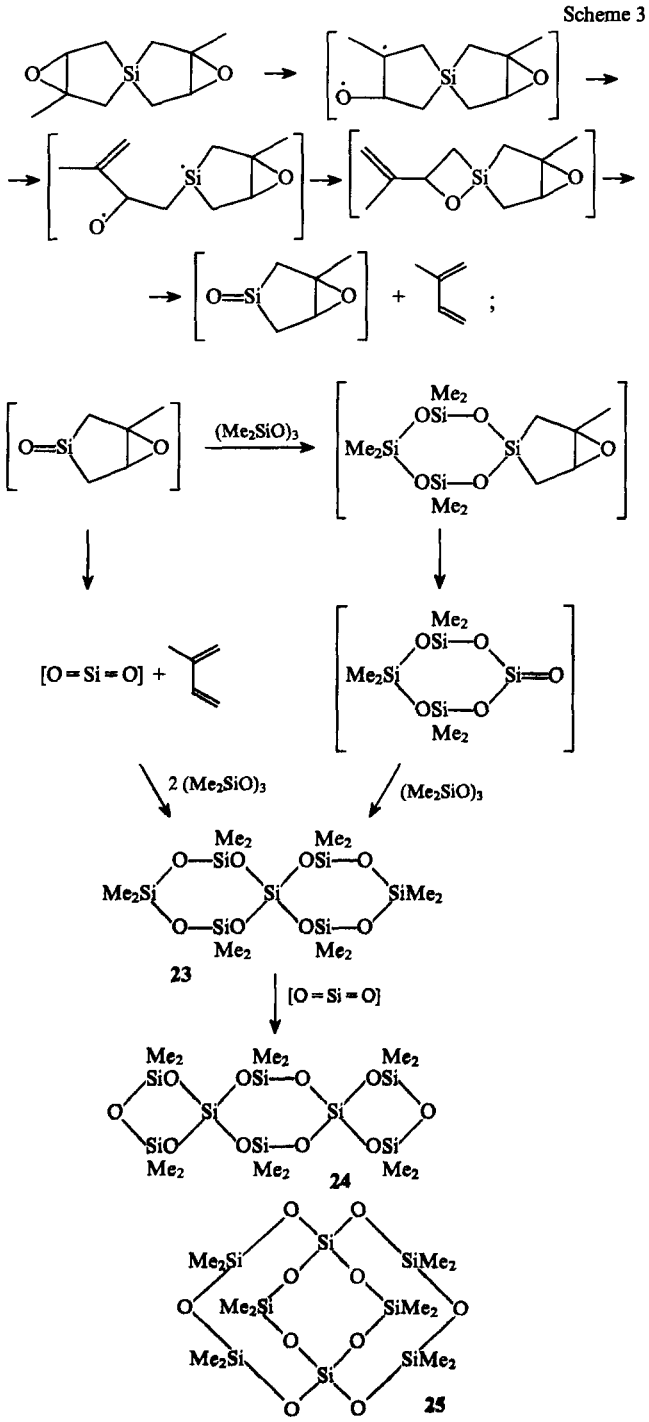
It is also noteworthy that the formation of spirocyclic compounds is observed only in the condensation of oligomers with low values of x.

The above method of synthesis of organospirocyclosiloxanes was not developed further because of its laborious nature.

4. Instantaneous vacuum pyrolysis

Communications describing the synthesis of organospirocyclosiloxanes by the "instantaneous" vacuum pyrolysis of dialkyldiepoxysilaspiroalkanes with organocyclosiloxanes have appeared in the literature in recent years.[41–43] The reaction proceeds in a complex manner via a series of intermediate stages accompanied by the formation of the monomeric silicon dioxide O=Si=O and the so called silanones—reactive intermediates containing silicon–oxygen bonds (silanone intermediates). The final reaction products are[41] isoprene **21** and the corresponding spirosiloxane **22**.

The copyrolysis of 2,3 : 7,8-diepoxy-2,7-dimethyl-5-silaspiro-[4.4]nonane with hexamethylcyclotrisiloxane has been studied in greatest detail. According to the authors,[42] it proceeds stepwise in accordance with Scheme 3.

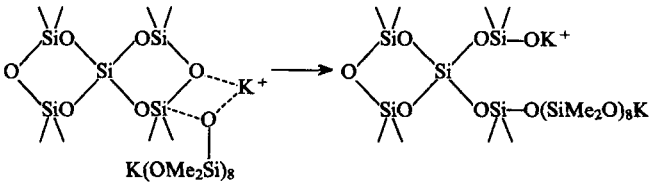


It has been suggested that the reaction begins with the dissociation of the C–O single bond of the bicycle epoxide and with formation of a biradical. The subsequent reactions with its participation lead to silanone intermediates, which are inserted in the Si–O single bonds of the cylcosiloxane and this entails a rearrangement of the siloxane skeleton and ultimately leads to the formation of the corresponding spirosiloxane and isoprene. However, the authors claim[42] that the reaction does not stop at this point and that, together with isoprene and the corresponding spirobicyclosiloxane **23**, a compound with a higher molecular weight is formed. According to X-ray diffraction data, this compound is the spirotricyclosiloxane **24**, which is a product of the interaction of the spirobicyclosiloxane with a second molecule of [O=Si=O]. The interaction of the spirobicyclosiloxane **23** with [O=Si=O] can also lead to the spirotricyclosiloxane **25** according to the results of another study.[43]

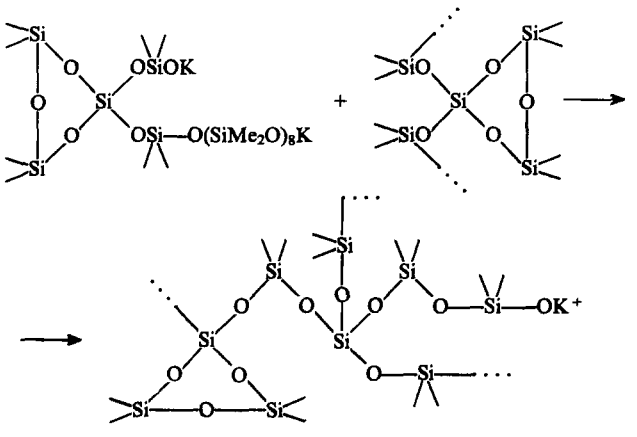
The pyrolysis of the above compounds is carried out *in vacuo* at 520 °C. Despite the short residence time of the reactants in the reaction zone, the spirosiloxanes formed under these conditions can probably undergo further reactions. This can be inferred from the low yield of the target products. Thus in most cases of the copyrolysis of 2,3 : 7,8-diepoxy-2,7-dimethyl-5-silaspiro[4.4]-nonane with substituted cyclotrisiloxanes and cyclotetrasiloxanes

(hexaethylcyclotrisiloxane, trimethyltrivinylcyclotrisiloxane, heptamethylcyclotetrasiloxane, heptamethylvinylcyclotetrasiloxane, heptamethylphenylcyclotetrasiloxane, and chloromethylheptamethylcyclotetrasiloxane) the yield of the organospirocyclosiloxanes does not exceed 9%–12%.[41, 42] The structures of all the compounds obtained by this method were confirmed by X-ray diffraction and by ^{29}Si NMR spectroscopy.

Thus, despite the fact that the mechanism of the copyrolysis of dialkyldiepoxysilaspiroalkanes with organocyclosiloxanes has not been elucidated completely and the yield of the target products is low, the method considered is in our view preparative in relation to the synthesis of organospirocyclosiloxanes, is fairly novel, and requires further development.

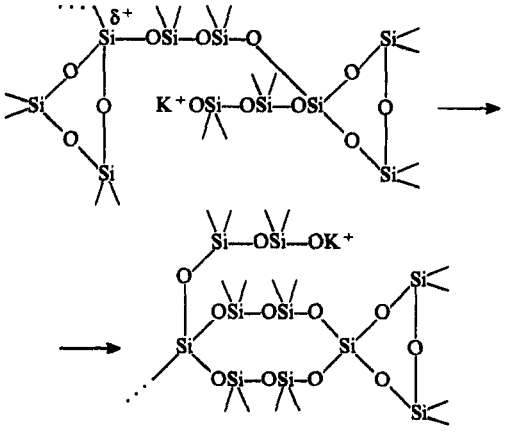


Scheme 3



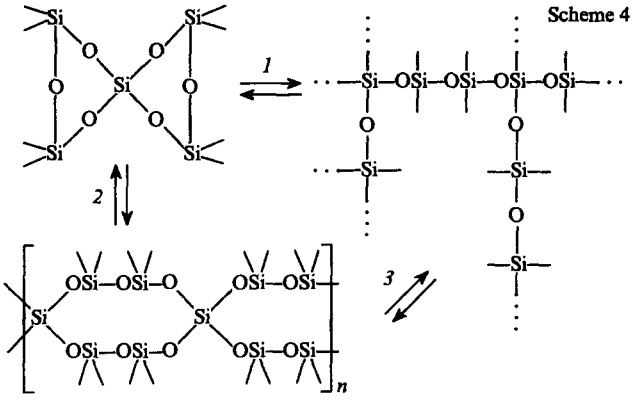
III. Conversion reactions of organospirocyclosiloxanes

The principal reactions involving the conversion of organospirocyclosiloxanes into polymers of different structure are their polymerisation and copolymerisation with organocyclosiloxanes. According to modern ideas, organospirocyclosiloxanes exhibit a functionality of two and four in polymerisation reactions and can form both linear polycyclic polymers and polymers with a three-dimensional structure.[11, 44–49] The catalytic polymerisation of organospirocyclosiloxanes has been little investigated and, in contrast to the polymerisation of organocyclosiloxanes, has a more complex mechanism. In the polymerisation of a spirocyclic compound, the growing polymer chain can enter into two competing reactions. There is then a possibility of either the addition to it of another monomer unit, leading to branching, or the formation of a ring.[11, 45]

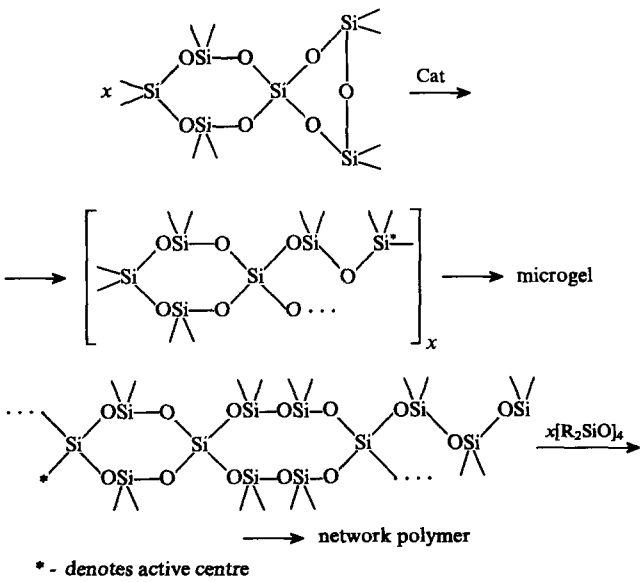


Initiation:

Interchain interaction:

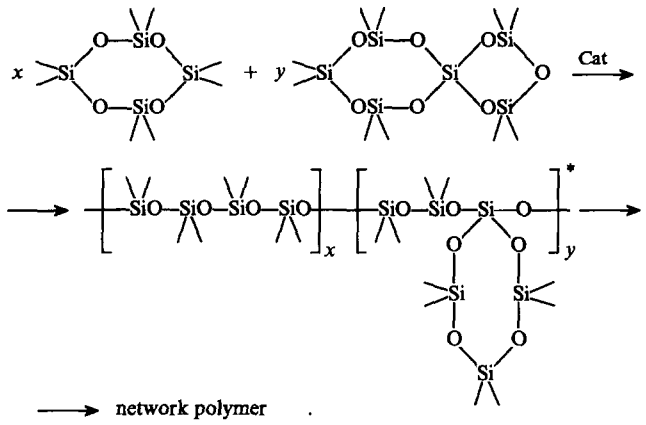


Intrachain cyclisation:



In a general form, the polymerisation of organospirocyclosiloxanes can be represented by Scheme 4, from which it is seen that the polymerisation of organospirocyclosiloxanes develops in the given instance in two directions (reactions *1* and *2* in

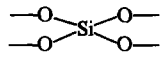
Scheme 4). The existence of equilibrium between the soluble and three-dimensionally cross-linked polymers (reaction *3*) has also been established.



The preferential occurrence of the process via a particular pathway depends mainly on the composition and structure of the initial monomers and also on the reaction conditions. For example, in the case of the anionic polymerisation of spirobicyclic compounds containing only methyl groups at the silicon atom, polymers with a three-dimensional structure are formed.[11, 13] The replacement of some of the methyl groups by phenyl groups leads to a decrease in the equilibrium yield of the gel fraction and, after the complete replacement of methyl groups by phenyl groups or tolyl groups, fully soluble polymers are formed.[14, 44, 46] Consequently pathway *1* predominates for spirosiloxanes with methyl substituents, while pathway *2* is the main one for spirocyclosiloxanes surrounded by phenyl groups. Both pathways operate for spirosiloxanes containing simultaneously both methyl and phenyl groups. It has also been established that there is a definite gel-formation temperature for the process under consideration, above which the formation of a three-dimensional polymer is thermodynamically impossible.[11, 45]

The joint catalytic polymerisation of organospirocyclosiloxanes with organocyclosiloxanes takes place in an even more complex manner and also leads to polymers with a three-dimensional structure.[13, 50–53] In this case, the linear sections of the polymer macromolecules are formed as a result of the polymerisation of the organocyclosiloxane, while the organospirosiloxane, plays the role of a branching agent.[50] A network polymer is formed in this case either as a result of the

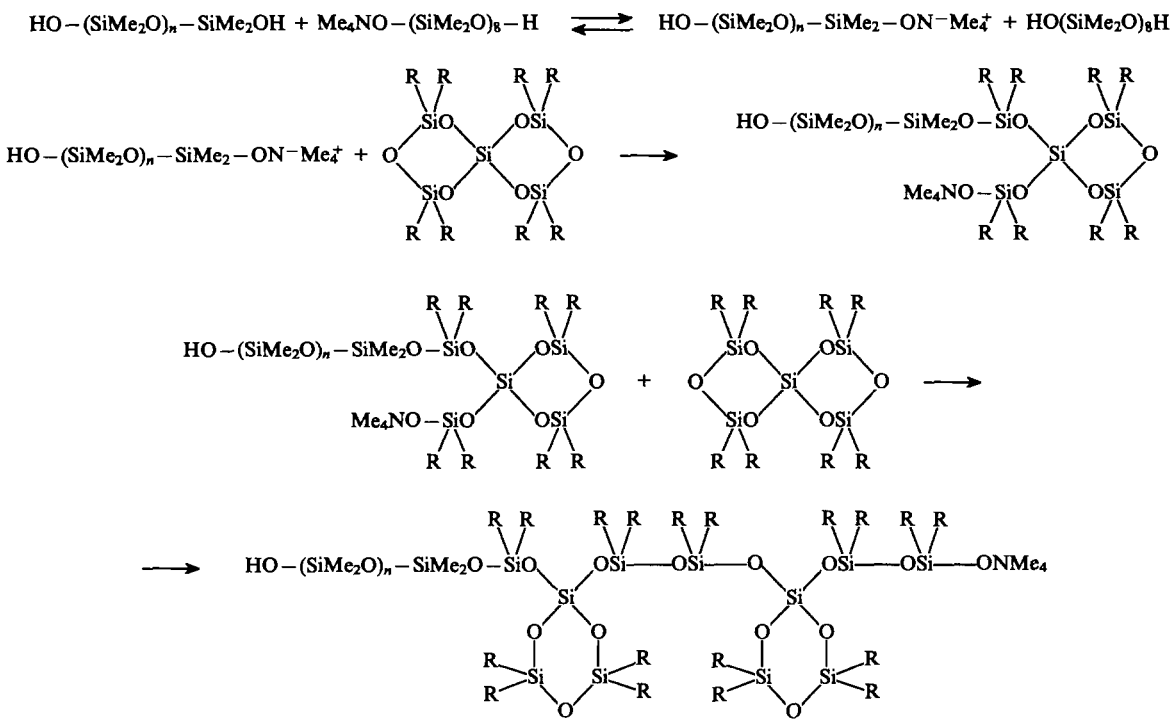
homopolymerisation of the spirosiloxane and the formation of microgel particles with subsequent polymerisation of the organocyclosiloxane on the resulting active centres[50] or as a result of the formation in the first stage of the process of a linear polymer containing cyclic fragments, which subsequently passes to an insoluble state as a result of the opening of these fragments by catalytically active centres.[50, 52] The predominance of a particular process is determined by the reactant ratio:



An example of a process leading to three-dimensional polymers may also be provided by the copolymerisation reactions of organospirocyclosiloxanes with linear dihydroxypolydimethylsiloxanes.[54] As in the previous cases, the spirosiloxane plays the role of a branching agent and the polymer chains are cross-linked as a result of the opening of the siloxane rings by the silanolate anions located at the ends of the polymer chains or arising as a result of the exchange between the proton of a hydroxy-group of the dihydroxypolydimethylsiloxane and the cation of the silanolate group of the initiator (Scheme 5).[55]

The subsequent attack by the cyclic fragments of the polymer chain leads to cross-linking. It has been shown that the introduction of α,ω-dihydroxypolydimethylsiloxanes (n = 24–270) into the polymerisation-exchange process makes it possible to obtain three-dimensionally cross-linked polymers with a regular distribution of branching nodes in the network.[56]

IV. Certain physicochemical properties of organospirocyclosiloxanes



A specific feature of organospirocyclosiloxanes, which distinguishes them from simple organocyclosiloxanes, is the presence of the group

which can be detected with the greatest reliability by means of NMR spectroscopic data. The study of the ^{29}Si NMR spectra of a series of organospirocyclosiloxanes with different surrounding organic groups and different ring sizes showed that signals in the range 6–30 ppm, referring to the silicon atoms of the siloxane rings, and signals in the range 95–105 ppm, corresponding to the silicon atom in the spiro-position, are characteristic of these compounds.[21, 41, 42]

The ring conformations and the geometrical features of the spiro-nodes of organospirocyclosiloxanes[2, 9, 42, 57–62] and organospirocyclosilazoxanes[63, 64] have been determined by X-ray diffraction. It has been shown that the silicon atoms at the spiro-nodes have a fairly rigid tetrahedral coordination; this structural feature is retained also on substitution of the oxygen atoms in the spiro-environment by nitrogen atoms.[64] As already mentioned above, the Si–O bonds at the spiro-nodes of siloxanes are usually somewhat shortened compared with the Si–O bonds of the cyclic

Scheme 5

fragments. On substitution of some of the oxygen atoms in the spiro-environment by nitrogen atoms in the molecules of organospirocyclosilaxanes, the shortening of the Si–O bond lengths becomes extremely insignificant or is altogether absent, which has been attributed to the lower electronegativity of nitrogen compared with oxygen.[62–64]

The trisiloxane rings forming part of spirocyclosiloxanes have an almost planar structure close to that of the molecules of organocyclotrisiloxanes.[58] Analysis of the conformations of the tetrasiloxane rings in the molecules of spirotricyclosiloxanes and spiropentacyclosiloxanes showed that the central rings in these compounds are appreciably flattened compared with the spiro-linked rings surrounding them, which in the authors view[9, 61] is due to steric factors.

The manifestation of the skeletal vibrations of the Si–O bonds of organospirocyclosiloxanes in the IR spectra is also of interest. As a result of the differences between the Si–O bonds of the spiro-node and the siloxane side fragments noted above, one may expect that the characteristic features of the structure of organospirocyclosiloxanes will be manifested in the IR spectra of these compounds.

The most intense absorption in the IR spectra of organo-spirocyclosiloxanes is observed in the range 1020–1100 cm^{-1}. It is characteristic of antisymmetrical stretching vibrations of the Si–O–Si bridge bonds. It has been shown in a number of studies that the Si–O bond vibrations in spirosiloxanes are manifested by a characteristic split ν_{as}(SiOSi) band with two maxima.[3, 8, 10, 15, 29, 31] The positions of these maxima depend on the number of silicon atoms in the ring. On passing from spirocyclic compounds with a smaller number of silicon atoms in the cyclic fragment to compounds with a larger number of such atoms, the ν_{as}(SiOSi) band undergoes a hypsochromic shift. At the same time, the symmetrical stretching vibration frequency ν_s(SiOSi) in the spectra of organospirocyclosiloxanes increases compared with the corresponding vibration in simple organocyclosiloxanes.[3, 15] The observed features of the IR spectra of the spirocyclic compounds of the siloxane series have been attributed[3, 15] to the presence of a branching centre and have been assigned to the vibrations of the Si–O–Si groups adjoining the central spiro-atom and constituting together with the latter a single structural nucleus. However, hitherto there is no unanimous view in the interpretation of the characteristics of the IR spectra of the above compounds. A number of investigators believe that a similar splitting of the ν_{as}(SiOSi) band is characteristic also of the spectra of linear and cyclic compounds containing more than four siloxane units.[2, 65–67]

In the case of spirocyclic compounds containing titanium as the spiro-atom,[3, 12, 15, 27, 28, 68, 69] the IR spectra show, apart from the splitting of the ν_{as}(SiOSi) band into two maxima mentioned above, an intense absorption in the range 910–930 cm^{-1} due to the vibrations of the TiOSi fragment.

In comparing the methods of synthesis of organospiro-cyclosiloxanes examined in this review, one should note that the heterofunctional condensation method is at present the most thoroughly developed and preparatively and technologically most convenient, ensuring a fairly high yield of the target products. Spirocyclic oligomers, on the basis of which a series of composite materials with unique properties have been developed, have now been obtained by this method. These materials are used successfully in various branches of modern engineering.

Abstract. The characteristic features of the kinetics and dynamics of processes occurring on laser heating of chemically reactive media are analysed. Attention is concentrated on effects due to the macroscopic disequilibrium and the feedbacks between various degrees of freedom of thermochemical systems. Processes stimulated by laser radiation in homogeneous media, the phenomena occurring on laser heating of metals, and the physicochemical processes occurring on laser heating of liquids are considered. Examples of certain technological applications of laser thermochemistry are presented: laser-induced precipitation of a substance from the gas phase, etching and modification of surfaces, synthesis of compounds, etc. The bibliography includes 123 references.

I. Introduction

Among the effects associated with the chemical reactions of substances in the field of a powerful light wave, the photochemical and thermochemical effects differ significantly. Until the end of the 1970s, mainly photochemical processes were investigated. However, during the last decade, there has been a sharp growth of interest in thermochemical processes. This is associated with their wide occurrence and the prospects for their employment to create new progressive technologies in many branches of industry, and effective research methods in the field of nonlinear dynamics.

The characteristic features of the kinetics of thermochemical processes occurring on laser heating of chemically reactive media are associated principally with two factors: with the disequilibrium due to the nonstationary and/or inhomogeneous occurrence of reactions and with the mutual influence (feedback) between the chemical state of the medium and energy and mass transfer processes in the field of the laser radiation. Therefore the main problems in modern laser thermochemistry are as follows: analysis of the mechanisms of the generation of feedbacks between the chemical, thermal, and other degrees of freedom† of the system in various problems; the discovery of the most typical nonlinear features and analysis of the influence of various feedback channels on the kinetics and dynamics of thermochemical processes; the study of self-organisation phenomena induced by the laser radiation during the heating of the test substances; the search for the possible ways of achieving an effective control of thermochemical processes with the aid of lasers.

The complexity of such studies is due to the great variety of specific conditions under which nonlinear thermochemical processes take place, the wide range of variation in the rates of chemical reactions, the different phase states of the reactants (solids, liquids, and gases), and the multiplicity of procedures for the laser heating of chemically reactive media.

In the present review, we have tried to describe the ideas and theoretical and experimental results constituting the basis of modern research into the nonlinear dynamics of laser-induced thermochemical processes. If one compares them with studies carried out within the framework of the macroscopic kinetics and physics of combustion, where the role of disequilibrium and of the feedbacks between different degrees of freedom of the system is also significant, then two factors should be noted. First, the thermochemical processes occurring under the influence of laser radiation are frequently characterised by a high level of disequilibrium. For example, in the laser-induced chemical precipitation of a substance from the gas phase, the temperature may vary at rates up to 10^{10} K s^{-1} and there is a possibility of temperature gradients up to 10^{7} K cm^{-1}. The latter factor leads, in particular, to an intense interaction of the thermal, concentration, charge, and other fluxes and can ultimately alter radically the kinetics of the respective processes. Second, laser radiation is itself capable of generating new feedback channels in

† The degree of freedom is a concept which arose from classical mechanics. In nonlinear dynamics, this concept is used to designate some kind of dynamic characteristic describing the state of the system, for example temperature, concentration of the reactants, etc. The term 'degree of freedom' is frequently used in relation to each differential first-order equation describing the variation of physically different characteristics (thermal degree of freedom, chemical degree of freedom, etc.). The reader may become acquainted with the principal concepts of nonlinear dynamics in the book by M I Rabinovich and D I Trubetskov, *Vvedenie v Teoriyu Kolebanii i Voln* (Introduction to the Theory of Vibrations and Waves) (Moscow: Nauka, 1984).

the system and of altering the dynamic properties of the medium. These factors do in fact indicate the specific features of the laser heating of chemically reactive media compared with heating by nonlaser sources.

II. History of the problem

Quantitative methods for the description of the dynamics of chemical systems arose long after the formulation of the fundamental theoretical ideas in mechanics, optics, theory of electricity, hydrodynamics, and classical electrodynamics. The first fundamental equations of the law of mass action were proposed by Guldberg and Waage, while the mathematical laws of chemical reactions were first formulated and elucidated by van't Hoff.‡ Arrhenius explained the mechanism of the temperature variation of the reaction rate constants and formulated the second fundamental law of chemical kinetics (the Arrhenius equation).

The fundamentally nonlinear nature of these laws makes it possible to understand the theoretical difficulties and problems in the analysis of the dynamics of chemical systems which arose in the initial stage of the development of chemical kinetics. These difficulties were overcome only as a result of the development and application to chemical systems of the ideas and methods of the theory of nonlinear oscillations. (The role which chemical systems have played in the formulation of nonlinear concepts and images such as autowave, reverberator, dissipative structure, etc. is in its turn also well known.)

During the period from 1928 to 1940, Semenov, Zel'dovich, Frank-Kamenetskii, Kharitonov, Todes, and others carried out fundamental studies in the field of the chemical kinetics and physics of combustion, where the dynamics of chemical systems with feedbacks between chemical, thermal, and other degrees of freedom came to the fore. These investigations served as the basis of a new scientific discipline — macroscopic kinetics, within the framework of which the most important basic models, specifying the mechanisms and dynamic manifestations of the action of feedbacks in thermochemical systems, were created and developed.[1,2] Studies on oscillatory chemical reactions have played an important role in the development of macrokinetics.[3-6]

Studies on chemical thermodynamics, devoted to the investigation of the states of equilibrium in chemical systems, served as an ideologically important addition to the research into chemical kinetics. This branch of research, associated with the names of Gibbs, Helmholtz, van't Hoff, van der Waals, Nernst, and others, underwent a qualitatively new development when the ideas of chemical thermodynamics began to be applied to the analysis of nonequilibrium systems. As a result of studies by Onsager, the linear nonequilibrium thermodynamics was created, while studies by Prigogine led to the formulation of nonlinear nonequilibrium thermodynamics and completed the process of merging chemical kinetics and chemical thermodynamics into a single integral science.

Laser thermochemistry constitutes in essence a development and a generalisation of the ideas of macroscopic kinetics and nonequilibrium thermodynamics in relation to a substance placed in the field of laser radiation.

Immediately after the creation of lasers, it was by no means a simple matter to decide whether this introduced anything new into chemistry. Lasers were used initially in photochemistry as sources with a high spectral brightness. The most important discoveries were made when quantum electronics 'assimilated' the IR range. These discoveries are well known (see, for example, Refs 7-12). They include the multiphoton IR photodissociation of molecules, selective as regards substances, which permits laser separation of isotopes, the elimination of small amounts of impurities from gases, etc., as well as effects associated with the generation of a disequilibrium at the level corresponding to the separation between the vibrational and translational temperatures, which permit the laser control of radical synthesis (in particular permit the synthesis of thermally less stable compounds on IR photolysis of more stable compounds — for example the synthesis of CF_3I by the photolysis of CF_3Br in an iodine atmosphere[13]).

Studies in the field of reactions initiated by laser heating developed more slowly. According to Tal'roze's estimates,[14] 170 studies devoted to the thermochemical effect of laser radiation were published in 1977. Among them, it is possible to distinguish three groups of investigations the results of which were of value for subsequent research into the nonlinear dynamics of thermochemical processes.

1. Experimental and theoretical studies devoted to the development of thermochemical instability in reactions involving the heterogeneous oxidation of metals in air under the influence of laser radiation.[15-17]

2. Studies on the thermal bistability and dissipative structures on heating gaseous media by optical radiation.[11,18,19] In a number of investigations,[15-19] attention was first drawn to the fact that a new feedback channel between the chemical and thermal degrees of freedom of the system is created in the field of laser radiation. This feedback is achieved via a change in the absorption characteristics of the system during chemical reaction. In particular, when radiation is absorbed preferentially by the chemical reaction product, a positive feedback is generated in the system, leading to thermochemical instability, bistability, etc.

3. Studies undertaken to determine the conditions governing the separation between the vibrational and translational temperature on laser stimulation of homogeneous reactions (see, for example, Refs 7, 9-14, 20-22). These investigations showed that, at pressures of the gas mixture above 1 torr under typical experimental conditions with continuous-wave CO_2 lasers, the thermal mechanism of chemical reactions predominates in the majority of substances. For this reason, all the remarkable properties of IR-photochemical processes, attention to the possible manifestation of which was drawn already in the studies by Askar'yan (1964) and other workers (for the history of this problem, see Dunskaya[23]), therefore occur as a rule only at fairly low gas pressures. On the other hand, in experiments (see, for example, Oraevskii[9] and Molin et al.[11]) at high pressures of the gas mixture, a marked difference is observed between the products of laser and nonlaser pyrolysis. A marked dependence of the yield of the reaction on the wavelength of the laser radiation, threshold phenomena, etc. were observed. The experimental results clearly indicated a specific disequilibrium of the chemical process during the IR-laser heating of the gases, but the fundamental details of the generation of such disequilibrium remained obscure. The observed discrepancy between the seemingly photochemical behaviour of a number of reactions and the explicit thermal regime governing the injection of the energy of the laser radiation aroused a lively controversy between supporters of particular mechanisms for these reactions. It was of interest to note that at approximately this time a controversy of a similar nature arose concerning the thermal and nonthermal nature of the laser-induced annealing of semiconductors.[24,25]

Thus towards the end of the 1970s, the situation was objectively prepared for the vigorous development of research into the dynamics of the laser heating of chemically reactive media, analysis of the dynamics of heating in the IR spectral range being particularly timely.

‡ Van't Hoff's book *An Outline of Chemical Dynamics* was published in 1884. It laid the foundations for the development of chemical kinetics and, in Semenov's words, outlined the path for its development during the next half century.

III. Thermochemical processes stimulated by laser radiation in homogeneous media

1. The macroscopic disequilibrium and feedbacks

The interaction of light with matter is a complex nonlinear process, which can be arbitrarily divided into several stages: the absorption of light by matter; energy and matter transfer (processes involving heat and mass exchange with the surrounding medium, redistribution of energy among the internal degrees of freedom); the chemical reaction proper. Definite degrees of freedom, the evolution of which actually determines the behaviour of the system, correspond to these stages. The nature of such evolution can change significantly as a result of the interaction (feedbacks) between various degrees of freedom.

Certain types of feedbacks generated in the presence or absence of radiation may be indicated.

1. Purely thermal feedbacks, arising as a consequence of changes in temperature caused by the evolution or absorption of heat in the course of various physicochemical processes. This alters the rates of chemical reactions and transfer processes. Such feedbacks play a key role in problems of the physics of combustion,[1,2] the stability of ideal mixing flow reactors,[5] etc.

2. Selective feedbacks due to local changes in the absorptance of the medium during the process (owing to changes in its chemical composition, density, etc.). As a result of these feedbacks, the local amounts of radiant energy introduced into the test substance are altered.

3. The feedbacks due to various nonlinear optical effects leading to a change in the spatial distribution of the radiation density.

4. Kinetic feedbacks. For example, in the case of multi-pathway chemical reactions, the rate of reaction via one pathway depends on the rates of reaction via the other pathways as a consequence of the change in the chemical composition of the medium. Such feedbacks are responsible for the development of auto-oscillations in Belousov–Zhabotinskii reactions.

In connection with the foregoing, the question arises of the construction and study of the basic mathematical models taking into account the most significant mechanisms affecting the process dynamics. Such study constitutes the basis for the subsequent construction of a theory permitting a quantitative comparison with the experiment. The mathematical procedures necessary for this are provided by the theory of nonlinear oscillations and the theory of stability, bifurcations, and catastrophes.

In the analysis of the chemical action of laser radiation towards the end of the 1970s, use was frequently made of the idea that, if an amount of energy E is introduced into the medium with the aid of laser radiation in the absence of heat and mass transfer, then the chemical result of such thermal action of the radiation should not depend on the particular substance (starting material, reaction product, or buffer component) which absorbs this energy. On the other hand, the dependence of the chemical result not only on the amount of absorbed energy but also on the wavelength of the laser radiation was regarded as indirect proof of a nonequilibrium distribution of the molecules among the vibrational–rotational energy levels. However, it was shown later that, generally speaking, this hypothesis is incorrect. This can be understood from the following considerations.

Evidently the radiant energy absorbed by the reactant determines the change in the temperature of the medium. On the other hand, the chemical result depends on the ratio of the rate of change of temperature $(dT/dt)/T$ and the rate of relaxation of the chemical composition $(dN/dt)/N$. If $(dN/dt)/N \gg (dT/dt)/T$, then the chemical composition is close to equilibrium for the given temperature. In this case, the concentration of the reacted substance (N) depends on the temperature and is determined by the constant for the chemical equilibrium in the reactor, i.e. for a slow change in temperature, the corresponding process is close to equilibrium. For the reverse ratio of the chemical and thermal rates, the process is of a nonequilibrium type. A well-known example, illustrating this fact, is provided by the quenching of the chemical composition on rapid cooling of the reactor. In the general case, the chemical result is a functional of temperature and depends on the way in which this temperature has been reached.

We shall now take into account the change in the absorptance capacity of the medium. Since the different components absorb radiation in different ways at different wavelengths, a feedback is established in the system between the chemical and thermal degrees of freedom. For example, this feedback is positive if radiation is absorbed by the reaction product.[18,19] Thus the dynamics of the change in temperature and hence the chemical result of the laser radiation depend in general not only on the amount of energy absorbed but also on the wavelength of the laser radiation.

We shall now consider the very simple reaction

$$A \rightarrow B + \text{heat}. \tag{1}$$

The dependence of the dynamics of this reaction on the wavelength can be conveniently characterised by the selectivity parameter

$$\mu = \frac{\sigma_A - \sigma_B}{\sigma_A + \sigma_B},$$

where σ_A and σ_B are the cross-sections for the absorption of radiation by substances A and B. When μ changes, there is a possibility of a change in the nature of the feedback, in the reactor dynamics, and, naturally, in the chemical result of the exposure to laser radiation. Depending on the chosen values of the parameters, the system can reach a stable stationary state or an auto-oscillatory regime[18,26] and the effect of the limit at the red end of the spectrum as well as threshold and other phenomena normally characteristic of photochemical reactions may be observed.

2. Bifurcations in the chemical state of the medium

In order to demonstrate the characteristic features of reactions in the field of laser radiation, we shall examine the simplest situation where only the reversible reaction

$$A \rightleftarrows B + \text{heat} \tag{2}$$

takes place in a chemical reactor with ideal mixing. The equation for the kinetics of this reaction is

$$\frac{dc}{dt} = k_1(1 - c) - k_2 c, \tag{3}$$

where c is the concentration of the product B and k_1 and k_2 are the rate constants for the forward and reverse reactions, which depend on temperature in accordance with the Arrhenius law:

$$k_1(T) = k_1^{(0)} e^{-T_1/T}, \quad k_2(T) = k_2^{(0)} e^{-T_2/T}. \tag{4}$$

The change in the temperature of the medium T is determined from the heat balance equation

$$C\frac{dT}{dt} = AP + W\frac{dc}{dt} - P_1(T), \tag{5}$$

where A is the absorptance of the medium, P the power of the radiation, W the heat of reaction, P_1 the power associated with heat losses, and C the total heat capacity of the medium.

The characteristics of the laser-induced heating are determined by the explicit dependence of the absorptance of the medium A on its chemical composition and temperature and also on the wavelength of the radiation. To make the treatment concrete, we shall assume that the reactor is optically thin in the direction of propagation of the radiation. Then

$$A = [(1 - c)\sigma_A + c\sigma_B]Nh, \tag{6}$$

where N is the total number of species of substances A and B per unit volume and h is the optical thickness of the reactor.

We shall consider separately the visible and infrared wavelength ranges. In the visible range, the energy of a quantum of the laser radiation $\hbar\omega$ is high, i.e. $\hbar\omega \gg kT$, the temperature dependence of the absorption cross-sections σ_A and σ_B is as a rule extremely weak, and one can assume that σ_A, σ_B = const. Analysis of Eqns (3)–(6) shows that the chemical system considered passes from any kind of initial conditions to a stable stationary state. Allowance for photochemical pathways with participation of electronically excited molecules does not alter this conclusion. There may be several final stationary states (this entails hysteresis phenomena when parameters such as the power and wavelength of the radiation are changed).

The number of stationary states changes when the parameters pass through certain critical (bifurcation) values, in the vicinity of which even slight changes in the latter lead to a sharp alteration of the chemical result. The point is that, starting from the same initial state, the system is able to enter the region of attraction by other final states after passing through the bifurcation point. In this connection, one should note that laser control in the vicinity of bifurcation values does not require much energy expenditure. In other words, even small influences can yield a major effect.

In contrast to the visible region, in the IR region $\hbar\omega \approx kT$ and the absorption cross-sections depends strongly on temperature. As a result, new dynamic regimes arise in the system — the number of stationary states increases and stable auto-oscillations in temperature and concentration and more complex types of hysteresis phenomena become possible.[27]

The foregoing explains the complexity of the behaviour of even simple chemical systems under the influence of laser radiation.

3. Transient regimes and metastable ordering

Sometimes not only the final states but also transient processes are of practical interest. This is associated with the fact that in chemistry transient processes may be extremely long. Furthermore, particular products of interest may be formed in the intermediate stages, vanishing as the final state is approached.

As an example, we shall consider the imidisation reaction in the field of the continuous radiation from a CO_2 laser.[28] The essential feature of the reaction is as follows. The starting material — the polyamidoacid (PAA) — is heated and water molecules are split off and removed. This results in the formation of a thermostable polymeric aromatic polyimide (PI) (polypyromellitimide), which has useful mechanical and electrical insulating properties. Studies have shown that the quality of the polyimide is higher the more complete the removal of water. In the usual technology for the manufacture of the polyimide (under isothermal conditions), the complete removal of water requires that the process be carried out at higher temperature ($T \gtrsim 670-770$ K, where the rate of evaporation increases); however, under these conditions polyimide thermal degradation processes begin and, in addition, the water formed may cause the hydrolysis of the polyimide. As a result, the degree of imidisation is usually 75%–80%.

If the polyamidoacid is heated with the aid of the radiation from a CO_2 laser, water is in fact fully removed and a degree of imidisation >95% is attained. This can be explained by the fact that water absorbs strongly the CO_2 laser radiation and the laser-induced heating of the polyamidoacid therefore develops as follows. The absorptance of the medium is initially low and at moderate temperatures water is evolved. Then, when a fairly large amount of water has formed, the degree of absorption of the radiation increases and this results in the heating of the substance, leading to the rapid evaporation of water. Subsequently the absorptance again falls and the temperature of the medium diminishes to a level at which there is virtually no degradation of the polyimide. The time during which the system is heated and water is fully removed is short and is insufficient for the development of hydrolysis and thermal degradation of polyimide. Thus a self-organising disequilibrium regime arises where the medium 'knows itself' at which instant it has to heat up more intensely, i.e. the optimum course of the reaction is ensured by the internal dynamic resources of the system and not by the time variation of external controlling parameters.

Compared with monotonic heating in a thermostat, the positive effect during laser-induced heating is attained as a result of the 'timely' rise and decrease in temperature. Such character of the thermal process is confirmed by the results of experiments and numerical modelling.

From a formal mathematical point of view, the polyimidisation reactions during heating in a thermostat and during laser-induced heating differ in the number of occasions when the rate of reaction reaches an extremum (bifurcations in the transient regimes).[30] Such nonmonotonic changes in the rate during laser-induced heating are characteristic of many reactions. For example similar transient oscillations in temperature and rate of reaction occur over a certain range of parameters even during the laser-induced heating of a binary gas mixture involving a reversible reaction.[18]

In the example of the laser-induced polyimide formation reaction examined above, a feedback is established as a result of the change in the absorptance of the system when the chemical composition of the medium is altered. Another mechanism of the appearance of a feedback is determined by the concentration- and temperature-induced changes in the parameters of the heat exchange leading to effects of the type of thermal explosion.[1] It is not difficult to understand that this mechanism can also lead to a different kind of bifurcations in transient regimes.

Thus, even in spatially uniform systems (for example in an ideal mixing reactor), nontrivial changes in both the stationary states and in the transient processes may occur. Table 1 presents the principal mechanisms of the feedbacks and the corresponding nonlinear thermochemical phenomena observed in the laser-induced heating of chemically reactive media. The table also indicates the feedbacks investigated in the usual (nonlaser) macrokinetics.

We have spoken hitherto about point systems. On passing to distributed systems, where heat and mass transfer processes play a significant role, the range of possible regimes expands sharply. The occurrence of diffusion and thermal conductivity can lead to phenomena involving the spontaneous loss of symmetry and spatiotemporal self-organisation and also to the formation of various nonequilibrium structures.[4,6,34] The theoretical dynamics of the corresponding processes is described by coupled diffusion equations:

$$\frac{\partial u}{\partial t} = \nabla(D\nabla u) + Q(u)\,, \tag{7}$$

where u is the vector of state, D the matrix of the diffusion coefficients (in the general case it is nondiagonal and depends on u), and Q the vector of nonlinear sources. A multiplicity of different problems, including the problems of the chemical dynamics of the reactor, reduce to an equation of type (7). In essence the spatiotemporal self-organisation is determined by the presence in Eqn (7) of new feedback channels between spatial gradients (fluxes) of the corresponding quantities. If the feedback generated is positive, then in distributed system instabilities may develop, leading to the formation of either dissipative structures or autowaves.

As an example we shall consider the appearance of thermal diffusion instability during the laser-induced heating of binary gas mixtures.[19,35] In the field of the laser radiation, the temperature gradients may be high and the thermal diffusion mechanism of the transport of matter may be significant. The thermal diffusion flux of the light component (B_l) is usually directed towards the hotter region of the medium, while that of the heavy component (B_h) is directed towards the colder region. This factor leads to separation in space of the components of the nonuniformly heated $B_l + B_h$ gas mixtures.

We shall consider the heating of an optically and thermally thin gas-containing cell (oriented along the x axis) by radiation incident on the cell at right angles to the x axis and having an intensity distribution $I(x) = I$ = const. ($0 < x < L$), where L is the length of the cell. It is assumed that the radiation is absorbed selectively by the light component of the gas. The appearance of instability in the homogeneous state of the gas is due to the fact

Table 1. Typical feedbacks and nonlinear phenomena in macroscopic kinetics.

Feedback mechanisms	Type of nonlinearity	Nonlinear phenomena	Ref.
Heat of zero-order reaction	$P_{exo} = Wk_0 e^{-T_0/T}$	Thermal explosion, thermochemical bistability	29, 1, 3
Heat of reaction of order α	$P_{exo}(N,T) = Wk_0 N^{\alpha} e^{-T_0/T}$	Thermokinetic oscillations	1, 5
Concentration-induced changes in absorption	$\sigma_A = \sigma_A(T)$, $\sigma_B = \sigma_B(T)$	Thermochemical bistability, auto-oscillations, bifurcation of transient regimes, self-stabilisation, Belousov–Zhabotinskii reactions	3, 18, 28
Temperature- and concentration-induced changes in absorption	$\sigma_A = \text{const}$, $\sigma_B = 0$, nonequilibrium chemical kinetic equation	Thermochemical bistability, auto-oscillations	26
Concentration-induced change in heat capacity	$C = C_1 c + C_2(1-c)$	Bifurcations in transient regimes	30
Change in the parameters of heat and mass exchange	$\eta = \eta(v, T)$, $\sigma_0 = \sigma_0(N, T)$	Crisis in heat exchange, thermal explosion, auto-oscillations	2, 31
	$v \neq 0$ (exposure to gas stream)	Auto-oscillations, dissipative structures	32, 33

Note. To make the illustration concrete, the results are presented for the reaction A $\rightleftharpoons$ B. Notation employed: P_{exo} is the power evolved in the reaction, k_0 and T_0 are the parameters of the rate of an Arrhenius-type reaction, N is the amount of the initial reaction component, c is its concentration, σ_A and σ_B are the cross-sections for the absorption of radiation by substances A and B, η is the Newtonian heat exchange coefficient, σ_0 is the blackbody coefficient for the radiative heat exchange, v is the velocity of the gas stream, and C is the heat capacity.

that, in the presence of local temperature fluctuations, a thermal diffusion flux directed to the hot region arises. A local increase in the concentration of the absorbing component and a further growth of temperature gradients then occur. However, by virtue of the thermal conductivity and the usual diffusion, the instability can develop only when the intensity of the radiation I exceeds a critical value. Such a mechanism has been proposed by Nitzan et al.[19] Stabilisation is achieved by virtue of some kind of nonlinear factors. Thus if there is a feedback $B_l \rightleftharpoons B_h$ between the components of the medium, the principal stabilisation mechanism consists in the fact that, in conformity with the reaction kinetics, an effective 'sink' of the light component B_l arises at the points with an excess of the latter, while a 'source' of this component arises at the points where its amount is deficient.

As a result of the development of the instability, the system passes to a stable stationary inhomogeneous state with distributions of temperature and concentrations of the gas components which are periodic with respect to the length of the cell.[19, 35] As a consequence of this transition, the average (with respect to space) absorptance of the medium changes. It is found that, over a wide range of values of the parameters, the absorptance diminishes, i.e. the fraction of absorbed energy of the radiation decreases.[36] In other words, the behaviour of the system corresponds qualitatively to the Le Chatelier principle familiar in classical thermodynamics. Nevertheless, this claim is invalid in the general case, i.e. one may indicate a range of parameters in which the average absorptance increases when the medium passes to the inhomogeneous state.

The breakdown of the Le Chatelier principle reflects the fact that the system is far from thermodynamic equilibrium. We may recall that the latter is manifested by the existence of bistability, which is impossible in the case of weak energy and mass exchange between the system and the surrounding medium.

Structure formation phenomena, similar to those examined above, have been widely discussed in various branches of physics and similar equations have been used for their description. Thus the dynamics of a homogeneous two-component system near the instability threshold depends only slightly on the specific form of nonlinearity and can be frequently described by one of the following equations:¶[36]

¶ See, for example, also the book *Nelineinye Volny. Dinamika i Evolyutsiya* (Nonlinear Waves. Dynamics and Evolution) (Moscow: Nauka, 1989) p. 113.

$$\frac{\partial u}{\partial \tau} = -\frac{\partial^2}{\partial x^2}\left(\frac{\partial^2 u}{\partial x^2} + \beta u + \varepsilon u^2 - u^3\right), \quad 0 < x < L, \tag{8}$$

or

$$\frac{\partial u}{\partial \tau} = \left[\beta - \left(\frac{\partial^2 u}{\partial x^2} + k_0^2\right)^2\right] u + \varepsilon u^2 - u^3, \quad 0 < x < L, \tag{9}$$

where τ, x, and L are respectively the dimensionless time, the coordinate, and the linear dimension of the system, u the deviation of any characteristic of the system (for example, temperature) from its value in the equilibrium homogeneous state, $\beta \simeq I - I_c$ characterises the extent by which the radiation intensity I exceeds the threshold intensity I_c, and the parameter ε is determined by the properties of the medium and describes the quadratic nonlinearity of the system. Eqns (8) and (9) can be obtained as special cases of Eqn (7). They have been proposed for the description of convective and thermoconvective instabilities in liquids, phase transitions in nuclear matter, and the separation of alloys and suspensions into layers.

Eqns (8) and (9) can be investigated by the known methods of the qualitative theory of nonlinear boundary problems. In the first place, it is evident that they have the homogeneous stationary solution $u = 0$. By linearising Eqns (8) and (9) in the vicinity of this solution and assuming that

$$\delta u = (\delta u)_0 \exp(\gamma \tau + iqx), \tag{10}$$

it is easy to find the dependence of the increment γ on the wave number q, which assumes the form

$$\gamma = q^2(\beta - q^2) \tag{11}$$

in the case of Eqn (8), and

$$\gamma = \beta - (q^2 - k_0^2)^2 \tag{12}$$

in the case of Eqn (9). If $\beta > 0$, there is always a range of wave numbers q in which $\gamma > 0$, i.e. the perturbations increase exponentially with time.

We shall now consider Eqn (8) in greater detail. It follows from Eqn (11) that perturbations with the wave numbers $q_m = (\frac{1}{2}\beta)^{1/2}$ grow at the fastest rate (γ is a maximum). The formation in the system of a spatially periodic structure with a period $\lambda_m \simeq 2\pi/q_m$ is therefore to be expected. Numerical integration of Eqn (8) confirms this conclusion. However, it can be demonstrated rigorously that only those solutions of Eqn (8) the period of which is $\lambda_a = 2L$ are asymptotically (at $\tau \to \infty$) stable.

Hence it follows that, for sufficiently large values of L, solutions with a period $\lambda \simeq \lambda_m$ are unstable and arise only as intermediate (transition) states.[37] Since states with $\lambda \simeq \lambda_m$ arise almost inevitably in the course of the evolution of the test system, they can be naturally referred to as metastable structures and the appearance of such states can be called metastable self-organisation. The term 'metastable structure' will also be applied because the lifetime of such structures is long: they decompose only under the influence of longer-wavelength perturbations, the time of the increase of which is long (since this process requires the synchronisation of the motion of more extensive sections of the medium). We may note that metastable ordering phenomena are characteristic of many nonlinear dynamic systems. They can arise, for example, in the thermal diffusion separation of gas mixtures, and in the laser-induced annealing and quenching of nonequilibrium vacancies in the surface layers of metals.[38]

4. Thermal diffusion oscillations during nonuniform heating of gas mixtures

We shall consider the heating of a chemically inert gas mixture by a beam of continuous laser radiation. We shall assume that the radiation is absorbed by the heavy component of the mixture via a resonance mechanism. The gas layer is assumed to be optically thin along the axis of the beam. The mathematical model of the process[39] includes diffusion (taking into account concentration and thermal diffusion) and thermal conductivity equations. In the latter, account must be taken of the fact that in the IR region of the spectrum the absorptances of many molecular gases depend strongly on temperature and are often described by the formula

$$A(N,T) = \beta N \exp\left(-\frac{T_a}{T}\right),$$

where N is the molecular density of the absorbing component of the medium.

If the radiation has a uniform intensity distribution with respect to the cross-section of the cell, then only stationary states are stable. In the same case, when the radiation beam has a finite radius stable nonstationary regimes become possible. The mechanism of the generation of oscillations in temperature and the concentrations of the components is as follows. Under the influence of radiation, the mixture is heated and temperature gradients directed towards the axis of the laser beam arise. As a result of thermal diffusion, the heavy component of the mixture is expelled from the beam, so that the absorptance of the medium diminishes, the gas cools, the temperature gradients diminish, and concentration diffusion returns the absorbing component to the region within the limits of the laser beam. The process is then repeated.

We shall now present the results of the numerical analysis of this process.[39] It was found that oscillatory regimes are possible in a restricted range of powers (P) and radii (r_0) of the radiation beam. This region is illustrated in Fig. 1*a*. It is divided into two subregions with different dynamic regimes. For the parameters in the subregion I, the system executes simple auto-oscillations, which are represented on the phase plane by a closed curve without self-intersections (the so called limiting cycle S^1).

On passing to the subregion II, the oscillations are become more complex as a result of the cascade of bifurcations involving the doubling of the period. Typical phase portraits of the complex limiting cycles are presented in Figs 1*b*–1*e*.

In the subregion II in Fig. 1*a*, the system is extremely sensitive to the choice of the radiation parameters. Therefore, under the conditions of a real experiment, when the radiation parameters have been determined with insufficient accuracy or fluctuate, it is difficult to obtain the required complex dynamic regime in a pure form. As regards the characteristic values of the periods of the oscillations, we may point out that, in the vicinity of the stability threshold of the stationary state, they are $\sim(5-10)r_0^2/D$. For typical experimental conditions with diffusion coefficient $D = 0.1$ cm^2 s^{-1} and the laser beam radius $r_0 = 1$ cm, this estimate yields a characteristic time of the order of 1 min.

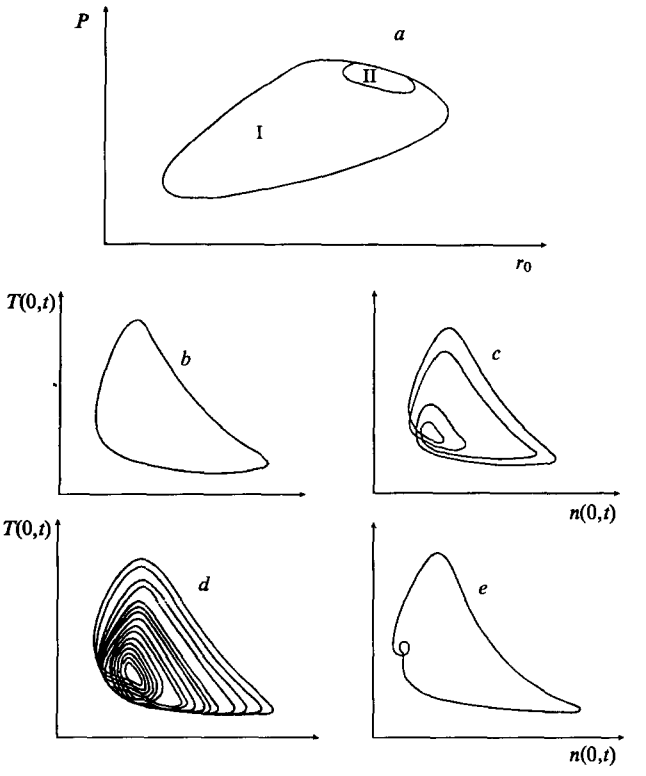

Figure 1. The region of existence of thermodiffusional oscillations (*a*) and typical phase portraits (*b*–*e*).

The diffusional oscillations examined above have been observed in experiments on the laser-induced heating of gas mixtures.[40] Fig. 2 presents the time variations of the power of the laser radiation which has passed through a cell containing a mixture of air and SF_6 as well as a mixture of NH_3 and SF_6. The radiation was absorbed selectively by the heavy component (SF_6). The oscillograms show that the heavy component is periodically ejected outside the limits of the laser beam. The characteristic process times show that there are no gas-dynamic motions of the medium (turbulence, convection) and that mass transfer is diffusional.

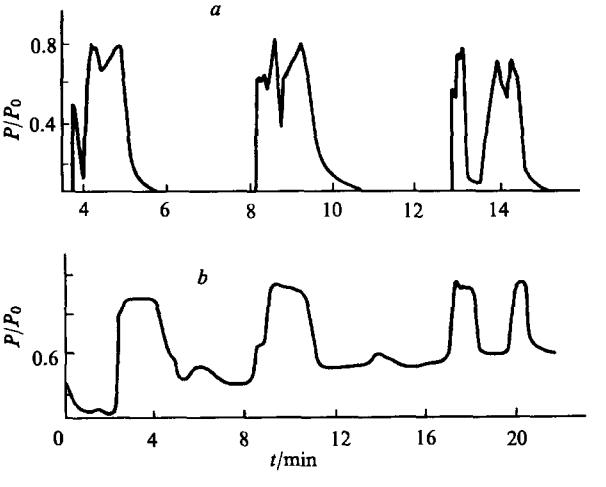

Figure 2. Time variation of the power of the laser radiation which has passed through a cell with SF_6+air (*a*) and SF_6+NH_3 (*b*) mixtures.[39] Power of the radiation incident on the cell $P_0 = 5$ W; length of the cell 20 cm; pressure (torr): (*a*) $P_{SF_6} = 2$, $P_{air} = 20$; (*b*) $P_{SF_6} = 2.5$, $P_{NH_3} = 19$.

5. Travelling fronts and 'chemical solitons'

Hitherto we have spoken of the heating of a gas mixture placed in an optically thin cell. On the other hand, if the optical thinness condition is infringed, there is a possibility of the appearance of qualitatively new dynamic regimes. In particular, combined waves may appear in which the concentration of the reactants and temperature differ markedly from the background values (travelling pulse or 'chemical soliton'). We shall consider this phenomenon in relation to the laser-induced heating of a gaseous medium involving a reversible chemical reaction.

Suppose that the gas mixture has been placed in a long thin cell illuminated from the end-face by radiation with a power P. As mentioned above, in a gaseous medium with a reversible chemical reaction there is a possibility of the phenomenon of thermochemical bistability on heating by laser radiation at a suitable wavelength. This means that, in a certain range of radiant powers ($P_1 < P < P_2$), there exist two stable stationary states differing in temperature and the concentrations of the components. The attenuation of radiation in accordance with the Bouguer (Beer–Lambert) law and transfer processes are not taken into account in this treatment, but they can in fact lead to new interesting effects.

Suppose that in the initial instant the system is in its lowest state as regards concentrations and temperature. If the medium in a certain part of the cell is transferred to a state with an increased concentration of the absorbing component, then the absorption of radiation in this region increases and heating of the gas begins. As a result of heat conduction and the absorption of the energy of the laser radiation, the neighbouring regions also begin to heat up. The size of the absorbing zone then increases until the radiant power behind it becomes less than W_1 — the minimum value necessary for the existence of bistability. The zone formed begins to move towards the laser beam, because, as a result of heat conduction, the region ahead of the zone heats up and the absorption in the latter increases, while the region behind the zone cools as a result of heat losses and the decrease in the heating power. This leads to the formation of a travelling pulse — a localised region in which the medium is in a high-temperature and strongly absorbing state. We may note that a similar phenomenon is observed not only in laser-induced thermochemical processes but also in many others, for example, in the generation of plasma in optical breakdown.[41]

The phenomenon considered above is formally described in terms of the following boundary-value problem.[42] The change in the concentration n of substance B is defined by the equation for reaction kinetics taking into account diffusion:

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial z^2} + k_A(1-c)\exp\left(-\frac{T_A}{T}\right) - k_B n \exp\left(-\frac{T_B}{T}\right). \qquad (13)$$

We shall assume that $T_A > T_B$, i.e. the equilibrium concentration of substance B,

$$c = \left[1 + \frac{k_B}{k_A}\exp\left(\frac{T_A - T_B}{T}\right)\right]^{-1} \equiv c(T), \qquad (14)$$

increases with temperature.

We shall assume that radiation is absorbed only by substance B

$$\frac{\partial I}{\partial z} = -\beta c I, \quad \beta = \text{const}, \quad I|_{z=0} = I_0, \qquad (15)$$

while the change in the gas temperature is described by the thermal conductivity equation

$$\frac{1}{a}\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial z^2} - \frac{1}{k}\frac{\partial I}{\partial z} - \frac{\eta}{k}(T - T_i), \qquad (16)$$

where η is the heat loss per unit length of the cell and T_i the initial temperature of the medium.

We shall assume that the length of the cell exceeds significantly the spatial size of the travelling pulse. Fig. 3 illustrates the dynamics of the formation of a chemical soliton.

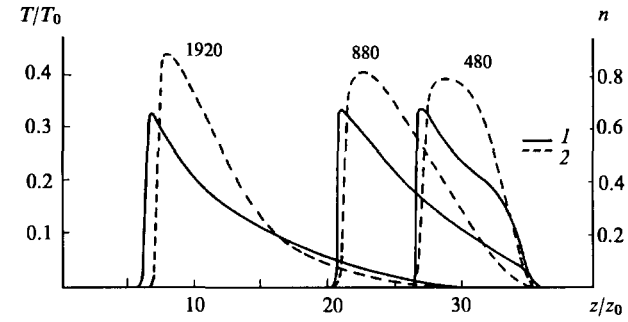

Figure 3. Dynamics of the formation of a chemical soliton. The dimensionless temperature (T/T_0), distance (z/z_0), and concentration c are plotted along the coordinate axes; the numerals opposite the curves denote the dimensionless time (t/t_0): (*1*) temperature profile; (*2*) concentration profile.

The switching caused by longitudinal bistability leads to additional characteristic modulation (kinks) of the intensity of the radiation at the outlet from the medium. For example, if the time variation of the radiation intensity at the inlet to the medium has the form of a triangle (Fig. 4*a*) with an amplitude higher than a certain critical value, the transmitted pulse has the form of a trident (Fig. 4*b*). Phenomena of this kind have been observed in the interaction of laser radiation with semiconductors.[43] The time constant corresponding to the mechanism of the chemical nonlinearity makes it possible to observe kinks in the range of intensities and for durations of laser action differing by several orders of magnitude from those where kinks are observed in semiconductors.

In a medium with a nonuniform energy exchange [the quantity T_i in Eqn (16) is, for example, a monotonically increasing linear function of the coordinate], a cyclic process may occur, consisting of stages involving the 'self-initiation' of the travelling pulse at the remote end of the cell, its subsequent propagation towards the beam, and its 'self-quenching' at the inlet to the reactor (Fig. 5). In terms of external features, such a system may be called a chemical analogue of the Gunn diode. The amplitude, width, velocity, and other parameters of a chemical soliton during its propagation in the medium may vary periodically (or even stochastically). Together with bifurcations, leading to identical changes in the system dynamics throughout the length of the reactor, there is a possibility of bifurcations leading to the appearance of dynamic regimes qualitatively different in different parts of the reactor. This can be manifested, for example, by the fact that part of the reactor is traversed by the 'chemical soliton' as a 'two-hump' species whilst another part is traversed by the soliton as a 'one-hump' species. From the formal point of view, such transformations correspond to bifurcations involving the doubling of the period along the spatial coordinate.

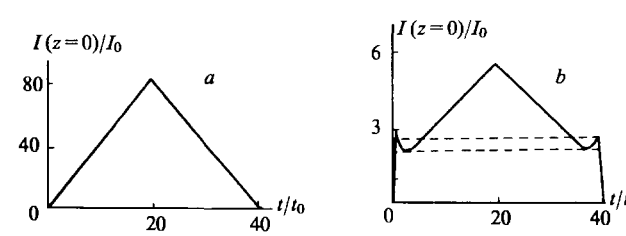

Figure 4. Time modulation of the triangular pulse arising during passage through a bistable medium.[44] Time profile of the incident (*a*) and transmitted (*b*) radiation.

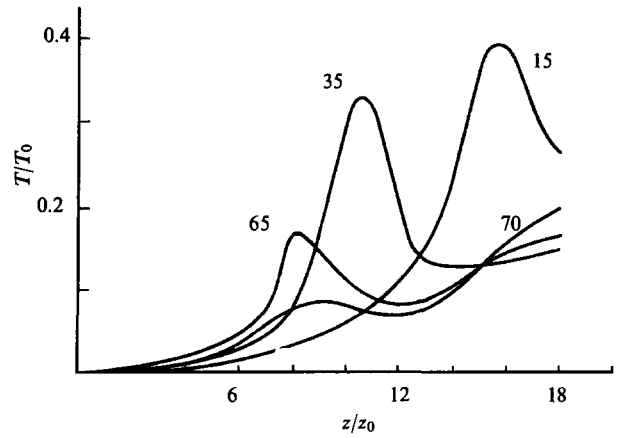

Figure 5. Chemical analogue of the Gunn diode: temperature profile of the field for different times in a medium with a nonuniform energy exchange. The legend is the same as in Fig. 3.

6. Nonlinear optical phenomena in a chemical reactor

The phenomena examined above belong to the class of nonlinear amplitude effects. Even these alone lead to complex dynamics of chemical processes in an optically thick reactor. In reality, together with amplitude effects there are also phase distortions of the wave front associated with the change in the refractive index of the medium during the reaction.

We shall consider this in greater detail. We shall suppose that a chemical reaction A → B takes place in the medium and that the initial substance A and the reaction product B have different optical properties. If the refractive index of substance B (n_B) is greater than that of substance A (n_A), a positive feedback is established, leading to instability. The mechanism of the instability is as follows. In the presence of perturbations, the medium is more strongly heated in the regions with increased intensity compared with the neighbouring regions and the reaction is activated sooner. As a result, the refractive index in these regions increases more rapidly, since $n_B > n_A$, which leads to the deviation of the light rays in this region and to a further increase in the local radiation intensity. The propagation of the radiation in a medium with a chemical inertial nonlinearity is described by the system of thermal conductivity and reaction kinetic equations (taking into account diffusion) together with the Maxwell equations specifying the distributed feedback.

Two cases are distinguished: those of narrow[44] and wide[45] radiation beams. A narrow beam is understood as one for which the radiation intensity distribution across a transverse section is nonuniform. A wide beam corresponds to the situation where the incident radiation is spatially uniform (planar wave).

We shall consider the characteristics of the formation of thermal structures in a nonuniform field of laser radiation. In the course of the development of instability, the optical nonuniformity of the medium increases and the self-focusing of the radiation take place. The self-focusing begins if

$$EN > (EN)_c , \tag{17}$$

where $E = \pi r_0^2 I_0 t$ is the energy of the radiation, N the concentration of the reaction products formed during time t, and $(EN)_c$ is determined by the parameters of the medium, the radiation wavelength, and the constants characterising the rate of reaction.[44] The effective width of the beam $r(z, t)$ may vary nonmonotonically along the beam z axis by virtue of the competition between the diffraction divergence and the focusing action of the 'chemical' lens: constrictions appear in the beam, their number varying in the course of the reaction. As can be seen from Fig. 6, when the self-focusing condition (17) is fulfilled, a beam constriction is generated, which moves from the point in which the radiation enters into the bulk of the medium ($z = 0$) and then, as the initial substance is 'burnt off' and the optical uniformity is restored, it moves in the opposite direction. The law governing the motion of the constriction can be explained qualitatively by considering the medium as an effective lens the focal distance R of which varies with time. The beam profile is now described by the expression

$$f(z) = \sqrt{\left(1 - \frac{z}{R}\right)^2 + \mu\left(\frac{z}{r_0}\right)^2} , \tag{18}$$

where the diffraction parameter $\mu = (kr_0)^{-2}$ and k is the radiation wavenumber.

The position of the constriction z_m corresponds to the minimum in the function $f(z)$:

$$f_{min} = f(z_m) = \sqrt{\frac{\mu(R/r_0)^2}{1 + \mu(R/r_0)^2}} , \quad z_m = \frac{R}{1 + \mu(R/r_0)^2} . \tag{19}$$

Hence it follows that, when $R = \infty$, i.e. when the medium is optically uniform, we have $z_m = 0$. Then, as R diminishes (the optical power of the lens increases), z_m reaches a maximum for a certain value of R and then begins to decrease as R diminishes further ($z_m \simeq R$ when $R \to 0$).

If the variation of the refractive index as a function of the radius is sufficiently great, then, when the beam passes from an optically denser medium to a less dense one, conditions for internal reflection may be fulfilled, as a consequence of which new constrictions appear on the beam — the beam acquires a corrugated profile. The appearance of constrictions implies the appearance of hot spots in which the reaction proceeds more vigorously. Evidently, this phenomenon may lead to the inclusion of high-temperature reaction pathways and hence to a qualitative change in the chemical composition of the reaction products. Under such conditions, it is difficult to predict the chemical result of the action of the laser radiation on the medium.

If the incident radiation has a spatially uniform intensity distribution, different aberrations of the radiation may be observed in the cross-section depending on the initial form of small perturbations — subdivision into 'filaments', the appearance of a nonstationary ring structure, etc. The instability can be convective (displacement) in nature: an intensity maximum arises at the inlet to the medium ($z = 0$) in an elementary tube, and then migrates into the bulk of the medium. The appearance of the maximum and its migration are caused, on the one hand, by the intensification of the optical strength of the chemical lens

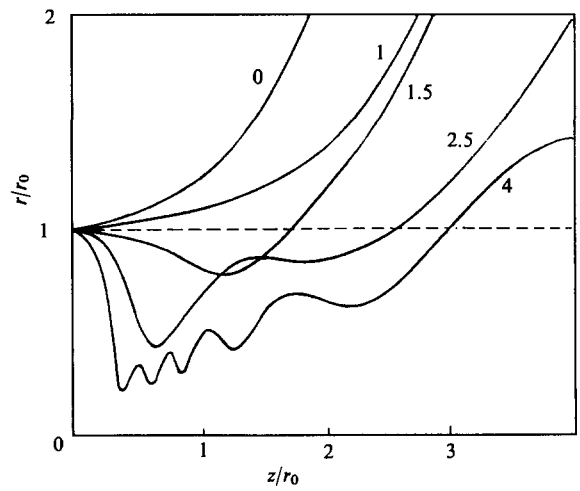

Figure 6. The profile of a radiation beam at different times during the reaction; r = beam radius, z = coordinate along the reactor axis, r_0 = radius of incident beam; the numbers opposite the curves denote dimensionless times.

during the reaction and, on the other, by two stabilising factors: the Bouguer attenuation of the radiation in the medium and the wave relaxation, which moves behind the instability front and is caused by the joint action of heat conduction and diffusion. The relaxation wave leads to the equalisation of the optical density of the medium, as a result of which the beams deviate only slightly from the initial direction before the attainment of the perturbation front.[45]

IV. Thermochemical processes in the laser heating of metals

1. Kinetics and dynamics of heterogeneous reactions and the morphology of the surface

Three major problems are associated with the laser stimulation of heterogeneous reactions.

The first refers to the reaction kinetics. During the last 10–15 years, many investigators observed that the kinetics of heterogeneous reactions in the field of the laser radiation are frequently characterised by different kinetic constants and even by different forms of the kinetic laws from those of the kinetics of isothermal processes (numerous reference data are available for the latter). This means that, for the development of the laser technology, it is essential to carry out an extensive set of studies in order to discover the form of the kinetic laws and the values of the corresponding kinetic constants, their dependence on the intensity and wavelength of the laser radiation, etc. As for homogeneous reactions, it is possible to differentiate photochemical and thermochemical effects. The photochemical effects are characteristic of laser-induced processes involving the oxidation of semiconductors and metals, the oxides of which have semiconducting properties. The 'red limit' of such photoactivity is usually in the visible or UV regions of the spectrum. On the other hand, the effects associated with the thermochemical influence of laser radiation on the reaction kinetics are associated with either high heating rates or high spatial temperature gradients in the oxidised layer.

The second problem concerns the kinetics of oxidation reactions. The observation of thermochemical instability and the first theoretical models of the development of instability on formation of strongly absorbing oxides have played an important role in this connection.[16] Such instability characterises the nonlinear dynamics of a system with a positive feedback in the initial stage. In later stages, where different stabilisation mechanisms begin to operate, the process dynamics become more complex. The experimental observation of the nonmonotonic dependence of the change in the absorption by metallic targets during their laser-induced heating in air has played an important role in the development of these studies.[17] It was found that the sign of the feedback, arising as a consequence of the change in absorption, can change during the process. More complex manifestations of the nonlinear dynamics of thermochemical processes were observed subsequently.

Finally, the third problem is that of the morphology of the surface in the laser initiation of heterogeneous reactions. As early as the beginning of the 1970s, studies on the heat-induced strengthening of metals and alloys led to the observation (see, for example, Rykalin et al.[46]) that in laser-induced heating the morphology of the surface is different from that found on heating in a furnace. The causes of this phenomenon were inadequately investigated at the time. Nowadays, numerous new results have been obtained. It is noteworthy that investigations of the structural changes in the surface under the influence of laser radiation are important for many technological applications, for example, in microelectronics, in integrated optics, in the laser-induced stabilisation of surfaces, etc.

2. The effect of laser radiation on the kinetics of heterogeneous reactions

The heterogeneous reactions at the solid–gas interface (oxidation, reduction, nitride formation, etc.) are known[47] to consist of many stages, the transfer of reactants in the gas or solid phase frequently playing the role of the rate-limiting stage. Accordingly, the kinetics of such reactions have a number of features in common with the kinetics of homogeneous reactions whose rate is limited by the diffusional transport of the components. Under these conditions, heterogeneous reactions should be more sensitive to changes in the parameters of the laser radiation than homogeneous reactions, because the diffusion coefficients of atoms in a solid vary more markedly with temperature than in gases (the variation is exponential and not of the power type).

However, as early as 10–15 years ago it was claimed that, for example, in metal oxidation reactions laser radiation exerts no specific influence on the reaction kinetics: the kinetics are exactly the same as during the heating of the target in a furnace. On the other hand, early experiments[48] already showed that the oxidation of copper in air under the influence of laser radiation is faster than in the furnace at the same temperature of the metal.

We shall consider the phenomena associated with the high rates of laser heating. For continuous emission, such rates are attained at the stage involving the development of thermodynamic instability, while for pulsed or repetitively pulsed emission they are attained in each individual pulse. Here it is significant that during rapid heating the distributions of the reactants deviate markedly from those which are established during slow heating. Evidently this is associated with the finite rate of diffusional transport of the components (oxidant and the metal) and with the migration of the metal–reaction product interface, the effective constants of which are functionals of the concentrations. Strictly speaking, the kinetic constants are not of this kind. For example, in relation to the oxidation of metals, the corresponding constants must be found by solving a system of equations for the diffusion of metal and oxidant ions in the layer of reaction products. The changes in the kinetics caused by the high rates of laser heating in heterogeneous reactions have been discussed.[48–52] Under stationary conditions, the kinetics of the heterogeneous oxidation are influenced by the nonuniformity caused by the spatial localisation of the reaction owing to the finite nature of the diameter of the laser beam and the temperature gradients in the oxidised layer. We shall consider the influence of these nonuniformities. The limited size of the laser beam leads, in particular, to the phenomenon of the diffusional limitation of the reaction as regards the supply of the oxidant from the gas phase (see, for example, Bunkin et al.[26] and Prokhorov et al.[49]).

The temperature gradients along the surface of the oxide layer are as a rule significantly lower than across it. The influence of these gradients on the reaction kinetics is various. The temperature gradients along the surface influence the transport of atoms via surface diffusion and thermal diffusion. This entails a change in the spatial distribution of the rate of reaction along the radial coordinate, which alters qualitatively the dependence of the increment in the instability of the planar oxidation front on the parameters of the laser radiation and the perturbation wave number.[53]

The temperature gradients across the oxide layer are more significant. They influence the transport of reactants in the solid phases. There are several mechanisms of the influence of such gradients on the reaction kinetics. The mechanisms determined by the temperature dependence of the diffusion coefficients and the thermal diffusion flux of atoms are fairly evident. Their effect in different models of the laser-induced oxidation has been investigated, for example, by Buzykin and coworkers.[54, 55] The phenomena caused by the influence of the temperature gradient on the electrical transport are of special interest. Owing to the high field of the thermo-e.m.f. in an oxide with semiconducting properties, the temperature gradients can lead to both

acceleration and retardation of the reaction. This has been demonstrated experimentally for the oxidation of copper (acceleration) and cobalt (retardation).[56]

Another important factor is accelerated diffusion via the grain boundaries and microcracks formed in the oxide film under the influence of thermal stresses. To a first approximation, the corrections to Wagner's parabolic law, caused by the increased permeability of the oxide, lead to a paralinear oxidation law. It has been observed experimentally[57] that, in the laser-induced heating of cobalt to 1300 K, a linear oxidation law holds up to an oxide thickness $h \simeq 10^5$ A, after which it is replaced by a parabolic law. On the other hand, under isothermal conditions (during oxidation in a furnace) the parabolic law is observed already for thicknesses $h > 10^2$ Å. Such 'extension' of the linear law into the region of high thicknesses may be associated with increased permeability of the oxide layer together with other causes (for example thermal diffusion).

The mechanisms of the influence of the generation of non-equilibrium point defects on the changes in the oxidation kinetics have been investigated vigorously in recent years.[38] The simplest mechanism of such influence may involve a change in the diffusion coefficients of atoms in the oxide, which, according to the Dienes–Damask theory[58] is described by an equation of the following form:

$$D(T) = D_0(T)\frac{N}{N_0(T)},$$

where $D_0(T)$ is the 'equilibrium' value of the diffusion coefficient at the given temperature and N is the concentration of non-equilibrium vacancies which exceeds significantly the equilibrium concentration $N_0(T)$ for the pulsed-periodic application of laser radiation. Such mechanisms make it possible to explain the accelerated growth of the oxide film in the 'low temperature' region which has been observed experimentally.[59]

Thus the studies of the last 10 years have yielded a result of practical and theoretical importance, namely that the kinetics of the laser-induced and isothermal oxidation are different. These differences depend greatly on the nature of the metal and the gas composition of the atmosphere and on the parameters of the target and the laser radiation. The specific mechanisms responsible for such differences proved to be varied. A number of them were discussed above.

3. Laser-induced oxidation

We shall now turn to the dynamics of oxidation reactions under the influence of laser radiation. In the simplest case, the rate of reaction can be characterised by the change in the thickness of the oxide layer dx/dt. This quantity depends on the temperature of the substance and can be expressed in the form

$$\frac{dx}{dt} = f(x, T). \tag{20}$$

In order to determine the reaction dynamics, it is essential to solve Eqn (20) simultaneously with the thermal conductivity equation. We shall consider such dynamics in relation to the problem of the growth of thick ($x > 10^3$ Å) compact oxide layers. In such layers, the reactants are transported by diffusion, which leads to the so called parabolic law

$$\frac{dx}{dt} = \frac{d(T)}{x}, \tag{21}$$

where the quantity $d(T)$ has come to be referred to as the parabolic law constant. At a constant temperature, the thickness of the oxide varies, according to Eqn (21), in conformity with the characteristic diffusion law $x^2 = 2dt$. The temperature variation $d(T)$ is frequently determined by the Arrhenius factor:

$$d(T) = d_0 \exp\left(-\frac{T_d}{T}\right), \tag{22}$$

which is valid within fairly wide temperature ranges.

The dynamics of such a system may be complex. The reason for this is that feedbacks arise in the system between the rates of heating and the rates of chemical reactions. The optical channel for the feedback, arising as a consequence of the dependence of the absorptance A of the irradiated specimen on the thickness of the oxide layer, plays a significant role in the laser-induced oxidation. The optical feedback may be both positive (along the section where the absorptance increases, $dA/dx > 0$) and negative ($dA/dx < 0$).

The positive feedback leads to thermochemical instability. We shall consider this phenomenon in greater detail.

The laser-induced heating of a thermally thin metallic film in an oxidising gas medium is described by the kinetic equations (21) and (22) and the heat balance equation (the heat of reaction is neglected):

$$mc_1\frac{dT}{dt} = PA(x) - P_1(T), \tag{23}$$

where m is the mass of the plate, c_1 is its specific heat, and P_1 is the power associated with the heat loss. Taking into account only the convective heat exchange, we assume that $P_1(T) = \eta S(T - T_1)$, where S is the total area of the heated specimen and η is the heat exchange coefficient.

An explosive increase in temperature (thermochemical instability) is observed after the thickness of the oxide film has increased so much that the change in absorption begins to alter significantly the heat balance, i.e. thermochemical instability develops after the elapse of a certain characteristic time, referred to as the activation time t_a, and not immediately after the start of irradiation. Under typical conditions, this time is proportional to $\exp(T_d/T_0)$, where T_0 is the quasi-stationary temperature to which the specimen is heated when its initial absorptance is equal to the absorptance of the unoxidised metal.

For nonuniform laser irradiation, the temperature maximum is located on the beam axis. Since the activation time increases exponentially with decrease in temperature and the temperature diminishes on moving away from the centre of the beam, an effective self-compression of the temperature field takes place in the course of development of thermochemical instability.

We may note that, by virtue of the temperature dependence defined by Eqn (22), the reaction takes place effectively in the vicinity of the centre of the laser beam. The size of the region may be small, compared not only with the characteristic width of the thermal field but also with the radius of the reaction-initiating beam itself. The above factor is important for laser technology, since it makes it possible to localise the chemical reaction. The effect involving the sharpening and localisation of the temperature field has been observed in experiments on the laser-induced heating of metals in air.[60] This is illustrated in Fig. 7, which shows the time variation of the spatial distribution of the temperature field for the heating of a titanium target by the radiation from a CO_2 laser. Evidently the self-acceleration of the temperature rise is accompanied by the self-compression of the temperature field.

We emphasise that the non-uniformity of the distribution of the radiation intensity is essential for the appearance of localisation effects only at the beginning. It serves as a 'seed' of the instability, which can then develop also in a uniform field. Therefore even small fluctuations in the distribution of the radiation intensity or in the optical characteristics of the test substances play an important role in laser-induced thermochemical processes.

For many metal oxides, the absorptance varies nonmonotonically with increase in thickness. This can be associated with interference due to the penetration of the light beam through a dielectric film the optical thickness of which is a multiple of an integral number of half-waves. Owing to interference oscillations in absorption, the sign of the feedback changes periodically, which results in the pulsation of the heating rate. Such pulsations are of a transient character and are not observed for asymptotic states (at $t \to \infty$).

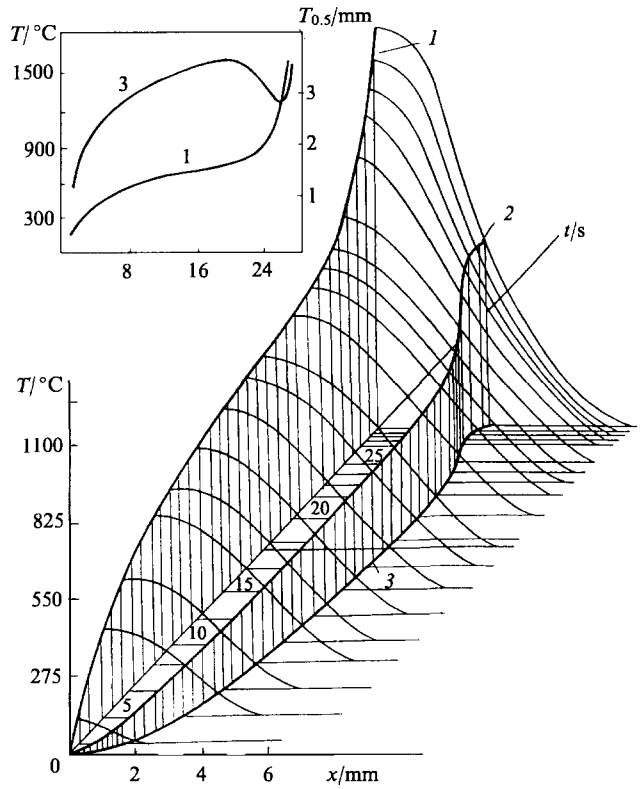

Figure 7. Time evolution of the spatial temperature profile of a titanium plate during its heating by the continuous radiation from a CO_2 laser:[60] power of the laser 40 W: (*1*) temperature $T(0, t)$; (*2*) temperature $0.5T(0, t)$; (*3*) effective radius of the localisation of the temperature field $r_{0.5}$, i.e. the value of the coordinate r for which $T(r_{0.5}, t) = 0.5T(0, t)$.

Another positive feedback channel is provided by the heat of a chemical reaction, which is responsible for the self-inflammation phenomenon[1] and for the appearance of auto-oscillations in a flow reactor with an exothermic reaction.[5] The heat of reaction plays a significant role in laser-induced inflammation processes. The following model, describing the qualitative features of the inflammation of tungsten, has been proposed:[61]

$$\frac{dx}{dt} = \frac{d}{x}\left(\exp\left(-\frac{T_d}{T}\right) - \upsilon_0 \exp\left(-\frac{T_s}{T}\right)\right),$$

$$mc_1 \frac{\partial T}{\partial t} = PA(x) - P_1(T) + \rho SW \frac{d}{x} \exp\left(-\frac{T_d}{T}\right) - \tag{24}$$

$$-\rho SL\upsilon_0 \exp\left(-\frac{T_s}{T}\right),$$

where W is the specific heat of the chemical reaction, L the specific heat loss on sublimation, ρ the density of the test substance, υ_0 the pre-exponential factor, and the subscripts s and d refer respectively to sublimation and diffusion processes.

In the kinetic equation, account was taken of the change in the thickness of the oxide layer x due to oxidation in accordance with the parabolic law (the first term) and the sublimation of the oxide WO_3 (the second term). The first term on the right-hand side of the heat balance equation describes the absorption of the laser radiation, the second term describes the heat losses caused by heat exchange with the surrounding medium, the third describes the evolution of energy in the reaction, and the fourth describes the loss of energy in sublimation. Analysis shows that there may be a limiting cycle on the phase plane of such a system, corresponding to the auto-oscillatory laser-induced combustion regime. The transitions between different regimes, for example, the trigger and auto-oscillatory regimes, can be achieved by altering the target parameters (mass, thickness) and the power of the incident laser radiation. All the regimes predicted by the theory—passive, latent, trigger, and auto-oscillatory—have been observed experimentally.

A model analogous to that defined by Eqn (24) can be used for the description of the laser-induced oxidation of molybdenum. In this case, the oxide MoO_3 at $T > 800$ °C is in the liquid phase and intense evaporation takes place from the surface of the liquid. The kinetic equation has the same form as Eqn (24), but for molybdenum $T_d < T_s$. The heat balance equation also retains its form, but the quantity W in it has the significance of the difference between the heat of the oxidation reaction and the heat of fusion. For MoO_3, this difference is negative ($W < 0$). Accordingly, the auto-oscillations are significantly associated with the presence of the MoO_3 melt. Experiments[57] confirmed the presence of the auto-oscillatory regime in the oxidation of molybdenum. The oscillations proved to be extremely stable and were observed for a long time— sometimes more than an hour. Part of the experimental oscillogram is presented in Fig. 8.

The oscillatory reactions examined are fairly simple from the standpoint of kinetics, being described by a single differential equation. As the kinetics become more complex, whereupon parallel or consecutive reactions arise, the oscillatory oxidation regimes can change similarly. An example is provided by the catalytic heterogeneous oxidation of ammonia in air on the surface of copper oxide and under the influence of the radiation of a CO_2 laser. The increase in the complexity of the oscillations, occurring apparently via a cascade of bifurcations associated with the doubling of the period, has been observed experimentally.[62]

An increase in the complexity of oscillations also takes place when the problem is transformed into one of the distributed type, i.e. under conditions where radial heat conduction phenomena play a significant role. Thus the transition from the stationary regime in the combustion of titanium to a stochastic regime on changing the conditions in the focusing of the laser radiation onto the surface of the specimen has been demonstrated.[63]

The nature of the complex oscillatory combustion regimes is determined to a large extent by the nature of the metal. We shall consider the case of tungsten. Suppose that the surface of a thin tungsten plate with a radius R is heated by a beam of laser radiation in which the intensity is distributed over the cross-section in accordance with the expression

$$I(r) = I_0 \exp\left(-\frac{r^2}{r_0^2}\right).$$

In contrast to Eqn (24), it is now necessary to take into account also the effects of radial heat conduction in the heated specimen. In the limit where $r_0 \gg R$ and the characteristic spatial scale of the changes in the variables is large compared with R, the effects of heat conduction are evidently insignificant. In conformity with the theory of nonlinear oscillations, there is then a possibility either of the attainment of stationary states or of simple auto-oscillations, depending on the radiation intensity. Such phenomena were discussed above.

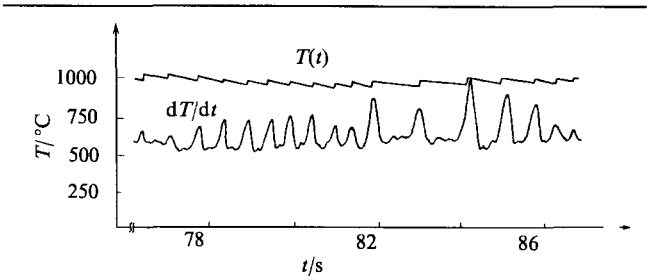

Figure 8. Experimental oscillogram of the $T(t)$ and dT/dt signals in the auto-oscillatory oxidation of molybdenum.[57]

Heat conduction and the nonuniformity of the radiation field lead not only to a quantitative but also to a qualitative change in the process dynamics. We shall fix the power of the radiation $P = \pi r_0^2 I_0$ and shall vary the focusing (i.e. the beam radius r_0) on the surface of the specimen. Numerical analysis leads to the following findings.[64]

In the first place, the presence of the simplest types of attractors—stable stationary states—was established. By virtue of the nonuniformity of the radiation field, the temperature $T(r)$ and the thickness of the oxide $x(r)$ are also found to be nonuniform and $x(r)$ may prove to be a nonmonotonic function of the coordinate r. With increase in the radiation beam radius r_0, the simplest nonstationary ordering arises. This is the limiting cycle S^1, corresponding to the situation where during the period of the oscillations the temperature $T(r, t)$ and the thickness of the oxide $x(r, t)$ reach a maximum once. The process is localised in a region of the order of magnitude of the size of the beam. On further increase in r_0, the dynamics become more complex—cycles S^n are generated corresponding to the situation where in the course of one period the number of local maxima reaches n, with $n > 1$. The increase in complexity takes place as a consequence of consecutive bifurcations associated with the doubling of the period as r_0 increases. This is followed by a range of values of r_0 to which stochastic regimes of different complexity correspond. Fig. 9 presents a diagram illustrating the change in the dynamic regimes as the parameters of the radiation are altered.

We may note that, apart from the complex oscillatory regimes examined above, the model under discussion describes the appearance of rotating spiral waves (reverberates) similar to those observed in the Belousov–Zhabotinskii reactions. Fig. 10 presents examples of the profiles of the temperature field in the form of single- and two-arm spirals rotating around the radiation beam axis. In the laser-induced heating of metals, such rotating structures are observed fairly frequently.

Another mechanism for the increase in the complexity of the dynamics operates when metals of the type of titanium are heated.

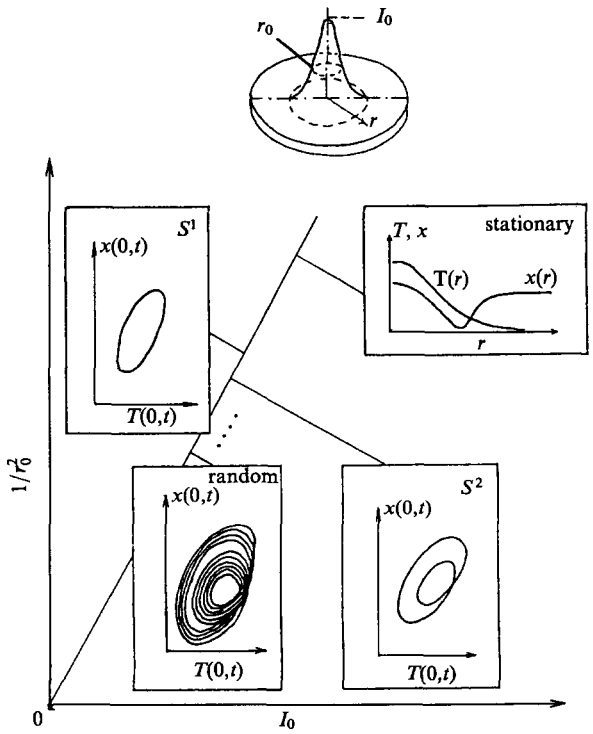

Figure 9. Dependence of the metallic target (tungsten) combustion regime on the beam radius r_0 for a fixed total power of the radiation $P = \pi r_0^2 I_0$.

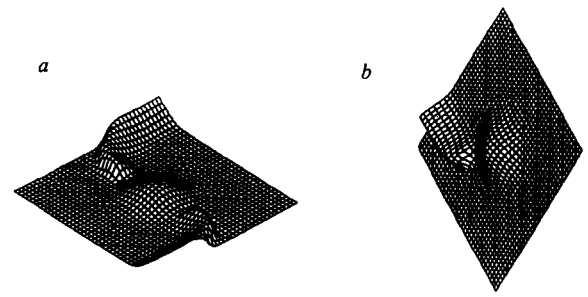

Figure 10. Rotating two-arm (*a*) and single-arm (*b*) spiral temperature field waves for nonuniform laser-induced heating of tungsten.[65]

It is determined by the transport of reactants or reaction products in the gaseous medium surrounding the heated specimen.[66] During the oxidation of the metal, oxygen is removed selectively from the surrounding medium, so that in the vicinity of the target surface the rate of reaction diminishes owing to the deficiency of the oxidant. There is a corresponding decrease also in the rate of consumption of oxygen. As a result of diffusion, its concentration increases again, the reaction is accelerated, and the process is repeated. The foregoing illustrates the possibility of the appearance of auto-oscillatory combustion regimes owing to the diffusion transport of the reactant (oxidant) in the gaseous medium.

Finally, yet another mechanism of the increase in complexity, qualitatively similar to the previous one, is induced by the diffusional transport of reactants through the layer of the oxide.[67] Other heterogeneous reactions with auto-oscillations have also been observed and other mechanisms of auto-oscillations, associated, for example, with the formation of oxide nitrides, the dissolution of scale, etc., have also been observed.

4. Laser-induced reduction

We have examined the dynamics of heterogeneous thermochemical processes due to the presence of a positive feedback between the chemical and thermal degrees of freedom of the system. Such a feedback was generated by the increase in the absorptance of the test substance or in the evolution of energy in the reaction. The opposite situation is one where a negative feedback is established on decrease in the absorptance of the substance or for a negative heat change (endothermic reaction). We shall consider the dynamics of systems with a negative feedback in relation to the reduction of metal oxides to the metals under the influence of laser radiation. In such a system, the negative feedback is established by virtue of the decrease in the absorptance of the test substance from A_{ox} (absorptance of the oxide) to A_m (absorptance of the metal). We have $A_{ox} > A_m$, which leads to a decrease in the energy introduced into the test substance and to a lowering of the heating rate.

We shall illustrate the characteristic features of the dynamics of the reduction reaction in relation to the laser-induced heating of a thermally thin specimen of oxidised metal. This problem is described by the heat balance equation

$$mc_1 \frac{dT}{dt} = PA(x) - P_l(T), \tag{25}$$

and the kinetic equation

$$\frac{dx}{dt} = d\exp\left(-\frac{T_d}{T}\right), \tag{26}$$

where x is the thickness of the layer of metal produced by the reduction process. For an absorptance $A(x)$, one can assume that

$$A(x) \simeq A_{ox}(1 - \beta x), \qquad \beta x \ll 1. \tag{27}$$

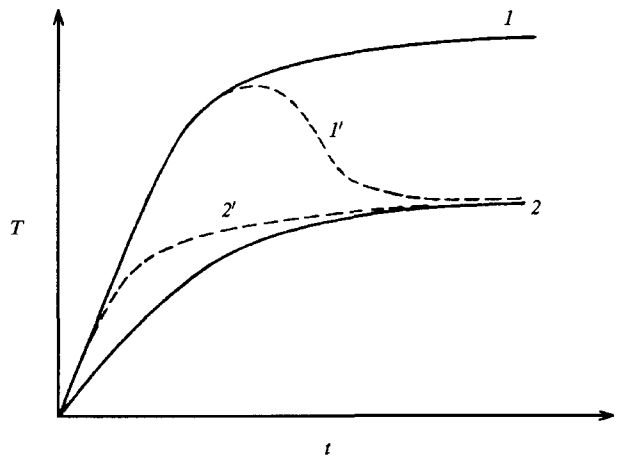

Figure 11. Time variation of the temperature of the specimen for $A(x) = A_{ox}$ (curve *1*) and $A(x) = A_m$ (curve *2*). (*1'*) activated reduction regime; (*2'*) nonactivated reduction regime.

For larger values of x, we have $\beta x \simeq 1$ and we can use the relation

$$A(x) \simeq \frac{x_0}{x}, \tag{28}$$

where x_0 is a characteristic scaling factor. In the reduction of Cu_2O to metallic copper, $x_0 \simeq 15$ Å and Eqn (28) fits satisfactorily the exact relation in the range of copper film thicknesses 50 Å $< x <$ 1000 Å. Fig. 11 presents curves illustrating the variation of the temperature of the specimen for two constant absorptances — corresponding to the pure oxide and the pure metal. In the reduction of the specimen, its heating begins in the state of the pure oxide, i.e. the specimen temperature follows initially curve *1* corresponding to the greater absorptance of the oxide. In the concluding state of the process, laser radiation acts on metallic film (complete reduction) and the temperature $T(t)$ should therefore tend asymptotically to curve *2* (heating of the pure metal). If the heating rate is high (large power of the radiation), the reaction begins in the early stages of the process. The transition from curve *1* to curve *2* takes place for a monotonic increase in temperature (curve *2'*). For slow heating, the reaction is unable to develop appreciably during the characteristic time of the establishment of the quasi-stationary temperature, so that heating takes place for a long time along curve *1*, the departure from it (curve *1'*) occurring at fairly late stages of the process. This in fact explains the nonmonotonic temperature variation for low powers.

The results of the direct numerical integration of Eqns (25) and (26) for the reduction of the lower oxide of copper to the metal under a hydrogen atmosphere are presented in Fig. 12.

We may note that in the laser-induced reduction the effects of heat conduction and of the nonuniformity of the heating process lead, as in the combustion processes discussed above, to changes in the dynamics.

There are numerous experimental situations where feedback channels of different signs exist simultaneously. For example, we have the negative feedback due to the change in absorptance and the positive feedback due to the exothermicity of the reaction. Such a situation is typical for the surface synthesis of titanium nitride on heating a titanium target in a nitrogen atmosphere with exposure to continuous IR radiation. In this case the chemical reaction may be a self-stabilising process for one set of parameters or a process with inflammation or thermochemical instability for another set. Such a combination of processes makes it possible to explain different complex transient pulsations in the heating rate which are not linked directly to the change in the power of the laser radiation, or, for example, to the interference oscillations in the absorption.

V. Physicochemical processes in the laser heating of liquids

We have considered hitherto processes in gaseous media or at solid–gas interfaces. Thermochemical processes initiated by laser radiation in a liquid are also of considerable interest.

1. Thermoelectrochemical instability in the laser-induced heating of absorbing electrolytes

Technologies based on the laser stimulation of electrochemical processes at conducting support–electrolyte solution interfaces have developed vigorously in recent years.[69,70] In the absence of laser radiation, such processes are the concern of classical electrochemistry.[71] The fundamental characteristic of electrochemical processes under equilibrium conditions is the electrochemical potential φ defined by the Nernst formula

$$\varphi = \varphi_0 + \frac{RT}{z_i F} \ln\left(\frac{a_i}{a_m}\right), \tag{29}$$

where z_i is the charge of the potential-generating ion and a_i and a_m are respectively the activities of the ion and the metal.

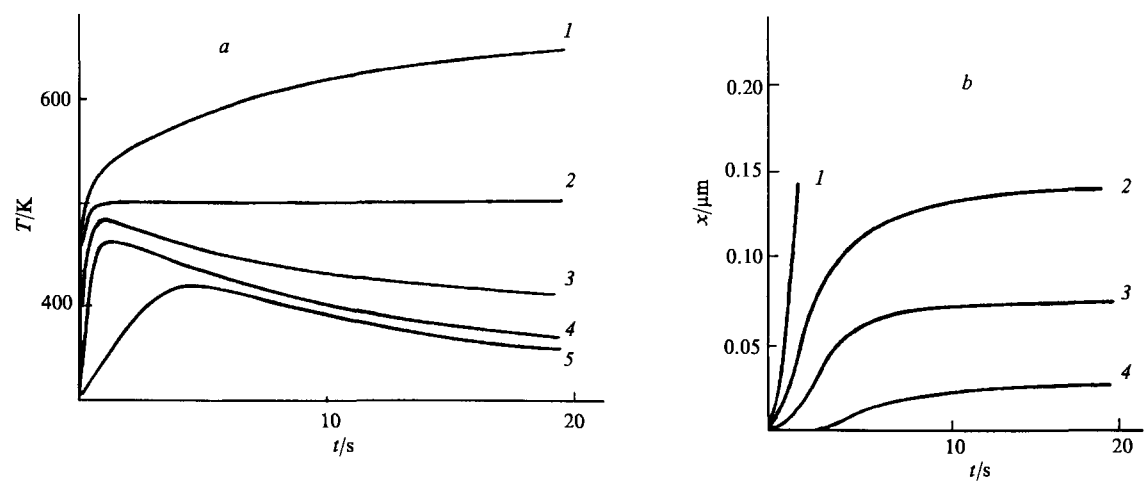

Figure 12. Variation of the temperature (*a*) and thickness of the copper layer (*b*) during its formation by the reduction of Cu_2O under a hydrogen atmosphere:[68] target mass 50 mg; target area 0.4 cm^2; continuous-wave CO_2 laser; power of the radiation (W): (*1*) 42; (*2*) 21; (*3*) 10; (*4*) 5; (*5*) 1.

The hierarchy of the electrode processes depends on the positions of the substances in the series of standard electrode potentials φ_0. For example, in order to precipitate from solutions metals which lie to the left of the material of the support in the above series, it is necessary to apply an external potential U exceeding the corresponding difference between the electrode potentials. However, the laser-induced precipitation of metals can take place in the absence of an external potential (see, for example, von Gutfeld[70] and Bunkin et al.[72]). Von Gutfeld[70] put forward the idea that the precipitation takes place under the influence of the e.m.f. of a microvoltaic cell associated with the temperature variation of the electrode potential $\varphi = \varphi_0(T)$. It was found[73] that the e.m.f. of the voltaic concentration cell associated with the local changes in the activity a_i of the potential-generating ions in solution also makes a comparable contribution. The change in activity is in its turn correlated with the change in the concentration of ions in solution as a result of thermal diffusion during nonuniform laser-induced heating.

We shall now discuss the characteristic features of the laser-induced heating of absorbing electrolytes. The absorption bands of the ionic complexes in solutions are fairly broad, but they are nevertheless well separated in many cases. At the radiation wavelengths in the vicinity of the absorption maximum of the corresponding complexes, the heating rate of the solution is determined mainly by their concentration. For example, in aqueous $CoCl_2$ solutions, the Co^{2+} absorption maximum corresponds to a wavelength of 510 nm,[74] whilst in aqueous $CuSO_4$ solutions the Cu^{2+} absorption maximum is at 800 nm. The sign of the thermal diffusion constant in solutions is such that positively charged metal ions migrate as a rule from the less heated to the more heated region. In nonpolar solvents with such a value of the thermal diffusion constant for the absorbing component of the solution, a positive feedback arises between the thermal and concentration degrees of freedom, which leads to thermal diffusion instability[75] analogous to the thermal diffusion instability in gases.[19] In electrolyte solutions, the development of thermal diffusion instability is complicated by the electrical interaction between the ionic complexes. Furthermore, the change in the distributions of the thermal and concentration fields entails a change in the distribution of the electrochemical potential. Therefore a thermal electrochemical instability may develop in electrolyte solutions.[76] It consists in an avalanche-like increase in the electrochemical potential.

Experimental studies have shown[74,76] that there is a range of parameters in which nonstationary changes in the electrochemical potential are observed: from simple and quasi-harmonic to complex stochastic oscillations. The oscillations are complicated by the cascade of bifurcations associated with the doubling of the period and by the increase in the complexity of the form of the limiting cycle (Fig. 13). A similar qualitative result was obtained in a theoretical study of the purely thermal diffusion instability in a mixture of gases.[39]

The spatially nonuniform distribution of the electrochemical potential on the surface of a metallic support coated by a layer of electrolyte solution leads to the formation of a microvoltaic cell, which permits electrochemical etching and precipitation.[70,74] Thus a microvoltaic cell with an e.m.f. of ~ 0.6 V can be induced with the aid of a CW YAG-laser having a power up to 50 W. The size of the cell amounts to tens of micrometers and the precipitation current density reaches ~ 1 A cm^{-2}, which is higher by several orders of magnitude than the values used in traditional electrochemistry. The laser-induced microvoltaic cell therefore permits the establishment of high-speed and at the same time low-temperature ($T < 373$ K) regimes in the laser treatment of conducting surfaces. This is of significant technological interest.

High-speed laser processes in the liquid-phase treatment of semiconductor surfaces can be achieved similarly. For this type of laser treatment, the use of the pulsed-periodic radiation of a copper vapour-based laser proved the most effective. Under these conditions, high rates of the photogeneration of electron–hole pairs in the semiconductor and fairly high temperature gradients in the electrolyte solutions are also ensured simultaneously. The formation of a microvoltaic cell is due in this case to the semiconducting nature of the support. Calculations have shown[77] that, in the deposition of metals on the surface of gallium arsenide, a microvoltaic cell with an e.m.f. of ~ 0.5 V is formed mainly due to the Dember effect (i.e. due to the appearance of an e.m.f. as a consequence of the separation in space of the charges of electrons and holes) and the thermo-e.m.f. in the semiconductor, the Dember effect making the main contribution ($\sim 75\%$).

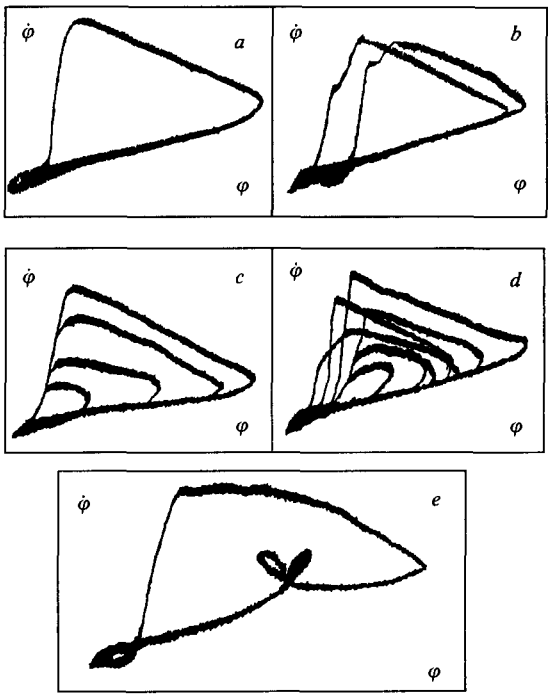

Figure 13. Phase portraits in terms of the variables φ, $\dot{\varphi}$ on the screen of an oscilloscope with a memory, obtained during the heating of an aqueous $CuSO_4$ solution by the radiation from a continuous-wave YAG-laser: (*a*)–(*d*) changes in the phase portrait as a result of the bifurcations involving the doubling of the period as the power of the laser radiation is varied; (*e*) increase in the complexity of the form of the simple limiting cycle (appearance of an additional 'small loop') as the beam width and the solution concentration are varied.

2. Dissipative structures in the laser-induced heating of thin layers of liquid

When the intensity of the laser radiation is insufficient for the bulk-phase ebullition or surface evaporation of the liquid it does nevertheless excite in the latter surface and bulk-phase hydrodynamic flows. These flows are caused by the convective instability of the nonuniformly heated stationary liquid.

Such convective flows play an important role in laser-induced thermochemical processes associated with the initiation of thermochemical and thermoelectrochemical reactions in solutions and also in processes associated with the formation of a melt on the surface of the test substance in the synthesis of surface compounds.

There exist several mechanisms for the influence of 'laser convection' on reaction kinetics. The rates of many processes in solutions are limited by the rate of supply of the reactant to the reaction zone. Initiation of convective flows promotes the removal of diffusional limitations and the acceleration of both pyrolytic and electrochemical reactions. In absorbing solutions, the situation is more complex because hydrodynamic flows are involved directly in the establishment of different feedbacks between the thermal and other degrees of freedom of the system. In particular, the eddies in the convective flows under the

conditions of nonuniform laser heating of the liquid can greatly intensify the effects of the thermal diffusion separation of the solution similarly to the situation arising in gas thermal diffusion columns with a heated filament in the centre. The hydrodynamic intensification of the separating effect can be characterised by the 'rate of rotation' of the convective eddy in the region of the separation of the test substance during the activation of the thermal diffusion instability. For example, according to Bunkin et al.,[78] the velocity of the convective streams initiated during the laser-induced heating of an aqueous $CuSO_4$ solution by the radiation of a continuous-wave YAG-laser with a power of 5–30 W is 1–30 cm s^{-1} and the rate of rotation of the eddy reaches $\sim 10^3$.

The 'hydrodynamic' feedback between the distributions of the temperature and concentration in the presence of laser-induced convection is established as follows. The increase in temperature gradient in the liquid increases the Rayleigh number. As the latter increases, the effectiveness of the thermal diffusion separation rises, as a result of which the region acted upon by the laser radiation is enriched in the absorbing ions. This increases the temperature gradient in the liquid, and so on. Experiments[73] showed that the effective thermal diffusion coefficient in the system acted upon by the laser radiation can reach values of $\sim 10^{-2}$ cm^2 s^{-1}. This exceeds by three orders of magnitude the molecular thermal diffusion coefficient of the ions in an electrolyte solution.

However, for large Rayleigh numbers (Ra > 5000), turbulence develops, leading to a sharp increase (by five orders of magnitude) in the effective normal diffusion coefficient, as a consequence of which the enriched region rapidly 'dissipates' and the homogeneity of the solution is restored. According to this scenario, auto-oscillations of the electrochemical potential, accompanied by the formation of bubbles and by the ebullition of the solution, may arise.

The development of hydrodynamic and thermal diffusion instabilities is accompanied in many instances by the formation of structures on the surface of the liquid differing from the familiar structures of the type of Benard or Marangoni cells. Among them, structures with a disturbed axial symmetry are of special interest. The appearance of such structures in a layer of a V_2O_5 melt during the laser-induced oxidation of vanadium in air has been noted.[79] It has been shown[80] that, on exposure to the continuous radiation of a YAG-laser with a power up to 150 W, there are three qualitatively different types of structures with a disturbed axial symmetry and three different scenarios for the increase in their complexity as the parameters of the laser radiation are altered (Fig. 14).

In wide beams (Fig. 14*a*), the formation of rotating spiral waves, the number of arms of which varied in the course of the oxidation process (with increase in the thickness of the fused layer of the oxide V_2O_5), has been observed. In the later stages of the oxidation process, the arms of the spiral closed, forming a stationary cellular structure. The rate of rotation of the spiral wave was 0.25–0.3 rev. s^{-1}. In beams having diameters of moderate size (Fig. 14*b*), stationary radial arms appeared, their number increasing as oxidation proceeded. Finally, following sharper focusing (Fig. 14*c*), a reverberator arose—a circular diffuse spot from which hot protuberances broke away periodically, rotating in one direction or another.

The effects observed in experiments[79,80] can be qualitatively explained as follows. During nonuniform laser-induced heating, surface flows arise in the liquid owing to the Marangoni effect together with bulk-phase flows associated with the instability of the radially and nonuniformly heated liquid. As a result, a flow with toroidal symmetry is initiated in the liquid layer, the flow rate becoming zero on the surface of the solid metal. This flow is analogous to the Couette flow between two rotating cylinders closed to form a torus. At certain rates of rotation of the cylinders, Taylor instabilities may develop in the Couette flow, as a result of which toroidal Taylor eddies arise along the entire length of the cylinder at regular intervals. The wave vector k of the resulting structure is then directed at a nonzero angle relative to the vector

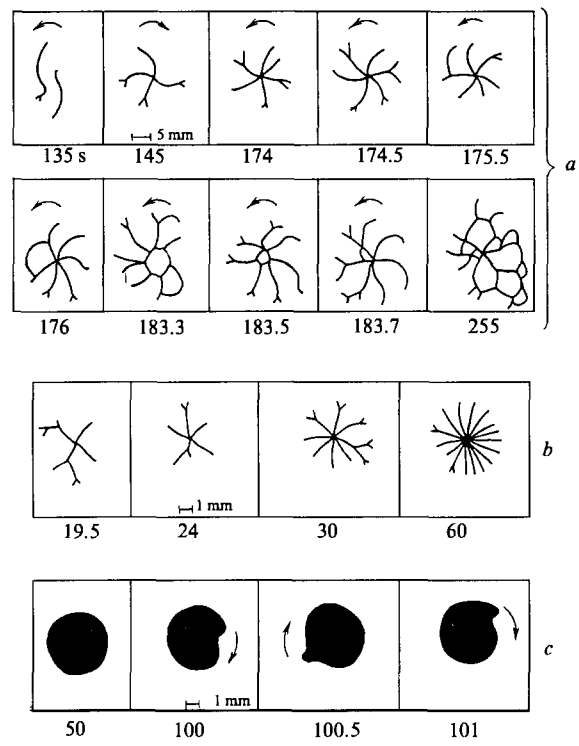

Figure 14. Dynamics of the variation of the thermal field during the heating of vanadium in air by the continuous radiation of an YAG-laser:[80] power of the laser 150 W; lines are streams of V_2O_5 melt at an elevated temperature; (*a*) wide beam 24 mm in diameter; (*b*) medium beam 18 mm in diameter; (*c*) focused beam 12 mm in diameter. The arrows in figures *a* and *c* indicate the direction of rotation of the structures and the numerals represent the times elapsed since the instant when the laser was switched on (seconds).

of the linear rate of rotation of the cylinders. For the geometry of the experiments considered, such instabilities lead to the loss of axial symmetry and to the appearance of isolated radial arms of the flow. In order that the structure obtained should rotate, the imaginary part of the increment at the instant of the loss of stability by the primary flow should be nonzero.

It has not so far been possible to create computer models of three-dimensional nonstationary structures in hydrodynamic streams, based on a direct numerical solution of hydrodynamic equations. For this reason, phenomenological or simplified models, obtained from hydrodynamic equations subject to certain assumptions, are frequently considered. Such are, for example, the Swift–Hohenberg, Kuramoto–Sivashinskii, etc. equations. The spiral waves of the type considered above are described satisfactorily by the phenomenological Arnol'd–Kirichenko equation:[81]

$$\frac{\partial w}{\partial t} = \left[\beta - A\left(k_r^2 + \frac{\partial^2}{\partial r^2}\right)^2 - 2C\left(k_r^2 + \frac{\partial^2}{\partial r^2}\right)\left(k_\varphi^2 + \frac{\partial^2}{\partial \varphi^2}\right) - \right.$$

$$\left. - B\left(k_\varphi^2 + \frac{\partial^2}{\partial \varphi^2}\right)^2\right] w + aw^2 - w^3 , \qquad (30)$$

where w is the order parameter having the significance of the deviation of the temperature from its value in the equilibrium homogeneous state, β the parameter of the supercritical state, r and φ are polar coordinates, and A, B, C, k_r, and k_φ are constants.

Numerical analysis of Eqn (30) makes it possible to describe various spatially nonuniform structures arising on development of thermocapillary instability in a thin layer of liquid. Some examples of such structures are presented in Fig. 15. The results of the calculations (Figs 15*a* and 15*b*) describe qualitatively

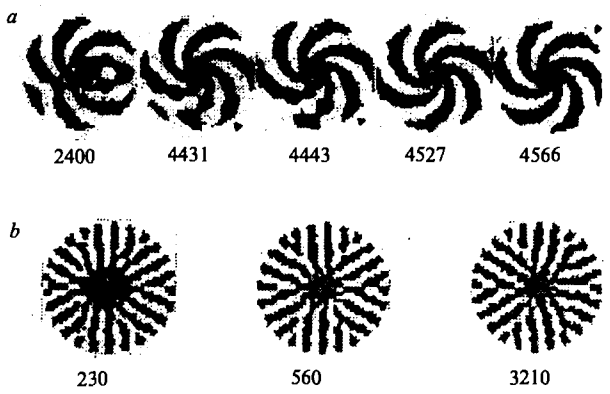

Figure 15. Two-dimensional structures found in the numerical solution of Eqn. (30) for different values of the parameters and different initial conditions (the numerals represent dimensionless times).[81]

correctly the experimentally observed structures (Figs 14*a* and 14*b*). We emphasise that the nonuniformity of the heat source is important for the appearance of these structures. This distinguishes them, for example, from the spiral waves in the Belousov–Zhabotinskii reactions arising in an initially homogeneous system.

VI. Some technological applications

1. Processes with participation of the gas phase: laser-induced precipitation and etching of a substance, separation of gases, and the synthesis of powders

The self-organisation phenomena considered above frequently lead to undesirable technological consequences. Processes with feedbacks due to the heat of a chemical reaction and the change in absorption are most dangerous in this respect. The few examples of a useful effect of the self-organisation phenomena (of the type of self-organising disequilibrium in the polyimide formation and the sharpening and localisation effects discussed above) merely emphasise the validity of the foregoing.

In addition, the dynamics of processes in the field of IR radiation are significantly more complex than in the field of radiation in the visible and UV regions. Therefore the application of the IR lasers such as the CO_2 or CO lasers is in many cases ineffective despite their great technological sophistication and excellent energy parameters. As a result of this, lasers working in the visible and UV ranges, primarily argon and excimer lasers, are mainly used in modern technologies.

Thus in order to achieve stable thermochemical processes, it is necessary to eliminate effects due to the concentration-induced change in absorption, laser radiation in the visible and UV ranges and thermally neutral or even endothermic reactions should be used, and the chemical reaction should be carried out in a region the size of which should not exceed the characteristic scale of unstable perturbations, i.e. a focused laser beam with a diameter not exceeding tens and sometimes even a few micrometers should be employed.

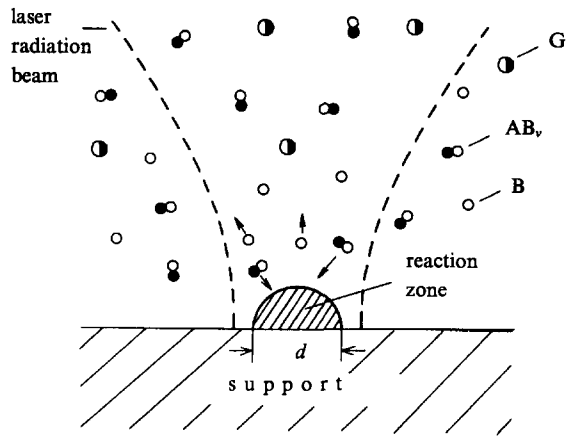

Figure 16. Typical geometry of the irradiation zone in experiments on the laser-induced deposition of a substance from the gas phase ($d = 2r_0$).

Virtually all these requirements are met in the modern technology for the laser-induced precipitation of a substance from the gas phase.[82,83] In the literature this process is frequently designated by LCVD (from the English language term Laser-induced Chemical Vapour Deposition). This technology is already used by a number of companies for the solution of certain problems in microelectronics, integrated optics, etc. and the processes achieved are indeed distinguished by their stability and by the high quality of their technological characteristics.

However, feedbacks cannot be fully excluded from laser-stimulated chemical processes. In the case of LCVD, the main cause of the disequilibrium is high temperature gradients (up to 10^6-10^7 K cm^{-1}), which lead to the interaction of different flows.

In many experiments on LCVD, the gas mixture is transparent to the laser radiation, while the deposit is thermally thin. A simplified scheme of the irradiation zone is illustrated in Fig. 16. The gas pressure usually selected is, on the one hand, not too great to avoid the appearance of an intense eddy convection in the gravitational field, and, on the other, is not too small to make sure that the thermal jump at the solid–gas interface is negligible. Typical ranges of pressures, temperatures, and activation energies for certain LCVD reactions are presented in Table 2.

In many instances, the LCVD process can be represented by the unimolecular decomposition reaction

$$AB_\nu + G \rightarrow A\downarrow + \nu B\uparrow + G, \qquad (31)$$

where AB_ν is a molecule of the gas being decomposed, G a molecule of the diluent gas, A a molecule (atom) of the substance forming the solid deposit, B a molecule of the gaseous fraction of the reaction product, and ν a stoichiometric coefficient. The processes involving the formation of solid carbon in the pyrolysis of methane and other hydrocarbons and the deposition of silicon on pyrolysis of monosilane may serve as examples of

Table 2. Activation energies for certain reactions involving the deposition of material from the gas phase at high temperatures.[83]

Reaction	T/K	Pressure range in mixture/mbar	ΔE/kJ mol^{-1}
$C_2H_2 + H_2 \rightarrow 2C\downarrow + H_2\uparrow + H_2$	1900–2450	50–1000	197.7±0.6
$C_2H_4 + H_2 \rightarrow 2C\downarrow + 2H_2\uparrow + H_2$	2000–2250	300–1000	242.7±1.3
$C_2H_2 + H_2 \rightarrow 2C\downarrow + 3H_2\uparrow + H_2$	2200–2250	300–1000	495.4±2
$CH_4 + H_2 \rightarrow C\downarrow + 2H_2\uparrow + H_2$	2850–3100	500–1000	180.8±1.4
$SiH_4 + H_2 \rightarrow Si\downarrow + 2H_2\uparrow + H_2$	1000–1800	10–1000	183.9±4

type (31) reactions. The elementary rate J of such reactions is described by the unimolecular decomposition law

$$J = k_0 N c_s \exp\left(-\frac{\Delta E}{k_B T_s}\right), \quad (32)$$

where N is the total density of the molecules in the gas, c_s the concentration of the substance AB_ν on the surface of the deposit, ΔE the activation energy for the chemical reaction, k_0 the pre-exponential factor, k_B the Boltzmann constant, and T_s the temperature of the surface. At low temperatures, the concentration of the substance AB_ν is virtually identical throughout the volume (kinetic region). At high temperatures, the rate of formation of the deposit is determined by the rate of supply of the reactant to the reaction zone (diffusional region) rather than by the rate of the elementary step involving the chemical decomposition of the molecules.

The diffusional rate limitation effect can be clearly observed in LCVD processes.[83] However, its manifestations are qualitatively different for equimolecular ($\nu = 1$) and nonequimolecular ($\nu \neq 1$) reactions. Among the reactions listed in Table 2, only that involving the deposition of carbon in the decomposition of acetylene is equimolecular.

The characteristic features of the kinetics of equimolecular reactions are determined mainly by factors such as the temperature dependence of the density and the diffusion coefficient, the existence of a thermal diffusion flux of the substance, and the presence of a diluent gas. On the other hand, the nonlinearity caused by the diffusional thermal effect as well as the concentration- and temperature-induced changes in the thermal conductivity are insignificant. In particular, thermal diffusion can lead to large (of 1–2 orders of magnitude) quantitative differences in the rate of reaction, depending on the choice of the diluent gas G.[84]

In nonequimolecular reactions, for example

$$Mo(CO)_6 \rightarrow Mo\downarrow + 6\,CO\uparrow ,$$

a directed gas flow (chemical convection) arises owing to the inconstancy of the number of molecules in the gas phase.[85,86] This effect exerts a strong influence on the reaction kinetics. In a theoretical analysis of the LCVD process, the viscosity and the nonisobaric effects are usually neglected and it is also assumed that the specific heats of the medium c_p and c_v as well as the thermal diffusion constant α are invariant. The kinetics of the LCVD process can then be described by a system of three equations: two continuity equations (for AB_ν molecules and for the gas as a whole) and the heat transfer equation (the equation for the thermal conductivity in a moving gas). This model presupposes a series of nontrivial phenomena due to the interaction of the diffusion and convective streams of the test substance. For example, for $\nu > 1$ the convective gas flow is directed away from the surface of the deposit into the bulk of the medium and therefore should seemingly inhibit the reaction. Indeed, at relatively low temperatures of the deposit this is what happens. However, at high temperature, over a certain range of values of the parameter $b = \nu - 1$, the convective flow directed from the reaction zone ($b > 0$) promotes not the retardation but actually the acceleration of the deposition of the substance. For simplicity, we shall assume that there is no thermal diffusion flow. The cause of this result is then the interaction of the flows, which takes place in accordance with the following scheme. Convection itself at $\nu > 1$ prevents diffusion (the displacement flow is directed in opposition to the diffusion flow) and at the same time it promotes the transfer of the more heated gas into the bulk of the medium and hence additional heating of the medium around the deposit. Such heating increases the diffusion coefficient, which entails an increase in the diffusion flux. The overall result is determined by the competition between two effects — the increase in the convective displacement and the increase in the opposed diffusion flux. If this leads to an increase in the concentration of the gas being decomposed in the vicinity of the surface of the support, then, by virtue of the concentration dependence of the rate of diffusion, a positive feedback arises between the concentration and diffusion fluxes.

Analysis shows that, when account is taken of the thermal diffusion flux, a complex system of feedbacks is generated between the convective, diffusion, thermal diffusion, and thermal fluxes. As a result, the overall effect cannot be determined merely on the basis of the principle of the superposition of independent material fluxes.

One of the consequences of the interaction of the fluxes is the possibility of the formation of a diffusion barrier in the vicinity of the zone where the nonstoichiometric reaction takes place.[86] This barrier is overcome by means of thermal diffusion, while ordinary diffusion and convection behind the diffusion barrier transfer the substance in the direction away from the deposit.

Thus the transfer of the test substance, which determines the reaction kinetics under the nonequilibrium conditions typical for LCVD, is complex even in the absence of a change in the absorptance of the substance or additional energy evolution by the chemical reaction itself. High temperature gradients entail effects, which cannot be eliminated, associated with the parametric interaction of different fluxes arising by virtue of the temperature and concentration dependences of the kinetic coefficients.

We have considered hitherto the LCVD process without paying attention to the form of the deposit obtained, actually assuming that it is spherically symmetrical. On the other hand, in many practical applications the spatial distribution of the deposit plays an important role. It is determined by the type of reaction and its conditions. Consider, for example, the laser-induced tungsten deposition reaction

$$WF_6 + 3H_2 + G \underset{k_{se}}{\overset{k_{sd},\,k_v}{\rightleftharpoons}} W\downarrow + 6HF + G . \quad (33)$$

In contrast to the reaction (31), the above reaction is not unimolecular. The forward pathway involves the decomposition of tungsten hexafluoride, which may occur both on the surface (rate constant k_{sd}) and in the bulk phase (k_v). The reverse reaction (etching) takes place on the surface and is characterised by the rate constants k_{se}. Different activation energies correspond to all three pathways, so that different reactions can predominate in different temperature ranges. Furthermore, the reaction rates depend greatly on the partial pressures of the components of the gas mixture. The combination of all these factors actually determines

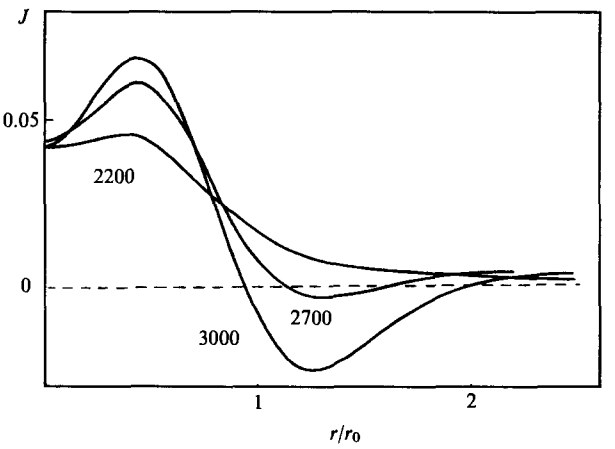

Figure 17. Typical spatial profiles of the deposit formed under the influence of laser radiation under the conditions of the diffusional limitation of the reaction for open surface and bulk-phase deposition reaction pathways and in the presence of the reverse reaction (etching).[83] The numerals opposite the curves denote the surface temperatures along the beam axis (in kelvins).

the form of the deposit produced. If the forward reaction (k_{sd}) predominates, the deposit is well localised within the limits of the radiation zone. On the other hand, if the bulk-phase reaction (k_v) predominates, then tungsten atoms are transported over large distances by diffusion in the gas and the characteristic dimensions of the deposit can appreciably exceed the size of the irradiation spot. As a result of etching, the thickness of the deposit diminishes and this can lead to the formation of a deposited substance profile which is nonmonotonic with respect to the radius. We may also note that the complex form of the deposit may be caused by the diffusional rotation of the transport of reactants in the gas phase as well.[87] Figs 17 presents the results of calculations[88] illustrating the foregoing. The minima on the curve are associated with the etching and/or diffusional limitation. The parts of the curve below the 'zero' level correspond to the etching of the support. The experimental results indicate the validity of the foregoing.[89] Fig. 18 presents photomicrographs of tungsten deposits obtained on decomposition of WF_6 and WCl_6.

Laser deposition from the gas phase is used in microelectronics not only in order to obtain localised deposits but also for the deposition of stripes with the aid of a moving laser source. The so called direct drawing regime is used for this purpose. As an example, Fig. 19 presents photographs of stripes of tungsten deposited by this method on silicon plates. The significant technological characteristics of the deposit are its height and width, conductivity, adhesion to the support, etc. It is fairly difficult to select a laser deposition regime in which the stripes possess the required technological characteristics.

The attempts to use lasers for the deposition of local structures by LCVD methods (for example from the vapours of organometallic compounds) were undertaken as early as the end of the 1960s.[91] However, the results of these studies were in most cases negative — it was not possible to ensure the required technological parameters. During this period, many specialists shared the view that the poor quality of the stripes is mainly caused by the inadequate characteristics of the lasers themselves. Almost fifteen years were needed in order to understand that the 'technological' difficulties have deep physical roots. They are associated with the capacity of nonequilibrium systems to undergo self-organisation.

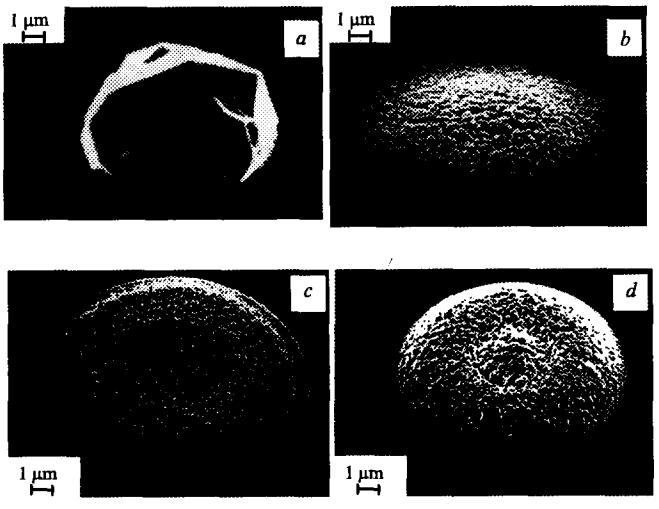

Figure 18. Photomicrographs of tungsten deposits in the decomposition of WF_6 (*a* and *b*) by the radiation of an argon laser (λ = 514.5 nm) and in the decomposition of WCl_6 by the radiation of a dye laser (λ = 680 nm) (*c* and *d*) at different partial pressures and for different irradiation conditions.

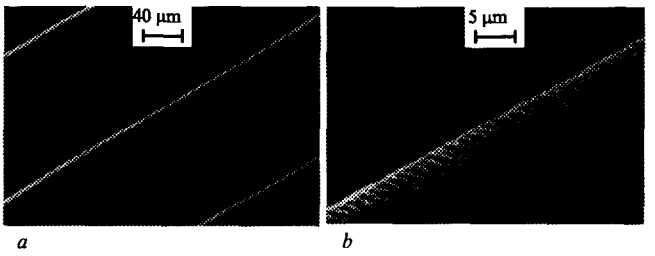

Figure 19. Photomicrographs of tungsten stripes deposited from a $WF_6 + H_2$ mixture on silicon plates under the influence of the radiation from a Kr^+ laser (λ = 647.1 nm).[90]

For a theoretical determination of the form of the deposited stripe it is necessary to solve chemical kinetic equations simultaneously with the equations for the thermal field generated by the moving laser source. In contrast to the problems discussed above, in problems of this kind the negative feedback between the deposition kinetics and temperature, determined by the influence of the form of the stripe itself on the distribution of the thermal field, proved to be significant. Since the thermal conductivity of the metallic stripe is many times greater than the thermal conductivity of the support (particularly a dielectric support), an additional heat flux arises from the irradiation zone towards the side away from the direction of movement of the source. Such outflow of heat is higher the greater the cross-section of the stripe. The presence of such 'geometrical' feedback together with other factors (for example, the change in absorption) leads to numerous instabilities and self-organisation phenomena: the deposits are formed in many cases with an internal structure, with various pulsations in the thickness and width of the stripe, etc.[83] In order to discover the optimum treatment conditions, it is in many cases necessary to employ the methods of the self-organisation theory.

The related problem of the high-temperature laser synthesis of powders from the gas phase is closely associated with LCVD processes. Many refractory compounds (boron nitride and carbide, silicon nitride, the oxides of certain metals, etc.) can be synthesised in the form of finely dispersed powders with particle sizes ranging from tens to hundreds of ångströms if the laser radiation is focused directly in the gas mixture.[92] Such powders have practical applications as abrasive materials and they can also be pressed and sintered in the form of shaped specimens. Examples are provided[92] by the synthesis of silicon carbide powders, i.e.

$$SiH_4 + CH_4 \rightarrow SiC\downarrow + 4H_2\,, \tag{34}$$

or

$$2SiH_4 + C_2H_4 \rightarrow 2SiC\downarrow + 6H_2\,, \tag{35}$$

and also the synthesis of silicon nitride, i.e.

$$4NH_3 + 3SiH_4 \rightarrow Si_3N_4\downarrow + 12H_2\,. \tag{36}$$

The reactions frequently have high activation energies and a high temperature is therefore required to carry them out. There is no special difficulty in attaining a local temperature of several thousand degrees with the aid of lasers. The particles formed in the course of the elementary reactions subsequently coalesce and form clusters. Similar processes have been observed at high temperatures also in the reactions occurring in the laser-induced deposition of a substance.[83] In this case the growth of the deposit is no longer a result of the elementary process (31) considered above, but is due to the transport of clusters in the gaseous medium and their subsequent deposition on the support.

Different mechanisms of the laser-induced nucleation are possible. For example, if the gaseous medium absorbs weakly the laser radiation, the reaction can be initiated first in the vicinity of impurity absorbing centres (impurity species, dust particles, etc.) and can then attain a self-supporting regime due to absorption in the cluster itself. A similar mechanism can operate in the nucleation in LCVD processes.[83]

The kinetics proper of the growth of the cluster constitute a separate problem. The cluster can grow both as a result of 'sticking' to other clusters and as a result of the increase in its intrinsic volume. In particular, if the synthesis on the surface of the nucleus takes place more effectively than in the bulk of the gas, then the cluster may grow via the same mechanism as the deposit in LCVD.

Effects associated with the change in activation energy due to strong surface tension forces play a significant role for microclusters. The physicochemical properties of microclusters differ markedly from those of the corresponding macroformations.[93]

In discussing LCVD processes above, we spoke of molecular mass transfer due to conventional diffusion, thermal diffusion, and chemical convection. By virtue of nucleation, other mass transfer mechanisms are also possible. For example, in the usual (nonlaser) problems of the chemical deposition of a substance, clusters migrate via thermophoresis,[94] as a result of which the particles are expelled from the more heated to the less heated region. It would therefore seem that microclusters should not settle at all on the heated surface. However, experiments have demonstrated an effective flux of clusters onto the heated surface. Direct experimental measurements of the distribution of temperature in the boundary layer over the heated deposition surface[95] showed that, owing to the considerable evolution of energy on coalescence of the microclusters, caused by the decrease in their surface energy, an additional intense heating of the gas takes place in the cluster growth zone. For example, on formation of carbon clusters from hydrocarbons, cluster formation leads to additional heating of the gas regardless of whether the decomposition reaction itself is exothermic or endothermic. This results in the establishment of a nonmonotonic distribution of temperature with a maximum which is separated from the heated wall by 200–500 μm. The temperature at the maximum exceeds by 300–500 K that of the wall itself.[95] As a consequence, a thermophoretic force directed towards the wall is generated. On the other hand, in the case of the laser-induced synthesis of powders, apart from thermophoresis, other forces acting on the particles arise, for example forces associated with the radiometric effect (at low gas pressures), etc.

In nonequimolecular reactions, the force due to the difference between the flux recoil momenta (associated with the chemical convection in the gas) on the 'hot' and 'cold' sides of the particle, also acts on the microparticle. In contrast to thermophoresis and the radiometric force, which expel the particle with the 'cold' side in front, the directional forces associated with the chemical convection depend on the stoichiometry of the reaction. This phenomenon can be properly referred to as 'chemophoresis'. The chemophoretic effect can be readily understood with the aid of the following considerations.

Suppose that a spherically symmetrical particle with a radius R is in a temperature field $T(z)$ with a constant gradient $\gamma = \mathrm{d}T/\mathrm{d}z$. Then the boundary condition for the rate of migration of a gas v on the surface of the particle is

$$v = bc_{AB}k_0 \exp\left(-\frac{T_a}{T}\right), \tag{37}$$

where c_{AB} is the concentration of the substance AB_ν on the surface of the particle, $b = \nu - 1$, and $T_a = \Delta E/k_B$. We shall assume that the reaction proceeds in the kinetic region (c_{AB} = const.). The temperature of the surface of the particle is

$$T = T(\theta) = T_0 + \gamma R\cos\theta, \tag{38}$$

so that the temperature drop across the particle is $2\gamma R$. The component of the gas momentum, summed over the surface, is

$$P_z \simeq Mbc_{AB}k_0 \int_0^\pi \left[2\pi R^2 \sin\theta\cos^2\theta \times \right.$$
$$\left. \times \exp\left(-\frac{T_a}{T_0 + \gamma R\cos\theta}\right)\right]\mathrm{d}\theta =$$
$$= Mbc_{AB}k_0 \exp\left(-\frac{T_a}{T_0}\right)2\pi R^2\varphi, \tag{39}$$

where in the limit $\gamma R \ll T_0$ we have

$$\varphi \simeq \int_{-1}^{1} y^2 \exp(-\xi y)\,\mathrm{d}y = \left(\frac{2}{\xi} + \frac{4}{\xi^3}\right)\sinh\xi - \frac{4}{\xi^2}\cosh\xi,$$

$$\xi = \frac{T_a}{T_0^2}\gamma R.$$

By virtue of the symmetry of the problem, all the remaining components of the momentum (P_x and P_y) become zero. Hence, as a result of the recoil, the particle acquires a nonzero momentum equal to $-P_z$. It is seen from Eqn (39) that the chemophoretic force depends not only on the gradient γ but also on the temperature T_0. Its pressure dependence is therefore different from that of the force due to the radiometric effect and is determined by the reaction kinetics. It is also noteworthy that the chemophoretic force may be considerable.

The laser-induced etching process is closely related to deposition. The etching effects arise when the chemical interaction of the surface atoms of the support (for example, a silicon plate) with the reactive molecules or radicals of the gas phase results in the formation of a more volatile substance (for example, a $SiCl_4$ molecule), which leads to the removal of the solid phase. Chemically reactive molecules can arise in the gas phase on laser-induced thermal dissociation of, for example, halogen-containing gases (for the specific features of such processes, see Karlov et al.[96]). Whilst referring the readers to the original communications as regards the details of this technology (see, for example, Bäuerle,[83] Takai et al.[97] as well as the references quoted therein), we may note that channels with a width and depth ranging from several to several tens of micrometers can be formed in semiconductors, ferrites, and other materials by means of laser-induced chemical etching. The rate of the laser-induced etching can greatly exceed[97] the rate of the plasma-chemical etching[98] usually employed in microelectronics. Apart from the evident applications of the laser-induced etching technology in microelectronics, to which many of the investigations have been directed, this technology can also be employed in micromechanics[99] (preparation of miniature mechanical components, for example, in accelerometers, with dimensions corresponding to several tens of micrometres, etc.).

Among the problems of the kinetics of the laser-induced etching, we may note the diffusional limitation of the reaction (as regards the supply of the etching agent and the removal of the volatile reaction products) similar to that examined above for the LCVD process. In the range of high temperatures, diffusional limitation should restrict the rate of reaction. On the other hand, experiments[97] have shown that the rates of etching are high compared with those which could occur under the conditions of diffusional limitation. One of the explanations of this technologically favourable effect is that, at the high pressures of the gas mixtures used for etching, an intense gravitational convection develops which removes the diffusional limitation.

There exist also purely chemical problems of etching associated with the multistage nature of many reactions and the participation in the latter of intermediate surface products.[100] As in the case of LCVD, further development of the technology of the laser-induced chemical etching requires special research which would make it possible to understand more fully the nature of the process and the possibility of its optimisation.

Laser-induced separation of gases is based on the thermal diffusion effect. In the usual thermal diffusion columns, a heated filament is used as the source generating a nonuniform thermal field.[101] Such a column operates also in the case where the function of the heated filament is assumed by a beam of laser radiation absorbed in the gas mixture. However, as we have seen above, laser radiation can intensify the effect associated with the thermal diffusion separation of the mixture as a result of the positive feedback established between the concentration and thermal degrees of freedom of the system. In the usual thermal diffusion column, convection in the gravitational field plays an

important role in intensifying the separation effect.[101] Laser radiation can enhance also this convective effect as a result of the positive feedback between convection, thermal diffusion, and the heat evolved. The existence of different kinds of positive feedbacks renders the separation of the gas mixture in a laser thermal diffusion column more effective than in the usual column. This has been confirmed by direct experiments.[102]

2. Processes at the interface between two solid phases: direct drawing, etching, and synthesis

The action of laser radiation on the surface of a solid on which films of other solids have been deposited leads to the modification of the properties of the film and/or the surface of the solid (support). With the aid of such solid-phase sandwich structures, it is possible to achieve virtually all types of microchemical treatment of the surface: deposition of metals, etching of the surface, syntheses of various compounds on the surface of the support. One is dealing with a solid-phase microtreatment technology which is an alternative to the traditional technologies (plasma, gas-phase, and liquid-phase technologies).

Certain metal salts, for example those of formic and oxalic acids, readily decompose on heating to the pure metal and volatile components. The decomposition of copper formate may serve as an example:

$$Cu(HCOO)_2 \rightarrow Cu\downarrow + H_2O\uparrow + CO\uparrow + CO_2\uparrow. \qquad (40)$$

The process temperature under the usual conditions is 598 K. Copper formate is deposited on the surface in the form of a powder or a suspension. The thin surface layer is then acted upon by a laser, which results in the formation of copper stripes on various supports.[91] It is possible to obtain solid films of organic substances by using various solvents, which then volatilise during drying. Metallic stripes, formed from the resinates of various metals,[83] triphenylphosphine complexes of univalent gold,[103] etc. are deposited by this procedure.

The laser-induced decomposition of certain substances, for example poly(vinyl chloride) films, results in the formation of free radicals, chlorine molecules, etc., which can etch the support. Multilayer structures of the support–decomposable film–glass type are used in the experiment. Laser radiation acts from the side of the transparent glass. Under these conditions, one can obtain etched channels in the glass several ångströms deep and several tens of micrometres wide.

The most detailed studies have been carried out on the laser-induced synthesis of substances from thin films.[104,105] Extremely pure compounds of various elements, including compounds of the type $A^{III}B^{V}$ (AlSb, AlAs), $A^{II}V_x^{VI}$ (CdTe, CdSe, ZnSe), $A^{IV}B^{VI}$ ($GeSe_2$, GeSe), ternary compounds ($CuInSe_2$), etc. have been synthesised. This technology can be used to record information on high-capacity optical discs and also in microelectronics and integrated optics.

Many scientific problems are associated with the preparation of compounds from thin-film structures. We shall elucidate some of them in relation to the synthesis of the binary compounds A+B → AB (in particular of AlSb from aluminium and antimony films). Experiments have shown[104] that, when such a structure is heated in an ordinary furnace up to the melting point of aluminium (933 K), about 100 s is required for the formation of the AlSb film. The reason for this is fairly simple: the initial AlSb layer is formed at the site of contact between aluminium and antimony. The melting point of AlSb (1353 K) exceeds the melting points of its constituent elements. The solid film formed therefore separates the components in space. In this case, the rate of reaction is limited by the diffusion of atoms through the layer of AB, as happens in reactions involving the heterogeneous oxidation of metals. On the other hand, under the conditions of pulsed laser action, which heats the film to the same temperature, the synthesis takes place effectively during the laser pulse of 10 ns. If the validity of the estimated temperature is accepted and it is postulated that the formation of the film is limited by diffusion, then this means that the coefficients of the diffusion of atoms through the AlSb layer acted upon by laser radiation should be anomalously high (of the order of 10^{-2} cm^2 s^{-1}). We recall that the phenomenon of the anomalously rapid diffusion first attracted attention in the analysis of the laser-induced annealing of semiconductors.[24,25] Experiments have shown[104] that in the laser-induced synthesis of films there is a threshold energy equal to the energy necessary to fuse aluminium. On the other hand, if the multilayer structure prepared is subjected to preliminary annealing at 623 K for 30 min and longer, then the threshold energy required for the synthesis increases by 60% and corresponds to the melting point of AlSb. The possible explanations of the results of these experiments are as follows: in contrast to experiments in a furnace, exposure to laser radiation does not result in the formation of a planar AlSb layer but instead the liquids are rapidly mixed with subsequent chemical reaction; owing to the heat of the chemical reaction in the film, under certain irradiation conditions, 'inflammation' takes place over a brief period, as a result of which the film of the compound synthesised melts.

The presence of a melt is indicated, for example, by structures of the type of Benard bridges (Fig. 20), which were observed in the synthesis of CdSe and a number of other films. However, there is also evidence that the laser-induced synthesis is accelerated also in the solid phase of the film. It may be that such increased 'permeability' of the solid films is associated with the presence in the latter of non-equilibrium vacancies. This mechanism of the acceleration has been discussed.[38] The experimental results can also be interpreted as the effect of the decrease in the melting point[104] of the solid film presaturated by nonequilibrium vacancies.[104]

Finally, yet another interesting problem, observed in the course of a study of the laser-induced synthesis of thin-film compounds, is that of the presence of large (up to 1 μm, i.e. many times greater than the thickness of the film) single crystals of many compounds (AlSb, $GeSe_2$, $CuInSe_2$, etc.) on irradiation of the initial structure with 10^{-6} s laser pulses. In order to account for these effects, the idea of the 'polymerisation' of liquids, in particular $GeSe_2$, has been put forward.[104] We may note that the rapid crystallisation of films from the melt in the synthesis of compounds differs significantly from the analogous process in the laser-induced annealing of semiconductors, where there is epitaxial growth of the film, for example of silicon, from the melt on an orienting support. In the synthesis of thin-film compounds, there is no orienting support and the crystal nuclei formed are oriented at random. Therefore, in the rapid laser-induced synthesis, polycrystalline or amorphous films should be

Figure 20. Photomicrograph of the convective ridges formed in the synthesis of the CdSe sandwich structure on glass in air;[104] power of the laser 1 W; typical cell size ~10 μm; ratio of the ridge width to thickness ~50.

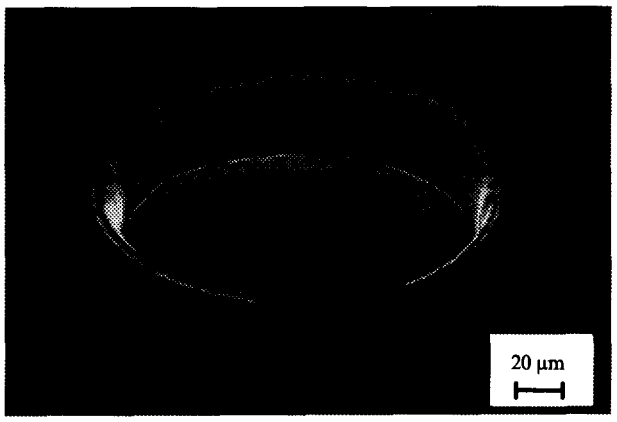

Figure 21. Crater formed in a $LiNbO_3$ single crystal on exposure to a XeCl excimer laser (500 pulses with an overall energy density of 2.7 J cm^{-2}). The half-height diameter of the beam was 175 μm.

observed depending on the rate of cooling, which does in fact frequently occur. On the other hand, the formation of large single crystals during rapid crystallisation on a nonorienting support is possible because of the orienting forces of the external mechanical stresses.[106] One should therefore analyse carefully the experimental conditions in order to eliminate fully the possibility of the generation of such stresses.

Other features of the laser-induced synthesis have also been noted—such as the retention of the high stoichiometry of the compounds obtained, the dependence of the orientation of the synthesised film on the wavelength of the laser radiation observed in certain cases, etc.[104, 105]

3. Laser-induced ablation of polymers

An important aspect of laser chemistry is associated with the phenomenon of laser-induced ablation, i.e. the effect of the removal of material under the influence of radiation, in which the resulting crater contains no traces of the melt or any kinds of mechanical failures (Fig. 21). The properties of the laser-induced ablation make it an attractive procedure for various applications in microelectronics, medicine, and other fields.[107-109]

The laser-induced ablation of polymers is usually carried out with the aid of excimer lasers. The characteristic features of this process are as follows: the existence of an irradiation energy density threshold, the change in the optical properties of the substance in the course of exposure to radiation, a nonequilibrium distribution with respect to the velocities of the products removed.

The existence of the threshold may be due to different causes. One of them is thermal sublimation with a pronounced Arrhenius temperature dependence of propagation of the velocity of the sublimation front.[109] Another cause is the development in the substance of elastic stresses,[107] which must reach critical values necessary for removing a significant amount of mass. Yet another cause may be multiphoton (or stepwise) absorption,[107, 108] which requires fairly high light intensities.

The change in the optical properties of the test substance may be associated both with irreversible processes, for example, with thermochemical or photochemical reactions,[107] as well as reversible processes, for example with the passage of light due to the saturation of the populations of the levels between which the transition responsible for the absorption of light takes place.[110]

The distribution with respect to composition and velocities of the products removed is of great interest.[107] Indeed, the products of the ablation of polymers include both low-molecular-mass fragments (pure carbon, simple organic molecules, and small clusters) as well as fragments with a moderate molecular mass close to that of the monomers (or part of the monomers) of the initial substance. In addition, the removal of large clusters (lumps of the initial polymer) and large carbon particles is observed. The latter is of particular interest in connection with the synthesis[111] of macromolecular carbon C_{60}. In the velocity distribution of products, the equilibrium (Maxwellian) fraction and the fraction comprising nonequilibrium fast particles are clearly differentiated.[107] So far this complex pattern cannot be convincingly explained within the framework of the concept of secondary photolysis or multiphoton absorption.

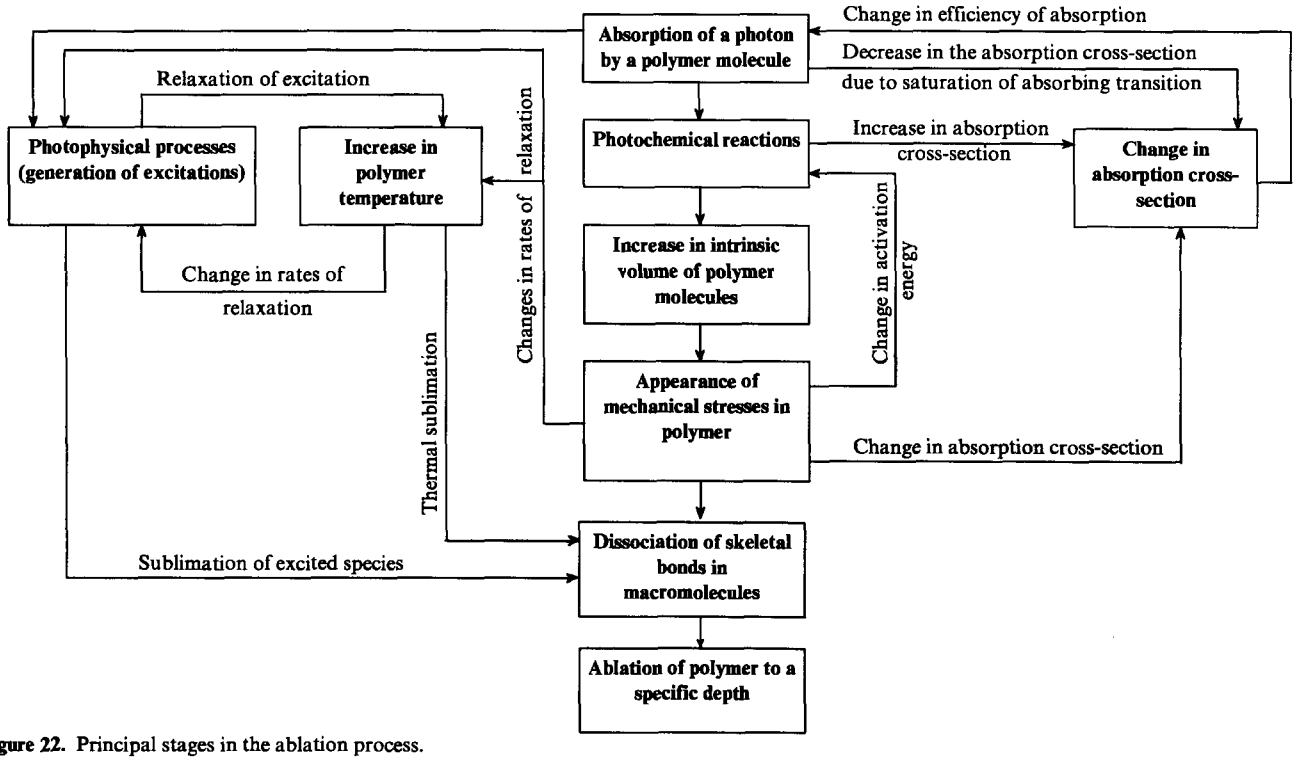

Figure 22. Principal stages in the ablation process.

The data on the dynamics of the development of mechanical stresses in the system and the dynamics of the removal of material during ablation[107] agree better with the thermal sublimation model than with the model involving the photothermomechanical removal, according to which the main bulk of the substance is carried away in the relaxation wave after the operation of the laser radiation pulse has ceased.

The behaviour of species in an electronically excited state plays an important role in the ablation process. The presence of such species in strongly absorbing polymers is not open to doubt.[110] Together with the change in the optical properties,[110] there exist many other pathways by means of which the excited species can affect the kinetics and dynamics of the laser-induced ablation. The sublimation of these species takes place with a reduced activation energy, which permits the assumption of the existence of a cold sublimation regime at a surface temperature below the melting point. Furthermore, such sublimation alters the velocity distributions of the species eliminated.

The characteristic features of the ablation can also be associated with the relaxation process during fusion. In view of the relative slowness of these processes even at temperatures appreciably greater than the melting point,[112] sublimation may be faster than fusion. This probably explains the absence of traces of fusion even at high surface temperatures.

Finally, mention may be made of an important factor associated with the influence of mechanical stresses in the substance on the activation energies of various processes.[113] Such stresses may arise both owing to the usual thermoelasticity and owing to the different volume of the products of the chemical reactions compared with the starting material.[114] Many other factors can also play an important role in the ablation processes. A scheme of the principal stages in the ablation process, similar to that quoted by Kitai et al.,[112] is presented in Fig. 22. Evidently the process is fairly complex and its complete description is almost impossible. Therefore simplified models have to be often used. The most pronounced simplification consists in the fact that the process is assumed to be purely photophysical and of the threshold type, i.e. the entire substance in which the density of the absorbed energy φ exceeds a certain threshold density φ_0 is removed. In this case the thickness of the layer of the substance removed is

$$h = \frac{1}{\alpha}\ln\left(\frac{\varphi}{\varphi_0}\right), \qquad (41)$$

where α is the absorption coefficient for the radiation. This empirical formula reproduces qualitatively the behaviour $h = h(\varphi)$ in the vicinity of the ablation threshold and is therefore frequently used in the analysis of the experimental data (as a rule without justification).

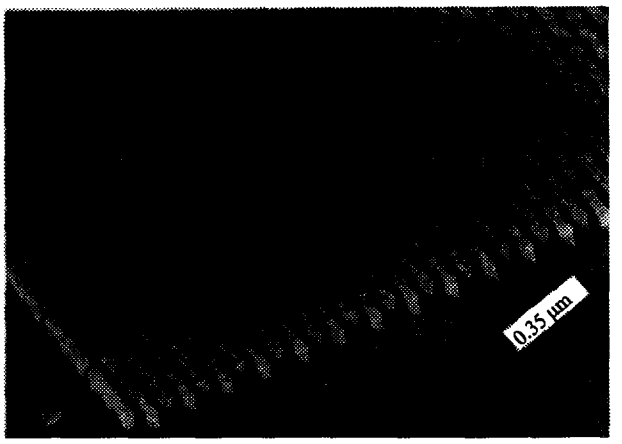

Figure 23. Specimen prepared from a multilayer photoresist with the aid of a KrF laser.[120]

Owing to the large number of positive feedbacks, the laser-induced ablation is characterised by many instabilities and spontaneously generated structures (some of them have been observed experimentally in a number of investigations[115–119]). However, it is possible to select empirically conditions under which polymers can be treated effectively and phototemplates for submicron lithography may be obtained. An example of one such structure is presented in Fig. 23.

* * *

Within the framework of a short review, it is difficult to provide an exhaustive list of the technological applications of laser thermochemistry. The foregoing text merely illustrates certain aspects of the applied research. The list may be significantly expanded, for example by including studies in the field of laser thermolithography,[121] microtreatment of a surface in a liquid,[70,74] selective laser-induced extraction from liquids,[122] etc. However, we believe that even the present review is sufficient to demonstrate that laser thermochemistry[123] is a rapidly developing field, which is of great scientific interest and has numerous practical applications.

Abstract. The phenomena responsible for the dependence of the rate of nucleation, growth, and aggregation of crystals on the concentration and state of trace impurities in the supersaturated medium are discussed. Methods of increasing the sensitivity of the crystallisation to the presence of trace impurities are described. Data on diagnostic systems capable of detecting ultrasmall quantities of impurities from their effect on crystallisation are presented. The bibliography includes 210 references.

I. Introduction

In recent years the well known effects of impurities on crystallisation has stimulated the development of a new field of science: the crystal diagnostics of impurities. The term crystal diagnostics describes the detection, identification, and determination of the amount and state of molecular or colloidal impurities in liquid or in gaseous media from their effect on the crystallisation of a specially chosen substance: the crystallisant. At present crystal diagnostics are used in many laboratories throughout the world. The method now has its own theory and research methodology, and it can claim remarkable success in the determination of extremely small amounts of impurities, down to a few thousand and even hundreds of molecules. Thus we can assert that the foundations of a special field of knowledge (the sensitivity of crystallisation to the presence of small traces of impurities, i.e. crystal sensorics) have already been laid.

The recent developments in crystal sensorics can be attributed to two reasons. One is the unexpectedly large effect of some trace components on crystallisation,[1-3] which stimulated theoretical studies and led to a deeper understanding of the role of microcomponents. The second is the ever-increasing concern with the behaviour of trace components in ecological problems.[4, 5] The need to determine tens of thousands of different ions, complexes, isomers, conformers, and aerosol species present at concentrations down to 10^{-9} g cm^{-3} has been met only in the chemistry of the hydrosphere and of the atmosphere,[6, 7] and the best solution of these problems is not always clear.[8] In some cases a suitable solution has been provided by crystal sensorics. Thus, Kogan[9] determined small quantities (20 – 50 atoms cm^{-3}) of lead by using pyridine-2,6-dicarboxylic acid. Under certain conditions he found that in the condensation of this compound from a vapour containing lead the number of condensate particles was equal to the number of lead atoms.

In 1980 Ansorge and Maeyer[10] found that the reduction of silver nitrate by formaldehyde in a solution containing traces of protein can be controlled so that one silver microcrystal appears on each protein molecule. In this way they could estimate the amount of protein in the sample (approximately 10^6 molecules) from the number of Ag microcrystals. Lastly, in 1983 Kucher[11] used solid hydrazine to detect traces of aldehyde in the atmosphere. The conditions of the reaction were chosen to make the number of resulting hydrazone crystals proportional to the concentration of aldehydes. By counting the hydrazone crystals aldehydes in air could be detected at concentrations down to 10^{-9} g cm^{-3}. These studies[10, 11] led to the development of crystal-sensor diagnostic systems whose most important properties are listed below.

II. Fundamentals of crystal sensor action

It has been established experimentally that when a liquid (or gas) containing a microscopic component is supersaturated with respect to a crystallisant, crystallisation centres appear in its volume and grow, relieving the supersaturation.[2] On the other hand if the crystals are formed in large numbers they coalesce and grow together into aggregates. In the presence of trace components these processes follow paths different from those of the same processes in the pure liquid. As a result the kinetic parameters of the crystallisation (induction period, rate, number of crystals produced) and the morphological properties of the crystals (size, shape, and defect density) depend on the nature of the microcomponent.[12] The dependence is specific. If several trace components are present simultaneously in the system it is usually possible to choose the crystallisant and the crystallisation conditions which make the contribution of one of the trace components to the process predominant. Under these conditions by varying the crystallisation conditions we can ensure that the action of the trace component is selective and restricted either to the formation of the nucleation centres or to their growth and aggregation.

Experiments have also shown that if the trace component is sparingly soluble and is present in the medium (liquid, or gaseous) in amounts which make it supersaturated with respect to the trace

component itself the concentration and state of the latter can be assessed from the kinetics of its spontaneous crystallisation.[13] It may therefore be useful to define the following limiting types of crystal sensor behaviour.

1. Impurity nucleation sensor action, i.e. the ability of the crystallisant to vary its rate of nucleation in response to the presence of the trace component.

2. Growth-related impurity sensor action, i.e. the ability of the crystallisant to vary its growth rate and surface features in response to the presence of the trace compound.

3. Impurity aggregation sensor action, i.e. the change in the rate of aggregation, size, and shape of the crystalline aggregates of the crystallisant under the influence of the trace component.

4. Spontaneous crystal sensor action, i.e. the ability of the trace component to vary the kinetic parameters of its spontaneous crystallisation and the properties of its crystals in response to changes in its concentration and state in the medium.

The sensor behaviour of any of these types can be characterised quantitatively by the functions $B_j(C, \Gamma)$, where B_j is the crystallisation parameter (or property of the crystal) which is sensitive to the trace component of concentration C and parameters of state Γ in the liquid. The simplest characteristics of the sensor behaviour could be the partial sensitivity factor A_j, the limit of detection Π, and the total sensitivity factor A:

$$A_j = B_{0j}^{-1}\left[C\frac{\partial B_j}{\partial C} + \Gamma\frac{\partial B_j}{\partial \Gamma}\right], \quad \Pi = \lim_{B_j \to B_{0j}} C, \qquad (1)$$

$$A = \sum_{j=1}^{n} A_j .$$

Here B_{0j} is the value of the parameter B_j in the absence of the trace component, and n is the number of crystallisation parameters and of properties of the crystals included in the diagnostic. Phenomena close to crystal sensor behaviour include catalysis with formation of a solid product, and photographic sensitivity. In the former case the crystallisant is formed in the medium by a chemical reaction, accelerated by the catalyst (trace component). In the latter the trace component is formed by a photochemical reaction.[14] In this respect both cases differ from the crystal sensor behaviour, in which the trace component and the crystallisant are both present in the medium initially.

III. Theory

The foundations of the theoretical studies of crystal sensorics include the models of condensation, crystal growth, and aggregation of colloids in a medium free from impurities (background models) and in the presence of trace component (working models). Most of the models are macrokinetic, with the nucleation and growth of the crystals expressed in terms of kinetic coefficients which require experimental determination.[15-18] Models in which the kinetic coefficients are expressed through the parameters of the molecular motion in the medium and on the surface of the crystals have also been developed.[19, 20]

The base model is the model of condensation in a dilute but slightly supersaturated vapour (or solution) in the presence of an impurity and of a carrier gas (to remove the heat of condensation), allowing for the formation of clusters of crystallisant and of impurity molecules and for their growth by the incorporation of free molecules or of other clusters.[21-26] The base models usually assume the existence of a critical size, below which the clusters can be treated as quasi-equilibrium formations. The probability of cluster formation is determined by the free energy of the formation, calculated quantum-chemically[27, 28] or estimated by processing data from molecular dynamics and from Monte Carlo calculations.[29-31]

Models of crystal growth include self-association and molecular adsorption processes, surface diffusion, surface clustering,[32-35] and interaction with growth steps.[36-38] The modelling of the aggregation allows for the successive addition of single microcrystals,[39-41] the equilibrium breakdown of the aggregated phase into fragments,[42-45] and the amalgamation of aggregates.[46-50] Recent developments have been reported in the numerical modelling of aggregation and fragmentation by the cluster dynamics and the Monte Carlo method,[51-55] and also analytical solutions of the kinetic balance equations describing the populations of aggregates.[56-60] The background models are the most generally used, the working models being confined to a small group of substances. Therefore the possibility of predicting the effect of the properties of the impurity and of the crystallisant on the rate of crystallisation is very limited at present.

IV. Basic relationships

1. Mechanism of the nucleation sensor action

In order to induce crystal sensor action we must generate a supersaturation with respect to the crystallisant in the diagnostic medium. In the supersaturated medium the molecules (or ions) of the crystallisant and the trace component combine to form clusters which grow by adding on single molecules or by the mutual aggregation of the clusters themselves.[61-72] The frequencies of the addition and removal of molecules vary irregularly with the size of the clusters (with a general trend for a decrease in the frequency of removal with increasing cluster size).[64] As a rule a cluster size can always be found for which the frequency of addition is smaller and that of removal is much greater than for both the smaller and the larger clusters. For example, in aqueous alkaline solutions of Fe(III) salts the critical cluster is the tetramer $[Fe(OH)_3]_4$,[65] whereas in solutions of 1,1′-diethyl-2,2′-cyanine chloride it is the pentamer.[72] When the number of molecules in the cluster is increased to $n = 500-1000$ regrouping can take place, and the structure of the cluster tends towards the structure typical of the macrocrystal.[61] After the rearrangement the properties of the cluster are indistinguishable from those of the massive body.[62, 63]

In a medium containing trace components heteroclusters containing molecules of both the crystallisant and the trace component can be formed. They grow, and become rearranged, in different ways from the homoclusters (consisting only of crystallisant molecules), as was established experimentally and by calculations.[73-79] In particular, heteroclusters are characterised by exchange reactions such as[80]

$$[Fe_6C(CO)_{16}]^{2-} + RhCl_3 \xrightarrow[80\%]{40\ ^\circ C,\ 2\ s} [Fe_5RhC(CO)_{16}]^{2-} + FeCl_3 .$$

No quantitative data on the kinetics of the growth of heteroclusters are yet available. Indirect information can be obtained from the frequency of the appearance of microcrystals: this involves the assumption that critical clusters are instantaneously converted into microcrystals. From the rate of appearance of the microcrystals we may conclude that in some cases the heteroclusters are formed many orders of magnitude faster than the homoclusters. Many solutions in which microcrystals are not formed even after several days in the absence of impurities produce crystal immediately when an impurity is added.[2] For example, in aqueous solutions an impurity of $PbCl_2$ accelerates the formation of K_4MnCl_6 microcrystals by more than 10^6.

Precise measurements have shown that the number of microdrops of water formed in a moderately supersaturated vapour containing ionised air molecules is proportional to the number of these molecules, the frequency of drop formation being at least three orders of magnitude greater than in the absence of ions.[76, 77] Atomic and molecular impurities have similar effects. Thus, if atomic lead ($10-100$ atoms cm^{-3}) is introduced into a stream of very pure saturated pyridine-2,6-dicarboxylic acid (dipicolinic acid) vapour, by cooling the vapour and measuring (after some time) the concentration of drops of the acid it can be shown[9] that if the supercooling is substantial each lead atom generates one drop of the acid (Figure 1). In a mixture of dilute $Fe_2(CO)_9$ vapour

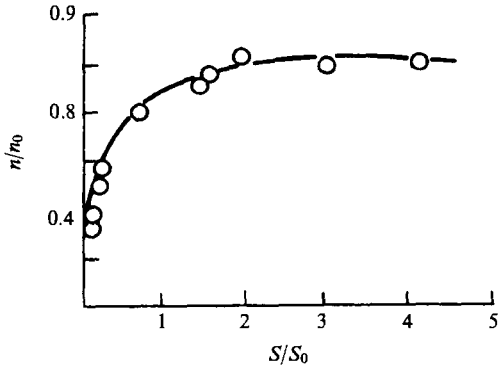

Figure 1. Dependence of the number of drops of dipicolinic acid in the vapour upon the supersaturation:[9] n and n_0 are the numbers of drops and of lead atoms in unit volume of the vapour, $S = [(C/C_\infty) - 1]$ is the supersaturation of the vapour, C_∞ is the concentration of the acid in the saturated vapour, and S_0 is the reference supersaturation.

($10^3 - 10^{18}$ molecules cm^{-3}) and slightly supersaturated dioxyethyl sebacate (DES) vapour drops of DES are nucleated exclusively on the $Fe_2(CO)_9$.[78] This means that in this case the rate of formation of critical heteroclusters is 10^5 times higher than in homoclusters.

In all the cases mentioned so far the heteroclusters develop so rapidly that each molecule of the trace component becomes overgrown with crystallisant and is converted into a microscopic drop or crystal, and thus produces a large number of homoclusters of the crystallisant of critical size. In these cases the crystals decorate the molecules of the trace component. Decoration of the molecules takes place also during the crystallisation of silver in solutions of large aminoacid or protein molecules.[10] Thus, if $AgNO_3$ is added to a solution of DNA or of protein, and a reducer (formaldehyde) is then added, silver microcrystals are nucleated and grow only on the protein molecules.[81-83] These microcrystals are strongly bound to the protein and follow it during the electrophoretic separation.[10] Evidently the $AgNO_3$ and the formaldehyde are taken up by the protein like the Cu(II) and Ni(II) salts[84, 85] and small organic molecules.[86] In the bound state the $AgNO_3$ and the formaldehyde can interact and deposit silver on the parts of the protein molecule between the domains.[87]

However, cases of full predominance of the heteroclusters over the homoclusters are only seldom met. Often the two types develop with comparable speeds, and as a result the effect of the trace components on the nucleation is less marked, and confined to relatively high concentrations.

It has been established experimentally[88-94] that the effect of the trace components on the nucleation is selective. They can both accelerate and retard the process, and often similar compounds have different effects.[88] In particular, organic substances can affect the crystallisation of metals (Cu, Ni, Co, Fe, Ag, Au, Ru, Rh, Pt, Pd, Re, Sn, Te, In, Cd, Bi, Pb) from aqueous solutions by the reduction of their salts (for example, by borohydride).[89, 90] Compounds containing nitrogen and sulphur (thiocyanates, polysulphides, dithionates, thiocarbamide, dithiocarbamates, thioaminoacids, dithiols, thiazines) lower the rate of nucleation at concentrations of $10^{-4} - 10^{-3}$ mol dm^{-3}, whereas other substances are effective only at concentrations of $10^{-2} - 10^{-1}$ mol dm^{-3}. Under these conditions the mutual enhancement of the inhibitors' effects is non-additive.[91]

As was concluded by processing the results of Tsebul'skaya et al.,[94] in the crystallisation of nickel the rate of nucleation B_N depends on the concentration C of the impurity as described by the formula

$$B_N = B_{N,0}[1 - a(C/C_r)^{1/2}]^{-1}, \qquad (2)$$

where $B_{N,0}$ is the rate of nucleation in the absence of the impurity, a is an empirical parameter, and C_r is the critical concentration.

For an alkyldimethylamine impurity $a = -1$ and $C_r = (3.5 \pm 0.2) \times 10^{-4}$ mol dm^{-3}; for methionine, cysteine, thiocarbamide, 5-nitrobenzimidazole, and the tetraalkylammonium bromides $a = -1$ and $C_r = 10^{-5} - 10^{-4}$ mol dm^{-3}, and C_r is independent of the length of the alkyl chain in the tetraalkylammonium molecules; for cetylpyridinium chloride $a = 1$ and $C_r = 5 \times 10^{-2}$ mol dm^{-3}.

It follows from formulae (1) and (2) that the limit of detection of these impurities from their influence on nucleation (assuming a minimum significance level of 5% in the difference between B_N and B_{N0}) is $\Pi = 2.5 \times 10^{-3}\ C_r = 10^{-8} - 10^{-4}$ mol dm^{-3}. The sensitivity factor of the nucleation towards these impurities is $A_N = -0.5a(C/C_r)^{1/2}(B/B_{N0})^2$ if the influence of the impurities is determined exclusively by their concentration, i.e. if $\Gamma = 0$.

The rate of nucleation is also dependent on the presence of colloidal impurities. In some solutions impurity particles about 1 nm in diameter are known to behave as giant clusters which absorb the crystallisant and are rapidly converted into crystals. It has been reported[95-97] that if a polystyrene strip is immersed in a solution of $PdCl_2$ and $SnCl_2$ (0.1 – 1.0 g dm^{-3}) in hydrochloric acid, washed with water, and then transferred to a solution of $NiCl_2$ containing a reducing agent, nickel hemispheres (which can easily be developed and counted) are formed on the surface. The following processes are probably involved. In the initial solution in hydrochloric acid the reaction $SnCl_2 + PdCl_2 = Pd + SnCl_4$ produces colloidal palladium, deposited on the polystyrene surface as particles 0.3 – 1 nm in diameter. These are not removed from the surface by washing, and when the strip is immersed in a solution of $NiCl_2$ they grow by nickel deposition. After some time each colloidal particle of palladium is converted into a nickel hemisphere large enough to be easily counted. New nickel particles are not nucleated on the surface during this time, and the rate of nucleation is controlled exclusively by the palladium particles. A similar state of affairs is found in the crystallisation of copper and of many other metals.[89]

2. Growth sensor action

The effect of trace components on the growth of crystals depends on the relative energies of the interactions between crystallisant, trace component, and solvent molecules. If the trace component interacts with the solvent more strongly than with the crystallisant the effect is principally an acceleration of the growth by the salting-out of the crystallisant. With comparable interaction energies the predominant effect is contributed by the formation of solvated impurity–crystallisant complexes, which can both accelerate and suppress the growth. On the other hand, if the impurity interacts with the crystallisant more strongly than with the solvent, adsorption blocking of the surface by the impurity takes place, and usually suppresses the growth. Many workers have discussed these effects,[37, 98-120] but a generally valid dependence of the growth rate on the concentration and state of the impurity has not yet been formulated. It has been shown experimentally[105-107] that the growth of many salt crystals in weakly supersaturated solutions containing trace impurities is described by the isotherm

$$B_G = B_{G0}\left[Q + \frac{1-Q}{1 + C/C_v}\right], \qquad (3)$$

where B_G and B_{G0} are the normal growth rate of the crystals with and without the impurity, Q is the maximum possible decrease in the growth rate under the influence of the impurity, and C_v is an empirical parameter, dependent on the supersaturation. From (1) and (2) we obtain

$$\Pi = \frac{C_v b}{1 - Q - b}, \qquad A_N = \frac{Q-1}{(1+C/C_v)^2}\,\frac{C}{C_v}, \qquad (4)$$

where b is the smallest statistically significant relative deviation of B_G from B_{G0}. According to formula (4) the growth rate is

sensitive to the impurity at a concentration of the order of C_v. At lower concentrations the amount of impurity is too small (and at higher concentrations it is too great) to produce a significant change in B_G.

There is evidence[37, 105–110] that for many (and possibly for all) of the crystallisants special impurities can be found for which $Q \to 0$ (superinhibitors). For example, hydroxyethylene-1,1'-diphosphonic acid (for $C_v = 10^{-8}$ mol dm^{-3}) is a superinhibitor for calcite,[105] triethylenediaminetetramethylenephosphonic acid ($C_v = 10^{-6}$ mol dm^{-3}) for gypsum, and $CrCl_3$ ($C_v = 5 \times 10^{-7}$ mol dm^{-3}) for KH_2PO_4 and $NH_4H_2PO_4$.[109, 110]

An important example of inhibition is the cyanide retardation of the growth of AgHal crystals by iron and cobalt cyanides during the preparation of photographic emulsions.[111] The acceleration of the growth of crystals by an impurity has also been reported.[112–114]

If the crystal grows by the layer mechanism not only the normal growth rate (i.e. the rate of growth of a face at right angles to the surface) but also the parameters of the surface morphology of the crystal are sensitive to the impurity.[98–114] In layer growth the crystallisant is deposited on the surface of the crystal in successive layers.[37] It was experimentally found that molecules of the trace component deposited on the sides of the steps formed by the growth layers can suppress the attachment of molecules of the crystallisant to those steps (poisoning of the steps). Furthermore the adsorbed impurity can form a molecular fence on the faces, which inhibits the extension of the layers over the face (cut-off retardation of the growth).[98–101] This effect makes the surface morphology sensitive to the impurity. It was shown[109, 110] that the steepness of the growth hillocks on the faces of growing crystals of KH_2PO_4 is no less sensitive to the presence of $CrCl_3$ than is the normal growth rate (Fig. 2). At low supersaturations the faces have a complex morphology and the crystals grow very slowly. The growth rate becomes appreciable only at supersaturations in excess of some threshold value S_r. By processing published data[109, 110] it was shown that the threshold supersaturation S_r for KH_2PO_4 crystals is

$$S_r = S_0[1 + 1.1C/C_K], \quad (5)$$

where S_0 is the threshold supersaturation in the pure solution, and C and C_K are the concentrations of $CrCl_3$ and of the crystallisant in the solution. It follows from (1) and (5) that if the threshold supersaturation is used as the diagnostic criterion, a detection limit of $\Pi = 9.1 \times 10^{-7}\, bC_K$ can be achieved for chromium. For a claimed[109] significance level of the deviation of $b = 0.05$, $\Pi = 4.5 \times 10^{-8}\, C_K$. Even lower limits of detection can be reached by choosing a crystallisant for which crystal growth takes place through the formation of intermediate surface compounds incorporating the impurity. It was established that metal crystals grow faster under the influence of impurity–crystallisant complexes which transfer an electron.[115] For example, the crystals of a series of metals dissolved as their chlorides MCl_2 in the presence of an alkali M'OH and of a reducing agent RH grow as a result of the reaction[83, 116]

$$RH + 2M'OH + MCl_2 = ROH + H_2O + M + 2M'Cl. \quad (6)$$

The reducing agent and the chloride interact when adsorbed on the crystal faces. The M adatoms produced in this way combine to form surface clusters, and subsequently ultramicrocrystals, which arrange themselves in a layer as in the layer growth mechanism.[117–119] In the absence of the impurity the reaction (6) is slow. However, if a crystal of copper or nickel is treated (before growth) for 40 s with a 10^{-3} mol dm^{-3} solution of cetylpyridinium chloride (CPC), its growth is accelerated by a substantial factor as a result of a charge-transfer reaction within the complex:

$$RH + CPC + MCl_2 \to [RH(CPC)MCl_2] \xrightarrow{2M'OH}$$

$$\to ROH + H_2O + M + 2M'Cl + CPC. \quad (7)$$

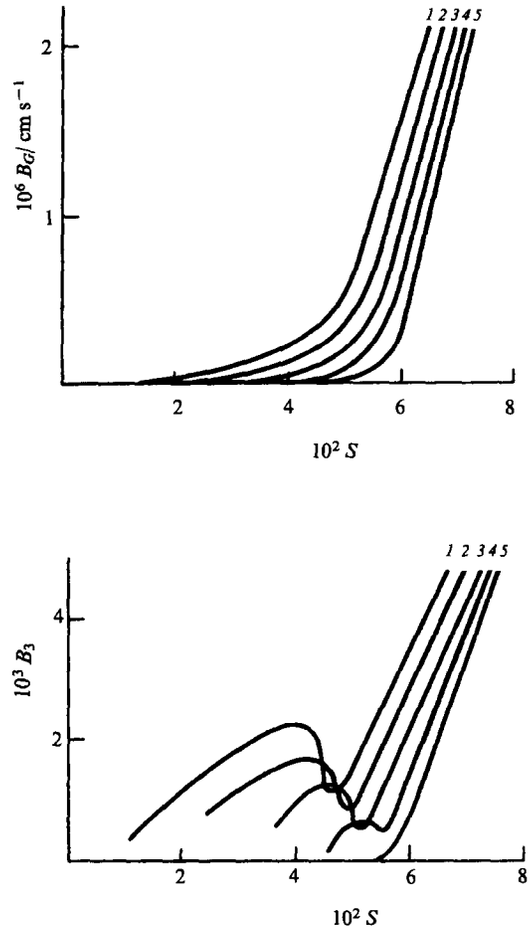

Figure 2. Dependence of the growth parameters of a KH_2PO_4 crystal on the supersaturation S for different contents of $CrCl_3$ in the solution.[109, 110] B_G is the normal growth rate, B_3 is the steepness of the growth hillocks; concentration of trace component: *1*) 0, *2*) 1.5, *3*) 3.3, *4*) 4.5, *5*) 6 ppm.

In reaction (7) the CPC acts as a catalyst, and the sensitivity of the crystal growth to this process can be maximised by choosing the most favourable conditions.

The action of trace components on faces with different surface morphologies is usually selective. As a result, the trace components can affect the habit of the crystals. Only $CdCl_2$, $MnCl_2$, $PbCl_2$, $ZnCl_2$, $HgCl_2$ influence the habit of NaCl crystals growing in an aqueous solution at low supersaturations: no other soluble chloride has any effect.[120] $CdCl_2$ and $ZnCl_2$ favour the formation of (111) faces instead of the more usual (100) for $\Pi = 5 \times 10^{-3}$ and 5×10^{-2} mol dm^{-3} respectively, but their analogue $HgCl_2$ produces (110) faces.[120]

3. Aggregation sensitivity

Crystalline aggregations are often formed as a result of collisions between the crystals. Thus, collisions can cause the crystals to merge, and finally to intergrow.[121–133] The most important manifestations of the effect of impurities on these process are the following.

1. Electrolyte impurities usually affect the coagulation threshold in accordance with the Deryagin–Landau–Verwey–Overbeek (DLVO) theory.[129] Low-molecular-mass electrolytes affect the properties of the electrical double layer, and therefore also the configuration of the aggregations and the radial distribution function of the crystals in the bulk of the aggregations.[134, 135] This effect is usually observed at electrolyte concentrations $C > 10^{-3}$ mol dm^{-3}.[129, 136]

2. Most trace impurities affect the aggregation as a result of specific adsorption.[134] For example, during the precipitation of

nickel by borohydride from an aqueous solution of $NiCl_2$ the primary Ni microcrystals (2–25 nm in size) are incorporated into spherical aggregations 100–200 nm in size if the solution contains alkylmethylamine oxide ($C = 5 \times 10^{-3}$ mol dm^{-3}) and 20–50 nm in size in the presence of 2-mercaptobenzimidazole or 6-methyl-2-thiouracil (5×10^{-4} mol dm^{-3}). On the other hand in a pure solution or in the presence of 6-methyluracil (5×10^{-4} mol dm^{-3}) aggregation of the microcrystals is not observed.[137]

In the crystallisation of $BaSO_4$ from an aqueous solution (37 °C, pH ~7)[128] in the presence of 1-hydroxy-1,1′-disulphonic acid the size of the aggregations decreases three-fold even for an impurity concentration $C = 2 \times 10^{-4}$ mol dm^{-3}, and in the crystallisation of AgI in the presence of $C_8H_{17}OC_6H_4 \cdot (OCH_2CH_2)_xOH$ ($x = 10-70$)[138] the same effect is reached for $C = 10^{-7}-10^{-8}$ mol dm^{-3}. If the impurity molecule is large enough it can be adsorbed on several crystals simultaneously.[139, 140] This effect was noted[141] in the flocculation of SKS-30ARK latexes and of polystyrene in the presence of polyethyleneimine (M = 4500) at a concentration $C = 4 \times 10^{-9}$ mol dm^{-3}. This type of adsorption has been observed only in aqueous gold and silver sols with microcrystals of about 50 nm.[142] In these sols aggregations containing $10-10^5$ microcrystals are formed within a few minutes of the addition of homo- and copolymers of aza-crown ethers (M = 55 000), in concentrations $C = 5 \times 10^{-6}-3 \times 10^{-5}$ mol dm^{-3}, irrespectively of the acidity of the sols. Measurements showed that the sol microcrystals had a negative charge, whereas the macromolecules were positively charged in an acid medium and uncharged in an alkaline medium. The similarity between the effects of the polymer in acid and in alkaline media suggests that charge neutralisation of the microcrystals does not play a major role in their mutual coupling, caused by the specificity of the adsorption. Conversely, in SiO_2, S, FeOOH, As_2S_3, and $CuFe(CN)_6$ sols the crown ethers induce aggregation only in an acid medium because of the charge neutralisation of the microcrystals. As a result the crown ethers affect only the gold and silver microcrystals in an alkaline medium. This observation suggests new diagnostic possibilities for crown ethers.

3. If the impurity macromolecule is much larger than the microcrystals it can act as an aggregation centre. In this case the microcrystals adhere to the impurity molecule and intergrow into a large aggregation long before homoclusters of the microcrystals are formed. The frequency of incorporation of the microcrystals is usually much greater on the large than on the small aggregations.[143] Therefore the overgrown impurity molecules rapidly grow into large particles from whose numbers the number of impurity molecules can be inferred. The reality of this interpretation has been demonstrated in a study[144] of the addition of a multitude of hydroxyapatite microcrystals to a molecule of DNA. Bacterial cells can be used as the aggregation centres in these studies:[145, 146] in the presence of biologically active impurities the bacteria add on microcrystals either selectively or in other ways.[146–148] For example, cells of *Bacillus sp. 1AC7* in an aqueous alkaline colloidal solution of gold can remove almost all the gold microcrystals in 1 h. By adding to the solution 2,4-dinitrophenol ($C = 10^{-6}$ mol dm^{-3}), gramicidin D (10^{-6} mol dm^{-3}), or pentachlorophenol (5×10^{-9} mol dm^{-3} most of the microcrystals can be removed from the surface of the cells. Increasing the concentration of these impurities by an order of magnitude removes the microcrystals completely.[146] Obviously, a colloidal solution of gold containing bacteria can be used as an aggregation sensor of the presence of pentachlorophenol offering a very low detection limit.

4. Spontaneous crystal sensor action

If the trace component undergoes a topochemical reaction with the crystals of the crystallisant it can be detected by the change in surface topology of the crystals. For example, if a crystal of fluoroapatite is introduced into a stream of water containing small quantities of H_3PO_4 its surface develops etch pits in which

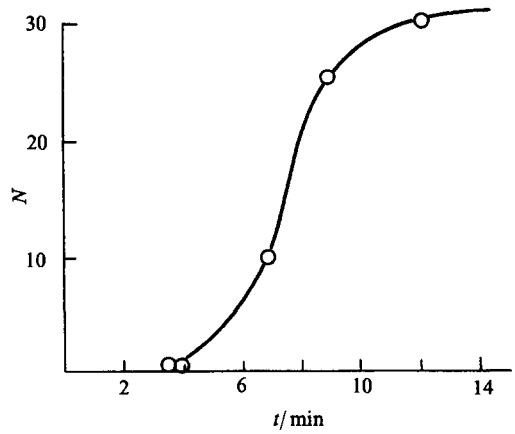

Figure 3. Rate of nucleation of microcrystals of sodium cyclophospate during the dehydration of $Na_3P_3O_9.6H_2O$.[152] Humidity of the air 26%; temperature 40 °C; N is the number of microcrystals on the (100) faces of the initial monocrystal ($F = 3$ mm^2).

$Ca(H_2PO_4)_2$ microcrystals are subsequently formed.[149–151] At the contact between a monocrystal of cyclophosphate ($Na_3P_3O_9 \cdot 6H_2O$) and moist air microcrystals of anhydrous cyclophosphate are produced on the crystal faces at a rate shown in Fig. 3.[152] The rate of nucleation of cyclophosphate crystals is sensitive to the water content of the air.

Monocrystals of fluoroapatite and of cyclophosphate hexahydrate also can be used as sensors for the presence of impurities. They should offer an enhanced sensitivity for the microcomponent if their surface morphology is determined by a microscopic method after a lengthy exposure to a stream of the medium under study. In this approach the long exposure and the small size of the morphological elements compensate for the low concentration of the trace component. Changes in morphology are revealed unambiguously if the size d of the new surface elements exceeds the resolution of the microscope and their number n is large enough. This requirement can be expressed as $d^2n > q$, where q is the minimum coverage of the surface by the new elements which can be identified unambiguously.[150] For an exposure time t and a growth rate of the topographic elements $B_G = B_{G0}C/C_K$ we have, for $d = B_G t$,

$$\Pi = (q/n)^{1/2} C_K / B_{G0} t, \tag{8}$$

where C_K is the solubility of the crystallisant. The new morphological elements are usually nucleated on active centres of the surface, so that the number n depends on the structural perfection of the monocrystal.[153–156] In monocrystals with a developed dislocation structure $n = 10^8-10^{10}$ cm^{-2}, and therefore a limit of detection $\Pi = (10^{-8}-10^{-7})C_K$ can be expected for the typical values $q = 10^{-6}$ and $B_{G0} t = 1$ cm.

Another method of revealing the trace component consists in localising its crystallisation on the surface of a specially provided collector and depositing on this surface the trace component from the largest possible volume of the medium.[157–161] The mass of the trace component removed from a volume V on a collector having a surface F is $\rho d^3 nF = CV$. Therefore if the condition $d^2n > q$ is obeyed we have

$$\Pi = \rho q^{3/2} \frac{F}{n^{1/2} V}, \tag{9}$$

where ρ is the content of the trace component in a unit volume of the reaction product.

If the reaction has a high activation energy, the process can be localised by heating the collector. Thus, in the pyrolytic reduction of silicon tetrachloride (activation energy 330 kJ mol^{-1}) or zirconium tetrachloride by hydrogen the product is collected quantitatively on the heated walls of the reactor.[157, 158] In the

pyrolysis of methylchlorosilane in a stream of hydrogen by a heated tungsten wire SiC was detected[159, 160] in 60–80% yield. TiC, NbC, HfC, BN, TiN, and TiB_2 have been obtained in a similar way.[158] An unusual method of localisation was reported by Givargizov.[161] If a single crystal of silicon heated to 1200 K is introduced into a stream of $SiCl_4$ vapour in H_2 carrier gas and a drop of molten gold is placed on the surface of the crystal the $SiCl_4$ is reduced on the drop surface and the resulting silicon dissolves in the gold. The drop becomes supersaturated in silicon, which crystallises at the contact surface with monocrystal. This produces a filamentary growth tipped with a drop of gold which collects $SiCl_4$ from the vapour. On the remainder of the monocrystal surface the reduction is negligibly slow. This technique was used to crystallise many trace components on collectors of various types.[161]

5. Selectivity of the effect of the trace component

The formation of excited and ionised forms of the trace component results in changes in the rate of crystallisation. This effect is observed as an acceleration of the crystallisation under the influence of an external ionising radiation.[162–165] The photolytic crystallisation of cadmium from the vapour of CdR_2 onto a silicon substrate was achieved by a preliminary exposure of the substrate to CdR_2 vapour followed by a brief irradiation with a laser beam (λ = 193 nm).[166, 167] If the substrate is not pretreated with the vapour, but is simply irradiated, crystallisation of cadmium is not observed. If the substrate, after being treated with vapour, is irradiated with a beam of irregular cross-section, the cadmium crystallises only on the illuminated part and its microcrystals are localised on an islet whose shape matches exactly the shape of the beam. Obviously, in this case the cadmium crystallisation centres are the radicals or ions adsorbed on the substrate.

Selective action has been observed[168] in metallic clusters of 2–10 atoms. Microcrystals of AgBr were irradiated as a layer with an Ag_n^+ ion beam, and after treatment with a reducing agent the microcrystals which had been reduced to silver were counted. The ion beam was produced in a mass spectrometer: it consisted of identical clusters accelerated to an energy of 8 eV per atom. The density of the beam and the exposure were chosen to produce at least 10 clusters for each microcrystal. It was found that after irradiation with a beam of Ag^+, Ag_2^+, or Ag_3^+ ions the microcrystals were not reduced. On the other hand irradiation with a beam of Ag_4^+ or with beams of larger clusters reduced 80% or more of the microcrystals.

In the crystallisation of metals by reaction (6) only the ultramicrocrystals of other metals, of given sizes, acted as crystallisation centres over a wide range of supersaturation.[89, 90] For example, in the crystallisation of nickel on polystyrene the crystallisation centres were particles of palladium (0.3–1 nm) or of silver (3–80 nm).

Alkyldimethylamine oxides do not affect the crystallisation of nickel, when present in solution in a molecular form, up to the micelle formation threshold, but they strongly retard the process when in the micellar form.[94] As reported,[94] near the micelle formation threshold the oxide lowers the rate of growth of nickel crystals from 1.7 ± 0.2 to 1.7×10^{-3} nm s^{-1}. Clearly, the microcrystals remain most of the time within the micelles, and the former rate characterises the growth outside the micelle whereas the latter refers to growth within the micelle.

V. Methods of increasing the sensitivity

Crystal diagnostics are most conveniently carried out under conditions of minimum B_{0j} but maximum number and size of the crystals formed under the influence of the impurity [Eqn (1)]. This objective can be achieved by the following procedures.

1. Lowering the supersaturation of the medium

At low supersaturations crystallisation in the absence of impurities is characterised by a long induction period.[169–174] Therefore in the diagnosis of impurities the supersaturation is lowered to a level for which the diagnosis time is substantially shorter than the induction period. The induction period t_0 has been measured by several workers.[2, 169–174] All their measurements are consistent with the formula

$$t_0 = KN_0S^{-n}\frac{RT^2}{H}M\frac{\mathrm{d}\ln C_K}{\mathrm{d}T}\exp\left(\frac{E}{RT}\right), \qquad (10)$$

where K and n are empirical parameters, N_0 is the minimum number of crystals which can be reliably determined, S is the supersaturation, M is the mass of one mole of crystallisant, and E is the activation energy for the nucleation of the crystals.

As has been reported,[2, 169, 173] the parameter K increases upon changing from anhydrous substances to crystal hydrates and from salts of univalent metals to salts of multivalent metals, i.e. as the composition of the crystallisant becomes more complex. In $Cu(NO_3)_2 \cdot 3H_2O$, $Na_2S_2O_3 \cdot 5H_2O$, $MnCl_2 \cdot 4H_2O$, and $Cd(NO_3)_2 \cdot 4H_2O$ and in many other complex crystallisants the K value is so high that in the absence of impurities their crystallisation is suppressed up to very high supersaturations. These crystallisants can be used at fairly high as well as at low supersaturations.

2. Overgrowing the primary crystals

The size of the crystals is increased by lowering the supersaturation S of the medium until new crystals cease to be nucleated, and holding it at this level for a long time.[175] In this case the crystals which had been nucleated before the decrease in supersaturation grow to an easily detected size without a change in their number. In a study[176, 177] of the overgrowing of ultramicrocrystals of metals in supersaturated zinc vapour it was shown that the rate of overgrowing can be controlled by electrically charging the ultramicrocrystals, and that the growth is completely suppressed at high enough negative charges. This suggests new prospects of controlling the overgrowing (in either direction) without altering the supersaturation.

3. Multiplication of the crystals

It has been established that a single primary crystal can produce a multitude of secondary crystals by three mechanisms.

Relay crystallisation. If drops of the supercooled melt of crystallisant (amorphous particles) are added to a medium containing a primary crystal the latter crystallises the drops with which it comes in contact. This effect was observed in a layer of amorphous $Ca_3(PO_4)_2$ powder as the formation of a group of secondary crystals round each primary crystal upon heating the medium,[178, 179] and also in a study[180] of an aqueous emulsion of molten hexachloro-*m*-xylene. Fig. 4 shows the result of the contactless crystallisation of a melt of *p*-bromoaniline dispersed in water and supercooled by 30 °C.[181] The drops of the melt and the primary crystal were deposited on an inert substrate and were not in mutual contact, but as a result of the dendritic overgrowth of the primary crystal the dendrite branches reached the nearest drops and crystallised them.

It has been established that ultramicrocrystals of silver are formed as a latent image in layers of AgBr crystal exposed to light. Treating the layer with a reducing solution produces growth of the ultramicrocrystal.[182–185] At a low and negative redox potential of the solution each ultramicrocrystal grows until it occupies the whole of the AgBr crystal in which it had been nucleated, but it does not extend to the neighbouring crystals.[182] On the other hand at a high negative potential each primary ultramicrocrystal emerges from its mother crystal and reaches the surface of the neighbouring crystals, inducing their reduction. As a result each microcrystal is surrounded by a cluster of secondary crystals.[183]

Multiplication by a topochemical process. It has been noted that when primary AgBr crystals are added to a solution of KI saturated with AgBr, microcrystals of AgI are nucleated at the corners of these crystals.[185] Their growth is accompanied by the dissolution of the adjacent parts of the AgBr crystal. However, the

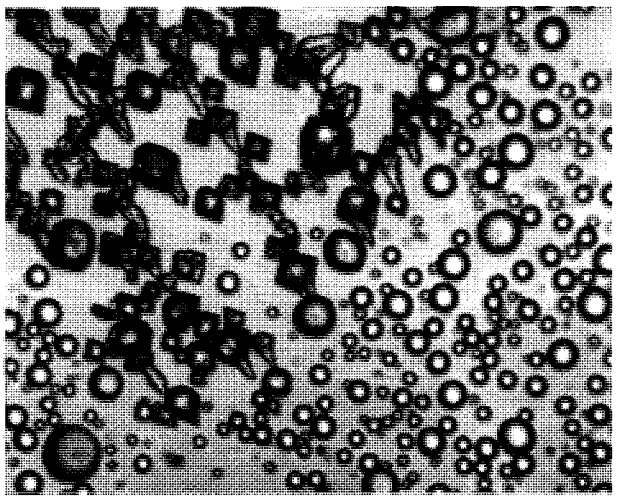

Figure 4. Relay crystallisation of a melt of *p*-bromoaniline dispersed in water (×20).[181]

microcrystals become separated from the mother crystals before reaching even one tenth of their size, and are replaced by new AgI microcrystals. In this way each primary crystal of AgBr generates hundreds of secondary AgI crystals. The same process is found in the interaction of fluoroapatite crystal with a mixture of sulphuric and phosphoric acid.[186]

Crystal showers. If a suspension of primary crystals is strongly stirred or irradiated with ultrasound the crystals can be broken down into a multitude of small fragments which grow to the size of the primary crystals as a result of overgrowth. This process has been observed in aqueous suspensions of $(NH_4)_2SO_4$, KCl, K_2SO_4, $CuSO_4 \cdot 5H_2O$, and $KAl(SO_4)_2 \cdot 12H_2O$.[187-190] A shower of secondary crystals is formed also by sliding a monocrystal of $MgSO_4 \cdot 7H_2O$ on a polished glass plate in a supersaturated solution of magnesium sulphate.[191]

VI. Diagnostic systems

Various systems based on nucleation and on growth sensor action have already been developed. Conditions suitable for the exploitation of aggregation sensor action have been formulated.[192, 193]

1. System for monitoring the concentration of carbonyl compounds

Fig. 5 shows a system developed for monitoring the concentrations of carbonyl compounds with $C = 10^{-7}-10^{-4}$ mol dm^{-3}. The system is prepared by depositing on an inert film an aerosol of a solution of the developer (a suitable hydrazide). After being dried the film is covered with a large number of microcrystals of the reagent.

The dried film acts as a crystal sensor. It is stored out of contact with the substance to be determined, and at the beginning of the experiment it is introduced into a stream of the gas to be analysed. After contact with the film the gas becomes supersaturated with the product, and ultramicrocrystals of the product are formed on the surface of the microcrystals of the reagent. The number of nucleated crystals is greater, the higher the concentration of the compound being monitored in the gas stream. The reagent is chosen so that the rate of nucleation is much smaller than the growth rate of the ultramicrocrystals. Therefore each nucleus grows over the whole volume of the mother microcrystal immediately after being nucleated, and the increase in the number of microcrystals of the product on the film is equal to the rate of nucleation. After being exposed to the flow the film is treated with a supersaturated solution of the product in order to overgrow the ultramicrocrystals to a conveniently detected size, ensuring that the supersaturation is kept below the level at which new crystals could be produced ($t \ll t_0$). When the crystals have been enlarged they are determined by counting them or by measuring any property which is dependent on their number. The sensitivity of the system increases when the drop size of the aerosol is decreased, the working area of the film is increased, and the supersaturation level used in the overgrowing is lowered. This system has been used to detect ketones, keto-esters, keto-acids, and other carbonyl compounds in gases and in solutions. 40 reagents offering a limit of detection of the carbonyl compound $II = 10^{-7}$ mol dm^{-3} have been found.[11]

2. Peptide visualisation system

The peptide visualisation system[81, 82] can be used to display and to determine amounts of protein down to 10^{-10} g. A layer of polyacrylamide gel[194] is deposited on a glass plate, and the solution of protein is admitted from the inlet side. The plate is then treated with a 0.1% solution of $AgNO_3$, and (after being washed) with a solution of formaldehyde (0.01–0.1%). Silver microcrystals are nucleated and grow on the protein molecules, which become decorated with silver.[82] The layer is examined by electrophoresis, and the localisation region of the protein is examined with a

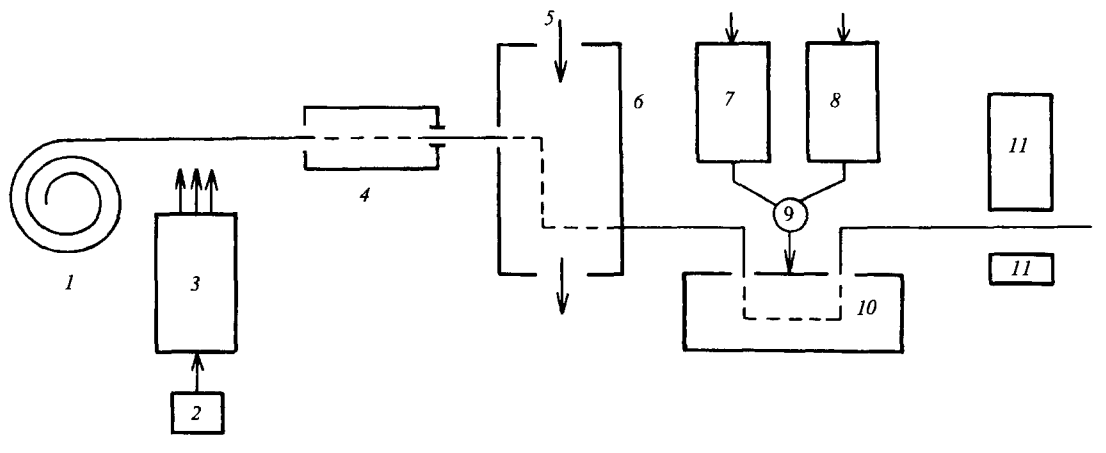

Fig. 5. System for monitoring the concentration of formaldehyde in a medium:[11] *1*) polymer film, *2*) methanolic solution of the hydrazide of *p*-hydroxybenzoic acid, *3*) aerosol generator, *4*) drying chamber, *5*) flow of gas (or liquid) containing formaldehyde, *6*) exposure chamber, *7*) aqueous solution of formaldehyde, *8*) aqueous solution of *p*-hydroxybenzoic acid hydrazide, *9*) mixer, *10*) chamber of contact of the film with the supersaturated solution of the hydrazone of *p*-hydroxybenzoic acid, *11*) photographic recording apparatus.

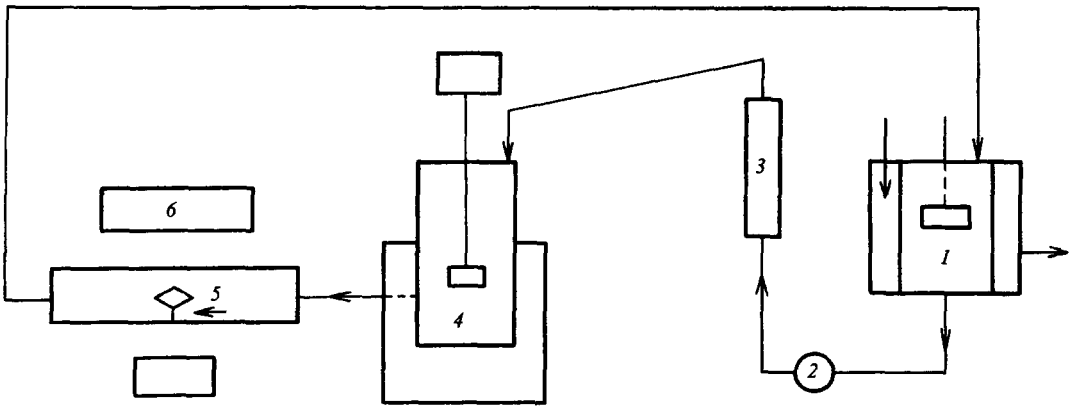

Figure 6. System for impurity diagnosis from the growth of crystals:[26] *1*) block for preparing a saturated solution of the crystallisant; *2*) pump; *3*) flow meter; *4*) cooling unit; *5*) growing crystal; *6*) block for monitoring the properties of the crystal *in situ*.

microphotometer. Occasionally the layer is treated, before the silver nitrate treatment, with a 0.01% solution of $KMnO_4$, which also stains the protein molecules with microcrystals of manganese dioxide.[81] A wide range of protein and DNA mixtures can be diagnosed from the position of the localisation region and from the intensity and nature of their coloration. The sensitivity is increased by treating the gel, after the formation of the silver microcrystals, with a mixture of iron cyanide and potassium bromide in order to convert the silver into AgBr. The AgBr is then converted into the sulphide by treating it with thiourea containing the ^{35}S radio-nuclide, which has a high specific radio-activity.[195, 196] In this case the localisation regions are delineated by autoradiography, which lowers the limit of detection of the protein by an order of magnitude.[83] Future improvements of the systems are expected to lower this limit still further.[82]

3. Growth systems

The basic system for monitoring the growth of crystals (Fig. 6) is designed for continuously recording the growth rate and the morphology of the growing faces.[29, 197] For β-methylnapthalene the growth rate is determined from the change in the interference colour of the crystals: this allows layers 2 nm thick to be determined.[198] By using the growing face of the crystal as one of the mirrors of a Michelson interferometer Rashkovich and Shekunov[199] were able to study the dynamics of the motion of layers more than 10 nm thick, and by including a Mach–Zehnder interferometer they lowered the thickness of the layer to 4 nm. Phase-contrast and reflection microscopy in conjunction with sensitive telephoto cameras and high-contrast video amplifiers allowed the *in situ* observation of the deposition of mono-molecular layers on the faces of calcium iodide, potassium hydrogen phthalate, and barium nitrate.[200–202] Other workers,[203] by including ellipsometry and low-angle scattering of synchrotron X-radiation, were able to demonstrate the effect of impurities on the composition and the crystal structure of the layers.

4. Autoradiographic system of detecting high-molecular-mass substances

The system relies on introducing into the molecule to be detected the ^3H, ^{35}S, ^{32}P, and ^{33}P radio-nuclides by isotope exchange or other methods.[204–206] The labelled substance is placed in contact with a layer of nuclear photographic emulsion which is then developed and examined in an electron microscope.[207–208] The system was used[209–210] for example, to detect DNA in aqueous solutions with a limit of detection $\Pi = 10^{-12}$ mol dm^{-3}. Under these conditions each molecule of DNA appeared in the field of the electron microscope as a circular conglomeration of silver microcrystals 0.4 μm in diameter.

VII. Conclusions

It has been established experimentally that crystal sensorics can offer a high sensitivity and selectivity in the detection of impurities. By using growth and aggregation sensor action a limit of detection of 10^{-9} mol dm^{-3} can be achieved. Intrinsic and nucleation sensor action give limits of 10^{-15} and 10^{-18} mol dm^{-3} respectively. These successes can be claimed even though crystal sensorics are a relatively new development: the theoretical foundations have been laid, but experimental data are still disconnected and incapable of answering the main question, i.e. of establishing the relationship between crystal sensorics and the nature of the impurity, the crystallisant, and the solvent. Working crystal sensorics systems offer an illustration of the problem rather than a scientifically well founded model. Very little use has been made so far of the fundamental methods of increasing the sensitivity (for example, crystal multiplication), and of the experimentally established special features of the crystallisation (for example, the transfer of the growing microcrystals into the volume of the micelles, or the formation of crystal islets on the illuminated substrate surface). Nevertheless recent progress in the use of crystal sensor systems strongly suggests that wide-ranging applications will be found in the near future.

Synthesis of thin-layer structures by the ionic layer deposition method

V P Tolstoi

Contents

I. Introduction	237
II. Conditions for the synthesis of thin-layer structures by ionic layer deposition	238
III. Preparation of thin layers of various compounds	238
IV. Conclusions	241

Abstract. A review is presented of ionic layer deposition, one of the methods of synthesising thin-layer structures of a predetermined composition with very precise thickness control on the surface of a support. Conditions for the synthesis of ultra-thin films of metal oxides, hydroxides, phosphates, chromates, sulphides, and tellurides on the surface of metals, semiconductors, and dielectrics are discussed. The advantages of the method are pointed out, including the possibility of synthesising layers in an automatic regime under mild conditions at room temperature on substrates of complex shape by using simple apparatus. The problems which prevent the wider use of the method are formulated, and ways of solving them are suggested. The bibliography includes 69 references.

I. Introduction

Recent developments in various fields of technology such as submicroelectronics, the production of catalysts and sorbents, and protective coatings have stimulated more demanding requirements for methods of synthesising thin-layer structures. Thus, specific technological problems in the synthesis of thin-layer structures currently being studied include controlling the disposition of different atoms to within one monolayer of the structural units.

This review covers existing methods of high-precision synthesis of thin-layer structures. One of these methods (ionic layer deposition) is examined in greater detail, because it appears to deserve wider recognition from specialists in solid-state surface chemistry.

The methods used to deposit thin layers of solid substances on the surface of various supports can be arbitrarily classified as physical or chemical. The former include methods in which the material to be deposited is evaporated in a vacuum or an inert medium by thermal, electron-beam, cathodic, or magnetron evaporation.[1–5] In the chemical methods the layer is formed by deposition from the gas or the liquid phase as a result of a chemical reaction initiated by thermal energy, by a plasma, by a change in pH, etc.[6,7] A feature common to all these methods is that the layer is formed as a result of a shift in the chemical equilibrium between the reactants in the gas or the liquid phase and the growing layer, in the direction of layer formation. This allows the thickness of the layer to be controlled though the concentration and temperature of the reactants as well as through the temperature of the substrate, the deposition time, and other parameters. However, changes in these parameters do not offer thickness control at the level of a monolayer of structural units.

Essentially new conditions of high-precision layer synthesis have been formulated for the preparation of thin-layer structures: conditions offering an unusual type of chemical assembly.[8–12] The most important of these is a special preparation of the substrate surface. A layer of functional groups is then formed on the prepared surface, and used to induce the chemisorption of bifunctional molecules containing atoms of the layer to be synthesised and of molecules of another reactant, not less than bifunctional, giving new functional groups which contribute to further chemisorption reactions. This removes the excess of reactants. As a result, the direct synthesis is replaced, in the complex conditions created by the thermodynamics of the process, by a stepwise synthesis with acts of irreversible chemisorption alternating in a predetermined sequence.

These ideas have been used in a series of studies[13–17] of the synthesis of various metal oxides (TiO_2, Cr_2O_3, etc.) on the surface of dispersed solids (mainly silica), and also of multizone layers based on these materials. Readily hydrolysed chlorides and water are most commonly used as reactants. The method of synthesis of layers of a single composition has been called molecular layer deposition. Organometallic compounds have also been used for this purpose,[18–21] for example $Ti(OC_2H_5)_4$, $Si(OC_2H_5)_4$, $Al(OC_3H_7)_3$, $Zn(CH_3)_2$, $Cd(CH_3)_2$, H_2S, etc. The advantages of this method include, in addition to a precise control of the layer thickness, the ability to deposit layers on the surface of porous supports having a complex shape.

This approach has been used in conjunction with molecular beam epitaxy[22] to expose the support in an ultra-high vacuum to alternating beams of atoms of different elements which react on the support but not in the gas phase. The method is also used to prepare various thin-layer materials used in microelectronics (for example, $Ga_{1-x}Al_xAs$).

A definite analogy has been reported also with the atomic beam epitaxy method,[23–25] in which a layer of ZnS is deposited on the substrate surface by heating the substrate above the evaporation temperature of both the reactants (in this case, zinc and sulfur), and the chemisorption of zinc and sulfur atoms is

obtained by successively exposing the surface to these atoms. The method has been used in the synthesis of high-purity layers of ZnS, CdS, ZnSe, CdSe, etc.

These methods require the use of vacuum or high-vacuum apparatus, or flow apparatus filled with a purified inert gas. The molecular layer deposition method has also been used[26] for synthesis experiments in inert solvents.

This interest in the preparation of layers by using liquid reactants is not new, mainly because the apparatus requirements are much simpler for synthesis in the liquid phase. Thus, the impregnation method is now widely used in the development of catalysts and sorbents.[27] An inert matrix is immersed in a solvent containing the substance to be deposited, and (without washing away the excess of reactants) the system is then heated or treated with another reagent which converts the deposited substance into a sparingly soluble compound. This technique infringes one of the fundamental requirements of precision synthesis by failing to remove the excess of reactants.

Evidently, the most stringent control over the synthesis conditions of the layers from the liquid phase can be exercised by using ion exchange reactions, now widely applied for the modification of solids.[28-30] However, the application of ion exchange reactions in the synthesis of thin-layer structures involves serious difficulties, mainly associated with the fact that these reactions are reversible, and therefore the layer produced in the first few layer deposition cycles can be lost in experiments involving repeated depositions.

II. Conditions for the synthesis of thin-layer structures by ionic layer deposition

The layer synthesis from solutions on a substrate surface was first proposed by Iler,[31] who prepared layers of silicon oxide by using charged particles of colloidal silica as the initial structural units for layer deposition. Treating the surface of a substrate carrying a charge opposite to that of the colloidal silica particles resulted in the deposition of a layer of the particles. A subsequent treatment of the substrate and the deposited layer with a salt solution produced charge reversal in the supported particles, with deposition of a second layer.

The application of these ideas to the synthesis of layers with very precise thickness control, with cations and anions used as the main structural building blocks, is complicated first and foremost by the reversibility of the ion exchange reactions taking place on the surface.

Nevertheless it has been shown[32,33] that the silica gel containing PO_4^{3-} as a substituent is an effective sorbent for the Hf^{4+}, Zr^{4+}, and Sn^{4+} ions. It has also been shown[34] that Ca^{2+}-substituted silica gel can be used as an anion exchanger for PO_4^{3-}. An increased adsorption of PO_4^{3-} ions on Zn^{2+}-substituted silica gel (as compared with the H^+-substituted silica gel) has also been reported.[35] It was suggested that one layer of metal phosphate is formed on the surface by the interaction with the solution.

These results can be explained by the well-known Fajans rule:[36] ions are adsorbed most effectively on a surface if they form a sparingly soluble or a weakly dissociated compound with an oppositely charged ion in the substrate.

Thus it may be possible to prepare thin-layer structures by using the principles of the chemical assembly of solid substances, realised by the molecular layer deposition method (which relies on the irreversible adsorption of easily hydrolysed metal chloride molecules). In other words, ions can be used for the synthesis instead of molecules, thus producing an ionic type of layer deposition.

The irreversible adsorption reactions of anions and cations, giving sparingly soluble compounds as a result of the interaction, provide the foundations of the ionic layer deposition method. In this approach the thickness of the layer is determined by the number of cycles of ionic layer deposition performed, including the removal of the excess of reagents between cycles. In this case the support behaves alternately as a cation exchanger and as an anion exchanger, which allows the now well-understood ion exchange concepts to be used. The conditions for the most complete ion exchange and the exchange capacity are well established for almost all the types of ion exchanger: furthermore, the appropriate thermodynamic and kinetic relationships have been obtained, sequences of exchanging ions have been formulated, and reaction mechanisms have been proposed.[37-47]

However, there is as yet no systematic treatment of the basic process involved in the synthesis by the ionic layer formation method (namely, the problem of the conditions for which the ion exchange reactions are irreversible). To some extent this state of affairs is exactly the opposite of the problems encountered in developing effective ion exchangers, since a long operating life in that case requires a knowledge of the reversibility conditions of the adsorption of ions on the surface. Very little is known about the ability of the layers synthesised in the first stages of layer deposition to take part in later ion exchange reactions during repeated exposures of the support to the reactants, and also about the properties of the layers synthesised in this way.

III. Preparation of thin layers of various compounds

Synthesis of manganese oxide and chromium hydroxide layers. At first sight layers of metal hydroxides and oxides can be synthesised by successively depositing layers of metal and of hydroxyl ions on the surface by the scheme

$$[M]OH + M_1^{n+} \rightarrow [M]OM_1^{(n-1)+},$$
$$[M]OM_1^{(n-1)+} + OH^- \rightarrow [M]OM_1(OH)_{(n-1)}.$$

However, this expectation is not fulfilled, since the layer of hydroxide formed after the first cycle redissolves in subsequent exposures to a solution of the metal salt, even at the highest pH values, by the reaction

$$[M]OM_1(OH)_{(n-1)} + H^+ \rightarrow [M]OH + M_1(OH)^+_{(n-1)}.$$

Therefore the writer proposed a method of synthesising hydroxide layers by converting the ions of the adsorbed metal layer into a higher valency state, for which the interaction with the solution of the metal salt is not reversible.[48] Layers of MnO_2 were synthesised in this way from $Mn(NO_3)_2$ or $MnSO_4$ and $KMnO_4$. As a result of these reactions every manganese ion was converted into the Mn^{4+} state of oxidation by the scheme

$$[M]OH + MnOH^+ \rightarrow [M]OMnOH + H^+,$$
$$[M]OMnOH + MnO_4^- \rightarrow [M]O(MnO_2)_2OH.$$

A more substantial adsorption of Mn^{2+} ions on the substrate surface was obtained by adding NaOH to a solution of $MnSO_4$ to give a pH value differing by a few tenths of a pH unit from the $Mn(OH)_2$ precipitation value. After each treatment the excess of reagent was removed by washing the sample with an aqueous solution saturated with Mn^{4+} ions. This suppressed the dissolution of the MnO_2 layer even at the stage of washing the support and its layer free from the excess of each of the reagents.

The synthesised layers were studied spectrophotometrically in the visible and UV regions and by IR spectroscopy. Their composition was found to correspond to hydrated MnO_2, and a regular increase in the layer thickness with the number of layering cycles was demonstrated.

The coating of the surface of carbon steel with a layer of chromium hydroxide has also been reported.[49,50] In this case the support was treated successively, several times, with aqueous solutions of H_2CrO_4, CrO_3, and $Na_2S_2O_3$ or $NaNO_2$, and washed free from the excess of reagent with water after each exposure. Irreversibility of the adsorption of the $HCrO_4^-$ ions on the surface of the growing layer of hydroxide was achieved by an intermediate heating of the substrate bearing a thin layer of CrO_3 solution to

150–200 °C. This heating stage evaporated the water and resulted in binding the $HCrO_4^-$ (for example) to the FeOH groups of the surface by forming Fe–O–Cr groups:

$$[Fe]OH + H_2CrO_4 \xrightarrow{T} [Fe](OCrO_2OH)_{ads}(CrO_3)_x ,$$

$$[Fe](OCrO_2OH)_{ads}(CrO_3)_x \xrightarrow{H_2O} [Fe](OCrO_2OH)_{ads} ,$$

$$[Fe](OCrO_2OH)_{ads} + Red \rightarrow [Fe]OCr(OH)_2 .$$

After this treatment in a reducing solution the adsorbed Cr^{6+} ions were converted into the Cr^{3+} ions of a layer of chromium hydroxide, which is insoluble at the given pH value.

A practically important result of these syntheses is a marked increase in the corrosion resistance of the steel surface, depending on the number of layer deposition cycles. Thus, whereas a repeated treatment with solutions of oxidiser and reducer produces a negligibly small change in the corrosion resistance, an alternating treatment by the ionic layer deposition mechanism gives an almost 15-fold improvement after 10 layer deposition cycles, as shown by measurements in a 2% solution of $CuSO_4$. It is also important to note that the observed corrosion resistance values greatly exceed the level of protection offered by existing methods of depositing chromate conversion coatings.

Synthesis of layers of barium phosphate and zinc chromate. Reference was made above to some studies[32–35] of the increased adsorption of PO_4^{3-} ions on the surface of cation-exchanged forms of silica gel and of metal ions which form sparingly soluble compounds with PO_4^{3-} on the surface of phosphate-substituted silica gel. However, no detailed mechanism of these interactions has yet been suggested.

A recent Patent[51] discloses a method of synthesising a layer of barium phosphate on a carbon steel surface by using $Ba(NO_3)_2$ and Na_2HPO_4 as reagents with an intermediate washing of the sample with water to remove the excess reactants and products:

$$[Fe]OH + Ba^{2+} \rightarrow [Fe]OBa^+ ,$$

$$[Fe]OBa^+ + HPO_4^{2-} \rightarrow [Fe]OBaHPO_4^- .$$

A result of practical value from this work was the achievement of an almost 10-fold increase in the corrosion resistance of the metal as compared with the existing method of producing phosphate conversion layers. This difference can probably be ascribed to a lower porosity of the coatings obtained by the new method.

Great interest has been shown in the synthesis of binary oxide layers not only on pure metal surfaces but also on a metal coated with a layer of oxide prepared (for example) by a passivation treatment. In this case we have shown[52] that a synthesis by the ionic layer deposition of $ZnCrO_4$ on a layer of the same compound on zinc (obtained in a passivating chromate solution) produces a greatly increased corrosion resistance of the surface after 10 layer deposition cycles, and solves the practically important problem of increasing to 200 °C the thermal stability of the passivating conversion layer, which had a limit of 60 °C before the layer deposition treatment. The reagents used in this study were $Zn(CH_3COO)_2$ and Na_2CrO_4. Irreversibility of the adsorption of CrO_4^{2-} on the $ZnCrO_4$ surface was achieved by an intermediate heating of the sample with a layer of Na_2CrO_4 solution at 150–200 °C for 1–2 min:

$$[Zn](ZnCrO_4)_mZnOH + Na_2CrO_4 \xrightarrow{T} \rightarrow [Zn](ZnCrO_4)_m(ZnCrO_4^-)(Na_2CrO_4)_x ,$$

$$[Zn](ZnCrO_4)_m(ZnCrO_4^-)(Na_2CrO_4)_x \rightarrow \rightarrow [Zn](ZnCrO_4)_m(ZnCrO_4^-)_{ads} ,$$

$$[Zn](ZnCrO_4)_m(ZnCrO_4^-)_{ads} + Zn(CH_3COO)_2 \rightarrow \rightarrow [Zn](ZnCrO_4)_m(ZnCrO_4)Zn^+_{ads} .$$

Synthesis of layers of copper and zinc sulphides. The first studies of the synthesis of ultra-thin layers of CuS were carried out by the method proposed by Rotrekl et al.[53] in the early 1970s. The method has been developed for the deposition of an electrically conducting layer on the surface of a dielectric. These layers are strongly bound (chemically) to the surface, and their electrical resistance is relatively low. Therefore they produce effective current-carrying layers for the electrochemical metallisation of dielectrics (and especially of plastics). Published work in this area has already been reviewed.[54]

In most cases the layers of CuS were synthesised by using solutions of $CuSO_4$ and Na_2S as reagents. When a layer is deposited on supports made of various materials (wood, fibrous silicates, unglazed porcelain) the first stage can be the adsorption of either Cu^{2+} or S^{2-} ions. To increase the thickness of the deposited layer the substrate should be washed free from the excess of Cu^{2+} with hot water, which hydrolyses the surface compounds of Cu^{2+} and inhibits their removal. In treatments by 3–5 exposures the sample is not usually washed free from the excess of S^{2-} ions: this also favours the deposition of thicker layers. In this way the resistance of a layer of CuS was lowered to 10^3–10^4 Ω cm^{-1} after three treatments. Even lower resistances have been obtained[56] by adding Zn^{2+} ions to the solution of $CuSO_4$.

All these studies had one feature in common: they aimed to solve a specific technological problem (in this case, the production of an electrically conducting layer). Little attention was paid to the special aspects of the synthesis or to the mechanism of the reactions.

These problems were adequately studied (in the case of ZnS and CdS layers) by Nikolau et al.,[56–60] who proposed the term SILAR (Successive Ionic-Layer Adsorption and Reaction) for the above method of synthesising metal sulphide layers. Other names have been used for the same procedure in the Russian literature: ionic layer epitaxy[61] and layer chemisorption.[62] We believe that all these names only partially reflect the true nature of the processes taking place on the surface, since the ionic layer deposition may not involve epitaxy, and the dominant process in the synthesis could be the interaction of layers of physisorbed ions. In this review we shall retain the term which has been adopted in the Russian literature, and call the process (by analogy with molecular layer deposition) ionic layer deposition. This term is only slightly different from the term proposed by Nikolau.

It has been established[56] that in the synthesis of a layer of ZnS on the surface of ITO the maximum growth rate (3.0–3.1 Å per cycle of layer deposition) is obtained by using a 5 M solution of $ZnCl_2$ and a 2.8 M solution of Na_2S. For CdS the maximum rate of 1.3–1.4 Å per cycle was obtained for a 5 M solution of $CdCl_2$ and a 2.8 M solution of Na_2S. The maximum surface coverages during the adsorption were calculated from the growth rates: $\Phi_{Zn} = 0.72$ and $\Phi_S = 0.72$ (for ZnS) and $\Phi_{Cd} = 0.23$ and $\Phi_S = 0.2$ (for CdS).

In order to identify the mechanism of the adsorption of Zn^{2+}, Cd^{2+}, and S^{2-} the ξ potentials were measured[58] in solutions of different concentrations and different pH. Three critical points were found on the experimental curves: CR1, CR2, and CR3. At pH values lower than CR1 (2.3 for ZnS and 1.8 for CdS) the sulphide surface is positively charged owing to the adsorption of H^+ on the sulfur adsorption centres. For pH values between CR1 and CR2 (up to 7.5 for ZnS and up to 10 for CdS) the charge can be both negative (because of the ionisation of Brönsted-acid centres) and positive (because of the adsorption of the Zn^{2+} and Cd^{2+} ions on these centres or of the chemisorption of $ZnOH^+$ on the S^{2-} ions). At pH > 9 for ZnS and pH > 11 for CdS the surface is charged negatively because of the adsorption of OH^- ions on $Zn(OH)_2$ and $Cd(OH)_2$.

If one allows for these results and for data on the growth rate of layers in solutions of reagents of different concentrations, the following model can be proposed for the growth of the layer.

As we know, the dissolution of $ZnSO_4$ and Na_2S in water is accompanied by dissociation and hydrolysis:

$$ZnSO_{4\,aq} \leftrightarrows Zn^{2+}_{aq} + SO^{2-}_{4\,aq} ,$$

$$Zn^{2+}_{aq} + H_2O \leftrightarrows ZnOH^{+}_{aq} + H^{+}_{aq} ,$$

$$Na_2S \leftrightarrows 2Na^{+}_{aq} + S^{2-}_{aq} ,$$

$$S^{2-}_{aq} + H_2O \overset{(HS^-)}{\rightleftharpoons} HS^{-}_{aq} + OH_{aq} .$$

As soon as the ZnS support is immersed in a solution of $ZnSO_4$ the Zn^{2+} and $ZnOH^+$ ions react with the HS^-_{ads} to form more ZnS:

$$Zn^{2+}_{aq} + HS^{-}_{ads} \rightarrow ZnS + H^{+}_{aq} ,$$

$$ZnOH^{+}_{aq} + HS^{-}_{ads} \rightarrow ZnS_{ads} + H_2O .$$

Under these conditions only the number of zinc ions determined by the number of adsorption centres on the surface is taken up by the substrate, and the synthesis takes place under the condition

$$[HS^{-}_{ads}] \geqslant \frac{SP_{ZnS} K_1 [H^+]}{[Zn^{2+}_{aq}]} ,$$

where SP ($\cong 2 \times 10^{-22}$) is the solubility product of ZnS and K_1 ($\cong 1 \times 10^{-15}$) is the protonation constant of S^{2-}. The following condition must also be fulfilled in order to avoid layer formation by the precipitation of colloidal ZnS:

$$[HS^{-}_{aq}] < \frac{SP_{ZnS} K_1 [H^{+}_{aq}]}{[Zn^{2+}_{aq}]} .$$

Beyond this point we find a superequivalent adsorption of Zn^{2+} and $ZnOH^+$ on the ZnS, and the charge on the surface becomes positive.

When the substrate is washed in distilled water some of the zinc ions are removed from the surface, but the pH at the surface is changed to 7 by the water, causing hydrolysis of the zinc ions which opposes the desorption.

If the substrate is then immersed in a solution of Na_2S, the S^{2-} and HS^- ions react on the surface, giving a layer of ZnS:

$$Zn^{2+}_{ads} + S^{2-}_{aq} \rightarrow ZnS ,$$

$$ZnOH_{ads} + HS^- \rightarrow ZnS + H_2O .$$

Because of their higher mobility the OH^- ions can reach the surface more rapidly when $[S^{2-}] = [OH^-]$, and react with formation of $Zn(OH)_2$. However, since the solubility product of $Zn(OH)_2$ (1.2×10^{-17}) is much greater than that of ZnS, the first formations are rapidly converted into ZnS and the positive surface charge disappears. The layer of ZnS is formed when the following condition is satisfied:

$$[Zn^{2+}_{ads}] \geqslant \frac{SP_{ZnS} K_1 [H^{+}_{aq}]}{[HS^{-}_{aq}]} .$$

To avoid the precipitation of colloidal particles of ZnS we also require that

$$[Zn^{2+}_{aq}] < \frac{SP_{ZnS} K_1 [H^{+}_{aq}]}{[HS^{-}_{aq}]} .$$

Thus the complete synthesis includes several different stages of diffusion and adsorption of ions.

As can be seen from the above description of the ionic layer deposition mechanism it should be possible to dope the layer with various ions and to create a distribution of the doping impurity over the thickness of the layer by exposing the substrate to solutions of various salts. This approach has been used in a study[59] of the synthesis of electroluminescent layers of ZnS and CdS doped with indium and manganese incorporated into the structure of the layer from solutions of $InCl_3$ and $KMnO_4$.

Layers of ZnS and CdS have also been produced[61-63] by using silicon and germanium in the (111) orientation as substrates and $Zn(NO_3)_2$, $Cd(NO_3)_2$, and Na_2S as reagents. Solid solutions of $Zn_{1-x}Cd_xS$ were synthesised from mixed aqueous solutions of $Zn(NO_3)_2$ and $Cd(NO_3)_2$.

The resulting layers, up to 200 nm thick, had a smooth mirror-like surface; the layer thickness produced by one layer deposition cycle was 3.2 Å for ZnS and 2.9 Å for CdS, corresponding to ~90% coverage of the surface by adsorbed ions.

Electron-diffraction studies of these materials showed that for ZnS the growth of the layer on the substrate surface begins with the formation of crystallites having a lattice of the wurtzite type, but when the layer thickness is increased (after 30–40 cycles) polycrystallites begin to grow with a lattice of the sphalerite type. The growth of CdS on Si(111) begins with the formation of a polycrystalline cubic structure, in which some of the crystallites are oriented in the (111) plane as the layer thickness is increased. On the other hand $Zn_{1-x}Cd_xS$ solid solutions are obtained only when the mole fraction of Cd in the solution is 0.0001–0.003, the most perfect layers being formed for $x = 0.0002$. When $x = 0.003$ the structure of the layer corresponds to the CdS cubic lattice.

Kutepov et al.[63] have studied the effect of the concentration and temperature of the solutions on the refractive index of the ZnS layers. It was established that the lowest density is found in layers grown from concentrated solutions and from solutions with identical concentrations of the reactants but prepared at low temperatures, and also in layers synthesised from the most dilute solutions. The highest refractive index was observed for solutions with a 5-fold excess of the concentration of $Zn(NO_3)_2$ over the concentration of Na_2S and at high temperatures.

In addition to ZnS, CdS, and $Zn_{1-x}Cd_xS$, layers of PbS have been synthesised by using aqueous solutions of $Pb(CH_3COO)_2$ and Na_2S as reagents on a Si(111) surface. These layers had a mirror-smooth surface and were strongly held on the substrate. After 100–200 deposition cycles their thickness was 30–50 nm, corresponding to a growth rate close to a monolayer per cycle. The structure of the PbS layers was assigned to the block monocrystal type, with a small disorientation of the blocks and a block size of 0.1 μm.

Klechkovskaya et al.[62] explained published results[56-63] on the growth mechanism of sulfide layers by postulating that the lattice parameters and the structural parameters of the substrate play a dominant role in the formation of the structure of the growing film (especially during the first stages of layer deposition). However, it was noted that under the conditions of the experiments the ordinary growth mechanism is predominant, including the adsorption of ions of both components, the formation of three-dimensional growth centres (which are not oriented with respect to the substrate in the initial stages when the mismatch of the lattice parameters is large), and their coalescence with a preferred orientation and the subsequent growth of a new layer on the substrate surface.

The growth mechanism suggested[61,63] for metal sulfide layers differs from the mechanism proposed by Nikolau,[58] probably because of the nature of the substrate materials. Thus, the former workers[61-63] used silicon and germanium as substrates, whereas Nikolau[58] used mainly ITO and molyb-denum, which adsorb S^{2-} ions as well as incorporating them in the structure of the layer growing on their surface. On the other hand when silicon or germanium are used as substrates allowance must be made for the reversibility of the adsorption of the Zn^{2+} and Cd^{2+} ions on SiOH and GeOH. Thus it has been shown[64] that in the adsorption of salts of these metals from aqueous solutions monolayer coverage of the surface by OH groups does not take place, and that when the sample is subsequently washed free from the excess of reagents the metal in the Si–O–M bond is replaced by a proton. Clearly, the first treatments do not form continuous layers of the sulfides on the surface. We must also allow for the possible adsorption, from solutions of metal salts at concentrations greater than

0.01 – 0.001 M, of clusters of metal hydroxides, formed (as reported[65–67]) during the ageing of the solutions. The subsequent treatment of these layers in a solution of sodium sulfide, which has a strongly alkaline reaction, should produce a partial dissolution of the hydroxides with precipitation of the sulfides by the destructive epitaxial interaction mechanism. Under these conditions a continuous layer cannot be produced during the initial stages of the treatment. A possible explanation of the mechanism of the three-dimensional growth of the layer may be found in the suggested[68] superequivalent adsorption of the ions on the surface at solution concentrations greater than 0.001 M.

A substantial contribution to the uncontrolled growth of the layer comes also from the incomplete removal of the excess of reagents from the substrate. In this case the thickness of the prepared layer is determined by the kinetic parameters of the washing operation. In spite of its importance this topic is not adequately dealt with in published papers.[56–63]

Synthesis of layers of cadmium telluride on a gold electrode surface. It has been pointed out[57] that the ionic layer deposition method can be used to synthesise layers on electrode surfaces by controlling the adsorption processes through the electric field. Clearly, the ions which interact on the surface have a charge, and their motion can therefore be controlled by an electric field.

Thus, Shtikin et al.[69] deposited, in a thin-walled electrochemical cell, two monolayers of CdTe on the surface of a gold single crystal which had been previously cleaned in an ultra-high vacuum. The reagents were a 1.0 μM solution of $CdSO_4$ in an acetate buffer and a 0.4 μM solution of TeO_2 in H_2SO_4 (pH 2.2). The potential of the electrode was varied between −0.6 and 0.8 V at a rate of 2 mV s^{-1} while measuring the current in the cell filled with each reagent successively. Two peaks, corresponding to the adsorption of the Cd^{2+} and the Te^{2-} ions, were detected in the current – voltage curves.

The composition of these layers was studied by low-energy electron diffraction and Auger spectroscopy, and a structure-chemical model of the arrangement of the atoms in the layer was constructed. This suggested a high degree of perfection of the layers and good control over the conditions of synthesis.

IV. Conclusions

The experimental information reviewed above makes clear several advantages of the ionic layer deposition method, such as the possibility of depositing layers of various substances (including pure substances and multicomponent binary compounds of the main classes of solids), the high precision of control over the layer thickness, and the ability to prepare layers in automated regimes at low temperatures on objects of complex shape. In spite of the simplicity of the method, the synthesis of a layer on the surface relies on several processes in parallel: the adsorption and desorption of the ions, their multistage hydrolysis, and diffusion from the bulk to the surface layer.

In all the substrate – growing layer systems considered here these processes allow the synthesis to be carried out by a chemical assembly mechanism and the growth of the layer to be controlled very precisely. Allowance is needed for the effect of the concentration and temperature of the reactants, the pH of the solutions and of the wash liquid, the time of treatment and of washing out the reagents, and the method of surface preparation before the synthesis. This is specially true of the synthesis of two or more regions in the layer, including the addition of a doping impurity with a prescribed distribution over the thickness of the layer. All these aspects constitute a fairly complex physico-chemical problem. Therefore at present it is as important to identify the general features of the synthesis in each class of materials (for example, metal sulfides and phosphates) as to produce still more experimental information on the synthesis of the layers, or to systematise it: this approach should allow the prediction and selection of the synthesis conditions for new types of layers. Special attention should be paid to the synthesis by the ionic layer deposition method of layers which cannot be prepared by other methods (for example, owing to the involatility of the starting compounds in the case of synthesis from the gas phase or because of thermal instability).

Phosphorus-containing nucleophiles in reactions with polyfluorinated organic compounds

G G Furin

Contents

I. Introduction 243
II. Reactions of phosphorus-containing nucleophiles with unsaturated perfluorinated compounds 222
III. P-Nucleophiles as synthons in the synthesis of perfluorinated organic compounds without phosphorus atoms 253
IV. Conclusion 257

Abstract. The review presents a compilation of new experimental data on the reactions of phosphorus-containing nucleophiles [triphenylphosphine, trialkylphosphines, trialkyl phosphites, phosphorus tris(diethylamide), etc.] with perfluorinated olefins and aromatic and heterocyclic compounds, leading to substances both with and without a phosphorus atom. It is shown that the interaction of phosphorus tris(diethylamide) and trialkylphosphines with organic polyfluoro-compounds and perfluoroolefins leads to the formation of phosphoranes, the decomposition of which is accompanied by the generation of aryl and alkenyl anions. The reactions of these anions with C-electrophiles and compounds containing mobile halogen atoms are examined. In addition, the pathways in the Arbuzov reaction involving a series of unsaturated perfluorinated compounds are analysed. Possible applications of these reactions in organic synthesis are demonstrated. The bibliography includes 120 references.

I. Introduction

The interest shown by investigators in the chemistry of organophosphorus compounds can be explained by their high reactivity and a unique set of properties, which make these substances valuable objects for theoretical research and impart to them practical importance.[1] However, organophosphorus compounds containing polyfluorinated alkyl and aryl substituents began to be investigated only recently. Bearing in mind the mutual influence of the fluorine and phosphorus atoms on the properties of the entire molecule, one can postulate that such compounds have many interesting properties.

The methods of synthesis of organophosphorus compounds are based on reactions involving the nucleophilic substitution of fluorine atoms in unsaturated organofluorine compounds on treatment with P-nucleophiles (compounds of trivalent phosphorus). Three types of reactions are then possible:

(1) substitution reactions without change in the valence of the phosphorus atom (one of the substituents at the phosphorus atom undergoes the usual exchange for a perfluorinated substituent);

(2) substitution reactions accompanied by the oxidation of the phosphorus atom (they lead to the formation of phosphonium salts, phosphoranes, and phosphinic and phosphonic acid esters in which the phosphorus atom is in pentacoordinate and tetracoordinate states);

(3) reactions in which compounds of tricoordinate phosphorus play the role of a synthon, the final product of such reactions being compounds with a new C–C bond and without a phosphorus atom.

Whereas the reactions of the first two types have long been known and have been thoroughly investigated for a wide range of P-nucleophiles, those of the third type are in fact characteristic of the polyfluorinated compounds. They have come to constitute one of the methods of synthetic organic chemistry used to introduce various perfluorocarbon groups into the molecule. One can now note that these procedures have a great future.

The introduction of a fluorine atom into organophosphorus compounds leads to extensive possibilities both in the synthesis of biologically active compounds and in the determination of the relation between the chemical structure and properties of compounds of this class. At the present time, the stage involving the accumulation of experimental data on the synthesis of compounds of this class may be regarded as completed and attention should now be concentrated on the study of their structures, reactivities, and reaction mechanisms. A series of experimental data on the reactions of triethyl phosphite with perfluoroisobutene and aromatic polyfluoro-compounds have been compiled in a number of reviews.[2–4] On the other hand, inadequate attention has been devoted in the literature to questions of the reactivity of other P-nucleophiles in reactions with organic polyfluoro-compounds. At the same time, the biological activity and unique properties of materials based on fluorine-containing organophosphorus compounds have created a basis for their practical use, so that systematic treatment and analysis of the accumulated extensive data are urgently required and the publication of a review on this topic should stimulate further research on these lines.

The arrangement of the data is based on the nature of the P-nucleophile because the latter actually introduces significant differences into the behaviour of perfluorinated compounds and determines the nature of the products formed.

II. Reactions of phosphorus-containing nucleophiles with unsaturated perfluorinated compounds

Nucleophilic reactions of derivatives of trivalent phosphorus are some of the most important and varied in the chemistry of organophosphorus compounds. One of the most widely used is the reaction of trialkyl phosphites and dialkyl phosphonites with alkyl halides and other alkylating agents, accompanied by the formation of phosphonic and phosphinic acid esters.[5] By virtue of the high electronegativity of the fluorine atom, its introduction into an organic molecule influences significantly the charge characteristics of the carbon atom, increasing its positive charge.[3] Nucleophilic substitution reactions become characteristic of compounds of this type and the nature of the products formed depends significantly on the structure of the initial compound.

1. Reactions with trialkyl-, dialkyl-, and triphenylphosphines

Trivalent phosphorus compounds, which are highly nucleophilic, are known to react readily with substances incorporating electronegative halogen, sulphur, and oxygen atoms. In conformity with their nucleophilicity, phosphines can be arranged in the following sequence in terms of their reactivities: $PPh_3 > Ph_2POEt > PhP(OEt)_2 > P(OEt)_3$. When halogen-containing compounds are acted upon by phosphines and phosphites, compounds of two types may be formed, in which the phosphorus atom either retains its valence (new phosphines and phosphites) or its valence increases (for example, with formation of phosphoranes). We shall consider reactions occurring with retention of the valence of the phosphorus atom.

It has been shown[6,7] that hexafluoropropene reacts with dialkylphosphines R_2PH, affording perfluoropropenyl derivatives and phosphonium fluoride $R_2P^+H_2F^-$. The reaction proceeds via the intermediate formation of two 1,3-betaines as a result of the nucleophilic attack by the phosphorus atom on the C(1) atom. The intermediate **A** is more favourable on energy grounds than **B**, because the steric hindrance generated by the bulky CF_3 and PR_2H groups is smaller in the latter.

The intermediates **A** and **B** can be stabilised in two ways: either as a result of the migration of the F(1) ion (pathway *a*) in the *trans*-position with respect to the electron pair of the C(2) atom (the quasi-phosphonium ions formed are deprotonated, affording the corresponding phosphines) or as a result of the 1,2-migration of the fluorine atom to the phosphorus atom (pathway *b*) [the (*Z*)- and (*E*)-fluorophosphoranes formed in this process are subsequently dehydrofluorinated].

In the reaction of tri(*tert*-butyl)phosphine with hexafluoropropene, the fluorine atom at the C(1) atom is substituted and the phosphine **3**, isobutene, and tri(*tert*-butyl)phosphonium fluoride are formed. The last two compounds are obtained from the initial phosphine and fluorotrimethylmethane — one of the products of the reaction of the perfluoroolefin with phosphine.

In contrast to this, in the reaction of phenylphosphine with

$$CF_3CF=CF_2 + P(Bu^t)_3 \longrightarrow [CF_3CF=CF-P(Bu^t)_3]^+F^- \xrightarrow{P(Bu^t)_3} CF_3CF=CFP(Bu^t)_2 + Me_2C=CH_2 + (Bu^t)_3\overset{+}{P}HF^-.$$

3

tetrafluoroethylene, nucleophilic addition to the double bond takes place with formation of phenyltetrafluoroethylphosphine **4**.[8]

In the presence of an excess of tetrafluoroethylene, the disubstituted phosphine $PhP(CF_2CHF_2)_2$ is formed as well as compound **4**. In the presence of an inhibitor of the polymerisation of tetrafluoroethylene and for the 1 : 1 reactant ratio, the yield of compound **4** is 84%. The adduct resulting from the addition of phenylphosphine to 1,1-difluoroethylene is formed in approximately the same yield.

$$CF_2=CF_2 + PhPH_2 \xrightarrow{150^\circ C} PhPHCF_2CHF_2.$$

4

Diethylphosphine reacts with perfluorobut-2-yne at −78 °C with formation of the *trans*-isomer **5**.[9]

$$CF_3C\equiv CCF_3 + Et_2PH \longrightarrow Et_2P(CF_3)C=CHCF_3$$

5 (45%).

According to Fild et al.,[10] the reaction of CF_2Br_2 with organylbis(trimethylsilyl)phosphine $RP(SiMe_3)_2$ and diorganyl(trimethylsilyl)phosphine R_2PSiMe_3 (R = Ph, Bu^t, Me) leads to the formation of the diphosphetan **6** and R_2PCF_2Br respectively.

$$RP(SiMe_3)_2 + CF_2Br_2 \longrightarrow \text{(6)};$$

6

$$R_2PSiMe_3 + CF_2Br_2 \longrightarrow R_2PCF_2Br.$$

The structure of compound **6** was confirmed by X-ray diffraction analysis and ^{19}F and ^{31}P NMR spectroscopy. It is suggested that the diphosphetan **6** is formed via an intermediate phosphaalkene as a result of its subsequent thermal decomposition.

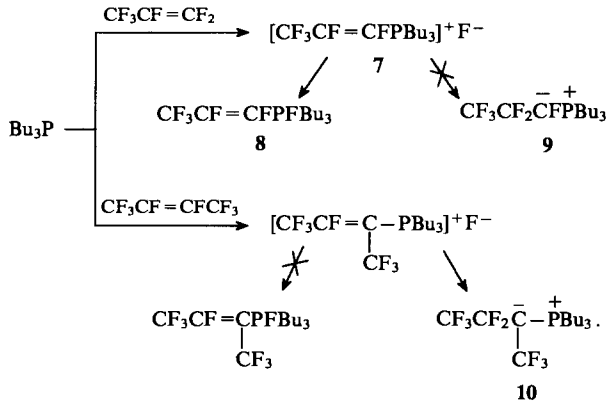
The reaction of diphenyltrimethylsilylphosphine with CF_3I at 20 °C leads to the formation of diphenyltrifluoromethylphosphine in 78% yield.[11] The same compound is obtained in a satisfactory yield by the reaction of CF_3I with triphenylphosphine at 185–200 °C.[12]

Table 1. Fluorophosphoranes obtained by the reaction of tributylphosphine with perfluoroolefins.[15]

Olefin	Reaction product	Yield (%)	*E*/*Z*
$CF_3(CF_2)_2CF=CF_2$	$CF_3(CF_2)_2CF=CFPF(Bu^n)_3$	81	100 (*Z*)
$CF_3(CF_2)_4CF=CF_2$	$CF_3(CF_2)_4CF=CFPF(Bu^n)_3$	83	100 (*Z*)
$CF_3CPh=CF_2$	$CF_3CPh=CFPF(Bu^n)_3$	84	91/9
$CF_3CF_2CPh=CF_2$	$CF_3CF_2CPh=CFPF(Bu^n)_3$	87	92/8

Trimethylphosphine reacts with trifluoroiodomethane to form dimethyltrifluoromethylphosphine and tetramethylphosphonium iodide.[13, 14]

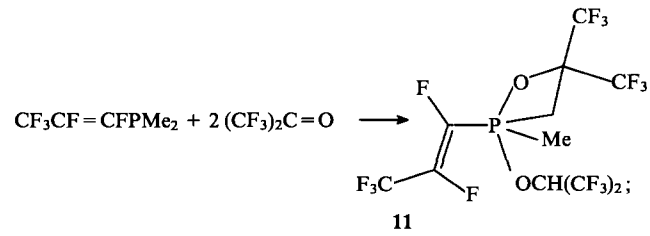
$$Me_3P + ICF_3 \longrightarrow [Me_3PCF_3]^+I^- \xrightarrow{Me_3P} Me_2PCF_3 + [Me_4P]^+I^-.$$



Reactions of another type, specific to perfluorinated organic compounds, involve the formation of fluorophosphoranes. Thus it has been shown[15] that tributyl- and trimethyl-perfluoropropenylfluorophosphoranes are formed in the reaction of hexafluoropropene with tributyl- and trimethylphosphines respectively.

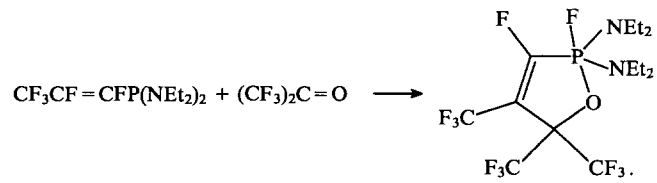
$$CF_3CF=CF_2 + R_3P \longrightarrow CF_3CF=CFPFR_3$$

R = Me, Bu^n.



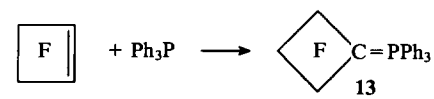
Other perfluoroalk-1-enes react similarly (Table 1), the *trans*-isomers being mainly formed (Scheme 1).

Scheme 1



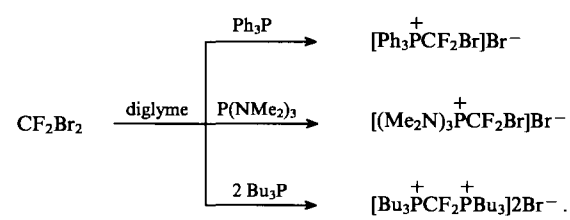
The primary step in these reactions involves the attack by the nucleophilic phosphorus atom on a carbon atom, leading to the quasi-phosphonium salt **7**, from which compound **8** is formed as a result of the 1,2-migration of the fluoride anion to the phosphorus atom. The phosphorus ylide **9** is not obtained in this reaction. On the other hand, in the case of perfluorobut-2-ene the main reaction product is believed[15] to be in fact the ylide **10** of this kind, while the corresponding phosphorane is not formed. The structure of compound **10** was confirmed by ^{31}P and ^{19}F NMR spectroscopy.

A series of phosphines react with carbonyl compounds. Thus it has been shown[6, 7] that dimethylperfluoropropenylphosphine and bis(diethylamino)perfluoropropenylphosphine react with hexafluoroacetone, affording cyclic phosphorus compounds: 1,2-oxaphosphetan **11** and 1,2-oxaphospholen **12** respectively.



11

12



By allowing triphenylphosphine to react with perfluorocyclobutene, Stochel et al.[16] obtained, instead of a phosphorus ylide, 2,2,3,3,4,4-hexafluoro(triphenylphosphoranylidene)cyclobutane **13**, the structure of which was later confirmed by X-ray diffraction.[17]

13

Perfluorobutadiene also reacts with triphenylphosphine to form 1 : 1 adducts, which consist of relatively unstable cyclic phosphoranes.

When the polyfluoroolefin molecule contains other halogen atoms as well as those of fluorine, stable phosphonium salts are formed. For example, the reaction of dibromodifluoromethane with triphenylphosphine[18] or tris(dimethylamino)phosphine[19] affords phosphonium salts in quantitative yields. A diphosphonium salt is formed in the presence of an excess of the phosphine. The reaction is of the S_N2 type.

2. The Arbuzov reactions of perfluorinated compounds

Trialkyl phosphites induce the dehalogenation of certain vicinal dihalo-derivatives.[21]

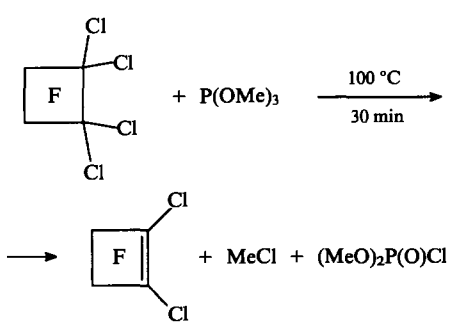
$$(EtO)_3P + BrCF_2CFBrCl \longrightarrow CF_2=CFCl + (EtO)_2P(O)Br + EtBr.$$

Table 2. Reactions of haloperfluoroalkanes with triethyl phosphite.[20]

Initial compound	Reaction product	Yield (%)
$I(CF_2)_6CFClCF_2Cl$	$I(CF_2)_6CF=CF_2$,	23,
	$I(CF_2)_6CF=CFP(O)(OEt)_2$	50
$I(CF_2)_4CFClCF_2Cl$	$I(CF_2)_4CF=CF_2$,	38,
	$I(CF_2)_4CF=CFP(O)(OEt)_2$	46
$I(CF_2)_2CFClCF_2Cl$	$I(CF_2)_2CF=CFP(O)(OEt)_2$	43.5
$ClCF_2CFCl(CF_2)_4CFClCF_2Cl$	$(EtO)_2(O)PCF=CF(CF_2)_4CF=CFP(O)(OEt)_2$	17

When trialkyl phosphites are heated with $Cl(CF_2CFCl)_nCl$, olefins are formed.[22] Having observed this property of trialkyl phosphites, the authors suggest that the reaction proceeds via the formation of the product **14** of the usual Arbuzov rearrangement, which subsequently decomposes, affording diethyl phosphorochloridate and a polyfluoroolefin.

$$CFCl_2CF_2CFClCF_2Cl + P(OEt)_3 \longrightarrow$$
$$\longrightarrow \underset{\mathbf{14}}{CFCl_2CF_2CFClCF_2P(O)(OEt)_2} \longrightarrow$$
$$\longrightarrow CFCl_2CF_2CF=CF_2 + ClP(O)(OEt)_2.$$



It has been shown[20, 23, 24] that the reactions of triethyl phosphite with α,β-dichloro-ω-iodoperfluoroalkanes does indeed involve dehalogenation, but the products are a mixture of ω-iodoperfluoroalk-1-enes and diethyl esters of ω-iodoper-fluoroalk-1-enylphosphonic acids (Table 2).

$$RCF(X)-CY_2(Cl) \xrightarrow[[-XCl]]{P(OEt)_3} [RCF=CY_2] \xrightarrow[-EtY]{P(OEt)_3}$$
$$\longrightarrow RCF=CYP(O)(OEt)_2$$

X = F, Y = Cl, R = $CFCl_2$;
X = Cl, Y = F, R = $I(CF_2)_2$, $I(CF_2)_4$, $I(CF_2)_6$.

Knunyants and Pervova[23] suggest a different mechanism of the dehalogenation process, consisting in the initial splitting off of two halogen atoms in vicinal positions with formation of diethyl phosphorochloridate and ω-iodoperfluoroalk-1-ene, which interacts with triethyl phosphite, affording the product of the Arbuzov rearrangement. Only in the reaction of triethyl phosphite with dichloroiodotrifluoroethane is the halogen split off without the formation of the corresponding phosphonates. Chlorotrifluoroethylene is then obtained in a quantitative yield.

The results of a study[25] in which it was shown that the dehalogenation of polyhalogenated cyclobutanes by trimethyl phosphite leads to polyfluorocyclobutenes are consistent with these ideas.

The defluorination of perfluoro-*N*-fluoropiperidine by triphenylphosphine, leading to perfluoro-1-azacyclohexene, was described previously.[26]

In the reaction of chlorofluoroalkanes with triethyl phosphite, attack by the chlorine atom on the phosphite molecule results in the intermediate formation of the phosphonium salt **16**.[27]

$$(EtO)_3P + CCl_3(CF_2)_nCl \longrightarrow$$
$$\longrightarrow \underset{\mathbf{16}}{[(EtO)_3PCl]^+[CCl_2(CF_2)_nCl]^-} \longrightarrow$$
$$\longrightarrow \underset{\mathbf{17}}{CCl_2=CF(CF_2)_{n-1}Cl} + \underset{\mathbf{18}}{EtCCl_2(CF_2)_nCl} +$$
$$+ \underset{\mathbf{19}}{(EtO)_2P(O)CCl=CF(CF_2)_{n-1}Cl} + (EtO)_2P(O)Cl.$$

The further reaction of the salt **16** leads to the dehalogenation and alkylation products **17** and **18** respectively. Furthermore, the Arbuzov reaction with participation of the olefin **17** affords compound **19**.

Certain perfluorohaloalkanes also enter into the Arbuzov reaction. In the presence of bromine as well as fluorine atoms in the alkyl group, the Arbuzov reaction then proceeds with participation of the bromine atoms (Table 3).[28]

$$CFXY_2 + P(OR)_3 \xrightarrow[25-50\ °C,\ 24\ h]{\text{triglyme}} (RO)_2(O)PCFXY + RY.$$

On the other hand, the compounds CF_3Cl, CF_3I, and $CFCl_3$ are inert under the conditions of the Arbuzov reaction.[29, 30]

The Arbuzov reaction with participation of polyfluorinated alkyl halides can be carried out under UV irradiation. Thus the reaction of perfluoroalkyl iodides with triethyl phosphite under UV irradiation,[31] leading to diethyl perfluoroalkylphosphonate **20**, has been achieved. The reaction probably proceeds in accordance with the following mechanism:

$$CF_3I \xrightarrow{h\nu} \dot{C}F_3 + \dot{I},$$
$$\dot{C}F_3 + (EtO)_3P \longrightarrow CF_3\dot{P}(OEt)_3 \xrightarrow{CF_3I}$$
$$\longrightarrow \underset{\mathbf{21}}{[CF_3P(OEt)_3]^+I^-} + \dot{C}F_3;$$
$$[CF_3P(OEt)_3]^+I^- \longrightarrow \underset{\mathbf{20}}{CF_3P(O)(OEt)_2} + EtI.$$

Table 3. Reactions of dibromodifluoromethane and tribromofluoromethane with trialkyl phosphites $P(OR)_3$ (data of Burton and Flynn[28]).

$CFXY^2$	R	Solvent	Yield (%)
CF_2Br_2	Me	triglyme	55
	Et	diethyl ether	95
	Et	triglyme	55
	Bu^n	diethyl ether	65
	Pr^i	triglyme	42
$CFBr^3$	Et	diethyl ether	78
	Et	triglyme	60
	Pr^i	diethyl ether	22

The trifluoromethyl radical, formed on dissociation of trifluoromethyl iodide, attacks a molecule of triethyl phosphite, giving rise to a phosphoranyl radical. The latter is oxidised by trifluoromethyl iodide to the quasi-phosphonium salt **21**, which decomposes with liberation of ethyl iodide and diethyl trifluoromethylphosphonate **20**. The reaction is carried out in an excess of trifluoromethyl iodide over a period of 10 h, the yield of the phosphonate being 51%.

Pentafluoroiodobenzene reacts with triethyl phosphite at the C–I bond also only on exposure to UV radiation (350 nm), whereupon diethyl pentafluorophenylphosphonate **22** is formed.

$$C_6F_5I + (EtO)_3P \longrightarrow \underset{\mathbf{22}\ (32\%)}{C_6F_5P(O)(OEt)_2} + EtI.$$

The reaction of dichlorotrifluoroethyl hexafluoroiodopropyl ether **23** with triethyl phosphite in the presence of *tert*-butyl peroxide takes place similarly.[32] The trivalent phosphorus derivative **24** is formed initially and is then oxidised to the phosphonate **25**.

$$\underset{\mathbf{23}}{CF_2ClCFClO(CF_2)_3I} + P(OEt)_3 \xrightarrow{(Bu^tO)_2} \underset{\mathbf{24}}{CF_2ClCFClO(CF_2)_3P(OEt)_2} \xrightarrow{Bu^tOOH} \underset{\mathbf{25}}{CF_2ClCFClO(CF_2)_3P(O)(OEt)_2}.$$

It is seen from these examples that an advantage of photochemical initiation of the Arbuzov reaction is the possibility of synthesising fluorine-containing phosphonates from available reagents in one stage.

The CH_2Br group and not CF_2Br participates in the reaction of the bromo-derivative **26** with triethyl phosphite, although the positive charge on the carbon atom of the CF_2Br group is higher than that on the carbon atom of CH_2Br.[33] Under these conditions, the (*Z*)-isomer of diethyl 4-bromo-3,4,4-trifluorobut-2-enylphosphonate **27** is formed. Steric factors probably play a role in this instance.

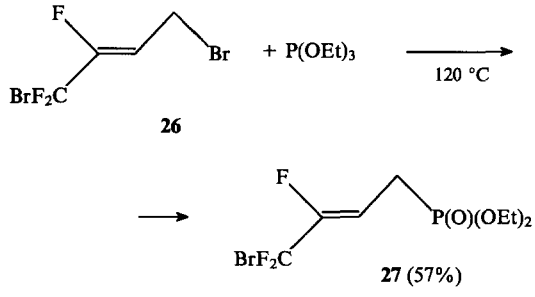


Table 4. Reactions of polyfluoroolefins with trialkyl phosphites.[36]

Fluorooelfin	Trialkyl phosphite	Reaction product	Yield (%)
$CF_2=CFCl$	$(EtO)_3P$	$CFCl=CFP(O)(OEt)_2$	10
$CF_2=CF_2$	$(Pr^iO)_3P$	$CF_2=CFP(O)(OPr^i)_2$	26
$CF_3CF=CF_2$	$(Pr^iO)_3P$	$CF_3CF=CFP(O)(OPr^i)_2$	48
$(CF_3)_2C=CF_2$	$(BuO)_3P$	$(CF_3)_2C=CFP(O)(OBu)_2$	35
$CF_3CF=CF_2$	$MeP(OPr^i)_2$	$CF_3CF=CFP(O)(OPr^i)$ | Me	51
$(CF_3)_2C=CF_2$	$(Pr^iO)_3P$	$(CF_3)_2C=CFP(O)(OPr^i)_2$	50

In contrast to perfluoroalkyl halides, perfluoroolefins react readily with trialkyl phosphites to form the esters of perfluoroalkenylphosphonic acids (Table 4).[34–36] Thus perfluoroisobutene reacts vigorously with triethyl phosphite even at −35 to 30 °C, affording the fluorophosphorane **28**, which is stable under the usual conditions. The phosphorane decomposes at 120 °C with formation of diethyl perfluoroalkenylphosphonate **29**.[37]

$$(CF_3)_2C=CF_2 + P(OEt)_3 \xrightarrow{-35\ ^\circ C} \underset{\mathbf{28}}{(CF_3)_2C=CFPF(OEt)_3} \xrightarrow{120\ ^\circ C} \underset{\mathbf{29}}{(CF_3)_2C=CFP(O)(OEt)_2}.$$

Perfluoroolefins behave similarly.[34–39]

The interaction of perfluoroolefins with triethyl phosphite takes place in two stages: the first stage of the reaction involves the formation of triethoxyperfluoroalkenylfluorophosphorane **28**, which then decomposes under more severe conditions with formation of the final products of the Arbuzov rearrangement—compound **29**. In the reaction of hexafluoropropene with triethyl phosphite, the intermediate fluorophosphorane cannot be detected, but the final product is diethyl pentafluoropropenylphosphonate.[37] The decomposition of the intermediate fluorophosphorane takes place via two pathways and leads, on the one hand, to ethyl fluoride and the full ester of perfluoroalkenylphosphonic acid and, on the other, to the fluoride of the acid ester of perfluoroalkenylphosphonic acid and diethyl ether.[37] This constitutes the specificity of the Arbuzov reaction for unsaturated perfluorinated compounds.

$$\underset{\mathbf{28}}{(CF_3)_2C=CFPF(OEt)_3} \longrightarrow \begin{cases} (CF_3)_2C=CFP(O)(OEt)_2 + EtF \\ (CF_3)_2C=CFPF(O)(OEt) + Et_2O. \end{cases}$$

The reactivity of perfluoroolefins in the reaction with triethyl phosphite diminishes in the following sequence:

$$\boxed{F} > (CF_3)_2C=CF_2 > CF_3CF=CF_2 \approx CF_2=CF_2.$$

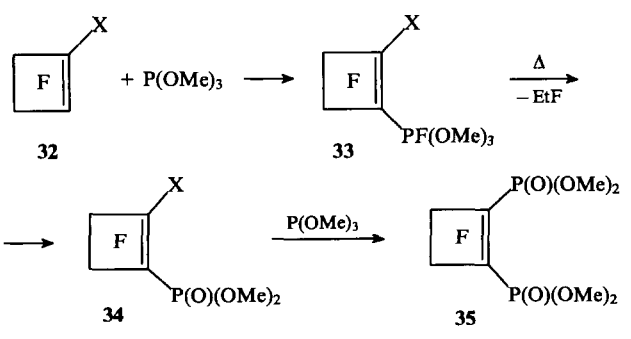
When one fluorine atom is replaced in perfluoroethylene by another halogen atom, a fluorine and not a chlorine[36] or iodine[40] atom participates in the reaction with phosphites.

Thus the reaction of trifluoroiodoethylene with tris(isopropyl) phosphite[40] affords the *trans*-di(isopropyl) ester of phosphonic acid **30**.

$$CF_2=CFI + (Pr^iO)_3P \longrightarrow \begin{cases} \xrightarrow[60\ h]{80^\circ C} \underset{\mathbf{30}\ (67\%)}{CFI=CFP(O)(OPr^i)_2} \\ \xrightarrow[80\ h]{100^\circ C} \underset{\mathbf{31}}{(Pr^iO)_2(O)P\diagdown\ \diagup F\ C=C\ F\diagup\ \diagdown P(O)(OPr^i)_2}. \end{cases}$$

However, when an excess of tri(isopropyl) phosphite is used, the iodine atom is also substituted with formation of the corresponding ester of the diphosphonic acid **31**. The reaction of trifluoroiodoethylene with other trialkyl phosphites (R = Pr^i, Et, Me) takes place similarly. We may note that in the case of bromotrifluoro- and chlorotrifluoro-ethylenes, the esters of phosphonic acids are obtained in very low yields. Thus the presence of an iodine atom at the double bond activates the fluorine atom involved in the reaction with trialkyl phosphites.

The interaction of pentafluoroazapropene $CF_3N=CF_2$ with triethyl phosphite leads to the formation of the stable trialkoxytetrafluoroazapropenylfluorophosphorane $CF_3N=CFPF(OR)_3$.[41]



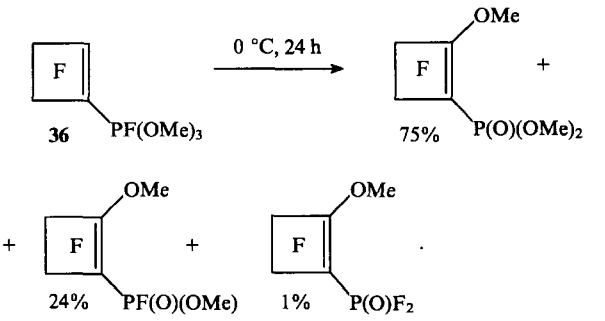
The bisphosphonate $(RO)_2P(O)CF=CFP(O)(OR)_2$ **32**, where R = Et or Pr^i, is formed when tetrafluoroethylene is treated with $(RO)_2POSiMe_3$.[42]

The reaction of triethyl phosphite with allenes results in the formation of the corresponding perfluorinated 1,3-dienylphosphonic acid esters.[43] Thus the corresponding 1,3-dien-2-ylphosphonate was obtained from tetrakis(trifluoromethyl)allene and triethyl phosphite probably as a result of the occurrence of a reaction of the S_N2 type.

$$(CF_3)_2C=C=C(CF_3)_2 \xrightarrow{P(OEt)_3} (CF_3)_2C=\underset{\displaystyle (EtO)_3PF}{\overset{\displaystyle CF_3}{\underset{|}{C}}}-\overset{\displaystyle CF_3}{\overset{|}{C}}=CF_2 \xrightarrow[-EtF]{\Delta} (CF_3)_2C=\underset{\displaystyle O=P(OEt)_2}{\overset{\displaystyle CF_3}{\underset{|}{C}}}-\overset{\displaystyle CF_3}{\overset{|}{C}}=CF_2 .$$

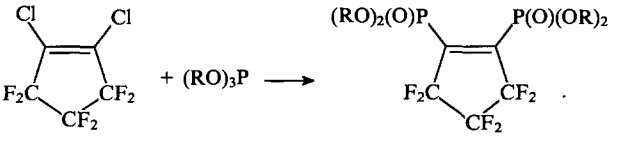
The synthesis of diethyl 2-trifluoromethylperfluoropenta-1,3-dien-3-yl-phosphonate from perfluoro-2-methylpent-2-ene and triethyl phosphite has been described[44] from the standpoint of the initial formation of tris(trifluoromethyl)allene as a result of the defluorination of the initial perfluoroolefin by triethyl phosphite and its subsequent reaction with the latter.

$$(CF_3)_2C=CFC_2F_5 + P(OEt)_3 \longrightarrow [(CF_3)_2C=C=CFCF_3] + F_2P(OEt)_3 \xrightarrow{P(OEt)_3} CF_2=\underset{\displaystyle O=P(OEt)_2}{\overset{\displaystyle CF_3}{\underset{|}{C}}}-\overset{\displaystyle CF_3}{\overset{|}{C}}=CFCF_3 .$$



X = F, Cl, Br, I.

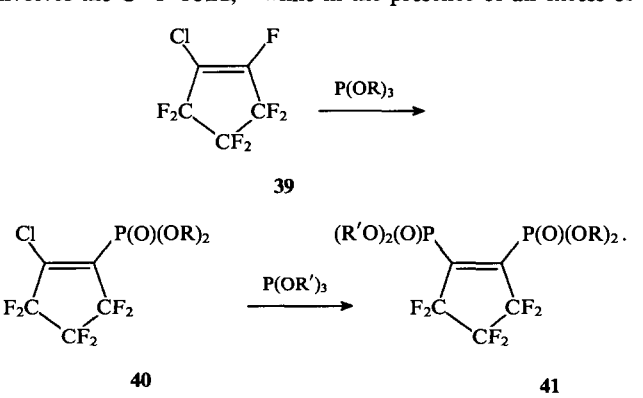
X	Yield of **33** (%)	Yield of **34** (%)
F	43	–
Cl	100	60
Br	100	49
I	100	45



Perfluorocycloalkenes can also be introduced into the Arbuzov reaction. Thus it has been shown[45, 46] that 3,3,4,4-tetrafluoro-1-halocyclobut-1-enyl-2-(trimethoxy)fluorophosphorane is formed as a result of the exothermic reaction of 1-halopentafluorocyclobut-1-ene **32** with trimethyl phosphite.

The phosphorane **33** is stable at 0 °C for several days. Its controlled decomposition leads to dimethyl cyclobutenylphosphonate **34**. On treatment of the ester **34** with an excess of trimethyl phosphite, the tetramethyl ester of 3,3,4,4-tetrafluorocyclobutenylenediphosphonic acid **35** is formed.

On the other hand, the decomposition of 1,3,3,4,4-pentafluorocyclobutenyl-(trimethoxy)fluorophosphorane **36** leads to a mixture of tetrafluorocyclobutenes, in which the fluorine atom at the multiple bond is replaced by the methoxy-group.



The reaction between 1,2-dichloro-3,3,4,4,5,5-hexafluorocyclopentene **37** and trialkyl phosphite affords tetraalkyl hexafluorocyclopentenylenediphosphonates **38**.[47]

R	Me	Et	Bu	$CH_2CH=CH_2$	Ph
Yield of **38** (%)	40	74	93	92	75

In the presence of two different halogen atoms at the double bond, for example of a chlorine and a fluorine atom, the reaction involves the C–F bond,[48] while in the presence of an excess of

R	Yield of **40** (%)	R	R'	Yield of **41** (%)
Et	33	Et	Et	50
Bu	88	Bu	Et	72.5
Me	38	CH_2CF_3	CH_2CF_3	51

trialkyl phosphite both atoms are substituted.[49] Thus the dialkyl ester of 2-chloro-3,3,4,4,5,5-hexafluorocyclopent-1-enylphosphonic acid **40** is obtained in the reaction of 1-chloro-2,3,3,4,4,5,5-heptafluorocyclopent-1-ene **39** with trialkyl phosphites, while in the presence of an excess of the phosphite the product is tetraalkyl 3,3,4,4,5,5-hexafluorocyclopent-1-en-1,2-ylenediphosphonate **41**.

It has been shown[50] that 2-chloro-1-ethylthiofluorocyclopent-1-ene is converted into diethyl 2-ethylthio-3,3,4,4,5,5-hexafluorocyclopent-1-enylphosphonate (yield 63.7%).

Arbuzov type reactions can be achieved also by treating hexafluoropropene with ethyl and isopropyl methylphosphonites.[51] The yield of the corresponding phosphinate esters **42** was 45% to 55%. The replacement of phosphites by phosphonites makes it possible to carry out the reactions under milder conditions.

$$CF_2{=}CFCF_3 + MeP(OR)_2 \xrightarrow[8-10\ h]{100-120\ ^\circ C} \underset{\mathbf{42}}{\overset{CF=CFCF_3}{\overset{|}{MeP(O)OR}}} + R-F$$

R = Et, Pr^i.

Knunyants et al.[52] introduced the chlorides of dialkylphosphinous, dialkylphosphorous, and *N,N,N',N'*-tetraalkylphosphorodiamidous acids into reactions with perfluoroolefins and, depending on the substituents and the reaction conditions, obtained different products of the reactions of the intermediate perfluoroisobutylfluorophosphoranes **43**, in particular the ester of perfluoroisobutenylphosphinic acid **44**.

$$(CF_3)_2C{=}CF_2 + X-PCl-Y \longrightarrow \underset{\mathbf{43}}{[(CF_3)_2C{=}CFPFClXY]} \xrightarrow[X=Y=OEt]{\Delta} (CF_3)_2C{=}CFPF(O)(OEt)$$

44

X = Y = Et, EtO, Me_2N, Et_2N.

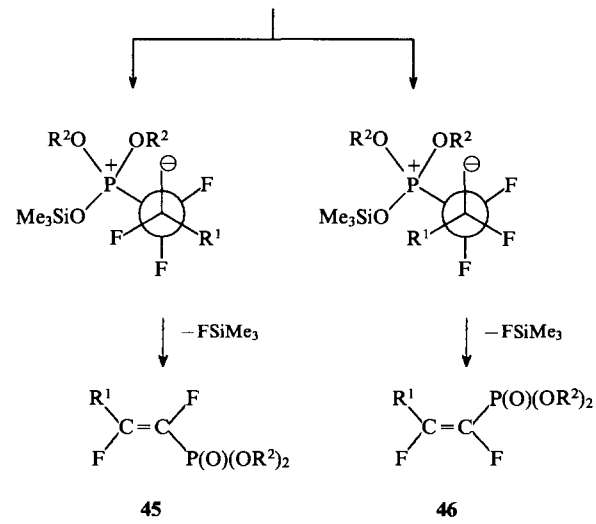
The reactivities of the chlorides of the above acids in relation to perfluoroisobutene proved to be lower than the reactivity of their full esters. Thus, whereas perfluoroisobutene reacts with triethyl phosphite at −30 °C, the acid chlorides react with the above olefin only at an elevated temperature, except for *N,N,N',N'*-tetraethylphosphorodiamidite, which reacts at room temperature. Knunyants et al.[52] derived the following reactivity series for the above reagents:

$$(Et_2N)_2PCl > (Me_2N)_2PCl > (EtO)_2PCl > Et_2PCl.$$

They explain the above decrease in reactivity by the decrease in the capacity of the substituents X for $p-d$ conjugation with the phosphorus atom. In the last compound, there is no $p-d$ conjugation.

It has been shown[6] that the reactions of the phosphites $(R^2O)_2POSiMe_3$ (R^2 = Et, $SiMe_3$) with the perfluoroolefins $R^1CF=CF_2$ ($R^1 = CF_3$, SF_5) give rise to fluorotrimethylsilane and the fluoroalkenylphosphonates **45** and **46** in conformity with the Arbuzov rule (Scheme 2). It is suggested that the reaction follows the pathway described above for perfluoroisobutene. In the case of $F_5SCF=CF_2$, the (*E*)-isomer **45** formed exclusively, whereas in the case of $F_3CCF=CF_2$ the product with the *cis*-configuration **46** is obtained in very small amounts, which indicates the occurrence of slight interaction between the substituents Et and $SiMe_3$, on the one hand, and the fluorine atoms of the CF_3 group, on the other.

It has been shown[53-55] that the derivatives of perfluoromethacrylic acid **47**, which is no less reactive than perfluoroisobutene, react with trialkyl phosphites to form the fluorophosphoranes **48**.



$$(RO)_3P + CF_2{=}\underset{CF_3}{\overset{|}{C}}-C(O)X \longrightarrow \underset{\mathbf{48}}{(RO)_3PFCF{=}\overset{|}{\underset{CF_3}{C}}-C(O)X}$$

47

R = Me, Et; X = OMe, OEt, NMe_2.

Scheme 2

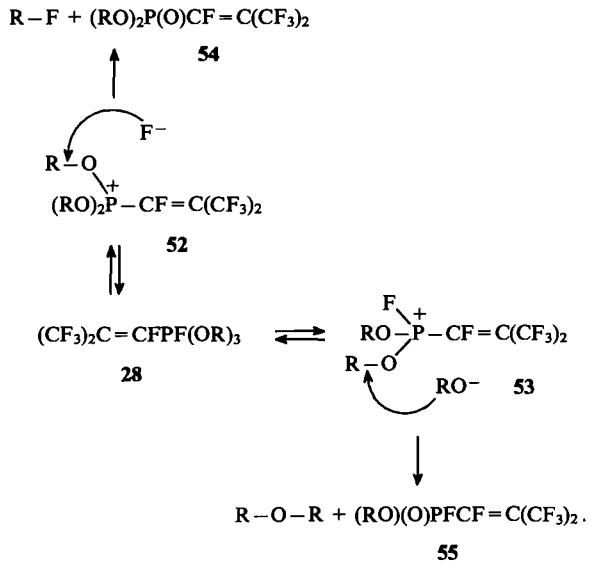
$$(R^2O)_2POSiMe_3 + R^1CF{=}CF_2$$

45 **46**

R^1	R^2	Yield of **45** (%)	Yield of **46** (%)
CF_3	Et	97	3
	$SiMe_3$	99	1
SF_5	Et	100	–
	$SiMe_3$	100	–

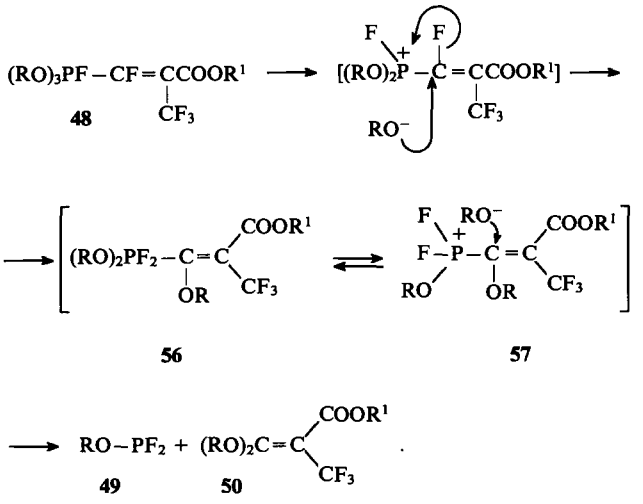
The phosphoranes **48** proved to be stable compounds, which decompose only on heating to 115–120 °C. They could be actually vacuum distilled without decomposition. It was then found unexpectedly that the main products of the decomposition of the phosphoranes **48** are alkyl phosphorodifluoridites **49** and the acetals of the substituted ketones **50**.

$$\underset{\mathbf{48}}{(RO)_3PFCF{=}\overset{|}{\underset{CF_3}{C}}COOR^1} \longrightarrow$$



$$\longrightarrow \underset{\mathbf{51}}{(RO)_2(O)P-CF{=}\overset{|}{\underset{CF_3}{C}}COOR^1} + R-F$$

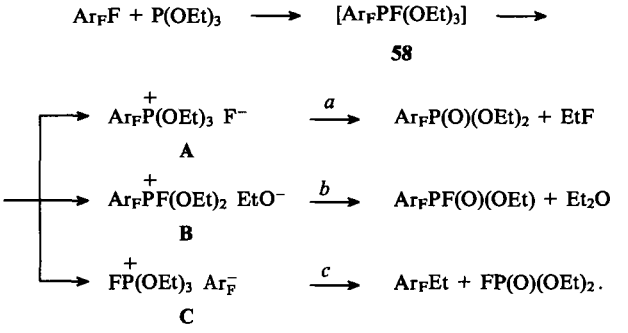
$$\longrightarrow \underset{\mathbf{49}}{RO-PF_2} + \underset{\mathbf{50}\ (70\%-90\%)}{(RO)_2C{=}\overset{|}{\underset{CF_3}{C}}COOR^1}$$



R = Me, Et; R^1 = Me, Et.

The Arbuzov reaction products **51** are not formed at all from the phosphoranes **48** or are obtained only in small amounts. On the other hand, the first stage of the decomposition of the phosphorane **28** is reversible dissociation leading to quasiphosphonium cations of type **52** or **53** and the anions F^- or RO^-. The authors explained this difference in the behaviour of the phosphoranes **28** and **48** by the much greater electrophilicity of the carbon atom of the CF group in the phosphoranes **48** compared with the phosphoranes **28**. In the decomposition of the phosphoranes **28**, the carbon atom of the alkyl group R functions as the electrophilic centre.

Attack by an alkoxide or fluoride ion on the carbon atom leads to the ester **54** or to the acid fluoride **55**.



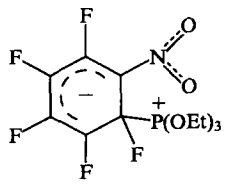
On the other hand, in the phosphoranes **48** the nucleophilic alkoxide anion attacks the β-carbon atom of the acrylic system with formation of the new phosphorane **56**. The dissociation of the latter leads to the quasi-phosphonium salt **57**, which is split into the acetal **50** and the alkyl phosphorodifluoridite **49** as a result of the attack by the alkoxide anion on the same carbon atom.

The possibility of carrying out the Arbuzov reaction with participation of aromatic polyfluoro-compounds of the type C_6F_5X (X = Cl, Br, F, H, OMe) and triethyl phosphite has been discussed.[56] Later this reaction was investigated in greater detail in relation to the interaction of pentafluorobenzonitrile, decafluorobiphenyl, and pentafluoropyridine with triethyl phosphite. The reaction takes place at 140–150 °C with formation of the diethyl esters of polyfluoroarylphosphonic acids in 25–30% yield and is accompanied by a series of side processes: triethyl phosphite, diethyl ethylphosphonate, diethyl phosphonofluoridate, and diethyl ether were detected in the reaction mixtures. An increase in temperature diminishes the yield of phosphonic acid esters. Markovskii et al.[58] determined the factors influencing the occurrence of the side reactions characteristic of compounds of the aromatic polyfluoro-series. In view of the fact that the rate of nucleophilic substitution diminishes significantly in the sequence $C_6F_5NO_2 > C_6F_5CF_3 > C_6F_5H$, a similar sequence might have been expected for the rate of the Arbuzov reaction. However, analysis of the compositions of the reaction mixtures showed that the overall yield of the phosphorylated polyfluorobenzenes increases, contrary to expectation, on passing from pentafluoronitrobenzene to pentafluorobenzene. Furthermore, compounds formed as a result of the reduction and alkylation processes were detected among the reaction products and their amount was actually found to decrease in the above series (Table 5).

This finding, which cannot be explained in terms of the S_N2 nucleophilic substitution mechanism, may indicate the influence on the Arbuzov reaction of factors specific to compounds of the aromatic polyfluoro-series. Apparently, the specific features lie in the fact that a mechanism similar to that proposed by Knunyants et al.[54] for the reaction between perfluoroisobutene and triethyl phosphite operates in the case of aromatic polyfluoro-compounds. A dominant role is assigned in this mechanism to the intermediate polyfluoroaryltriethoxyfluorophosphorane **58**, the reactions of which actually lead to the observed set of products (Scheme 3). The type of the reactions of the phosphorane **58** should be determined both by the stability of the phosphonium cations **A**, **B**, and **C** formed and by the stability of the polyfluoroaryl anion.

Scheme 3

Indeed, with increase in the stability of Ar_F^-, the yield of the alkylation (ethyltetrafluorobenzene Ar_FEt) and reduction (tetrafluorobenzenes Ar_FH) products as well as diethyl phosphorofluoridates should increase (pathway *c*), while the yield of diethyl esters of polyfluoroarylphosphonic acids should diminish (pathway *a*) (Table 5). The reduction process comes down in this instance to the reaction of the polyfluoroaryl anion with a proton from the medium. Indeed, when the reaction of triethyl phosphite with octafluorotoluene or pentafluoropyridine is carried out in the presence of methanol as a source of protons, the yields of heptafluorotoluene and 2,3,5,6-tetrafluoropyridine increase.



We may note that, together with 4-ethyl-2,3,5,6-tetrafluoronitrobenzene, 2-ethyl-3,4,5,6-tetrafluoronitrobenzene is formed in the reaction of triphenyl phosphite with pentafluoronitrobenzene. This is due to the *ortho*/*para* directing effect of the nitro-group in the nucleophilic substitution reaction.[59]

Table 5. The products of the Arbuzov reaction in $Ar_FF + P(OEt)_3$ reaction mixtures (data of Markovskii et al.[58]).

Ar_F	$Ar_FP(O)(OEt)_2$	$Ar_FPF(O)(OEt)$	Ar_FEt	Ar_FH
$4\text{-}NO_2C_6F_4$	2.2 [a]	0	4.2; 30.0 [a]	3.8; 44.1 [a]
$4\text{-}CF_3C_6F_4$	8.5	5.0	12.8	14.5
$4\text{-}HC_6F_4$	44.0	0	traces	2.0

[a] The product of *ortho*-sustitution relative to the NO_2 group is quoted.

The dominant yield of the product of *ortho*-substitution (Table 5) may be due to the formation of the more favourable transition complex **59** as a result of the interaction of the oxygen of the nitro-group with the phosphorus atom.

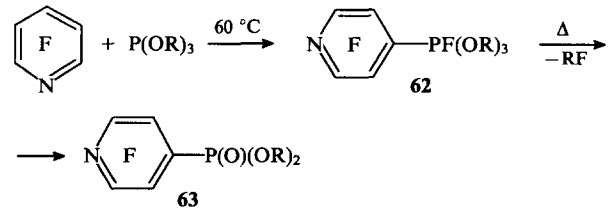
59

In addition, triethyl phosphate and the ethyl esters of (1′-ethylethoxy) (4-trifluoromethyl-2,3,5,6-tetrafluorophenyl)-phosphinic and bis(4-trifluoromethyl-2,3,5,6-tetrafluorophenyl)-phosphinic acids were detected among the products of the reaction of octafluorotoluene with triethyl phosphite. The authors[59] explain the formation of the phosphonous acid ester **60** as well as the appearance of the H^+ cation in the system by the following reactions of the phosphonium cation:

$$[Ar_FP(OEt)_3]^+ \longrightarrow \underset{\mathbf{60}}{Ar_FP(OEt)_2} + [OEt]^+ \longrightarrow H^+ + MeCHO.$$

Compound **60** can react in its turn both with acetaldehyde and with octafluorotoluene. The fact that, despite the presence of a 20% excess of triethyl phosphite relative to octafluorotoluene, the entire triethyl phosphite is consumed can be explained by the oxidation of triethyl phosphite with acetaldehyde to triethyl phosphate[60] and also by the rearrangement of triethyl phosphite to diethyl ethylphosphonate.

The results obtained in the reaction of octafluorotoluene and pentafluoropyridine with triethyl phosphite in the presence of Lewis acids ($FeCl_3$, $ZnCl_2$, $SnCl_4$) can serve as yet another confirmation of the formation of the polyfluoroaryl anion. A Lewis acid is known to promote the occurrence of the Arbuzov reaction by activating the carbonium centre.[61] However, octafluorotoluene and pentafluoropyridine do not enter into the Arbuzov reaction and their interaction with triethyl phosphite is unaffected by the presence of Lewis acids. Perfluorobitolyl and octafluoro-4,4′-bipyridyl are then formed as the main products together with the phosphorylation, reduction, and alkylation products. It is natural to suppose that the formation of octafluorobiphenyl derivatives is induced by the generation of polyfluoroaryl anions during the reaction and their subsequent interaction with pentafluorobenzene derivatives.



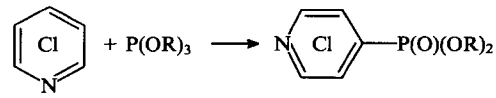
It may be that the diethyl esters of 4-trifluoromethyl-2,3,5,6-tetrafluorophenylphosphonic and 2,3,5,6-tetrafluoropyridyl-phosphonic acids can afford the activated complex **61** in their reactions with $FeCl_3$ as a consequence of the coordination of the Lewis acid to the phosphoryl oxygen atom, from which the corresponding anion Ar_F^- is generated on thermolysis.

$$\underset{\mathbf{61}}{Cl_3Fe...O=P(OEt)_2-Ar_F} \longrightarrow FeCl_3 + [O=P(OEt)_2]^+ + Ar_F^-.$$

However, in the reaction of octafluorotoluene and pentafluoropyridine with the corresponding alkylphosphonic acid esters in the presence of $FeCl_3$ under the conditions of the Arbuzov reaction, the initial compounds are returned unchanged and 1% of a polymeric product is formed. Evidently the Lewis acids play an active role in the stage involving the postulated formation of triethoxypolyfluoroarylfluorophosphorane **58**, which is in equilibrium with quasi-phosphonium compounds containing fluoride and heptafluorotoluene or tetrafluoropyridine anions. The formation of the stable anions $FeCl_3 \cdot Ar_F^-$ and $FeCl_3F^-$ actually determines the further course of the reaction. The $FeCl_3 \cdot Ar_F^-$ anions are apparently more active nucleophiles than the $FeCl_3F^-$ anions. They enter vigorously into competing reactions with the phosphonium cation and the initial compound, forming the corresponding alkylation products.

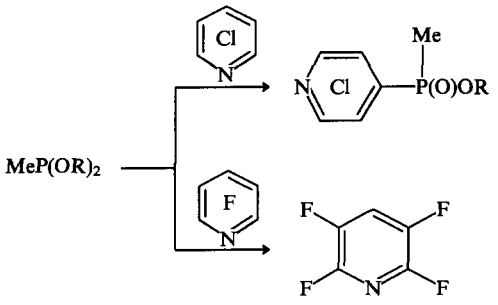
On the other hand, the reaction of tris(trimethylsilyl) phosphite with pentafluoropyridine, pentachloropyridine, and 3-cyanotetrachloropyridine in the presence of catalytic amounts of nickel chloride leads to the formation of the corresponding phosphonates in virtually quantitative yields. The reaction takes place at 150 °C over a period of 30 min.[62] The authors[62] note that under non-catalytic conditions tris(trimethylsilyl) phosphite reacts with pentafluoropyridine more effectively than do trialkyl phosphites. The yield of the final products is 60–69%.

Boenigk and Hagele[63] were able to isolate the stable trialkoxy-(2,3,5,6-tetrafluoro-4-pyridyl)fluorophosphorane **62** (stable for several days) in the reaction of pentafluoropyridine with trialkyl phosphites (R = Et, Pr^i) at 60 °C. When the temperature is raised, the phosphorane **62** decomposes with formation of dialkyl esters of 2,3,5,6-tetrafluoro-4-pyridylphosphonic acid **63** and alkylation (4-alkyl-2,3,5,6-tetrafluoropyridine) and reduction (2,3,5,6-tetrafluoropyridine) products. On passing from triethyl phosphite to triisopropyl phosphite, an increase in the yield (up to 90%) of diisopropyl 2,3,5,6-tetrafluoro-4-pyridylphosphonate is observed.



62 **63**

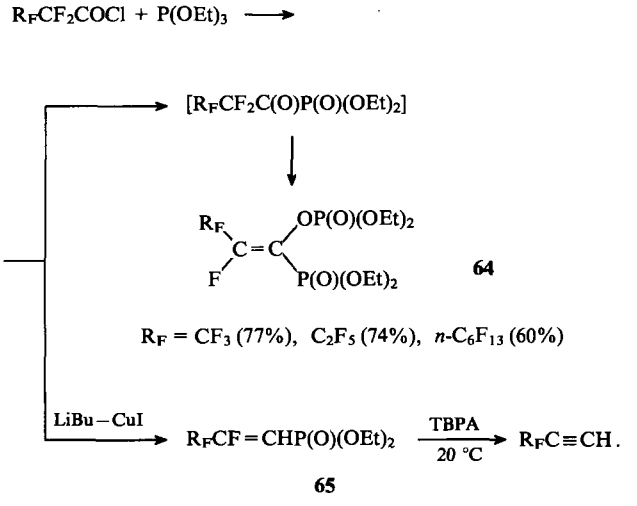
R = Et (50%, 80 °C, 24 h);
Pr^i (90%, 90 °C, 10 h).



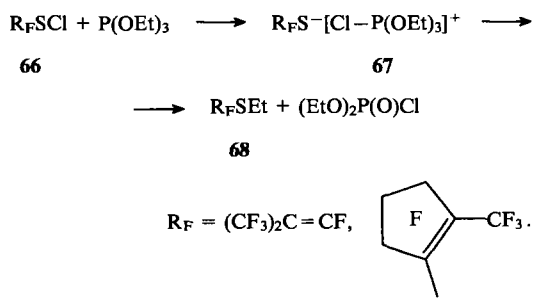
On the other hand, when trimethyl phosphite is introduced into the reaction with pentafluoropyridine, dimethyl 2,3,5,6-tetrafluoro-4-pyridylphosphonate is not formed, the reduction product 2,3,5,6,-tetrafluoropyridine and trimethyl phosphate being obtained instead.

When pentafluoropyridine is replaced by pentachloropyridine, the formation of a stable phosphorane is not observed, the dialkyl esters of 2,3,5,6-tetrachloro-4-pyridylphosphonic acid being isolated as the main products.

R = Me (45%, 120 °C, 15 h); Et (48%, 150 °C, 15 h);
Pr^i (60%, 130 °C, 16 h).

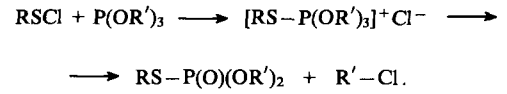


It has been shown[64] that pentachloropyridine enters into the Arbuzov reaction with dialkyl esters of methylphosphonous acid, affording the corresponding phosphinic acid ester, whereas pentafluoropyridine reacts with these esters to form the reduction product — 2,3,5,6-tetrafluropyridine.



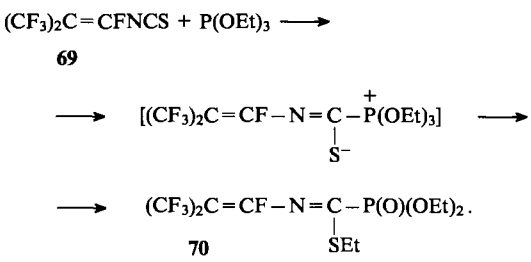
R = Et (20%), Pr^i (14%).

Trialkyl phosphites react with the chlorides of carboxylic perfluoroacids[65] giving rise to the phosphonic acid esters **64**. However, when this reaction was carried out in the presence of LiBu–CuI at temperatures ranging from 0 °C to room temperature, diethyl perfluoroalkenylphosphonate **65** was obtained (Scheme 4).[66] A convenient method of synthesis of perfluoroalkylacetylenes, involving treatment of the ester **65** with tetrabutylphosphoramidite (TBPA), was developed on the basis of this reaction.

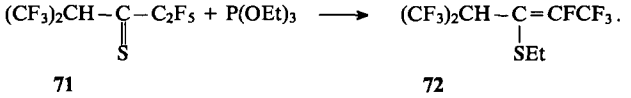


Scheme 4

The unsaturated sulphenyl chlorides **66**, containing fluorine atoms in the carbon chain, react with triethyl phosphite via the chlorine atom with formation of the unstable intermediate **67**, the decomposition of which leads to ethyl perfluoroalkenyl sulphides **68** and diethyl phosphorochloridate.[67]



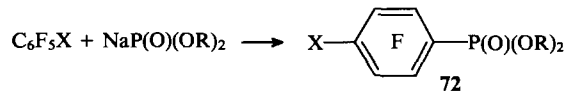
Trialkyl phosphites react with non-fluorinated sulphenyl chlorides via the sulphur atom, affording alkyl halides and phosphates.[68]



Trifluoromethanesulphenyl chloride reacts with trimethyl phosphite via two pathways simultaneously, which results in the formation of the sulphide CF_3SMe and the phosphorothioate $CF_3SP(O)(OMe)_2$.

The reaction of perfluoroisobutenyl isothiocyanate **69** with triethyl phosphite leads to the formation of the diethyl ester of the phosphonic acid **70** as a result of the nucleophilic atack by the trivalent phosphorus atom on the carbon atom of the C = S bond. Under these conditions, the fluorine atoms attached to the double bond are not substituted.[69]

On the other hand, treatment of the thione **71** with triethyl phosphite affords the product **72**, which contains no phosphorus atom.[70]



3. The Michaelis–Bekker reaction in the series of aromatic polyfluoro-compounds

The reactions of perfluoroolefins with dialkyl phosphites have been achieved only under radical conditions,[71] which resulted in the formation of a mixture of telomeric fluorinated alkylphosphonic acid esters of the type $H(CF_2CF_2)_nP(O)(OR)_2$ (n = 1–7). Alkyl esters of difluoromethylphosphonic acid were synthesised from chlorodifluoromethane and sodium dialkyl phosphite.[72]

It has been shown[73] that pentafluorobenzene derivatives and pentafluoropyridine enter into the Michaelis–Bekker reaction with the sodium salts of dimethyl and diethyl phosphites in tetrahydrofuran and afford the corresponding esters of polyfluoroarylphosphonic acids **72** in 10–60% yields.

X = NO_2, CN, CF_3, H, F, OMe;
R = Me, Et.

The low yield of the polyfluoroalkylphosphonic acid esters may be due to the interaction of the nucleophile with the phosphorus atom.[74] The Michaelis–Bekker reaction takes place similarly with pentachlorobenzene,[75] hexachlorobenzene,[76] and certain chlorine-containing heterocyclic compounds.[77] Iodobenzene interacts with the sodium salt of diethyl phosphite to form diethyl phenylphosphonate only when the reaction is carried out under irradiation.[77]

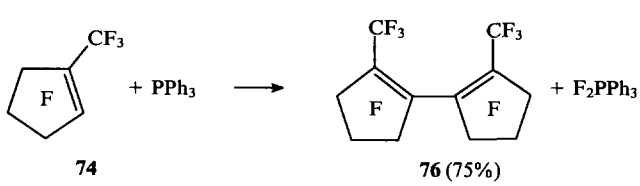
III. P-Nucleophiles as synthons in the synthesis of perfluorinated organic compounds without phosphorus atoms

As shown above, the reactions of phosphines with perfluoroolefins and aromatic polyfluoro-compounds lead initially to the formation of fluorophosphoranes, which proved to be extremely stable in some cases. The stability of fluorophosphoranes is determined by the electronegativity of the atoms of the substituents attached to the phosphorus atom: its increase entails an increase in the stability of the phosphorane.

The cleavage of the P–X bonds in phosphoranes generates a stable phosphonium cation. Such cleavage is controlled by thermodynamic factors. Because of this, the cleavage of the P–C bond, and not P–F and P–O, is energetically more favourable.[78] The thermolysis of phosphorane accompanied by the formation of the P=O bond is even more effective.

These factors suggested that the generation of carbanions, the transfer of the organic fragment in the form of an anion, and the formation of a new C–C bond may be expected for phosphoranes having a specific structure. In synthesis, the phosphorane need not necessarily be isolated beforehand. The most important factor is that a phosphorane of this kind should be formed during the reaction, whereupon the entire process can be carried out in one stage. We shall consider certain examples of reactions in which trialkylphosphines or triphenylphosphines are reactants in the synthesis of fluorophosphoranes, the subsequent interactions of which with unsaturated polyfluorinated compounds can lead to the formation of new C–C bonds. In this case, there is a possibility that the entire process can be achieved in one stage. We shall therefore consider primarily the reactions of trialkylphosphines or triphenylphosphine with organic perfluoro-compounds containing mobile fluorine atoms.

1. Reactions of organic perfluoro-compounds with trialkyl- and triphenyl-phosphines in the presence of C-electrophiles

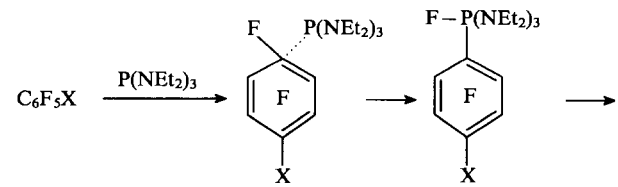


It has been found[79] that the reactions of fluoroolefins having three perfluoroalkyl substituents with phosphines lead to the reductive dimerisation of the olefins, as a result of which conjugated dienes are formed. Thus, when perfluoro-2-methylpent-2-ene **73** is acted upon by phosphorus tris(diethylamide) or perfluoro-1-methylcyclopent-1-ene **74** is acted upon by triphenylphosphine, perfluoro-3-ethyl-2,5-dimethylocta-2,4-diene **75**

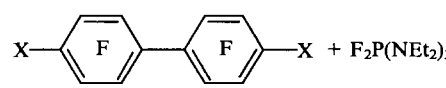
$$(CF_3)_2C{=}CFC_2F_5 + P(NEt_2)_3 \xrightarrow[-F_2P(NEt_2)_3]{}$$

73

$$\longrightarrow (CF_3)_2C{=}\overset{C_2F_5}{\overset{|}{C}}{-}CF{=}C(CF_3)C_3F_7$$



75 (61%)



74 **76** (75%)

and perfluoro-1-methyl-2-(2′-methylcyclopent-1′-enyl)-cyclopent-1-ene **76** are formed respectively.

According to the data of Markovskii et al.,[80] the reaction of compounds of the type C_6F_5X with phosphorous tris-(diethylamide) results in the formation of symmetrically substituted octafluorobiphenyls, while in the reaction with pentafluoropyridine the product is octafluoro-4,4′-bipyridyl (yield 50–60%).

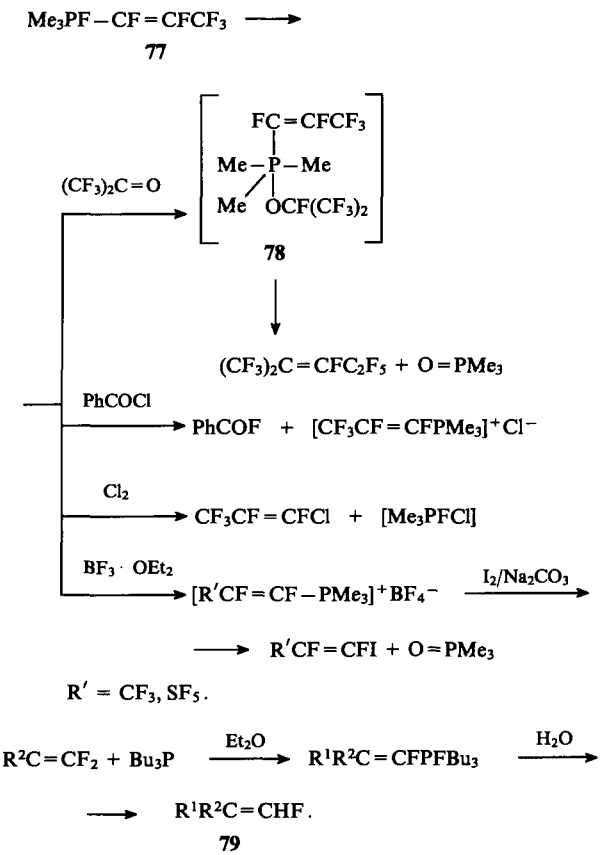
$$\longrightarrow [4\text{-}XC_6F_4]^- + [FP(NEt_2)_3]^+ \longrightarrow$$

X = CF_3, COOMe.

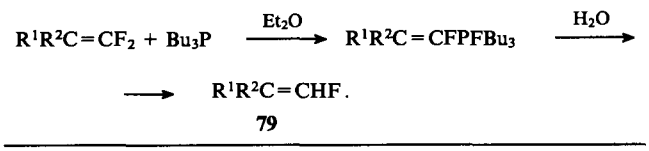
Presumably, in the reactions of perfluoroalkenes or substituted perfluorobenzenes, the trivalent phosphorus atom attacks in the first stage the electrophilic carbon atom involved in the multiple bond or in the benzene ring with subsequent migration of the fluoride anion to the phosphorus atom. The resulting phosphorane is thermally unstable and decomposes, affording a phosphonium cation and a perfluoroalkenyl or pentafluorophenyl anion, which subsequently react with the initial substrates, affording the reaction products. The pentafluorophenyl anion generated in this way reacts further both with the initial aromatic polyfluoro-substrate and with other compounds having more mobile halogen atoms. For example, the addition of chlorotrimethylsilane to a mixture of octafluorotoluene and phosphorus tris(diethylamide) leads to 4-trifluoromethyltetrafluorophenyltrimethylsilane.[81] Pentafluoropyridine and 3-chlorotrifluoropyrimidine have also been introduced into this reaction.

$$C_6F_5R + Me_3SiCl + P(NEt_2)_3 \longrightarrow$$

$$\longrightarrow 4\text{-}RC_6F_4SiMe_3 + P(NEt_2)_3FCl$$



R = CF_3, CN, COOEt.

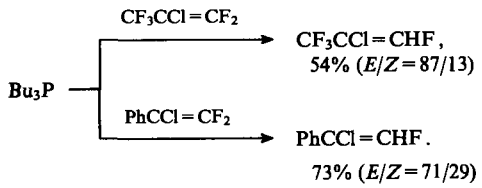


This opens a pathway to the synthesis of various polyfluoro-derivatives of Group IV–VI elements, which were previously difficult to obtain. It is particularly significant that compounds containing strong electron-accepting substituents in the benzene ring can be obtained by this method.

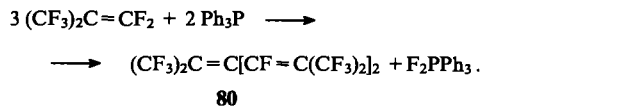
It has been shown[82] that the phosphorane **77**, formed in the reaction of triphenylphosphine with hexafluoropropene, reacts further with hexafluoroacetone in the presence of the fluoride ion, affording triphenylphosphine oxide and perfluoro-2-methylpent-2-ene. The authors assume that these products are obtained as a result of the decomposition of the phosphorane **78**. Scheme 5 presents other reactions of the phosphorane **77**.

Using this approach, a method has been developed for the reduction of perfluoroolefins. The first stage of this reaction involved the formation from the perfluoroolefin and tributylphosphine of a fluorophosphorane, the subsequent hydrolysis of which leads to the olefin **79**. This reaction can be regarded

Scheme 5



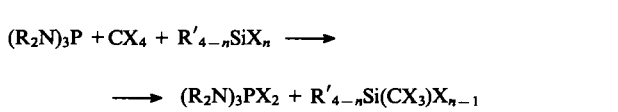
R^1	R^2	*E*/*Z*	Yield of **79** (%)
CF_3	F	100(*E*)	97
$CF_3(CF_2)_2$	F	100(*E*)	72
$CF_3(CF_2)_4$	F	100(*E*)	85
Ph	CF_3	12/88	100
Ph	C_2F_5	100(*Z*)	47
4-$MeOC_6H_4$	CF_3	9/91	100



formally as substitution of a fluorine atom at the multiple bond by a hydrogen atom.[83, 84]

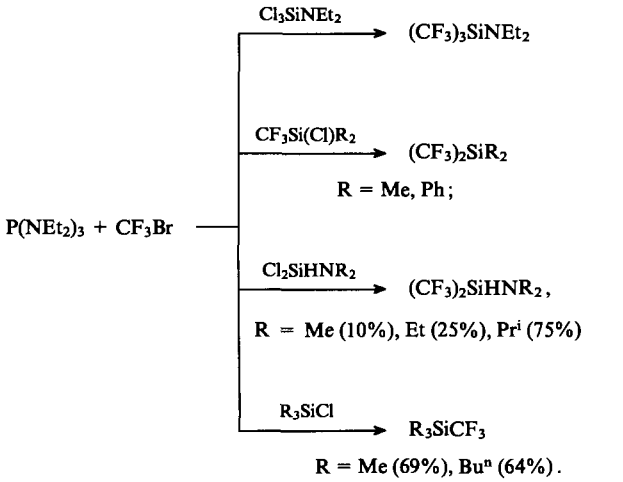
Since treatment of chloroperfluoroolefins with tributylphosphine involves a fluorine atom and not the chlorine atom, a fluorine atom is formally split off from the final product.

Hydrolysis of the *cis*-isomer of vinylphosphorane in moist dimethylformamide (DMF) proceeds stereoselectively. When the reaction of β,β-difluorostyrene with tributylphosphine is carried out in the presence of $BF_3.OEt_2$, the *trans*-isomer of the vinylphosphonium salt is obtained and subsequently hydrolysed. The selectivity of the formation of the (*Z*)- and (*E*)-isomer is 100%, but it diminishes after the introduction into the alkene, together with the perfluoroalkyl group, of substituents such as phenyl and *p*-methoxyphenyl.



In contrast to the examples mentioned above, where triphenylphosphine behaves as a nucleophile and the final product contains a phosphorus atom, in the reaction with perfluoroisobutene it behaves as a defluorinating agent and the final product—1,1-divinylalkene **80**—does not contain a phosphorus atom.[85]

The authors suggest that the triene **80** is formed from an intermediate fluorophosphorane.



2. The use of perfluoroalkyl bromides (or bromopolyfluorobenzenes)-phosphorus tris(dialkylamide) systems as nucleophiles

If the aromatic compounds contain a halogen atom with a low mobility, for example, iodine or bromine, there is a possibility of a situation where the rate of nucleophilic substitution of such a halogen by trivalent phosphorus derivatives is very low and there is only polarisation of the C–halogen bond under the influence of the phosphorus atom. However, in this case too it is possible to make use of the nucleophilic properties of such a complex. It has been found that the phosphorous tris(diethylamide)–alkyl bromide system is a unique nucleophile. This system has found extensive applications in organic synthesis in recent years owing to the formation in the intermediate stage of the trihalomethanide ion, which is highly reactive towards proton-donating agents and electrophiles.[86, 87]

Ruppert and coworkers[88, 89] showed that bromotrifluoromethane enters into this reaction. It was later found that the $CF_3Br–P(NEt_2)_3$ system is fairly universal and can be used as the reagent for the introduction of the trifluoromethyl group. Thus it has been shown[90, 91] that this system is effective in the synthesis of various organosilicon compounds (Scheme 6).

Scheme 6

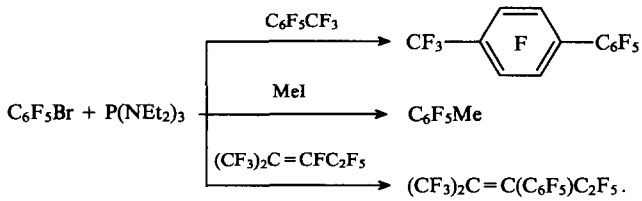
Instead of halotrimethylsilanes, it is possible to use trimethylsilyl azide, trimethyl isothiocyanate, and trimethyl isocyanate.[92, 93] A number of workers[94–99] have used the $CF_3Br–P(NEt_2)_3$ system for the trihalomethylation of organophosphorus compounds containing P–halogen bonds, while Burger et al.[100] used it for the methylation of boron compounds.

$$R_nE-X + CF_3Br + P(NEt_2)_3 \longrightarrow$$
$$\longrightarrow R_nE-CF_3 + [XP(NEt_2)_3]Br$$

E = P, Si, B.

Wakselman and Tordeux[101] used the $CF_3Br-P(NEt_2)_3$ system for the direct introduction of the trifluoromethyl group into anilines.

Bardin et al.[102] used the $C_6F_5Br-P(NEt_2)_3$ system instead of $CF_3Br-P(NEt_2)_3$. A method of synthesis of polyfluoroaryl-substituted silanes, germanes, and stannanes was developed on its basis.



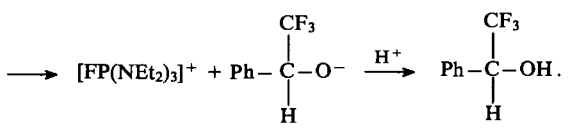
$$4\text{-}R'C_6F_4Br + P(NEt_2)_3 + R_3MX \longrightarrow$$
$$\longrightarrow 4\text{-}R'C_6F_4MR_3 + (NEt_2)_3PXBr$$

R = Me, Et; R′ = F, PrO, CF_3;
M = Si (66%), Ge (57%), Sn (50%); X = Cl, Br.

Pentachlorobenzene, bromobenzene, 3-bromo-1-trifluoromethylbenzene, and benzyl bromide do not react under these conditions. Pentafluoroiodobenzene reacts with the above system, giving rise to methyl(pentafluorophenyl)silane.

The nucleophilic phosphorus atom in the $C_6F_5Br-P(NEt_2)_3$ system attacks the bromine atom, affording a phosphonium cation and a carbanion. The subsequent reactions of these species depend on the presence of C-electrophiles. It has been shown,[102, 103] that this system is convenient for the introduction of the polyfluoroaryl fragment into aromatic polyfluoro-compounds and perfluoroolefins. Certain reactions are illustrated in Scheme 7 below.

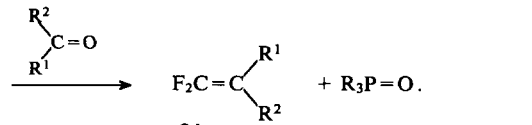
Scheme 7



The interaction of CF_3Br with $P(NR_2)_3$ (R = Me, Et) leads to the phosphonium salt **81** in a virtually quantitative yield.[104] The structure of the latter was confirmed by NMR spectroscopic data and X-ray diffraction.

$$(R_2N)_3P + BrCF_3 \longrightarrow [CF_3P(NR_2)_3]^+Br^-.$$
81 (95%–100%)

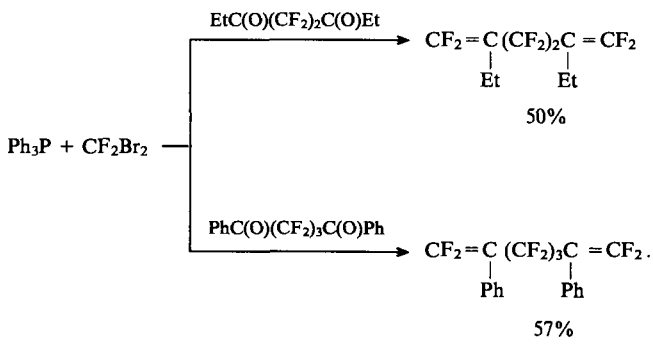
On the other hand, in the reaction of CF_3I and $P(NEt_2)_3$ other products are formed, namely $CF_3P(NEt_2)_2$ and the salt $[P(NEt_2)_4]^+I^-$.[105] The salt **81** is stable up to the melting point. The high positive charge on the phosphorus atom in this compound promotes the reaction with the fluoride anion (arising from CsF, TASF, etc.). The fluorophosphorane **82** is formed as an intermediate in this reaction. It reacts, for example, with benzaldehyde to form the alcohol **83**.



$$[CF_3P(NEt_2)_3]^+Br^- + F^- \longrightarrow [(Et_2N)_3PFCF_3] \xrightarrow{PhCHO}$$
81 **82**

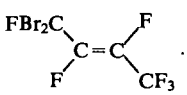
83 (73%)

Phosphonium salts may react with salts of type **81** also via a different pathway. Thus, in the presence of an excess of this P-nucleophile, the corresponding ylide, having pronounced nucleophilic properties, is formed. It reacts with aldehyde and ketones, forming terminal olefins.[106]



$$[R_3PCF_2Br]Br^- + R_3P \longrightarrow [R_3P-CF_2] + [R_3PBr]Br^- \longrightarrow$$

84



R	R^1	R^2	Yield of **84** (%)
Ph	Ph	H	65
	C_6F_5	H	20
	Ph	CF_3	85
	C_6H_{11}	CF_3	90
	Ph	C_2F_5	82
	3-BrC_6H_4	CF_3	83
NMe_2	Ph	Me	81
	Ph	Et	82
	Et	Et	75
	Me	Me	60
	Ph	CF_3	25

Polyfluorinated ketones react similarly.

The PPh_3-CFBr_3 system is capable of reacting with perfluoroolefins, substituting a fluorine atom at the double bond by the $CFBr_2$ group.[107]

$$Ph_3P + CFBr_3 + CF_3CF=CF_2 \longrightarrow$$

$P(NEt_2)_3$ may be used instead of triphenylphosphine.[108]

$$P(NEt_2)_3 + BrCF_2X + Me_3SiCl \longrightarrow$$
$$\longrightarrow Me_3SiCF_2Cl + [(Et_2N)_3PX]^+Br^-$$

X = Cl, Br, I.

The reaction of the $CF_3Br-P(NEt_2)_3$ system with benzaldehyde[109] leads to the formation of the phosphonium salt **85**, which decomposes at 140 °C, affording α-bromophenylethane and not the alcohol **83**. Owing to the ease of formation of a phosphorus compound with P=O bond, in this case the intermediate carbonium ion reacts with the bromide anion,

giving rise to the final reaction product. The reaction is general in character. Perfluoroalkyl bromides with different carbon chain lengths (from 2 to 6) have been used as reactants in it.

$$PhCHO + CF_3Br + P(NEt_2)_3 \longrightarrow$$

$$\longrightarrow [PhCH(CF_3)OP(NEt_2)_3]^+Br^- \xrightarrow{140\ ^\circ C}$$

85 (77%)

$$\longrightarrow PhCHBrCF_3 + O{=}P(NEt_2)_3.$$

99% 95%

According to the data of Kolomeitsev et al.,[110] chloro- and bromo-alkanes **86** react in the presence of $P(NEt_2)_3$ with $PhCH_2SCN$, affording the product **87** resulting from the substitution of the CN group.

$$PhCH_2SCN + F(CX_2)_mY \xrightarrow[CH_2Cl_2,\ -70\ ^\circ C]{P(NEt_2)_3} PhCH_2S(CX_2)_mF$$

86 **87**

X = Cl, F; Y = Cl, Br; m = 1–3.

The interaction of the $C_2F_5I-P(NEt_2)_3$ system with benzoyl chloride[111] in a non-polar solvent results in the formation of the product of the substitution of the chlorine atom — the corresponding ketone (yield 58%).

The reaction of the partly fluorinated aliphatic-aromatic ketones **88** with $CF_3Br-P(NEt_2)_3$ leads to the formation of the tertiary alcohol **89**.

$$PhCOC_2F_5 + CF_3Br + P(NEt_2)_3 \xrightarrow[-70\ ^\circ C,\ 5\ h]{H^+} Ph-\underset{\displaystyle C_2F_5}{\overset{\displaystyle CF_3}{\overset{|}{\underset{|}{C}}}}-OH.$$

88 **89** (56%)

On the other hand, in the case of benzoyl fluoride, the reaction is very slow and leads to the ultimate formation not of a tertiary alcohol but of the products of the esterification of benzoic acid by the latter. The yield of the ester is 81%.

In the presence of $P(NEt_2)_3$, polyfluoroalkyl iodides react with various aroyl chlorides to form aryl polyfluoroalkyl ketones (Table 6).[112]

$$R_FI + ArCOCl + P(NEt_2)_3 \longrightarrow ArCOR_F + ClP(NEt_2)_3.$$

The primary step in this reaction is nucleophilic attack by the phosphorus atom on the iodine atom. The subsequent nucleophilic attack by the anionoid polyfluoroalkyl group on the electrophile present in the reaction mixture affords the corresponding ketone and phosphorane.[113] The reaction between the phosphonium ylide and acetyl halide usually leads to the ylide acylation product. The Wittig reaction also occurs here. This has been used to obtain olefins from acyl halides.[114]

Table 6. Reactions of polyfluoroalkyl iodides with aroyl chlorides in the presence of phosphorus tris(diethylamide).[112]

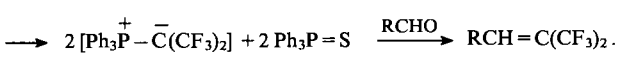
$$\longrightarrow \begin{matrix}H\\R\end{matrix}\!\!>\!C{=}C\!<\!\begin{matrix}CF_3\\CF_3\end{matrix} + Ph_3P{=}O + Cl_2PPh_3$$

93

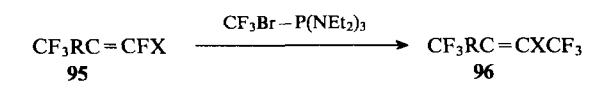


R = Et (31%), Pr (22%), 4-ClC_6H_4 (88%), 4-$MeOC_6H_4$ (27%), C_6H_{11} (4%), $Cl_2C{=}CH$ (83%), Ph (54%), $Me_2CHCHCl$ (62%).

The mechanism of this reaction is so far obscure. Two pathways have been suggested: either the carbanion reacts directly with the aldehyde or the phosphorus ylide is formed as an intermediate and then reacts with the aldehyde.

The phosphorus ylide **94** can be obtained also by the reaction of triphenylphosphine with tetrakis(trifluoromethyl)-1,3-dithietan.[117] Its subsequent interaction with aldehydes leads to the corresponding perfluoroolefins.

$$4\,Ph_3P + (CF_3)_2C\langle S\rangle C(CF_3)_2 \xrightarrow[-78\ ^\circ C]{Et_2O}$$



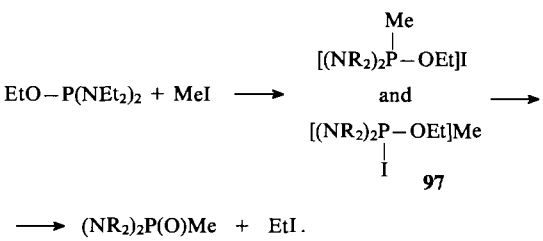
$$\longrightarrow 2\,[Ph_3\overset{+}{P}-\overset{-}{C}(CF_3)_2] + 2\,Ph_3P{=}S \xrightarrow{RCHO} RCH{=}C(CF_3)_2.$$

94

R	Ph	C_6F_5	$Me(CH_2)_5$
Yield of olefin (%)	99	100	100
R	MeCHPh	PhCH=CH	4-$MeOC_6H_4$
Yield of olefin (%)	61	60	52

The effectiveness of the PPh_3–F_3CCCl_3 system in reactions with aldehydes, which lead to the formation of trifluoromethylolefins, has been demonstrated.[118] The reaction with aromatic and α,β-unsaturated aliphatic aldehydes proceeds with a high stereoselectivity [the (*Z*)-isomers are formed exclusively], whereas the reaction with other aliphatic aldehydes affords a mixture of the (*Z*)- and (*E*)-isomers in proportions ranging from 2 : 1 to 3 : 1.

The highly reactive perfluoroolefins **95** react under mild conditions with the CF_3Br–$P(NEt_2)_3$ system, giving rise to monosubstitution products **96**.[119]



$$\underset{\mathbf{95}}{CF_3RC{=}CFX} \xrightarrow{CF_3Br-P(NEt_2)_3} \underset{\mathbf{96}}{CF_3RC{=}CXCF_3}$$

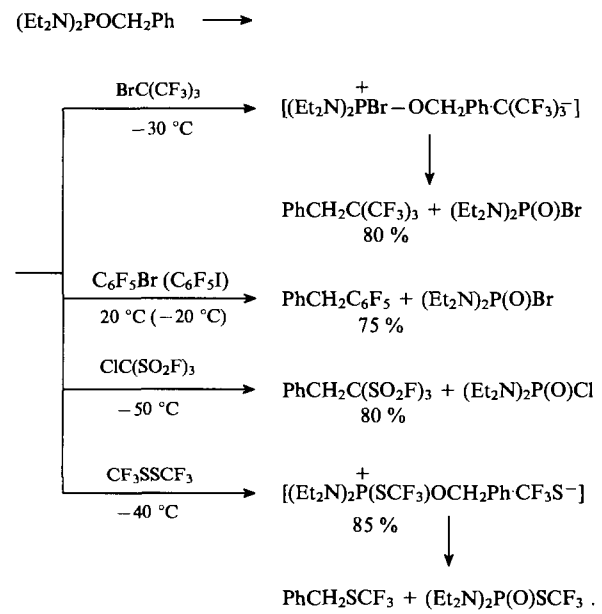
R = CF_3, X = F; R = F, X = C_2F_5; R = $CONEt_2$, X = F.

In the reaction of perfluoro-2-methylpent-2-ene and perfluoromethacrylamide with the above system, the products of the substitution of two fluorine atoms are formed together with the monosubstituted products (the yields are 45 and 34% respectively). The reaction with perfluoroisobutene gives rise to a mixture of isomeric perfluorodienes, whilst the reaction with octafluorotoluene affords a mixture of isomeric perfluoroxylenes in a yield of only 7%.

3. Reactions with phosphines containing P–O and P–N bonds simultaneously

In an early study, Michaelis[120] reported two stable quasi-phosphonium salts **97**, formed when methyl iodide is acted upon by alkyl *N,N,N',N'*-tetraalkylphosphorodiamidites. The salts decompose in accordance with the scheme.

$$EtO-P(NEt_2)_2 + MeI \longrightarrow \underset{\text{and}}{\overset{Me}{\underset{|}{[(NR_2)_2P-OEt]I}}} \longrightarrow$$



$$[(NR_2)_2P-\underset{|}{\overset{Me}{OEt}}]I$$

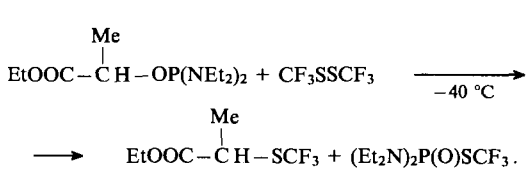
97

$$\longrightarrow (NR_2)_2P(O)Me + EtI.$$

Wakselman and Tordeux[101] developed the research based on this observation and showed that such phosphorodiamidites react exothermally with fluorine-containing electrophiles incorporating mobile groups such as Br, SCF_3, etc., forming *N,N,N',N'*-tetraethylphosphorodiamidic halides and fluorinated compounds with new C–C bonds. Thus it became possible to synthesise a series of phosphorus-containing compounds which are otherwise difficult to obtain. Some examples of these reactions are presented in Scheme 8.

Scheme 8

$$(Et_2N)_2POCH_2Ph \longrightarrow$$



$$\xrightarrow[-30\ ^\circ C]{BrC(CF_3)_3} [(Et_2N)_2\overset{+}{P}Br-OCH_2Ph\cdot C(CF_3)_3^-] \longrightarrow PhCH_2C(CF_3)_3 + (Et_2N)_2P(O)Br \quad 80\,\%$$

$$\xrightarrow[20\ ^\circ C\,(-20\ ^\circ C)]{C_6F_5Br\ (C_6F_5I)} PhCH_2C_6F_5 + (Et_2N)_2P(O)Br \quad 75\,\%$$

$$\xrightarrow[-50\ ^\circ C]{ClC(SO_2F)_3} PhCH_2C(SO_2F)_3 + (Et_2N)_2P(O)Cl \quad 80\,\%$$

$$\xrightarrow[-40\ ^\circ C]{CF_3SSCF_3} [(Et_2N)_2\overset{+}{P}(SCF_3)OCH_2Ph\cdot CF_3S^-] \quad 85\,\% \longrightarrow PhCH_2SCF_3 + (Et_2N)_2P(O)SCF_3.$$

Instead of the benzyl residue, other groups can also be used, for example:

$$EtOOC-\underset{|}{\overset{Me}{CH}}-OP(NEt_2)_2 + CF_3SSCF_3 \xrightarrow[-40\ ^\circ C]{}$$

$$\longrightarrow EtOOC-\underset{|}{\overset{Me}{CH}}-SCF_3 + (Et_2N)_2P(O)SCF_3.$$

IV. Conclusion

The examples presented in this review show that phosphorus-containing nucleophiles play an important role not only in the synthesis of organophosphorus compounds containing perfluorinated substituents but also in reactions where they behave as synthons. This has made it possible to develop novel methods of synthesis of compounds with new C–C bonds. There is no doubt that all these features have enriched synthetic organic chemistry by a series of new approaches to the specific synthesis of interesting organic compounds. Further development of this field of chemistry and the discovery of new possibilities in the reactions of phosphorus-containing nucleophiles with unsaturated halogen-containing substances may be expected. The author does not claim to have given an exhaustive bibliographic survey in the present review, but the latter reflects fully the principal aspects of studies both in the field of methods of synthesis of organofluorine compounds and as regards the principal trends in the development of methods for the introduction of organophosphorus fragments into various molecules and also in the application of organo-phosphorus synthons in the synthesis of compounds with new carbon–carbon bonds. The author hopes that the review will be useful not only to investigators working in the field of the organic chemistry of fluorine but also to a wider range of chemists concerned with synthesis.

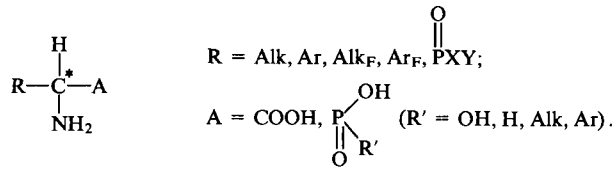
Abstract. The available literature data on the methods for the asymmetric synthesis of fluorine- and phosphorus-containing aminoacids are surveyed. The chemical and enzymic methods of the asymmetric synthesis of the above compounds are considered. The bibliography includes 139 references.

I. Introduction



The synthesis of organoelement analogues of natural products and in the first place of element-containing aminoacids is one of the most vigorously developing fields in modern organic chemistry.[1] There exist natural element-containing aminoacids; bromine-,[2] chlorine-,[3] fluorine-,[4] and phosphorus-containing aminoacids[5, 6] have been isolated from various sources. The unique biological activity of natural element-containing aminoacids has served as a powerful stimulus which initiated vigorous research in this field.

Numerous element-containing aminoacids have been synthesised hitherto, among which special emphasis must be laid on fluorine- and phosphorus-containing aminoacids. The majority of these aminoacids are metabolites of the 'normal' aminoacids. They exhibit the properties of highly selective (as regards the specificity of their activity) inhibitors of enzyme reactions and they possess high carcinostatic, bactericidal, cytotoxic, and other forms of biological activity. Thus more than 20 studies devoted to various aspects of the synthesis and biological activity of fluorine-,[7–24] phosphorus-,[25–35] boron-,[36] and selenium-containing aminoacids[37] have now been published.

Analysis of the literature data shows that the most urgent problem in the chemistry of organoelement aminoacids is that of the development of methods of synthesis of these compounds in an enantiomerically pure form, which is dictated by modern requirements in biology and medicine. Unfortunately, in most cases racemic synthesis is considered in the reviews quoted above and the main aspects of the asymmetric synthesis of element-containing aminoacids (the nature of the enantioselectivity, the optical purity, and the absolute configuration) are hardly discussed.

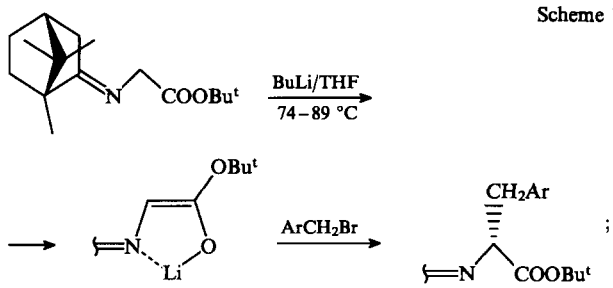
The present review deals with the methods of asymmetric synthesis of fluorine- and phosphorus-containing aminoacids published up to the middle of 1992 inclusive. We were guided by the fundamental classical definition of asymmetric synthesis, given in the monograph of Morrison and Mosher,[38] as a process in which a prochiral molecule or its fragment is converted into a chiral molecule with unequal amounts of the stereoisomeric products. The process takes place under the influence of chiral reagents, part of the initial molecule, or the catalyst. The methods of synthesis of enantiomerically pure or optically active organoelement aminoacids (C–F, C–P) involving the direct introduction of the element into complete aminoacid enantiomers or involving enzymic or chemical separation of racemic compounds will therefore not be considered in the present review.

The entire data are described in five main sections depending on the type of bond formed at the chiral centre of the α-aminoacid, while syntheses using enzymes have been collected in a separate section.

II. Enantioselective formation of the C–C bond

The asymmetric synthesis of element-containing aminoacids is most widely represented by examples of the enantioselective formation of the C–C bond on alkylation of chiral Schiff bases. These can be readily obtained from the esters of the simplest aminoacids and chiral carbonyl compounds, which can be regenerated and used in new syntheses. The formation of Schiff bases increases the CH acidity of the aminoacid fragment and permits the generation of a carbanion under the influence of bases of different strengths and its subsequent reactions with various electrophiles.[39]

Camphor and its derivatives are frequently used as the chiral carbonyl compound in the above synthesis, which is due to their ready availability in both enantiomerically pure forms.

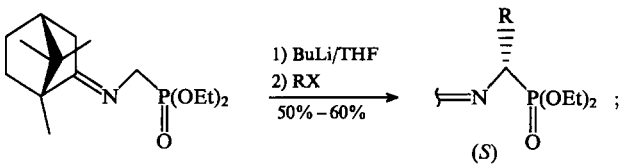


V P Kukhar', N Yu Svistunova, V A Solodenko, V A Soloshonok Institute of Bioorganic Chemistry and Petrochemistry, Academy of Sciences of the Ukraine, Murmanskaya ul. 1, 252660 Kiev-94, Fax (7-044) 543 5152

Received 14th December 1992
Uspekhi Khimii **62** (3) 284 – 302 (1993); translated by A K Grzybowski

In most cases the chiral Schiff base is deprotonated with butyllithium or lithium diisopropylamide and the carbanion formed is made to react with alkyl halides, carbonyl compounds, or Michael acceptors.

Thus the (*R*)-enantiomers of *p*-fluoro- and *p*-trifluoromethylphenylalanines have been synthesised[40] by alkylating the Schiff base formed from the *tert*-butyl ester of glycine and (*R*)-camphor with the corresponding benzyl bromides (Scheme 1).

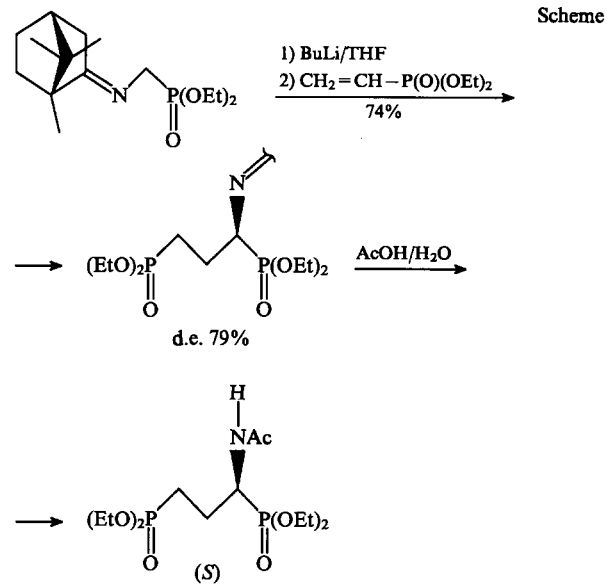


Scheme 1

Ar = 4-FC_6H_4, 4-$CF_3C_6H_4$.

The attack by the lithium derivative comes predominantly from the *re*-side [the side opposite to the C(8) atom of camphor], affording products with a diastereo-isomeric excess (d.e.) > 98% (F) and 79% (CF_3), which is controlled kinetically. It is of interest to note that high values of d.e. are observed in this synthesis only when benzyl and allyl halides are used as alkylating agents (in the case of EtBr, d.e. = 33%). This has been attributed[40] to the additional $\pi-\pi$ interaction in the transition state between the π-system of benzyl or allyl halides, which has a positive character after the partial dissociation of the C–Br bond, and the π-system of the enolate. This hypothesis has been confirmed by the dependence of the d.e. on the nature of the substituent in the benzene ring and benzyl bromide. A series of (*S*)-α-aminoalkylphosphonic acids have been synthesised by a similar procedure using the Schiff base obtained from (*R*)-camphor and diethyl aminomethylphosphonate (the phosphonoglycine synthon),[41] the maximum enantioselectivity of the alkylation being achieved, as in the study of McIntosh et al.,[40] in the case of allyl and benzyl halides (Scheme 2).

Scheme 2



R	$CH_2CH=CH_2$	$PhCH_2$	$CH_2-C\equiv CH$

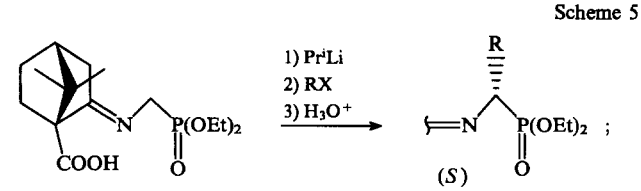
The possibilities of the phosphonoglycine synthon may be expanded by using it for the Michael addition to activated carbon–carbon double bonds.[42]

The kinetically controlled addition of vinylphosphonate or methyl acrylate to the lithium derivative of the Schiff base takes place with high values of the d.e., affording esters of the phosphono-analogues† of (*S*)-$Glu^{\alpha,\omega\text{-}P}$ and (*S*)-$Glu^{\alpha\text{-}P}$. The ester of (*S*)-phosphonoproline was obtained from the latter in two stages (Scheme 3 and 4).

Scheme 3



Scheme 4

e.e. = enantiomeric excess.

The use of (*R*)-ketopinoic acid (a camphor derivative), instead of camphor itself, for the synthesis of the chiral phosphonoglycine synthon hardly affects the enantioselectivity of the alkylation and leads to the (*S*)-phosphonic acid with high values of d.e. only in the case of the allyl and benzyl derivatives (Scheme 5).[43]

† Three-letter designations of aminoacids with the superscript 'P' are used to designate the phosphorus analogues of natural aminoacids. In the case of the phosphorus analogues of aspartic and glutamic acids, the additional superscripts α, β, and γ, indicating the position of the phosphorus-containing group, are introduced.

The phosphonoglycine synthon, obtained from (1*R*, 2*R*, 5*R*)- or (1*S*, 2*S*, 5*S*)-2-hydroxypinan-3-one, gives a more stable stereochemical result which depends little on the nature of the alkylating agent (Scheme 6).[41, 44–46]

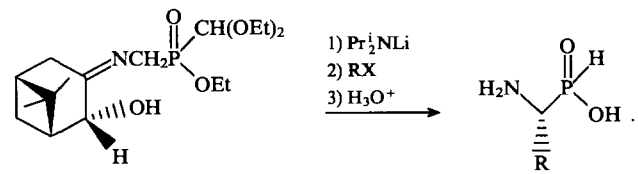
LDA = *N*-lithium diisopropylamide, OTHP = *O*-tetrahydropyranyl.

In this case, phosphonic aminoacids can be obtained with a high optical purity even when their alkyl groups are small.

The nature of the asymmetric induction in the alkylation of the Schiff base obtained from phosphonoglycine and hydroxypinanone has not been discussed,[44, 45] but one can postulate the important role of the hydroxy-group in the α-position relative to the C=N bond in the coordination of the metal during the reaction. Thus the replacement of LDA by *tert*-BuOK in this synthesis leads to the alkylation of the hydroxyl (MeI) and a decrease in the diastereoselectivity of the alkylation of the Schiff base from 85% to 45% (R = Me).

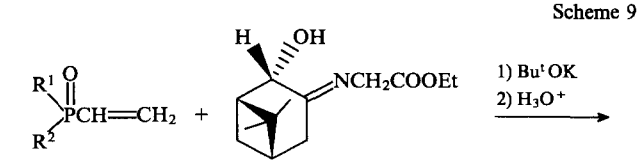


The use of α,ω-dihaloalkanes makes it possible to obtain cyclic phosphonic aminoacids (proline homologues), which is illustrated in relation to the synthesis of (*S*)- or (*R*)-homoproline, while the Michael addition of methyl acrylate affords the α-phosphonic analogue of glutamic acid with 87% enantiomeric purity, from which the esters of (*S*)- and (*R*)-Pro^{P} were obtained in several stages (Scheme 7).[44]

Scheme 7

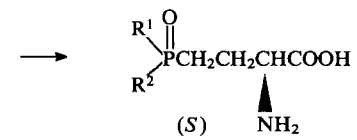
The only example of the asymmetric synthesis of α-aminoalkylphosphonous acids also involves the stereoselective alkylation of a chiral Schiff base obtained from (1*R*, 2*R*, 5*R*)-2-hydroxy-3-pinanone and ethyl aminomethyl(diethoxymethyl)-phosphinic acid with benzyl bromide (d.e. > 99%) and methyl iodide (d.e. 56%).[47] After the hydrolysis of the alkylation products under mild conditions, optically active phosphonous analogues of phenylalanine (*R*)-Phe^{P-H} (d.e. > 99%) and alanine (*R*)-Ala^{P-H} (d.e. 46%) were isolated (Scheme 8).

Scheme 8



(1*R*, 2*R*, 5*R*) (*R*)

The use of the Schiff base derived from (1*S*, 2*S*, 5*S*)-2-hydroxy-3-pinanone leads to the formation of another enantiomer of the phosphonous analogue of phenylalanine–(*S*)-Phe^{P-H} (e.e. > 99%).

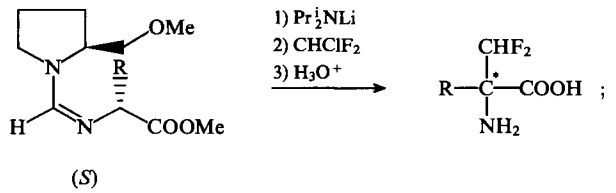


The authors note the dependence of the stereoselectvity of the alkylation of the Schiff base on the nature of its acid function: the diastereoselectivity of the benzylation ($PhCH_2Br$) increases appreciably in the sequence COOEt < $P(O)(OEt)_2$ < P(O)··$(OEt)CH(OEt)_2$ and amounts to 75%, 83%, and 99% respectively.

The addition of chiral Schiff bases derived from hydroxypinanones to vinylphosphonates and vinylphosphinates has been used for the asymmetric synthesis of α-amino-γ-phosphonobutyric acid [(*S*)-(+)-Glu$^{\gamma\text{-P}}$] and (*S*)-(+)-phosphinotricin [(*S*)-(+)-Glu$^{\gamma\text{-P-Me}}$] as well as their (*R*)-(−)-enantiomers (Scheme 9).[48]

Scheme 9

R^1 = Me, R^2 = OMe (1*S*, 2*S*, 5*S*)
$R^1 = R^2$ = OEt



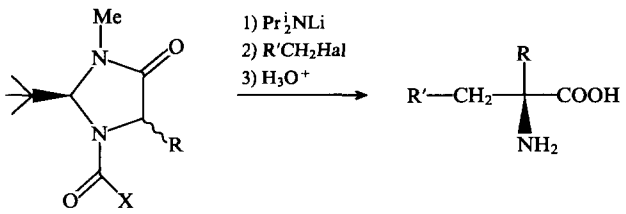
R^1 = Me, R^2 = OH,
$R^1 = R^2$ = OH.

The stereoselectivity of the process is appreciably higher in addition to vinylphosphinate (d.e. 73% and 79%) than in addition to vinylphosphonate (45% and 50%) and decrease by 25% – 30% in the presence of additives which effectively solvate the cation (hexamethylphosphoramide, crown-ether). On this basis, the authors conclude that the coordination of the electron pairs of the nitrogen atom and of the oxygen atom of the phosphoryl group to the metal ion (K^+) exerts a decisive influence on the stereoselectivity of the addition reaction.

The use of chiral inducing reagents of another type — proline derivatives — in the asymmetric synthesis of element-containing aminoacids has been demonstrated in relation to the synthesis of α-difluoromethylalanine and α-difluoromethylphenylalanine by alkylating with chlorodifluoromethane the lithio-derivative of

the Schiff base obtained from (*S*)-1-dimethoxymethyl-2-methoxymethylpyrrolidine and the esters of the corresponding aminoacids (Scheme 10).[49]

Scheme 10



(*S*)

R = Me, CH_2Ph.

The enantioselectivity of the reaction and the absolute configuration of the aminoacids formed are not discussed in the above communication.[49] However, the [1,5]-asymmetric induction occurring in this instance is as a rule weak.[50]

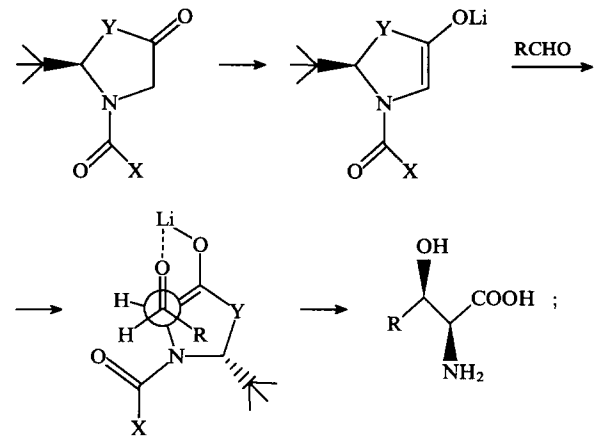
The alkylation of rigid cyclic synthons usually takes place with a higher diastereoselectivity than in the case of linear systems. The advantages of using cyclic synthons have been demonstrated particularly convincingly in the studies by Seebach et al.,[51] Schöllkopf,[51] and Belokon' et al.[53] Thus the lithio-derivative obtained from (*S*)-1-*tert*-butoxycarbonyl-2-(*tert*-butyl)-3-methyl-4-imidazolidinone (R = H) is alkylated diastereospecifically with *p*-fluoro- or pentafluoro-benzyl bromides, affording, after the hydrolysis of the alkylation products, (*S*)-*p*-fluoro- and (*S*)-pentafluoro-phenylalanines with an optical purity >98% (Scheme 11).[54, 55]

Scheme 11

R = H, Me; R′ = 4-FC_6H_4, C_6F_5, 2-FC_6H_4, 3-FC_6H_4; X = CH_2Ph, $OCMe_3$.

The alkylation of the alanine synthon (R = Me) with fluorobenzyl halides led to the formation of the isomeric (*S*)-α-methyl derivatives of *o*-, *m*-, and *p*-fluorophenylalanines with an equally high optical purity.[56]

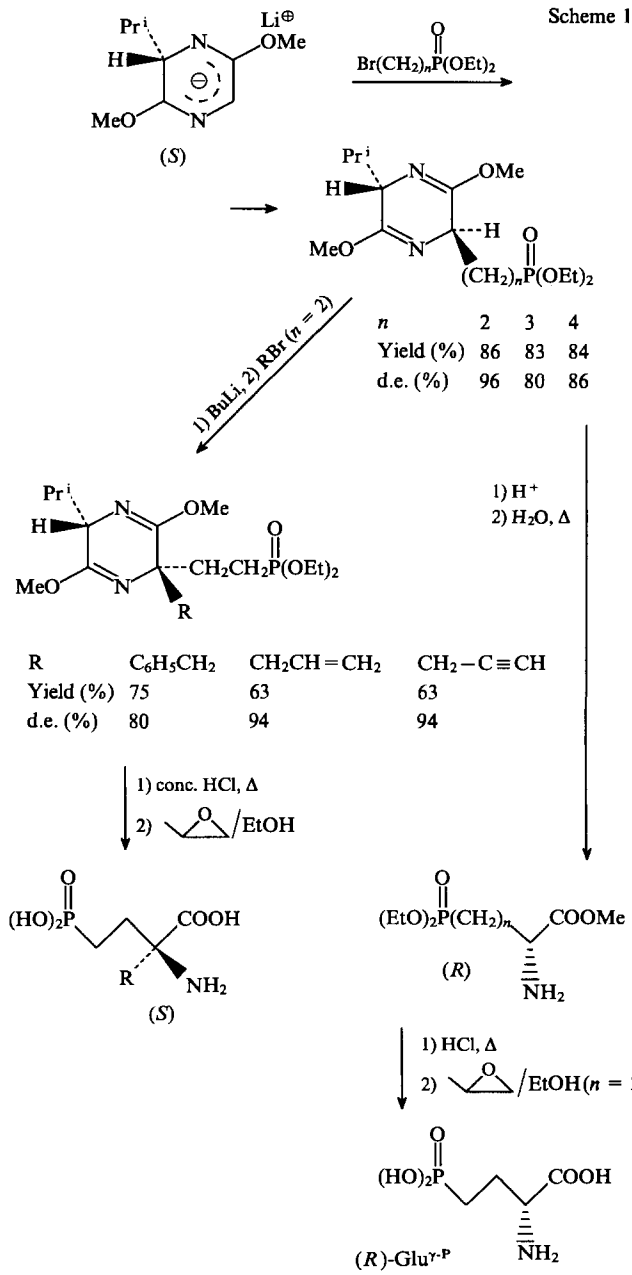
The lithio-derivative of imidazolidinone (R = H) as well as another chiral glycine synthon used by Seebach, namely benzyl-(*R*)-2-(*tert*-butyl)-5-oxo-3-oxalidine carboxylate, have been used in the synthesis of (2*S*, 3*S*)-trifluorothreonine‡ and (2*S*, 3*R*)-*p*-trifluoromethyl- and (2*S*, 3*R*)-*o*-fluorophenylserines (Scheme 12).[57, 58]



The high stereoselectivity of the reaction can be explained by the preference for one of the possible transition states in which minimum steric interactions and maximum overlap of the donor and acceptor π-systems of the reacting molecules are insured.

The alkylation of the lithio-derivative of the chiral bislactim ether with ω-phosphonoalkyl bromides (Schöllkopf's method) takes place with a high stereoselectivity, which has been used for the asymmetric synthesis of optically active carboxylic α-amino-ω-phosphono-acids and their esters (Scheme 13).[59]

The phosphorus-containing bislactim ether formed in the first stage can be realkylated, which ultimately leads to α-substituted γ-phosphonic analogues of (*S*)-glutamic acid.



‡ Seebach et al.[58] erroneously attributed the (2*S*, 3*R*)-configuration to the aminoacid obtained.

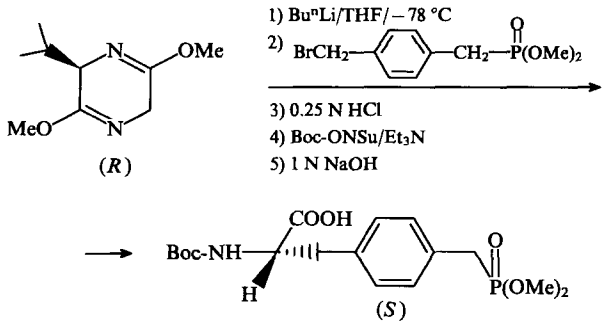
Both enantiomers of phosphinotricin were obtained by Schöllkopf's method involving the alkylation of the lithio-derivative of the bislactim ether containing a valine residue as the stereodifferentiating group (Scheme 14).

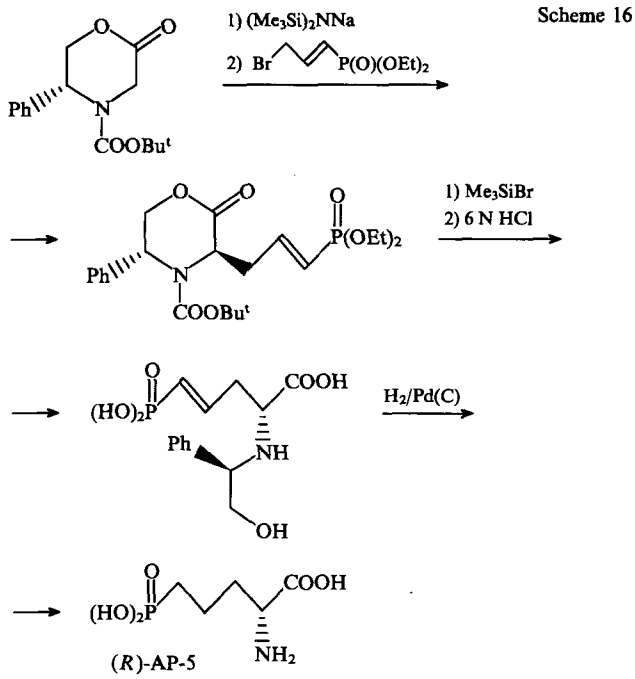


Scheme 14

As in all the syntheses by Schöllkopf's method, in this case the chiral anion is alkylated with a high degree of stereoselectivity (93.5%), affording phosphorus-containing (*S*)- or (*R*)-amino-acids when the (*R*)- or (*S*)-bislactim ethers are used respectively.[60]

The same method has been employed to synthesise an analogue of phosphonotyrosine—*p*-phosphonomethyl-(*S*)-phenyl-alanine, which was subsequently incorporated in the peptide chain of angiotensin in the search for biologically active peptides (Scheme 15).

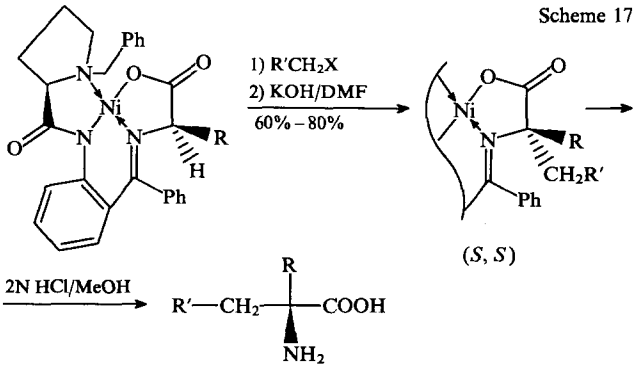
Scheme 15



In order to estimate the optical purity of the product, the P- and N- substituted aminoacid was condensed with the methyl ester of (*S*)-leucine and the content of the diastereoisomeric dipeptides obtained was determined by high performance liquid chromatography (HPLC): the ratio of the (*S*,*S*)- and (*R*,*S*)-dipeptides was 95.3 : 4.7.[61]

Alkylation of the chiral oxazinone, obtained from D-phenyl-glycinol, has been used in the first enantioselective synthesis of (*R*)-(−)-2-amino-5-phosphonopentanoic acid (AP-5).[62] This compound is a selective antagonist of *N*-methyl-D-aspartate and is widely used in biochemical research.[63] The glycine synthon employed requires an active alkylating agent. In this instance, 3-phosphonoallyl bromide was used for this purpose (Scheme 16).

After the removal of the protecting groups and the hydrogenation of the carbon–carbon double bond, the target phosphorus-containing aminoacid was obtained in a high yield, its optical purity being estimated as 'high' from high performance liquid chromatographic data and the analysis of the NMR data for the diastereoisomeric precursors.

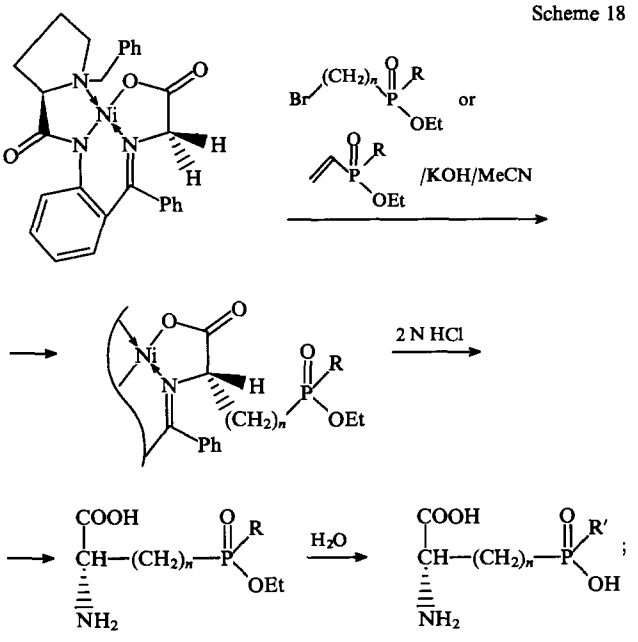


Scheme 16

In Belokon's chiral glycine synthon, the carboxy-group of the Gly (or Ala) fragment is not esterified and is not bound in a ring by a covalent bond, as in the previous methods. Nevertheless, the nickel(II) complexes of the glycine Schiff base are rigid cyclic systems in which [1,7]-asymmetric induction occurs as a result of the distortion of the chelate rings, which leads, when (*S*)-proline is used, to the shielding of the *re*-side of the methylene group of glycine by the benzene ring of the *o*-aminobenzophenone fragment. In order to generate the corresponding carbanion in these complexes, it is sufficient to use ordinary KOH in a dry organic solvent (DMF, MeCN), or NEt$_3$, or diazabicyclooctane in methanol or CHCl$_3$.

Alkylation with the appropriate fluorine-substituted benzyl chlorides or bromides of the nickel(II) complex of the Schiff base obtained from glycine and (*S*)-2-[*N*-(benzylprolyl)amino]-benzophenone afforded a series of (*S*)-phenylalanines containing from one to five fluorine atoms (as well as other halogens—Cl and Br) in the benzene ring as well as the trifluoromethyl group in the *para*- or *meta*-position.[64, 65] The attempts to obtain by this method (*S*)-*o*-trifluoromethylphenylalanine were unsuccessful, apparently owing to the steric effect of the trifluoromethyl group. The use of the nickel(II) complex of the Schiff base derived from alanine makes it possible to obtain fluorine-substituted α-methylphenylalanine derivatives (Scheme 17).

Scheme 17

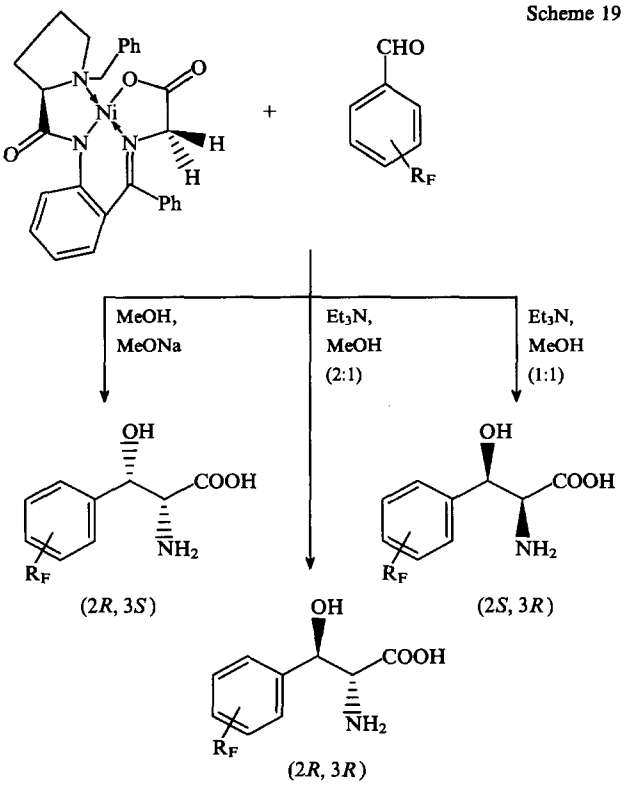


R = H, Me; R' = 2-FC$_6$H$_4$, 3-FC$_6$H$_4$, 4-FC$_6$H$_4$, 2-Cl,6-FC$_6$H$_3$, 4-CF$_3$C$_6$H$_4$, 2-F,6-BrC$_6$H$_3$, 2,6-Cl$_2$C$_6$H$_3$; X = Br, Cl.

The high chemical (50% – 80%) and optical (~90% d.e.) yields in the stage involving the alkylation of the nickel complexes render this method preparative.

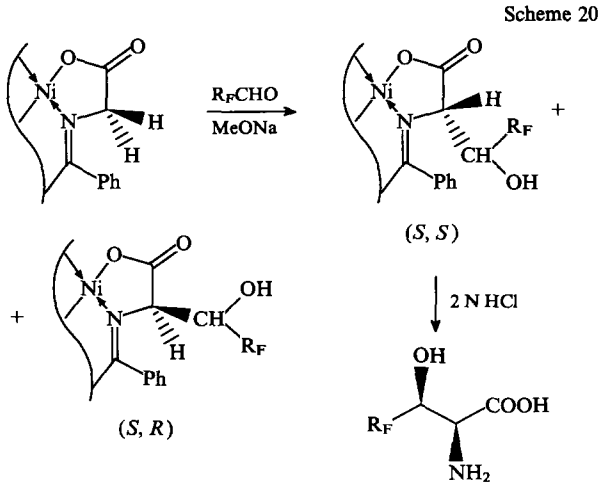
The (*S*)-enantiomers of ω-phosphonic and ω-phosphinic analogues of carboxylic α-aminoacids have been obtained by alkylating the nickel complex of glycine with the corresponding phosphonoalkyl bromides or, in a synthesis of homoglutamic acid and phosphinotricin, with vinyl phosphonate and vinyl phosphinate (Scheme 18).[66, 67]

Scheme 18



n = 2, 3; R = Me, OEt; R′ = Me, OH.

The enantioselectivity of the alkylation of the nickel complex with the diesters of ω-haloalkylphosphonic acids is >90%, while the kinetically controlled Michael addition takes place with only 60% diastereoselectivity. However, thermodynamic control (in the presence of MeONa) leads[67] to a 95 : 5 ratio of the diastereoisomeric complexes.

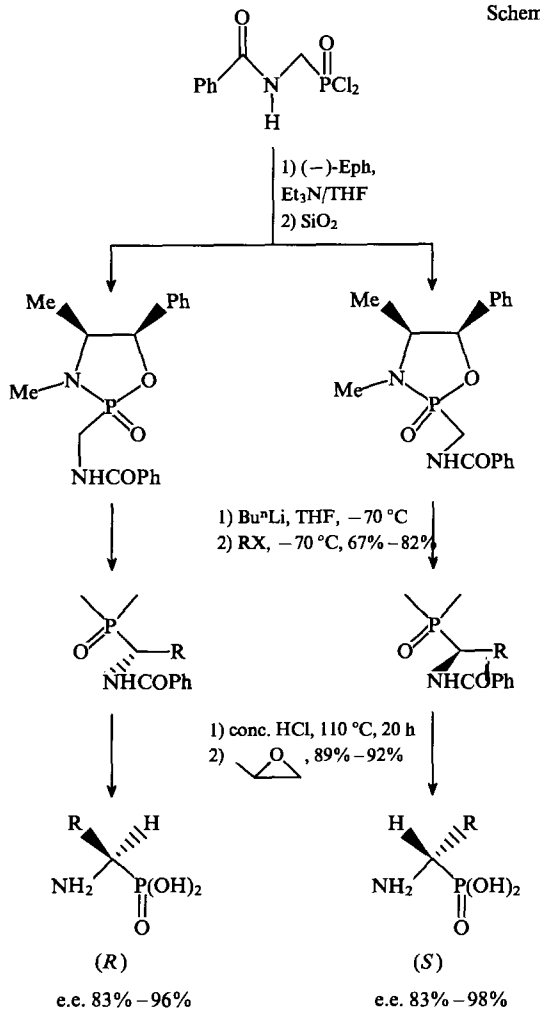


From the standpoint of the stereochemical result (diastereoselectivity of the alkylation), the method considered has no advantage over the Seebach or Schöllkopf methods in the synthesis of α-aminoacids, while its application to the synthesis of α-amino-β-hydroxyacid produces a unique result associated with the fact that at high pH the ionised β-hydroxy-group of the aminoacid fragment can substitute the carboxy-group at the nickel atom in the coordination plane, which results in the inversion of the absolute configuration at the α-carbon.[68] Thus, depending on the conditions in the condensation of the nickel(II) complexes of the Schiff bases obtained from glycine and fluorobenzaldehydes, the corresponding β-(fluorophenyl)serines with the absolute (2*R*, 3*S*)-, (2*R*, 3*R*)-, and (2*S*, 3*R*)-configurations respectively of the chiral atoms were obtained in an optically pure form (Scheme 19).[69–71]

An interesting example of the critical influence of the fluorine-containing substituent on the stereochemical outcome of the reaction has been demonstrated in the condensation of a chiral glycine complex with aliphatic perfluorinated aldehydes.[71] The interaction of fluoral or its hydrate (hemiacetal) with the glycine complex in methanol under the influence of MeONa leads to the formation of (2*R*, 3*S*)-4,4,4-trifluorothreonine, whereas acetaldehyde afford (2*R*, 3*S*)-threonine under analogous conditions (Scheme 20).[68]

Scheme 19

Scheme 20



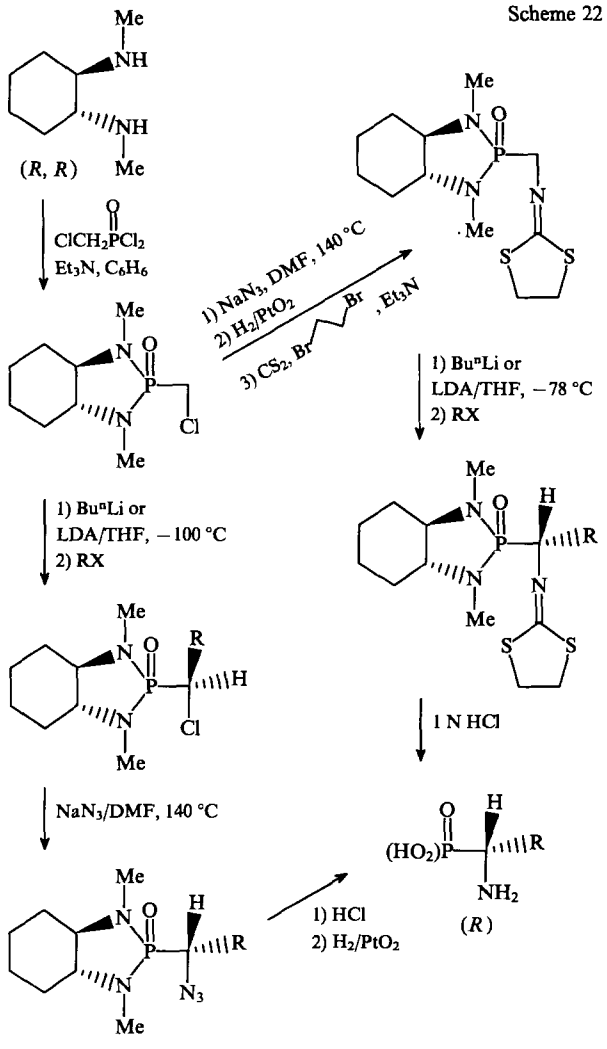
The same method has been used to synthesise (2*R*, 3*S*)- and (2*S*, 3*R*)-ω-phosphonic analogues of glutamic and homoglutamic acids with a β-hydroxy-group.[72, 73] The phosphonate group in the ω-position in the corresponding aldehyde does not exert in this instance any influence on the stereochemistry of the reaction.

In the examples examined above, the chiral auxiliary reagent is bound to the amino-group of the glycine or phosphonoglycine synthon. In an alternative approach, the chiral auxiliary reagent is bound to the acid functional group of the aminoacid. In the case of carboxylic α-aminoacids, it led to disappointingly low optical yields[50] but in the synthesis of phosphonic α-aminoacids it afforded a remarkable result. This was based on the possibility of obtaining cyclic esters, amides, or amidoesters in which the stereodifferentiating fragment is bound directly to the phosphorous atom ('chiral phosphorus').

Thus epimeric (with respect to the phosphorus atom) 2-benzamidomethyl-3,4-dimethyl-2-oxo-5-phenyl-2λ^5-1,3,2-oxazaphospholidines have been obtained from the dichloride of *N*-benzamidomethylphosphonic acid and (−)-ephedrine (Eph). After resolution on SiO_2, they were used[74] in the synthesis of the (*R*)- and (*S*)-enantiomers of Ala^P, Phe^P, and 1-aminobut-3-enylphosphonic acid (Scheme 21).

Scheme 21

RX = MeI, $PhCH_2Br$, $CH_2=CHCH_2I$.

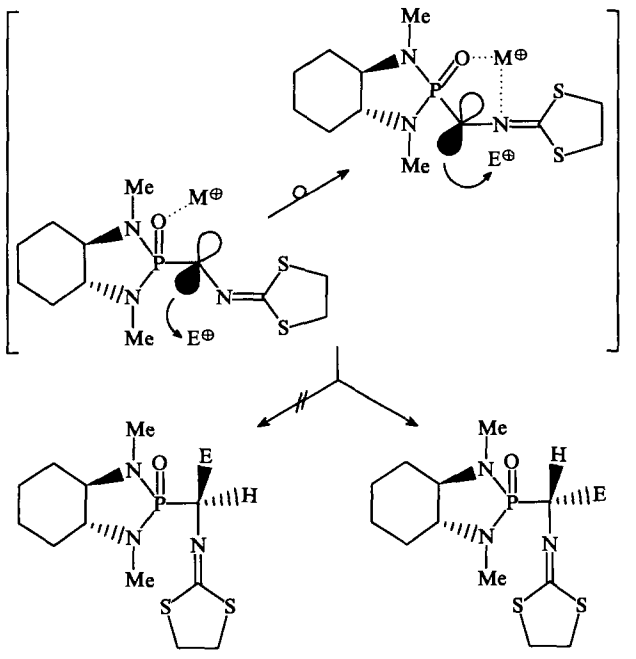


The diastereoselectivity of the alkylation reaction depends on the bulk of the substituent in the alkylating agent and is in the range form 58%−73% (MeI) to 84%−92% ($PhCH_2Br$). The chemical yield of the alkylation product is 67%−82%.

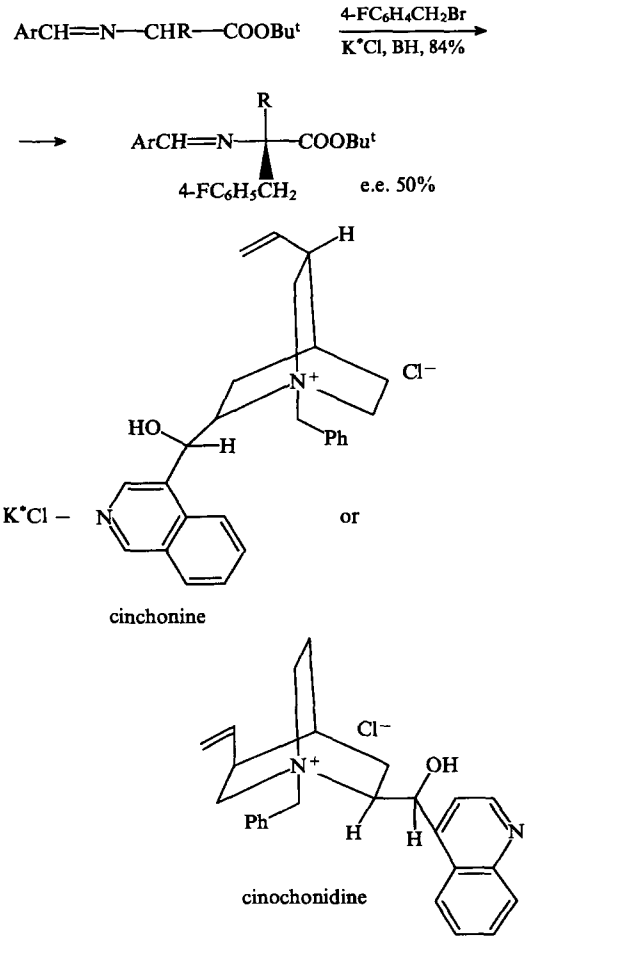
It is of interest to note that the diastereoselectivity of the alkylation of oxazaphospholidines diastereoisomeric with respect to the phosphorus atom is not the same. Thus in the case of the diastereoisomer with the (S^P)-configuration, this parameter is appreciably higher (up to 15%).

A method has been described in which a ligand with C_2 symmetry, namely (1*S*, 2*S*)- or (1*R*, 2*R*)-1,2-bis(methylamino)-cyclohexane, was used as the chiral inducing fragment bound to the phosphorus atom.[75, 76] The chiral methyliminodithiolan obtained from it can be alkylated with a high degree of diastereoselectivity (up to 98% d.e.), affording, after the removal of the protecting groups, phosphonic α-aminoacids in a satisfactory chemical yield and with a satisfactory chemical purity (Scheme 22).[75]

Another version of the method involves the alkylation of the chiral chloromethylphosphonate with subsequent replacement of chlorine by the amino-group and leads to optically active phosphonic α-aminoacids with the same stereoconfiguration,



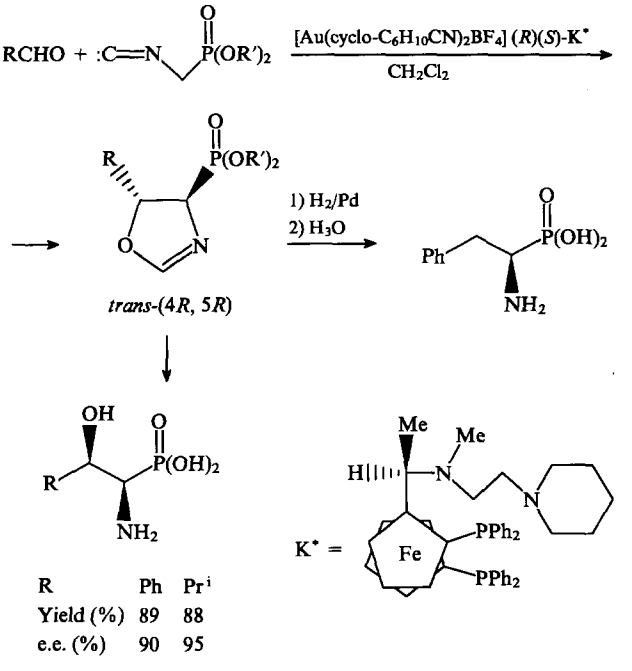
Scheme 22



despite the fact that the sequence of reactions employed involves the replacement of chlorine by the azido-group as a result of a reaction of the S_N2 type with inversion of the configuration at the C_α-atom. This is associated with the fact that in the given instance, while a high degree of stereoselectivity in the alkylation reaction is retained, the absolute configuration of the alkylation product is different from that in the alkylation of the corresponding methyliminodithiolan. The authors assume[75] that in the case of the methyliminodithiolan the metallation of the latter is followed initially by the formation of a chelate with participation of the nitrogen atom in the iminothiolan fragment, leading to the complete inversion of the configuration of the carbanion, and then by alkylation predominantly the 'opposite side' of the anion (Scheme 23).

There is no doubt that the most effective method of using optically pure compounds in asymmetric synthesis involves their application as catalysts. Major advances in asymmetric catalysis have been achieved in the hydrogenation of unsaturated bonds, while instances of the enantioselective formation of a C−C bond in the presence of a chiral catalyst are still fairly rare.[50] Two widely known methods for the catalytic asymmetric synthesis of α-aminoacids, developed by O'Donnell and Hayashi, have been used successfully for the preparation of element-containing aminoacids. Thus alkylation with alkyl halides of the Schiff bases of the *tert*-butyl esters of glycine or alanine under phase transfer conditions in the presence of quaternary salts of cinchonine or cinochonidine makes it possible to obtain the corresponding α-aminoacids, including *p*-fluorophenylalanine, with a moderate enantiomeric excess (Scheme 24).[77, 78]

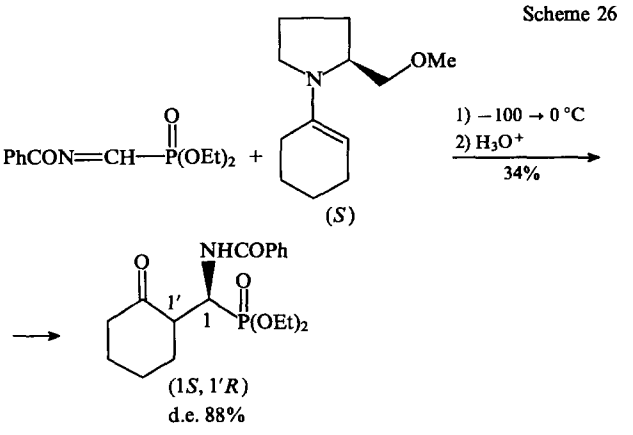
Scheme 23



Scheme 24

The use of the quaternary cinchonine salt as the catalyst yields an excess of the (*R*)-aminoacid, while 'pseudoenantiomeric catalysis' by the cinochonidine salt leads to the formation of (*S*)-4-fluorophenylalanine.

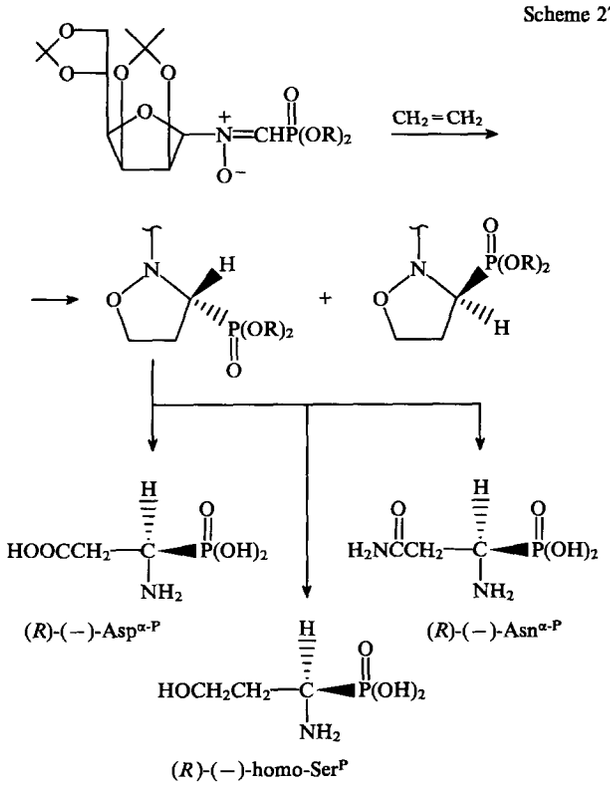
Optically pure α-phosphonic analogues of phenylalanine and β-alkyl(aryl)serines can be obtained by the asymmetric aldol reaction [condensation ?] between isocyanomethylphosphonates and various aldehydes in the presence of catalytic amounts of chiral ferrocenylphosphine complexes of gold(I) (Scheme 25).[79–81]



Scheme 25

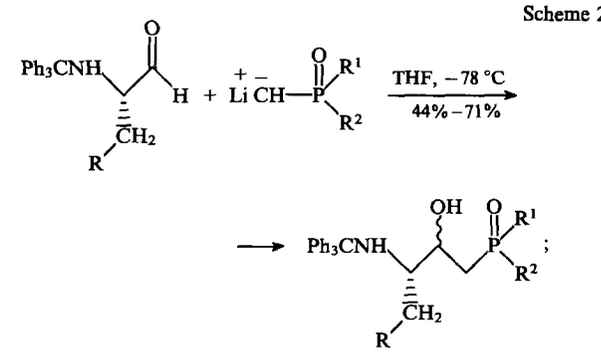
The highest enantioselectivities of the reaction (94%) were obtained when diphenyl isocyanomethylphosphonate was used. It is noteworthy that only one hundredth of a mole of the catalyst is sufficient for effective asymmetric catalysis in this reaction.

The only example of the asymmetric synthesis of phosphonic aminoacids (with formation of a C–C bond) using the substituent group itself as the chiral auxiliary group is the nucleophilic addition of a chiral enamine to an acyliminoalkylphosphonate,[82] which affords the target aminoacid with a 88% diastereoisomeric excess (Scheme 26).



Scheme 26

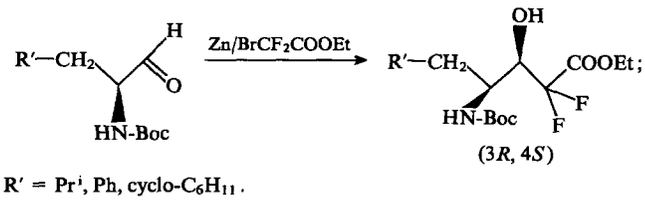
N-Glycosyl-*C*-dialkoxyphosphonylnitrones based on α-D-mannofuranose combine with ethylene, forming diastereoselective cyclic adducts (yield 80%–85%) in proportions of 3 : 1, diastereoisomers with the configuration of the aminoalkylphosphonate fragment corresponding to that of natural L-aminoacids being formed preferentially. After the chromatographic separation, the dominant diastereoisomers were converted in high yields[83] into (*R*)-(–)-phosphonic analogues of homoserine, aspartic acid, and asparagine (Scheme 27).



Phosphonic acid analogues of statine—an unusual natural carboxylic γ-amino-β-hydroxy-acid with two chiral centres [4-(*S*)-amino-3-(*S*)-hydroxy-6-methylheptanoic acid], forming part of the natural peptide pepstatin,[84] have been synthesised by

Scheme 27

adding a stabilised anion, generated from the dialkyl ester of methylphosphonic acid by treatment with butyllithium or sodium bis(trimethylsilyl)amide, to enantiomeric α-(*N*-trimethylamino)-aldehydes obtained from the corresponding *L*-aminoacids.[85] It was found that the diastereoselectivity of the addition depends only slightly on the nature of this group in the initial amino-aldehyde and on the ester groups in the phosphonate anion: the ratio of the (2*R*, 3*S*)- and (2*S*, 3*S*)-diastereoisomers formed varies within narrow limits—from 2.3 : 1 to 3.0 : 1 (Scheme 28).



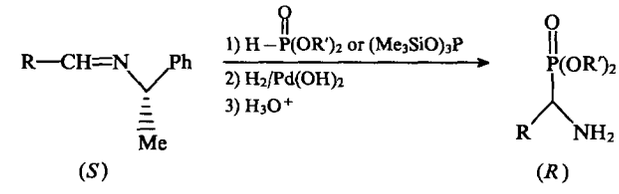
Scheme 28

R = Pr^i, cyclo-C_6H_{11}, Ph; R^1 = R^2 = MeO, BuO; R^1R^2 = $O(CH_2)_3O$.

The possibility of introducing the esters of bromodifluoroacetic acid into the Reformatskii reaction[86] has been used in the asymmetric synthesis of 2,2-difluoro-substituted analogues of statine (Scheme 29).

Scheme 29

R' = Pr^i, Ph, cyclo-C_6H_{11}.



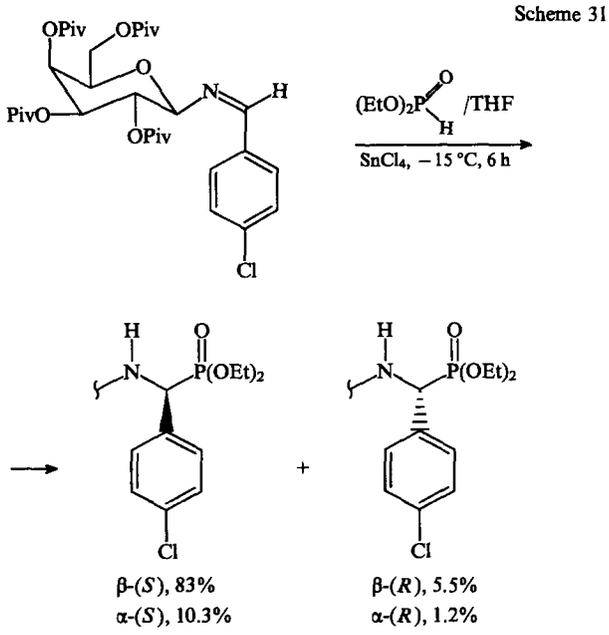
Two methods have been proposed for the condensation of *N-tert*-butoxycarbonyl-(*S*)-leucinal with bromodifluoroacetic ester in the presence of activated zinc.[87–91] Refluxing of the reagents in tetrahydrofuran (THF) affords a mixture of the (3*R*, 4*S*)- and (3*S*, 4*R*)-diastereoisomers in proportions of ~9 : 1, which is associated with the partial racemisation of the initial (*S*)-leucinal on heating. Milder condensation conditions at low temperatures under the influence of ultrasound lead to a 7 : 3 mixture of the (3*R*, 4*S*)- and (3*S*, 4*R*)-diastereoisomers. Almost the same stereochemical result was obtained on using the (*S*)-enantiomers of α-aminoaldehydes containing the phenyl or cyclohexyl group instead of the isopropyl group.

III. Enantioselective formation of the C–P bond

The nucleophilic addition of hydrophosphoryl compounds with a carbon–nitrogen double bond has been used extremely widely for the asymmetric synthesis of phosphonic α-aminoacids. This approach was used for the first time more than twenty years ago, and, although the optical yield of the aminoacids in these syntheses is as a rule not very high, the method still continues to attract the attention of investigators in view of its simplicity and accessibility.

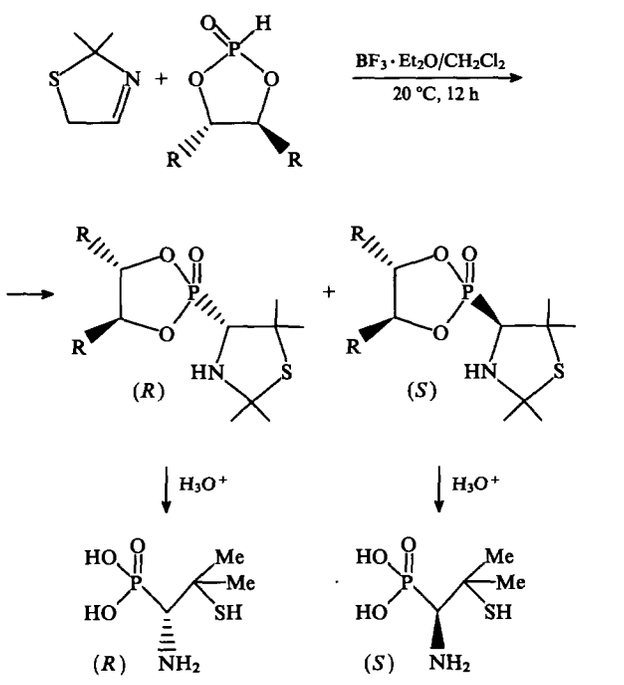
In the first syntheses of this type,[92–95] the Schiff bases derived from α-phenylethylamine enantiomers were used as the chiral inducing agent. The addition of acid phosphites to the corresponding aldimines under the conditions of acid catalysis (organic and inorganic acids, Lewis acids) takes place with a fairly high diastereoselectivity only in the case of bulky substituents in the aldehyde fragment in the initial aldimine (R = Ph, Pr^i; up to 80% d.e.) and decreases on passing to small aliphatic substituents (R = Me, Et) (Scheme 30). The attempts to increase the stereoselectivity of the addition by increasing the bulk of the substituent in the second reactant (the phosphite), by employing tris-(trimethylsilyl) phosphate, did not produce the desired result.[95]

Scheme 30



R = Me, Et, Pr^i, Ph.

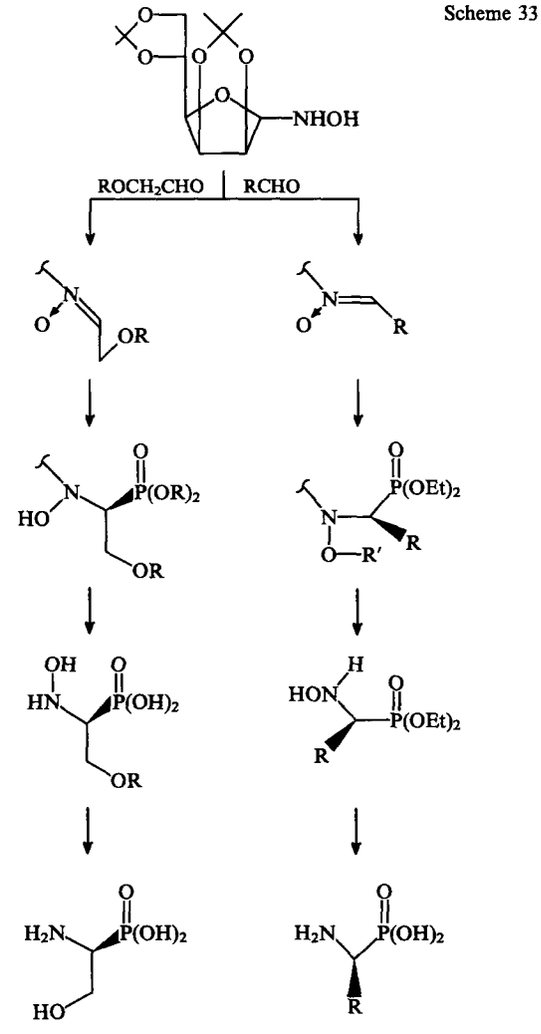
A satisfactory result, within the framework of this method, has been obtained using Schiff bases obtained from aldehydes and pivaloylated glycosylamines (Scheme 31).



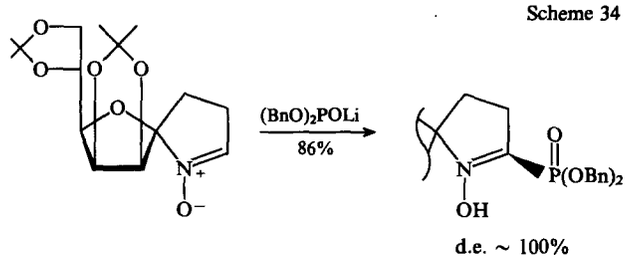
The nucleophilic addition of the acid phosphite in the reaction catalysed by $SnCl_4$ proceeds with high chemical and optical yields, affording as the main product (*S*)-amino-substituted phosphonates when β-D-galactosylimine (shown in Scheme 31) is used and (*R*)-amino-substituted phosphonates when α-D-arabino-pyranosylimine is used.[96] The resolution of the optical isomers is complicated in this case by the α,β-anomerisation of the products, but it can be achieved effectively by a combination of crystallisation and chromatographic methods.

In the syntheses of this type, the chiral inducing group can also be located at the phosphorus atom (nucleophilic diastereoselective addition of the chiral phosphite to the achiral azomethine), which has been demonstrated in relation to the synthesis of the enantiomers of the phosphonic analogue of penicillamine,[97] where the diastereoisomers are formed in the first stage in the proportions (*R*) : (*S*) = 2 : 1 (Scheme 32).

Scheme 31



Scheme 32

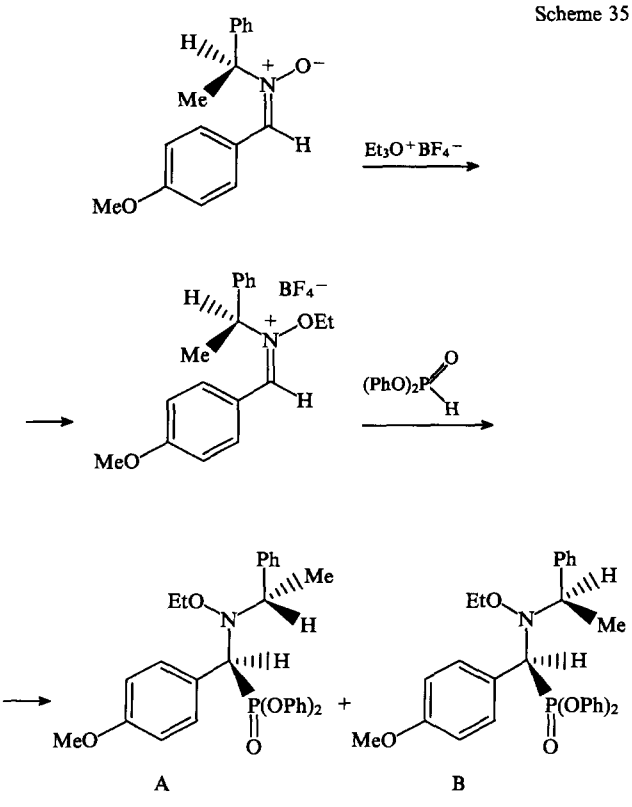


Hydrophosphoryl compounds can be added to, apart from Schiff bases, a series of other compounds with a C=N bond, which has been used for the asymmetric synthesis of α-amino-substituted phosphonic acids. Considerable advances have been achieved by Vasella and coworkers,[98-100] who investigated the reactions involving the addition of phosphites to *N*-α-D-mannofuranosylnitrones (Scheme 33).

This method[98] makes it possible to obtain aminoacids with small alkyl substituents (Ala^P, Val^P) in high optical yields, although the chemical yield does not exceed 50%. The diastereoselectivity of the addition of lithium dialkyl phosphites to *N*-glycosyl-*C*-alkylnitrones is 78%–93%, decreasing appreciably when potassium dialkyl phosphites are used.[98] We may note that 100% diastereoselectivity is observed in addition of lithium dibenzyl phosphite to *N*-glycosylspironitrone (Scheme 34).[100]

Scheme 33

Scheme 34



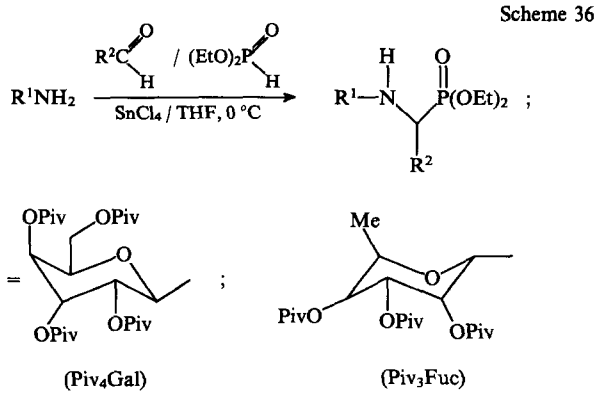
d.e. ~ 100%

The synthetic possibilities of the method are not limited to the synthesis of α-aminoalkylphosphonic acids. One of the advantages of the method is the possibility of isolating optically active *N*-hydroxy-α-aminoalkylphosphonic acids which cannot be obtained by other methods. In addition, the use of the corresponding aldehydes with protected functional groups makes it possible to obtain β-hydroxy-α-aminoalkylphosphonic acids (Ser^P) and γ-alkylthio-α-aminoalkylphosphonic acids (Met^P).[99]

It has been found that *N*-glycosyl-*C*-arylnitrones do not interact with the anions of dialkyl phosphites but do readily combine with tris(trimethylsilyl)phosphite in the presence of Lewis acids ($ZnCl_2$, $HClO_4$) with a diastereoselectivity of 79%–93%, which has been used to obtain optically active phosphonic analogues of phenylglycine.[99] The interesting inversion of the absolute configuration of the α-aminoalkylphosphonate on changing the relative amount of the catalyst present ($ZnCl_2$) is noteworthy. This made it possible to obtain both enantiomers of the phosphonic analogue of phenylglycine using the same reagents.

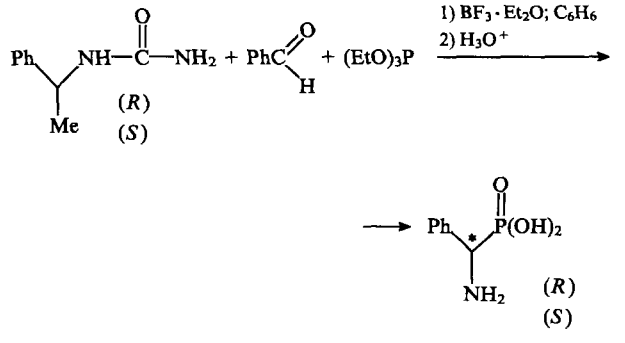
After *O*-ethylation, the nitrone with the chiral α-phenylethyl substituent at the nitrogen atom gives rise to an oxoiminium salt,[101] which combines diastereoselectively with diphenyl phosphite to form two diastereoisomers in proportions of 3 : 2. The absolute configurations of the diastereoisomers, which can be resolved by chromatography on an alumina column, were determined, but the authors suggest that the diastereoisomer A should be formed preferentially as a result of the attack on the C = N bond from the *si*-side (Scheme 35).

Scheme 35



The *N*-acyliminoester obtained from (−)-ω-camphanic acid combines with dialkyl phosphites to form diastereoisomeric adducts from which optically active phosphonic analogues of phenylalanine [(+)- and (−)-Phe^P] were obtained[102] by the reductive elimination of the alkylthio-group and subsequent hydrolysis.

Other methods for the formation of the carbon–phosphorus bond, widely used in the synthesis of racemic α-aminoalkylphosphonic acids,[31] are represented by only isolated examples in the asymmetric synthesis of aminoalkylphosphonates. Thus β-D-galactosylamine and β-L-fucopyranosylamine have been used as the amino components in the Kabachnik – Fields reaction. Asymmetric induction, leading preferentially to (*S*)- and (*R*)-α-aminoalkylphosphonates respectively (from 42 to 96% d.e.), was then observed.[96] The level of this induction was virtually the same as in the addition of acid phosphites to the Schiff bases derived from the corresponding glycosylamines (Scheme 36).



The intereaction of neutral phosphites with aldehydes and ureas or carbamates (a non-classical version of the Arbuzov reaction) has also been used for the asymmetric synthesis of a series of α-aminoalkylphosphonic acids. *N*-Monosubstituted ureas, obtained from (*R*)- and (*S*)-α-phenylethylamine,[103] or carbamates based on (−)-menthol or 1,7,7-trimethylspiro{bicyclo-[2.2.1]heptane-3,2′-indan}-2-ol, obtained from (*R*)-(+)-camphor, were introduced into the reaction (Scheme 37).[104]

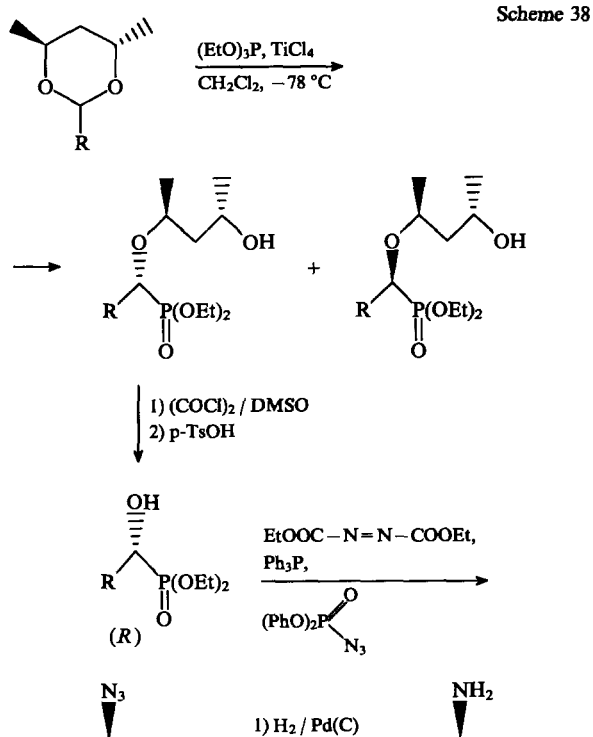
The optical purity of the aminoalkylphosphonic acids obtained by this method — the phosphonic analogues of alanine, valine, and phenylglycine, as well as 1-amino-propylphosphonic acid — is low (e.e. = 8.3% – 42.2%), but one should note the inversion of the stereochemical outcome of this reaction relative to the reaction,

Scheme 36

Scheme 37

examined above, involving the addition reaction of acid phosphites with the C = N double bond. Thus, when the urea based on (*R*)-α-phenylethylamine is used, (*R*)-aminoalkylphosphonic acids are formed preferentially, while the addition of acid phosphites to aldimines based on (*S*)-α-phenylethylamine leads to (*S*)-aminoalkylphosphonates.[92, 103]

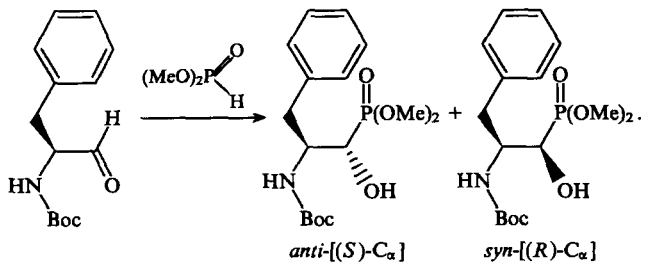
In the presence of titanium tetrachloride, triethyl phosphite effects the stereoselective opening of the homochiral acetals based on (+)-(2*S*, 4*S*)-pentanediol. The principal diastereoisomers, which are readily separated by column chromatography, were converted by the Swern oxidation into α-hydroxyalkylphosphonates with the (*R*)-configuration (e.e. > 95%), which were converted in their turn into α-azidoalkylphosphonates via reactions which occur with inversion of the configuration of the chiral centre (the Mitsunoba reaction or the reaction of sodium azide with the corresponding methanesulphonate) (Scheme 38).[105]



The catalytic hydrogenation of the azides leads to α-aminoalkylphosphonates, the hydrolysis of which afforded (*S*)-α-aminoalkylphosphonic acids (Val^P and Leu^P).

The base-catalysed diastereoselective addition of dimethyl phosphite to the chiral aldehyde obtained from L-phenylalanine leads to the formation of diastereoisomeric β-amino-α-hydroxyalkylphosphonates. Depending on the solvent and base used, the ratio of the *anti*- and *syn*-isomers varies from 1.2 : 1 (DBU/DMF) to 12 : 1 (KF/DMF) (Scheme 39).[106] The *anti*-diastereoisomer was used to synthesise an effective renin inhibitor.

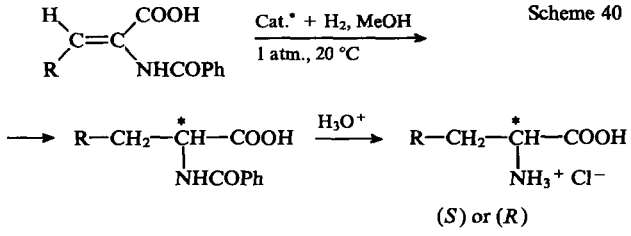
IV. Enantioselective formation of the C–H bond



The reduction of the prochiral derivatives of α,β-dehydroaminoacids to the corresponding optically active aminoacids is one of the most vigorously developing fields of asymmetric synthesis. The rigidity of the intermediate complexes between the α,β-dehydroaminoacids and the catalyst is an important factor influencing the enantioselectivity of the reduction. It has been suggested that this factor is the cause of the lower optical yields in the reduction of (*E*)-dehydroaminoacids compared with the (*Z*)-isomers.[107]

Scheme 38

R	Pr^i	Bu^i	$PhCH_2$
d.e. (%)	86	88	82

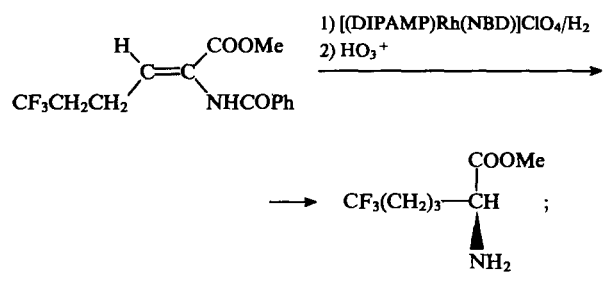


Scheme 39

The wide scale employment of rhodium catalysts is restricted by the necessity to select both the catalyst and the reaction conditions for each new substrate.[50]

In a recently published study,[108] a whole series of rhodium catalysts for the reduction of the corresponding (*Z*)-α-*N*-benzamido-β-(fluorophenyl)acrylic acids or their esters were investigated in order to achieve the asymmetric synthesis of fluorine-substituted phenylalanines. The best result (e.e. ≃ 90%) was obtained using rhodium complexes with PROPRAPHOS and *O*,*N*-bis(diphenylphosphino)-2-*exo*-hydroxy-3-*endo*-methylaminonorbornene as the chiral ligand (Scheme 40).

Scheme 40

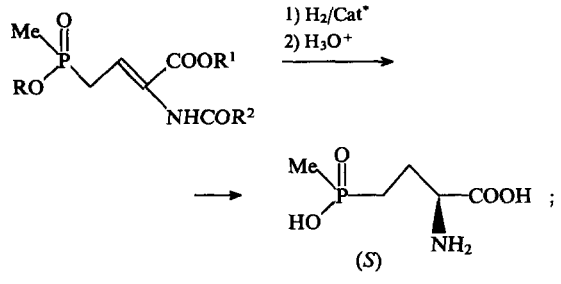


(*S*) or (*R*)

R = 2-FC_6H_4, 3-FC_6H_4, 4-FC_6H_4, 4-$CF_3C_6H_4$, C_6F_5.

It is noteworthy that in the reduction of (*Z*)-α-*N*-benzamido-β-pentafluorophenylacrylic acid a higher optical yield is observed than in the reduction of the monofluoro-substituted analogue under identical conditions.

Methyl (*Z*)-α-*N*-benzamido-β-3,3,3-trifluoropropylacrylate was reduced to the methyl ester of (*S*)-*N*-benzoyl-6,6,6-trifluoronorleucine in the presence of the rhodium complex of (1*R*, 2*R*)-1,2-ethanediylbis[(*o*-anisylphenyl)phosphine] (DIPAMP) with the same optical yield (e.e. = 90%) (Scheme 41).[109, 110]



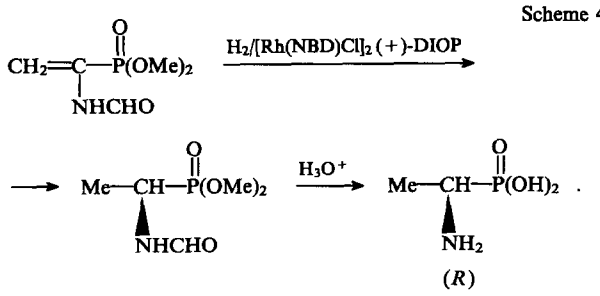
Scheme 41

NBD = *norbornadiene*

The asymmetric synthesis of phosphorus-containing amino-acids using rhodium catalysts was demonstrated in relation to the synthesis of (*S*)-phosphinotricin (Scheme 42).[111]

Scheme 42

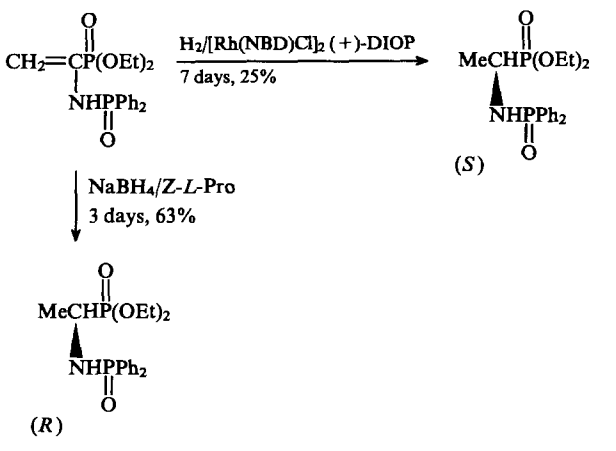
Cat* = (*R*, *R*)-NORPHOS, (*S*, *S*)-CHIRAPHOS



The best optical yield in the reduction stage was obtained using the rhodium complex of (*S*, *S*)-CHIRAPHOS (e.e. 91%).

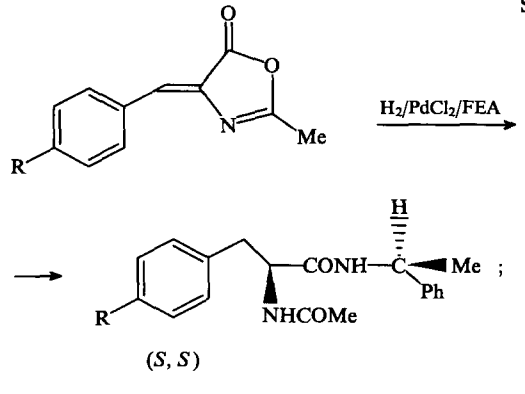
In the cases examined above, the presence of fluorine or phosphorus atoms in the substituent in the γ-position in the corresponding acrylic acid does not apparently exert a significant influence on the catalytic process. The study of the possibility of using rhodium catalysts in the synthesis of α-aminoalkylphosphonic acids in which the phosphono-group adjoins the C=C double bond and can participate in the formation of the transition complex with the rhodium catalysts has therefore aroused much interest.

Schöllkopf et al.[112] showed that α-(*N*-formamido)vinylphosphonate, obtained by the Horner–Wittig reaction from *N*-formamidomethylenediphosphonate and paraformaldehyde, can be reduced in the presence of the rhodium complex of (+)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis-(diphenylphosphino)butane [(+)-DIOP], which results in the formation of (*R*)-(−)-α-(*N*-formamido)ethylphosphonate with an enantiomeric excess of 76% (Scheme 43).



The attempts to use (+)-DIPAMP or (+)-NORPHOS instead of (+)-DIOP as the chiral ligands were unsuccessful—hydrogenation did not take place at the normal pressure. The asymmetric hydrogenation process in the presence of rhodium catalysts depends not only on the chiral ligand employed but also on the structure of the substrate. Thus the reduction of α-(*N*-diphenylphosphinylamino)vinylphosphonate in the presence of the chiral rhodium catalyst based on (+)-DIOP takes place extremely slowly and with a low asymmetric induction [e.e. ~ 3%;

Scheme 43

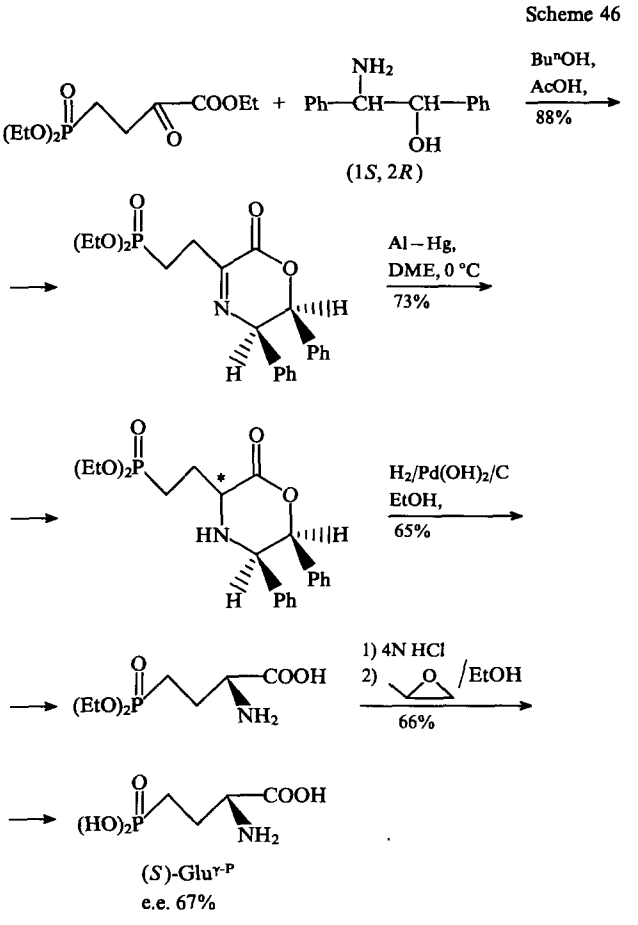


(*S*)-aminoalkylphosphonate predominates]. It is of interest that the reduction of this substrate with sodium tetrahydroborate in the presence of *N*-benzyloxycarbonyl-*L*-proline results in the preferential formation[113] of the (*R*)-aminoalkylphosphonate (e.e. 12%) (Scheme 44).

Scheme 44

The hydrogenation of azlactones in the presence of $PdCl_2$ and added (*S*)-α-phenylethylamine (PEA) (up to 55% d.e.) has been used to synthesise fluoro-derivatives of (*S*)-phenylalanine (Scheme 45).[114, 115]

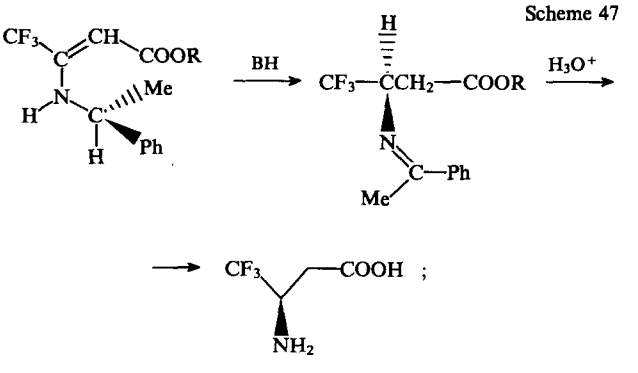
Scheme 45



R = F, $OCHF_2$.

The dihydrooxazinone obtained from the ester of a γ-phosphono-α-ketoacid and the optically active (+)-*erythro*-2-hydroxy-1,2-diphenylethylamine, acted upon by aluminium amalgam, undergoes stereoselective reduction with formation of the corresponding tetrahydrooxazinone, which is subsequently converted by a standard procedure into the γ-phosphonic analogue of (*S*)-glutamic acid (e.e. 67%) (Scheme 46).[116]

The hydrogenation of the C=N double bond takes place more effectively in the presence of catalysts such as Raney nickel and platinum or palladium on carbon but under these conditions there is also simultaneous decomposition of the oxazinone ring,

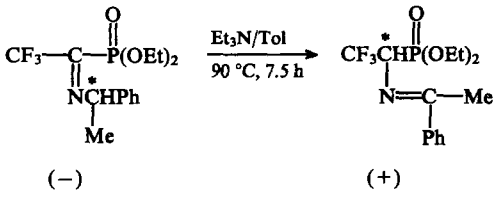


Scheme 46

playing the role of the stereodifferentiating fragment, which results in the formation of the racemic product.

The asymmetric version of the general method of synthesis of α-difluoromethylamines and -aminoacids via the irreversible isomerisation of α-trifluoromethyl-*N*-benzylimines[117] has been proposed for the enantioselective synthesis of (*S*)- and (*R*)-β-trifluoromethyl-β-alanine (Scheme 47).

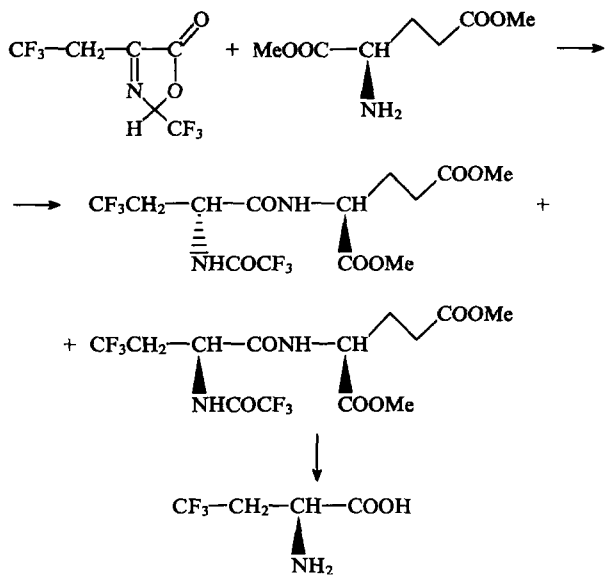
Scheme 47



R = Me, Et.

The isomerisation in the above process, the [1,3]-proton shift, takes place on heating in the presence of bases (DBU, DBO) with a moderate enantioselectivity (up to 75% e.e.), which is determined by the preferential proton transfer from the *re*- or *si*-sides of the intermediate [1,3]-azaallyl anion. The catalytic version of this isomerisation [chiral enamine, chiral base (cinchonidine)] has also been examined but the asymmetric outcome of the reaction did not exceed 10% e.e.

N-(α-phenylethyl)trifluoroacetimidoylphosphonate, obtained from (−)-α-phenylethylamine, also undergoes a [1,3]-H shift on heating in the presence of triethylamine, which proceeds with a

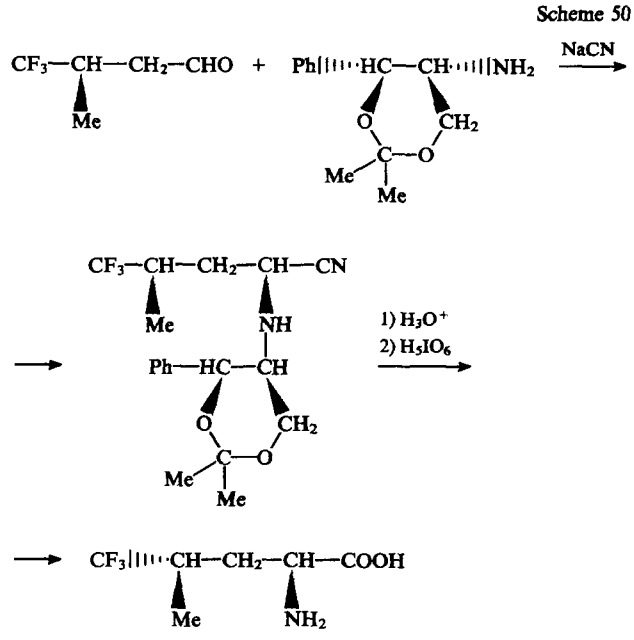


low asymmetric induction (e.e. 22%) and results in the formation of an optically active phosphonic analogue of trifluoroalanine (Scheme 48).[119]

Scheme 48

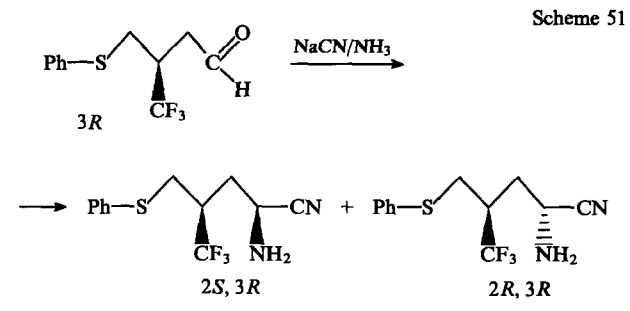
An asymmetric process has been proposed for the synthesis of the *L*-enantiomer of 4,4,4-trifluoro-2-aminobutyric acid. It consists of the stereoselective opening of the ring in 4-(2,2,2-trifluoroethyl)-2-trifluoromethyl-Δ^3-5-oxazolinone by the dimethyl ester of *L*-glutamic acid, which affords a mixture of diastereoisomeric dipeptides in the proportions (*L*, *L*) : (*D*, *L*) = 83 : 17. Optically pure *L*-4,4,4-trifluoro2-aminobutyric acid has also been obtained after repeated crystallisation of a diastereoisomeric mixture with subsequent elimination of the *L*-glutamic acid residue (Scheme 49).[120]

Scheme 49



V. Enantioselective formation of the C–N bond

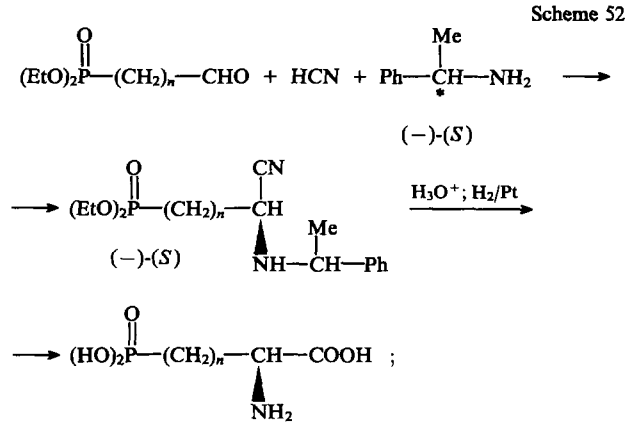
The asymmetric synthesis of (2*S*, 4*R*)-5,5,5-trifluoroleucine from the optically pure (3*R*)-3-trifluoromethylbutanal and (4*S*, 5*S*)-5-amino-2,2-dimethyl-4-phenyl-1,3-dioxane was carried out by the strecker reaction.[121] The reaction takes place with a moderate diastereoselectivity (d.e. 60%), affording the target aminoacid with the α-(*S*)-configuration of the chiral carbon atom (Scheme 50).



The asymmetric induction is apparently determined in this instance by the stereochemical structure of the substituent at the nitrogen atom, while the chiral centre in the aldehyde fragment has virtually no stereodifferentiating effect. Thus the Strecker synthesis using the 4-phenylthio-derivative of (3*R*)-3-trifluoromethylbutanal affords a mixture of the corresponding diastereoisomeric aminonitriles in proportions of ~1 : 1, from which the optically pure (2*R*, 3*R*)- and (2*R*, 3*S*)-5,5,5-trifluoroleucines were obtained after resolution, the hydrolysis of the nitrile group, and desulphurisation (Scheme 51).[122]

The use of ω-formylalkylphosphonates and (*S*)-α-phenylethylamine in the Strecker synthesis makes it possible to achieve the asymmetric synthesis of the (*S*)-enantiomers of the ω-phosphonic

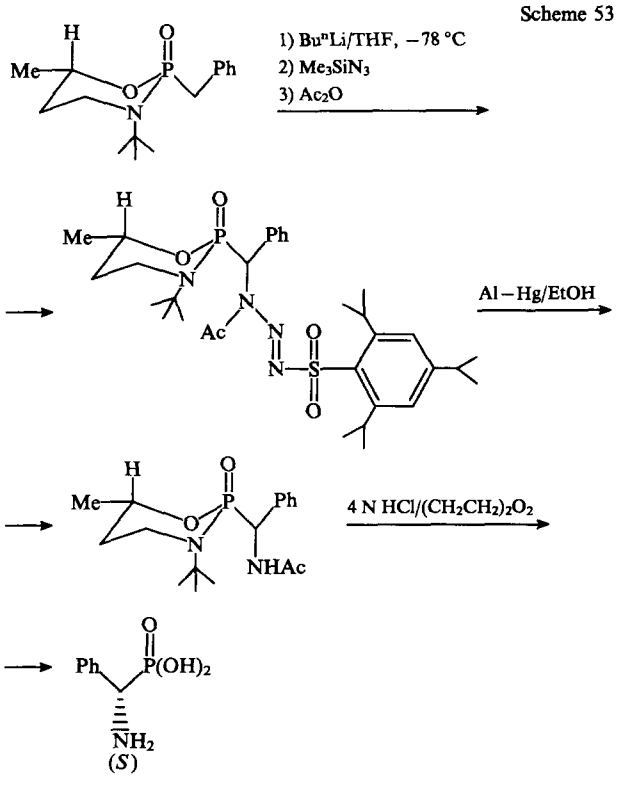
Scheme 50



Scheme 51

analogues of aspartic and glutamic acid with e.e. up to 50% (Scheme 52).[123]

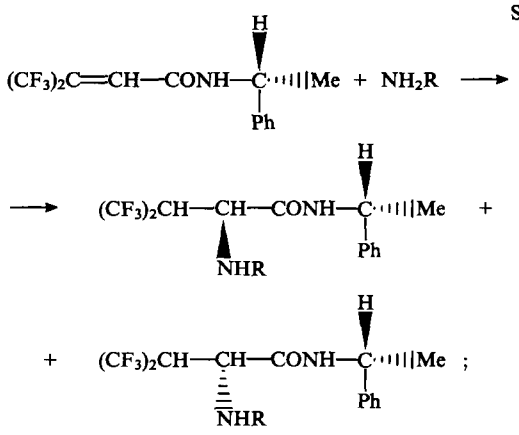
Scheme 52



n = 1, 2.

The asymmetric electrophilic amination of stabilised phosphorus-containing carbanions, developed recently by Denmark, is a promising aspect of the asymmetric synthesis of α-aminoalkylphosphonic acids. The electrophilic amination of a series of chiral oxazaphosphorinanes and oxaphospholidines, obtained from the dichlorides of alkylphosphonic acids and the corresponding chiral 1,3- or 1,2-aminoalcohols has been investigated.[124] Trimethylsilyl azide was used as the aminating agent. It was established that the stereochemical outcome of the reaction depends on the structure of the stereodifferentiating aminoalcohol fragment, the nature of the *P*-alkyl substituent,

and the choice of the amination method and it has been shown that under optimum conditions it is possible to achieve an extremely high level of asymmetric induction. This was demonstrated in relation to the synthesis of the (*S*)-enantiomer of the phosphonic analogue of phenylglycine with an optical purity of 92% in accordance with Scheme 53.

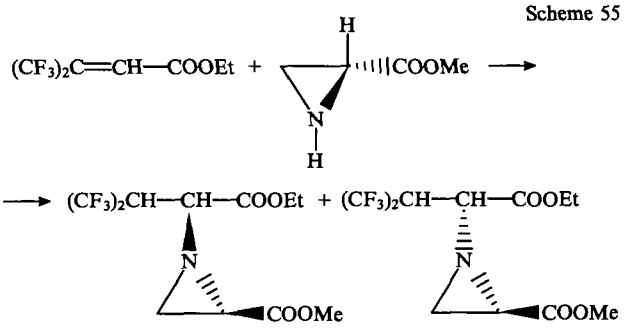


Scheme 53

When the *P*-benzyl substituent in the oxazaphoshorinane was replaced by the ethyl substituent or the 2-phenylethyl group, an appreciable decrease in the stereoselectivity of the amination was observed.

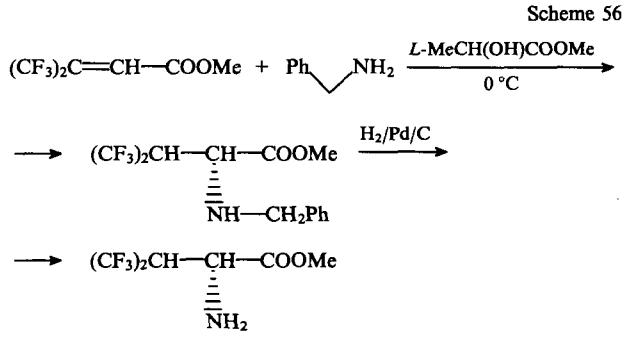
A simpler but much less effective method of asymmetric amination has been investigated by Solodin and coworkers[125, 126] in order to synthesise optically active hexafluorovaline (Scheme 54).

Scheme 54



R = H, CH_2Ph.

It has been stated[125] that the addition of ammonia or benzylamine to the chiral *N*-phenylethylamide of 3,3-bis-(trifluoromethyl)acrylic acid leads to the formation of the corresponding hexafluorovaline derivatives with 20% – 41% d.e. However, neither the nature of the asymmetric induction nor the fact that the diastereoisomer is formed in excess were discussed.



The asymmetric synthesis of hexafluorovaline derivatives can be achieved also by the addition of the chiral esters of (*S*)- or (*R*)-aziridine-2-carboxylic acids to ethyl 3,3-bis(trifluoromethyl)-acrylate. The stereochemical aspects of the addition were not discussed (Scheme 55).[126]

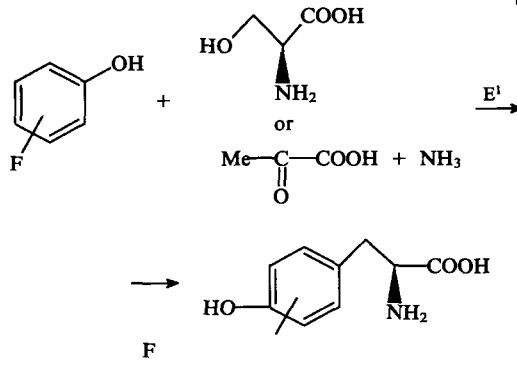
Scheme 55

The addition of benzylamine to methyl 3,3-bis(trifluoro-methyl)acrylate in a chiral medium (solution in *L*-methyl lactate) made it possible to obtain the methyl ester of (*R*)-hexafluoro-valine with a low optical purity (9.2%) (Scheme 56).[125]

Scheme 56

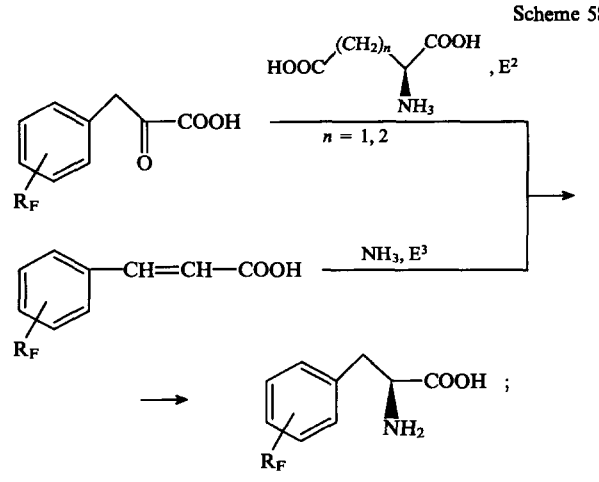
VI. Asymmetric synthesis with the use of enzymes

One of the promising methods of the industrial production of the *L*-enantiomers of proteinogenic aminoacids is their enzymic synthesis.[127] The enantiomeric purity of the aminoacids obtained approaches 100%. Salt suspensions in the culture liquid, disrupted cells, or the purified enzymes in a free state can be used as the source of enzymes effecting the asymmetric synthesis. The economy and simplicity of the method ensure a lower, compared with the chemical asymmetric synthesis, cost of the aminoacids obtained. This field is developing particularly vigorously at the present time in Japan.



The possibility of obtaining element-containing aminoacids by enzymic synthesis arises from the fact that the majority of the enzymes used in this method have a fairly broad substrate specificity.

Thus β-tyrosinase (E^1), used successfully for the synthesis of various halogen-containing (Cl, Br) tyrosine analogues, was also employed to obtain (*S*)-2-fluoro- and (*S*)-3-fluoro-tyrosines in 75 and 50% yields respectively (Scheme 57).[128–133]

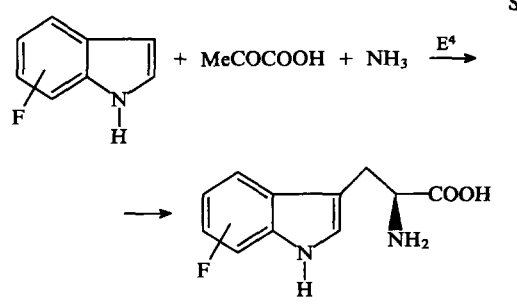


Fluorophenols and (*S*)-serine or a mixture of pyruvic acid and ammonia are used as starting compounds in the synthesis.

β-Phenylpyruvic acid with fluorine atoms or the trifluoro-methyl group in the benzene ring can be converted into the corresponding fluorine-substituted (*S*)-phenylalanines with a chemical yield up to 90% using the transaminase (E^2) from *Alcaligenes falcalis* and aspartic or glutamic acid as the donor of the amino-group (Scheme 58).[14, 132, 134]

Scheme 57

Scheme 58

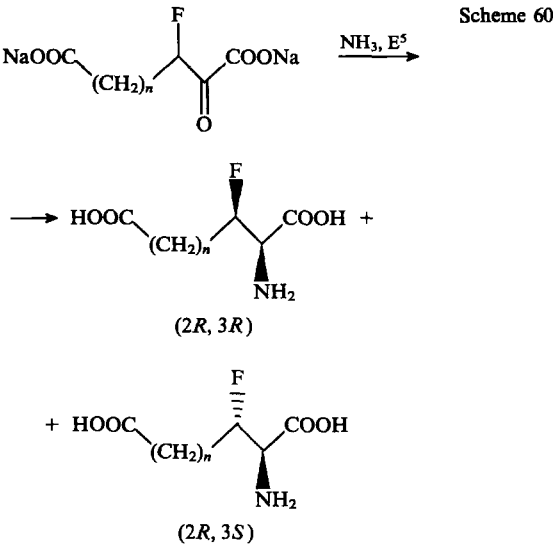


R_F = F, F_5, CF_3.

The rate of the enzymic transamination of phenylpyruvic acid depends on the nature of the substituents in the benzene ring and decreases appreciably on passing from the monofluoro- to the pentafluoro-, and trifluoro-methyl derivatives.

Phenylalanine ammonium lyase (E^3), can also be used for the synthesis of fluorophenylalanines, but this enzyme is more substrate-specific than the transaminase and cannot be employed for the synthesis of trifluoromethylphenylalanines.[14]

All the isomeric (*S*)-4-, (*S*)-5-, (*S*)-6-, and (*S*)-7-fluoroindoles as well as the (*S*)-5,7-di- and (*S*)-trifluoroindoles can also be obtained with an optical yield up to 90% from the corresponding fluoroindoles, pyruvic acid, and ammonia in the presence of tryptophanase (E^4) (Scheme 59).[14, 135]

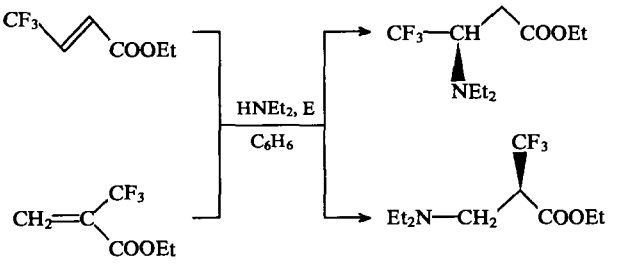


Scheme 59

The methods examined have also been used to synthesise ^{13}N- and ^{11}C-labelled aromatic fluoro-derivatives of amino-acids.[133, 135]

Optically pure (2*R*, 3*R*)- and (2*R*, 3*S*)-3-fluoroglutamic acids have been synthesised effectively from (*R*, *S*)-3-fluoro-2-oxo-glutaric acid under the influence of glutamate dehydrogenase (E^5) (Scheme 60).[136, 137]

Scheme 60



n = 0, 1.

The (2*R*, 3*R*)- and (2*R*, 3*S*)-diastereoisomers are formed in almost identical chemical and stereochemical yields (e.e. 97 and 98% respectively), which indicates the absence of any kind of stereodifferentiating effect on the fluorine atom in the initial racemate of 3-fluoro-2-oxoglutaric acid.

The racemate of 3-fluoro-2-oxosuccinic acid was converted by similar procedure in the presence of aspartate dehydrogenase into a mixture of the diastereoisomeric (2*R*, 3*R*)- and (2*R*, 3*S*)-3-fluoroaspartic acids, isolated in an optically pure form by ion exchange chromatography.[138]

Yet another example of the use of enzymes in the asymmetric synthesis of fluorine-containing aminoacids is the Michael addition of diethylamine in benzene to esters of trifluoromethylacrylic acids catalysed by lipases, amidases, or esterases.[139] The enantiomeric purity of the (−)-β-diethylamino-derivatives of aminoacids obtained in the reaction catalysed by the lipase MY from *Candida cylindracea* approaches 40%, but the absolute configuration of the aminoacid was not discussed (Scheme 61).[13]

Scheme 61

	Yield (%)	e.e. (%)
Lipase MY	47	37
α-Chymotrypsin	36	19
Esterase (from pig liver)	41	8

* *
*

As can be seen from the foregoing, the asymmetric synthesis of element-containing analogues of carboxylic aminoacids has passed through the foundation stage and is now in the dynamic development stage. Both traditional methods of synthesis of aminoacids (for example the alkylation of glycine synthons or the hydrogenation of α,β-dehydroaminoacids) as well as specific approaches associated with the characteristic features of the

chemistry of the corresponding elements are used for the asymmetric synthesis of element-containing aminoacid analogues. The latter appraoches are particularly valid in relation to phosphonic analogues of aminoacids, for the synthesis of which special methods of the chemistry of organophosphorus compounds have been used — the addition of hydrophosphoryl compounds to azomethines and aldehydes and the Arbuzov and Kabachnik–Fields reactions. The development of the methods of asymmetric synthesis has led to the availability of a wide range of optically active fluorine- and phosphorus-containing aminoacid analogues. On the other hand, by no means all the problems associated with the synthesis of specific enantiomerically pure element-containing aminoacid analogues with a high optical purity have found optimum solutions within the framework of the existing methods, which means that further development of the methods of asymmetric synthesis is required.

It may be expected that further research in the field of the asymmetric synthesis of element-containing aminoacid analogues will be directed primarily to the search for new highly effective chiral reagents and to the development of catalytic methods for the asymmetric synthesis of the of these compounds. There is no doubt that the use of enzymes also constitutes a promising approach to the synthesis of enantiomerically pure element-containing aminoacid analogues.

Abstract. The experimental data on the oxidation–reduction catalysis by coordination compounds of manganese(II) of reactions involving the decomposition of H_2O_2 and the oxidation of organic substances by hydrogen peroxide and molecular oxygen are surveyed and modern ideas on these topics are described. The bibliography includes 170 references.

I. Introduction

Coordination compounds of transition metals are known to promote the occurrence of many industrially important technological processes under milder conditions than traditional heterogeneous catalysts, sometimes with a much greater activity and selectivity. The role of the active centre also in enzyme-like (analogue) systems designed to effect particular catalytic processes in homogeneous media has been attributed to the coordination compounds of transition metals. The study of the oxidation–reduction catalysis by transition metal compounds has made a definite contribution to the development of the theory of homogeneous catalysis. Homogeneous catalysis by coordination compounds in the liquid phase is a rapidly developing field of physical chemistry.

The interest in the study of the catalase, peroxidase, and oxidase properties of coordination compounds of manganese has been aroused by the presence of the latter in the active centres of manganese-containing catalases[1,2] and also by the discovery of the role of manganese in the oxidation of H_2O_2 to O_2 (in the photosystem II in photosynthesis),[1–5] in the dismutation of the superoxide radical in the living cell,[6,7] and in the catalytic oxidation–reduction reactions of organic substances in the tricarboxylic acid cycle (the Krebs cycle),[8] as well as the unique ability of the manganese ion to undergo relatively readily the change in the oxidation state from +2 to +7.

The coordination compounds of manganese with ligands containing nitrogen, oxygen, and both nitrogen and oxygen are effective catalysts of the decomposition of hydrogen peroxide, the liquid-phase oxidation of various organic compounds by molecular oxygen (synthetic molecular oxygen transferring agents have been obtained on the basis of manganese complexes), and also the oxidation of substrates by periodate and other oxidants, in contrast to the aquo-ions. There are numerous data on the reactivity of manganese complexes in such reactions and on the mechanisms of their catalytic action.[9,10]

All the studies devoted to the catalytic decomposition of hydrogen peroxide and the oxidation of substrates in the presence of manganese compounds can be divided into two large groups: studies of a phenomenological character[11–26] and studies in which the detailed kinetic characteristics of processes under the influence of catalysts were obtained and the mechanism of the corresponding process was established.[9,10,27–60]

From the practical point of view, studies in which the high peroxidase and oxidase activities of manganese complexes were established are of special interest.[10] Such complexes can be used to develop new highly sensitive and selective kinetic methods for the determination of microamounts of Mn^{2+} and also for the synthesis of new compounds. Since manganese complexes are effective catalysts of the oxidation by hydrogen peroxide (and its decomposition) and by oxygen of organic compounds, the investigation of the possibility of using such systems for the purification of waste water (especially from dye industries) is of special interest.

II. Catalase properties. The mechanisms of the catalytic decomposition of H_2O_2

Many transition metal compounds, including a series of coordination compounds of manganese, exhibit catalase activity.[11–60] In some studies, only the presence of catalase activity in particular manganese complexes was stated,[11–26] in others a comparative analysis of their activities was carried out, whilst in a third group attempts were made to elucidate the mechanism of the decomposition of hydrogen peroxide by manganese(II) complexes. At the same time, during the last 20 years a series of novel investigations have been carried out[10,31–60] † in which the

† The results of the study of the catalytic properties of manganese aquo-ions permit an unambiguous conclusion: Mn^{2+} aquo-ions have no catalase, peroxidase, and oxidase activity.[10] On the other hand, they exhibit a definite catalytic activity in reactions involving the oxidation of certain substrates by periodate.[50] The Mn^{3+} aquo-ions catalyse the H_2O_2 decomposition reactions[61,62] and reactions involving the oxidation of organic substrates by molecular oxygen,[63–67] but the mechanisms proposed for these processes[61–67] cannot be regarded as being even qualitatively well-founded.

kinetics of the process and the composition and stability of the catalytically active complex were established and the mechanisms of the catalytic decomposition of hydrogen peroxide were justified on the basis of systematic investigations. It has now been established that the coordination compounds of manganese(II) with triethylenetetramine (Trien),[11,26,38] diethylenetriamine (Dien),[39,42] tetraethylenepentamine,[13] α,α′-bipyridyl (Bipy),[11] *o*-phenanthroline (Phen),[1,48,51] 2,2′,2″-terpyridyl,[11] 2- and 3-aminopyridines,[11] 2,9-dimethyl- and 4,7-diphenyl-1,10-phenanthrolines,[11] diethanolamine,[11,36,40] *N,N′,N″*-trimethyldiethylenetriamines,[11] acetylacetone (Acac),[31,32] the hydrogen carbonate ion,[29,33] histidine (His),[28,52] glycine (Gly),[43-45] sorbitol,[10] sucrose,[10] 8-hydroxyquinoline,[23,55] a series of α-aminoacids (Am),[46,47] and certain other substances[58-60] possess catalase activity.

The above compounds can be regarded as functional models of catalase (because, like the enzyme catalase itself, they catalyse the decomposition of H_2O_2 to O_2 and H_2O). It has come to be assumed that they possess catalase activity.

The catalase activity in the Mn(II)–Phen–H_2O_2 system is known to be determined[48,49] by the complex $Mn(Phen)_2^{2+}$, while in the Mn(II)–HCO_3^-–H_2O_2 system it is determined by the complex[10] $Mn(HCO_3)_2$. The decomposition of H_2O_2 is catalysed by the complex $MnEn_2^{2+}$ (En = ethylenediamine) in the Mn(II)–En–H_2O_2 system,[36,40] by the complex $Mn(Bipy)_2^{2+}$ in the Mn(II)–Bipy–H_2O_2 system, and by the complexes $MnTrien^{2+}$ and $MnTEA_2^{2+}$ (TEA = triethanolamine) in the Mn(II)–Trien–H_2O_2[27,38] and Mn(II)–TEA–H_2O_2[54] systems respectively. The complexes $Mn(Am)_2$ and $Mn(Am)_3$, incorporating bidentate and tridentate aminoacids and H_2O_2 in the corresponding systems,[46,47] $MnDien_2^{2+}$,[35,42] and the dinuclear complexes Mn_2His_3 [52] and $MnAcac_2$ [31,32] have the same properties.

Complexes having this composition manifest as a rule a high peroxidase activity. This has been confirmed by the results of studies on the oxidation reactions of various organic compounds in the Mn(II)–ligand–H_2O_2–S (S is the substrate) systems. The hydrogen carbonate ion,[68-70] triethylenetetramine,[71-74] ethylenediamine,[72] diethylenetriamine,[75,76] acetylacetone,[77,78] *o*-phenanthroline,[79-81] α,α′-bipyridyl,[50,78-81] and glycine[82] have been used as the ligands. The substrates are indigomonosulfonate, indigocarmine, indigotetrasulfonate, murexide, and carmine, which do not form complexes (or form only weak complexes) with Mn^{2+}, and also chelating ligands lumomagneson, lumogallion, alizarin C, tiron, and catechol.

A number of manganese complexes exhibit also oxidase activity. The catalytic oxidation of organic substances by molecular oxygen is carried out as a rule in non-aqueous media. The catalysts of such processes are manganese stearate and a series of manganese complexes:[83-86] porphyrin,[87-90] phthalocyanine,[91,92] caprylate,[93] carboxylate,[93] naphthenate,[94] tripropyl phosphate,[94] and other complexes.[95-97] The oxidation in the presence of manganese stearate $MnSt_2$ has been studied in greatest detail.

On the basis of literature data, manganese(II) complexes can be arranged in the following sequence in terms of their catalase activity:

$$Mn(HCO_3)_2 > MnTrien_2 > MnHis_2^{2+} > MnDien_2^{2+} >$$
$$> MnAcac_2^{2+} > MnEn_2^{2+} > MnBipy_2^{2+} > MnPhen_2^{2+} >$$
$$> MnAla_3 > MnVal_3 > MnGly_3 \simeq MnTre_2 >$$
$$> Mn(\beta\text{-Phen-}\alpha\text{-Ala})_3 > MnSer_2 > MnAsp_2 \simeq Mn(Aspa)_2$$

(Ala = alanine, Val = valine, Tre = threonine, Ser = serine, Asp = asparagine, and Aspa = aspartic acid).

The manganese(II) hydrogen carbonate complexes exhibit the highest catalase activity. In terms of their activity in the hydrogen peroxide decomposition reactions, they are inferior only by an order of magnitude to the iron(III) complex of triethylenetetramine — the most effective catalyst of the decomposition of hydrogen peroxide among low-molecular-mass compounds.‡

‡ The complex Fe^{3+}Trien has been called 'inorganic catalase' in the literature.[98]

Manganese complexes with ligands containing nitrogen and oxygen and both nitrogen and oxygen are catalytically active in the reactions involving the decomposition of hydrogen peroxide and the oxidation of substrates. Coordinatively unsaturated complexes catalyse the above processes as a rule, but coordinatively saturated complexes as well as a series of dinuclear compounds exhibit a catalytic activity in certain cases. The following oxidation–reduction reactions can occur in the course of the process:

$$L_nMn(II) \underset{+2e}{\overset{-2e}{\rightleftharpoons}} L_nMn(IV)\,,$$

$$L_nMn(III) \underset{+e}{\overset{-e}{\rightleftharpoons}} L_nMn(IV)\,,$$

$$L_nMn(III) \xrightarrow{e} L_nMn(II)\,.$$

Depending on which oxidation–reduction reactions occur in the decomposition of hydrogen peroxide by specific coordination compounds of manganese(II), the process proceeds via a radical-ion (radical-chain or cyclic) or ion-molecule mechanisms.

The radical-ion (radical-chain) mechanism of the decomposition of hydrogen peroxide operates in the following systems: Mn(II)–HCO_3^-–H_2O_2, Mn(II)–Triene–H_2O_2, Mn(II)–His–H_2O_2–H_3BO_3, Mn(II)–Phen–H_2O_2, and Mn(II)–Bipy–H_2O_2.[28,31,33,37,38,50,51] The kinetics and mechanisms of the decomposition of hydrogen peroxide by manganese(II) complexes of HCO_3^- and triethylenetetramine have been examined.[33,37,38,52] The catalase activity of these systems is due respectively to the complexes $Mn(HCO_3)_2$ and $MnTrien_2$.

The radical mechanism of the process has been confirmed by data on the inhibiting effect of the specific $\dot{O}H$ and $\dot{O}_2$ radical acceptors on the catalase process[27,30,37,38] and the fact that the rate of chain propagation (the rate of gas evolution) W_{O_2} exceeds appreciably the rate of initiation W_i [the ratio of these rates is $\sim 10^3$ for the Mn(II)–HCO_3^-–H_2O_2 system[30]]. This has been established[37,38] by introducing into the reaction medium before the start of the process a $\dot{O}H$ indicator (*N,N*-dimethyl-*p*-nitrosoaniline) and a $O_2^{\cdot-}$ acceptor (tetranitromethane). In both systems, $O_2^{\cdot-}$ radical-ions are generated on initiation of the process, and the radicals ·OH are formed in the subsequent stages. Data obtained by the spectrophotometric detection of the manganese(III) complexes indicate the generation in the system also of manganese(IV) complexes.[10,37,38,99] These results served as a basis for the formulation of the radical-chain mechanism of the decomposition of hydrogen peroxide by the complexes $Mn(HCO_3)_2$ and $MnTrien^{2+}$ in the following form:[10]

initiation:

$$Mn(II)L + H_2O_2 \longrightarrow Mn(IV)L + 2\,OH^-\,,$$
$$Mn(IV)L + HO_2^- \longrightarrow Mn(III)L + O_2^{\cdot-} + H^+\,;$$

chain propagation:

$$Mn(IV)L + O_2^{\cdot-} \longrightarrow Mn(III)L + O_2\,,$$
$$Mn(III)L + H_2O_2 \longrightarrow Mn(IV)L + \dot{O}H + OH^-\,,$$
$$\dot{O}H + H_2O_2 \longrightarrow O_2^{\cdot-} + H^+ + H_2O\,;$$

chain termination:

$$Mn(III)L + O_2^{\cdot-} \longrightarrow Mn(II)L + O_2$$

(L = 2 HCO_3^- or Trien).

Comparison of the rate constants and the corresponding concentrations in solution showed that[33,37] the following stage also occurs in the Mn(II)–HCO_3^-–H_2O_2 system:

$$\dot{O}H + HCO_3^- \longrightarrow CO_3^{\dot{-}} + H_2O ,$$

$$CO_3^{\dot{-}} + H_2O_2 \longrightarrow HCO_3^- + O_2^{\dot{-}} + H^+ .$$

The above reactions ensure the additional generation of the $O_2^{\dot{-}}$ radical-ions in the chain propagation process. This promotes the effective decomposition of hydrogen peroxide in the presence of the $Mn(HCO_3)_2$ complex. The decomposition of hydrogen peroxide in the Mn(II)–HCO_3^-–H_2O_2 system via this mechanism has also been confirmed by the results of other investigations.[100,101]

A similar mechanism operates in the decomposition of hydrogen peroxide in the Mn(II)–His–H_2O_2 system in borate buffer solutions.[31,102]

A somewhat different mechanism is observed in the Mn(II)–Phen(Bipy)–H_2O_2 systems. As noted above, the catalysts are the complexes $MnPhen_2^{2+}$ and $MnBipy_2^{2+}$.[48–51] The catalase process in the above systems is influenced by inhibitors such as specific $\dot{O}H$ radical acceptors (in particular, *N,N*-dimethyl-*p*-nitroso-aniline).[50] On the other hand, the gas evolution process is effectively inhibited by ascorbic acid, hydroquinone, *p*-benzoquinone, and tetranitromethane.[50,51] The radical-chain nature of the mechanism is indicated by the finding that in this case $W_{O_2}/W_i \simeq 10^3$.[50] Since $\dot{O}H$ radicals are not generated in these systems, one can justify the occurrence of a two-electron transfer stage:[50,51]

$$Mn(II)L_2 + H_2O_2 \longrightarrow Mn(IV)L_2 + 2\,OH^-$$

(L = Phen, Bipy).

The interaction of manganese(IV) compounds with hydrogen peroxide includes consecutive one-electron transfer steps with the generation of $O_2^{\dot{-}}$ in the reaction medium (this has been demonstrated by the method of inhibitors[50]). The complete process mechanism in the Mn(II)–Phen(Bipy)–H_2O_2 system under stationary conditions is as follows:[50]

initiation:

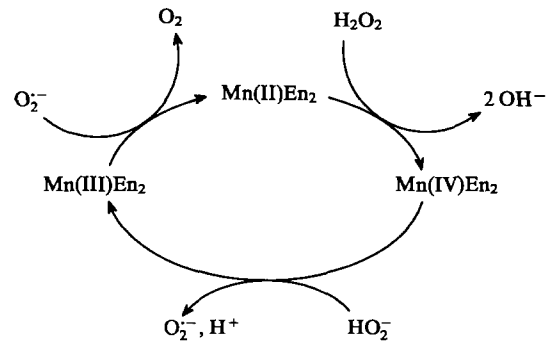
$$L_2Mn(III) + HO_2^- \longrightarrow L_2Mn(II) + HO_2^{\dot{}} ;$$

chain propagation:

$$L_2Mn(II) + H_2O_2 \longrightarrow L_2Mn(IV) + H_2O,$$

$$L_2Mn(IV) + H_2O_2 \longrightarrow L_2Mn(III) + HO_2^{\dot{}} + H^+ ,$$

$$HO_2^{\dot{}} \longrightarrow O_2^{\dot{-}} + H^+ ,$$



$$L_2Mn(III) + O_2^{\dot{-}} \longrightarrow L_2Mn(II) + O_2 ;$$

chain termination:

$$L_2Mn(II) + HO_2^{\dot{}} \longrightarrow L_2Mn(III) + HO_2^- .$$

Thus the characteristic features of the radical-chain mechanism of the decomposition of hydrogen peroxide by manganese complexes are as follows: the generation of the $O_2^{\dot{-}}$ and $\dot{O}H$ radical species (or of $O_2^{\dot{-}}$ alone) in the reaction volume; the formation of manganese(IV) and manganese(III) compounds owing to the catalase process; a significantly greater rate of chain propagation compared with the rate of initiation.

The formation of the $O_2^{\dot{-}}$ radical-ions has been observed also in the Mn(II)–En–H_2O_2 and Mn(II)–His–H_2O_2 systems, but in this case a distinctive feature of the process is the equality of the rates of gas evolution and initiation. This provided a basis for the classification of the given mechanism as of the radical-ion cyclic type. In relation to catalysis by the $MnEn_2^{2+}$ complex, this mechanism assumes the form shown below.[36,52,53,72] The radical-ion cyclic mechanism also operates in the Mn(II)–ethylenediaminetetramethyl phosphate–H_2O_2 system.[58] In the Mn(II)–His–H_2O_2 system, the reaction proceeds via a radical-ion mechanism with participation of dinuclear complexes of the type His–Mn(II)–His–Mn(II)–His (the formation of the latter has been demonstrated by EPR.[10,52,60]

The ion-molecule mechanism differs from that examined above primarily by the fact that free radicals are not formed in the reaction system. The absence of the inhibition of the catalase process by specific acceptors of the $\dot{O}H$ and $O_2^{\dot{-}}$ radical species (at concentrations such that they compete with the other reactants for free radicals) suggests that an ion-molecule mechanism of the decomposition of hydrogen peroxide operates in the system. In such cases, the reaction can proceed with formation of mono- or di-peroxo-compounds and may be accompanied by oxidation–reduction processes within the complex catalyst.[9] If such compounds are not formed, the mechanism includes stages involving the transfer of two electrons from the complex catalyst to hydrogen peroxide and conversely. This is clearly illustrated by the following general scheme:

$$Mn(II)L_n + H_2O_2 \longrightarrow Mn(IV)L_n + 2\,OH^- ,$$

$$Mn(IV)L_n + HO_2^- \longrightarrow Mn(II)L_n + H^+ + O_2 .$$

The decomposition of hydrogen peroxide proceeds via this mechanism in the Mn(II)–Dien–H_2O_2,[39,42] Mn(II)–sorbitol–H_2O_2,[10] Mn(II)–sucrose–H_2O_2,[10] Mn(II)–Gly–H_2O_2,[43–45] Mn(II)–Ala–H_2O_2,[46] and Mn(II)–Val (ser, Tre, Asp)–H_2O_2[46,47] systems. If the second stage is rate-limiting in the above mechanism, then one can write the following expression for the Mn(II)–Dien–H_2O_2 system:

$$W = \frac{k_2 K_{H_2O_2}[MnDien_2][H_2O_2]}{[H^+]} .$$

This expression agrees with the experimental equation, which confirms the reality of the proposed mechanism. The ion-molecule mechanism of the catalysis by manganese(II) complexes of sorbitol, sucrose, and a number of aminoacids has been demonstrated similarly.[10,43–47] In fact, the same mechanism operates also in the Mn(II)–Acac–H_2O_2 system.[31,32] The decomposition of hydrogen peroxide by trivalent manganese compounds in the Mn(III)–5,10,15,20-tetrakis-(2,6-dimethyl-3-sulfonatophenyl) porphyrinate–H_2O_2 system also proceeds via an ion-molecule mechanism.[59]

Thus one may conclude that hydrogen peroxide is capable of oxidising manganese(II) compounds to monomeric manganese(IV) compounds in neutral (and in a number of cases also weakly alkaline) media. One cannot rule out the possibility that such a process consists of two consecutive one-electron transfers without the emergence of the $\dot{O}H$ radicals from the inner sphere into the reaction volume,[50] but there is no rigorous evidence in support of the mechanism (with participation of manganese complexes).

At the same time, the unique ability of hydrogen peroxide to oxidise manganese(II) compounds to the permanganate ion is manifested in alkaline media. This has been demonstrated in relation to the catalytic decomposition of H_2O_2 by the manganese(II) complexes of triethanolamine.[10] The hypothetical

mechanism of this process, in which free radicals are not formed in the reaction volume (this has been demonstrated by the method of inhibitors), is as follows:[10]

$$Mn(II) + H_2O_2 \longrightarrow Mn(IV) + 2\,OH^-,$$

$$Mn(IV) + H_2O_2 \longrightarrow Mn(VI) + 2\,OH^-,$$

$$2\,Mn(VI) \longrightarrow Mn(V) + Mn(VII),$$

$$Mn(V) + Mn(II) \longrightarrow Mn(III) + Mn(IV),$$

$$Mn(III) + H_2O_2 \longrightarrow Mn(V) + 2\,OH^-,$$

$$Mn(V) + H_2O_2 \longrightarrow Mn(VII) + 2\,OH^-$$

[Mn(II)–Mn(V) are understood as the corresponding complexes, while Mn(VI) and Mn(VII) form the MnO_4^{2-} and MnO_4^- ions in alkaline media].

Thus in the systems of the type Mn(II)–ligand–H_2O_2 considered, manganese(III) manganese(IV) species (compounds) as well as $\dot{O}H$ and $O_2^{\cdot-}$ are generated and it is to be expected that they should ensure the effective oxidation of organic compounds.

III. Peroxidase properties. Oxidation of organic substrates

The high reactivity of many coordination compounds of manganese in catalytic hydrogen peroxide decomposition reactions has stimulated studies of the use of the Mn(II)–ligand–H_2O_2 systems for the oxidation of substrates and also of the application of manganese complexes as catalysts of the oxidation of organic compounds by molecular oxygen and periodate. The aim of such studies has been the search for new catalysts of the peroxidase oxidation of substrates, the establishment of the mechanism of the catalytic effect of the coordination compounds of manganese and of the role of the ligand environment of the central metal ion in this process, of the nature of the substrate being oxidised, of the experimental conditions (aerobic, anaerobic), and of the relation between the catalase and peroxidase properties of the manganese complexes, and the development on this basis of a new procedure for the synthesis of organic substances of practical importance and of new catalymetric analytical methods, and also the discovery of the general features of the catalytic oxidation of organic substrates.

The kinetics and mechanisms of the peroxidase activity of the coordination compounds of manganese with various ligands, including oxygen-containing (the monodentate hydrogen carbonate ion,[68-70] the bidentate acetylacetone,[77,78] and the tridentate triethanolamine[10]), nitrogen-containing (the bidentate ethylenediamine,[72] phenanthroline,[50] and bipyridyl,[50] the tridentate diethylenetriamine,[75,76] and the tetradentate triethylenetetramine[71,72,74]), as well as both nitrogen- and oxygen-containing (the tridentate histidine), have been investigated in detail hitherto in the oxidation reactions of organic substrates — both substrates with a weak capacity for the formation of complexes with Mn^{2+} (indigomonosulfonate, indigocarmine, indigotetrasulfonate, murexide, carmine, Procion Blue, Direct Bordeaux 150, Disperse Violet K) as well as ligands forming fairly stable complexes with Mn^{2+} (lumomagneson, lumogallion, alizarin, alizarin C, tiron, catechol). Alcohols are oxidised similarly under aerobic conditions (monohydric — methanol, ethanol, and isopropyl alcohol; dihydric — ethylene glycol; polyhydric — glycerol). In systems of the type Mn(II)–ligand–H_2O_2–substrate, the coordination compounds of manganese catalyse the oxidation of substrates and one can therefore regard them as functional models of peroxidase.¶

Among the reactions where molecular oxygen is used as the oxidant, the oxidation reactions of 8-pentadecanone and hexadecanone catalysed by manganese stearate have been investigated in greatest detail.[83-86] Systems incorporating porphyrin complexes, sodium tetrahydroborate, olefins, or other organic compounds[87-92] as well as the oxidation reactions of α-aminoacids, α-ketoacids, and other compounds, catalysed by the coordination complexes of manganese(II) with Schiff bases[94-97] have also been studied in detail.

The above analysis of the mechanisms operating in the Mn(II)–ligand–H_2O_2 systems shows that, in the course of the decomposition of hydrogen peroxide by manganese complexes, intermediate species (compounds $\dot{O}H$, $O_2^{\cdot-}$, $L_nMn(IV)$, and $L_nMn(III)$, with a high oxidising capacity, are generated in the reaction medium. The oxidation–reduction potentials of the corresponding pairs are as follows:

Pair	φ/V	Ref.
Mn^{4+}/Mn^{3+}	1.63	103
Mn^{3+}/Mn^{2+}	1.51	9
Mn^{4+}/Mn^{2+}	1.57	103
$\dot{O}H/H_2O$	2.83	104
$O_2^{\cdot-}/O_2$	−0.16	104

Subsequently, when the substrate S is introduced additionally into such systems, it can be oxidised by precisely these species. The mechanism of the oxidation reaction can include the following stages:

$$\dot{O}H + S \longrightarrow P_1,$$

$$O_2^{\cdot-} + S \longrightarrow P_2,$$

$$L_nMn(III)[L_nMn(IV)] + S \longrightarrow P_3 + L_nMn(II)[L_nMn(III)],$$

$$L_nMn(III)S[L_nMn(IV)S] \longrightarrow P_4 + L_nMn(II)[L_nMn(III)],$$

$$L_nMn(IV)S[L_nM(IV)\,S] \longrightarrow P_5 + L_nMn(II).$$

The substrate may be oxidised by active species (compounds) in the reaction volume (outside the first sphere of the complex catalyst). In this case, the mechanism is classified as of the outer-sphere type.[10,37,68,70,105] If the substrate S is oxidised by manganese ions in high oxidation states within the coordination sphere of the complex catalyst, an inner-sphere mechanism operates.[10,37,68,70,106]

The outer-sphere mechanism. In the systems where the radical-chain decomposition of hydrogen peroxide with generation of $\dot{O}H$ radicals takes place, various organic dyes are oxidised effectively.[37,68,71,72,74,82,105] The results of the study of the kinetics of the oxidation of the substrates having a weak complex-forming capacity (organic dyes, alcohols) shows that the same coordination compounds of manganese which determine the catalase activity of the given systems catalyse the above process. One can postulate that in the Mn(II)–HCO_3^-–H_2O_2,[33] Mn(II)–Trien–H_2O_2,[38,72] and Mn(II)–His–H_2O_2–H_3BO_3[31] systems the substrates are oxidised by the $\dot{O}H$ and $O_2^{\cdot-}$ radical species as well as the Mn^{4+} and Mn^{3+} ions forming part of the composition of the corresponding complexes. The above species (compounds) compete with one another for the substrate molecule. In terms of their 'oxidising strength', they can be arranged in the following sequence:[10]

$$\dot{O}H > L_nMn(IV) > L_nMn(III) > O_2^{\cdot-}.$$

The experimental results[10,37,53,105,107] indicate the dominant role of the $\dot{O}H$ radicals in the oxidation of the above substrates, in particular, potassium indigotetrasulfonate, murexide, and carmine.

The same type of kinetics of the catalase and peroxidase processes in the Mn(II)–ligand–H_2O_2 and Mn(II)–ligand–H_2O_2–S systems (where HCO_3^-, Trien, and His are used as the ligands, while the substrates are organic compounds with a weak complex-forming capacity), the equality of the rates of conversion

¶ The enzyme peroxidase is an effective catalyst of the decomposition of H_2O_2 and the oxidation of substrates by the intermediate compounds formed on decomposition of the peroxide. It has therefore come to be assumed that the above manganese compounds possess peroxidase activity.

of the substrate under aerobic and anaerobic conditions, and also the fact that the interaction of the selected substrates S with ȮH results in the formation of inactive substrate radicals permitted the conclusion that the reaction

$$\dot{O}H + S \longrightarrow S \text{ oxidation products}$$

can be included in the mechanism of the catalase decomposition of hydrogen peroxide as the chain termination stage.[10, 37, 53, 68, 105]

Thus substrates with weak complex-forming capacity in relation to Mn^{2+} do not affect the fundamental process mechanism. The radical-chain mechanism of the decomposition of hydrogen peroxide, established for the catalase process, is retained under these conditions.

In the systems considered, the mechanism of the oxidation of substrates by ȮH radicals is of the outer-sphere type. The above data permit the conclusion that the outer-sphere mechanism of the oxidation of substrates with a weak complex-forming capacity in relation to Mn^{2+} {$pK_s < 3$ for $K_s[S]/K_s[L] < 1$, where K_s is the stability constant} can operate in all catalytic systems of the metal–ligand–H_2O_2 type in which hydrogen peroxide undergoes a radical-chain decomposition with generation of ȮH radicals and a relatively inactive substrate radical is formed. In such systems, the mechanisms of the catalase and peroxidase activities of the complex catalyst should be to a certain extent similar. The mechanism becomes complicated when, as a result of the interaction with ȮH radicals, the oxidation of substrates involves the formation of reactive substrate radicals, which, possessing reducing properties, can react with manganese(III) and manganese(IV) compounds and, under aerobic conditions, also with molecular oxygen. The oxidation of alcohols (methanol, ethanol, isopropyl alcohol, ethylene glycol, and glycerol) in the Mn(II)–HCO_3^-–H_2O_2 systems under aerobic conditions can serve as an example.[108, 109]

Analysis of the results of a number of studies[108–110] shows that at certain concentrations of the test substances in the Mn(II)–HCO_3^-–H_2O_2–ROH systems the role of hydrogen peroxide reduces to the preparation of the alcohol (by converting it into the alkoxy-radical R_α) for interaction with oxygen. Consequently molecular oxygen participates in the oxidation of alcohols as a consequence of the formation of the reactive substrate radical R_α, which leads to an increase in the complexity of the process mechanism, namely to the appearance of a series of new stages:[10, 37, 53, 110]

$$R_\alpha + O_2 \longrightarrow RO_2^\cdot ,$$

$$RO_2^\cdot \longrightarrow ROHO + HO_2^\cdot ,$$

$$RO_2^\cdot + ROH \longrightarrow R_\alpha + RCHO + H_2O_2 .$$

These do not occur in the absence of substrates or in their presence if the substrate radical formed is inactive. Since alcohols are oxidised in the reaction volume (outside the coordination sphere of the catalyst), such a mechanism may be also referred to as of the outer-sphere type. The results of studies on the Mn(II)–HCO_3^-–H_2O_2–ROH systems under aerobic conditions permit the conclusion that alcohols and other organic compounds are oxidised effectively by hydrogen peroxide under aerobic conditions provided that the catalyst is a complex with a distinct catalase activity and that H_2O_2 decomposes via a radical-chain mechanism with generation of ȮH radicals. The following conditions must be maintained if this is to be achieved:

$$\frac{k_{S+\dot{O}H}[S]}{k_{\dot{O}H+H_2O_2}[H_2O_2]} \gg 1 \quad \text{and} \quad \frac{k_{S+\dot{O}H}[S]}{k_{P+\dot{O}H}[P]} \gg 1,$$

where $k_{S+\dot{O}H}$, $k_{\dot{O}H+H_2O_2}$, and $k_{P+\dot{O}H}$ are the corresponding rate constants for the interaction of ȮH with the alcohol (or the organic substrate S), hydrogen peroxide, and other system components (P). The above relations may serve as criteria for the selection of catalysts for the liquid-phase oxidation of alcohols (and other organic compounds) under mild conditions.

It is noteworthy that the active principle in the oxidation of organic substrates with a weak complex-forming capacity in relation to Mn^{2+} in the Mn(II)–HCO_3^-–H_2O_2, Mn(II)–Trien–H_2O_2, and Mn(II)–His–H_2O_2–H_3BO_3 system is the ȮH radical. However, such radicals are not generated in the disproportionation of hydrogen peroxide by manganese(II) complexes of *o*-phenanthroline, α,α′-bipyridyl, histidine (in the absence of borate buffer), ethylenediamine, diethylenetriamine, acetylacetone, and other compounds. At the same time, indigocarmine, potassium indigomonosulfonate and indigotetrasulfonate, murexide, and carmine are effectively oxidised in the above systems.[37, 68, 70, 72, 111] The results of the study of the kinetics and mechanisms of the decomposition of hydrogen peroxide and of the oxidation of substrates have shown that manganese(IV) compounds are the oxidant in the given instance. The general process mechanism can be represented as follows:

$$L_nMn(II) + H_2O_2 \longrightarrow L_nMn(IV) + 2\,OH^- ,$$

$$L_nMn(IV) + S \longrightarrow L_nMn(II) + P \text{ (S oxidation products)}.$$

The oxidation of substrates by manganese(IV) compounds has been demonstrated in cases where the catalysts are manganese(II) complexes of phenanthroline and bipyridyl,[50] as well as the acetylacetonate and histidine complexes.[10, 53, 78, 111]

Thus one may conclude that, in the oxidation–reduction decomposition of hydrogen peroxide by manganese(II) coordination compounds without the formation of hydroxyl radicals in the reaction medium, substrates having a weak complex-forming capacity in relation to Mn^{2+} are oxidised by manganese(IV) via an outer-sphere mechanism. The process takes place as a result of two-electron transfer. One cannot rule out the possibility that, when substrates incapable of being oxidised via a two-electron mechanism are used, consecutive one-electron transfer steps take place involving also manganese(III) compounds in the oxidation process.

The inner-sphere mechanism. The nature of the substrate oxidised affects the mechanism of the catalytic decomposition of hydrogen peroxide, particularly if the substrate has a chelating capacity and is able to form fairly stable complexes with Mn^{2+} ($pK_s > 3$). Such substrates are lumomagneson, lumogallion, alizarin, and alizarin C, the kinetics and mechanisms of the oxidation of which in the Mn(II)–ligand–H_2O_2 systems have been thoroughly investigated.[10, 37, 53, 69, 106] The above substrates, which play simultaneously the role of a ligand (S_L), are effectively oxidised [especially in a system such as Mn(II)–HCO_3^-–H_2O_2]. A distinctive feature of these processes is the fact that free hydroxyl and superoxide radicals are not generated in the reaction volume, but the substrates are oxidised within the coordination sphere of the metal complex catalyst (the inner-sphere mechanism).

A similar fundamental mechanism operates in the oxidation of lumomagneson in the Mn(II)–Triene–H_2O_2 and Mn(II)–En–H_2O_2 systems[106, 112] and in the oxidation of tiron and catechol in the Mn(II)–Phen(Bipy)–H_2O_2 systems.[50] The characteristic difference between the process in the above systems and that occurring in the latter without a substrate (the radical-chain mechanism) consists in the absence of the inhibiting effect and a diminishing role of radical acceptors in the course of the reaction. These data indicate unambiguously that hydrogen peroxide is decomposed and the substrate oxidised via a fundamentally new mechanism, differing from the mechanism of the catalase process. The substrate is oxidised in these systems via an inner-sphere mechanism[50, 106, 112] [as in the Mn(II)–HCO_3^-–H_2O_2–S_L systems]. The general process mechanism[106, 112] can be represented by the following set of stages:

$$Mn(II) + S_L \rightleftarrows Mn(II)S_L ,$$

$$Mn(II)S_L + H_2O_2 \longrightarrow Mn(IV)S_L + 2\,OH^- ,$$

$$Mn(IV)S_L \longrightarrow Mn(II) + P \text{ (S_L oxidation products)};$$

[Mn(II)–Mn(IV) are understood as the corresponding complexes $MnEn_2$ and MnTrien]. One cannot rule out the possibility that a peroxo-complex of the type $Mn(II)S_LH_2O_2$ is formed in the reaction of the complex catalyst with hydrogen peroxide, as has been suggested[69] for the catalysis by the manganese hydrogen carbonate complex, but this has not been confirmed experimentally. A somewhat different sequence of stages (within the framework of the same fundamental mechanism) occurs in the oxidation of tiron and catechol in the Mn(II)–Phen(Bipy)–H_2O_2 system:[50]

$$L_2Mn(II) + H_2O_2 \longrightarrow L_2Mn(II)HO_2^+ + H^+,$$

$$L_2Mn(II)HO_2^+ \longrightarrow L_2Mn(IV) + H_2O,$$

$$L_2Mn(IV) + S_L \rightleftarrows L_2Mn(IV)S_L,$$

$$L_2Mn(IV)S_L \longrightarrow L_2Mn(II) + P$$

(L = Phen, Bipy).

The mechanism of the oxidation of substrates of the type S_L in the Mn(II)–Acac–H_2O_2 system is much more complex,[77,78] since in this case a dinuclear complex participates in the reactions with hydrogen peroxide.

The coordination compounds of manganese [systems of the type Mn(II)–ligand–H_2O_2] and in the first place the hydrogen carbonate complexes exhibit a high peroxidase activity, so that they could be used in the development of new catalymetric methods for the determination of microamounts of Mn^{2+}, for preparative purposes, as polymerisation initiators, and for the removal of organic impurities from waste waters.

Catalymetric analytical methods. The effective catalytic activity of manganese compounds in reactions involving oxidation by hydrogen peroxide of various indicator substances made it possible to use them for the development[113–116] of catalytic methods for the determination of microamounts of manganese. Such indicator substances are alizarin C in the presence of HCO_3^- (the lower limit of the detection of Mn^{2+} ions is 0.4 ng ml^{-1}),[117] Catechol Violet in the presence of ethylenediamine (0.5 ng ml^{-1}),[118] lumomagneson (0.1 ng ml^{-1}),[119] sodium carminate in the presence of ethylenediamine and lead (0.1 ng ml^{-1}),[120] H-acids in the presence of ethylenediamine (0.1 ng ml^{-1}),[121] and Pyrogallol Red in the presence of bipyridyl (0.01 ng ml^{-1}).[122]

Catalymetric methods for the determination of Mn^{2+}, based on the oxidation with hydrogen peroxide of indigosulfonic acids,[117,123] *o*-dianisidine, Variamine Blue, gallion, and other indicator substances,[113–116] have been proposed. A series of kinetic methods have been developed in which use is made of the catalytic oxidation of dyes by molecular oxygen, for example, in the Mn(II)–morin–O_2 system,[124] or by periodate.[10,114–116,125]

The method based on catalytic oxidation with hydrogen peroxide in the presence of the manganese hydrogen carbonate complex of alizarin, alizarin C, and other organic dyes, is especially selective.[117,125] This method is highly sensitive: the lower limit of the detection of Mn^{2+} ions in the oxidation reaction is 0.4 ng ml^{-1}.

Catalymetric methods for the determination of microamounts of manganese in specially pure substances have found the widest application.[114]

A general deficiency of the kinetic methods developed for the determination of microamounts of Mn^{2+} is the large error of the determination caused by the occurrence of a rapid background reaction. Therefore one of the important tasks is the search for such new systems in which the rate of the background reaction is low or the development of methods of inhibiting the background reaction in known systems.

IV. Oxidase properties

Many coordination compounds of the 3*d* transition metals in low oxidation states are capable of binding reversibly molecular oxygen, as a consequence of which they are classified as synthetic O_2 transferring agents.[126–128] The coordinated oxygen is in an activated state in many compounds, which permits its use to effect various oxidation–reduction processes, in particular for the oxidation of organic substrates, in which transition metal complexes behave as catalysts. The coordination of molecular oxygen to transition metal complexes is one of the most effective methods of activating this commonest and cheapest oxidant.

A number of coordination compounds of manganese also have notable properties, although very little information is available about such compounds (O_2 transferring agents) and also about the reactivity of coordinated O_2 in manganese complexes. The reversible binding of molecular oxygen by manganese complexes takes place as a rule in non-aqueous media. The formation of oxygenated manganese complexes with porphyrin,[129] *para*-substituted *meso*-tetraphenylporphyrins,[130] dibutylcatechol, semiquinone,[131] picoline,[132] pyridine,[133] *N*,*N*-bis(salicylidene)ethylenediamine,[134] tetraphenylporphyrin,[135] threonyl- and phenyl-dialkylphosphines,[136] tripropylphosphine,[138] and others[137–140] has now been demonstrated. Certain coordination compounds of manganese(II) are oxygenated irreversibly. As a consequence of the activation of O_2, the central ion in the coordination sphere of the complex is oxidised with formation of manganese(III) and manganese(IV) complexes. It has been established that such oxygenation occurs in a series of porphyrin complexes,[141] in manganese complexes of phthalocyanine,[132] Schiff bases,[142,143] and triethanolamine,[144] and also in the gluconate[145] and sorbitol[146] complexes.

Studies on the activation by manganese complexes of molecular oxygen in the oxidation of organic substrates by the latter are of special interest. Such complexes may be regarded (subject to certain assumptions) as functional models of oxidases. As mentioned above, manganese stearate and a series of porphyrin, phthalocyanate [phthalocyanine?], and other complexes are used as catalysts of the oxidation of substrates by molecular oxygen. Thus, in catalysis by manganese(III) aquo-ions, the latter oxidise the substrates, forming at the same time radicals and manganese(II).[62–65] In the subsequent stages, manganese(II) is oxidised by the reaction products to manganese(III), i.e. the catalytic process includes the redox reactions:

$$Mn(III) \underset{-e}{\overset{+e}{\rightleftarrows}} Mn(II)$$

and a radical-chain or a radical-ion (non-chain) mechanism of the oxidation of substrates by molecular oxygen. The role of manganese(III) ions consists in preparing the substrate (by converting it into a radical) for the subsequent interaction with oxygen.

Catalysis by manganese(II) aquo-ions occurs apparently only when the substrate has a chelating capacity and a metal–substrate complex effectively reacting with oxygen is formed during the process. The oxidation of the substrate proceeds most probably within the coordination sphere of the metal–substrate complex under the influence of the manganese ions in the highest oxidation states.[65,147–149]

Coordination compounds of manganese are more effective catalysts of the oxidation of substrates by molecular oxygen. In such processes the initial stage involves the formation of an intermediate compound incorporating the complex catalyst and O_2, in which the latter is in fact activated. The mechanism of the activation of O_2 has not been ultimately elucidated. It has been suggested that there is no spin density and no appreciable negative charge on the oxygen in such an intermediate complex, so that O_2 is bound in a quasi-singlet state ($^1\Delta_g$).[88] One may therefore expect

the manifestation by the oxygen in such complexes of the chemical reactivity characteristic of O_2 in its singlet state.§

The composition of the intermediate active oxygen complex formed has been given in a number of studies[83,91] as $L_n(Mn(II)^{\delta+}\ldots O_2^{\delta-}$. For example, the mechanism of chain initiation in the oxidation by molecular oxygen of a series of organic substrates (8-pentadecanone, hexadecanone) in the presence of manganese stearate has been expressed as follows:

$$MnSt_2 + O_2 \longrightarrow MnSt_2^{\delta+}\ldots O_2^{\delta-},$$

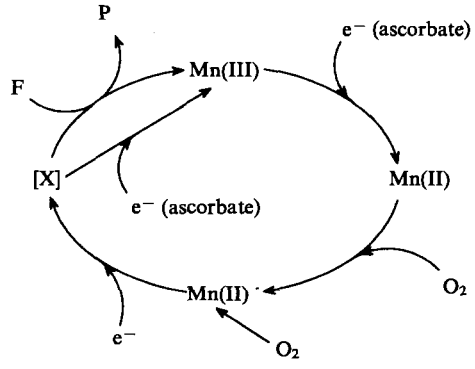
$$MnSt_2^{\delta+}\ldots O_2^{\delta-} + RH \longrightarrow \begin{cases} MnSt_2OH + RO, \\ MnSt_2OOH + R. \end{cases}$$

In most studies, it is assumed that the process proceeds via a stage involving the formation of a ternary catalyst–O_2–substrate complex, the decomposition of which leads to the formation of the reaction products.[88]

If the substrates are oxidised with trivalent manganese compounds used as the catalysts, an additional reductant (usually tetrahydroborate) is introduced into the system. The process mechanism under such conditions becomes appreciably more complex, which hinders its rigorous justification. It has been established reliably that in such cases the manganese(III) compounds are initially reduced to manganese(II) compounds, after which the substrate–O_2–catalyst ternary complex is formed. A process of this kind occurs in the oxidation of cholesterol, androst-5-en-5β-ol, and a number of aliphatic olefins in the presence of porphyrin complexes of manganese(III).

The general mechanism can be represented in the following form:[90,151]

$$TPPMn(III) + NaBH_4 \rightleftarrows TPPMn(II) + P_1,$$



$$TPPMn(II) + S + O_2 \rightleftarrows S{-}O{-}O{-}Mn(II)TPP,$$

$$S{-}O{-}O{-}Mn(II)TPP \longrightarrow TPPMn(III) + P_2,$$

$$S{-}O{-}O{-}Mn(II)TPP \longrightarrow P_3,$$

$$TPPMn(II) \longrightarrow P_4,$$

where P_1 are the $NaBH_4$ reaction products, P_2 the olefin oxidation products, P_3 and P_4 the catalyst reaction and dehydration products respectively, [and TPP is tripyhenylphosphine]. A similar mechanism has been proposed also for the oxidation of olefins in the Mn(III)(TPP)–O_2–ascorbic acid–olefin system;[87] and the formation of a complex between O_2 and the catalyst, and the fact that $O_2^{\cdot-}$ and H_2O_2 are not involved in the process have been demonstrated. The mechanism can be represented by a sequence of stages.

[Mn(II) and Mn(III) are understood as the corresponding complexes with TPP, F is the olefin, and P is its oxidation product]. Competition between the ascorbate ion and the substrates for the active species [X] is postulated.

The mechanisms of substrate oxidation presented above are of the inner-sphere type. Complete schemes for the oxidation of substrates with formation of the experimentally established final products have been put forward in a number of studies[88,89,93] taking into account the operation of the inner-sphere mechanism. Such mechanisms must be regarded as tentative, because they have been set up purely speculatively in order to express clearly the possible pathways leading to the formation of the oxidation products.

Substrates may be oxidised by oxygen also via an outer-sphere mechanism, for example in the oxidation of hydrazine [the Mn(III)–Hm–O_2–N_2H_4 system, where Hm = haemoglobin]:

$$Mn(III){-}Hm + O_2 \rightleftarrows Mn(III)_2Hm\ldots O_2,$$

$$Mn(III)_2Hm\ldots O_2 + N_2H_4 \longrightarrow Mn(III)Hm + N_2 + 2\,H_2O.$$

An outer-sphere mechanism operates also in the Mn(II)–L–O_2–leuco-base (LO) systems:[10]

$$MnL_2 + O_2 \rightleftarrows MnL_2O_2,$$

$$MnL_2O_2 + LO \longrightarrow MnL_2 + LO \text{ oxidation products}$$

(L = Phen, Bipy).

A distinctive feature of this process is that it occurs in neutral aqueous media and that the rate of oxidation of the leuco-base increases appreciably when the system is irradiated with UV light (λ = 314–334 nm).

An outer-sphere mechanism (without the activation of O_2 in the coordination sphere of the complex catalyst) also operates in the liquid-phase oxidation of organic substances in the presence of initiators or when manganese(III) complexes, which react effectively with the substrate, are used as the catalysts.[84,97]

It is noteworthy that occasional studies on the oxidation reactions of organic substances by molecular oxygen in the presence of manganese ions and coordination compounds do not permit the development of a unique point of view on their mechanisms. At the same time, one may conclude that such systems may be used for the synthesis of certain organic compounds of practical interest.

Many studies devoted to the liquid-phase oxidation of organic compounds by molecular oxygen in the presence of manganese ions had preparative aims. For example, optimum conditions have been found {[$MnSt_2$] = 16.5 mmol litre^{-1}, 393 K} for the oxidation of 8-pentadecanone by oxygen, in which the yield of caprylic and oenanthic acids (51.9%) is a maximum.[88]

The main products of the liquid-phase oxidation of *n*-pentane in solution in acetic acid in the presence of 10^{-3} mole of manganese acetate per mole of *n*-pentene are lower aliphatic carboxylic acids.[152]

Preparative methods of synthesis of new organic substances with manganese complexes used as catalysts have also been described in a number of other studies.[10,84,89,92–94,96,147] The manganese(II)–ligand–H_2O_2 systems, in which ȮH radicals are generated, can be used to obtain aldehydes (ketones) from the corresponding alcohols.[103,104,116] By virtue of their high effectiveness in the hydrogen peroxide decomposition reactions, manganese(II) complexes are suitable for the elimination of H_2O_2 at high concentrations from waste waters.[153]

§ Questions concerning the activation of O_2 by coordination compounds have been considered in detail in a number of communications.[126,131,150]

V. Manganese compounds as catalysts of processes in the environment

One of the consequences of the increasing amount of anthropogenic waste discharged into the atmosphere is the precipitation of acid rain, the main components of which are sulfuric and nitric acids. The oxidation processes in the atmosphere, leading, for example, to sulfur(IV) (in the form of SO_2) and sulfur(VI) (in the form of H_2SO_4) are usually accelerated catalytically by transition metal ions and compounds, particularly those of manganese and iron. The concentrations of the latter in rain water are usually $\sim 2.6 \times 10^{-7}$ and $\sim 3.8 \times 10^{-6}$ M respectively.[154] This is sufficient to exert a strong catalytic effect on many processes.[10, 149, 155] The oxidants are usually O_2, H_2O_2, or their reactive activation products — the $\dot{O}H$ and $H\dot{O}_2$ radicals.

Metal (manganese, iron) complexes participate in the oxidation of sulfur(IV) by ozone in the aqueous phase of the atmosphere.[156, 157] Furthermore, compounds of these metals may concentrate in the moist aerosol particles and there is therefore a possibility of an appreciable increase in the rate of oxidation of SO_2.

The mechanisms of this process under laboratory conditions and in the real atmospheric moisture can differ appreciably (for example, the SO_2 oxidation reactions in the water of a mist, in rain water, or in aerosol water). The rate of oxidation of SO_2 in aerosols diminishes in the following sequence of metal salts:

$$Mn(NO_3)_2 > MnCl_2 > Cu(NO_3)_2 > MnSO_4 > CuSO_4 > CuCl_2.$$

This indicates the strong influence of the nature of the ligand. For example, the formation of complexes with participation of manganese ions and various volatile organic ligands leads to the appearance of fairly effective catalysts activating the molecules of the oxidant (O_2, H_2O_2) and the substrate (SO_2). The rate of the catalytic oxidation of SO_2 depends on a multiplicity of causes: on the ratio of the manganese ions and ligand molecules, on the pH of the medium, and other factors. The observed rates of this oxidation process at different sites and at different times can therefore also be different. However, an appreciable fraction of sulfur dioxide in a water drop within the mist is usually rapidly converted into sulfuric acid. For example, during summer approximately half of the atmospheric SO_2 and NO_2 waste is converted into H_2SO_4 and HNO_3 after 180 and 14 h respectively.[158] The detailed mechanisms of these processes have so far been poorly determined.

The overall reaction involving the catalytic oxidation of sulfur(IV) to sulfur(VI) by oxygen can be as follows:

$$SO_2(aq) + H_2O + \tfrac{1}{2}O_2 \xrightarrow{Mn^{2+}L_n} \longrightarrow H_2SO_4 \rightleftarrows HSO_4^- + H^+.$$

The study of the model $Mn(II) - SO_2(aq) - HSO_3^- - O_2$ system showed that the order of the reaction with respect to manganese is two (there is a possibility of the participation of species of the type of Mn_2^{4+}). A radical-chain mechanism has been postulated:[159]

$$Mn^{2+} + HSO_3^- \rightleftarrows MnHSO_3^+ ,$$

$$2\,Mn^{2+} \rightleftarrows Mn_2^{4+} ;$$

intiation:

$$Mn_2^{4+} + HSO_3^- \xrightarrow{slow} Mn_2HSO_3^{3+} ,$$

$$Mn_2HSO_3^{3+} + O_2 \xrightarrow{fast} 2\,Mn^{2+} + \dot{O}H + SO_4^{\cdot -} ,$$

$$\dot{O}H + HSO_3^- \longrightarrow H_2O + SO_3^{\cdot -} ;$$

branching:

$$SO_4^{\cdot -} + HSO_3^- \longrightarrow HSO_4^- + SO_3^{\cdot -} ,$$

$$SO_3^{\cdot -} + O_2 \longrightarrow SO_5^{\cdot -} ,$$

$$SO_5^{\cdot -} + HSO_3^- \longrightarrow SO_4^{\cdot -} + HSO_4^- ,$$

$$MnHSO_3^+ + HSO_3^- \longrightarrow Mn(HSO_3)_2 ,$$

$$Mn(HSO_3)_2 + O_2 \longrightarrow Mn^{2+} + 2\,HSO_4^- ;$$

termination:

$$SO_5^{\cdot -} + \text{organic compound} \longrightarrow \text{inert products.}$$

This mechanism of the oxidation of sulfur(IV) to sulfur(VI) corresponds to the following rate equation:[159]

$$\frac{d}{dt}[S(VI)] = \left[10 \exp\left(\frac{6.4 - 4\sqrt{I}}{1 + \sqrt{I}}\right)\right][Mn^{2+}]^2 + \left[10 \exp\left(\frac{3.5 - \sqrt{I}}{1 + \sqrt{I}}\right)\right][Mn^{2+}][HCO_3^-] ,$$

where I is the ionic strength.

In contrast to the catalytic oxidation of sulfur(IV) to sulfur(VI) in the presence of iron compounds, in the case of compounds of manganese the catalyst is its dinuclear form Mn_2^{4+} [apparently in the form of some kind of complex, for example, $(MnSO_2)_2^{4+} \cdot O_2$].[160] A powerful oxidant (the $\dot{O}H$ radical), participating in the process, is formed under these conditions.

One of the problems in passing from the model mechanism to the mechanism of the oxidation of SO_2 in the atmosphere is the presence in the latter of both manganese(II) and iron(III) compounds. They exert jointly a much greater catalytic effect than they do separately, as under laboratory conditions. In addition there is a possibility of a difference between the mechanisms due to the difference between the concentrations of the interacting substances under laboratory conditions and in the atmosphere. Thus, at low SO_2 (HSO_3^-) concentrations, the following mechanism of the oxidation of sulfur(IV) by oxygen has been proposed:

$$Mn^{3+} + HSO_3^- \xrightarrow{k_1} HSO_3^{\cdot} + Mn^{2+} , \quad (1)$$

$$HSO_3^{\cdot} + O_2 \xrightarrow{k_2} HSO_5^{\cdot} , \quad (2)$$

$$HSO_5^{\cdot} + HSO_3^- \xrightarrow{k_3} HSO_5^- + HSO_3^{\cdot} , \quad (3)$$

$$HSO_3^- + HSO_5^- \xrightarrow{k_4} 2\,HSO_4^- , \quad (4)$$

$$HSO_5^{\cdot} + HSO_5^{\cdot} \xrightarrow{k_5} S_2O_6^{2-} + 2\,O_2 . \quad (5)$$

Then

$$\frac{d}{dt}[SO_4^{2-}] = k_3 \frac{k_1^{1/2}}{k_5}[HSO_3^-]^{3/2}[Mn]^{1/2} ,$$

if it is assumed that the rate is determined by stage (3).

On raising the concentration of SO_2 (HSO_3^-), the mechanism may change and the reaction

$$HSO_3^{\cdot} + HSO_3^- \xrightarrow{k_6} H_2S_2O_6 + e^- , \quad (6)$$

will appear instead of stage (5). The chain termination stage is now represented by reaction (6) instead of reaction (5) and the rate is determined by stage (2). In this case

$$\frac{d}{dt}[SO_4^{2-}] = k_2 \frac{k_1}{k_6}[Mn^{2+}][O_2] .$$

The catalytic oxidation of SO_2 by oxygen in the presence of the chloride of the tetraolylporphyrin (II) complex of manganese [Mn(III)II] and a reductant can be represented schematically in the following way:[162]

$$SO_2 \cdot H_2O \rightleftharpoons HSO_3^- + H^+ \rightleftharpoons SO_3^{2-} + 2H^+,$$

$$Mn^{3+}\Pi...O_2 \xrightarrow{+e^-} Mn^{3+}\Pi...O_2^- \xleftarrow{Mn^{3+}\Pi} O_2^- \xleftarrow{+e^-} O_2$$

$$+O_2 \uparrow\downarrow -O_2$$

$$Mn^{3+}\Pi \xrightarrow{+e^-} Mn^{2+}\Pi \xrightarrow{+O_2} Mn^{4+}\Pi...O_2^-$$

$$\downarrow +HSO_3^-$$

$$Mn^{3+}\Pi + SO_4^{2-} + HSO_3^{\cdot} + OH^-,$$

$$HSO_3^{\cdot} + O_2 \longrightarrow HSO_5^{\cdot},$$

$$HSO_5^{\cdot} + HSO_3^- \longrightarrow HSO_5^- + HSO_3^{\cdot},$$

$$HSO_5^- + HSO_3^- \longrightarrow 2\,HSO_4^-,$$

$$HSO_4^- + H^+ \rightleftharpoons H_2SO_4.$$

The initiation stage involves the reduction of MnΠ, O_2, or MnΠ ... O_2. The catalyst promotes the coordination and specific reduction of O_2 to the peroxide ions O_2^{2-} and also the generation of the active form of the substrate ($H \cdot SO_3^{\cdot}$ radicals), which is the initiator of the autoxidation of sulfur(IV). The oxide ($Mn^{3+}\Pi$ ... O_2), superoxide ($Mn^{3+}\Pi$ ... O_2^-), and peroxide ($Mn^{4+}\Pi$ ... O_2^{2-}) complexes formed were detected spectrophotometrically.

Hydrogen peroxide plays an even more important role than O_2 as the oxidant in the catalytic conversion of SO_2 into H_2SO_4 in the atmosphere. The H_2O_2 concentration in an atmospheric moisture drop is $\sim 10^{-6}$–10^{-4} M.[163] Typical catalytic oxidation–reduction systems are then produced:

$$M^{z+} - H_2O_2 - SO_2,\ M^{z+} - L - H_2O_2 - SO_2$$

(M = Mn, Fe, Cu, etc),

in which sulfur dioxide is oxidised to sulfuric acid:

$$SO_2 + H_2O_2 \xrightarrow{Mn^{z+}\ (Mn^{z+}L)} H_2SO_4.$$

Thus in the majority of the aqueous atmospheric systems (pH < 5) the main oxidant for SO_2 is H_2O_2.[164] At pH > 5, other oxidants [OH, O_3, Fe(III)–O_2] begin to play an important role and the contribution of H_2O_2 to the oxidation reaction diminishes. Similar catalytic oxidation–reduction systems arise in atmospheric water with participation of O_3 and O_2.

The conditions in certain model experiments on the catalytic oxidation of SO_2 were close to the atmospheric conditions [the concentrations of the reacting components — Mn(II), SO_2, and H_2O_2, acidity, and temperature].[165] Thus the concentration of manganese(II) was 10^{-6} to 4×10^{-6} M, which corresponds to its content in the atmosphere. Under these conditions, the rate of oxidation of sulfur(IV) is given by

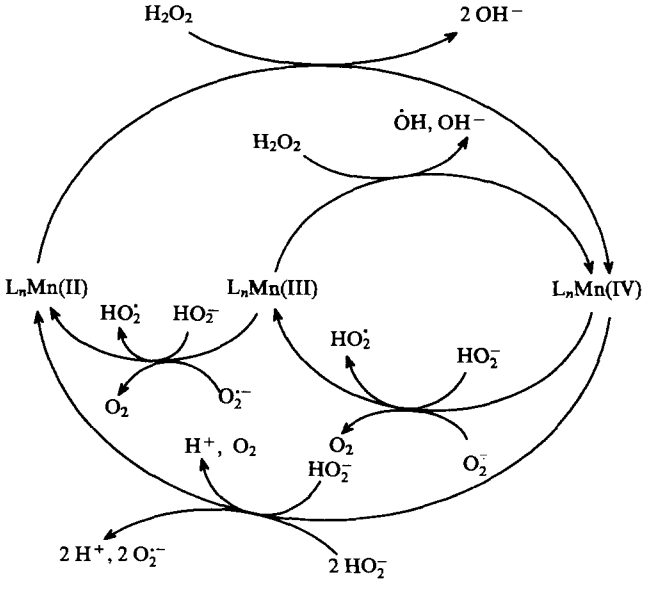
$$-\frac{d}{dt}[S(VI)] = k[S(IV)][Mn(II)].$$

In different studies, the order of the reaction with respect to manganese(II) varied from 1 to 2. The rate constant for this reaction at pH 3–6 remained invariant also for $[Mn(II)]_0 = 10^{-6}$ M and amounted to 5.1×10^3 litre mol^{-1} s^{-1}, which was approximately 6 times greater than the value of k at the same iron(III) concentration. The reaction involving the catalytic oxidation of sulfur(IV) to sulfur(VI) proceeds via the formation of the complex $Mn(II)(HSO_3^-)_x^{2-x}$, the composition of which has not been ultimately determined. It is of interest that similar manganese hydrogen carbonate complexes $[Mn(HCO_3)_2]$ are[10] active catalysts of the decomposition of H_2O_2 with subsequent formation of $HO_2^{\cdot -}$ and $\dot{O}H$ free radicals species. The sequence of metals forming the catalyst is as follows when account is taken of the rate constants for the oxidation of sulfur(IV) to sulfur(VI):

Mn(II) > Fe(III), Cu(II) ≫ non-catalytic reaction.

Thus the non-catalytic and catalytic oxidation of SO_2 to H_2SO_4 by various oxidants (especially H_2O_2) is the most important process leading to the acidification of rain water. Apparently the key catalysts of this process (together with iron compounds) are manganese compounds and the rates of formation of SO_4^{2-} (mol litre^{-1} s^{-1}) in model experiments are described by the expressions

$$\frac{d}{dt}[SO_4^{2-}] = 0.142[Mn(II)] \text{ at } [SO_2] > 4 \times 10^{-5}\ M,$$



$$\frac{d}{dt}[SO_4^{2-}] = 0.142[Mn][SO_2]^{3/2} \text{ at } [SO_2] < 4 \times 10^{-5}\ M.$$

The mechanism of the oxidation of SO_2 in the atmosphere apparently involves free radical species.

In the atmosphere, 20%–40% of the acidity is caused by the oxidation of NO_x to nitric acid.[166] This reaction can also occur under the influence of catalysts.[167–170] However, the number of reliable data concerning the mechanism of this process is much smaller than for the mechanism of the oxidation of sulfur and they will not therefore be considered here.

VI. Conclusion

Many coordination compounds of manganese(II) with ligands containing nitrogen, oxygen, and both nitrogen and oxygen can be regarded as functional models of catalase (they catalyse the decomposition of H_2O_2 to O_2), peroxidase (they catalyse reactions involving the oxidation of organic and inorganic compounds by hydrogen peroxide oxidation products), superoxide dismutase (they catalyse the destruction of superoxide radical-ions O_2^-), and oxidase (they activate O_2 in the oxidation reactions of various compounds). The set of oxidation–reduction reactions which can occur in Mn(II)–ligand–H_2O_2 systems with participation of the complex catalyst is reflected by the following general scheme:

In each specific case, the mechanism of the decomposition of H_2O_2 by manganese complexes includes a definite set of oxidation–reduction reactions (presented above). The operation of a radical-ion (chain or cyclic) or ion-molecule mechanism is determined by the ligand environment of Mn^{2+} and the process

conditions. A clear relationship between the composition of the complex, the ligand environment in which the manganese ion exists, its reactivity, and the mechanism of the catalytic action has not so far been established.

The catalase-active coordination compounds of manganese(II) possess also a definite peroxidase activity because the catalytic decomposition of hydrogen peroxide generates ȮH radicals and manganese(IV) and manganese(III) compounds which have a high oxidising capacity. If a radical-chain mechanism of the decomposition of hydrogen peroxide operates in the systems with generation of ȮH radicals, the latter make the main contribution to the oxidation of the substrates. When an ion-molecule or a radical-ion cyclic mechanism of the decomposition of hydrogen peroxide operates, the oxidant consists mainly of manganese(IV) compounds. Substrates with relatively weak complex-forming capacity in relation to Mn^{2+} {$pK_s < 3$ for $K_s[L]/K_s[S] \gg 1$} are oxidised via an outer-sphere mechanism in the Mn(II)–ligand–H_2O_2 systems. Substrates forming fairly stable compounds with Mn^{2+} {$3 < pK_s < 8$ for $K_s[L]/K_s[S] \geqslant 1$} are oxidised within the coordination sphere of the complex catalyst (inner-sphere oxidation mechanism). If reactive substrate radicals are formed in the reaction volume, molecular oxygen participates in the oxidation process under aerobic conditions and the role of H_2O_2 reduces to the preparation of the substrate, by converting it into an active radical, for subsequent oxidation by molecular oxygen.

The liquid-phase catalytic oxidation by molecular oxygen in the presence of coordination compounds of manganese proceeds as a rule in non-aqueous media. Oxygen is activated mainly as a consequence of the formation of an intermediate active catalyst–O_2 compound and the mechanism of the oxidation of the substrate is then of the outer-sphere type. A ternary complex of the type MnL_n-O_2-S is sometimes formed in the course of the process. In such cases an inner-sphere mechanism of the oxidation of the substrate operates. The factors determining the operation of a particular oxidation mechanism, which permit a purposeful search for catalytically active manganese compounds and also characterise the role of the substrate and the medium in the liquid-phase oxidation by molecular oxygen, have by no means been fully established.

The high reactivity of individual manganese complexes can be used to develop catalymetric analytical methods (tens of such methods are already known) for preparative purposes (for the synthesis of particular organic compounds via liquid-phase oxidation) and for the solution of other applied problems (-elimination of organic contaminants from waste waters, etc.). The role of manganese compounds as catalysts of the processes occurring in the environment has been demonstrated on model systems for the conversion of sulfur(IV) (as SO_2) into sulfur(VI) (as H_2SO_4), which play an important role in the formation of acid rain.

I. Introduction	291
II. Metal-containing ionic liquid crystals	291
III. Liquid-crystal coordination compounds	294
IV. Conclusion	310

Abstract. Data on the synthesis, structures, and properties of ionic, coordination, organometallic, and organoelement compounds with liquid-crystal properties are surveyed. The substances examined are new in the chemistry of liquid-crystal compounds. Their potential applications are described. The bibliography includes 211 references.

I. Introduction

Liquid crystals have been known for more than 100 years but the number of structural types and of classes of chemical compounds capable of exhibiting mesomorphic properties has increased significantly only during the last 15 – 20 years. For example, discotic, columnar, and nematic phases,[1-3] cup-shaped liquid crystals,[4] and columnar associated species in which the molecules are linked by a system of hydrogen bonds have been added recently to the structural types of low-molecular-mass liquid crystals alone.[5,6] New classes of mesogenic chemical compounds include also coordination compounds, usually complexes of mesogenic ligands with various metals,[7,8] as well as certain organometallic and organoelement compounds. Furthermore, new data have appeared recently on salts of organic acids possessing mesomorphic properties, which have been known for a long time.[9]

Evidently the physical properties of the compounds listed above should differ from those of classical organic mesogenic substances. Thus metal containing mesogenic substances are usually paramagnetic and this leads to new possibilities for their practical use.

In the present review, we have attempted to survey data on the methods of synthesis (in those cases where they are not trivial), structures, and properties of new metal-containing mesogenic substances. Furthermore, we endeavoured to trace, wherever possible, the relation between molecular structure, type of packing in the crystal, and the nature of the existing intermolecular interactions, on the one hand, and the tendency manifested (or not manifested) by the given compound to form definite types of mesophases, on the other. Such analysis permits a deeper understanding of the characteristics of the structures of liquid crystal phases, the discovery in many cases of new types of mesophases, and also the prediction of the presence of mesogenic activity in specific compounds.

It is noteworthy that analysis of the authors' own studies occupies an appreciable place in the present review, since the studies by foreign investigators have been described in fair detail in the review of Giroud-Godquin and Maitlis.[7] Unfortunately, the latter review includes hardly any work published in Soviet journals and we believe that the present article should fill this gap.

In analysing the relevant data, one can employ different approaches to the classification of the test objects. We believe that it is most useful to arrange mesogenic metal-containing compounds in groups in the following way: ionic compounds, coordination compounds (the most numerous group which can be subdivided in terms of the types of ligands), organoelement compounds, and organometallic compounds. However, one should bear in mind the arbitrary nature of this classification and the possibility of assigning the same compound to different groups simultaneously.

We shall not dwell on the structural classification of the types of liquid crystals, since it has been described in fair detail in a monograph[10] and also in other reviews.[3,11] We shall restrict consideration to principal low-molecular-mass thermotropic liquid crystals, since high-molecular-mass as well as lyotropic liquid crystals constitute separate independent groups.

II. Metal-containing ionic liquid crystals

Ionic liquid crystals have long been known. A characteristic feature of these compounds — the possibility of the separate existence of the cationic and anionic components of the molecules in the mesophase (in contrast to molecular liquid crystals in which the metal is firmly coordinated to the ligand atoms) — gives rise to a series of new properties of such phases. Typical representatives of ionic liquid crystals are carboxylic acid salts.

1. Carboxylic acid salts

As early as 1910, Vorländer[12] first observed the liquid-crystal state on fusion of salts of long-chain carboxylic acids referred to as soaps.

Structural studies at high temperatures on the anhydrous thermotropic mesophases of a series of homologues of salts of long-chain aliphatic acids $C_nH_{2n+1}COOH$ (n = 9 – 19, odd values of n) have been described in a number of communications.[13-16] The following structures were established in these investigations on the basis of X-ray diffraction data: layered (smectic) structures with an ordered or disordered

disposition of aliphatic chains, discotic structures with an orthogonal lattice (for example, in the sodium salts of aliphatic acids), and columnar (ribbon) structures with a hexagonal packing of the columns. In layers of homologues of the same metal, it is possible to observe the entire set of structural types described. For example, calcium carboxylates are characterised below 100 °C by a layered structure with the disposition of the alkyl chains at right angles to the plane of the layer, while in the range from 120 to 180 °C they are characterised by hexagonal packing of cylindrical associated species.[16] Unfortunately, X-ray diffraction studies on the mesophase do not permit the determination of the detailed pattern in the packing of the molecules in discs and cylinders[13-16] and the most likely hypotheses concerning their structures can be formulated only on the basis of X-ray diffraction studies of the corresponding single crystals.

At the beginning of the 1970s, it was observed that the homologues of the salts of lower carboxylic acids also exhibit thermotropic mesomorphism.[17] Their structures and thermodynamic, transport, and optical properties have been reviewed.[9]

The observation of mesophases in such compounds, which have been called ionic liquid crystals (ILC), was fairly unexpected since the presence of extended molecules, usually one of the main conditions for the manifestation of mesomorphism, is not characteristic of these substances. It is believed[9] that the species constituting these mesophases are quasi-globular associated formations containing metal cations (Na^+, K^+, Ba^{2+}, Tl^+, Cd^{2+}, Cs^+) and carboxylate anions (n-$C_nH_{2n+1}COO^-$, $2 \leqslant n < 7$). The latter do not exhibit an explicit anisometry (the length to width ratio does not exceed 2). Furthermore, in contrast to the classical molecular liquid crystals, ionic liquid crystals are characterised by a high ratio of the electrostatic charges on the constituent components to the total number of atoms, which leads to the predominance of Coulombic forces over van der Waals forces in the formation of their structure. Ionic liquid crystals have an intrinsic conductivity which exceeds by 6–8 orders of magnitude the impurity conductivity in classical organic liquid crystals. Data obtained by Meisel et al.[18] indicate that the charge transfer in the carboxylate melts is effected mainly by metal cations.

The structure of the mesophases of ionic liquid crystals has been investigated by X-ray diffraction, ^1H NMR, and ^{23}Na NMR for sodium butyrate and isovalerate[19-21] and by X-ray diffraction for potassium caproate (hypotheses concerning the structure were put forward on the basis of X-ray diffraction studies on single crystals[22]) and thallium and sodium n-alkanoates.[23-25] It has recently been possible to investigate a series of crystal structures of such salts and this yielded more refined and detailed information about the structure of the mesophases.

There have been few structural studies on the single crystals and thermotropic mesophases of metal alkanoates and complete X-ray diffraction analysis has been achieved mainly for certain hydrated formates and acetates.[26] The reason for this is the difficulty of obtaining single crystals of salts of this group. However, reports have recently appeared concerning structural studies on such salts, in particular barium butyrate ($BaBut_2$), which forms a smectic phase A:

$$\text{Crystal (C)} \xrightarrow{240\ ^\circ\text{C}} \text{smectic phase (SmA)} \xrightarrow{304\ ^\circ\text{C}} \text{isotropic liquid (IL).}$$

This compound was synthesised by the method described by Hazlewood et al.[27]

The crystal structure of $BaBut_2$ contains two symmetrically independent barium atoms, each of which is coordinated to eight oxygen atoms.[28] The coordination of the barium atoms can be described in terms of a polyhedron, the lower and upper bases of

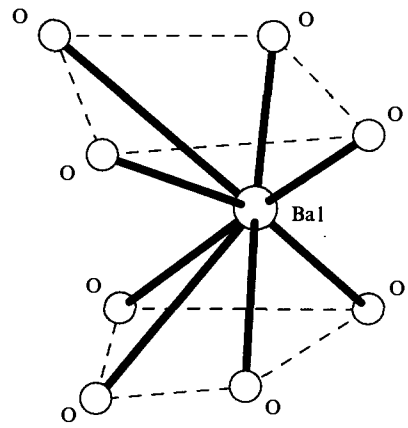

Figure 1. Coordination of the Ba(1) atom in the $BaBut_2$ structure.[28] The angle between the planes formed by the oxygen atoms is 9°.

which comprise irregular rectangles rotated relative to one another (Fig. 1). In this coordination, the barium atom is, as it were, compressed by two 'oxygen lids', on either side of which the alkyl chains of the butyrate anions are disposed. The metal–oxygen bonds are significantly ionic (the sum of the ionic radii is less than or equal to the Ba–O distances found in the crystal: 2.687–2.936 Å). It should be especially noted that Mirnaya et al.[28] established for the first time the disposition of the metal cations and the carboxylate groups of the anions for ionic liquid crystals. Since the type of packing of the molecules in the mesogenic crystal can be to some extent inherited by the mesophase, the observed coordination of the metal should be retained, at least in broad outline, also in the mesophase, as has been observed, for example, for metal complexes of Schiff bases and a number of other compounds.[5,6,8] The packing of the molecules in the $BaBut_2$ crystal has an explicit bilayer character and within each double layer hundreds of barium and oxygen atoms form electrically charged cation–anion strata separated from one another by layers of alkyl substituents (Fig. 2). One may postulate that during fusion the 'acceleration' of the alkyl substituents occurs before the breakdown of the barium–oxygen strata. As a result, the sliding of the alkyl layers relative to one another becomes possible, which favours the formation of the smectic mesophase.

Low angle scattering studies on the vitrified $BaBut_2$ mesophase showed[28] that the thickness of the bilayer (14.02 Å) is somewhat smaller than that of the corresponding bilayer in the crystal (14.63 Å). This may be associated with the partial compression of the layers in the mesophase due to the strong electrostatic interactions between neighbouring bilayers. The same effect has been observed also for homologues of thallium n-alkanoates,[29] where there are considerable possibilities for conformational changes in the alkyl chains. The addition of different amounts of sodium butyrate (20, 40, and 50 mol%) to the $BaBut_2$ melt hardly alters the interlayer distance in the mesophase. This can be explained by the similar polarising capacities of both cations and also by the fact that the changes in composition indicated do not entail appreciable changes in the nature of the electrostatic interactions in the cation–anion stratum and hence in the bulk of the stratum.

The smectic mesophase A has been observed[30] also for the hydrated form of cadmium isovalerate, the structure of which is in broad outline similar to that of $BaBut_2$.

$$\text{C} \xrightarrow{180\ ^\circ\text{C}} \text{SmA} \xrightarrow{237\ ^\circ\text{C}} \text{IL}$$

The metal atom in the crystal occupies a specific position on the twofold axis and is coordinated to six oxygen atoms, two of which belong to water molecules. The coordination environment of the

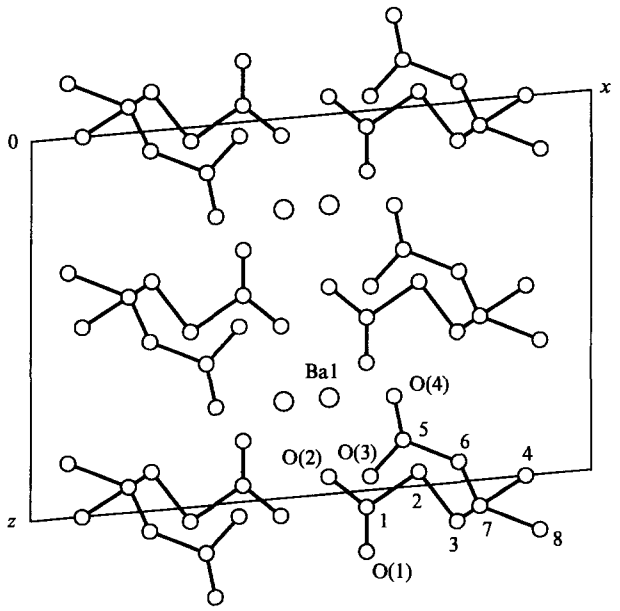

Figure 2. The packing of the first independent barium butyrate molecule in projection onto the *xz* plane.

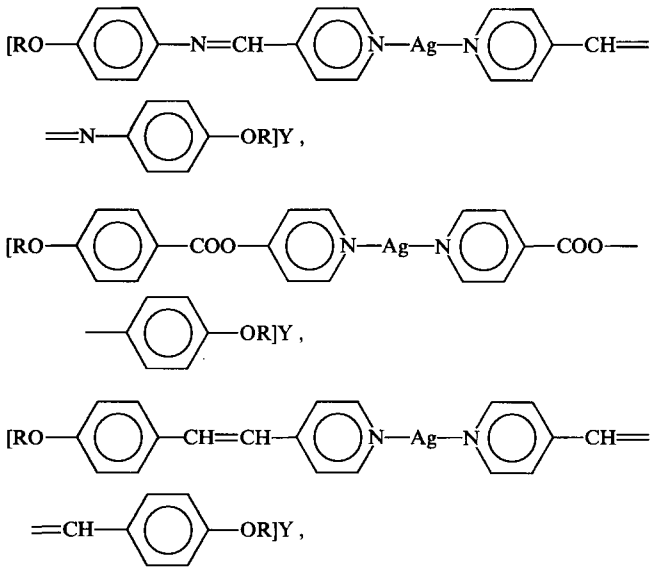
cadmium atom is represented by a polyhedron, the lower and upper bases of which comprise triangles made up of oxygen atoms and linked by a twofold crystallographic axis. The angle between them is 14.8°. The disposition of the molecules in the cadmium complex is of the double layer type, as in the $BaBut_2$ crystal: the cadmium and oxygen atoms form strata between which the alkyl chains are accommodated. The presence in the structure of two water molecules leads to the formation of two chains of hydrogen bonds which join together the anions within one bilayer.



The thickness of the bilayers in the mesophase (14.1 Å) exceeds appreciably the thickness of the layers in the crystal (12.29 Å). This can be explained by the inclined disposition of the molecules in the crystal relative to the plane of the layer, which changes to an orthogonal disposition on passing to the smectic phase A. IR spectroscopic studies have shown that, when crystals of cadmium isovalerate are heated and pass to the mesophase, there is only partial loss of water, the presence of which is responsible for the mesomorphism (the anhydrous substance does not form the mesophase).[30]

The absence of mesomorphism in magnesium butyrate hydrate ($MgBut_2.4H_2O$), the crystal structure of which is also characterised by a bilayer disposition of the molecules,[30] can be attributed to the high polarising capacity of the cation, as a result of which the condition for the existence of ionic liquid crystals, namely $Z_k/r_k^2 < 1.05$ (Z_k and r_k are respectively the charge and radius of the cation) is not fulfilled because of the small radius of the metal.[31] However, we believe that the presence in the crystal of a branched three-dimensional network of hydrogen bonds is also unfavourable for the manifestation of mesomorphism. Furthermore, water molecules shield the Mg^{2+} cation in such a way that the second butyrate anion is not linked directly to the metal cation. The presence of such a bond is apparently essential for the formation of ionic liquid crystals.

It is noteworthy that ionic liquid crystals and their binary mixtures are promising materials for the preparation of supercooled mesomorphic substances—liquid-crystal glasses. Furthermore, ionic liquid crystals exhibit a high optical sensitivity, which can be varied by the application of even weak electric fields.

2. Salts of complex cations

Silver salts with complex cations and various anions constitute a fairly numerous group of ionic liquid crystals:[32, 34]

where $Y = BF_4^-$, NO_3^-, $CF_3SO_3^-$, or $C_{12}H_{25}SO_4^-$ and $R = C_nH_{2n+1}$. Wider ranges of conditions for the existence of mesophases and a greater variety of polymorphic modifications than for salts with imino-ligands are characteristic of salts with ester ligands in this group. The greatest number of mesomorphic phases has been observed for salts with stilbazole ligands and the dodecyl sulphate anion (DOS), this being particularly notable for the alkoxy-homologues with $n > 5$.

Fig. 3 presents the phase diagram for the homologues of the last of the salts listed above [derivatives of *trans*-4-alkoxy-4′-stilbazole (TAS)]. The columns on the diagram correspond to phase transitions investigated by differential scanning calorimetry and X-ray diffraction, including the procedure using synchrotron radiation. For example, on the X-ray diffraction pattern for the $[Ag(TAS)_2][DOS]$ ($R = C_3H_7$) nematic phase, a peak was found corresponding to a distance of 33.1 Å, in good agreement with the length of the complex anion, which is 35.1 Å. For the homologue with $R = C_{12}H_{25}$, the phase at 138 °C was identified as cubic with a unit cell parameter of 73.4 Å. This isotropic cubic phase (M_I on the phase transitions scheme—see Fig. 3) proved to be similar to the phase D found earlier for biphenylcarboxylic acids.[35] The properties of salts with other anions (NO_3^-, $CF_3SO_3^-$) are close to

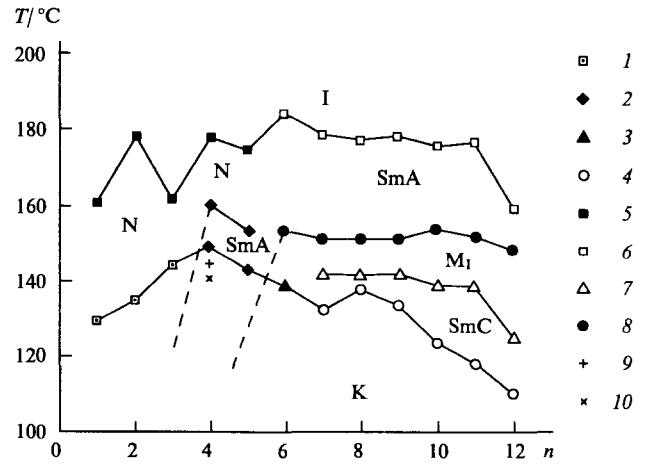


Figure 3. Phase diagram for the $[Ag(TAS)_2][DOS]$ homologues.[34] The region of existence of the SmA phase is indicated by dashed lines. Phase transitions: (*1*) C → N; (*2*) C → SmA and SmA → N; (*3*) C → M_I; (*4*) C → SmC; (*5*) N → I; (*6*) SmA → I; (*7*) SmC → M_I; (*8*) M_I → SmA; (*9*) SmA → N_R; (*10*) N_R → SmC; N = nematic phase, N_R = reverse nematic phase; C = crystal; I = isotropic liquid.

those found for the DOS salts, but they do not form so many polymorphic phases. The pronounced poly-morphism of the silver salts examined may find applications in electrochemistry.

III. Liquid-crystal coordination compounds

At the present time coordination compounds constitute the most numerous group of metal-containing liquid-crystal substances which has also been investigated in greatest detail. Their behaviour is similar to that of classical organic liquid crystals, since, in contrast to ionic liquid crystals, they represent molecular phases. However, the presence of a metal naturally gives rise to a series of new properties.

In this section we shall consider complexes with carboxylate, β-diketonate, salicylaldiminate, and other ligands, the majority of which are also mesogenic compounds in the noncoordinated state. Comparison of the structures of the mesophases of the coordination compounds and the free ligands is of interest in many instances since it makes it possible to predict the trend in the variation of the properties of these compounds.

1. Complex mesogenic substances with carboxylate ligands

Copper stearate was the first to be investigated among the mesogenic carboxylates.[36] The method of synthesis, the structures of the solid and liquid crystal phases, and the mobilities of the molecules of the above compound and other carboxylates of the type $M_2(\mu\text{-}O_2CC_nH_{2n+1})_4$, where $n > 4$ and M = Cu, Ru, Rh, or Mo, have been investigated by many workers.

Divalent metal carboxylates are usually obtained by the exchange reactions between alkali metal salts of aliphatic acids and the salts of the corresponding divalent metals. Furthermore, it is possible to obtain them by fusing aliphatic acids together with metal hydroxides.[37] The molecular structure of the carboxylates is fairly well known[38-40] on the basis of X-ray diffraction data for single crystals of copper alkanoates with n = 4, 8, and 10. Their molecules are dinuclear complexes in which each copper atom is involved in a square-bipyramidal coordination and is surrounded by four oxygen atoms in the equatorial plane. One of the vertices of the pyramid is occupied by the copper atom and another is occupied by an oxygen atom of a neighbouring complex (Fig. 4). The average Cu–O distance for all five oxygen atoms is 2.01 Å and the Cu–Cu distance is 2.59 Å. The molecules in the crystals of the alkanoates investigated are packed in stacks in such a way that the axis of the stack passes through the centres of gravity of the molecules.

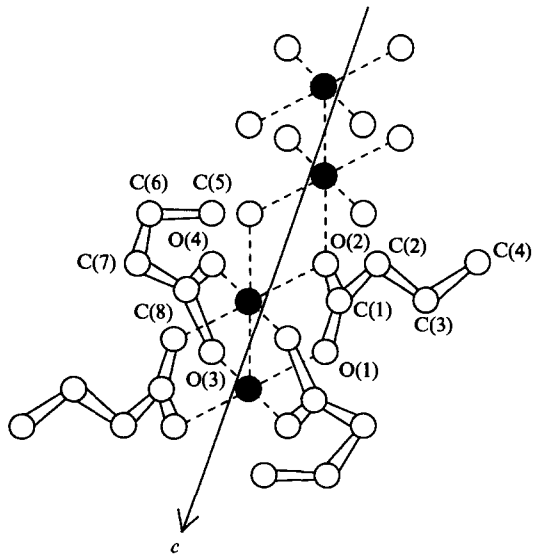

Figure 4. The structure of the copper carboxylate complex (n = 4) in the crystal.[38] The arrow indicates the direction of the column.

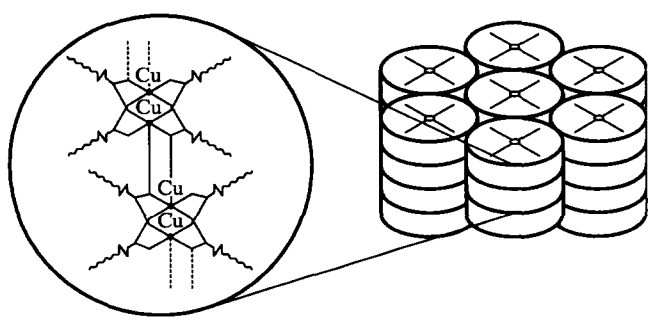
Systematic studies have been made[41-45] on copper carboxylates with n = 4–24 by differential scanning calorimetry, optical microscopy, X-ray diffraction of the mesophase, and EXAFS spectroscopy. X-Ray diffraction study of the mesophase showed[45] that, at temperatures above 120 °C, copper carboxylates form a columnar discotic phase with a planar hexagonal lattice. In the mesophases investigated, the nuclei of the dinuclear complexes are arranged along the axis of the column and, regardless of the length of the alkyl chains, the distance between the neighbouring complexes in the column is 4.7 Å. The distances between the columns themselves vary as a function of the length of the alkyl chains and amount to 15–25 Å. We may note that the disposition of the molecules in the mesophases considered (Fig. 5) and in the single crystals of these compounds is similar. It is believed[42] that the mesophases of the copper carboxylates are the first example of a thermotropic columnar liquid crystal phase in which the molecules with four equivalent substituents (the intrinsic symmetry of the molecule approaches the quaternary symmetry) form a hexagonal phase. EXAFS spectroscopic data confirmed that the metal–metal distance in the dinuclear complex remains unchanged when the crystal passes to the mesomorphic state.[43]

The carboxylate complexes of tetrakis[2,2-(dioctyl)acetate-*O*,*O*′]dicopper(II) have been investigated.[46] A distinctive feature of these complexes with branched substituents is the fact that the temperature of the range corresponding to the existence of the mesophase is reduced below room temperature and reaches −20 °C. It may be that, apart from the chain branching, this is influenced also by the presence of impurity ions in the mesophase. X-Ray diffraction study made it possible to assign this mesophase to the discotic columnar hexagonal type with distances of 4.6 Å between the discs and 21.5 Å between the columns. Molecular complexes between the above copper carboxylate and pyrazine and 4,4′-bipyridyl also form mesophases, the structure of which has not yet been established unambiguously.

A similarity in the behaviour and structure has been noted for divalent rhodium carboxylates and the analogous copper complexes.[47] According to EXAFS spectroscopic data, the Rh–Rh distance in the dimeric complex $Rh_2(\mu\text{-}O_2CC_7H_{15})_4$ is 2.38 Å, while the intermolecular distance Rh...Rh, which completes the coordination of the metal atom, is 3.16 Å. The presence of the additional coordination in the mesophase has been confirmed also by Raman spectroscopic data.[48] This suggested that the authors dealt in this instance for the first time with a columnar type complex in which there is a chain of metal–metal bonds within the discotic column. Mesophases with a similar structure have been observed also for dinuclear chromium and molybdenum complexes,[49,50] in the latter case the metal atoms being linked by a quadruple bond. Similar phases have been found for dinuclear ruthenium(II) complexes. The synthesis and properties of the mixed valence ruthenium complexes $Ru(RCO_2)_4X$, where R = C_8H_{17} or $C_{11}H_{23}$ and X = Cl or RCOO, have been described.[51] It was found that the complexes with X = Cl are nonmesogenic, while those with X = RCOO form hexagonal (R = $C_{11}H_{23}$) or orthogonal (R = C_8H_{17}) columnar mesophases.



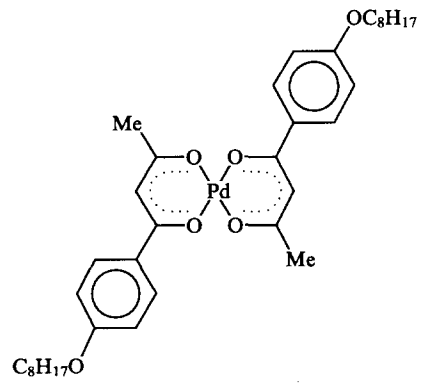


Figure 5. The columnar mesophase of copper carboxylates.[7]

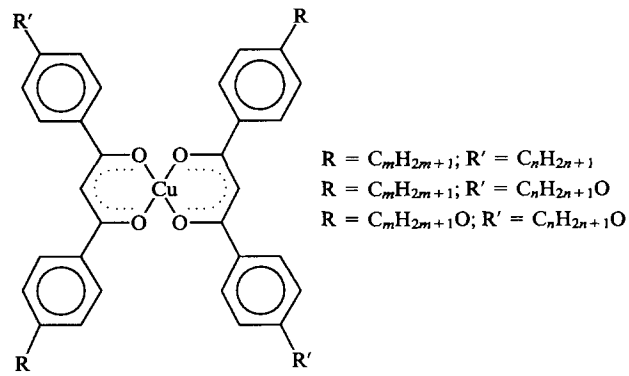
These compounds are apparently the first example of liquid crystals with a mixed valence.



2. Mesogenic complexes of β-diketonates

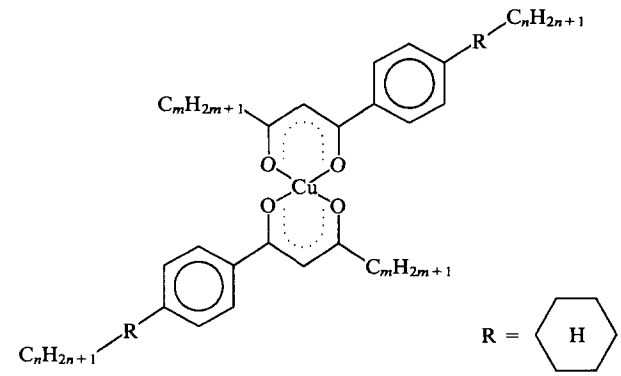
The diligand complexes of β-diketones, especially those with palladium and copper having suitable substituents, exhibit mesomorphic properties in many cases. These complexes can be obtained by the reaction of β-diketones with the salts of the corresponding metals. Mesomorphism was first observed and described[52] for the palladium complex, the molecule of which is rod-shaped.

It has been stated[52] that, although the above complexes exhibit mesomorphism (according to differential scanning calorimetric data), it has not been possible to investigate it by optical methods owing to the darkening of the specimens on heating. The analogous copper complexes with alkyl substituents of different lengths do not exhibit mesomorphism.[53]

The copper complexes, first described by Giroud-Godquin and Billard,[54,55] in which the β-diketonate ligands each have two phenyl groups with the same or different terminal substituents in the *para*-position, are assumed to be much more promising mesogenic substances.

Complexes of this type tend to form highly ordered discotic, especially layered, phases. The complexes of β-diketonates with identical alkyl substituents at the phenyl groups have higher melting points and clarification temperatures than the same complexes with different substituents. For example, the range of existence of the mesophase is 71–122 °C for $n = 7$ and $m = 13$, 89.5–128.5 °C for $n = m = 10$, and 95.1–113.4 °C for $n = m = 12$. It has been established[7] that the region corresponding to the existence of the mesophase is wider for complexes with terminal alkyl substituents than for complexes with alkoxy-substituents. On the other hand, the analogous nickel diketonate complexes do not form mesophases at all.[55]

The structures of the single crystals of two complexes of this series with R = R' = $C_8H_{17}O$ and R = R' = C_8H_{17} have been established.[56–58] We may note that hitherto this has been achieved only for very few compounds forming discotic phases. According to X-ray diffraction data, the copper atom has a square planar configuration and the angle of rotation of the benzene rings relative to the plane of the central nucleus does not exceed 20°. As in other mesogenic molecules,[5,8] the alkyl chains are characterised by high thermal factors, indicating their appreciable mobility, which decreases even further in the mesophase.



The packing of the molecules in the crystal with R = OC_8H_{17} is of the layered-columnar type.[57] In contrast to the usual discotic phases, the molecules in the column are grouped into centrosymmetric dimers and each column is surrounded by six neighbouring columns, but their relative disposition is far from being of the hexagonal type. The central part of the column is surrounded on all sides by alkyl substituents belonging to the given column and neighbouring columns (Fig. 6).

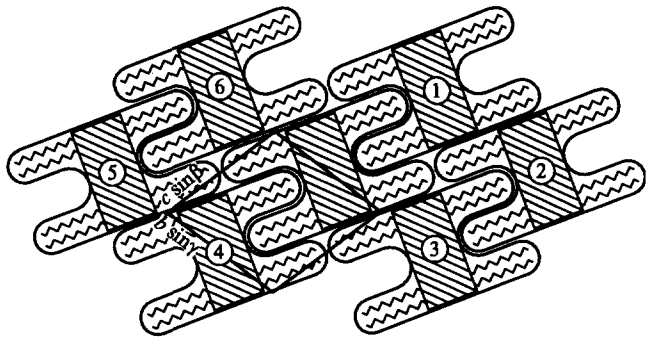
The columnar arrangement is not, however, characteristic of all compounds of this series. Thus X-ray diffraction data for the mesophase of molecules with R = R' = $C_{12}H_{25}$[59] made it possible to attribute to it a layered structure with a uniform distribution of molecules in the layer and without a columnar ordered arrangement.

It has been shown[60,61] that an increase in the number of substituents in the benzene rings of 1,3-diphenyl-β-diketones also makes it possible in a number of instances to obtain discotic compounds. Discotic phases have been observed for phenyl-substituted copper complexes with hydroxyalkyl substituents in the 3- and 4-positions, but have not been found for 3,5-diphenyl-substituted complexes. The analogous nickel complexes do not form mesophases. Mesophases have also not been observed for a number of other complexes with alkyl substituents.[62]

In the presence of substituents in the benzene rings, imparting to the β-diketone compounds a significant anisometry (for example in the case of copper complexes[63,64] with R = Ar-$C_{10}H_{21}$ and R' = Me, Et, OMe, OEt, or OPr), the type of the mesophase formed changes. It becomes nematic, retaining at the same time features characteristic of discotic nematic phases. It is believed[65] that this group of compounds is the first example of biaxial nematic metallomesogenic substances.

Similar complexes with one phenyl and one alkyl substituent in the β-diketone ligand also form nematic phases.[66]

It has been possible to investigate the crystal structures of two of them with $n = 3$ and $m = 1$, and with $n = 3$ and $m = 8$.[66] The structure of the first molecule is nearly planar (with the exception of a slight rotation of the benzene rings, by not more than 12°, relative to the plane of the metal chelate ring). On the other hand, the second molecule is significantly nonplanar: not only the benzene rings have been displaced from the central plane (by not more than 21°) but also the alkyl substituent (by ~40°). Evidently, the compound constructed from rod-shaped molecules with $n = 3$ and $m = 1$ exhibits nematic properties. The molecules with $n = 3$ and $m = 8$ are packed in the crystal in layers, which indicates the possibility of the existence of the smectic phase. However, the compound forms only a monotropic nematic phase. In our view, this can be explained precisely by the presence in the crystal of layers, which must be disrupted to achieve the transition to the nematic phase directly from the solid phase. Apparently such disrupting effect on the layered structure



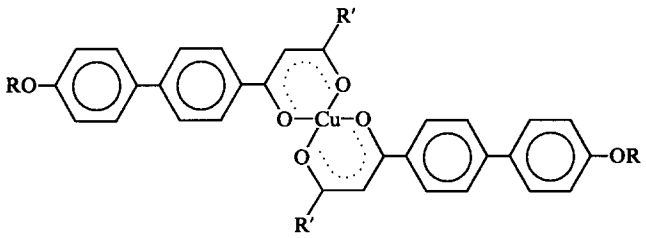


Figure 6. Columns in the crystal[57] of a copper β-diketonate complex (R = OC_8H_{17}). The dimers are surrounded by a continuous line and their central parts are shaded. The numerals denote the nearest neighbours of the dimer.

is exerted by the added 4-cyano-4′-(4″-*n*-pentylcyclohexyl)-biphenyl. The reason for the absence of the smectic phase can be found by analysing the energy of the intermolecular interaction, for example by the method used by Polishchuk et al.[8]

At first sight it is entirely natural to postulate, on the basis of the shape of the molecule, the presence of a nematic mesogenic phase for compounds having the general formula

the synthesis, properties, and structure of which have been described in the case of homologues with R′ = Me, R = C_nH_{2n+1}, and n = 8–12, 16, or 18.[67]

All the homologues indicated, except that with n = 8, form the so called orthogonal columnar ordered discotic mesophase D_{ho}, which had not been mentioned initially in the classification of discotic mesophases proposed by Destrade et al.,[68] but which has been recently added to this classification.[69] The mesophase of the homologue with n = 16 has been studied in greatest detail by X-ray diffraction. The results made it possible to construct a model of the mesophase (Fig. 7). The molecules of this homologue are rod-shaped and not disc-shaped and the authors therefore assume that the elementary units from which the columns are made up are molecular dimers. Similar dimers had been detected also previously in the crystal structures of discotic substances, in particular in the complexes, mentioned above, described by Usha et al.[56] and Muhlberger and Haase.[66] The dimers (Fig. 7*a*) are arranged in an ordered fashion along the column axis (Fig. 7*b*). The disposition of the columns is characterised by a planar orthogonal lattice $C2/m$ symmetry having the parameters indicated in Fig. 7*c*. This example confirms yet again that not only the shape of the molecule but also the nature of their aggregation within the mesophase is important for the formation of a columnar discotic phase. In our view, however, this phase should not be referred to as discotic, since it contains no disc-shaped molecules and should probably be assigned to the class of phases made up of columnar associated nondiscotic molecules, for example, of the kind described by Polishchuk and coworkers.[5,6]

As a result of the introduction into the above complexes of more bulky substituents R′, for example, C_4H_9, C_8H_{17}, and $C_{12}H_{25}$, the molecules become less anisometric and cease to form discotic phases of type D_{ho}, forming instead enantiotropic or

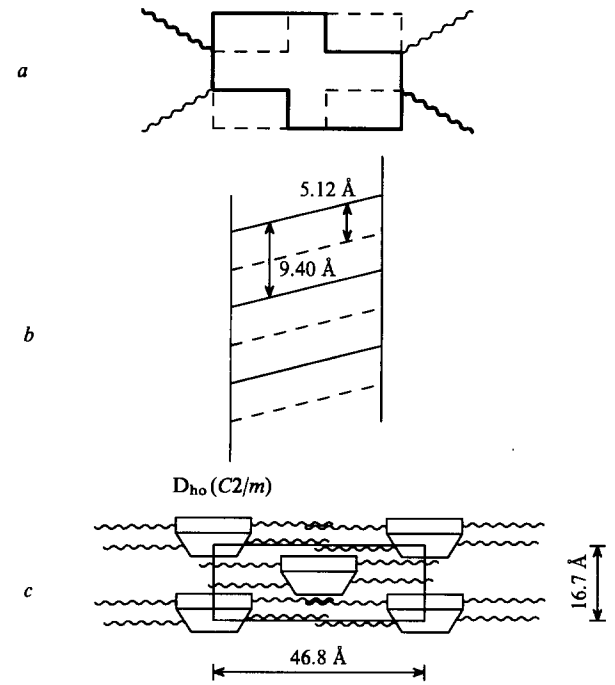

Figure 7. 'Discotic' phase made up of rod-shaped molecules:[67] (*a*) schematic illustration of the structure of the molecular dimer; (*b*) disposition of the dimers in stacks (interdimer distance 9.40 Å, intradimer distance 5.12 Å); (*c*) schematic illustration of the packing of the columns in the orthogonal mesophase — the parallelopipeds represent the central parts of the molecular dimers.

monotropic nematic phases.[70] The phase transitions in these compounds are illustrated schematically in Table 1. The nature of the nematic mesophase is determined by the ratio of the lengths of the substituents R and R′, i.e. by the shape of the molecule. The replacement of the small methyl groups (Fig. 8*a*) by the more bulky n-butyl groups (Fig. 8*b*) prevents the formation of the discotic phase D_{ho} and, on still further increase in their length and hence in the mobility and disorder of the terminal alkyl substituents, the nematic phase can be obtained only from the isotropic liquid on rapid cooling. After prolonged maintenance of the melt at a temperature several degrees below the clarification temperature, the formation of helicoidal mesophases was

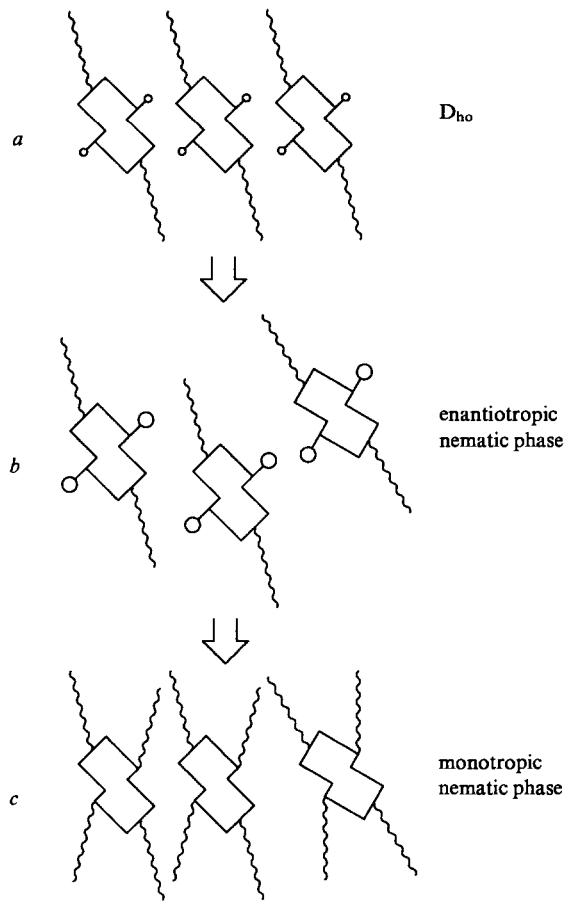

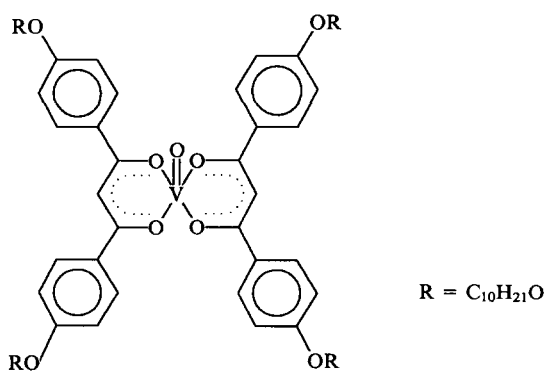

Figure 8. Three types of molecules forming the 'discotic' (*a*), enantiotropic (*b*), and monotropic (*c*) nematic phases.[70]

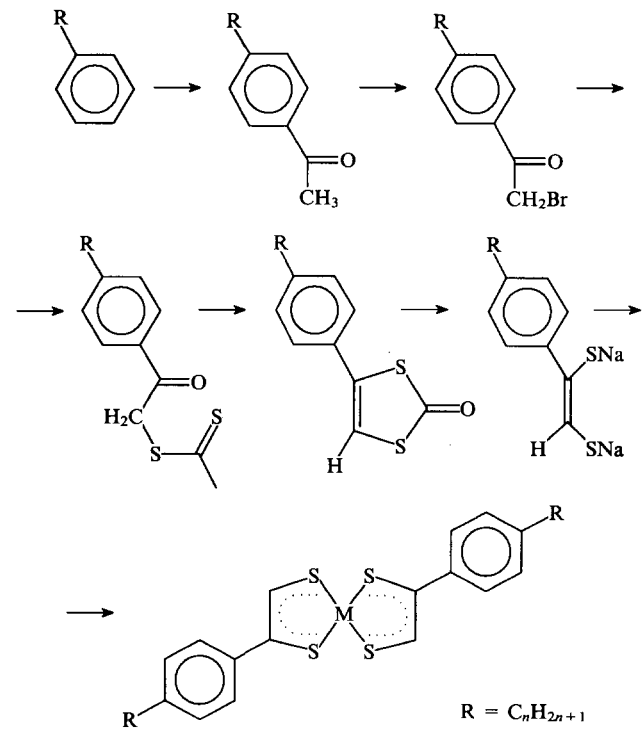
observed for compounds exhibiting monotropic nematic mesomorphism (Fig. 8*c*). It is of interest that the corresponding noncoordinated ligands form smectic phases.[70]

Nematic mesophases of the enantiotropic or monotropic types[71] (except for one case where a smectic mesophase was found) have also been observed for a large number of similar complexes in which one of the phenyl rings has been replaced by a cyclohexyl or fluorophenyl ring.[71] In contrast to the previous group of complexes, here the mesomorphism of the ligands themselves is more varied. Nematic phases and smectic mesophases of different types have been observed for such ligands.

So far few mesogenic complexes of other metals with β-diketonate ligands have been found. One may mention the octahedral complex of trivalent iron[7] $Fe(RCOCHCOR)_3$, which

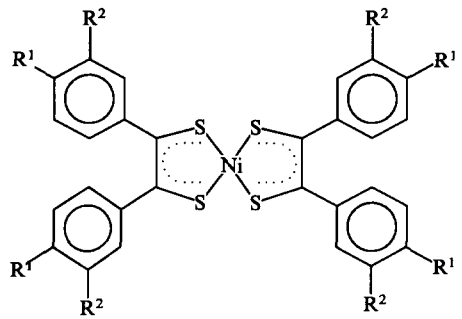


R = $C_{10}H_{21}O$

is apparently the first example of an octahedral metallomesogenic substance, and mesogenic oxovanadium(IV) complexes[72] for which discotic hexagonal columnar phases D_h have been found.

3. Mesogenic dithiol metal complexes

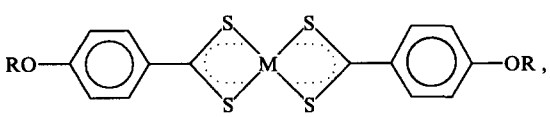
Dithiol complexes have structures similar to those of carboxylate complexes and, depending on the nature of the terminal substituents, it is possible to observe nematic, smectic, or discotic phases for such compounds. We shall describe the first series of dithiols, one of the most thoroughly investigated, which have been synthesised in accordance with the following scheme.[73-76]



The above complexes (M = Ni, Pt)[75] exhibit nematic mesomorphism for n = 4 and 5 and form the SmA phase when $n \geqslant 6$.

A structural study on a single crystal of the nickel complex (n = 8) showed[76] that the coordination of the metal atom is planar and the substituents are distributed in the *trans*-orientation, which is the reason why the molecule has the shape extended to the maximum degree. The molecules in the crystal are packed in layers, which is apparently a precondition for the manifestation by these compounds of smectic mesomorphism.

It has been suggested that the molecules of dithiol complexes, having appreciable electron-accepting properties, can form charge-transfer complexes (CTC) with electron-donating molecules, for example, with liquid-crystal derivatives of tetrathiofulvalene.[77] However, it has been found that the compounds synthesised do not form charge-transfer complexes.[77] On the other hand, they can be used in a mixture with cyanobiphenyls as laser dyes.[78] Finally, it has been noted[75] that palladium complexes do not exhibit the properties of liquid crystals for the entire series of homologues, in contrast to the analogous nickel and platinum complexes. The authors believe that the reason for this difference is the dimerisation of the palladium complexes as a result of the metal–metal interaction, which predominates over the dispersion forces.

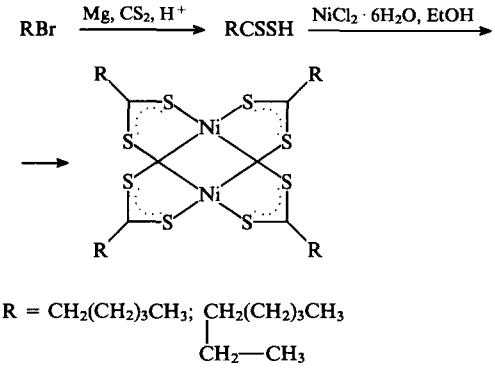


Complexes with two phenyl substituents in each dithiol ligand, whose structure is similar to that of the diphenyl-substituted β-diketonates, also exhibit discotic mesomorphism, the type of mesophases being different for complexes with monosubstituted and disubstituted phenyl groups.

For the monosubstituted phenyl derivatives with four substituents $R^1 = p\text{-}C_nH_{2n+1}$ (n = 8–12), R^2 = H and $R^1 = p\text{-}C_nH_{2n+1}O$ (n = 7–12), R^2 = H, the formation of only layered discotic phases has been established.[79,80] The search for columnar phases in compounds of the above type has continued, since these compounds could have interesting electrochemical properties. It has been observed[81] that the introduction of two alkyl substituents $R^1 = R^2 = p\text{-}C_nH_{2n+1}$ (n = 6, 8) does not lead to the formation of a mesophase at all, while the compound with the alkoxy-substituents $R^1 = R^2 = p\text{-}C_{10}H_{21}O$ forms a hexagonal phase D_{hd} with disordered columns (the hexagonal lattice parameter is 32.7 Å and the distance between the mobile alkyl chains is 4.4 Å). Subsequently the entire series of complexes with $R^1 = R^2 = p\text{-}C_nH_{2n+1}O$ (n = 1–12) was investigated systematically.[82] It was found that all the complexes with $n \geqslant 5$ form enantiotropic discotic phases D_{hd}, while the first members of the series (n = 2–4) form monotropic discotic phases. The half-wave potential for the reduction of these complexes is independent of the length of the substituents and its values are close to −0.05 to 0.06 V. This is somewhat smaller than the value for the unsubstituted complex, which indicates the independence of the electrochemical properties of the mesogenic nature of the specimens.

4. Metal dithiocarboxylate complexes

By analogy with metal carboxylates, it was natural to expect the manifestation of mesogenic activity by thiocarboxylates. Their synthesis and study by differential scanning calorimetry and X-ray diffraction[83] did indeed confirm the validity of such hypotheses. The mesogenic properties of the complexes $M(C_nH_{2n+1}OC_6H_4CS_2)_2$,



where M = Zn, Ni, or Pd and n = 4–10, were investigated.

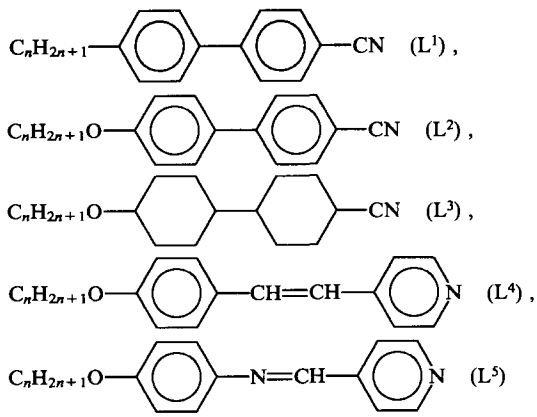
An analogous mercury complex, described by Adams et al.,[83] has also been mentioned.[7] The replacement of the metal in the complex leads to the appearance of different types of mesophases. For example, for n = 8 the zinc complex forms only nematic phases, whereas the palladium and nickel complexes give rise to several smectic phases in addition to the nematic phases. This may be associated with the different types of coordination of the metal in these complexes. Thus a tetrahedral coordination is usually characteristic of zinc, although in the case of the complex with n = 4 dimers were found in the crystal in which the eight-membered ring Zn–S–C–S–Zn–S–C–S is present. In the crystal of the planar palladium complex, the metal atoms are involved in an additional coordination as a result of the interaction with the sulfur atoms of neighbouring molecules (the intramolecular Pd–S distances are 2.29–2.35 Å and the intermolecular Pd ... S distances are 3.38 Å). A similar molecular packing was found also in the mercury complex: the Hg–S distances within the complex are significantly nonequivalent, amounting to 2.41 and 2.96 Å, while the lengths of the Hg ... S intermolecular contacts are 3.36 Å.

It has been stated[84] that the palladium and nickel complexes exhibit a significant dichroism: after the passage of light along the molecular axes, the extinction coefficient is appreciably higher than in the case where light is transmitted at right angles. This property may be used to devise displays of the 'guest–host' type. For example, the nickel complex can serve as the guest in the cell, while the host is an organic liquid-crystal compound. If the molecules are oriented at right angles to the direction of light in the absence of an electric field and parallel to this direction in the presence of the field, then in the former case the cell is coloured purple while in the latter it is transparent.

Gold(III) alkoxydithiobenzoate complexes $ROC_6H_4CS_2AuCl_2$, forming SmA phases on heating, have been investigated.[84]

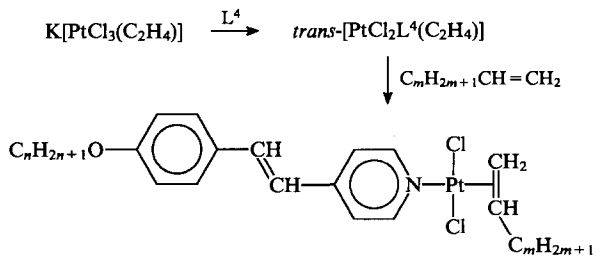
Apart from the nickel(II) bisthiocarboxylate complexes, the synthesis and properties of nickel(II) tetrakisdithiocarboxylate complexes have been described.[84,85]

Two series of tetrakis-complexes with linear and branched alkyl substituents were obtained.



The results of differential scanning calorimetric and X-ray diffraction studies have shown that complexes with linear chains form monotropic lamellar (layered) discotic phases of the type D_l, whereas the presence of an enantiotropic discotic phase with a hexagonal columnar ordered arrangement of the type D_{hd} is characteristic of complexes with a branched alkyl chain. On heating of the given substance or on its dissolution in chloroform, the tetrakis-complexes are converted into the bis-complexes.

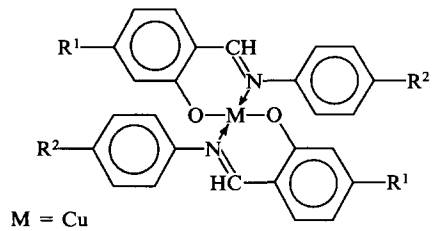
5. Mesogenic metal complexes with monodentate nitrogen-containing ligands



The widely known organic mesogenic substances, containing a nitrogen atom capable of forming a coordinate bond, can serve as monodentate ligands. Such mesogenic substances form metal complexes in reactions with platinum group metal halides or carbonyls. The complexes may contain one or two mesogenic ligands. Their properties have been thoroughly investigated. For example, the mesogenic properties of the free ligands and complexes with different metals have been compared.[7,86]

The majority of complexes of the type ML^2Cl_2 (M = Pt, Pd; n < 9) exhibit only nematic mesomorphism. With increase in chain length, smectic SmA and/or SmC phases are also observed.

The introduction into the complex of two different ligands, for example π-olefin and monostilbazole ligands, leads to an appreciable decrease in the temperature of the appearance of the mesophase. Such complexes were synthesised in accordance with the following scheme:[7]



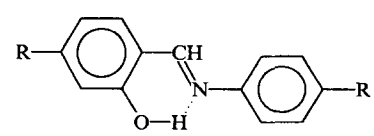
The presence of L^4 and L^5 ligands makes it possible to classify these complexes both as coordination and as organometallic compounds. The mesogenic properties of the complexes depend on the overall length of the alkyl chains of the two ligands. For $m+n < 8$, such complexes are nonmesogenic, forming a SmA phase with increase in chain length. They are monotropic for $m+n = 8-11$ and enantiotropic for $m+n > 11-13$.

6. Salicylideneamine metal complexes

The liquid-crystal properties of copper complexes of Schiff bases have been vigorously investigated in recent years. The synthesis of such compounds was first described by Ovchinnikov et al.[87] They obtained Schiff bases as a result of the interaction of 4-*n*-heptyl-oxy-2-hydroxybenzaldehyde with substituted anilines, after which the corresponding complexes were isolated by treating the bases obtained with copper acetate in ethanol.

M = Cu
$R^1 = OC_7H_{15}$
R^2 = H, F, CH_3, OC_nH_{2n+1} ($n = 1-8$)

In order to elucidate the influence of the nature of the metal atom on the mesomorphic properties, the analogous compounds with M = Zn, Co, Ni, Pd, and also VO were synthesised[88] ($R^1 = p$-OC_7H_{15}; $R^2 = p$-OC_8H_{17}). These compounds were obtained by refluxing in ethanol the corresponding metal acetate (potassium tetrachloropalladate was used for the palladium complex) with 4-heptyloxysalicylaldehyde and subsequent addition of 4-octyloxyaniline to the reaction mixture.



Studies by polarisation polythermal microscopy and differential scanning calorimetry showed that the substances obtained (Table 2) can be divided into two groups in terms of the nature of the phase transitions. The first includes copper, palladium, and vanadyl complexes, which have the properties of liquid crystals manifesting smectic or nematic mesomorphism. The second group includes cobalt, zinc, and nickel complexes, which in most cases do not form mesophases.

In order to establish the relation between the structure and liquid-crystal properties, single crystals of the metal complexes of the above series were investigated by X-ray diffraction, EPR spectroscopy, and electronic spectroscopy and also by the method involving low-angle X-ray scattering in the mesophase. Conformational calculations and calculations of the intermolecular interaction energy (IMIE) in the crystal were carried out on the basis of structural data.

In considering the complexes **1**–**13** in Table 2, we concentrated attention on the geometry of the metal chelate unit, because the ability of the metal complexes to exhibit mesomorphism is to a large extent determined by the coordination of the metal atom. Depending on the type of coordination of the metal, the molecules can assume a form with different degrees of anisometry, which plays a decisive role in the formation of the mesophase. Furthermore, as will be shown below, the liquid-crystal properties depend significantly on the possibility of the additional intermolecular coordination of the metal atom.

From the standpoint of understanding the causes responsible for the mesophase, compounds **1** and **2** proved to be the most important.[8,89] The crystal structures of these complexes are made up of two systems of symmetrically independent molecules with different coordinations of the copper atoms. In compound **1**, both molecules exist[8] in specific positions at the centre of symmetry and on the twofold axis (Fig. 9). The centrosymmetric molecules contain a copper atom involved in *trans*-square planar coordination, while the copper atom in the molecules on the two-fold axis is involved in a tetrahedral coordination characterised by a dihedral angle of 60° (angle of twist) between the coordination planes of copper, nitrogen, and oxygen of the two ligands. In the structure of complex **2**,[89] one of the independent molecules is also located at the centre of symmetry, which predetermines the *trans*-square planar coordination of the metal, while the other occupies a general position with an approximate C_2 crystallographic symmetry and an angle of twist of 31°. A similar disposition of two independent molecules has been found[90] for the crystal of compound **3**, which is isostructural with compound **2**. The different coordinations of the copper atoms in the crystals of compounds **1**–**3** lead to different Cu–O and Cu–N bond lengths. For the tetrahedral coordination, these bonds are shorter, which is characteristic of complexes of the type considered.[100]

Comparison[8] of the conformations of the ligands in compound **1** with that of the similar noncoordinated nematogenic molecules of *p*-ethoxy-[101] and *p*-(n-propoxy)-salicylidene-*p*-(n-butyl)aniline[102] (ESBA and PSBA respectively) showed that the formation of the complexes does not entail significant changes in the conformation of the ligands. In particular, both in the complexes and in the noncoordinated molecules the benzene rings of the nitrogen atom have been significantly rotated relative to the chelate unit, while the benzene rings condensed with the unit are virtually coplanar with the latter (in ESBA and PSBA, the six-membered chelate ring, closed by a hydrogen bond, is entirely planar, while in the metal complexes the planar fragment of the chelate unit is made up of five nonmetal atoms). In both cases, the significant rotations of the benzene rings can be accounted for by intramolecular steric interactions.

R = OC_2H_5 (ESBA),
R = OC_3H_7 (PSBA),

Analysis of the configurations of the planar molecular complexes showed[95] that such molecules are incapable of forming the discotic mesophases postulated initially.[87] A discotic mesophase is not formed owing to the lack of an overall planar anisometry characteristic of it.[2] This is associated with the

Table 2. Phase transition temperatures (°C) and the type of coordination of the metal atoms in complexes of Schiff bases.

rotation of the benzene rings[90] and with the stepped form of the coordination unit in molecules with the *trans*-square planar coordination of the metal atom.[95]

It was stressed for the first time[95] that, for the manifestation of mesomorphism, the square planar coordination is preferable to the tetrahedral coordination. Molecules with a *trans*-square planar coordination of the metal are characterised by a shape extended to the maximum extent by virtue of the parallel arrangement of the axes of the ligands (the angle of twist is 0°). On the other hand, the tetrahedral coordination leads to the rotation of the ligands relative to one another, which results in a decrease in the anisometry of the molecules. Thus the angle between the long axes of the ligands in the tetrahedral† molecules of compound **1** is[8] approximately 20°, but the most striking decrease in anisometry was manifested in a tetrahedral cobalt complex[91] (Table 2, compound **4**), in which the analogous angle of rotation is about 100° (Fig. 10). The absence of anisometry in the molecules has also been observed for an octahedral cobalt complex[91] (Table 2, compound **5**; Fig. 11).

†Here and subsequently in the text, the terms tetrahedral and planar molecules imply molecules with the corresponding coordination of the metal atom.

Thus the tetrahedral and octahedral coordinations of the cobalt atoms in complexes **4** and **5** actually preclude the formation of the mesophase in these compounds. The same causes

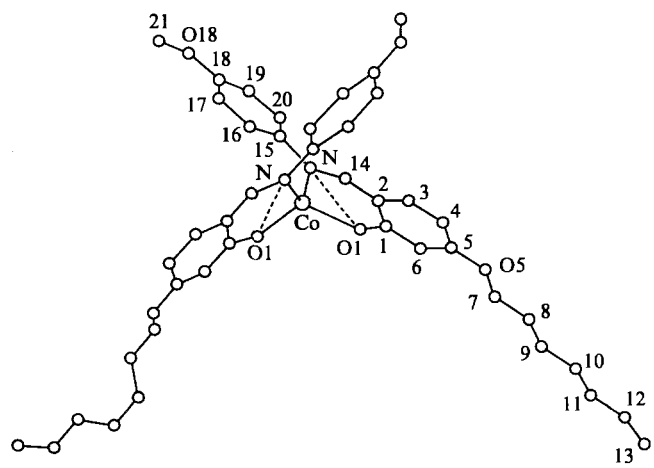

Figure 10. Molecular structure of a tetrahedral cobalt complex.[91]

apparently explain the absence of mesomorphism in zinc complexes with similar ligands as in complex **4**, because these compounds have the same structures.[91] An additional confirmation of the similarities of the structures of the zinc complexes and compound **4** is provided by the description[103] of the structure of a zinc complex of a Schiff base (R^1 = H; R^2 = CH_3), in which the metal atom has a tetrahedral coordination.

The presence in complexes **1**–**3** of two types of coordination of copper atoms indicates the conformational nonrigidity of the coordination metal unit. Therefore both planar and tetrahedral molecules may be present in the smectic phase.[8] This hypothesis was confirmed by the results of EPR studies. Bichkantaev et al.[104] investigated a single crystal of compound **1**, the EPR spectrum of which consists of a single Lorentzian line for all orientations of the crystal despite the presence of different types of complexes. The g-factors and their directions {g_1 = 2.2080, $\mathbf{n}_1$ = (0, 1, 0); g_2 = 2.0985, $\mathbf{n}_2$ = (0.866, 0, 0.5); g_3 = 2.0590, $\mathbf{n}_3$ = [$\mathbf{n}_1$, $\mathbf{n}_2$]} are inconsistent with the magnetic parameters of the individual complexes and are a result of the partial averaging of molecular g-factors due to spin exchange. The knowledge of the crystal structure of complex **1** made it possible to find the molecular magnetic parameters of each of the two types of complexes: $g_\perp^p \simeq 2.049$ and $g_\parallel^p \simeq 2.190$ ($g_o^p \simeq 2.096$) for the planar molecules and $g_\perp^t \simeq 2.068$ and $g_\parallel^t \simeq 2.298$ ($g_o^t \simeq 2.144$) for the tetrahedral molecules (g_i^t is greater than g_i^p, which is characteristic of distorted copper complexes). These g-factors made it possible to interpret subsequently the EPR spectra of the tested complexes in different phase states. In particular, it has been established for compounds **1**–**3** as well as other homologues of this series[105] that the isotropic melt actually consists of planar complexes giving rise to only one line in the EPR spectrum. Two independent lines with g-factors close to the values found for the planar and tetrahedral molecules in a single crystal of compound **1** are present in the spectrum of the mesophase (Fig. 12). It is postulated that the viscous mesophase proper is in fact formed by planar complexes, while the tetrahedral complexes are present in it as isotropic 'impurity' drops of low viscosity,[105] i.e. these molecules are separated in space.

The conformational changes in the chelate unit (*trans*-square planar → tetrahedral coordination), arising in some of the molecules during the liquid → smectic mesophase phase transition, suggest that the planar molecules are favoured by energy factors compared with the tetrahedral molecules. The corresponding calculations[89] based on the real molecular structures of compound **1** show that the conformational energy of the planar molecules is indeed smaller by ~5 kcal mol^{-1} than that of the tetrahedral molecules.

We believe that there is no doubt about the fact that two types of coordination of the metal atoms occur for copper complexes in the smectic mesophase, i.e. both planar and tetrahedral molecules are present in the mesophase. However, the specific structure of such a mesophase requires further refinement, because the claim[105] that the planar and tetrahedral complexes are separated in space is not unquestioned. Such separation actually implies the separation of the mesophase into layers, as a result of conformational transformations due to the different coordinations of the copper atoms. However, one should bear in mind that the tetrahedral complexes are nevertheless fairly anisometric, although to a lesser extent than the planar complexes, because the rotations of the ligands (~20° in compound **1** and ~10° in compounds **2** and **3**) are not so pronounced as in the classical tetrahedral complex **4** (~100°). It therefore appears doubtful that the planar molecules displace the tetrahedral molecules from their matrix, which would result in the latter being grouped together to form nonmesogenic 'impurity' drops.

The available information about the crystal packing in mesogenic substances is very useful, since certain features of the disposition of the molecules, i.e. different types of molecular associated species which are retained to some extent in the liquid-crystal state, are inherent in the mesogenic crystal. This was first pointed out by Bernal and Crowfoot[106] as early as 1933. It is essential to note that molecular packing is analysed not only with geometrical criteria (the presence or absence of layer motifs, parallel arrangement of molecules) but also energetic criteria[107] involving the analysis of the energy of molecular pair interactions. Here use is made of the concept of the structural subclass describing the relative orientation and symmetry of the molecular associated species most strongly bound by nonvalence interactions. The search for such associated species is based on the calculation of the intermolecular interaction energy by the method of atom–atom potentials. This procedure was first applied to liquid crystals by Polishchuk et al.[108] The advantage of this method, like that of conformational calculations, also based on the atom–atom approximation, consists in the fact that it operates with the structures of specific molecules and not with the approximation to the latter in the form of structureless formations (rods, discs, etc.).

A layered disposition of molecules is characteristic of the crystalline complexes **1**–**3** (Fig. 9). For compound **1**, this has been confirmed by the IMIE calculation, according to which the intralayer energy exceeds the interlayer energy by a factor of ~3.5.[8] We may note that the crystals of compounds **1**–**3** are unique objects as regards both structure (they consist of different conformers) and magnetic properties, because the magnetic interaction between the molecules within the limits of the layer is much stronger than between the layers, i.e. these objects constitute dimeric magnetic systems (see, for example, Bichkantaev et al.[104]). This is associated with the fact that the closest distance between the copper atoms in the layer is 6.5 and 5.5 Å whilst that between the layers is 21.8 and 24.7 Å for compounds **1** and **2** respectively (in the crystal of compound **3**, these distances are close to those in that of compound **2**). The data indicated above have led to the conclusion[8,89,90] that the explicit layered character of the molecular packing in compounds **1**–**3** actually predetermines the smectic mesomorphism of the above compounds.

Low-angle X-ray studies have shown that the thicknesses of the SmA layers in compounds **1** and **2** (d_1 = 23.6 Å, d_2 = 26.0 Å) agree with the lengths of the ligands in the corresponding complexes. Comparison of these quantities with the overall length of the molecules (30 Å in compound **1** and 26 Å in compound **2**) made it possible to put forward[109] the following models of the structures of these phases. In the case of compound **2** and also of its isostructural homologue **3** (d_3 = 26.1 Å),[90] in which the length of the molecular complexes is approximately equal to the length of their ligands, the structure of the SmA phase is usual in the sense that the thickness of the layers is specified by the overall length of the metal complexes. This is associated with the fact that in the complexes, having a transoid form, the geometrical parameters of the substituents R^1 and R^2 (Table 2) are approximately the same. On the other hand, owing to the different nature of R^1 and R^2, the overall length of the transoid complex **1** exceeds the dimensions of its ligands by a factor of approximately 1.3. Therefore the most reliable model of the layered structure of the mesophase of compound **1** is believed[109] to be that based on the crystal packing of the projection–hollow type. Fig. 9 illustrates schematically the molecular packing in the mesophase, showing the mutual migration of molecules from one layer to the other. We may note that the closest interlayer distances in the crystals of compounds **1** ($a/2$ = 21.8 Å) and **2** (c = 24.7 Å) are similar to the thickness of the layers in the mesophases (23.6 and 26.0 Å). A similar picture is observed in the smectic mesophases of the homologues with $R^1 = OC_7H_{15}$ or $OC_{12}H_{25}$ and $R^2 = C_4H_9$. Low-angle X-ray studies[110] indicate the mutual interlayer penetration of the fused alkyl 'tails' and the possible formation of pairs of copper atoms within the layers.

In order to confirm the importance of the *trans*-square planar coordination of the metal atom for the establishment of liquid-crystal properties in complexes of Schiff bases, structural and spectroscopic studies have been carried out[92] on the palladium complex **6**. It is of interest to compare the coordinations of the metal atoms and the mesomorphic properties of the palladium and copper complexes.

The replacement of copper in compound **1** by palladium does not entail a significant change in the structure of the planar molecules.[92] However, in contrast to the crystals of compounds **1**–**3**, in which both planar and tetrahedral molecules are present, the crystal structure of compound **6** is made up of only planar molecular complexes located at the centres of symmetry. The *trans*-square planar coordination of the palladium atom then remains unchanged in all phase states. This is indicated by the presence of the absorption band with λ_{max} = 402 nm in the electronic spectra of both crystalline modifications of the solution and the vitrified mesophase.[92] A similar absorption band has been attributed[111] to the square planar coordination of the palladium atom in complexes of Schiff bases.

The layered disposition of the molecules in complex **6** (Fig. 13) has been confirmed by IMIE calculations.[92] It has been noted that the presence of only planar molecules in compound **6** alters the intermolecular interaction compared with compound **1**. It is believed that the planar molecules, arranged one on top of another, interact more strongly than only tetrahedral or planar and tetrahedral molecules. This is due to the greater number of van der Waals contacts between the planar molecules, which increases their intermolecular interaction energy. The energies of the maximum pair interactions of the molecules in the layers of compounds **6** (−13.5 kcal mol^{-1}) and **1** (−11.0 kcal mol^{-1}) may be quoted to confirm this. Under these conditions, the layers in compound **6** are energetically more distinct ($U_{layer}/U_{interlayer} \simeq 5$ for compound **6** and 3.5 for compound **1**), which naturally predetermines the formation of a layered mesophase. According to Polishchuk et al.,[92] the above factors influence appreciably the range of existence of the smectic mesophase and its thermal stability, which are appreciably greater for compound **6** than for compound **1** (Table 2).

Despite the inclination of the long axes of the molecules of compound **6** relative to the layer boundary, the layered packing is similar in crystals of compounds **1** and **6**; in both cases, the arrangement of the molecules is of the projection–hollow type. Evidently, in the formation of the SmA phase the inclination of the molecules of compound **6** changes, but the characteristic features of close packing remain. This is indicated by the equal thicknesses of the smectic layers: d_6 = 23.7 Å and d_1 = 23.6 Å. Thus, in both cases the periodicity of the smectic layers is determined not by the overall length of the complexes but by the sizes of their ligands, which corresponds to distance of 22.64 Å in the crystal of compound **6** (Fig. 13).

The *trans*-square planar coordination of the metal atom has been observed also in the palladium complex **7**, having the same substituents as compound **3** (Table 2). However, in contrast to the crystal of compound **3**, in compound **7** there are only planar molecules, forming layers and evidently, as for complexes **1** and **6**, such coordination leads to higher phase transition temperatures in compound **7** than in compound **3**.

The absence of mesomorphism in the nickel complex **8** proved unexpected.[94] This complex has the same structural characteristics as the palladium complex **6** because these compounds are isostructural. It has been established that the crystals of compound **8** fuse at two temperatures (138° and 155 °C) but they do not form a mesophase, which is indicated by the absence of textures characteristic of liquid crystals in observations under a polarisation microscope. It has been noted[94] that, after the first fusion (138 °C), a dark green isotropic amorphous phase is formed, the outward form of which changes little in the second phase transition (155 °C). It is remarkable that, on repeated heating (after 24 h) of the cooled melt of compound **8**, the phase transition occurs at 348 °C and is accompanied by the decomposition of the specimen.

The authors[94] see the reason for such behaviour in the change of the coordination of the nickel atom during the fusion of the

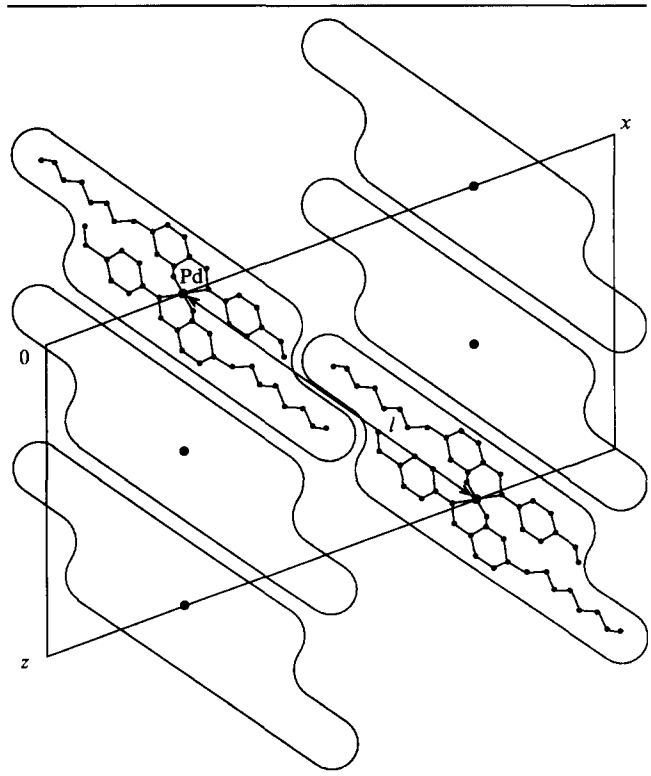

Figure 13. Molecular packing in a palladium complex. The overall form of the molecules arranged in accordance with the projection–hollow principle is indicated; l = distance between the molecules in neighbouring layers in the direction of long axes.

substance. Nickel complexes with a planar geometry of the coordination unit are diamagnetic, while those with a nonplanar coordination are paramagnetic.[112-114] The crystals of compound **8**, with a square planar coordination of the nickel, are indeed diamagnetic, which is indicated by the absence of an EPR signal in the powder of this compound at −196 °C. However, after heating to 140 °C and subsequent cooling of the melt to −196 °C, two broad lines appear in the EPR spectrum with effective *g*-factors of ~7 and ~3, indicating the transition of the test substance to the paramagnetic state. A similar situation arises[94] on fusion of the initial specimen of complex **8** to 160 °C.

Unfortunately, owing to the short spin relaxation times of the nickel compounds, their EPR signal can be recorded only at temperatures close to that of liquid nitrogen. The configurational transitions of the molecules involving a change in the coordination of nickel cannot therefore be observed by the EPR method during the heating of the specimen and directly in the melt. Studies have therefore been made[94] on the electronic spectra of the diamagnetic complex **8**, which showed that in solution in chloroform the spectrum exhibits absorption bands with maxima at 354 and 610 nm. On the other hand, an additional maximum appears in the region of 1005 nm in the spectrum of the melt after the first phase transition. These bands are retained also after the second phase transition with a slight change in their shape. According to Yamada and Takeuchi,[112] these data show that the diamagnetic complex **8** retains in solution its initial planar configuration of the unit, but on fusion and in the melt it most probably assumes a tetrahedral configuration. On the basis of the above facts, it is concluded[94] that the planar molecules of the initial specimen of compound **8** assume the tetrahedral configuration during fusion (there is a possibility of another nonplanar configuration — the octahedral configuration), which is an unfavourable factor for the establishment of the liquid-crystal state.

It is stated in a review[115] that an equilibrium mixture of isomers with planar and nonplanar structures exists as a rule in solutions of nickel complexes of Schiff bases and that the free energy of their interconversion is low (ΔG = 0.15–0.20 kcal mol^{-1} depending on the nature of the substituents in the ligands). One may postulate that the equilibrium in the melt of complex **8** is displaced towards the isomer with a nonplanar metal chelate unit. Finally, it has been noted[94] that yet another possible cause of the absence of mesomorphism in compound **8** may be a significant change in molecular structure, for example, polymerisation of the compound on fusion; the polymeric specimen then melts with decomposition at a high temperature (348 °C).

The square planar coordination of the copper atoms is very often built up to the tetragonal-pyramidal or octahedral configuration as a result of an additional intermolecular interaction. The influence of such coordination on the liquid-crystal properties of metal complexes of Schiff bases has been analysed.[95-98] Thus the copper atoms in the isostructural crystals of compounds **9** and **10** (Table 2) are in general positions and have the *trans*-square planar coordination. However, in contrast to compounds **1**–**3**, this coordination is built up to the square pyramidal as a result of the Cu ... O intermolecular interaction [the oxygen atom belongs to the metal chelate ring of a neighbouring molecule (the corresponding Cu ... O distances are 2.60 Å for compound **9**[95] and 2.62 Å for compound **10**[96])]. Such additional interaction leads to the formation of centrosymmetric coordination dimers (Fig. 14) in which the distance between the copper atoms is 3.44 Å in compound **9** and 3.46 Å in compound **10**, which is appreciably less than in compounds **1**–**3**.

The dimers in the crystals of compounds **9** and **10** form a layered packing and under these conditions the intermolecular interaction energy in the layer exceeds the interlayer energy by a factor of 3.5 for compound **9** and 4.4 for compound **10**. We may note that, in the calculation of the intermolecular interaction energy, an attempt was made[8,95] to take into account not only the dispersion component (the '6-exp' potential) of the nonvalence interactions but also the electrostatic component. However, this could not be done correctly because

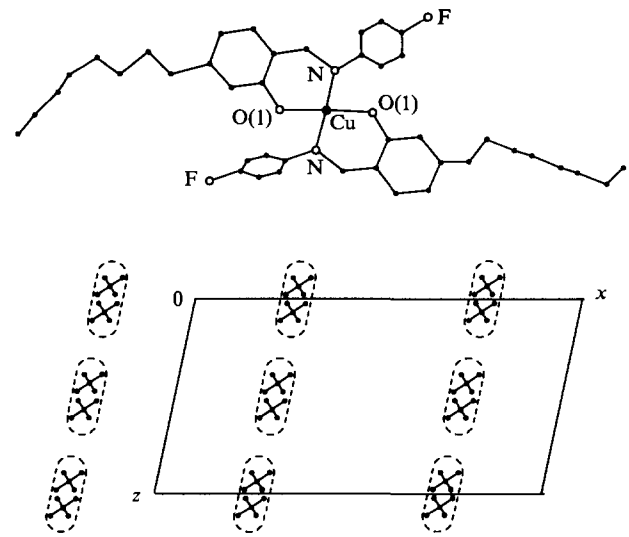

Figure 14. Molecular structure of the copper complex **9** and the packing of the central parts of the complex species in the crystal.[95] The centrosymmetric dimers are indicated by dashed lines.

it proved impossible to take into account accurately the charge distribution of the copper, nitrogen, and oxygen atoms by the semi-empirical methods employed. On the other hand, it was established that the additional intermolecular coordination enhances the interaction of the molecules in the dimers via the electrostatic component.

The observed ratio of the intermolecular interaction energies within the layers and between them for complexes **9** and **10** suggests the manifestation of smectic mesomorphism by the latter. However, an enantiotropic smectic mesophase is observed only for compound **9** (Table 2). It was assumed earlier that compound **10** does not exhibit liquid crystal properties at all (whilst the corresponding ligand does form a nematic phase[87]), but its more thorough investigation led to the observation of the monotropic SmA phase.[96] On cooling of the isotropic liquid, this phase appears just before the onset of crystallisation and exists in a very short time interval and over a very narrow temperature range. According to Polishchuk et al.,[96] the different mesomorphic behaviour of the isostructural compounds **9** and **10** can be accounted for by the different dissociation energies of the coordination dimers. This has been confirmed[95,96] by calculations of the intermolecular interaction energy: U_{dim} (**9**) = −13.9 kcal mol^{-1}; U_{dim} (**10**) = −15.2 kcal mol^{-1}. It has been noted[96] that the existence of dimers by itself need not necessarily be accompanied by the disappearance of liquid-crystal properties. Furthermore, if the dimers are characterised by an adequate anisometry, then mesomorphism is extremely likely. This is clearly seen in relation to *p*-n-alkoxybenzoic acids.[116] The O ... H–O bonds in these substances lead to the formation of dimers the anisometry of which exceeds significantly that of individual molecules. On the other hand, the dimers detected in compounds **9** and **10** have a smaller anisometry than the initial complexes of the monomeric compound. The length of such coordination dimers in fact remains the same as that of the monomer, while its transverse dimensions (or at least one of them) increase approximately by a factor of two. In this case, the dissociation energy of the dimers should play a decisive role in the formation of the mesophase. Its value should not be very great, so that the dimers do not decompose during the heating of the crystals even before the formation of the isometric liquid.

The hypothesis that the liquid-crystal properties depend on the presence or absence of coordination dimers has been confirmed by EPR studies. It has been noted[96] that he EPR spectra of compounds **9** and **10** are identical and that they are characterised by the presence of a fine structure and a forbidden

transition ($\Delta M_s = \pm 2$) (Fig. 15). When powdered compound **9** is heated, the EPR spectrum is modified at the instant of the formation of the SmA phase (130.1 °C, Table 2): the fine structure vanishes and a spectrum characteristic of monomeric copper complexes appears (Fig. 12).[105] The spectra indicate the absence of dimers over the entire range of existence of the SmA phase and also in the isotropic phase on further heating. We may note that the mesophase of compound **9** is characterised by a layer thickness of 22.4 Å, which is close to the length of an individual ligand. This finding indicates, as for the smectic phases of compounds **1** and **6**, an arrangement of the molecules of the projection–hollow type, which is characteristic also of the crystal structure itself, where the distance between the molecules in neighbouring layers is equal to half the maximum period $a/2$ = 19.91 Å.

Heating of compound **10** entails the same changes in the EPR spectrum as in the spectrum of compound **9**. However, in this case the fine structure due to the dimeric organisation of the molecules vanishes at the instant of fusion of the substance to the isotropic liquid (150.1 °C), in which only monomeric complexes are present.

Thus EPR data show that the dimers in compound **10** decompose at a higher temperature than in compound **9**, which is the reason for the monotropic smectic mesomorphism of compound **10**. In other words, the temperature range of the possible existence of the mesophase in compound **10** is, as it were, 'jumped over' on heating by virtue of the higher dissociation energy of the dimers compared with compound **9**. At the same time, the temperatures of the transition to the isotropic liquid are virtually identical for both compounds.

The negative influence of the additional intermolecular coordination on the formation of the mesophase was manifested even more evidently in the isostructural copper complexes **11** and **12** containing polar ligands. These compounds were obtained by procedures similar to those used for the compounds described by Ovchinnikov et al.[87]—by refluxing in absolute ethanol equivalent amounts of the 4-heptyloxy-*N*-(4′-cyanophenyl)- and 4-heptyloxy-*N*-(4′-nitrophenyl)-2-benzylidenehydroxyamine with copper acetate for compounds **11** and **12** respectively. In the crystal structures of compounds **11**[97] and **12**[98], the copper atoms occupy general positions and are characterised by a *trans*-square planar coordination. As in complexes **1**–**10**, the benzene rings in these compounds, condensed with chelate rings, are parallel to the planar fragments of the chelate rings, while the phenyl substituents at the nitrogen atoms have undergone significant rotation. At the same time, the presence of the polar CN and NO_2 groups in the ligands builds up the coordination of the copper atoms to the square-bipyramidal as a result of the Cu...N intermolecular interaction for compound **11** and the Cu...O interaction for compound **12**. Such additional coordination promotes the formation in these crystals of the so called infinite coordination strata, the thickness of which is determined by the transverse dimensions of the molecules (Fig. 16). The thickness of the layered associated species is determined by the length of the molecule and this constitutes the main difference between strata and layers. The presence of strata has been confirmed by calculations of the intermolecular interaction energy (without taking into account the electrostatic component), according to which the energy of the interaction of the molecules in the strata is approximately six times greater than that between them.[97] One has to assume that the additional intermolecular coordination intensifies to an even greater extent the interactions of the molecules in the strata via the electrostatic component, which is evidently responsible for the high temperatures of the conversion of compounds **11** and **12** into the isotropic state (Table 2).

According to Polishchuk and coworkers,[97,98] the formation of the mesophase by compounds **11** and **12** is accompanied by the disruption of the infinite coordination strata and the disappearance of the additional intermolecular coordination, which is similar to the decomposition of the dimers in compounds **9** and **10**. Indeed, when the crystals are heated, an isotropic liquid consisting of individual molecules with the anisometry of the molecular complexes characteristic of the square planar coordination of copper is formed. During the heating of the isotropic melt of compound **11**, the planar molecules form a nematic mesophase in a narrow temperature range near 10 °C, which vanishes following the onset of the restoration of the additional coordination, i.e. on crystallisation. In the case of compound **12**, the intermolecular coordination is evidently restored faster on cooling of the isotropic melt, as a result of which the crystallisation of the specimen sets in immediately. The absence of the liquid-crystal state for compound **12** (in contrast to the monotropic mesomorphism of complex **11**) is associated, according to the authors,[98] with the stronger additional interaction in the latter case. This is indicated indirectly by the intermolecular coordination distances. When account is taken of the van der Waals radii of the oxygen atoms (1.29 Å)[117] and nitrogen atoms (1.50 Å),[118] they are smaller for the complexes with the NO_2 group (Cu...O = 2.88, 2.91 Å[98]; Cu...N = 3.10, 3.47 Å[97]).

Thus analysis of the above studies[96–98] indicates the negative influence of the additional intermolecular coordination in

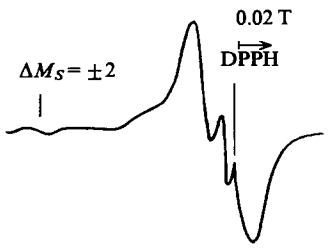

Figure 15. EPR spectrum of the powdered crystalline copper complex **10** at room temperature.[96] The presence of the fine structure and of the forbidden transition $\Delta M_S = \pm 2$ is due to the presence of coordination dimers.

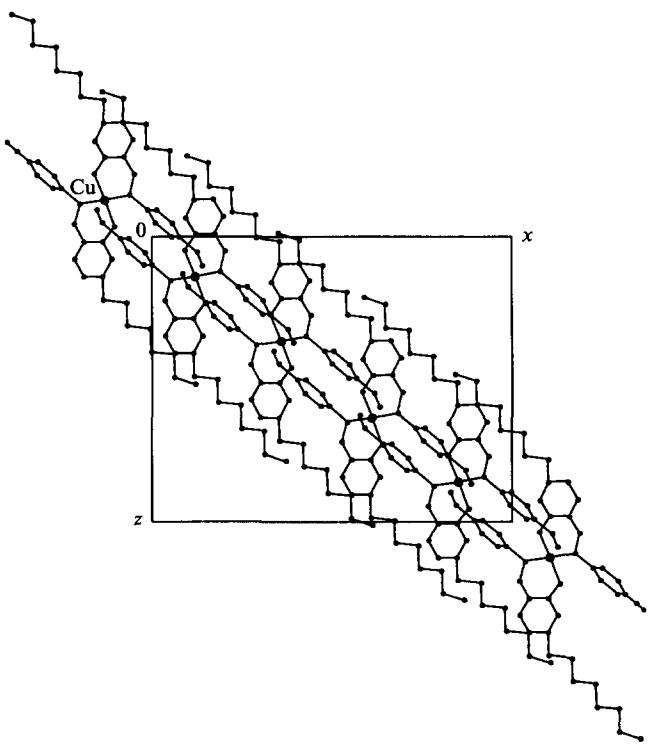

Figure 16. Molecular packing in strata in the crystalline copper complex **11**. Only the central stratum is shown. The thickness of the strata is determined by the transverse dimensions of the molecules.

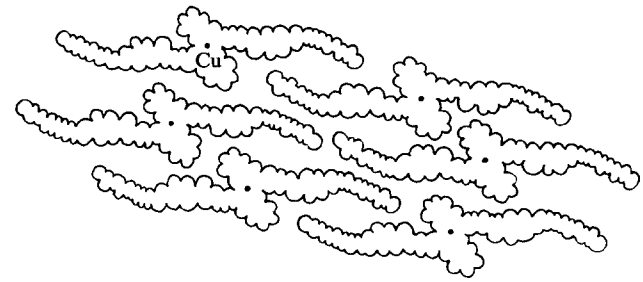
compounds **10**–**12** and the establishment of the liquid-crystal state, which is expressed either by the presence of only monotropic mesomorphism or by the absence of any kind of liquid-crystal properties. This claim is supported by the finding that individual ligands of the above complexes do exhibit mesomorphism.[87,119]

Among all the complexes of Schiff bases considered here, compound **13** exhibits the maximum molecular anisometry. In the crystal, its molecules are located[99] at the centres of symmetry and are characterised by a *trans*-square planar coordination of the copper atoms. The increase in the length of the mesogenic molecules intensifies the lateral interaction between them, which ensures the appearance of the smectic mesophase. We may note that the copper complexes tend in the main to exhibit smectic mesomorphism (Table 2), while their ligands form a nematic phase. This has been explained in a study,[96] where it was stated that transoid metal complexes are longer by a factor of 1.3–1.4 than their ligands. Furthermore, the lateral interaction of the metal complexes intensifies as a result of the greater number of benzene rings in the central part of the molecules. Taking these facts into account, one would expect the formation of the smectic phase of compound **13**, particularly since its ligands exhibit these properties (smectic phase A at 43–148 °C and a nematic phase at 148–164 °C). However, this compound forms only a nematic mesophase (Table 2), which is caused, according to Polishchuk et al.,[99] by the characteristics of the molecular packing, especially by the presence of chain associated species. Calculations of the intermolecular interaction energy showed that energetically segregated chains of molecules are formed in the crystal in the direction along the x axis and that the energy of the strongest interaction in them is -16.4 kcal mol^{-1}. The assembly of such chains forms strata parallel to the crystallographic xy plane. It is emphasised[99] that the energetic preference for the formation of strata (the interaction of the molecules within the strata is more than 8 times more intense than the interaction between the strata) is in the main associated with an intrachain interaction, which contributes about 55% to the total energy of the interaction of molecules in the strata. It has also been suggested[99] that this interaction intensifies still more via the electrostatic component, because the coordination of the copper atoms in the chains is close to the square-bipyramidal owing to the additional Cu ... O (3.94 Å) intermolecular interaction.

According to the authors,[99] the intense interaction between the molecules in the chain inhibits smectic isomorphism just as the dimers or coordination strata prevent the formation of the mesophase in complexes **10**–**12** examined above. However, such interactions were apparently insufficient to inhibit also the nematic phase. When complex **13** is heated, the formation of the nematic phase entails the rupture of the chain associated species without affecting at the same time the parallel arrangement of the long molecular axes characteristic of this mesophase. On cooling the melt of compound **13**, such associated species are not restored immediately owing to thermal motion and the temperature range of the existence of the nematic phase is appreciably extended (ΔT = 75 °C) compared with the analogous region arising on heating (ΔT = 5 °C, Table 2). In other words, the chain associated species in compound **13** prevent the appearance of the smectic mesophase both on heating and on cooling and, furthermore, cause significant narrowing of the temperature range corresponding to the existence of the nematic mesophase during the heating of the specimen.



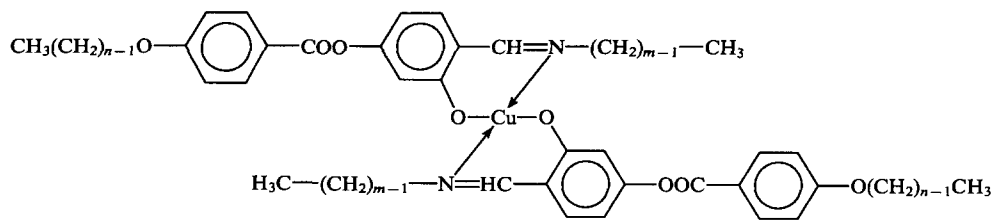


Figure 17. Model of the molecular packing in the nematic phase of the copper complex **13**.

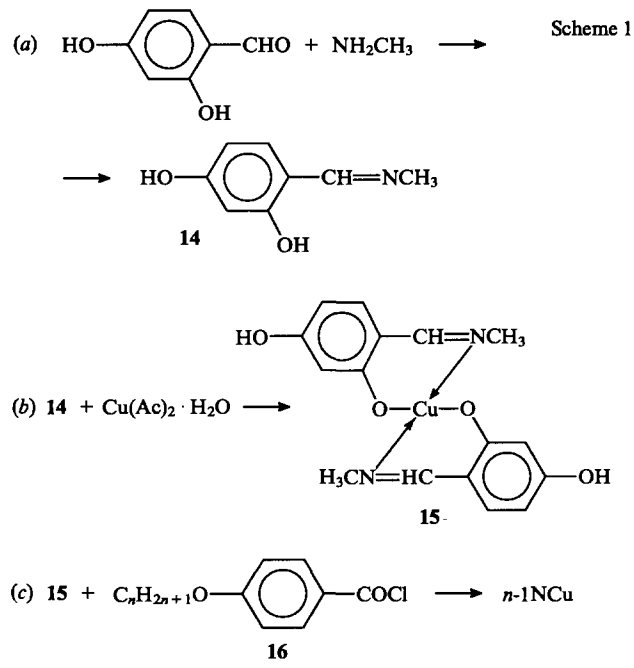
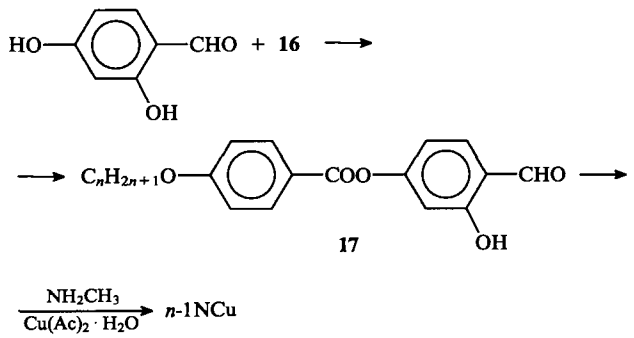
Together with the description of the dependence of the liquid-crystal properties on the additional coordination of the metal atom, much attention has been devoted by Polishchuk et al.[97–99] to the analysis of the geometrical characteristics of the molecular associated species. In particular, it is emphasised that[97] the formation of molecular strata is unfavourable for the manifestation of smectic mesomorphism. As mentioned above, the thickness of the strata in compounds **11** and **13** is determined by the transverse dimensions of the molecules, whereas in the classical smectogenic crystals the thickness of the layer is comparable to the longitudinal dimensions, i.e. the length of the molecules. Furthermore, in smectogenic crystals the interlayer interaction energy is largely determined by the 'end-face' interactions between the alkyl chains of the molecules in neighbouring layers (see, for example, Fig. 9). On heating such crystals, the 'fusion' of the chains, characterised in the crystalline state by high thermal parameters,[8] begins at lower temperatures compared with the central rigid fragments. As a result of such partial fusion, there is a possibility of almost free sliding of the smectic layers relative to one another. Such nature of the fusion with the initial increase in the mobility of the terminal alkyl substituents has been demonstrated by NMR[120] and EPR methods with the aid of spin labels in the aromatic and aliphatic parts of the molecules.[121] On the other hand, in crystals with a stratified structure the sliding of the strata relative to one another is difficult, because not only the atoms of the alkoxy-chain but also those of the central rigid fragments, characterised by significantly weaker thermal vibrations, participate in the contacts between the strata.



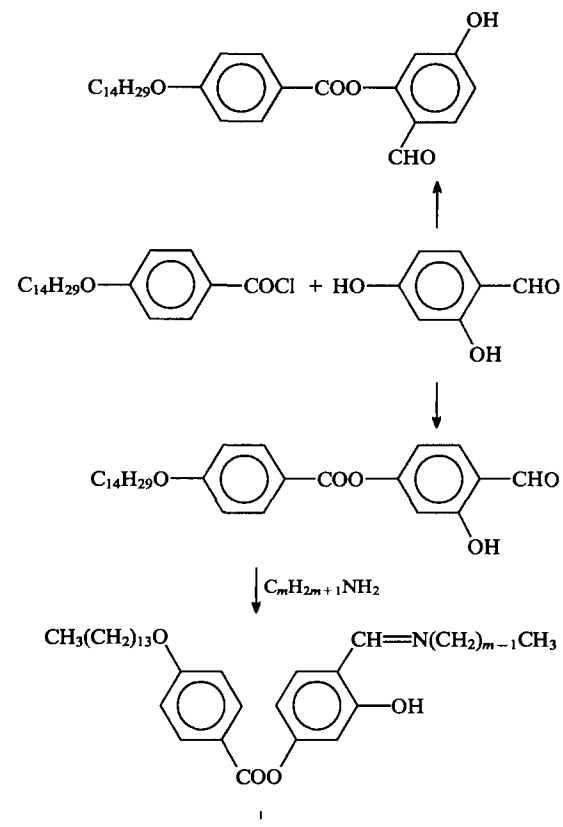
As in the smectic mesophases of compounds **1**, **6**, and **9**, the periodicity of the nematic phase in compound **13** (l_{13} = 34.0 Å) is determined by the length of the ligands (~37 Å). This leads to molecular packing of the projection–hollow type. However, in contrast to the smectic mesophases, in the nematic mesophase of compound **13** the intermolecular end-face contacts are varied. In particular, contacts between the carbon atoms of the condensed benzene rings, contacts between the same rings and the alkoxy-chains, and finally contacts between the chains themselves occur in this case (Fig. 17).

A series of studies devoted to new copper complexes with similar ligands have been published recently. Thus the synthesis and characteristics of the phase transitions in the metal complexes *n*-*m*NCu with the structural formula have been described by Caruso and coworkers.[122,123] The compounds with m = 1 and n = 6–14 (*n*-1NCu) were synthesised as follows.[122]



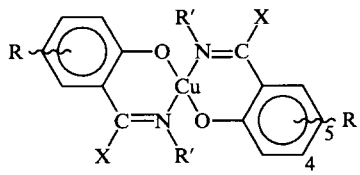
Complex *n*-*m*NCu

Scheme 1



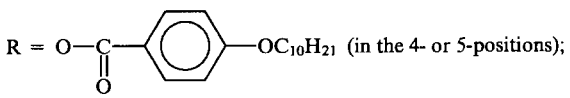
Scheme 2

The compounds with n = 7, 10, and 14 were obtained in accordance with Scheme 1, whilst all the others were obtained in accordance with Scheme 2. All the compounds with n = 6–14 can be obtained in accordance with one of the two schemes, but the authors[122] quote two schemes in order to illustrate different versions of the synthesis. All the compounds are enantiotropic mesogenic substances. For n = 6–9, only the nematic phase is observed, but, with increase in n from 10 to 13, both nematic and smectic phases appear. Finally, for n = 14 only the SmC phase exists. It is noted that in the above homologues there is no even-odd effect in the temperatures of the transition to the isotropic state and the enthalpies per unit mass are appreciably smaller compared with the usual organic mesogenic substances containing symmetrical alkoxy-chains of the corresponding length. It is of interest that in all the smectogenic homologues with n = 10–14 solid-crystal transitions were observed. Thus, in the compounds 13-1NCu and 14-1NCu, these transitions have been confirmed by X-ray powder diffraction studies. It is emphasised here that the layered character of the packing in the crystalline modifications, which are precursors of the mesophase, is correlated with the smectic mesomorphism.



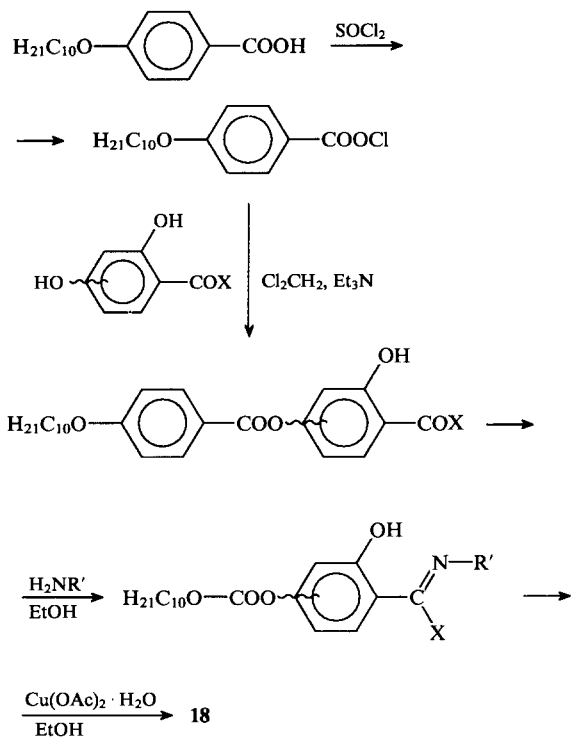
Data have been published[123] on the liquid-crystal properties in the homologous series of copper complexes containing alkylamino-groups with m = 2–15. The need to elucidate the dependence of the mesogenic properties on the length of the alkylamino-groups in the complex 14-1NCu, which itself forms only the SmC phase, led to the synthesis of these compounds.

The compounds with m = 2–15 (14-mNCu) were synthesised in accordance with the following scheme.



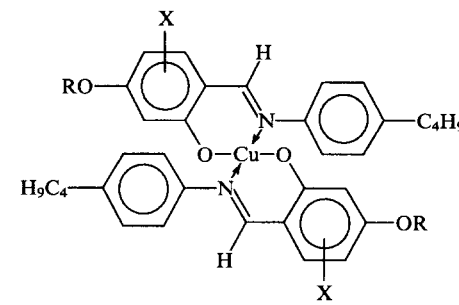
In the series of metal complexes 14-mNCu obtained, only the homologue with m = 2 has no liquid-crystal properties. This has been explained[123] by the impairment of the conditions for the effective packing of molecules along their short axis, which is induced by changes in molecular structure compared with the smectogenic homologue with m = 1. Evidently the conformation of the ethyl groups at the nitrogen atoms weakens the lateral interaction between the molecules. The presence of only the nematic phase N is characteristic of the homologues with m = 3–9, while the presence of the mesophases N and SmC is characteristic of the homologues with m = 10–15. Low-angle X-ray studies on the compounds 14-14NCu and 14-15NCu showed[123] that the periodicities of their smectic layers, amounting to 35.3 and 36.3 Å respectively, are significantly smaller than the analogous periodicity for the compound 14-1NCu (43.3 Å).[122] These results show that, despite the identical type of the mesophases (SmC), the molecular packing within smectic layers changes appreciably. These changes are most probably associated with the inclination of the long molecular axes with respect to the boundary of the layer, which is smaller for 14-1NCu. The majority of the compounds of the 14-mNCu series undergo solid-crystal phase transitions, which are not always reproducible and which depend on the rate of heating and cooling of the specimens. It has also been noted[123] that the crystals of certain homologues, obtained from solution and the melt, have different structures and melt at different temperatures. We emphasise that the solid-crystal polymorphism, characteristic of liquid-crystal compounds, is as a rule associated with conformational changes in the mobile groups, in particular in aliphatic chains. Cholesteryl benzoate, for which six modifications have been found[124] and the single crystals of three of them have been investigated by X-ray diffraction,[125] may serve as a typical example.

A more detailed analysis of the dependence of the liquid-crystal properties on the structural characteristics of the molecule has been carried out[126] for complexes of the type

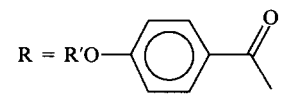


18

R' = CH_3, *p*-$C_{10}H_{21}$, $C_6H_4OC_{10}H_{21}$; X = H, CH_3.



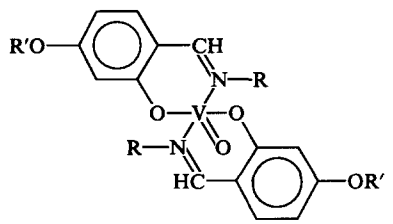
They were synthesised as follows:



Mesomorphism is characteristic of complexes of this kind (Table 3). Its manifestation is legitimately attributed to the molecular shape, which depends significantly on the disposition of the substituents (Figs 18 and 19). Table 3 shows that the complexes with X = H and R in the 4-position possess liquid-crystal properties and for R' = $C_6H_4-OC_{10}H_{21}$ two smectic phases, SmC and SmI, have been found. The latter has been identified as SmG.[10,127] The authors[126] mention particularly the different types of mesophases for *N*-alkylimines. For complexes with R' = CH_3, there exist both SmC and N mesophases, while for R' = *p*-$C_{10}H_{21}$ there is only an N mesophase. The reason for this is that the long and conformationally mobile decyl groups, parallel to the main molecular axis (Fig. 18), interfere with the establishment of the packing equivalent to the smectic mesophase. They can serve as a shield preventing interaction between the rigid aromatic rings of the molecules. On the other hand, the comparatively small size of the methyl groups makes it possible to increase the effectiveness of this interaction, which results in the appearance of the more ordered mesophase SmC and the thermal stability increases by 90 °C (Table 3). We may note that the interaction between the central parts of the mesogenic molecules should be optimum for the formation of the smectic mesophase. When the layers are insufficiently distinct in energetic terms, they do not persist during fusion. As a consequence of the unduly intense interaction (the presence of coordination dimers, chains, networks, etc.), the melting point increases and the temperature range corresponding to the smectic mesophase can be 'jumped over' under these conditions and in many cases there may be no mesomorphism at all. We believe that the second factor is the reason why only the nematic mesophase arises[128] at 223 °C in one of the representatives of the 2,4-hydroxy-derivatives of the complexes considered (X = H, R' = $C_6H_4-C_5H_{11}$, n = 4). It has been established that the copper atom is involved in a distorted square-pyramidal coordination with an angle of twist of 22° between the two coordination planes formed by copper, oxygen, and nitrogen atoms and is also involved in an additional interaction (Cu ... O = 3.04 Å) with the ester carbonyl group of a neighbouring molecule.

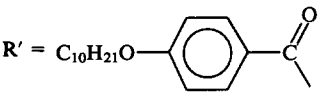
The overall structure of 2,5-dihydroxy-derivatives of the complexes differs appreciably from that of the 2,4-disubstituted derivatives. Such complexes can be represented schematically by a long rod with side substituents R', which prevent a parallel ordered arrangement of the molecules in the mesophase (Fig. 19). This is why only the *N*-methylamine complex (R' = CH_3, X = H) forms a mesophase (Table 3). For longer substituents R', such molecules undergo a decrease in their anisometry, as happens on replacement of a copper atom in complex **18** (see above) by a cobalt atom. The absence of liquid-crystal properties in the complexes with X = CH_3 is due to the steric effects of the methyl groups, which distort the square planar coordination of copper in the direction of tetrahedral coordination.[126]

The mesomorphism of copper complexes with halide substituents in the 3- and 5-positions has been examined.[129] It was noted that the overall anisometry of the molecular complexes and the transition temperatures vary little as a



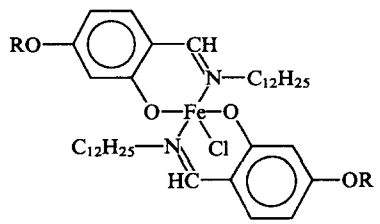
R' = C_nH_{2n+1}, n = 4, 8, 12, 16;
X = Cl, Br (in the 3- or 5-positions).

function of the positions of the halogen atoms.

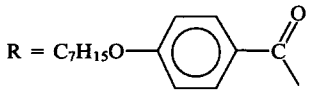


Complexes of other metals [VO[130,131] and iron(III)[132]] with Schiff bases have been investigated in lesser detail hitherto. In particular, the VO complexes (R = Me, C_5H_{11}, $C_{10}H_{21}$, etc.) described[131] have a square-pyramidal coordination and form both nematic and smectic (SmC) paramagnetic mesophases.

The synthesis of these compounds has been undertaken in order to obtain a biaxial nematic mesophase, but this attempt proved unsuccessful. Nevertheless, it has been observed that these compounds have a series of interesting properties.

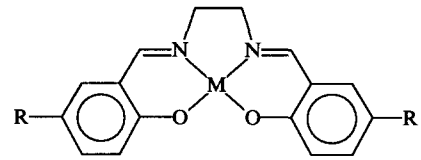


Thus the low viscosity of the nematic mesophase permits a ready orientation of the molecule by a magnetic field, such orientation remaining unchanged also in the solid-crystal state (in the presence of a magnetic field), which indicates the similarity of the molecular packing in these states.



R = Me, *p*-C_5H_{11}, *p*-$C_{10}H_{21}$, C_6H_4–OMe, C_6H_4–OEt, $C_6H_4-OC_5H_{11}$, $C_6H_4-OC_{10}H_{21}$;

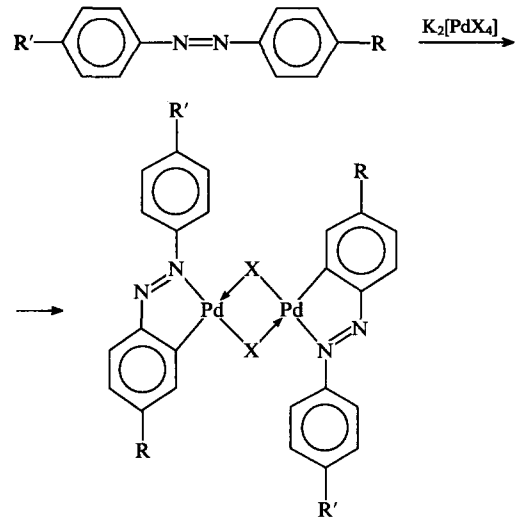
The paramagnetic mesogenic iron(III) complex **19** (g_1 = 2.096, g_2 = 4.30) forms a smectic phase (85–151 °C) and is probably characterised by a square-pyramidal coordination of the metal atom.[132]



19

Another type of coordination of the metal atom to salicylideneanime ligands occurs in di(5-substituted) salicylideneethylenediamine complexes of nickel(II) and copper(II) described by Paschke et al.[133]

The formation of type SmA smectic phase is characteristic of these complexes. It has been possible to carry out an X-ray diffraction study on a single crystal of the nickel(II) hydrate complex with R = OC_6H_{13}. Layered associated molecular formations, characteristic of crystalline precursors of smectic mesophases, were not detected in the crystal. The molecules in the crystal form centrosymmetric dimers, which are arranged in stacks with a superimposed 'herringbone' pattern. However, on the basis of these results, one cannot conclude that there is no similarity between the structures of the solid- and liquid-crystal phases, since the hydrate of the complex was investigated by X-ray diffraction and the presence of water molecules might have exerted a significant influence on its packing in the crystal.



R = OC_nH_{2n+1}, C_nH_{2n+1}, n = 5–10.

7. Mesogenic palladium complexes

Mesogenic palladium complexes are usually segregated in a separate group, since mesogenic compounds in which the metal atom forms part of a cyclic fragment have been found only among them. A distinctive feature is that the palladium atom in the complexes forms a Pd–C(sp^2) σ-bond with a carbon atom of the benzene ring, i.e. such compounds can be regarded as organometallic.

The synthesis of liquid crystals of cyclopalladate complexes has been described for the first time by Chedini et al.[134]

X = Cl; R = OEt or Et; R′ = $COOC_4H_9$, $COOC_5H_{11}$, $COOC_6H_{13}$, or $COO(CH_2)_8CH=CH_2$.

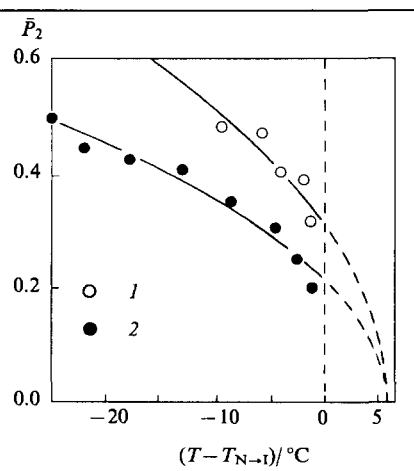
CH_3	4	p-$C_{10}H_{21}$	C $\xrightarrow{142.3}$ I
CH_3	5	p-$C_{10}H_{21}$	C $\xrightarrow{115.6}$ I

These compounds form a nematic phase at a fairly high temperature (~200 °C), which rises in the sequence I > Br > Cl (R = OEt, R′ = C_6H_{13}).[135,136]

The results of optical, calorimetric, and IR spectroscopic studies on certain mesogenic azobenzene compounds and their metallocyclic palladium complexes with R = CH_3 or C_2H_5, R′ = C_nH_{2n+1}, and n = 1, 2, 7, and 12 have been compared.[137] The mesophase consists of a 1 : 1 mixture of complexes in which R and R′ change places. These investigations enabled the authors to observe an optically biaxial nematic mesophase in the palladium complexes. The presence of the biaxial nematic phase in these complexes was detected by observing the conoscopic pattern, which was found to contain split monoaxial crosses.[137] This effect (the splitting of the crosses) intensifies still more on imposition of a magnetic field. It has also been noted that the changes in the enthalpies and entropies of the N → I phase transitions are appreciably smaller for the complexes than for the ligands. According to Galerne,[138] this is associated with the molecular biaxial arrangement. It is emphasised[137] that the order parameter P_2 for the complexes is systematically lower than the analogous value for the corresponding ligands (Fig. 20).

The authors discussed this change in P_2 within the framework of the theory of Luckhurst et al.[139] for biaxial molecules and concluded that the incomplete agreement with this theory can be accounted for either by the inaccurate expression for the pseudopotential or by the fact that the biaxial ordering occurs only at a local level, where P_2 is merely one of the components of the order parameter tensor. We emphasise that in the complexes described the biaxial nature of the nematic phase is due to the molecular structure, because the length of the molecules in the complexes is identical with the length of the molecules of the monoaxial ligands, while the width is approximately twice as great.



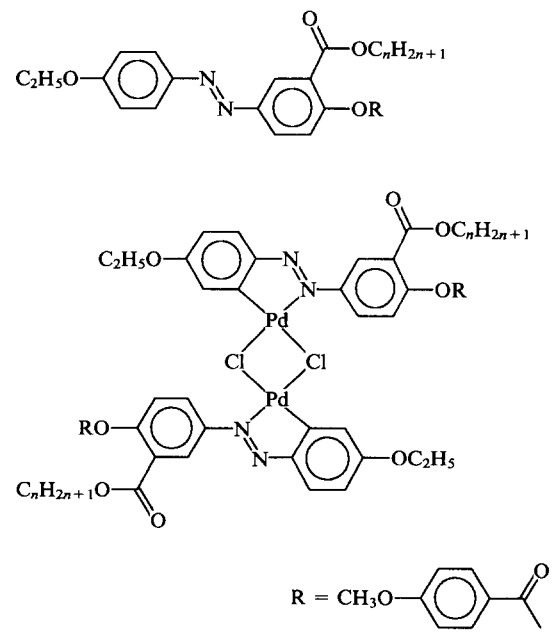


Figure 20. Temperature variation of the order parameter P_2. $T_{N\to I}$ is the temperature of the phase transition N → I; (*1*) complex; (*2*) ligand.

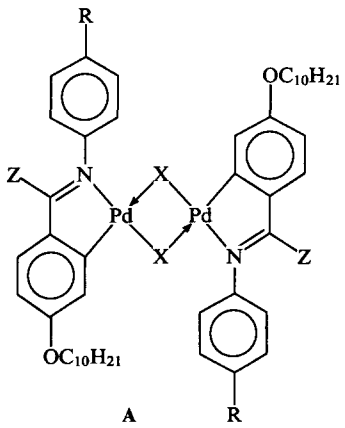
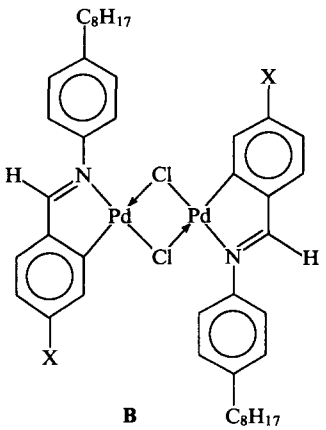


Similar complexes have been obtained from ligands containing three benzene rings and which have been described by Hoshino et al.[140] The ligand and the complex have the following form:



The homologous series with n = 1–10, 12, 14, 16, and 18 has been investigated. Both the ligands and the complexes proved to be nematogenic compounds, the temperature ranges corresponding to the existence the mesophases of these homologues varying in parallel. The average melting point of the complexes is higher by 87 °C and the clarification temperature is higher by 126 °C than the corresponding temperatures for the ligands. ^{1}H NMR data suggested that the most favourable conformation, at least for long-chain homologues, is that in which each substituent

$COOC_nH_{2n+1}$ occupies a position between the main phenyl-containing chains of the ligands. According to Hoshino et al.,[140] this conformation is most favourable for the formation of a nematic phase by the above compounds.

The synthesis of complexes of two types from the corresponding Schiff bases and $Pd_3(OAc)_6$ has been described.[141–144] Complexes A form mainly mesophases of the SmA type with the following bridging groups: X = Cl, Br, or SCN; the acetate-bridged complexes are in most cases nonmesogenic, which may be associated with the distortion of the planarity of the central part of the molecules. Mesomorphic behaviour is also characteristic of chloride complexes of type B.

A

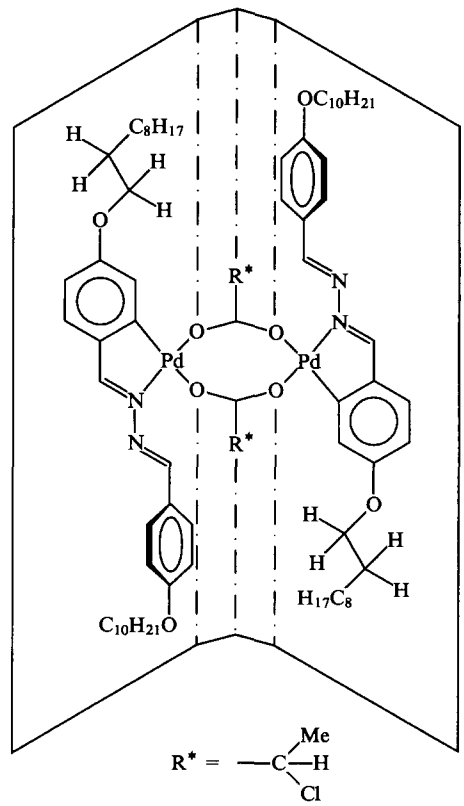
B

In contrast to the complexes mentioned above, a complex with a different type of acetate bridge (X = $MeCO_2$), obtained from the symmetrical 4,4′-bis(alkoxybenzylidene)hydrazine $C_nH_{2n+1}OC_6H_4CH = N-N = CHC_6H_4OC_nH_{2n+1}$ (n = 7, 10, 12, 14), forms an SmC mesophase. Evidently the μ-acetate ligands distort the planarity of the central part of the molecular complexes, which made it necessary to segregate them[145] as a new type of structure referred to as 'open book' structures (Fig. 21).

Special mention should be made that, according to NMR data, an optically active complex of this series (n = 10) (Fig. 21) contains a mixture of the *trans*-λ-R,R-, *trans*-δ-R,R-, and *cis*-R,R-isomers.[146] This compound forms an enantiotropic SmC* phase and is the first organometallic ferroelectric substance. However, its electrooptical response is significantly weaker than for organic calamitic phases SmC* owing to its high viscosity, which is probably due to its large molecular volume.

8. Liquid-crystal complexes of phthalocyanines

Mesogenic phthalocyanines (Pc) constitute a new class of potential liquid-crystal one-dimensional conductors,[147–150] in which the direction with maximum conduction coincides with the direction of the columns. The columns themselves are made up of flat polar



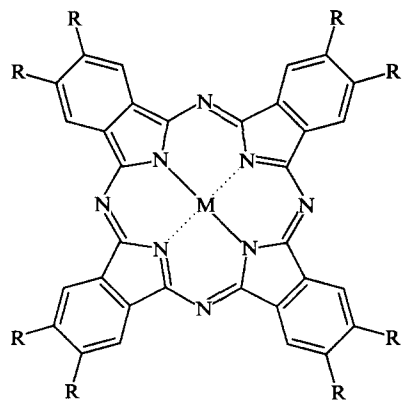


Figure 21. An optically active complex having the open book conformation.[146]

aromatic nuclei separated by neutral fused paraffin chains. It is possible to obtain phthalocyanine complexes of different metals: Fe, Co, Ni, Cu, Zn, and Pt. This allows one to vary their electronic properties. The presence of stacks with a fairly strong interaction of the molecules within them and appreciably weaker interactions of the molecules between the stacks is characteristic of such compounds in the crystalline and liquid-crystal states. Thus such interaction gives rise to anisotropy of the electronic transport properties.

The mesomorphic, structural, optical, and electrical properties of a large number of phthalocyanine compounds having the general formula

M = 2H, Cu,
R = OC_nH_{2n+1}, n = 6–12.

have been examined in detail in a review article.[151]

The copper complexes (CuPc) were synthesised by deprotonating the free ligands with sodium pentyloxide and subsequent interaction with anhydrous copper(II) chloride. Low-angle X-ray studies[151] showed that all the Pc homologues

and the corresponding copper complex CuPc form a discotic ordered hexagonal mesophase D_{ho}. According to electron-diffraction data, the molecular stacks in the crystals are then disposed along the long axes of the acicular crystals, for which ~20–25 diffraction lines are observed. The indexing of these lines showed that the crystals belong to the orthorhombic system with $Z = 4$. The calculated densities (1.1 g cm^{-3} for $n = 12$ and 1.4 g cm^{-3} for $n = 6$) of the complexes CuPc agree with the values established previously (1.6 g cm^{-3} for CuPc[152] and 1.1 g cm^{-3} for the phthalocyanine complex with R = $CH_2OC_{12}H_{25}$[148]). In all cases the (001) reflections correspond to a distance of ~4.3 Å between neighbouring molecules within each stack. This fairly large distance indicates an inclined disposition of the molecules relative to the axes of the stacks. This is also indicated indirectly by the change in the unit cell parameters a and b as a function of n (Fig. 22). On average, both parameters increase with increase in n, but van der Pol et al.[151] suggest that the more marked change in the parameter b indicates a change in the inclination of the molecules precisely relative to this direction.

The electron diffraction pattern of the mesophase in the region of low angles contains five reflections ($l/d = 1 : \sqrt{3} : \sqrt{4} : \sqrt{7} : \sqrt{9}$) corresponding to a hexagonal lattice, the broad diffuse reflection (4.6 Å) corresponding to the disordered structure of the aliphatic chains. At the same time, the X-ray diffraction patterns of all the homologues of Pc and CuPc contain an intense and sharpened reflection (3.4 Å) due to the ordered arrangement of the molecular discs within one column. Finally, the weak and broad reflection (7.0 Å) is attributed to some kind of ordering within the columns, but one cannot rule out the possibility that this is a second-order manifestation of the 3.4 Å periodicity.

The dependence of the distances D between the columns in Pc and CuPc (parameter of the planar hexagonal unit cell) on the length of the alkyl chain is almost linear (Fig. 23).

Comparison of the values of D found with the calculated diameter of the nuclei (taking into account the oxygen atoms) D_c = 16.8 Å and with the length of the extended n-alkyl chain indicates an appreciable interpenetration of the alkyl chains of neighbouring columns up to their contact with the phthalocyanine nuclei of neighbouring columns. The fact that the value D_c = 16.8 Å does not differ greatly from that established (13.9 Å) for unsubstituted phthalocyanine[153] and is close to the model estimates (17.0 Å) led the authors[151] to the conclusion that the planes of the nuclei of the phthalocyanine molecules in the mesophase are on average disposed at right angles to the axis of the column (if they were inclined, the value of D_c would be even

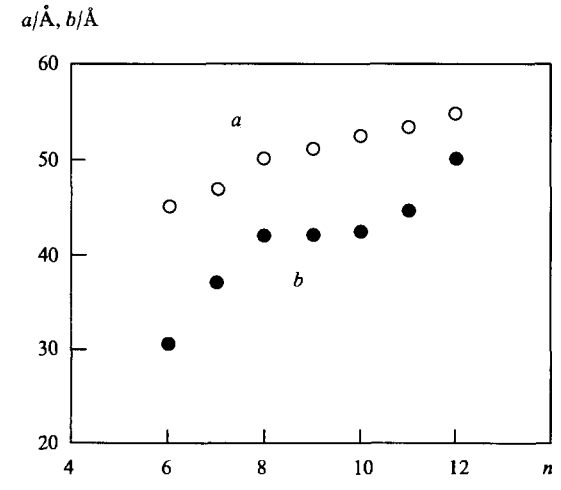

Figure 22. Dependence of the parameters a and b of the orthorhombic lattice on n in the homologous series of complexes CuPc.

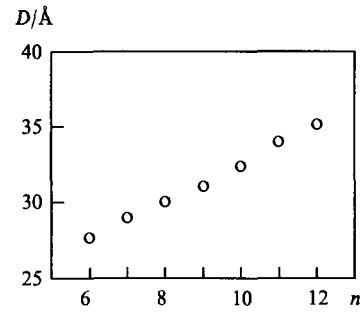

Figure 23. Variation of the distance between the columns in Pc and CuPc as a function of the length of the alkyl chain.[151]

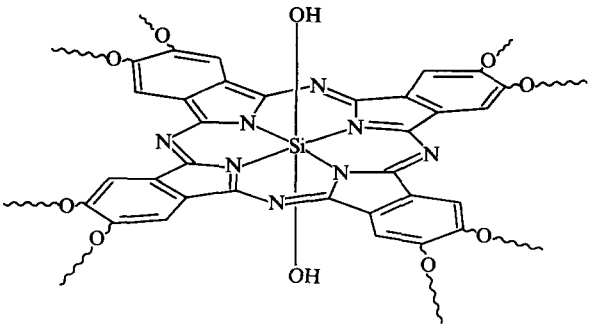
smaller). Such stacked arrangement of the nuclei of the molecules is in fact favourable for the exciton and electron migration through the column. We may note that the inclined disposition of the molecules is frequently encountered in discotic mesophases. Thus the study of freely suspended films of triphenylene hexa-n-dodecanoate using synchroton radiation established[154] that in both phases, D_{hd} and D_{rd}, the nuclei of the molecules are inclined relative to the column axes at an angle of ~28°. An even more marked inclination has been observed in the columnar orthogonal mesophase D_{rd} of triphenylene hexahexyloxybenzoate, in the structure of which the molecular planes form an angle of about 40° with the column axes.[155]

The electrical conductivities of the CuPc metal complexes in the form of compressed discs (n = 8, 12) have been measured. Such measurements have become possible by virtue of the high viscosity of the mesophase, the conductivity of which increases with increase in temperature. On passing from the crystalline to the liquid-crystal state, a slight increase in the conductivity is observed: $\sigma_{n=8} = 5 \times 10^{-8}\ \Omega^{-1}\ m^{-1}$ and $\sigma_{n=12} = 7 \times 10^{-8}\ \Omega^{-1}\ m^{-1}$ at 175 °C. The activation energies for the mesophases of the above homologues E_a = 0.5–0.6 eV are appreciably smaller than for the unsubstituted crystal (R = H, $\sigma = 6 \times 10^{-8}\ \Omega^{-1}\ m^{-1}$, E_a = 1.4 eV). The measured difference can be explained by the fact[151] that a more effective overlap of the orbitals of the central parts of the molecules in the stacks occurs in the mesophase. We may recall that the central parts of the molecules in the mesophase are arranged at right angles to the stack axes, as a result of which there is an appreciable decrease in the forbidden gap between the valence and conductivity bands. This conclusion agrees with the measurements of the microwave conductivity with time resolution.[151]

It was noted above that the conductivities of the compounds CuPc with n = 8 and 12 are of the same order of magnitude. This demonstrates the independence of this property of the length of the alkyl chains. At the same time, the conductivity increases sharply after the introduction of electron-donating or electron-accepting compounds into these materials, because this leads to the appearance of free electrons or holes. Thus the addition of I_2 to CuPc (n = 8) in proportions of 1 : 1 by weight leads to an increase in conductivity by four orders of magnitude.[151] A gigantic increase in conductivity (by 9–10 orders of magnitude) compared with the initial MPc has been observed[156] in crystals of the nonstoichiometric compounds $MPcI_x$ ($x < 3$; M = Cu, Ni, Pt, Co, 2H). It is believed that the high conductivity is caused in this case by the incomplete oxidation of the MPc molecules within the stacks by the I_3^- anions, which results in the formation of 'holes'. Bearing in mind the fact that the conductivity of PcH_2I_x is of the same order of magnitude as that of the metal complexes $MPcI_x$, Peterson et al[156] concluded that the conductivity of these materials depends not so much on the metal–metal overlap as on the π–π or π–d overlap. This is attributed to the fact that the holes formed on partial oxidation can be concentrated either on the metal or on the ligand.

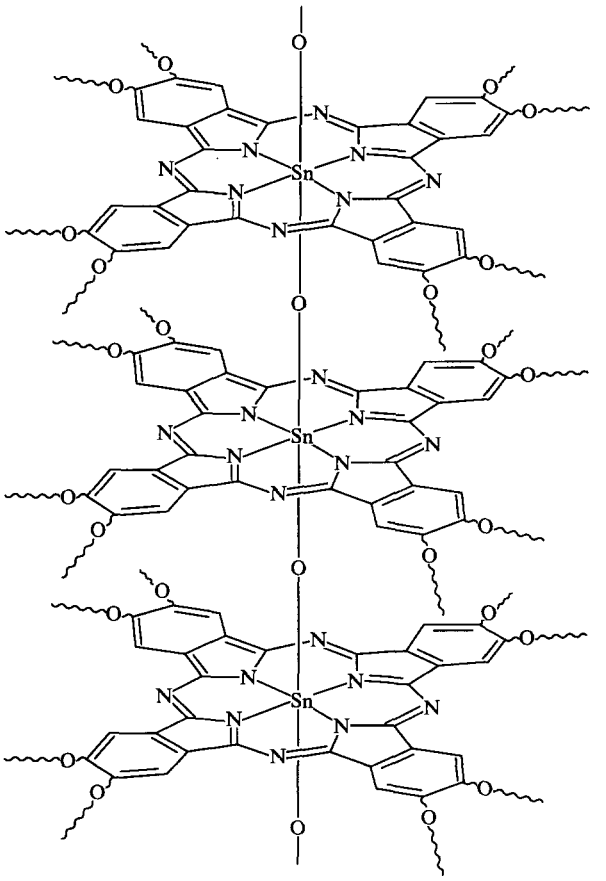
In the studies discussed, the conductivity was measured for powdered specimens and nonoriented mesophases, which naturally reduced its value. The small size of the CuPc (n = 8 and 12) single crystals and their acicular form, for which the molecular stacks are arranged along the long axis, made it impossible for the investigators to carry out measurements on single crystals. For comparison, we may point out that the conductivity of the single crystal specimen of (Qn) $(TCNQ)_2$, measured[157] at room temperature in the direction along the stacks ($\sigma = 10^4\ \Omega^{-1}\ m^{-1}$; $E_a \simeq 0$ eV), exceeds significantly the conductivity of the powder of this compound ($\sigma = 4 \times 10^2\ \Omega^{-1}\ m^{-1}$; $E_a \simeq 0.03$ eV).[158] We may note that an even greater conductivity in the direction of the chain axis has been observed for a single crystal of the Krogmann salt $K_2Pt(CN)_4Br_{0.30}\cdot 3H_2O$ ($\sigma = 3 \times 10^4\ \Omega^{-1}\ m^{-1}$).[159]

The phthalocyanine with R = $CH_2OC_{12}H_{25}$ forms a disordered hexagonal discotic mesophase D_{hd} with distances between the molecules in the columns of ~4.5 Å and a hexagonal lattice parameter of 31.2 Å.[148] The X-ray diffraction patterns of the mesophase show an additional intense reflection due to the periodic distortion of the columns with a wavelength of 20.5 Å. On the other hand, the copper complex of this compound forms an ordered mesophase D_{ho} in which the distance between the plane of the metallocycles is 3.8 Å and that between the columns is 34.0 Å.[147]



The introduction of other substituents into the phthalocyanine nucleus does not as a rule alter the columnar character of the mesophase formed, although the latter may be characterised by different structural types. For example, a series of polymorphic mesophases have been found for the copper complexes of phthalocyanine with chiral substituents R = $C_{12}H_{25}OC^*H(Me)CH_2OCH_2CH_2$, whereas the analogous complexes with nonchiral substituents form only one mesophase.[160] The influence of the length of the substituent on the type of mesophase has been investigated[161] for the copper complexes of phthalocyanine with R = $C_nH_{2n+1}OC_6H_4$ (n = 8, 10, 12, 18) and the analogous free nonmetallated phthalocyanines. For n = 12 and 18, the nonmetallated phthalocyanines form hexagonal phases with disordered columns D_{hd}, while the copper complexes form orthogonal phases D_{rd} (with $C2/m$ symmetry).

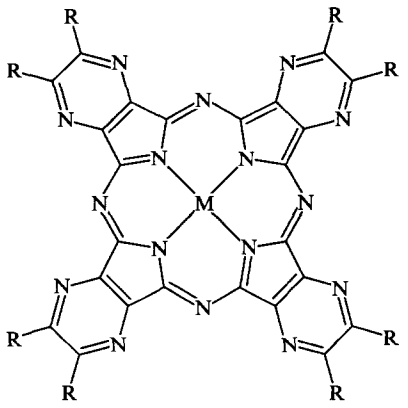
The copper complexes of phthalocyanines in which the substituents are crown-ethers, in particular 15-crown-5, are unusual. It has been suggested[162] that such molecules can form channels through which ions may be transported.



The complexes of phthalocyanines with other metals (Co, Ni, Pb, Zn, Mg) also form mesophases,[163-165] which, by virtue of their bright colour, have found extensive and varied applications.

Unusual discotic mesophases have been found[166-169] for two forms of bis(phthalocyanine)lutetium $Lu\{(ROCH_2)_8C_{32}H_8N_8\}_2$ ($LuPc_2$) with R = $C_{12}H_{25}$. It is emphasised that the red oxidised form, constituting a salt of the anion $SbCl_6^-$, is more stable than the green neutral form. X-Ray diffraction study of the $LuPc_2$ (R = $C_{18}H_{37}$) mesophase showed[7] that the distance between the columns is 37.0 Å, while the periodicity within the column (7.3 Å) is equal to twice the thickness of the phthalocyanine rings (Fig. 24). It is of interest that the form of the X-ray diffraction pattern at room temperature remains unchanged up to the transition of the isotropic phase, which indicates the similarity of the crystal and liquid-crystal structures. The conductivities of these phases are also approximately the same ($1.8 \times 10^{-7}\ \Omega^{-1}\ m^{-1}$ for the neutral form) and the probability of electron jumps within the columns is greater by a factor of 10^7 than the probability of the jumps between them for the same activation energy.

The phthalocyanine complexes in which the metal (Si or Sn) atoms are linked by oxygen bridges can be classified as liquid-crystal polymers. They are formed on heating from dihydroxy-complexes of the type:[170-172]



Bridged tin complexes form a columnar mesophase in the temperature range 59–114 °C, which is characterised[170] by a rectangular planar unit cell (25.2 Å × 30.7 Å) in which the distance between the metal atoms is 3.85 Å. The liquid isotropic phase of this compound is slowly transformed into a highly viscous anisotropic material, which contains polymer type bonds $(-O-Sn-)_n$ and a new temperature of transition to the isotropic phase (290 °C).

The analogous silicon phthalocyanine complex (n > 4) forms a hexagonal columnar mesophase of type D_{hd} in the temperature range from 20 to 300 °C. During heating in air at 180 °C, water evaporates, which is accompanied by the oligomerisation of the specimen to dimers, trimers, and higher oligomers.[171,172] We may note that a dimeric organisation of molecules, due to antiferroelectric pairing, has been observed in the phthalocyanine complexes of lead,[173] which form discotic mesophases with intercolumn distances of 26.9, 31.0, and 36.0 Å for R = $C_8H_{12}OCH_2$, $C_{12}H_{25}OCH_2$, and $C_{18}H_{37}OCH_2$ respectively.[174]

The synthesis and properties of substituted tetrapyrazinoporphyrazines and their complexes, similar to the phthalocyanine complexes, have been described.[175-177]

Discotic phases D_{rd} (with $C2/m$ symmetry) with an orthogonal centred cell and a disordered disposition of molecules in the column have been found for the complexes with M = Cu, Ni, or Co and R = $C_{12}H_{25}$. The similar phthalocyanine complexes have an analogous structure. The nonmetallated tetrapyrazinoporphyrazines form hexagonal columnar mesophases also with a disordered disposition of the molecules in the columns (D_{hd}). The compounds investigated are π-acceptor mesogenic substances. They are reduced more readily than the analogous phthalocyanine derivatives and this feature can be used to create discotic liquid crystals with mixed columns.

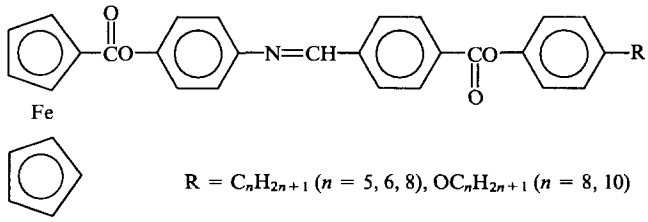
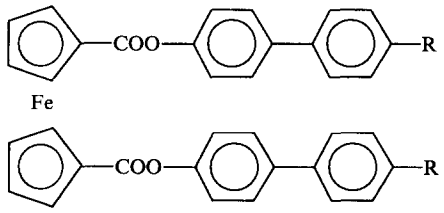
9. Organometallic and organoelement liquid-crystal compounds

Some of the first liquid-crystal compounds synthesised were organometallic mesogenic compounds. In particular, Vorländer obtained in 1923 the diarylmercury derivatives[7]



which exhibit smectic mesomorphism. The first example of a liquid-crystal π-complex (a ferrocene derivative) was described[178] in the middle 1970s. At the present time the number of studies devoted to such complexes is continually increasing. The first mentions of mesogenic materials belonging to the class of organoelement silicon derivatives were made at the beginning of the 1950s,[170,180] but such studies underwent a vigorous development only recently.

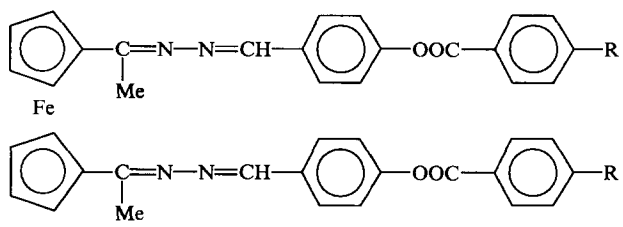
a. Ferrocene derivatives



Ferrocene derivatives with Schiff bases as substituents are some of the first liquid-crystal smectic transition metal complexes obtained. They were synthesised by the reaction of the corresponding benzal-dehyde derivative with 4-aminophenyl-ferrocenyl carboxylate.[178]

Mesogenic ferrocene diesters, forming monotropic smectic mesophases,[181] were synthesised subsequently.[181]

R = C_nH_{2n+1} (n = 5, 6, 8), OC_nH_{2n+1} (n = 8, 10)



An X-ray diffraction study of one of these compounds (R = OC_5H_{11}) was carried out.[182] It showed that the molecule in the crystal occupies a specific position (at the centre of symmetry) and has a transoid form. The plane of the carbonyl group is coplanar with the plane of the cyclopentadienyl ring, but is almost perpendicular to the nearest benzene ring. The dihedral angle between the benzene rings (23°) is appreciably smaller than in the crystals[183,184] and mesophases[185] of various cyanobiphenyls.

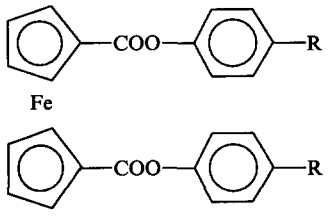
R = OC_5H_{11}, C_6H_{13}.

Low-angle X-ray studies on the mesophase yielded little information compared with the study of the single crystals, which was attributed[182] to the thermal instability of the mesophase. However, for the homologue with R = C_6H_{13} it has nevertheless been possible to establish a layer periodicity (~47 Å) at the instant when the specimen consisted of a mixture of crystals and the mesophase. This quantity corresponds to an extended transoid molecular shape. Taking this factor into account and also the fact that in the crystal with R = OC_5H_{11} the molecule has the transoid form, the authors[182] concluded that the smectic phase contains precisely such molecules. It is emphasised that the bulky substituents in the mesogenic diesters prevent the torsional vibrations of the cyclopentadienyl rings around the C_5 axis.[186]

A nematic type of mesophase has been observed in the mesogenic series of compounds

R = OC_nH_{2n+1} (n = 1–8).

As in the case of the ferrocene diesters, the most probable form of these molecules is either U-shaped or S-shaped. In order to establish reliably the structure of the nematic mesophase of such compounds, a structural study was carried out[187] on a single crystal of 1,1′-bis[4′-(n-propoxy)benzoyl-4″-methyldiphenoxy-



azinomethyl]ferrocene‡ (PBIFF, R = OC_3H_7), forming a mesophase in the temperature range 210–220 °C. Evidently, depending on the U- or S-shaped molecular structure, the nematic phase can be constructed in two ways (Fig. 25) within approximately the same characteristic periodicity of the mesophase ($d_1 \simeq d_2$) in both cases.

A molecule in the PBIFF crystal occupies a general position and has a U-shape in which the long axes of the ligands are almost parallel (Fig. 26). The conformations of two crystallographically independent ligands are similar; in each of them the carbonyl group is coplanar with one benzene ring [C(16)–C(21)] and has rotated by approximately 50° relative to the plane of the other ring [C(9)–C(14)], the planar fragments of one ligand being parallel to the analogous fragment of the other.

In the crystal (Fig. 27), the molecules are packed in an antiparallel arrangement, forming layers, and an interpenetration of the ferrocene component of the molecules from one layer into the other is observed. Despite the layered character of the packing, [the layers are energetically appreciably less distinct ($U_{layer}/U_{interlayer} \simeq 2.8$) than in the metal complexes of Schiff bases], the contacts between the rigid ferrocene components of the molecules rule out the possibility of the formation of a smectic mesophase, because such layers cannot slide freely relative to one another. On the other hand, the antiparallel arrangement of the molecules does not conflict with the structure of the nematic phase. The investigation described[187] permits the conclusion that the nematic phase of PBIFF consists of cisoid molecules. The presence in the crystal of energetically indistinct layers agrees with X-ray diffraction studies on mesophases of this series,[188] from which it follows that the molecules in the nematic phase can form small lamellar associated species.

We may note that the S-shape of the mesogenic ferrocene molecules is more favourable than the U-shape for the formation of the smectic mesophase, since mobile alkyl substituents would be involved in the interlayer contacts on either side for this shape. Conformational calculation carried out for disubstituted ferrocenes showed[187] that the U-shape is more favourable for an isolated molecule, whereas in the crystal and in the mesophase the energies of the U- and S-shaped forms may be similar when account is taken of the nonvalence intermolecular interactions.

Yet another series of ferrocene derivatives

with R = OC_7H_{15}, $OC_{10}H_{21}$, OH, and OCH_2Ph has been described.[189] For R = OC_7H_{15} and $OC_{10}H_{21}$, the compounds form a nematic phase, the phase of the compound with R = OH being characterised by the largest temperature range (hydrogen bonds can probably be formed under these conditions). For the homologue with R = OCH_2Ph, a mesophase is not formed.

b. Organoelement liquid crystals

The majority of the thermotropic mesophases known at the present time are made up of molecules having an anisometric shape — rods or discs. At the same time, data are being published with an increasing frequency concerning the formation of mesophases by compounds the molecules of which do not possess the classical anisometry. The unusual mesophase formed by one of the representatives of the series of silanediols $R_2Si(OH)_2$

‡ 1,1′-Bis[*p*-(*p*′-n-propoxybenzoyloxy)benzylidenehydrazono(α-ethyl)]-ferrocene? [Translator].

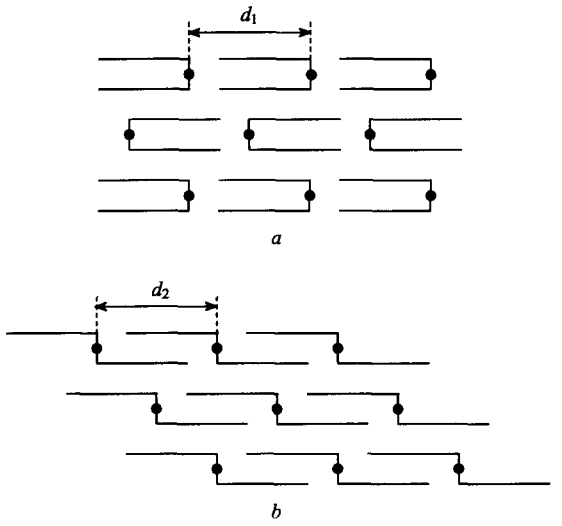


Figure 25. The structure of the cisoid (*a*) and transoid (*b*) molecules in the nematic mesophase of disubstituted ferrocene.[187]

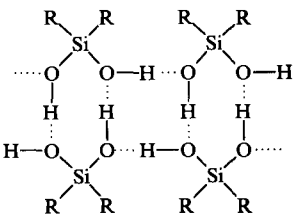
(R = Bu^i)—diisobutylsilanediol (DISD)—may be included among them.[179,180]



As early as 1952, the unusual behaviour of DISD on fusion was noted.[179] It is due to the existence of a mesophase in the temperature range 89.5–101.5 °C. For other derivatives of this series with R = Me, Et, Ph, Pr^i, or Bu^t, the manifestation of mesomorphism was not observed.[179,180] The DISD mesophase was initially identified as smectic, consisting of extended chains of hydrogen-bonded molecules. The accumulated data on the structures of liquid crystals and especially the discovery of discotic mesophases[1] made it necessary to return to the investigation of the structure of this unusual mesophase after almost 30 years.[190]

Calorimetric study of DISD demonstrated the similarity of the enthalpies of the phase transitions

$$C \xrightarrow[7.6\ kJ\ mol^{-1}]{89.5\ °C} LC \xrightarrow[7.2\ kJ\ mol^{-1}]{101.5\ °C} IL.$$

According to Bunning et al,[190] this shows that only some of the hydrogen bonds present in the crystal are disrupted in the first phase transition, while some remain and are disrupted only on transition to the isotropic liquid. We may note that discotic mesophases, where there are no hydrogen bonds, are also characterised by similar enthalpies of the phase transitions C → LC and LC → IL.[54] It has been emphasised[190] that the textures of the DISD mesophase resemble those of discotic materials and their continuous miscibility with a classical discotic compound, namely hexa(n-heptyloxy)benzene, has been observed.

The X-ray diffraction patterns of the DISD mesophase contain[190] two diffuse rings corresponding to interplanar distances of 4.7 and 11.0 Å. The crystal structure of this compound has not been established, but the parameters of a nearly hexagonal triclinic cell with $a \simeq 12$ Å have been found. It has been possible to carry out a structural study on single crystals for a

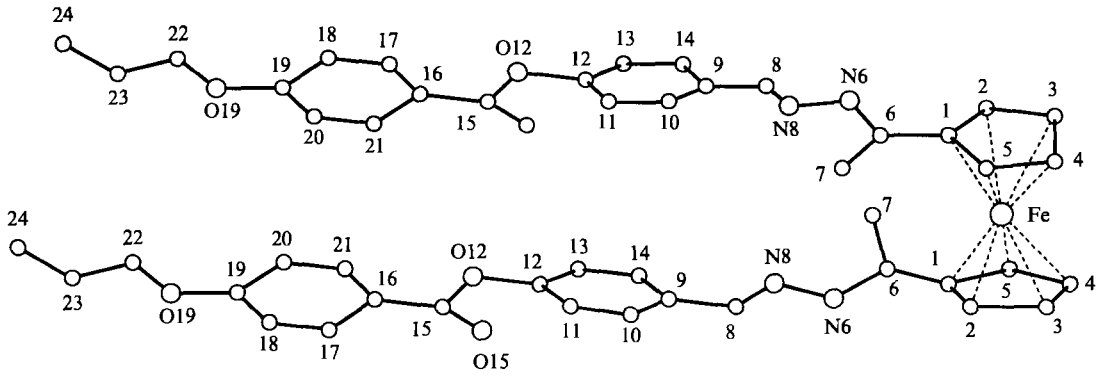


Figure 26. The structure of the PBIFF molecule.

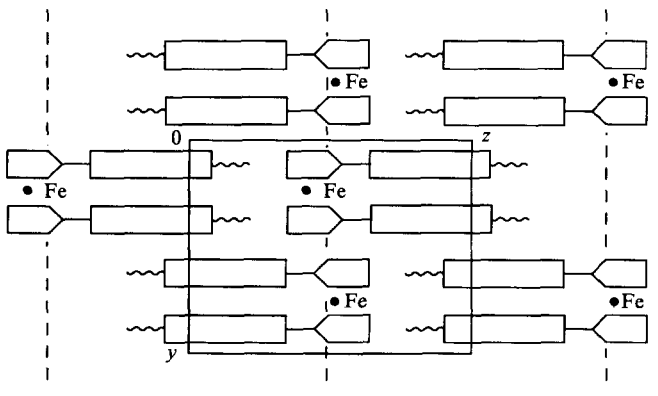
series of DISD homologues.[191-193] Thus hydrogen-bonded strips made up of dimers have been observed for crystals with R = Pr^i and Bu^t.

On the basis of the above data, it was concluded[190] that the DISD mesophase is discotic. The role of discoid molecules is assumed in this case by the hydrogen-bonded dimers. In the DISD crystal, these dimers are joined together by hydrogen bonds into inclined stacks (Fig. 28) with an approximately hexagonal arrangement. It is believed that during heating, in the transition of the crystal to the mesophase, the interdimer hydrogen bonds are broken, while the intradimer hydrogen bonds are retained. However, it is noteworthy that the latter requires significant evidence, since it is not entirely clear why selective and not random dissociation of hydrogen bonds takes place (in crystals with R = Pr^i and Bu^t, all these bonds have virtually the same lengths and hence similar energies).

In the related series of lower-melting disiloxanediols,[194] thermotropic mesomorphism proved to be a more general property. It has been observed for compounds with alkyl substituents having the normal structure (R = n-C_nH_{2n+1}, n = 2–4), but not for compounds with R = Me, Ph, or isoalkyl.

The results of X-ray diffraction studies on single crystals and mesophases as well as IR spectroscopic, calorimetric, and optical studies on compounds of the class of DISD and its analogues have been surveyed,[5,6,195-197] which has made it possible to characterise fairly fully the mesophases examined and to assign them to a new structural type.

The crystal structures of three nonmesogenic and two mesogenic compounds of the DISD series are now known. Studies have shown that 1,3-dihydroxy-1,1,3,3-tetraalkyldisiloxanes (DTADS), namely DTPDS (R = Pr^n),[195] DTMDS (R = Me),[6] DTEDS (R = Et),[197] and DTPDS (R = Ph),[198] have the same molecular packing in the crystals and the same system of intermolecular cooperative hydrogen bonds, without dimeric organisation, regardless of the fact that their crystals belong to different structural classes.



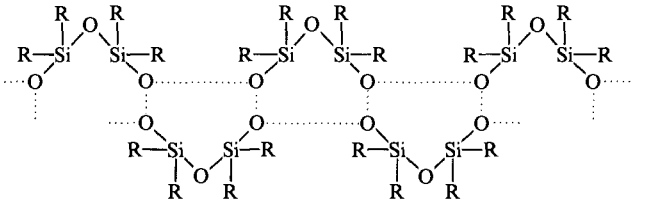


Figure 27. The layered packing of the molecules in the PBIFF crystal. The layer boundaries are shown dashed.[187]

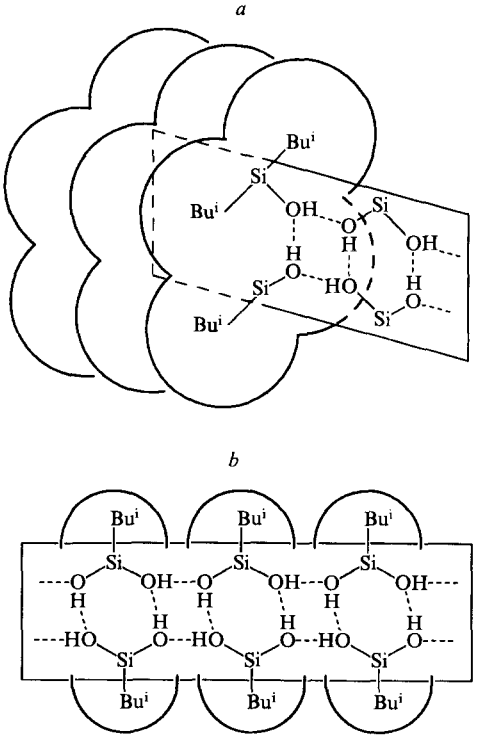
The system of hydrogen bonds in the DTMDS crystal can be described as two chains of hydrogen-bonded molecules linked by transverse hydrogen bonds into infinite strips with 2_1 symmetry and extended along the b axis (Fig. 29). In contrast to DTMDS, the crystal of which contains one system of independent molecules, in the DTPDS crystal the analogous strips are formed by six independent molecules A–E (Fig. 30), while in DTEDS



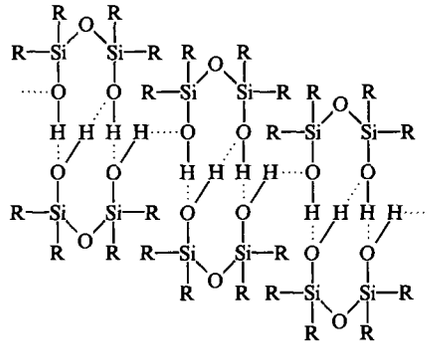


Figure 28. The structure of the dimeric discotic DISD phase: (*a*) perspective view along the column; (*b*) view at right angles to the column.

centrosymmetric hydrogen-bonded strips are formed by two independent molecules. Similar strips are observed also in the DTPDS crystal, but here they are made up of three symmetrically independent molecules. In the majority of the crystals which we examined there are conformational differences between symmetrically independent molecules, which is indicated by the differences between the SiOSi bond angles and the pseudotorsional (H)SiO ... OSi(H) angles characterising the overall molecular conformation.

In the crystal of the isopropyl homologue of DTPDS, i.e. $Pr^i_2(OH)SiOSi(OH)Pr^i_2$, the hydrogen bond system is somewhat different, although here too strips of hydrogen-bonded molecules are observed.[199]

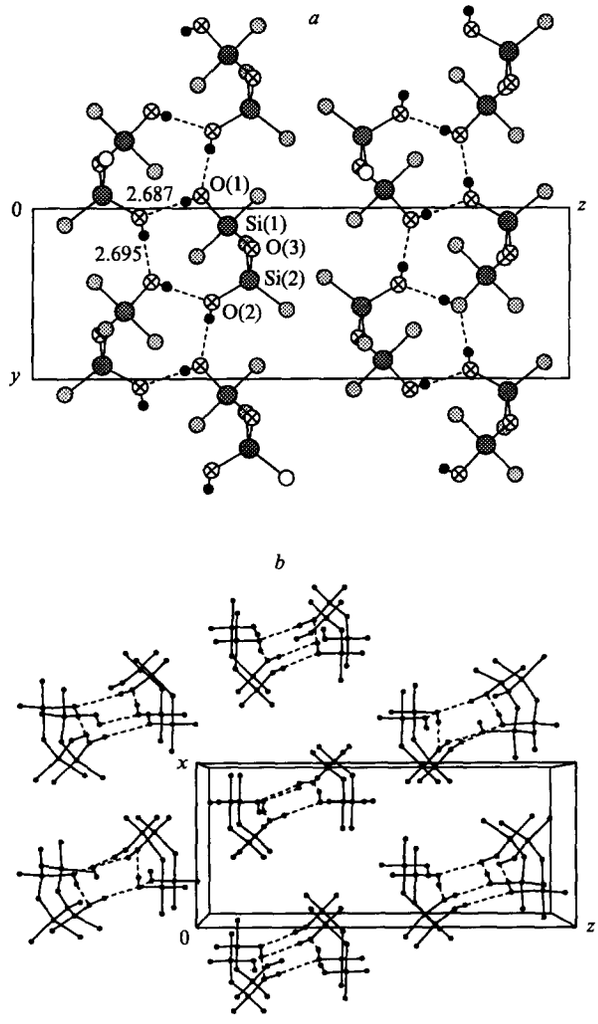

Figure 29. Projection of the crystal structure of DTMDS onto the *yz* (*a*) and *xz* (*b*) planes:[6] (*a*) view at right angles to the column; (*b*) view along the column.

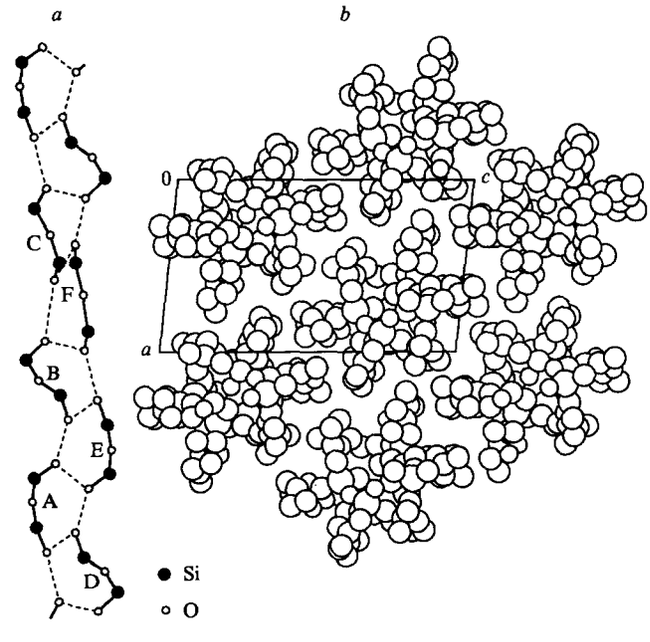
In this structure, made up of two crystallographically independent molecules, three out of the four hydrogen bonds combine the molecules into dimers whilst the fourth hydrogen bond combines the dimers into strips.

The shape of the molecular strips in the structures of disiloxanediols, considered along the long axis, i.e. the crystallographic *b* axis (Fig. 30), is of great interest. These strips are approximately cylindrical, the surface layer of the quasi-cylinders, especially in the Pr^n and Et homologues, being framed by conformationally flexible alkyl substituents. The alkyl environment of the quasi-cylindrical strips (columns) is very similar to that in columnar discotic mesophases.[2] The similarity of the alkyl frame around the quasi-cylindrical strips in the crystal to the structure of the columns in the mesophase is manifested by the presence in the crystal of several independent molecules with different conformations of the alkyl substituents and by the lack of order in the arrangement of these substituents.

The quasi-cylinders formed by hydrogen bonds in the crystals of three alkyl homologues are arranged pseudohexagonally in the *ac* plane. The parameter of the planar pseudohexagonal unit cell in the crystal is $a = 12.66$ Å for DTPDS and $a = 10.69$ Å for DTEDS. According to X-ray diffraction studies on the mesophases of the corresponding compounds,[194] the parameters of the planar hexagonal unit cells are 12.58 and 11.10 Å, i.e. are close to those observed in the crystal. The hexagonal type of the cells and the similarity of the parameters permit the conclusion that the crystalline and liquid crystal phases in DTPDS and DTEDS are structurally continuous. The diffractometer trace for the Bu^n derivative (DTBDS), the structure of the single crystal of which could not be investigated, indicates that its mesophase also belongs to the hexagonal type.

The characteristic features of the textures of the mesophases of the compounds DTEDS, DTPDS, and DTBDS have been investigated.[5] It was shown that they resemble the textures of the hexagonal columnar discotic phases.[200,201] A model of the structures of DTEDS, DTPDS, and DTBDS, similar to the structure of the DISD mesophase in which the hydrogen-bonded dimers play the role of discoid units and their assembly forms the column, was proposed initially.[194] However, the crystal structures of the homologues investigated suggested another model, namely



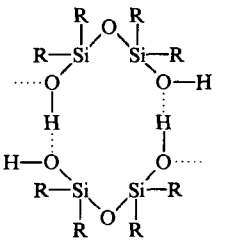


Figure 30. Projection of the crystal structure of DTPDS onto the *bc* (*a*) and *ac* (*b*) planes: (*a*) view at right angles to the column; (*b*) view along the column. The arrangement of the quasi-cylindrical molecular columns is pseudohexagonal.[196]

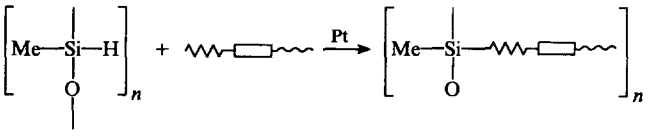
the presence in the mesophases of columns of hydrogen-bonded molecules (observed in crystals) and not of dimers.

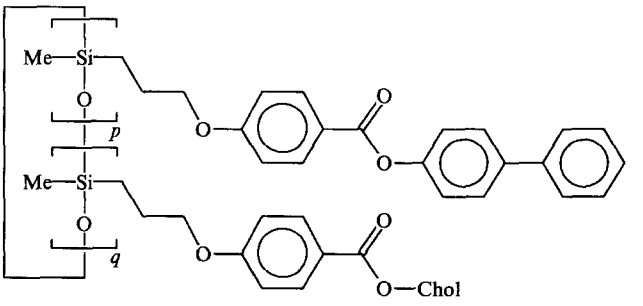
Spectroscopic studies[5,196] have demonstrated the retention of a considerable number of 'crystalline' hydrogen bonds in the mesophase, i.e. in the crystal → liquid-crystal phase transition columns of hydrogen-bonded molecules, present in the crystals, may be retained. Furthermore apart from the similarity of the parameters of the hexagonal cells, the similarity between the crystal and liquid-crystal structures of disiloxanes was demonstrated by optical measurements of the refractive index along and at right angles to the columns. It was found that $n_{\parallel} < n_{\perp}$ both in the DTPDS crystal and in the mesophase.[5] Naturally, in contrast to the crystals, in the liquid-crystal state these columns have finite and different lengths and there is no translational order along their long axes, but there is a certain long-range orientational order. In the perpendicular direction, the long-range translational order is manifested by the occurrence of a planar hexagonal cell.



The absence of mesomorphic properties from the Ph and Me homologues is due to the fact that in DTPDS the outer layer of the column is made up of the rigid Ph substituents, while in DTMDS the surrounding layer of alkyl groups is minimal. The absence of the mesophase from diisopropyldisiloxanediol can be explained by the fact that in this case there is no infinite system of hydrogen-bonded molecules but dimers connected by hydrogen bonds do exist.

In our view, the DTEDS, DTPDS, and DTBDS mesophases, made up of molecular columns constructed as a result of the formation of cooperative hydrogen bonds and surrounded by alkyl substituents, should be assigned to a new structural type of liquid crystals. This type has been called[5,6] 'mesophases with columnar hydrogen-bonded associated species', since such liquid-crystal phases differ significantly in the mode of their formation both from phases made up of rod-shaped molecules and phases constructed from discoid molecules. The DISD mesophase can also be assigned to this class, because it is more likely that, in the transition to the liquid-crystal state, the hydrogen bonds are ruptured at random and the mesophase is formed not so much by free dimers or other associated species (for example trimers)¶ as by columns formed by hydrogen bonds.

c. Cyclic siloxanes



There exist many data on the mesomorphism of polylinear siloxanes. The mesomorphic properties of these polymers are manifested both in the presence[202,203] and absence[204,205] of mesogenic side substituents.

Low-molecular-mass cyclic siloxanes with mesogenic substituents, exhibiting liquid crystal properties, were obtained at the beginning of the 1980s.[206] One of the methods of synthesis of such compounds is hydrosilylation of cyclic siloxanes in accordance with the scheme[207]

¶ J E Lydon, personal communication.

Derivatives of biphenylenes, esters, and cholesteryl (Chol) benzoate can be used as substituents. In a number of instances derivatives with substituents of two types are also possible.

Even small siloxane rings are appreciably flexible.[208] This makes it possible to postulate that, although the mobility of the long mesogenic substituents in the molecules of cyclic siloxanes is limited by their incorporation in a ring, it does have sufficient degrees of freedom. Computer modelling showed that such molecules can have different configurations and can form both discotic and nematic phases.[209]

The study of the phase state of the cyclic siloxanes with the ring sizes $p+q = 4-7$[207] and 4–24[210] demonstrated the presence of mesophases of the nematic and smectic types for these compounds. The properties of such mesophases depend both on the number of chain units and on the dimensions of the side substituents. For example, virtually no change in the thickness of the layers with increase in the size of the ring is observed for type SmA mesophases with the same side substituents.[207]

X-Ray diffraction studies on the mesophases made up of siloxane rings with two types of substituents showed that they possess a high degree of order. In the analysis of the structure of a type SmA mesophase, three types of molecules were considered:[211] discotic, cylindrical, and conical (Fig. 31), and it was concluded that the cylindrical type is most likely. It has been noted that the thickness of the layer is usually determined by the

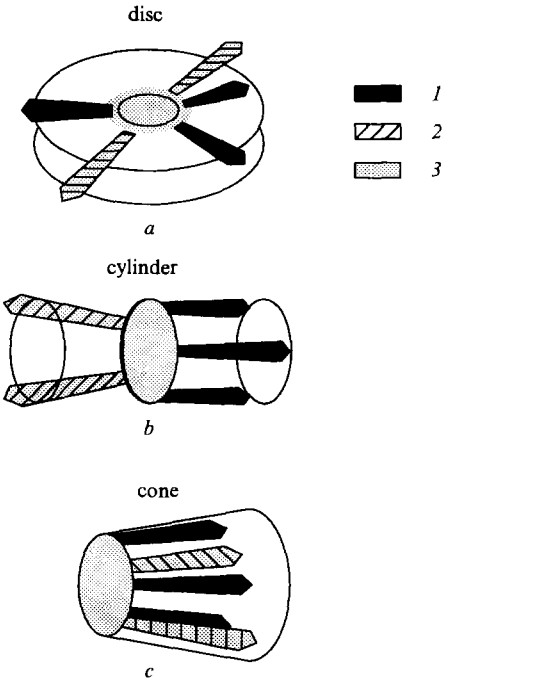


Figure 31. Molecules made up of cylindrical siloxanes with two types of substituents.[213] Molecules: (*a*) discotic; (*b*) cylindrical; (*c*) conical; (*1*) biphenyl nuclei; (*2*) cholesteryl nuclei; (*3*) cyclic siloxane.

length of the large substituent and can change when the ratio of the substituents $p:q$ in the ring is altered.[211] According to the results of optical studies, the layers in smectic specimens have a helicoidal twist (Fig. 32). The latter factor and also the tendency of the above compounds to vitrify create good prospects for their application in optical systems.

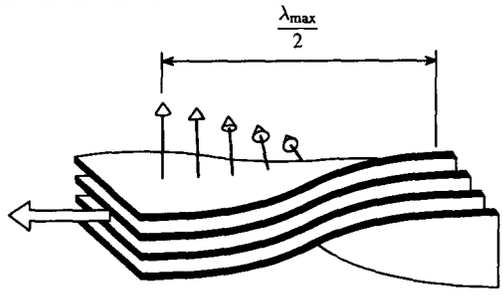

Figure 32. Helicoidal twisting of the smectic layers in cyclic siloxanes.[213]

IV. Conclusion

The above analysis of the literature and the authors' own data permits certain conclusions concerning the structural aspects of metallomesogenic substances. Despite the fact that metal complexes have not been investigated as extensively as classical organic liquid crystals, nevertheless one may say that, as in the case of organic liquid crystals, for the manifestation of mesomorphism the molecules of metal complexes must possess either intrinsic anisometry or they must form anisometric associated species the shape of which may differ significantly from that of the initial molecules. The discotic mesophases of β-diketones, made up of extended molecules, may serve as an example. Special mention should be made of the fact that in metal complexes the anisometry of the molecule depends significantly on the coordination of the metal atom, which has been manifested most clearly in the complexes with Schiff bases.

The presence of additional intermolecular coordination can have a dual effect on the mesomorphic properties. If this coordination leads to the formation of anisometric associated species, for example, columns in columnar phases, mesomorphism is possible. However, in the majority of cases such coordination plays a negative role, because the coordination dimers, strata, etc. are as a rule characterised by a lower anisometry. The EPR spectra of copper complexes of Schiff bases indicate unambiguously the absence of additional coordination in the mesophase.

In ionic liquid crystals, the smectic mesomorphism is due to the bilayer nature of the ordering of the molecules in which the metal and oxygen atoms within the bilayer form cation–anion strata separated by layers of alkyl substituents. It is of interest that in the strata the metal atom is located between oxygen planes and that water molecules are involved in the formation of such planes in the structure of, for example, $Cd(Isoval)_2 \cdot 2H_2O$. Apparently this is the first compound in which the presence of water molecules determines the appearance of the liquid-crystal state.

The mesophases based on silanediols are a striking example of the dependence of the mesomorphism on the type of aggregation of the molecules. The unusual feature of these substance consists in the fact that their molecules, which have no anisometry, form columnar associated species via hydrogen bonding, which give rise to hexagonal mesophases. The completely new structure of these mesophases (mesophases with columnar hydrogen-bonded associated species) is in many respects determined by the conformational flexibility of the molecules.

Finally, we may note that X-ray diffraction data for single crystals are very useful for the understanding of the relationship between the structure of the molecules and their ability to form liquid crystals. Such studies make it possible to determine reliably the molecular and crystal structures and then to extrapolate them to the mesophase in which the principal features of the crystal structure (layers, columns, coordination of the metal atoms, etc.) are retained. As regards the practical use of the compounds examined in this review, the prospects for their application have already been outlined.[7] We only wish to note the ability of ionic liquid crystals to form stable anisotropic glasses, which can be used for various spectroscopic purposes.

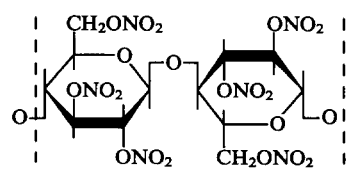
Abstract. The application of low-frequency IR spectroscopy in the structural analysis of polymers is examined. The vibrations of crystal lattices and polymer chains as well as deformation and torsional vibrations manifested in the low-frequency part of the IR spectrum are discussed. Studies in this field are reviewed critically and the experimental and theoretical data concerning the interpretation of the low-frequency spectra of monosaccharides, polysaccharides, and their nitro-derivatives are surveyed. Attention is concentrated on the establishment of 'spectrum–structure' correlations for cellulose in the course of its physical modification and chemical reactions (nitration). The bibliography includes 79 references.

I. Introduction



The high practical value of cellulose and its derivatives, especially its ethers and esters, has necessitated the study of the structural features of macromolecules in the course of their physical and chemical modifications. The structure of the polymer at the molecular and supermolecular levels of its organisation is associated with the packing of the macromolecules, intramolecular and intermolecular interactions, and the spatial orientation of the individual structural fragments.[1–15] The study of slight structural changes in the polymer requires the use of spectroscopic characteristics which are especially sensitive to such changes. The region of the 'atypical' low-frequency vibrations (30–700 cm^{-1}) is most sensitive to the changes in the structure of the polymers.[9–12] The interpretation of the spectrum in this region is impossible without theoretical calculations. Extensive experimental and theoretical data on model compounds of cellulose and cellulose nitrates (monosaccharides and disaccharides) have now accumulated. Their comparative analysis has made it possible to discover a series of spectroscopic features characterising the structural features of these low-molecular-mass polymer analogues.

A rigorous theoretical analysis of the vibrational spectra of such polymers is as yet impossible. On the other hand, in a number of recent studies it has been possible to find fairly rigorous correlations of the 'spectrum–structure–property' type in the analysis of the experimental spectra of cellulose in the course of its physical and chemical (nitration) modification and by comparing them with the spectra of model systems. The present review is devoted to the analysis of these investigations.

The cellulose macromolecule consists of a linear chain made up of β-D-glucose residues connected by 1,4-β-D-glycoside linkages.[1–3] The elementary unit of cellulose comprises two glucopyranose rings **1**. Different conformers can arise as a result of the change in the spatial orientation of the pyranose rings relative to one another and the hindered internal rotation of the OH and CH_2OH groups. In cellulose nitrates **2**, the hydroxy-groups have been substituted by nitrate groups and the polymer can contain units substituted to different extents (tri-, di-, and monosubstituted as well as unsubstituted units). Monosaccharides, disaccharides, and their nitro-derivatives are analogues of the structural fragments in the monomeric unit of cellulose and cellulose nitrates.

II. Monosaccharides and disaccharides. Methyl β-D-glucoside nitrates

The experimental and theoretical methods of vibrational spectroscopy have been used fairly successfully for the analysis of monosaccharides, disaccharides, and their derivatives. It has been established that the vibrations at frequencies of 750–950 cm^{-1} depend on the type of the anomer: D-glucose, D-mannose, and D-galactose.[16–18] It has been shown[19, 20] that this dependence persists on formation of disaccharides and polysaccharides. Analysis of the low-frequency vibrations in the spectra of the monosaccharides was initiated in a number of studies,[21–23] which are mainly descriptive in character and do not contain correlations with the structural features of the molecules. Individual attempts have been made[24] to find the relationship between the structures of monosaccharides and disaccharides and their spectra. In particular, according to the authors, vibrations at frequencies in the range 500–700 cm^{-1} characterise the crystal structure of the compounds, while the vibrations at frequencies in the range 800–1 000 cm^{-1} characterise the type of configuration (α-, β-) of the glycoside bond in the disaccharides. The authors did not analyse the 40–500 cm^{-1} spectral range. A detailed study of the low-frequency vibrations resorting to data derived from theoretical calculations of the spectra of monosaccharides, disaccharides, and their nitro-derivatives[25–34] made it possible to solve a number of problems associated with the determination of the structure-

sensitive absorption bands. Monosaccharides with different chemical structures of the fragments at the C(1) and C(5) atoms of the pyranose ring (OH, OCH_3, CH_2OH, H) (Table 1) and different configurations of the hydroxy-group at the C(1) atom [axial (*A*) and equatorial (*E*)], exhibiting rotational isomerism due to the rotation about the C–O bond, have been analysed.[26, 28, 29] In disaccharides, it is essential to note the difference between the types of glycoside bond connecting the glucose residues (the α- and β-configurations). The frequency ranges of the intermolecular vibrations of the crystal lattices (30–200 cm^{-1}) and of the intramolecular vibrations (150–700 cm^{-1}) were established in the above studies. The spectra of crystals of monosaccharides with a hydroxy-group at the C(1)

Ribose	H(OH)	H	H
Rhamnose	H(OH)	CH_3	H

atom (β-D-glucose, β-D-mannose are characterised by moderately intense absorption bands near 80, 120, and 170 cm^{-1} (Fig. 1). When the OH group is substituted by OCH_3, the 'crystallinity' bands undergo a slight hypsochromic shift owing to the change in the hydrogen bonds determining the crystal packing. This is also indicated by the results of Husain et al.,[34] who showed that, when the influence of the configurations of the CO(CH) bonds in the side fragments of the saccharide on the low-frequency vibrations is considered, it is essential to take into account the nearest structural elements. For the configurations *AEEEE* (α-D-glucose), *EAEEE* (β-D-mannose), and *AEEAE* (α-D-galactose) of the CO bonds at the atoms of the pyranose ring, the spectra show clearly an absorption band near 200 cm^{-1} (Fig. 2), while for the *EEEEE* configuration (β-D-glucose, methyl β-D-glucoside) this absorption is absent. In the region of the bands due to the 'crystallinity' of the disaccharide and the monosaccharides which it comprises, for example α-D-glucose and maltose or β-D-glucose and cellobiose, the spectra of all the substances were found to contain absorption bands at 200–220 cm^{-1} and 150–170 cm^{-1} (Fig. 3). This is explained by the similarity of the parameters of the crystal structures of the monosaccharide and disaccharides.

The uncharacteristic nature of the intramolecular vibrations in the range 200–700 cm^{-1}, deduced from theoretical calculations,[30–35] and their high sensitivity to slight structural changes in the crystal packing complicate the interpretation of the spectrum. Nevertheless, by analysing the spectra of crystalline and fused specimens and by resorting to calculated data for the steric structures of the saccharides, it has been possible to discover[26, 28, 29] the spectroscopic manifestations of different types of spatial orientation of individual fragments. It was shown that the position of the absorption band in the range 200–400 cm^{-1}, determined by the τ(CO) and τ(CC) torsional vibrations, depends on the orientation of the hydroxy-group at C(1) (Fig. 4). In the case of the axial disposition of the bond (α-D-glucose and α-D-sorbose), an intense absorption is observed near 300 cm^{-1}, while for the equatorial disposition (β-D-glucose, methyl β-D-glucoside, and β-D-xylose) it is observed near 312–325 cm^{-1}. The higher τ(CO) frequency for the equatorial orientation of the CO bond may be associated with its 'strained' state owing to the interaction with the lone pair of the oxygen of the pyranose ring. Calculations of the steric structures and the vibrational spectra of monosaccharides differing in the stereochemical disposition of the CO bonds at the C(1)–C(4) atoms confirmed the dependence of the torsional vibrations on the configuration of this group.[32] However, the calculations demonstrated a different trend in the variation of the frequencies on passing from axial to equatorial anomers. This can be explained by the fact that, in the calculations

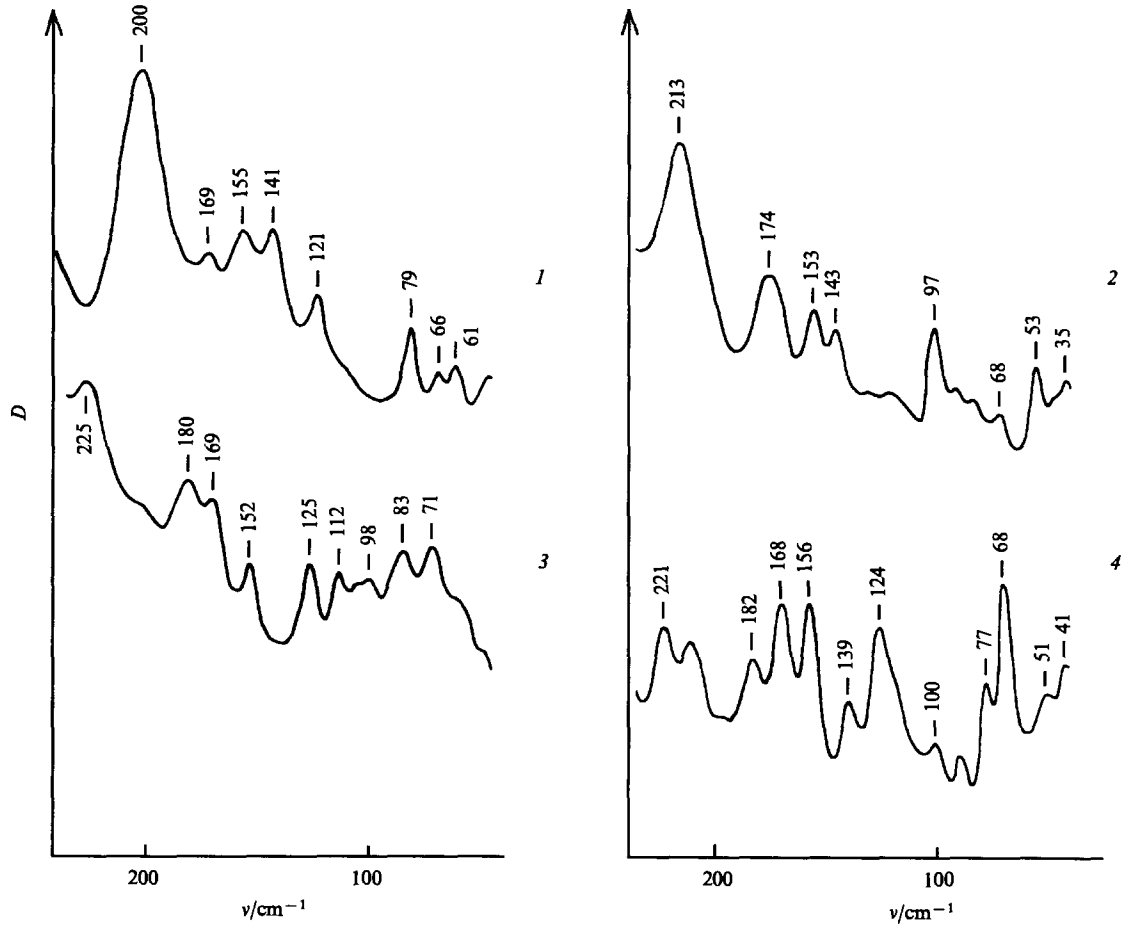

Figure 3. IR spectra of monosaccharides and disaccharides: (*1*) α D-glucose; (*2*) maltose; (*3*) β-D-glucose; (*4*) cellobiose.

performed for isolated systems, no account was taken of the effects of the intermolecular interactions and of the crystal packing. Indeed, theoretical analysis of the spectrum of α-D-glucose taking into account the crystal field[33] demonstrated the dependence of the torsional vibration frequencies on the intermolecular interactions—the hydrogen bonds, determining the crystal packing of the molecules. Together with this, according to the calculations,[25, 29, 31, 32] the torsional vibrations and frequencies in the range 280–330 cm^{-1} are determined by the orientation of the CO bond of the hydroxy-methyl group at the C(6) atom. The conformational sensitivity of the torsional vibrations has been examined in fair detail in two investigations.[25, 29] The influence of the orientation of the hydroxymethyl group on the τ(CO) torsional vibrations in the range 160–400 cm^{-1} proved to be the most significant: variation of the frequencies by 30–60 cm^{-1} depending on the orientation of the CO and OH bonds of the CH_2OH fragment was observed. An increase in the complexity of the τ(CO) absorption band contour owing to the appearance of new constituent components was noted on fusion of the monosaccharides. One of the possible causes of this is the conformational transformations accompanying the fusion of the specimens. The influence of the spatial disposition of the structural fragments of monosaccharides and disaccharides on the vibration frequencies in the range 400–700 cm^{-1} has been treated systematically.[29, 35] According to calculations, this range contains the frequencies of the deformation vibrations of the CCO and COH groups at the C(1) and C(6) atoms, as well as those of the torsional vibrations of the C–OH bond. It has been shown that the transition from the *gauche*- to the *trans*-orientation of the C(6)–O(6) bond [relative to the C(5)–H(5) bond] is accompanied by an increase in the δ(CCO) and δ(COH) frequencies (620 and 470 cm^{-1}) by 30–40 cm^{-1}. The calculations made it possible to explain the experimentally observed differences between the spectra of the crystals and melts of β-D-glucose and methyl β-D-glucoside in the range 400–660 cm^{-1} by the difference between the conformations of the fragments at the C(1) and C(6) atoms. The dependence of the frequencies in the range 400–660 cm^{-1} on the configuration has also been noted.[29] A distinctive feature of the spectrum of the monosaccharide with the axial orientation (α-D-glucose) is the appearance of absorption bands at 514, 529, and 566 cm^{-1}. This frequency range is sensitive to the type of bonding of the glucose residues in the disaccharides. In the case of the α-configuration of the C–O–C group (maltose), the spectrum shows distinct absorption bands at 518 and 541 cm^{-1}. An intense absorption at 465 and 486 cm^{-1} is characteristic of the β-con-figuration (cellobiose).

The nitro-derivatives of monosaccharides and disaccharides are models of the monomeric unit of cellulose nitrate. The low-frequency spectra of selectively substituted methyl β-D-glucoside nitrates, namely 2,3-dinitro-, 2,3,6-trinitro-, and 2,3,4,6-tetranitro-methyl β-D-glucosides (Fig. 5), were first analysed by Mukhamadeeva and coworkers.[26, 29] According to the calculations, the frequencies and modes of the normal vibrations[36–39] corresponding to the absorption bands in the range 400–660 cm^{-1} are determined mainly by deformation vibrations involving the CCO, CON, and ONO group of atoms; in the frequency range 200–400 cm^{-1}, they are determined by the τ(CO) and τ(NO) torsional vibrations and δ(CCO) and δ(ONO) deformation vibrations. The characteristic features of the intermolecular interactions and the conformations of the hydroxy- and nitro-groups in the crystals and melts determine the contours and positions of the absorption bands. The sensitivity of the deformation vibrations at 400–660 cm^{-1} to the spatial orientation of the nitrate groups was predicted by calculations.[29, 37, 38] A characteristic feature of the spectra of methyl β-D-glucoside nitrates is absorption in the range 540–548 cm^{-1} (Fig. 5). According to calculations, these frequencies are characteristic of deformation vibrations involving nitrate groups: ON(2)O in the dinitrate, ON(6)O and CON(6) in the trinitrate, and ON(2)O and ON(4)O in the tetranitrate of methyl β-D-glucoside. It has been proposed that the absorption in this frequency range be used for the analysis of the nitrate groups. The frequencies in the range 30–200 cm^{-1} are sensitive to the presence of a crystal structure and the nature of the packing of the molecules in the crystal (Fig. 5).

Analysis of the spectra of model compounds made it possible to interpret the low-frequency spectra of cellulose and its nitrates.

III. Celluloses with different degrees of structural order

The properties of a polymer are determined by the structure of both its elementary unit and of the macromolecule as a whole.[9, 40] The intermolecular interaction forces between the polymer chains are significantly weaker than the intramolecular forces and, to a first approximation, their influence on the vibrational spectrum can be regarded as a perturbing factor. As mentioned above, in the interpretation of the spectrum of cellulose use is made of the comparative analysis of the spectra of the polymer and of the corresponding low-molecular-mass analogues. The identity of the structural elements of cellulose, β-D-glucose, and cellobiose is responsible for a series of similar absorption bands in the range of the δ(CCO), δ(CCH), and δ(COH) deformation frequencies and the τ(CO) and τ(CC) torsional frequencies at 200–700 cm^{-1} (Fig. 6). The complex diffuse contour of the absorption bands in the spectrum of cellulose compared with those of the low-molecular-mass analogues can be explained by a characteristic feature of the structure of its macromolecules: the multiplicity of intermolecular and intramolecular interactions and the conformational properties of the fragments of the polymer chain. In the range of the vibration frequencies of the crystal lattices (30–200 cm^{-1}), the differences between the spectra of cellulose and the model compounds are more significant (Fig. 7). The spectrum of cellulose shows moderately intense bands at 70, 100, and 170 cm^{-1}. A series of bands characteristic of mono-saccharides and disaccharides vanish. The reason for this is the complex structural organisation of the highly ordered cellulose formations.[28, 29]

The intermolecular order (two- and three-dimensional), determined by the conformation of the macromolecular chain and the system of intermolecular interactions, and the intramolecular order, characterised by the conformations of the pyranose rings and the hydroxy-groups and by the mutual spatial disposition of the elementary units, are distinguished in the structure of cellulose. The existing experimental methods[41–44] make it possible to estimate the degree of order in the polymer.

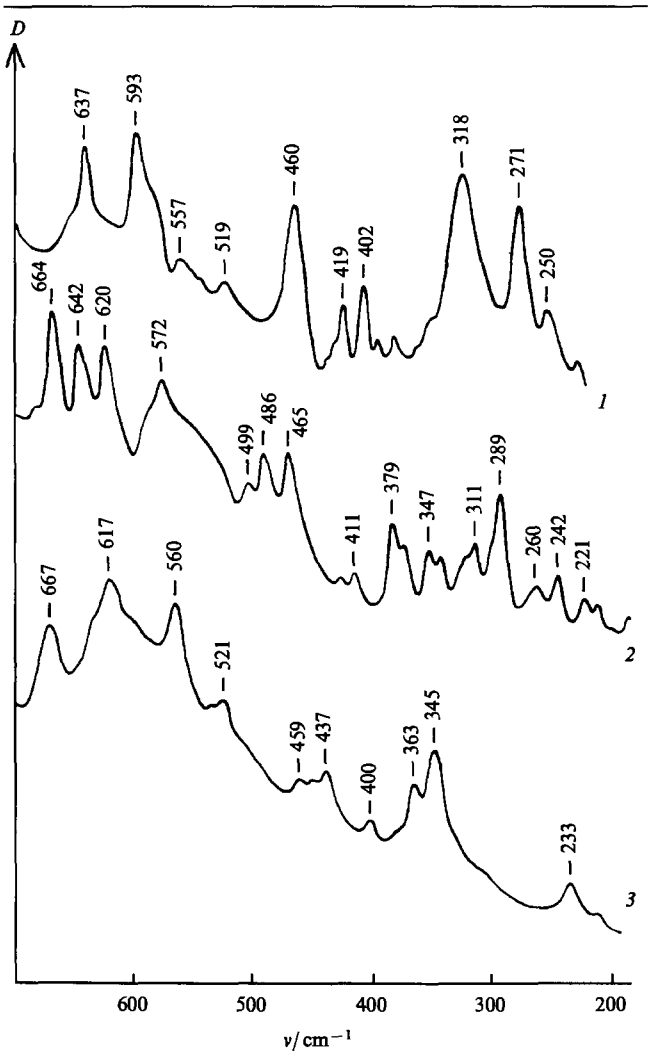

Figure 6. IR spectra (200–700 cm^{-1}): (*1*) β-D-glucose; (*2*) cellobiose; (*3*) cellulose.

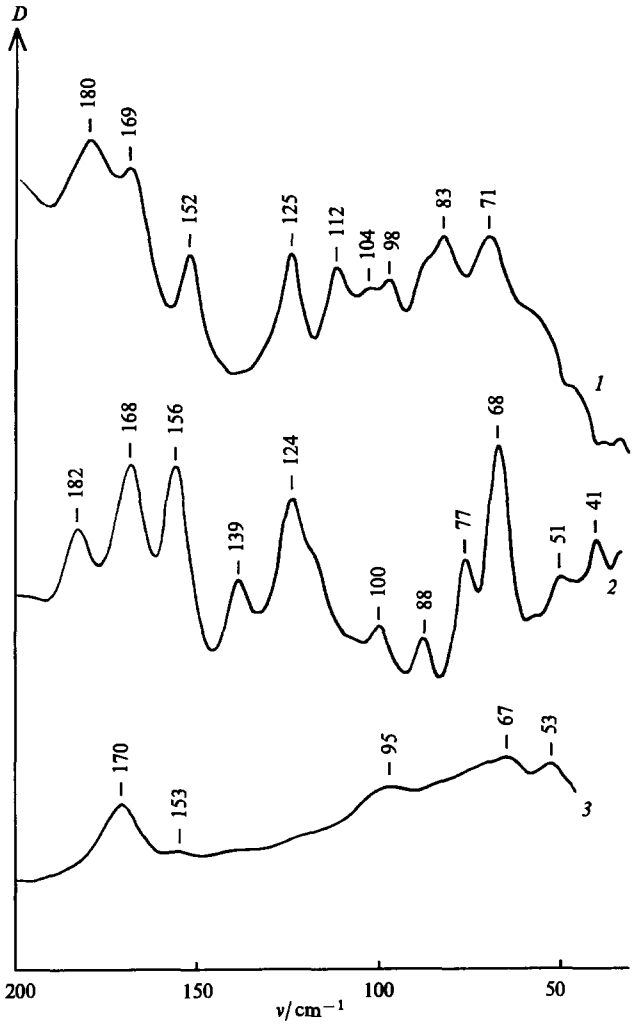

Figure 7. IR spectra (30–200 cm^{-1}): (1) β-D-glucose; (*2*) cellobiose; (*3*) cellulose.

X-Ray diffraction methods permit the estimation of the intermolecular three-dimensional order. The degree of intramolecular order associated with the rotation of the CH_2OH groups in the ordered sections of cellulose can be determined by analysing the IR absorption in the ranges 1 200–1 400 and 800–900 cm^{-1}.[3, 4] The study of the spectra in the range 30–200 cm^{-1} on these lines is particularly valuable, because low frequencies are characteristic of vibrations of the more complex structural elements—crystal lattices and polymer chains.[11, 12] A detailed quantitative analysis of the low-frequency absorption bands in the spectra of cotton and wood celluloses with different degrees of order has been carried out.[28, 29] Below 200 cm^{-1}, no distinct absorption bands were observed in the spectrum of disordered cellulose. Bands at 70, 100, and 170 cm^{-1}, which are a manifestation of the crystalline structure and can be used for the quantitative determination of the degree of order in cellulose, are characteristic of highly ordered cellulose.[29] According to the existing methods for the spectroscopic estimation of the degree of order in polymers,[9] the Beer–Lambert law for the optical density of the 'crystallinity' band (170 cm^{-1}) is defined by a relation of the type

$$D_{rel} = \varepsilon_{rel} K ,$$

where D_{rel} is the ratio of the optical density of the absorption band at 170 cm^{-1} to the optical density of the 'standard' absorption band at 520 cm^{-1} (the intensity of this absorption band is independent of the treatment of celluloses), ε_{rel} is the relative extinction coefficient at the above frequencies, and K is the degree of order (the volume concentration of the ordered fraction). The coefficient ε_{rel} can be determined by measuring D_{rel} in the spectrum of microcrystalline cellulose with a known degree of order—$K = 0.64$ (Magdalev et al.[43]); in this case $K = 0.54D_{rel}$. The spectroscopic estimates of the degree of order in natural celluloses based on low-frequency spectra and X-ray diffraction studies are presented in Table 2. Thus quantitative estimation not only of the intramolecular degree of order but also of the intermolecular degree of order (two- and three-dimensional) is possible with the aid of IR spectroscopy.

Table 2. Estimates of the degree of order in celluloses from spectroscopic and X-ray diffraction data.

Cellulose	IR spectroscopy[29]	X-Ray diffraction analysis[42, 43]
Microcrystalline	–	0.64
Cotton	0.45	0.50
Wood	0.36	0.41
Mercerised	0.14	0.42
Treated with liquid ammonia	0.22	–

IV. Celluloses of different origin and with different structural modifications

Cellulose can exist in different structural modifications.[1] The main ones are cellulose I (CI)—natural cellulose—and cellulose II (CIII), obtained from natural cellulose by reaction with concentrated solutions of alkali (NaOH). Treatment of CI and CII with liquid ammonia and subsequent removal of NH_3 vapour yields cellulose III (CIII).

Significant differences between CI and CII are observed in the study of these structural modifications by IR spectroscopy.[3–7, 45–47] Compared with the spectra of CI, the spectra of CII exhibit a broadening of the ν(OH) absorption band (3 000–3 600 cm^{-1}) and a change in the intensities of the absorption bands at 1 300–1 500 and 900 cm^{-1}. The spectral differences between CI and CII reflect the differences between the systems of hydrogen bonds and the orientations of the hydroxymethyl and hydroxy-groups noted in theoretical calculations.[48–51] The spectral changes in the structural transition from CI and CII (in the mercerisation process) have been established in a number of studies.[45–47] The process was monitored by measuring the optical densities of the 1 375 and 1 325 cm^{-1} absorption bands. A linear dependence of the absorption band intensities at 900 and 1 430 cm^{-1} on the sodium hydroxide concentration was established.[46] The spectroscopic characteristics of CI and CII have been explained by the conformations of the hydroxymethyl groups—the hydroxymethyl groups in the disordered regions make the main contribution to the absorption band at 900 cm^{-1} in the spectrum of natural cellulose, while in the spectrum of cellulose hydrate the main contribution comes from the hydroxymethyl groups in the ordered regions. Analysis of the characteristics of the ν(OH) absorption band (3 000–3 600 cm^{-1}) showed[45] that the cellulose mercerisation process is associated with the increase in the number of energetically weaker hydrogen bonds. A number of studies have been made on the low-frequency spectra of celluloses modified in different ways.[52–54] The most marked differences occur in the IR spectra in the frequency range 300–500 cm^{-1}. Differences in the range 200–600 cm^{-1} have also been observed in the Raman spectra of CI and CII. According to the results of Atalla and Dimick,[53] these spectroscopic features are due to the specific characteristics of the mutual orientation of the D-glucose residues in the polymer chain. A detailed study has been made[26, 29] of the spectra of different structural modifications of cellulose in the frequency range 30–700 cm^{-1} using data for model compounds. Characteristic features were observed in the spectra of celluloses I, II, and III in the frequency range corresponding to the vibrations of the ordered structural elements—crystal lattices and

polymer chains (30–200 cm^{-1}). The lattice vibrations in CI and CIII have frequencies of 100 and 170 cm^{-1}, while those in CII have frequencies of 125 and 170 cm^{-1}. A complex multicomponent absorption with maxima at 364 and 344 (CI), 380 and 351 (CII), and 349 cm^{-1} (CIII) was noted in the frequency range 200–400 cm^{-1}. These vibrations are sensitive to conformations[29] and are determined by the spatial orientation of the hydroxymethyl groups. Calculations showed that[29] the vibrations with frequencies of 340 cm^{-1} are characteristic of the *gauche*-orientation of the CO bond in the CH_2OH group regardless of the disposition of OH. These vibrations are more distinctive in CI, which indicates the predominance of the *gauche*-conformation in this structural modification. The data obtained agree also with the results of conformational calculations on the isolated cellulose I helix.[48–51] According to Mukhamadeeva,[29] the more distinct manifestation of the component at 380 cm^{-1} is due to the presence of the *gauche*-conformation of the CO bond for the *gauche*, *trans*-orientation of the hydroxy-group. The ratio of the intensities of the components of the 300–400 cm^{-1} absorption band is used for the comparative estimation of the conformational composition of the hydroxymethyl groups in various celluloses. Table 3 shows that the conformations of the hydroxymethyl groups are similar in celluloses of different origin and prepared in different ways but are different in CI and CII. Analysis of the spectra of model disaccharides[28, 29] demonstrated the possibility of estimating the comparative orientations of glucose residues along the glycoside linkage from the absorption bands in the frequency range 500–600 cm^{-1}. In the spectra of celluloses, the 520 and 560 cm^{-1} bands are most distinct in this range. The quantitative estimate based on the intensities of these absorption bands (Table 3) indicates significant differences between the celluloses as a function of their modification. The origin and the method of preparation of the cellulose have less influence on the degree of order in the macromolecules and on the conformational properties of individual fragments.

Low-frequency IR spectra have also been used to discover the mechanism of the structural (physical) modification of cellulose when it is treated with a solution of sodium hydroxide. The heterogeneity of the physical structure of cellulose is known to be responsible for the presence of two stages in the mercerisation process. In the initial stage, the interfibre space is filled (impregnation of pores) and this is followed by the diffusion of the reagent into the cellulose fibres. It was important to detect the second stage of the reaction. The principal structural changes in the cellulose at the molecular and supermolecular levels occurred at this instant. Three stages in the structural changes in cotton and wood celluloses have been differentiated[29] on the basis of spectroscopic data. In the first stage (Fig. 8), the structure of the celluloses is almost unaltered for a sodium hydroxide content up to 8%. In this case, the interfibre pores are filled with the alkaline solution. In the second stage of mercerisation, involving the penetration of the reagent into the fibre (8%–14%), there is a sharp change in the intensity ratios of the spectra of the absorption bands D_{560}/D_{520} (D_1), reflecting the characteristics of the orientation of the elementary units of the macromolecules, and D_{363}/D_{344} (D_2) and $D_{1\,430}/D_{900}$ (D_3), associated with the spatial orientation of the side fragments, particularly the CH_2OH groups. The hypsochromic shift of the ν(OH) absorption band maximum is induced by the increase in the number of energetically weaker hydrogen bonds[15, 55]—changes in the system of intramolecular hydrogen bonds of the type O(2)–H ... O′(6)H and O′(6)H ... O(2). These features are closely related to the conformational composition of the hydroxymethyl groups. Analysis of the 'crystallinity' band (170 cm^{-1}) showed that the second mercerisation stage (8%–12%) is accompanied by a sharp increase in the disorder in the cellulose chains (the degree of crystallinity K decreases from 0.44 to 0.16). At a solution concentration of 14%–18% (third mercerisation stage), the spectral changes associated with the structural transformations outlined above are gradually completed.

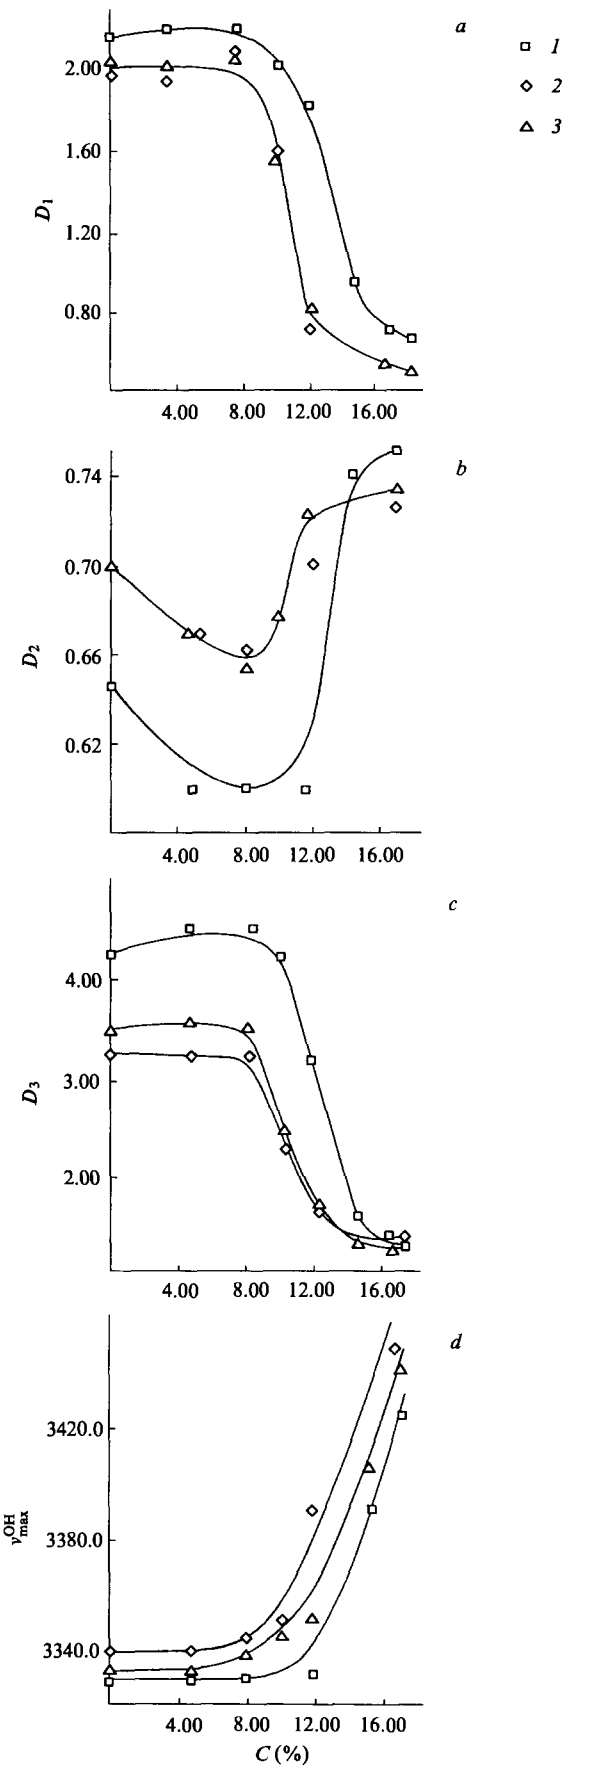

Figure 8. Dependence of the intensities D_1 (*a*), D_2 (*b*), and D_3 (*c*) and of the ν(OH) maxima (*d*) of the absorption bands on the concentration of sodium hydroxide (*C*, %): (*1*) cotton cellulose; (*2*) wood cellulose fibres; (*3*) wood cellulose paper.

Table 3. Intensity ratios of the low-frequency bands of different celluloses.[28, 29]

D_{rel}	Origin			Method of preparation			Structural modification		
	CC	WCF	WCP	SFI	SFA	NA	I	II	III
363/344	0.65	0.73	0.70	0.72	0.70	0.71	0.65	0.85	0.78
560/520	2.18	2.22	2.06	2.02	2.41	2.32	2.18	0.61	1.35

Note. CC = cotton cellulose, WCF = wood cellulose in the form of fibres, WCP = wood cellulose in the form of paper, SFI = cellulose obtained by the sulfite method, SFA = cellulose obtained by the sulfate method, NA = cellulose obtained by the nitric acid method.

A method has been proposed for monitoring the amount of CI which has been converted into CII in terms of the optical densities of the low-frequency absorption bands.[28, 29]

V. Formation of the structure of cellulose nitrate

The nitration of cellulose takes place, like the mercerisation process, in a heterogeneous medium, the rate of nitration being determined by the ratio of the rate of diffusion of the reagent into the fibre to the rate of the chemical reaction. The chemical reaction and the diffusion of the reagent are related in their turn to the accessibility of the reaction centres (hydroxy-groups) and the structure of the initial cellulose.[1] IR spectroscopy combined with other physicochemical methods, particularly with X-ray diffraction analysis and high-resolution ^{13}C NMR spectroscopy in the solid phase, is a fairly effective method for the investigation of the formation of the cellulose nitrate structure.[3, 7] The spectra of cellulose nitrate in the frequency range 600–4000 cm^{-1} contain absorption bands characteristic of the nitrate groups: an intense absorption in the frequency ranges 1500–1700 cm^{-1} and 1200–1300 cm^{-1}, due respectively to the antisymmetrical and symmetrical $\nu(NO_2)$ vibrations, and moderately intense absorption bands at 650, 750, and 840 cm^{-1} referring to ν(NO) and $\delta(ONO_2)$.[56, 57] In addition, the IR spectra of incompletely esterified specimens contain in the frequency range 3100–3600 cm^{-1} a diffuse absorption due to the residual OH groups. The position of the maximum of this band indicates the presence in cellulose nitrate (CN) of weak hydrogen bonds of the type OH ... ONO_2.[56] The molecular structure of cellulose nitrate has been analysed[58–60] as a function of the origin of the cellulose and the composition of the nitrating mixture. The degree of asymmetry of the ν(OH) absorption band contour has been used to estimate spectroscopically the uniformity of the substitution of the hydroxy-groups.[61] It was shown that, during the nitration of cellulose with nitric acid in a medium with methylene chloride, the hydroxy-groups are substituted fairly uniformly. This is associated with the ability of methylene chloride to loosen the packing of the polymer chains, which facilitates the penetration of the nitrating agent to the reaction centres.[58]

It has been proposed in a number of studies[57, 62–66] that the $\nu_{as}(ONO_2)$ absorption band (1500–1700 cm^{-1}) be used for analytical purposes in order to determine the nitrogen content and the locations of the nitric groups. However, the study of model compounds[62, 63] and cellulose nitrates in different stages of aggregation[4, 64] demonstrated that the determination of these structural parameters yields uncertain results. The complex contour of the $\nu_{as}(NO_2)$ absorption band is due to the superposition of the effect due to the crystal packing of the molecules, intermolecular interactions, the environment of the nitrate groups, and their conformational state. The spectroscopic manifestation of each of the above effects is determined by the state of aggregation of the cellulose nitrate test specimen and the degree of its esterification.

A theoretical study of the conformational properties of the monomeric and dimeric fragments of the cellulose trinitrate (CTN) macromolecules within the framework of the method of atom–atom potentials has been described.[65, 66] The stable conformations, determined by the rotation about the CO and CC bonds, were established. It was shown that, in the case of the nitrate groups at the C(2) and C(3) atoms, four rotational isomers can be formed preferentially. The CH_2ONO_2 group has a large number of stable conformations. The conformations of the dimeric fragment (elementary unit) of the cellulose trinitrate molecule have been calculated.[66] In the analysis of the potential surface as a function of the torsional angles at the glycosidic bond, which determine the conformation of the chain skeleton, two regions with low energies were discovered in the ranges from 0° to 20° and from 20° to 40°. It was established that the allowed region of possible cellulose nitrate conformations is smaller than a similar region in cellulose, which indicates a lower conformational liability of the monomeric units of cellulose trinitrate compared with cellulose. The steric forms of the macromolecules produced are determined mainly by the orientation of the side fragments.[3] As in the case of cellulose trinitrate, the conformational analysis of partly substituted cellobiose nitrates demonstrated the presence of two deep minima on the potential surface.[67] The authors noted only a slight difference in the steepness of the potential energy surfaces for partly and fully substituted cellobiose nitrates. Furthermore, in the partly substituted cellobiose nitrates the formation of intramolecular hydrogen bonds of the type O(3)H ... O(5) and O(3)H ... O(2)H or O(3)H ... O(2)NO_2 has been postulated. They are important for the stabilisation of cellobiose nitrate. The possibility of the formation of hydrogen bonds in partly substituted cellulose nitrates had been confirmed earlier in an analysis of experimental spectra.

A number of studies have been made on the low-frequency spectra of cellulose nitrates.[29, 68–71] The high sensitivity of the low-frequency vibrations to the characteristics of the crystal and molecular structures enabled the authors to solve a series of practical problems associated with the assessment of the kinetics of the nitration of cellulose. In the nitration of celluloses, the chemical reactions involve the formation of new structures.[3] The establishment of the relationship between the stages in the chemical synthesis, determined by the kinetic and diffusional processes, and the stages in the structural transformation, characterised by the disordering of the cellulose chains, the mutual orientation of the monomeric units, and the conformational state of the fragments of the macromolecules, is important. The spectra of cellulose nitrates with different degrees of substitution (γ) have been investigated.

Fig. 9 presents the low-frequency spectra of cellulose and cellulose nitrate. The frequencies and the assignments of the vibrations are given in Table 4. Analysis of the model compounds showed that the range of intramolecular vibrations of the macromolecules (200–700 cm^{-1}) and the frequency range of the intermolecular vibrations of the ordered polymer chains (30–200 cm^{-1}) can be differentiated arbitrarily in the spectra. During nitration, virtually the entire low-frequency spectrum changes. In the range of frequencies of the intramolecular vibrations, there are significant changes in the range 480–600 cm^{-1}. The multicomponent absorption observed in this frequency range is due to mixed vibrations with participation of the CCO, CON, and ONO groups of atoms.[29, 36–39] The positions of the bands and their intensities depend on the degree of substitution. Thus, for low values of γ, the spectra contain distinct bands with maxima at 560 and 520 cm^{-1}. The intensity of the 560 cm^{-1} band diminishes

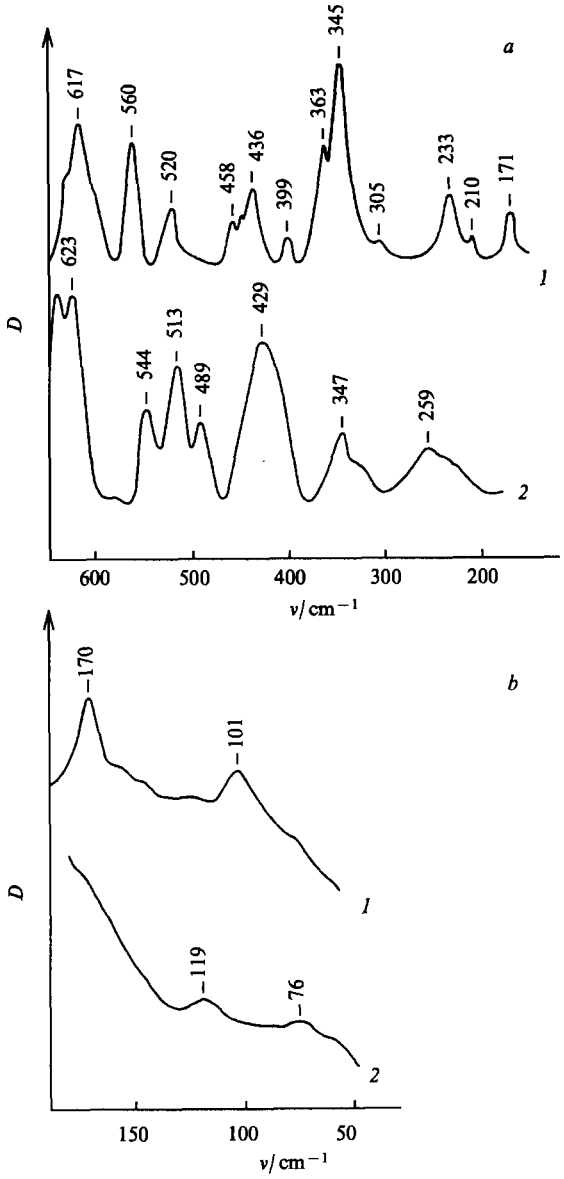

Figure 9. IR spectra of cellulose (curves *1*) and cellulose nitrate (curves *2*) (200–700 cm^{-1}).

with the increase in the degree of substitution. This has been explained by the characteristic features of the environment of the carbon atom involved in the glycosidic C–O–C linkage and by the orientation of the monomeric units. These structural changes are most significant in the first stage of the chemical synthesis (up to a degree of substitution of 1.6). The conclusions reached for vibrations at frequencies of 480–600 cm^{-1} are important. The increase in the absorption intensity at 544 cm^{-1} is explained by the substitution of the hydroxy-groups located at the C(6) atom. The triplet structure of this absorption band with maxima at 490, 513, and 544 cm^{-1}, manifested in the spectra for degrees of substitution in excess of 1.6 (the second stage of the chemical synthesis), has been attributed to the formation of the trinitrate units in the cellulose nitrate.

In the frequency range 300–500 cm^{-1}, where the δ(CCO), δ(CON), δ(ONO), τ(CO), and τ(NO) vibrations are manifested according to calculations,[29, 38] the increase in the intensity of the 436 cm^{-1} absorption band entails a decrease in the intensity of the absorption at 344 cm^{-1}. These spectral changes during the nitration processes have been attributed to the increase in the content of nitrate groups and the decrease in the number of residual hydroxy-groups. The spectra in this range are sensitive to conformations.[27–29, 38] For degrees of substitution of 1.6–1.8,

[a] Vibration frequencies sensitive to conformations.

the conformational structure of the nitrate and the residual hydroxy-groups is virtually stabilised. In the frequency range 200–300 cm^{-1}, the frequencies of the τ(CO) and τ(NO) torsional vibrations shift from 233 to 251 cm^{-1} with increase in the degree of substitution of cellulose. The reason for this is the increase in the barrier to the internal rotation of the nitrate groups compared with the hydroxy-groups.

The absorption at 170 cm^{-1} has been used to analyse the changes in the crystal structure of cellulose. A significant disordering in the cellulose chains for a degree of substitution of 1.6 has been observed. At the same time, the appearance of new absorption bands at 80 and 120 cm^{-1} has been noted in the spectra of cellulose nitrates with increase in γ. They were assigned to the low-frequency vibrations of the cellulose nitrate macromolecules in the ordered regions. The disruption of the crystal structure of cellulose and the presence of elements of an ordered structure in cellulose nitrates for a degree of substitution of 1.6 have been confirmed also by the results of X-ray diffraction analysis.[67]

VI. Kinetics of the nitration of celluloses of different biological origin and with different structural modifications

The chemical reactions of cellulose and the formation of the structure of cellulose nitrates are in many respects determined by the biological origin and the structural modification of cellulose and by the conditions in its nitration. A number of studies[58, 59, 72] have been devoted to the X-ray diffraction analysis of the characteristic features of the formation of the crystal structures of different cellulose nitrates. By means of high-resolution ^{13}C and ^{15}N NMR spectroscopy,[73, 77] the establishment of the monomeric composition of cellulose nitrate was analysed. A number of studies[28, 29, 69–71] were devoted to investigations on the low-frequency IR spectra of the nitrates of cotton celluloses (CCN), wood celluloses in the form of fibres (WCNF) and paper (WCNP), as well as the nitrates of different types of cellulose (CCNII, CCNIII). The influence of the composition of the nitrating mixture on the formation of the structure of cellulose nitrate has

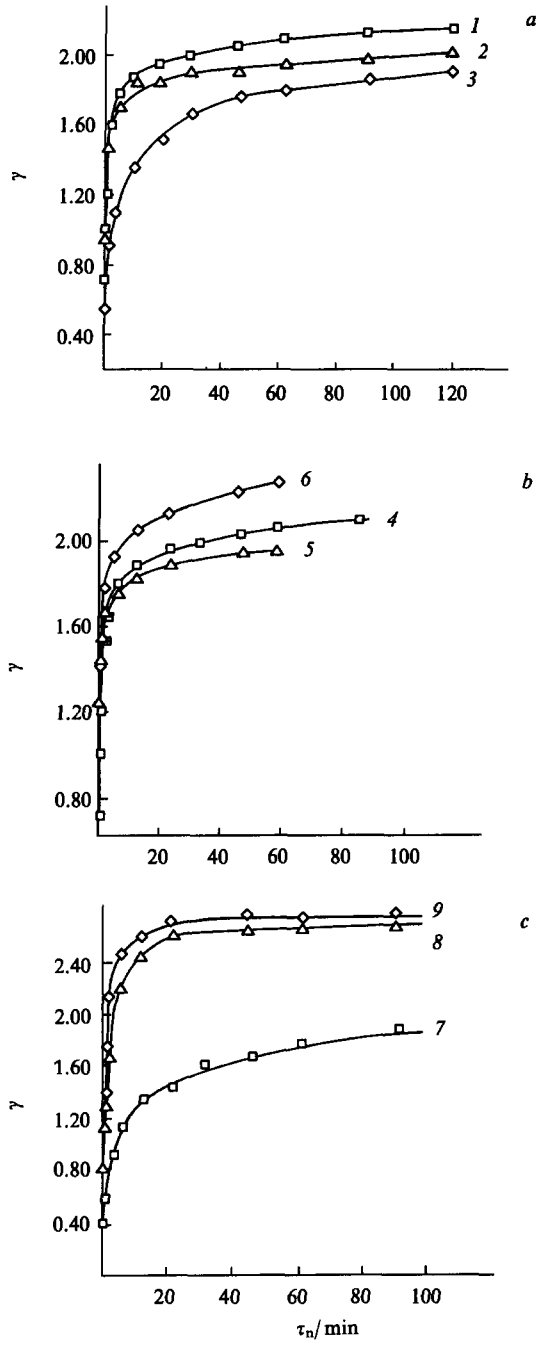

Figure 10. Kinetics of the nitration process: (*a*) cotton cellulose (curve *1*), wood cellulose fibres (curve *2*), and wood cellulose paper (curve *3*); (*b* cotton cellulose I (curve *4*), cotton cellulose II (curve *5*), cotton cellulose III (curve *6*); (*c*) cotton cellulose in reaction mixtures with different water contents (%): (*7*) 15; (*8*) 5; (*9*) 0.

also been investigated. The kinetic relations obtained are presented in Fig. 10. They are described fairly satisfactorily by an equation similar to that put forward in Refs. 78 and 79:

$$\gamma = \gamma_0[1-\exp(-k\tau^{\alpha})] ,$$

where $K = k^{1/\alpha}\alpha$ is the reaction rate constant. The parameters of this equation are listed in Table 5. The physical modification of cellulose and the composition of the nitrating mixture exert the strongest influence on the reaction rate constant K. The transition from the first (kinetic) to the second (diffusional) stage of the chemical synthesis takes place for degrees of substitution from 1.6 to 2.2.

Fig. 11 presents the spectra of cellulose nitrates with low degrees of substitution (γ = 0.5–1.8). Judging from the spectra, ordered cellulose chains are retained in nitrated cotton and wood celluloses for the above values of γ regardless of the composition of the nitrating mixture. In the cellulose nitrates subjected to a preliminary treatment (CCNII, CCNIII), the 'amorphisation' of the cellulose chains takes place virtually in the first seconds of the nitration process. The changes in the structure of the fragments of the macromolecules can be monitored on the basis of the frequencies of the intramolecular vibrations in the range 480–600 cm^{-1} [δ(CCO), δ(CON), δ(ONO)]. The ratio of the intensities of the 520 and 560 cm^{-1} absorption bands characterises the features of the environment of the C–O–C glycosidic linkage (Fig. 12). The relation can be represented approximately by a mathematical expression of the following type:

$$D_1 = D_{1,0}\exp(-B\gamma) ,$$

where D_1 and $D_{1,0}$ are the relative optical densities for a degree of substitution γ and for γ close to zero respectively and B are experimental constants. Their values for the spectra of the nitrates of different celluloses are presented in Table 6. The dependence of the relative optical density of the 544 cm^{-1} absorption band on the degree of substitution (Fig. 12), characterising the accumulation of nitrate groups at the C(6) atom, has been represented approximately by a mathematical expression of the type

$$D_2 = D_{2,0}[1-\exp(-A\gamma^{n})] .$$

The experimental constants A and n are listed in Table 7. The constants $D_{2,0}$, A, and B are maximum for CCNII and CCNIII. Bearing in mind the feature, noted above, involving the existence of order in the residual cellulose chains in cellulose nitrates with low degrees of substitution, the authors suggest that the characteristics of the spatial orientation of the monomeric units and the substitution of the primary hydroxy-groups on nitration of CCII and CCIII are associated mainly with the "amorphous" regions, while those in the nitration of cotton and wood celluloses are associated with sections of the polymer which are non-uniform as regards the degree of order. For $\gamma > (1.6-2.0)$ (the second stage of the chemical synthesis), the contour of the absorption band at 480–600 cm^{-1} in the spectra of cellulose nitrates (Fig. 13) assumes the form of a triplet with maxima at about 490, 514, and 544 cm^{-1} regardless of the biological origin of the celluloses

and their structural modification. Comparison with experimental and calculated spectra of model compounds led to the conclusion that trinitrate units are formed when the nitrate groups are located at the C(2), C(3), and C(6) atoms. The triplet structure is distinctly manifested on nitration of cellulose under anhydrous conditions. The structural data for the cellulose nitrate molecules obtained from the spectra agree well with the results of the study of the monomeric composition of cellulose nitrates by ^{13}C NMR spectroscopy:[74–76] the cellulose nitrate specimens obtained in anhydrous nitrating mixtures and such mixtures diluted with water are characterised respectively by 75% and 46% contents of trinitrate units in the polymer chain.

The data presented indicate the important role of low-frequency IR spectroscopy in the study of the structural features of monosaccharides and polysaccharides, including cellulose and its nitrates. Comparison of the experimental spectra with the results of calculations of the frequencies and modes of the normal vibrations and also of the steric structure of monosaccharides, disaccharides, and their nitro-derivatives permitted a detailed interpretation of the low-frequency vibrations. The frequency ranges of the vibrations of the crystal lattices (30–200 cm^{-1}) and intramolecular (deformation and torsional) vibrations (200–700 cm^{-1}) were established. It is shown that the frequencies of the 'lattice' vibrations are determined by the structure of monosaccharides and disaccharides: by the chemical structure of the side fragments (OH, OCH_3, CH_2OH, CH_2ONO_2), the spatial orientation of the OH groups (axial or equatorial), and the characteristic features of the bonding of the glucose residues (the α- and β-configurations). The observation of the conformational sensitivity of the δ(CCO), δ(CON), τ(CO), and τ(NO) vibrations in the range

$200-700\ cm^{-1}$ and the identification of the spectral manifestations of the location of the nitrate groups at the C(2), C(3), and C(6) atoms of the pyranose ring are important.

The use of the analysis of model compounds for the interpretation of the low-frequency spectra of cellulose and cellulose nitrates in order to solve a number of structural problems is of special interest and practical value: the determination of the three-dimensional degree of order in cellulose and cellulose nitrates and physically and chemically modified cellulose. Spectroscopic study of the mechanism of the physical modification of cellulose on treatment of the latter with aqueous solutions of alkali made it possible to identify three stages in the structural changes in the polymer determined by the degree of order in the macromolecules, the conformational state of the hydroxymethyl groups, and the system of hydrogen bonds. Analysis of the formation of the molecular crystal structures of cellulose nitrate demonstrated that the principal structural changes in cellulose nitrate, associated with the disorder in the cellulose chains and the spatial orientation of the fragments of the macromolecules, nitrate groups, and the residual hydroxy-groups, occurs in the first stage of the chemical synthesis for a degree of substitution in cellulose nitrate less than 1.6.

Contents

I. Introduction	337
II. Methods of synthesis of acetylcyclopropane	337
III. Chemical properties of acetylcyclopropane	338
IV. The use of acetylcyclopropane in the synthesis of natural and practically useful compounds	352

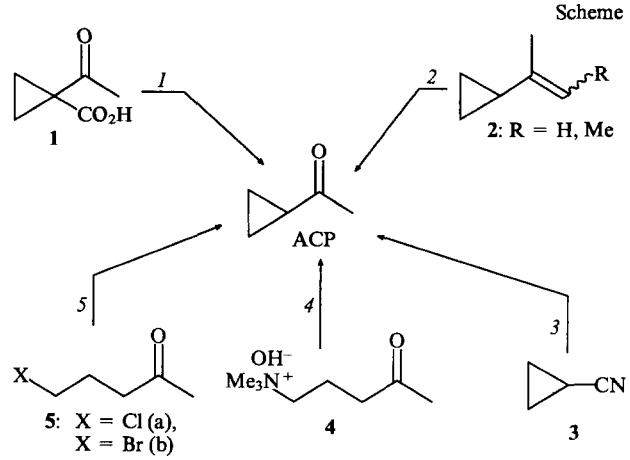
Abstract. Data on the synthesis chemical reactions of acetylcyclopropane are presented. A systematic account is given in terms of the reactions of the functional groups of the above compound (methyl, carbonyl, and cyclopropyl). The extensive possibilities of acetylcyclopropane as a convenient five-carbon building block in organic synthesis are demonstrated. The bibliography includes 268 references.

I. Introduction

During the more than one hundred years that have elapsed since W A Perkin, Jr[1] first described the synthesis of acetylcyclopropane (ACP) and especially during the last decades, extensive structural data have accumulated on the use of this five-carbon synthon in organic synthesis. The presence of the keto-group in acetylcyclopropane in combination with a three-membered carbocycle is responsible for the specific bifunctional properties of this compound and, apart from the multiplicity of classical reactions characteristic of methyl ketones, it is possible to carry out with this compound also reactions involving the opening and retention of the cyclopropane fragment. Organic compounds of various classes have been synthesised from acetylcyclopropane. Acetylcyclopropane and its derivatives are widely used in the preparation of substances which have found applications in engineering, agriculture, and medicine.

Despite the existence of fairly extensive data on the chemical reactions of acetylcyclopropane, they have not so far been treated systematically and the present review was undertaken to fill this gap.

II. Methods of synthesis of acetylcyclopropane



Acetylcyclopropane was first synthesised in a moderate yield in 1887 by the thermolysis of acetylcyclopropanecarboxylic acid **1** (Scheme 1).[1] At the present time, acetylcyclopropane is a commercially available product. A compilation of the methods of its synthesis known at the end of the 1950s has been published.[2]

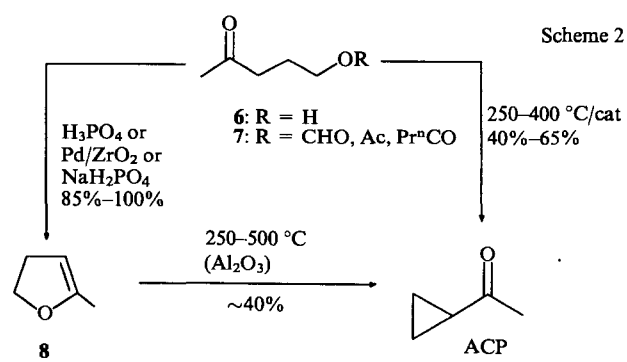
Uspekhi Khimii **62** (4) 365–386 (1993); translated by A K Grzybowski

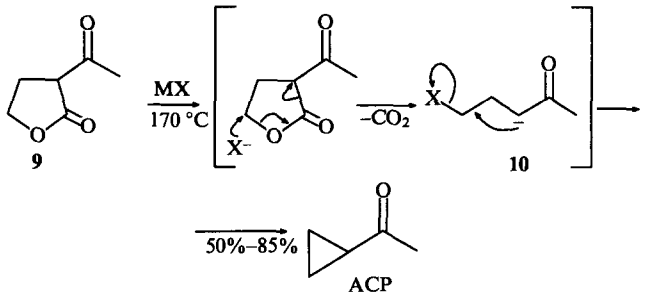
Apart from the thermolysis mentioned above, these include the oxidation of alkenes **2**.[3,4] Grignard synthesis from the cyano-derivatives **3**,[5] thermal decomposition of the ammonium salt **4** in the presence of KOH,[6] as well as cyclisation of γ-acetylpropyl halides **5**.[2] These and related methods are in fact most widely used.



Scheme 1

(*1*) Δ(30%);
(*2*) $KMnO_4$ or O_3 (~50%);
(*3*) MeMgBr (40%);
(*4*) Δ/KOH (45%);
(*5*) EtONa or KOH (40%–95%).

The methods of synthesis of acetylcyclopropane developed during the last three decades, among which special mention should be made of the synthesis of acetylcyclopropane from acetylpropyl alcohol **6** and some of its derivatives, are summarised below (Scheme 2).[7–13]

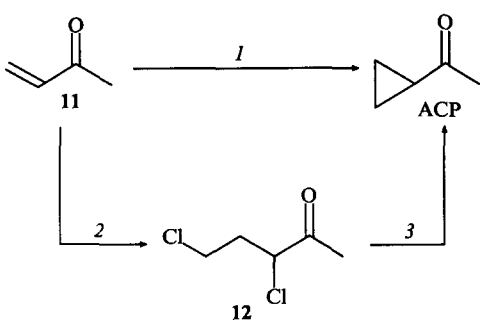


Scheme 2

The cyclodehydration of compound **6** proceeds readily and affords the dihydrofuran **8**,[7,14,15] the (thermo)catalytic isomerisation of which in a flow system leads to acetylcyclopropane.[7-11,13,16] The efficiency of this stage depends on a series of parameters (the temperatures used, contact time with the catalyst, etc.) and can reach 40% for a low overall conversion of the ketoalcohol **6**. The use of the esters **7** makes it possible to increase the yield of acetylcyclopropane to 65%.[11,12] The catalysts used in this process are zeolites[12] or metal oxides, mainly transition metal oxides.[11,12]

Acetylcyclopropane can be obtained by the thermolysis of α-acetylbutyrolactone **9** in the presence of catalytic amounts of alkali ,metal halides (Scheme 3).[17-20]

Scheme 3

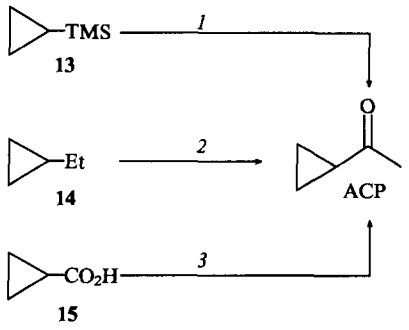


MX = NaI, NaBr, LiCl.

The reaction evidently proceeds via stages involving the opening of the five-membered ring and the generation of the carbanion **10**, which subsequently undergoes intramolecular cyclisation.[17,18] The maximum yield of acetylcyclopropane was achieved under these conditions using NaI in hexamethylphosphoramide (HMPA).[17]

One of the evident approaches to the synthesis of acetylcyclopropane involves the transformation of methyl vinyl ketone **11** (Scheme 4).

Scheme 4



(*1*) CH_2I_2–Zn/Cu (50%), CH_2I_2–Zn/Ag (60%), CH_2Br_2–Ni(0)/Zn/NaI (> 95%);
(*2*) CH_2Cl_2/MeCN, CuCl, Bu^n_4NBr, *hν*;
(*3*) e^- (45% from **11**).

The classical version of the Simmons–Smith reaction leads in this instance to acetylcyclopropane in approximately 50% yield.[21] The use of a modified version of this method, in which the Zn/Cu couple has been replaced by the Zn/Ag couple, proved to be somewhat more effective.[21] A virtually quantitative yield of acetylcyclopropane was achieved when CH_2Br_2 and the complex Ni(0)/Zn/NaI were involved in the reaction.[22] Finally, the possibility of converting compound **11** into a cyclopropane derivative using CH_2Cl_2 as the methylenating agent has been demonstrated by the two-stage version of this process, including the cathodic dechlorination of the intermediate photoadduct **12**.[23]

A small group of methods is based on the use of cyclopropane precursors (Scheme 5). Thus the acylation, catalysed by a Lewis acid, of the cyclopropylsilane **13**, which was obtained in its turn by the Simmons–Smith conversion of trimethylvinylsilane into a cyclopropane derivative, leads smoothly to acetylcyclopropane virtually without the competing reaction involving the opening of the three-membered ring.[24] The oxidation of ethylcyclopropane **14** by ozone in the presence of SiO_2 is also characterised by a satisfactory yield of acetylcyclopropane.[25] The single-stage conversion of the acid **15** into acetylcyclopropane on treatment with LiMe,[26] in principle related to the conversion into acetylcyclopropane of the nitrile **3** of the above acid on treatment with MeMgBr, is almost just as effective.

Scheme 5

(*1*) AcCl/$AlCl_3$–CH_2Cl_2 (60%);
(*2*) O_3/SiO_2 (~60%);
(*3*) MeLi (~65%).

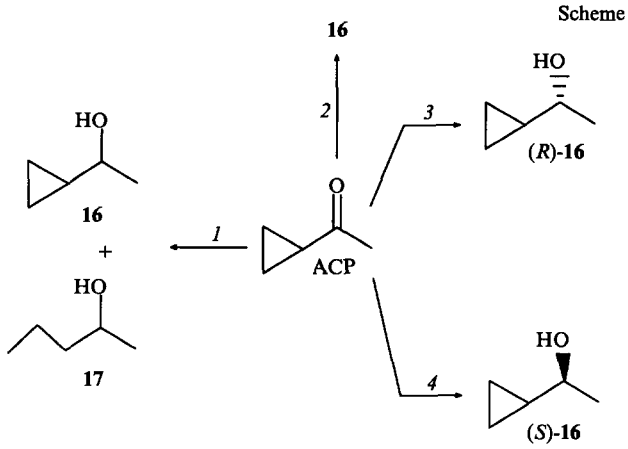
It follows from the data presented that, among the various methods of synthesis of acetylcyclopropane available at present, the procedures based on γ-acetylpropyl chloride **5a** and the corresponding alcohol **6** are the most attractive and technologically most sophisticated.

III. Chemical properties of acetylcyclopropane

Numerous reactions of acetylcyclopropane, occurring both with participation of its carbonyl or methyl group and with the opening of the three-membered carbocycle, have now been described. This will be the subject of the further consideration of the literature data available at present, which do not so far contain information about the direct introduction of functional groups into the cyclopropane fragment of this molecule.

1. Reactions involving the carbonyl group

Reactions of this type constitute the commonest series of reactions of acetylcyclopropane. They are similar to the known reactions of aliphatic ketones.



a. Reduction

Acetylcyclopropane is an extremely popular substrate for the study of the properties of new reductants. In particular, it has become one of the first objects to which the Bouveault–Blanc reaction has been applied.[27] The reduction of acetylcyclopropane by the Bouveault–Blanc method leads to a mixture of secondary alcohols with cyclic (compound **16**) and linear (compound **17**) structures (Scheme 6).[27,29] Hydrogenation of acetylcyclopropane over a nickel catalyst is also accompanied to a significant extent by the opening of the three-membered ring,[28] which can be appreciably suppressed by using platinum[30] and can be almost entirely excluded in the presence of a chromium-containing catalyst.[28] The complete retention of the cyclopropane ring is attained when a zinc-based catalyst is employed,[31,32] although the degree of conversion of acetylcyclopropane is then fairly low.

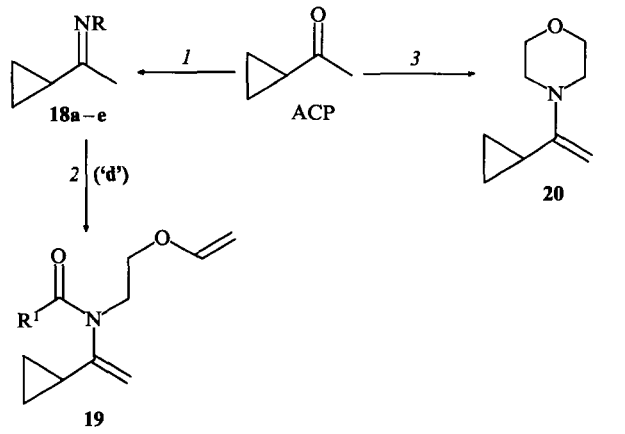
Acetylcyclopropane is reduced chemoselectively by Bu^n_3SnH under mild conditions but with a moderate yield.[33] The Meerwein–Pondorf reduction of acetylcyclopropane makes it possible to obtain the alcohol **16** in ~90% yield[29] under

conditions involving the rapid decomposition of the intermediate organoaluminium complexes, inducing the formation of high-molecular-mass side products.[34] The same complications may arise in the treatment of the reaction mixtures formed as a result of the hydride reduction of the acetylcyclopropane with the aid of lithium tetrahydroaluminate ($LiAlH_4$)[28,31,35-39] or KBH_4.[40]

Scheme 6

(*1*) Na/EtOH (~50%), H_2/Ni-Ra (~70%, **16**:**17** ≃1:1), H_2/Pt (~50%), H_2/Cr_2O_3, 100°C (90%);
(*2*) H_2/Zn, 160°C (45%), H_2/Zn–Cu, 125°C (65%), Bu^n_3SnH/Bu^n_4NCl (~25%), Bu^n_3SnH/Bu^n_4NF (~45%), $(Pr^iO)_3Al/Pr^iOH$ (~90%), $LiAlH_4/Et_2O$ (~75%), KBH_4/MeOH (~75%);
(*3*) enzymes from the fungus *Pseudomonas* (> 60%);
(*4*) (*R*)-β-isopinocamphenyl-9-borabicyclo[3.3.1]nonane.

Data on the enantioselective reduction of acetylcyclopropane have been published recently. Thus the chemoenzymic method, using the enzyme system from fungi of the genus *Pseudomonas*, makes it possible to obtain the optically pure (> 98%) isomer (*R*)-**16** in a satisfactory yield.[41-43] Its enantiomer (*S*)-**16** has been synthesised with an optical purity of 69% with the aid of the bulk-phase chiral tetrahydroborate reagent.[44]



b. Synthesis of nitrogen-containing derivatives

The interaction of acetylcyclopropane with various nitrogen-containing bases afforded a large number of its different derivatives involving the carbonyl group—from the simple oxime[45,46] and hydrazones[47-54] to structurally more complex systems, some of which serve as the starting materials in the synthesis of medicinal preparations and herbicides.[46,49,55-58]

The interaction of acetylcyclopropane with primary amines leads smoothly to the Schiff bases **18a–e** (Scheme 7),[58-63] which have recently found synthetic applications on an increasingly wide scale. In particular, the acylation of the imine **18d** leads to the smooth formation of the vinylamides **19**, which are of interest as monomers; in this reaction, only the nitrogen atom is subjected to electrophilic attack in the initial molecule.[61-63] The direct conversion of acetylcyclopropane into the enamine **20** has been achieved, admittedly only in a low yield, by the Lewis-base catalysed reaction of acetylcyclopropane with morpholine.[64,65]

The primary amine **21** was obtained by the reductive amination of acetylcyclopropane[66,67] (Scheme 8).† In contrast to the hydrogenation over Raney nickel, in this case the reaction is not accompanied by the opening of the cyclopropane ring, which can be explained by the partial deactivation of the catalyst in the presence of NH_3.[66] Nucleophilic substitution of the hydroxy-group by the amino-group in the intermediate cyanohydrins, arising in the interaction of acetylcyclopropane with HCN, leads to the aminonitriles **22a**[55,56,68] and **22b**.[69]

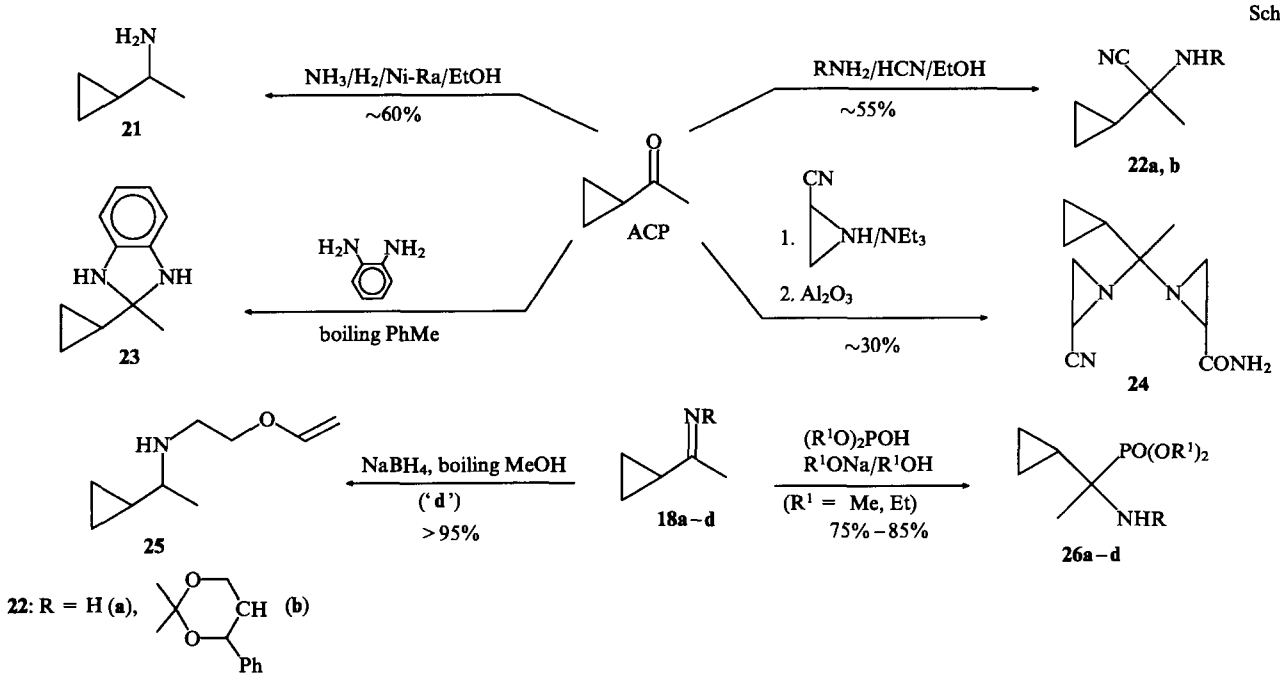
Scheme 7

18: R = Bu^n(**a**), cyclo-C_6H_{11}(**b**), CH_2CH_2OEt (**c**), $CH_2CH_2OCH=CH_2$ (**d**), $CH_2CH_2CO_2TMS$ (**e**),
19: R^1 = Me, Et, Pr^n, Bu^n, Ph

(*1*) RNH_2/H^+, boiling PhH (50%–90%);
(*2*) R^1COCl/NEt_3, PhH (70%–80%);
(*3*) morpholine/$TiCl_4$, pentane (> 30%).

The reaction of acetylcyclopropane with *o*-phenylenediamine affords the aminal **23**.[70] Another representative of substances of this class is the amidonitrile **24**, which exhibits mutagenic properties. It was synthesised by the condensation of 2-cyano-aziridine with acetylcyclopropane and subsequent hydrolysis of one of the two nitrile groups in the molecule of the intermediate adduct.[57]

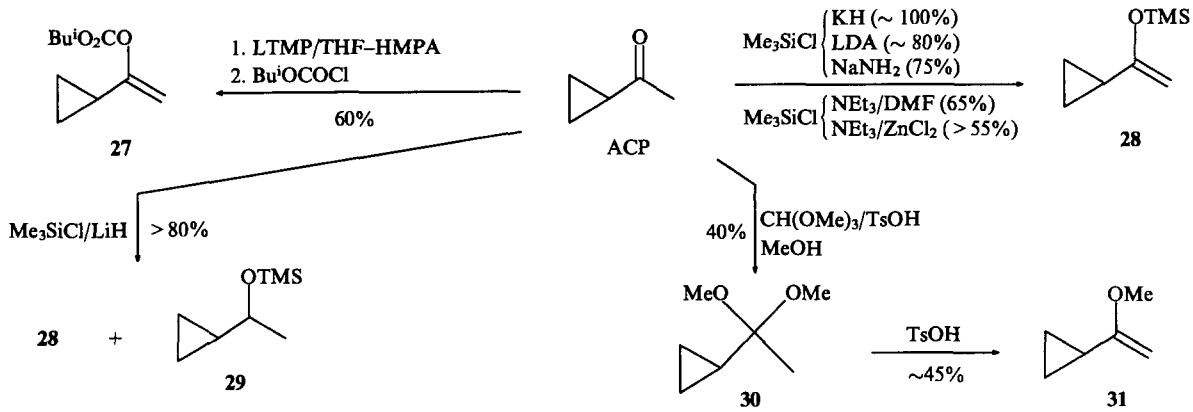
Individual α-cyclopropyl-containing secondary amines have been obtained from the Schiff bases **18a–d**. Thus the aminoester **25** has been synthesised in an almost quantitative yield by the hydride reduction of the imine **18d**.[61] The alkoxide-catalysed addition of dialkyl phosphites to the azomethine bond in the imines **18a–d** involves the Arbuzov rearrangement, affording high yields of the aminoalkylphosphonates **26a–d**, among which compounds with insecticidal properties were found.[58]



c. Enolic derivatives of acetylcyclopropane

On treatment with strong bases of the type of lithium tetramethylpiperidide (LTMP),[71] lithium diisopropylamide (LDA),[72] $NaNH_2$,[73] KH,[74] LiH,[75] and even NEt_3,[20,76-79] acetylcyclopropane is deprotonated under mild conditions, which leads to a simple and regioselective synthesis of its enolic derivatives (Scheme 9). Thus treatment of lithium acetylcyclopropane enolate with isobutyl chlorocarbonate leads to the smooth formation of the enol carbonate **27**.[71] The TMS-ester‡ **28**, which has found extensive synthetic applications, is obtained similarly to the interaction of Me_3SiCl with the acetylcyclopropane enolate generated *in situ* by various methods,[20,72-74,76-79] for example by treatment with NEt_3 in dimethyl formamide (DMF).[76-79] The yield of compound **28** is in this case ~65%, diminishing somewhat when catalytic amounts of $ZnCl_2$ are used,[20] although overall this version of the silylation reaction is comparatively more convenient, because it simplifies the isolation of the ether. The deprotonation of acetylcyclopropane with the aid of LDA, $NaNH_2$, or KH promotes an increase in the yield of compound **28**. The LiH obtained *in situ* by the hydrogenation of the complex Bu^nLi-TMEDA (TMEDA = tetramethylethylenediamine) partly reduces acetylcyclopropane, affording, after treating the reaction

† The absence from the schemes of information about the yield and/or the proportions of the products (for example, in ACI[e] → **23**) always implies the absence of such data from the original sources.



‡ TMS = trimethylsilyl (translator).

Scheme 8

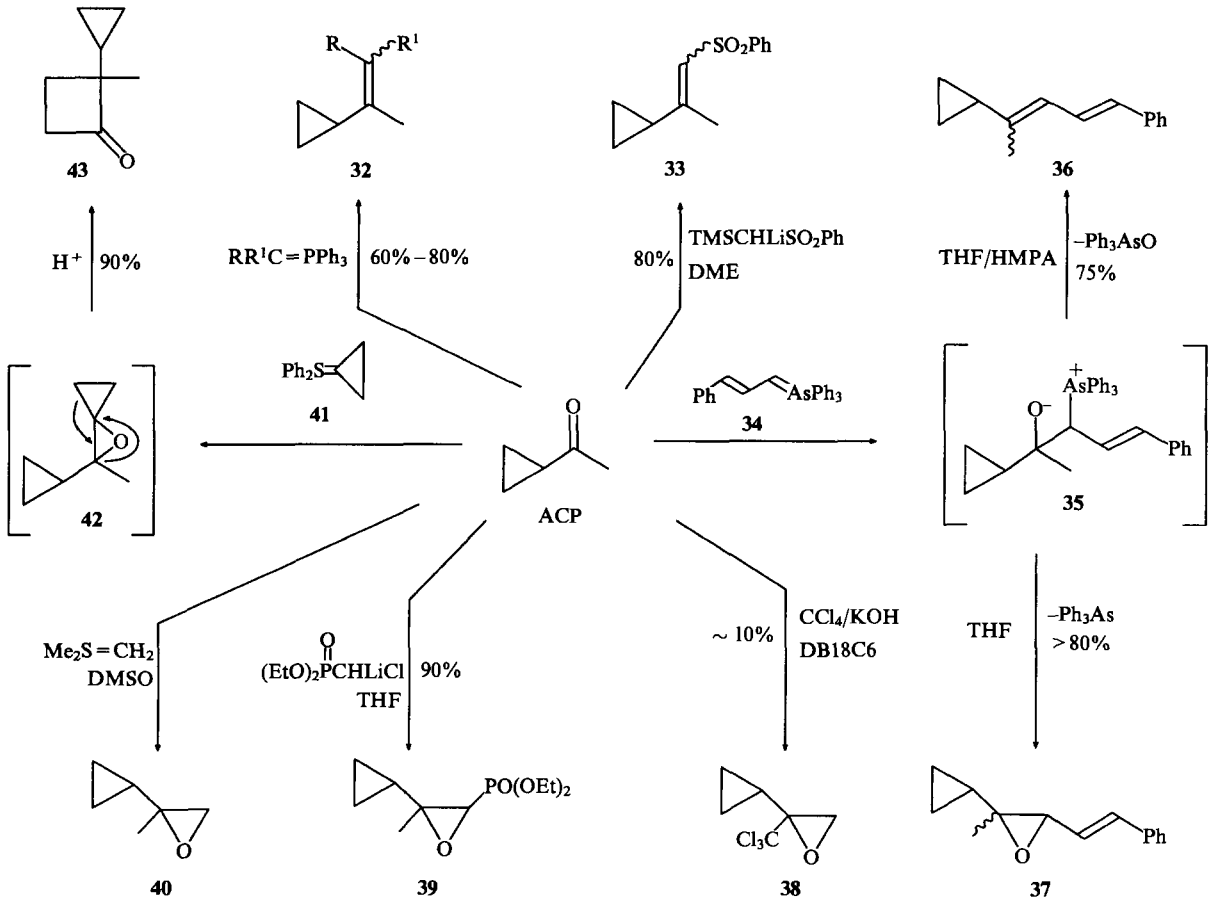
26: R = Bu^n (**a**), cyclo-C_6H_{11} (**b**), CH_2CH_2OEt (**c**), $CH_2CH_2OCH=CH_2$ (**d**).

Scheme 9

mass with Me_3SiCl, a mixture of the ethers **28** and **29** in proportions of ~2:3.[75]

The methyl ether **31** was synthesised in a moderate yield by eliminating the elements of MeOH from the dimethyl ketal **30** obtained by a standard method.[80]

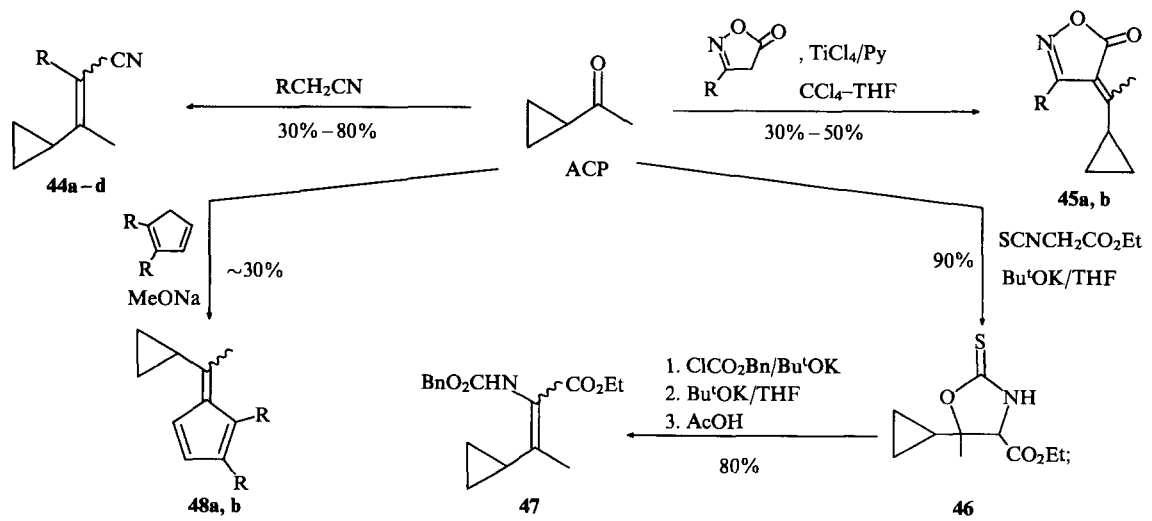
d. Conversion into olefins and related reactions of acetylcyclopropane



Reactions of acetylcyclopropane with phosphorus, arsenic, and sulfur ylides, leading to the corresponding olefins and epoxides, are widely represented in the literature. For example, the Wittig conversion of acetylcyclopropane into olefins proceeds without complications, affording vinylcyclopropanes **32** in preparative yields and with the expected ratio of the stereoisomers[81–87] (Scheme 10). The Peterson reaction of acetylcyclopropane with the lithio-derivative of trimethylsilylbenzenesulfonylmethane leads similarly to the smooth formation of a mixture of the vinyl sulfones **33** ($Z:E \simeq 3:1$).[88]

The arsorane **34** interacts with acetylcyclopropane via one of two possible pathways depending on the reaction conditions. Thus, when a 1:1 THF–HMPA (HMPA = hexamethylphosphoramide) mixture was used as the solvent, the product **36** of the olefin formation reaction was obtained exclusively ($E:Z \simeq 1:1$),[89,90] whereas in tetrahydrofuran (THF) only the epoxide **37** is formed.[89] The authors correctly explain this effect by the ability of HMPA to stabilise the positive charge in the betaine intermediate **35**, which should diminish the polarity of the C–As bond and thereby promote the generation of the alkene.[89]

The substituted oxiran **38** has been synthesised by the reaction of acetylcyclopropane with CCl_4 in the presence of alkali and the crown-ether, although the yield was low.[91] The mechanism of this reaction has not been explained.



The epoxide **39** has been obtained almost quantitatively by condensing acetylcyclopropane with the lithio-derivative of diethyl chloromethylphosphonate, evidently via an intermediate chlorohydrin stage.[92] This reaction is in principle related to the Corey–Chaykovsky reaction with the sole difference that the leaving group is in this instance the chlorine atom and not the sulfonium group. The involvement in this reaction of acetylcyclopropane and dimethylsulfonium methylide leads to the epoxide **40**.[93] The analogous interaction with the ylide **41** affords a high yield of the cyclobutanone **43**, which evidently arises as a result of the ready rearrangement of the intermediate spiroepoxide **42**.[94,95]

Scheme 10

32: R = H, R^1 = Me, OMe; R = R^1 = Me; RR^1 = $(CH_2)_2$, $(CH_2)_3$;
DB18C6 = dibenzo-18-crown-6.

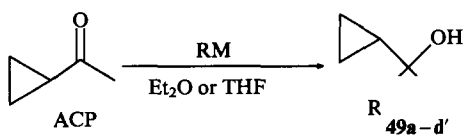
Scheme 11

44: R = CN (**a**), Bz (**b**), CO_2Et (**c**), $CONH_2$ (**d**);
45: R = Me (**a**), Ph (**b**);
48: R = H (**a**), RR = $(CH{=}CH)_2$ (**b**);
Bn = benzyl, Bz = benzoyl.

The Knoevenagel reaction with participation of acetylcyclopropane has been used to obtain the unsaturated nitriles **44a–d**[96,97] (Scheme 11), which have served, in their turn, as key intermediates in the synthesis of 2-aminothiophenes and some of their derivatives with antitumour activity. It is noteworthy that the effectiveness of the condensation depends on the nature of both the initial malononitrile and the chosen catalyst. For example, on catalysis with an ion-exchange resin[97] or an AcOH/$AcONH_4$ mixture,[98] the yield of the dinitrile **44a** (or the ester **44c**) is 50%, falling to 30% in the case of the amide **44d**.[97] The use of the AcOH–β-alanine system as the catalyst makes it possible to obtain the nitriles **44a**[99] and **44b**[96] in 81% and 58% yields respectively. The stereochemistry of the olefins **44b–d** remains unelucidated.

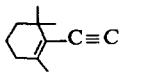
The Lewis acid-catalysed condensation of acetylcyclopropane with 3-methylisoxazolone leads stereoselectively to the adduct **45a**, which is a mixture of isomers ($E:Z$ = 85:15).[100] In the case of the 3-phenyl derivative, both stereoisomers of compound **45b** are formed in approximately equal amounts.[100]

The reaction of ethyl isothiocyanatoacetate with acetylcyclopropane in the presence of *tert*-BuOK affords the oxazolidinethione **46** as a result of the intermolecular cyclisation of the intermediate tertiary alcohol.[101,102] The product of the acylation of compound **46** isomerises under the influence of the excess of *tert*-BuOK, which is accompanied by the elimination of COS. This leads ultimately to the vinylcyclopropanes **47** in an overall yield >70%.[102] Finally, condensation of acetylcyclopropane with CH acids, catalysed by a strong base, led to the formation of the corresponding fulvenes **48a**[103] and **48b**[104] in moderate yields.



Thus conversion into olefins and nucleophilic reactions of acetylcyclopropane of a similar nature provide an easy access to functionalised vinylcyclopropanes and related epoxides, which have a high synthetic potential.

e. Reactions of acetylcyclopropane with organometallic compounds



The data described above cover only a small number of examples of the use of acetylcyclopropane as a convenient and readily available compound for the study of the properties of various nucleophiles, leading at the same time to products with a wide variety of synthetic applications. The main bulk of the data published until recently refer to the synthesis and subsequent chemical reactions of cyclopropyl alcohols **49** formed in the reactions of acetylcyclopropane with various organometallic compounds—primarily with Grignard reagents (Scheme 12).

It is seen from the data presented that the Grignard reaction involving acetylcyclopropane proceeds as a whole with fairly high yields, which decrease, as was to be expected, when sterically bulky allyl halides are used. In the case of MeMgI, a significant amount (~15%) of 1-iodo-4-methylpent-3-ene—the acyclic product of the cyclopropylcarbinyl rearrangement (CPCR)—is

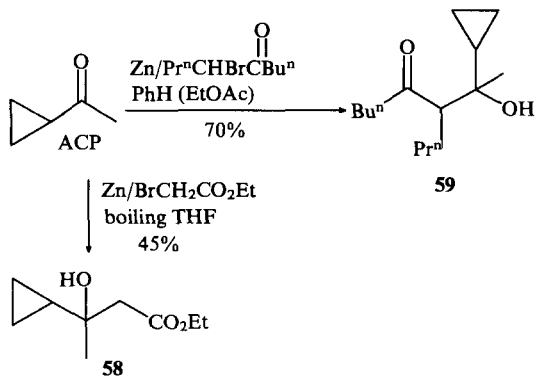
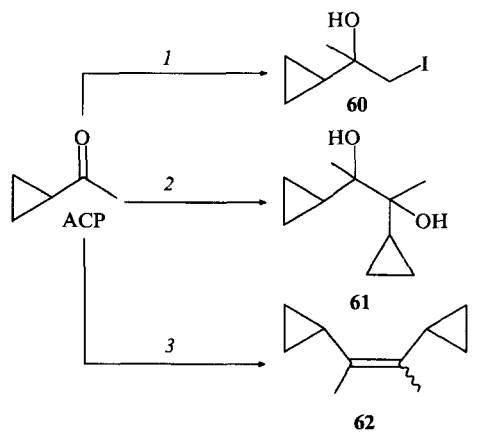


Scheme 13

formed together with the corresponding cyclopropyldimethylcarbinol **49a**.[112,114] Sodium[129,144,145] and potassium acetylides[132,146–148,151] interact with acetylcyclopropane without complications, affording the corresponding ethynylmethylcarbinols. Substituted acetylides have been used successfully under these conditions as Iotsich reagents or as alkali metal derivatives.

Examples of the interaction of certain functionalised organolithium reagents are presented in Scheme 13. Thus silylation of the products of the condensation of dihalomethyllithium with acetylcyclopropane leads to the trimethylsilyl ether **50**, which can readily undergo β-elimination on treatment with bases to form *gem*-dihaloalkenes.[155] The introduction of the acetonyl fragment into the acetylcyclopropane molecule has been achieved with the aid of the lithio-derivative of the dithiocarbamate **51**, which interacts with acetylcyclopropane, affording a mixture of the regioisomers **52** and **53** in proportions of 4 : 1.[156] Their hydrolysis and subsequent reductive desulfurisation of the intermediate dithio-carbamates led to the formation of the β-hydroxyketone **54** in a high overall yield.

Scheme 14

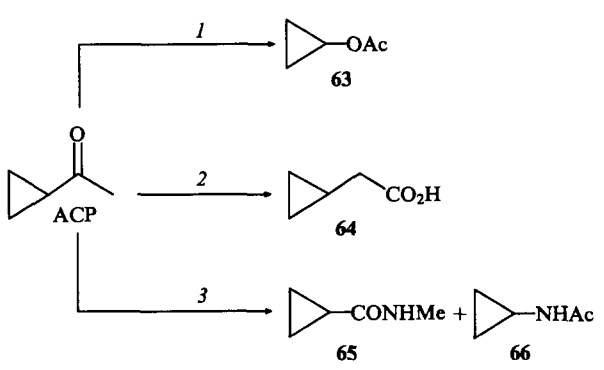


The reaction of the lithio-derivative of isocyanocyclopropane with acetylcyclopropane leads to an intermediate isocyano-derivative, which undergoes spontaneous intramolecular cyclisation to the oxazoline **55**.[157] Yet another example of the use of acetylcyclopropane for the synthesis of various heterocycles is provided by its reaction with the metallated dithioimide **56**, which leads to the carbinol **57** — a precursor of oxathiolans.[158]

Another interesting but hitherto inadequately developed approach to the synthesis of functionalised cyclopropylmethylcarbinols involves the use of organozinc reagents. For example, the synthesis of the tertiary alcohols **58**[159] and **59**[160] from acetylcyclopropane by the Reformatskii reaction has been described (Scheme 14).

The radical–ion reactions with participation of acetylcyclopropane have also been investigated extremely inadequately.

Scheme 15

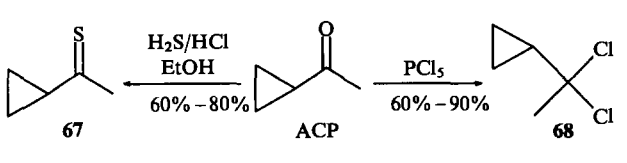


(*1*) CH_2I_2/Sm(0)–THF (60%);
(*2*) Al/Hg (30%), $TiCl_4$/Mg–Bu^{t}OH (60%);
(*3*) $TiCl_3$/$LiAlH_4$–THF (30%).

Reactions of this kind include, for example, the Sm(0)-initiated iodomethylation of acetylcyclopropane with CH_2I_2, which leads effectively to the iodohydrin **60** related to the carbinols **49**[161] (Scheme 15). The conversion of acetylcyclopropane into the vicinal glycol **61**, which takes place smoothly under the influence of aluminium amalgam, also belongs to this class.[162] The yield of compound **61** increases by a factor of 2 when low-valence titanium ions, suppressing the opening of the three-membered ring, are used.[163] When the McMurry reagent[164] is employed, the final products are tetra-substituted olefins **62**, which evidently arise via the pinacol **61** stage.[165]

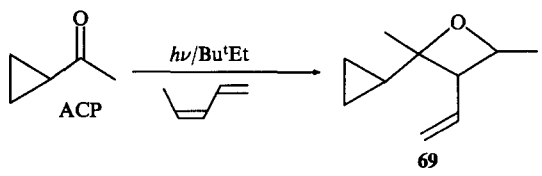
f. Other reactions of acetylcyclopropane involving the carbonyl group

In conclusion of this Section, we shall consider the individual reactions of acetylcyclopropane in which this compound was used simply as a standard carbonyl substrate, the products of the reaction of which have not so far found a fitting synthetic application. Thus the Baeyer–Villiger oxidation of acetylcyclopropane with the aid of CF_3CO_3H affords smoothly the acetate **63** (Scheme 16).[166] On the other hand, acetylcyclopropane is resistant to the action of weaker peracids of the type of perbenzoic acid.[167] The conversion of acetylcyclopropane into cyclopropyl acetic acid **64** by the Willgerodt–Kindler reaction takes place only with an insignificant yield.[168] Under the conditions of the Schmidt reaction, acetylcyclopropane affords a mixture of both expected regioisomeric amides **65** and **66**,[169–171] the ratio of which in a strongly acid medium depends on the pH of the reaction mixture and can be logically explained by the different rates, under such conditions, of the competing migration to the nitrogen atom of the methyl and cyclopropyl residues in the key intermediate.[170,171]



Scheme 16

(*1*) CF_3CO_3H/Na_2HPO_4 (~55%);
(*2*) S/Pi/Δ (~10%) (Pi = piperidine);
(*3*) NH_3 (90%).



The thione **67** and the *gem*-dichloro-derivative **68**, obtained in high yields by treating acetylcyclopropane with H_2S in an alcoholic solution of HCl[172,173] and with PCl_5 in chlorinated solvents[73,174–176] respectively (Scheme 17), may be of definite synthetic interest. The yield of the dichloro-derivative **68** increases appreciably when the reaction is carried out in the presence of a base (pyridine,[177,178] Na_2CO_3[179]), although partial dehydrochlorination of the product is then observed.

Scheme 17

The photochemical [2 + 2]cycloaddition with participation of the central C=C bond of (*Z*)-piperylene and the carbonyl group of acetylcyclopropane leads regiospecifically to the oxetan **69**, the geometry of which has not been established;[180] the reaction is complicated by the formation of significant amounts of the photodimer of (*Z*)-piperylene (Scheme 18). Other examples of the involvement of acetylcyclopropane in photochemical reactions with retention of the three-membered ring are lacking in the literature.

Scheme 18

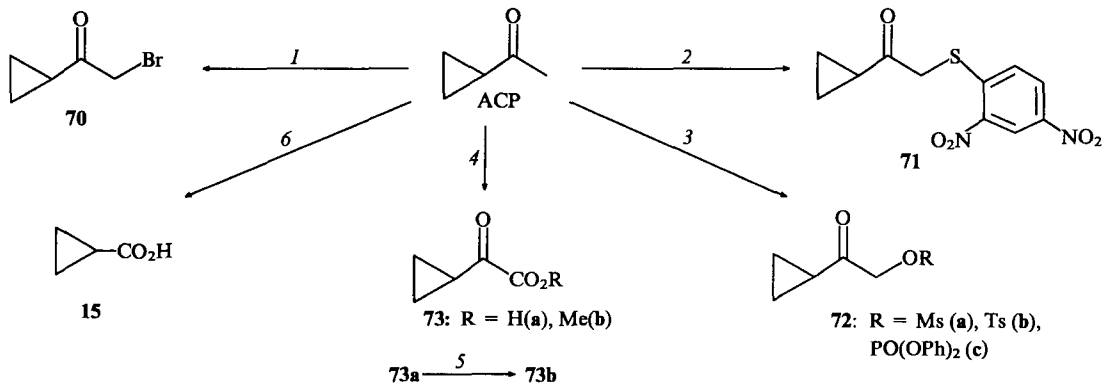
Thus the reactions with participation of the carbonyl group of acetylcyclopropane considered above illustrate the extensive possibilities of the use of this ketone for the introduction of the ethylcyclopropane carbon skeleton into various organic compounds, making available thereby a large number of oxygen- and nitrogen-containing derivatives of acetylcyclopropane — important intermediates in organic synthesis.

2. Reactions with participation of the methyl group of acetylcyclopropane

Numerous reactions based on the use of acetylcyclopropane as a typical CH acid, reacting, in contrast to other aliphatic cyclic methyl ketones, with participation of only the methyl group, have been described nowadays. Such unique regiospecificity is the main reason why ways of using acetylcyclopropane as an effective C_5 building block in the synthesis of certain biologically active substances are being sought. The activation of the carbonyl functional group of acetylcyclopropane by its conversion into the imino- or enol form proves to be superfluous in many instances, although it does promote an increase in the yield of the target product and sometimes an enhancement of the chemoselectivity of reactions with certain electrophiles.

a. Synthesis of α-functionalised derivatives of acetylcyclopropane

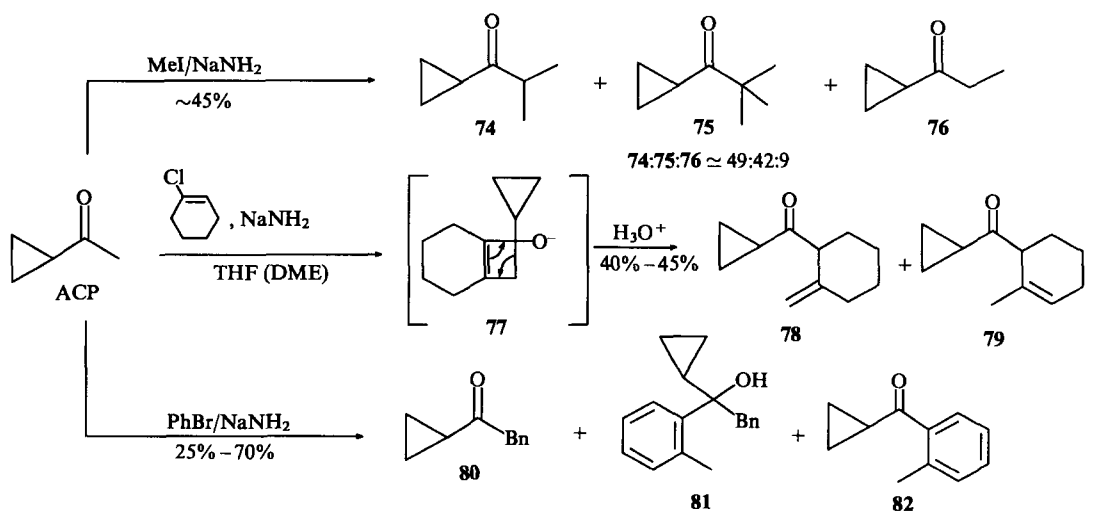
Treatment of acetylcyclopropane with Br_2 in methanol affords smoothly and selectively the monobromo-derivative **70**[181–185] (Scheme 19). The reaction of acetylcyclopropane with 2,4-dinitrobenzenesulfenyl chloride, leading to a virtually quantitative yield of the ketosulfide **71**, is just as selective.[186] The methanesulfonate **72a**,[187] the toluene-*p*-sulfonate **72b**,[188] and the phosphate **72c**[189] have been obtained by the reaction of acetylcyclopropane with the corresponding derivatives of trivalent iodine. In all the cases indicated, the process evidently includes a stage in which the enolic form of acetylcyclopropane is generated.[187,188]



The oxidation of acetylcyclopropane with $KMnO_4$ leads to cyclopropylglyoxalic acid **73a**, which is characterised as the keto-ester **73b**.[190,191] The use of NaOBr as the oxidant opens an effective pathway to cyclopropanecarboxylic acid **15**.[70]

b. Reactions leading to the formation of a new carbon–carbon bond

The Neff methylation of acetylcyclopropane by treatment with $NaNH_2$ (Scheme 20) is characterised by low selectivity. A mixture of all three possible products **74–76** is then formed with the dimethyl derivative **74** predominating.[125]



The condensation of acetylcyclopropane with 1-chlorocyclohexene in an aprotic medium, catalysed by a strong base, leads to the unsaturated ketones **78** and **79** in proportions of ~4 : 1.[192] Cyclohexyne is apparently formed initially and then interacts with the acetylcyclopropane enolate anion, affording the product **77**.

Scheme 19

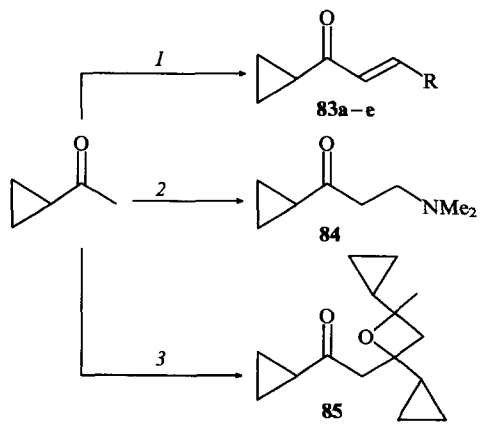
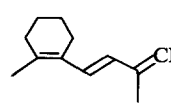
(*6*) NaOBr, H_2O (~80%).

Scheme 20





Isomerisation of the cyclobutene fragment in the adduct **77** leads to the main product **78**. Its allyl isomer **79** is probably obtained as a result of the shift of the exocyclic C = C bond on treatment with the base. The reaction of acetylcyclopropane with the dehydrobenzene generated from bromobenzene proceeds similarly, affording the product of phenylation at the methyl group **80**, the alcohol **81** and the ketone **82**, related to cyclohexene, the ratio of the latter depending on the reaction conditions.[193]

The condensation of acetylcyclopropane with trioxane in the presence of an equimolar amount of the salt CF_3CO_2H.PhNHMe affords a high yield of cyclopropyl vinyl ketone **83a**, which is evidently formed from the intermediate thermally unstable Mannich base[194] (Scheme 21). When this reaction is carried out in the classical version, the β-dimethylaminoketone **84** is formed smoothly. Its thermal decomposition led to the isolation of only the polymerisation product of the expected vinyl ketone **83a** instead of the vinyl ketone itself.[195]

Fairly numerous examples of the involvement of acetylcyclopropane in the base-catalysed condensation of the aldol-crotonic type with aliphatic[126,195–197] and aromatic[182,198–206] aldehydes have been described. The reaction undoubtedly proceeds via the corresponding aldol, which has been detected, for example, for isobutyraldehyde;[195,196] further dehydration leads to the formation of the thermodynamically preferred (*E*)-isomers **83b–e**, the yield of which depends on the nature of the aldehyde.

Scheme 21

83: R = H (a), Pr^i (b), cyclo-C_6H_{11} (c),  CH (d), Ar (e)

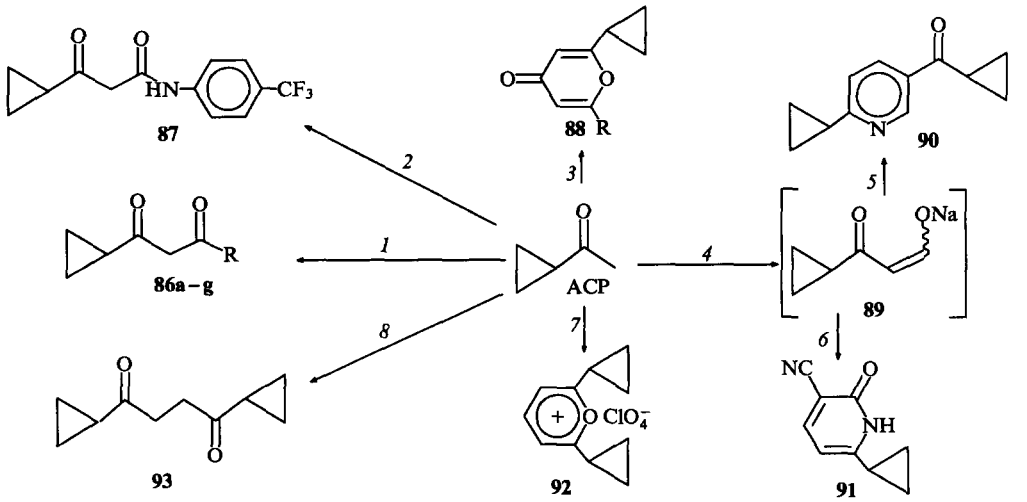
(*1*) $(CH_2O)_3/CF_3CO_2H$·PhNHMe (~75%) (for **83a**), RCHO/NaOH or Bu^tOK (30% – %90%) (for **83b–e**);
(*2*) CH_2O/Pr^iOH, Me_2NH·HCl (60%);
(*3*) KOH/Δ (25%).

The main cause of the decrease in the effectiveness of the reaction in the case of aliphatic aldehydes is their competitive reactions (self-condensation, polycondensation, and others).[195,196] The cyclopropyl tetraenyl ketone **83d**, prepared by this method (yield ~90%), was used in the synthesis of a retinal analogue.[197]

Direct condensation of the aldol–crotonic type of ketones with acetylcyclopropane is an uncharacteristic reaction in view of the tendency of the latter to form condensation products. In particular, when acetylcyclopropane was boiled (refluxed?) in the presence of powdered KOH, a compound was isolated, to which the structure of the oxetan trimer **85** with an unknown configuration was attributed.[126]

The involvement of acetylcyclopropane in a Claisen type reaction makes it possible to obtain a large series of β-dicarbonyl compounds **86** (Scheme 22). It may be catalysed by Lewis acids, for example BF_3,[207] although bases are used more often and more effectively ($NaNH_2$,[207] MeONa, EtONa,[208,209] NaH[210,211]). The result of the reaction, leading to the β-dicarbonyl derivatives **86a–g** depends significantly on the nature of the substrate. Thus condensation of acetylcyclopropane with acid anhydrides is as a rule less effective than the condensation with esters. For example, in the $NaNH_2$-initiated interaction of acetylcyclopropane with ethyl acetate, the yield of acetoacetylcyclopropane **86a** is 75%. The replacement of AcOEt by Ac_2O lowers the yield of compound **86a** almost by 20%.[207] The condensation of acetylcyclopropane with $(EtCO)_2O$, leading to the diketone **86b**, is characterised by an even lower yield (< 20%).[207]

The reaction of acetylcyclopropane with carbonates is in many respects determined by the choice of the catalyst. The best result is achieved usually when NaH is employed. Thus the replacement of $NaNH_2$ by NaH makes it possible to raise the yield of the β-ketoester **86e** from 55% to 85%.[211] Similarly diethyl oxalate reacts smoothly with acetylcyclopropane in the presence of only EtONa with formation of the highly reactive diketoester **86g**.[207] The ketoamide **87**, related to compound **86** and used as an intermediate in the synthesis of certain medicinal preparations, has been obtained by treating lithium acetylcyclopropane enolate with fluorinated aryl isocyanide and subsequent hydrolytic decomposition of the intermediate adduct.[212] Finally, one should note that the reaction of acetylcyclopropane with propiolates proceeds initially as the Claisen condensation and is terminated by the cyclisation of the intermediate acetylenic diketones to γ-pyrones **88**, which are formed in moderate overall yields.[213]

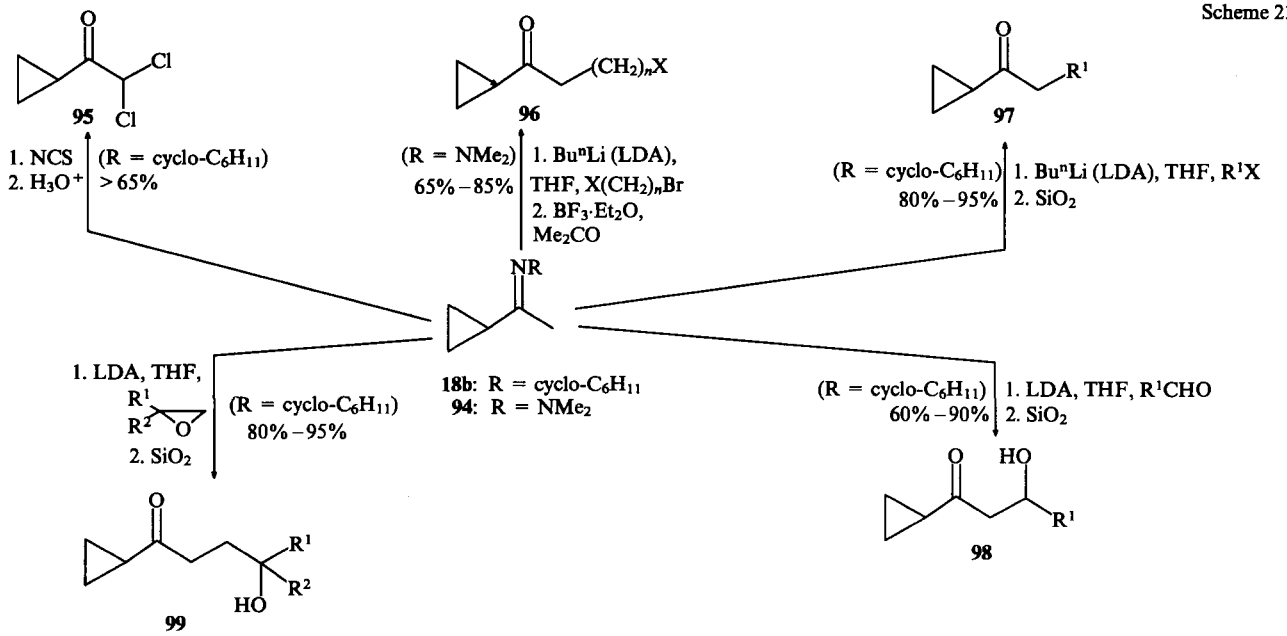


The Claisen condensation examined above, leading to the β-dicarbonyl compounds **86**, implies in the case of the formate the formation of the corresponding labile β-ketoformyl derivative. One of the interesting synthetic applications of the fairly stable sodium enolate **89**[214,215] involves its simple conversion into certain six-membered heterocycles. Thus, on treatment with ammonium acetate in acetic acid, the enolate **89** dimerises readily to the pyridine **90**[215] and reacts smoothly with cyanoacetamide in the presence of Pi.AcOH (Pi = piperidine), affording the pyridone **91**.[214] The thermal reaction of acetylcyclopropane with orthoformic ester, initiated by $HClO_4$, takes place similarly and proceeds evidently via the stage of a 1,5-dicarbonyl intermediate to the pyrylium salt **92**.[216]

In conclusion, one should note that the synthetic possibilities of enolates of type **89** as highly reactive intermediates are far from being exhausted. In particular, the lack of data on their involvement in a reaction of the Michael type and in radical-ion reactions is noteworthy. The latter apparently include the copper(II)-catalysed dimerisation of the lithium acetylcyclopropane enolate to the 1,4-diketone **93**.[217]

c. Certain reactions of activated acetylcyclopropane

Examples of the use of three readily available activated derivatives of acetylcyclopropane — the imine **18b**, the silyl ether **28**, and the hydrazone **94** — are considered below. With their aid, it is possible to achieve more effective regioselective and chemoselective reactions involving the methyl group than with the methyl ketone itself. Thus the direct chlorination of acetylcyclopropane proceeds non-selectively, affording a complex mixture of chloro-derivatives which are difficult to separate.[59] On the other hand, the ketimine **18b** reacts smoothly with *N*-chlorosuccinimide (NCS) and is converted, after the hydrolysis of the intermediate Schiff base, into the dichloroketone **95**[59] (Scheme 23).



Scheme 22

88: R = H, *o*-ClC_6H_4, *p*-ClC_6H_4, *p*-$MeOC_6H_4$

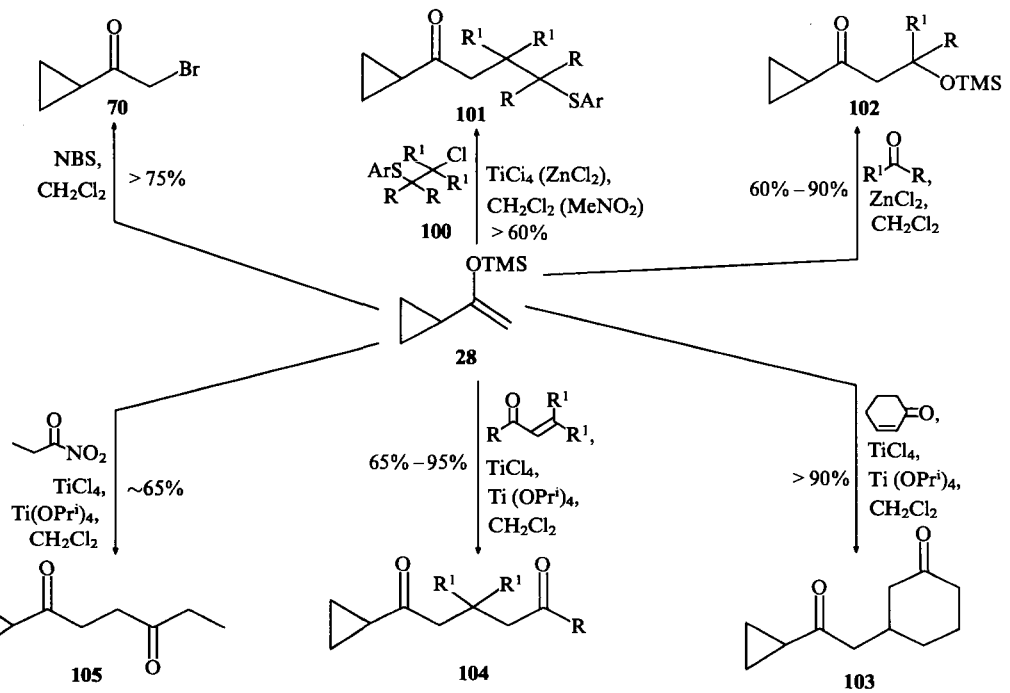
Scheme 23



96: X = Cl, $n = 3, 4$; X = Br, $n = 5$;
97: R^1 = Me, Pr^n, n-C_7H_{15}, n-C_9H_{19}, $Me_2C{=}CHCH_2$, (*E*)-$Bu^nCH{=}CH(CH_2)_3$, (*Z*)-$Bu^nCH{=}CH(CH_2)_7$;
98: R^1 = Et, Bu^n, n-C_6H_{11}, n-C_8H_{17}, (*E*)-$MeCH{=}CH$, (*Z*)-$Bu^nCH{=}CH(CH_2)_3$;
99: $R^1 = R^2 = H$; $R^1 = H$, $R^2 = Me$; $R^1 = Me$, $R^2 = CH_2{=}CH$.

Alkylation of the products of the deprotonation of the dimethylhydrazone **94** with ω-haloalkyl bromides affords, after the hydrolytic cleavage of the corresponding adducts, the ketones **96** in high overall yields.[218] Similarly the lithio-derivative of the imine **18b** interacts readily and selectively with primary alkyl halides, aldehydes, and epoxides, affording the ketones **97**, the β-hydroxyketones **98**, and the γ-hydroxyketones **99** respectively after the hydrolysis on silica gel of the imines formed.[219–223]

Treatment of the silyl ether **28** with *N*-bromosuccinimide leads to the monobromo-derivative **70**[224] (Scheme 24) without any appreciable advantage compared with the same reaction using acetylcyclopropane itself. On the other hand, the employment of compound **28** leads to the possibility of obtaining the products of the alkylation of acetylcyclopropane by sterically very greatly hindered electrophiles of the type of vicinal arylthiochloro-derivatives **100** on treatment with Lewis acids. The γ-arylthio-substituted ketones **101** have been effectively synthesised by this method.[225,226] The interaction of aliphatic aldehydes and ketones with the silyl ether of the enol **28** is effectively catalysed by $ZnCl_2$. This reaction results in the smooth formation of β-siloxyketones

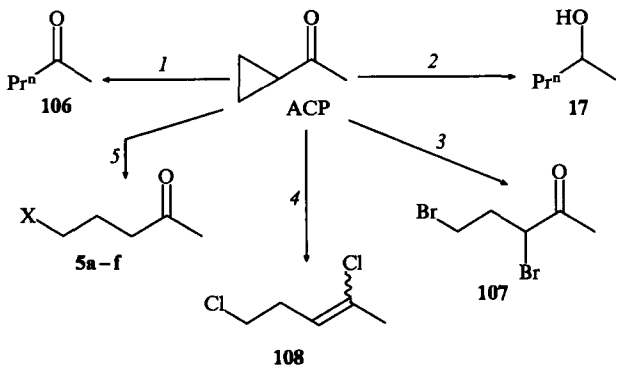
Scheme 24

101: R = H, R^1 = Me; R = CMe_2, R^1 = H;
102: R = H, R^1 = Et, Pr^i, Bu^n, n-C_6H_{11}, n-C_8H_{17}, $MeCH{=}CH$, (*E*)-$Bu^nCH{=}CH(CH_2)_2$; R = Me, R^1 = Me, cyclo-Pr;
104: R = R^1 = Me; R = Et, R^1 = H.

102, which makes it possible to solve the problem of the synthesis from acetylcyclopropane of the product of its aldol-crotonic condensation with carbonyl compounds.[227-231]

An extremely interesting synthetic application of the silyl ether **28** is based on the little investigated possibility of involving acetylcyclopropane in a reaction of the Michael type. Thus the reaction of compound **28** with conjugated ketones in the presence of mixed titanium(IV) salts leads to high yields of the 1,5-diketones **103** and **104**.[72] When nitrobutene was used as the acceptor, the 1,4-diketone **105** was obtained.[72]

Thus the large set of selective transformations of acetylcyclopropane involving its methyl group, presented in this Section, opens an extremely effective pathway to various functionalised cyclopropyl ketones, many of which are important synthons.



3. Reactions with participation of the cyclopropane fragment

The data examined above demonstrate the properties of acetylcyclopropane as a typical representative of aliphatic methyl ketones. The presence of the cyclopropane residue in its molecule is responsible for additional synthetic possibilities associated with the transformation of the strained three-membered carbocycle. The data described below refer to this feature of the acetylcyclopropane molecule and its derivatives and, mainly, to the ability of the corresponding secondary and tertiary amines to undergo the cyclopropylcarbinyl rearrangement (CPCR).

a. Hydrogenolysis and heterolysis of acetylcyclopropane

Catalytic hydrogenation of acetylcyclopropane leads in many instances to the initial opening of the three-membered ring and the formation of the ketone **106**, which is capable of being further reduced to the alcohol **17**[31,232-234] (Scheme 25). The maximum yield of the ketone **106** was attained when 10% Pd/C was used as the catalyst;[31,232,233] when it is replaced by the mixed Pd–Ni catalyst, the complete conversion of acetylcyclopropane into the alcohol **17** is observed.[234] The pentanone **106** has also been obtained in a high yield by the homolytic reduction of acetylcyclopropane via its photolysis or thermolysis in the presence of the $Bu^n_3SnH/AIBN$ couple (AIBN = azobisisobutyronitrile).[235-237] The Birch radical-ion reduction of acetylcyclopropane leads non-selectively to a mixture of both expected products — **17** and **106**.[34]

Scheme 25

5: X = Cl (**a**), Br (**b**), I (**c**), SPh (**d**), $P^+Ph_3Br^-$ (**e**), SePh (**f**)

(*1*) H_2/Cu, 80 °C (~20%), H_2/Pd–C (90%), $Bu^n_3SnH/AIBN/h\nu(\Delta)$(85%), Na/NH_3 (in a mixture with compound **17**);
(*2*) H_2/Cu, 125 °C (55%), H_2/Pd–Ni (> 90%);
(*3*) Br_2/CH_2Cl_2 ($CHCl_3$, AcOH) (~30%);
(*4*) PCl_5/boiling CH_2Cl_2;
(*5*) Py·HCl (> 80%), P_2I_4 (~90%), Me_3SiX (X = Cl, Br, I) (85% – 95%), $AlCl_3$/PhSH (Me_3SiSPh) (35% – 45%); Ph_3P·HBr (> 90%), PhSeLi (90%).

The results of the hitherto little investigated interaction of various cationoid reagents with acetylcyclopropane may be of great synthetic interest. The electron-accepting nature of the acetyl residue of acetylcyclopropane induces via an inductive mechanism the polarisation of the C–C 'banana' bond,[238] as a result of which this molecule resembles to some extent electrophilic olefins. The competition (evidently in favour of the C=O group) between the intermolecular and intramolecular coordination of the electrophile to the acetylcyclopropane molecule should promote additional polarisation of the above bond and hence an increase in the reactivity of the cyclopropane fragment.

In conformity with the foregoing considerations, the bromination of acetylcyclopropane in chlorinated hydrocarbons leads to a moderate yield of the acyclic dibromo-derivative **107**.[239,240] When the reaction is carried out in acetic acid, its effectiveness is not significantly affected but it becomes complicated by a competing process leading to the formation of appreciable amounts of γ-bromoketone **5b**.[240] Taking into account the data examined above in the synthesis of the α-bromoketone **70**, the data discussed here may serve as a good illustration of the influence of the polarity of the medium on the result of the electrophilic reaction in relation to a chemically fairly simple substrate. The conversion of acetylcyclopropane into a mixture of (*E*)- and (*Z*)-dichloro-derivatives **108** under the influence of PCl_5 in boiling CH_2Cl_2 may be referred to the same type of reactions.[241]

Data obtained recently on the interaction of acetylcyclopropane with soft acids may have significantly more important synthetic consequences. Thus the γ-chloroketone **5a** is formed smoothly when acetylcyclopropane is treated with pyridinium chloride.[242,243] There is no information about a similar reaction with pyridinium bromide, although it is known that in the case of the related pyridinium iodide, which has reducing properties, a complex mixture of substances of unknown structure is produced.[243] However, the γ-iodoketone **5c** can be obtained in a high yield by treating acetylcyclopropane with P_2I_4 under mild conditions.[244]

The use of available or generated *in situ* trimethylsilyl halides is a universal and effective procedure for transforming acetylcyclopropane into the γ-haloketones **5a–c**,[245,246] with *O*-silyl ethers as reaction intermediates. The $AlCl_3$-catalysed effective transformation of acetylcyclopropane into the γ-phenylthioalkyl ketone **5d** on treatment with thiophenol or its trimethylsilyl derivative[246] and the synthesis of the phosphonium salt **5e** on treatment of acetylcyclopropane with PPh_3·HBr have been achieved in conformity with the same principle.[247]

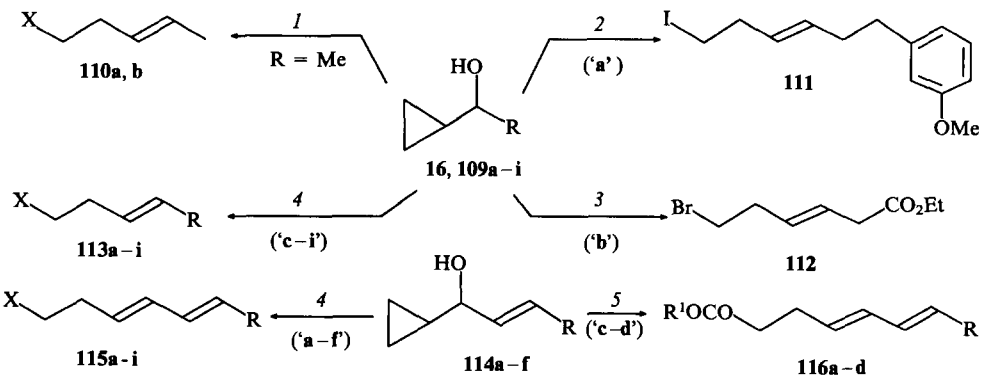
In conclusion of this Section, the absence of data on the anionoid opening of the acetylcyclopropane ring and hence on its involvement in a series of synthetically useful transformations should be noted. So far the effective conversion of acetylcyclopropane into the ketoselenide **5f** on treatment with PhSeLi may serve as the only example of this kind.[248]

b. The cyclopropylcarbinyl rearrangement

The data discussed below refer to the chemistry of secondary and tertiary cyclopropylcarbinols, readily obtainable from acetylcyclopropane, which have recently found extensive applications by virtue of their unique ability to undergo the cyclopropylcarbinyl rearrangement on treatment with protic and Lewis acids.[249-251] It is now well known that such rearrangement of secondary alcohols takes place highly stereoselectively, affording as a rule, high yields of the corresponding (*E*)-olefins. Thus cyclopropylmethylcarbinol **16** readily isomerises under the conditions of the Julia reaction (48% HBr) to the homoallyl bromide **110a**[35,36,38-40] (Scheme 26). A similar transformation can be readily achieved with the aid of $MgBr_2$ and this approach has proved extremely effective also for the preparation of the iodide **110b** from compound **16** on treatment with MgI_2.[112] Another version of the transformation of cyclopropylcarbinols into homoallyl iodides involves the use of 40% HI in DME (dimethoxyethane?). This method was applied to the synthesis

of the anisyl derivative **111** from the alcohol **109a** prepared by the two-stage reduction of the enone **83e** (R = *m*-$MeOC_6H_4$).[182] The conversion of the alcohol **109b**, obtained from the ketoester **86e**, into the bromoester **112** has been achieved successfully on treatment with a solution of $ZnBr_2$ in 48% HBr.[211,252] It was shown recently that the cyclopropylcarbinyl rearrangement of the saturated (compounds **109c–i**) and allylic (compounds **114a–f**) cyclopropylcarbinols obtained from acetylcyclopropane takes place readily under mild conditions under the influence of trimethyl silyl halides and catalytic amounts of zinc halides, affording the corresponding (*E*)-homoallyl halides **113a–i** and **115a–i** in high yields.[219–223,227–231] The method makes it possible to obtain equally effectively both the bromides **113c–i** and **115e–i** and the chlorides **113a, b** and **115a–d**. In contrast to the saturated alcohols, the allyl alcohols **114** are capable of rearranging with the aid of HCO_2H and AcOH to the transoid homoallyl formates and acetates of the type **116a, b** and **116c, d** respectively.[253]

Numerous tertiary cyclopropylmethylcarbinols **49**, readily obtained in one stage from acetylcyclopropane, have been involved in the classical Julia reaction with the use of 48% HBr (Scheme 27). In contrast to the secondary carbinols, tertiary cyclopropylcarbinols afford under these conditions as a rule mixtures of (*E*)- and (*Z*)-stereoisomeric bromides **117** in different proportions, mainly with one of them predominating. The ethynylcarbinols **49u, v** are an exception. Their Julia conversion under the conditions indicated leads almost wholly to the (*Z*)-isomers **117u, v**,[129,131] which has been used successfully in one of the simple schemes for the total synthesis of the juvenile hormone I.[256] There is as yet no rational explanation of this unique steric effect, although in purely qualitative terms it may reduce to the fact that the conformation of the transition state in the rearrangement is determined by the minimum overlap of the cyclopropyl substituent with the methyl substituent, which is significantly more bulky than the ethynyl substituent.[129]



The homoallyl bromides **117**, which are stereochemically inhomogeneous as regards the trisubstituted C=C bond, have nevertheless found practical applications in the synthesis of various natural products, predominantly of the isoprenoid series.

The cyclopropylcarbinyl rearrangement of alcohols **49** proceeds almost always with high yields and without complications and for this reason only certain features of this reaction are noted below. Thus the formation of up to 14% of the olefin hydrobromination product **117a** has been noted in the isomerisation of compound **49a**.[111] The conversion of the homoallyl alcohol **49k** is partly (~15%) accompanied by a shift of the terminal double bond of the product **117k** with formation of a conjugated diene.[131]

Scheme 28 presents other versions of the procedure for carrying out the cyclopropylcarbinyl rearrangement of tertiary carbinols **49** different from that in the standard Julia method. Thus the unusual LiBr/TsOH/AcOH/Ac_2O system has been used to obtain the 3,5-dienyl bromide **117h** without explanation of its advantage over 48% HBr.[130] As in the case of secondary cyclopropylcarbinols, the tertiary carbinols rearrange smoothly and almost quantitatively under the influence of $MgBr_2$ and MgI_2 to the corresponding homoallyl halides **117** with the (*E*)-isomer predominating in the case of compound **117b**.[112]

The use of aqueous HCl to convert cyclopropylcarbinol into homoallyl chlorides is characterised by the absence of regioselectivity. Thus in the four instances of this reaction, only one, leading to the homoprenyl chloride **118a**, can be regarded as unambiguous.[106] Apart from the expected olefins **118e, r, u**, in the remaining three cases the corresponding dienes and their hydrochlorination products as well as the corresponding cyclobutyl chlorides were detected.[124,139,258]

[a] Data on the isomeric composition are not available.

Extremely varied products were obtained when aqueous H_2SO_4 was used for the cyclopropylcarbinyl rearrangement of tertiary alcohols. For example, in the case of compounds **49a, b, u**, mixtures of the homoallyl alcohols **119a, b, u**, together with the products of their dehydration, intramolecular cyclisation, and dimerisation were isolated in low yields.[109, 139, 147] Under the same conditions, the benzyl alcohol **49r** is converted predominantly into cyclobutanol **120**.[139]

The selectivity of the isomerisation of tertiary cyclopropylcarbinols under the influence of HCO_2H depends to a significant extent on the conditions in this reaction. Thus heating of compounds **49a, b, r, u** with 20%–50% aqueous solutions of HCO_2H affords a complex mixture of substances with a low content of the formates **121a, b, r, u**.[108, 116, 140, 258] On the other hand, the use of 98% HCO_2H in THF leads smoothly to the formates **121a, b, d**.[259, 260]

A successful modification of the two-stage synthesis, examined above, of homoallyl halides from cyclopropyl ketones via a stage involving tertiary carbinols consists in the treatment with 50% H_2SO_4 of the alkoxide formed in the reaction between a Grignard reagent and acetylcyclopropane (Scheme 29).

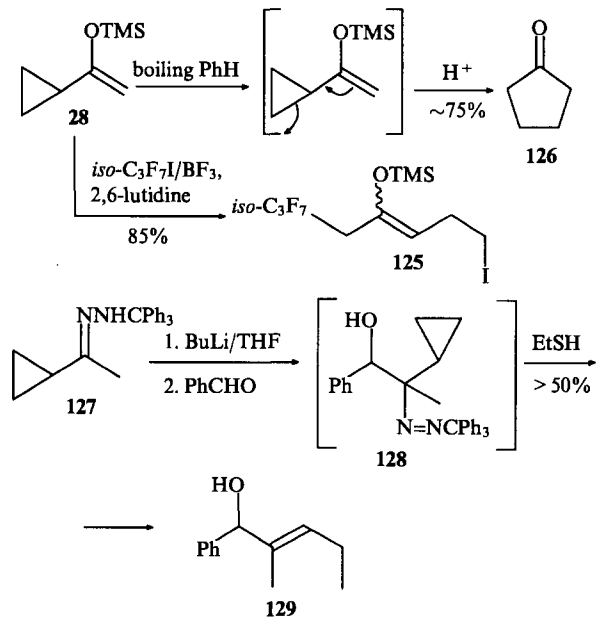
[a] Data on the isomeric composition are not available.

A large number of halides **117**, used in the synthesis of pheromones, juvenile hormones, and other biologically active substances, have been synthesised by this single-stage method. Yet another example of the cyclopropylcarbinyl rearrangement without the isolation of the intermediate tertiary alcohol consists in the $TiCl_4$-initiated condensation of acetylcyclopropane with the ketene acetal **122**, which leads smoothly to a mixture of the stereoisomeric homoallyl chlorides **123** (Scheme 30).[265]

Scheme 30



In conclusion, mention should be made of the isomerisation of the epoxide **40**, which takes place in accordance with the mechanism of the cyclopropylcarbinyl rearrangement under the influence of 48% HBr and is distinguished by a high stereoselectivity [> 96% of the (*E*)-isomer] and affords an almost quantitative yield of the bromohydrin **124**.[93]

c. Other reactions with participation of the three-membered ring

Individual examples of the involvement of certain derivatives of acetylcyclopropane in reactions via the carbonyl group, which proceed formally with participation of the acetyl and cyclopropane fragments of this molecule, have been described. Thus, treatment of the trimethylsilyl ether **28** with perfluoroisopropyl iodide in the presence of a base and BF_3 leads selectively to a mixture of the isomeric siloxyiodo-derivatives **125** ($Z:E$ = 4:1)[266] (Scheme 31). The reaction apparently proceeds via a radical ion mechanism involving the cyclopropyl-carbinyl rearrangement at an intermediate stage.

Scheme 31

The thermolysis of the enolate **28** induces its rearrangement with ring expansion and the formation of the cyclopentanone **126** in a high yield after the hydrolysis of the intermediate trimethylsilyl ether.[76]

The deprotonation and subsequent treatment with benzaldehyde of the hydrazone **127**, readily obtainable from acetylcyclopropane, afford the intermediate azo-compound **128**, which undergoes under mild conditions the radical homoallyl rearrangement to the (*E*)-olefin **129** with a stereochemical purity of 93%.[52]

Thus the reactions of acetylcyclopropane and its derivatives with participation of the three-membered ring permit convenient and in many instances the most rational synthesis of various acyclic functionalised compounds, including ketones and saturated and unsaturated halides and alcohols.

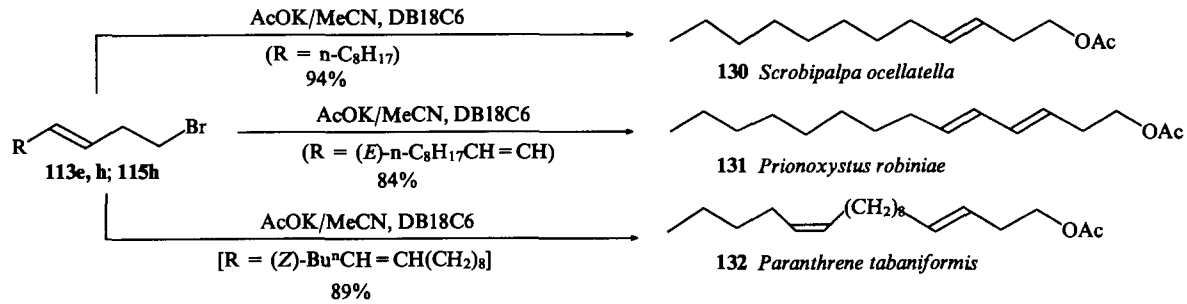
IV. The use of acetylcyclopropane in the synthesis of natural and practically useful compounds

Some of the reactions of acetylcyclopropane examined above served as a basis for a series of schemes for the specific synthesis of pheromones, terpenoids, steroids, vitamins, prostanoids, alkaloids, as well as medicinal preparations and herbicides.

1. Synthesis of acetogenin pheromones

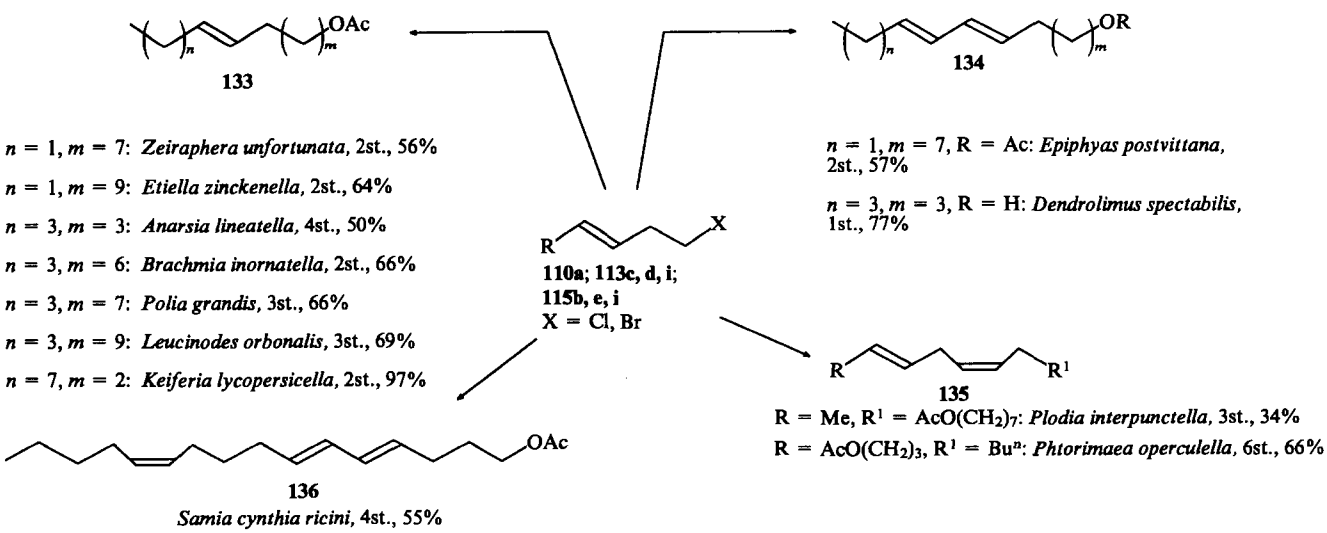
The use of acetylcyclopropane as the five-carbon (*E*)-fragment served as the basis for the stereoselective synthesis of a whole series of acetogenin transoid pheromones of the insects of the order Lepidoptera. The pheromones, having the structure of (*E*)-homoallyl acetates **130–132**, were obtained in one stage and in high yields from the corresponding bromides **113e, h** and **115h** (Scheme 32).[222,228,229,267]

The synthesis of a large number of other acetogenin pheromones, including alkene (**133**[219–221,223,231,267]), diene (**134**[220,267] and **135**[39,221,223]), as well as triene (**136**[221,222]) representatives has been achieved with the aid of various methods for increasing the length of the carbon–carbon linear chain in the homoallyl halides **110a, 113c, d, i**, and **115h, e, i** (Scheme 33).



2. Synthesis of terpenoids

The method developed by Julia for the synthesis of homoallyl bromides has served as a key procedure in the synthesis of acyclic terpenoids based on acetylcyclopropane.[35,115,117,120–122,135,145,150,160,256,257,261–264,268]



One of the simplest syntheses of linalool **137** includes the metallation of the bromide **117a** and subsequent condensation of the resulting lithio-derivative with methyl vinyl ketone[11] (Scheme 34). In many cases, acetylcyclopropane is introduced into a Grignard reaction with the homoallyl bromide prepared from it; repetition of this operation ensures the successive growth of the linear isoprenoid chain.[110,111,129,132,133,137,262] This simple procedure has been used, in particular, for the synthesis of the (*E*)- and (*Z*)-isomers of homogeraniol **138** (*n* = 1) and homofarnesol **138** (*n* = 2) by the reaction of the Grignard reagents obtained from the bromides **117a** and **117p** (*n* = 1) with acetylcyclopropane and the subsequent cyclopropylcarbinyl rearrangement of the cyclopropylcarbinols formed. The conversion of the bromide **117p** into the corresponding alcohols **138** was carried out by their standard acetolysis and the hydrolysis of the acetates in the final stage.[111]

It is noteworthy that the advantages of this universal method are partly abolished by the absence, already mentioned above, of the stereoselectivity in the rearrangement of the tertiary cyclopropylcarbinols. The syntheses of the racemates of saturated isoprenoids based on acetylcyclopropane are free from this disadvantage.[118,121,122,211,252,262] Thus (±)-5,9-dimethylheptadecane **139**, which is the sex pheromone of the apple leafminer moth *Leucoptera malifoliella*, has been obtained by the cross-coupling of the homoallyl bromide **117n** with pentylmagnesium bromide in the presence of the Cauchy reagent [sic. lithium copper chloride in original paper. (Translator)] and the subsequent hydrogenation of the resulting diene.[262] The bromide **117n** was synthesised for this purpose from acetylcyclopropane and Bu^nMgBr via its C_5-norhomologue **117e** involving two applications of the cyclopropylcarbinyl rearrangement.

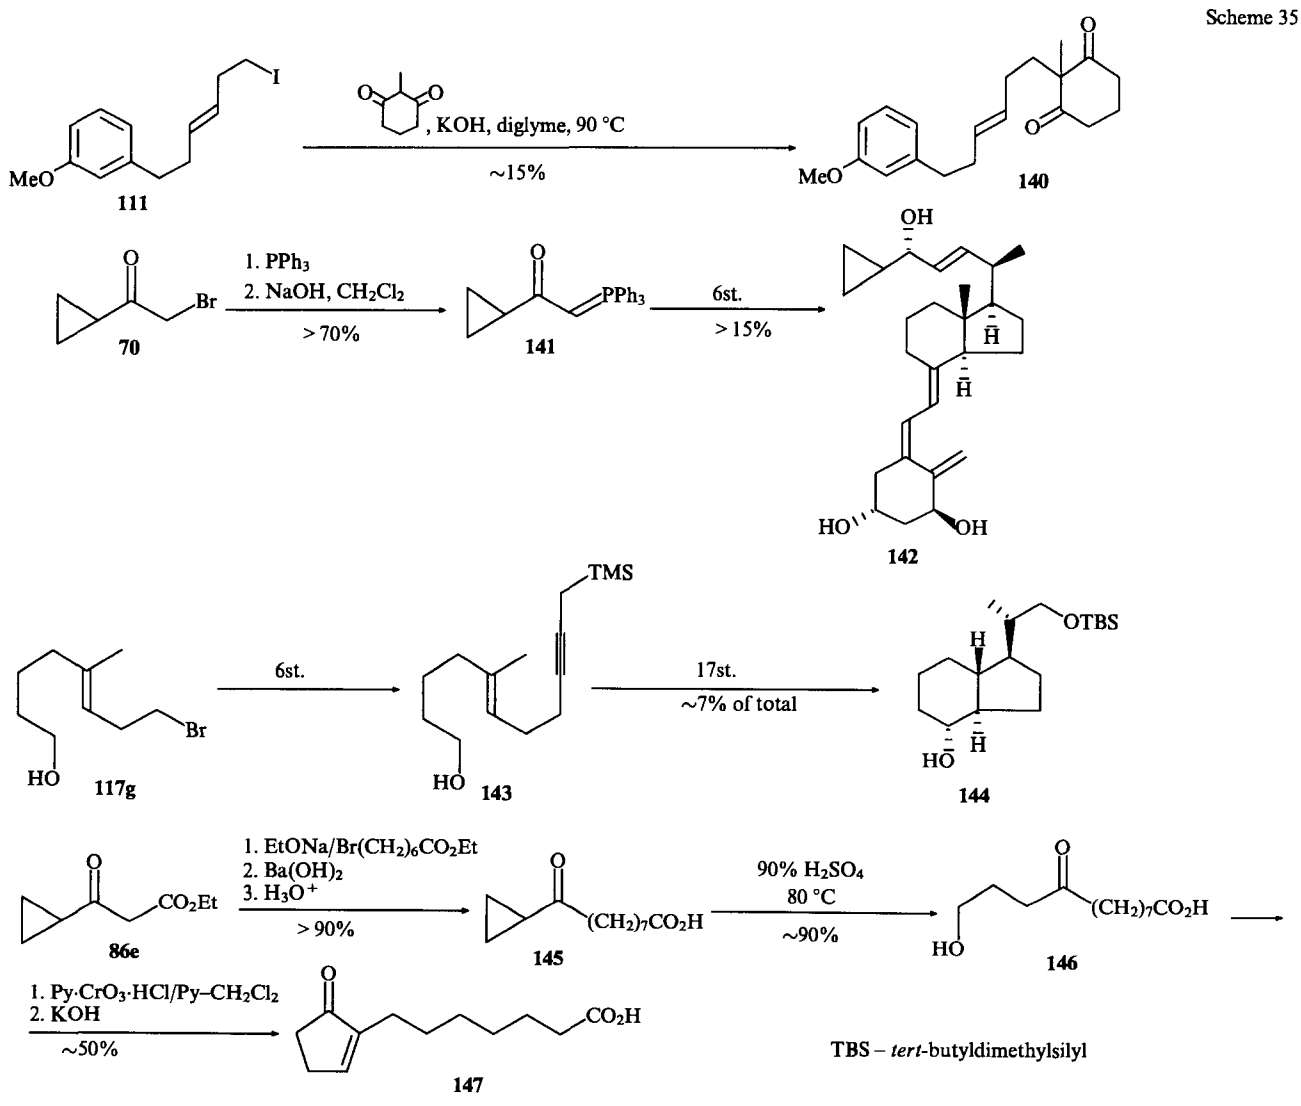
(*7*) Pe^nMgBr, Li_2CuCl_4/THF;
(*8*) H_2/Pd–C (85% from **117n**).

3. Conversion into steroids, vitamins, and a prostanoid synthon



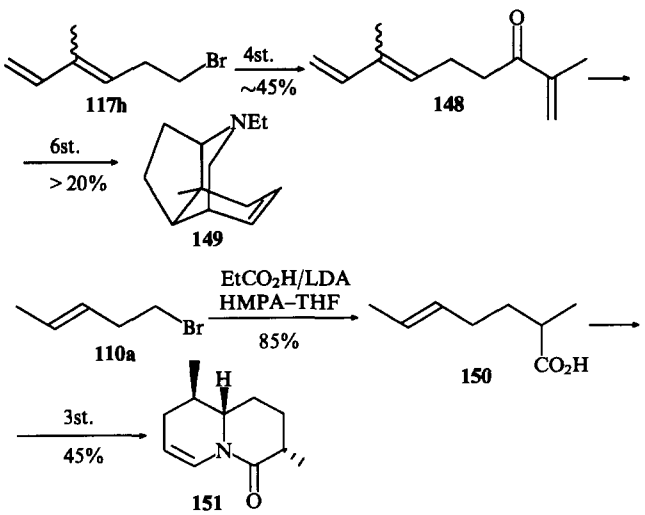
The homoallyl iodide **111**, prepared in three stages from acetylcyclopropane, has been used in the synthesis of D-homodehydrooestranes by Torgov's method. The key stage in this process is the alkylation by the iodide **111** of 2-methylcyclohexane-1,3-dione with formation of the diketone **140** (Scheme 35).[182]

The cyclopropyl analogue of vitamin B **142**, which exhibits a high physiological activity,has been synthesised using in one of the stages the phosphorane **141** prepared from the bromoketone **70**.[184]

The key intermediate **144** in the synthesis of vitamin D_3 was obtained in 25 stages from acetylcyclopropane.[127] The main strategy reduces in this case to the formation in the early stages of the functionalised *trans*-perhydroindan skeleton, which is achieved on the basis of the unsaturated silane **143**, prepared in its turn from the available homallyl bromide **117g**.

The increase in the length of the ketoester **86e** by a six-carbon fragment and the subsequent hydrolytic opening of the cyclopropane residue in the ketone **145** by heating it with concentrated H_2SO_4 lead to the ketol **146**, which is converted by the oxidation and intramolecular condensation of the intermediate ketoaldehyde into the cyclopentenone **147** — a widely used prostanoid synthon.[210]

Scheme 35



TBS – *tert*-butyldimethylsilyl

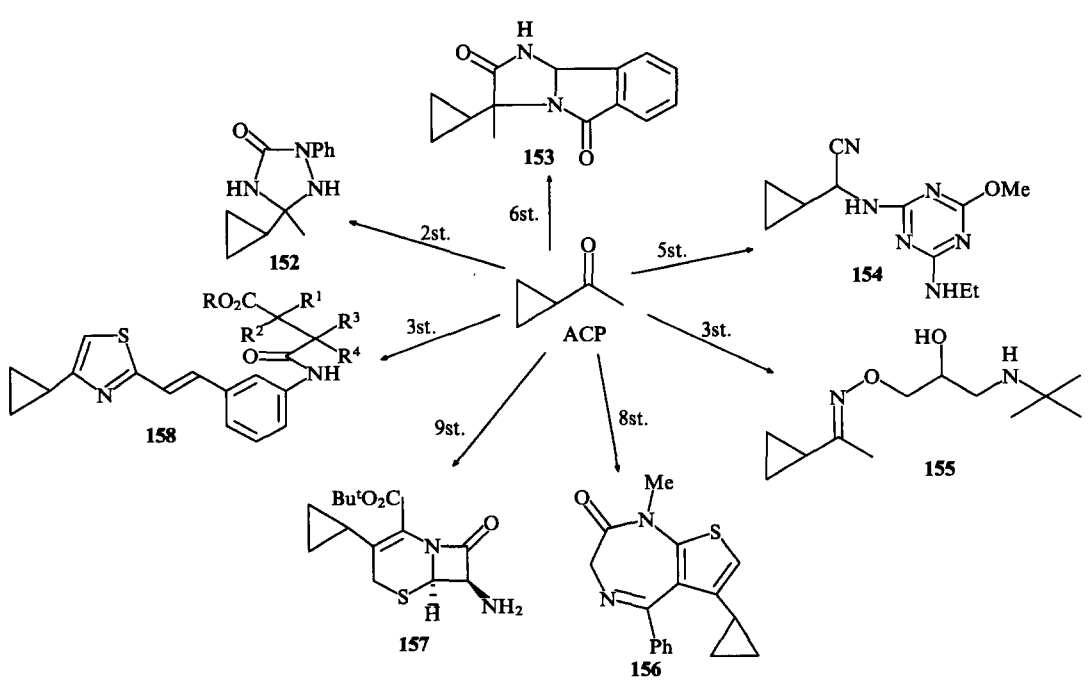
4. Synthesis of alkaloid fragments

Acetylcyclopropane has served as the starting compound in the model syntheses of the hexacyclic diterpene alkaloids of the aconitine series and also of tricyclic sesquiterpene alkaloids of the nupharidine type. In the first case, the increase in the length of the carbon chains of the homoallyl bromides **117h** afforded the key trienones **148**, transformed subsequently into the tricyclic aminoalkene **149** (Scheme 36).[254,255] In the second case, alkylation of the dilithio-derivative of propionic acid with the bromide **110a**, readily obtained from acetylcyclopropane, led to the unsaturated acid **150**, which is a key intermediate for conversion into the quinolizidinone **151**.[38]

Scheme 36

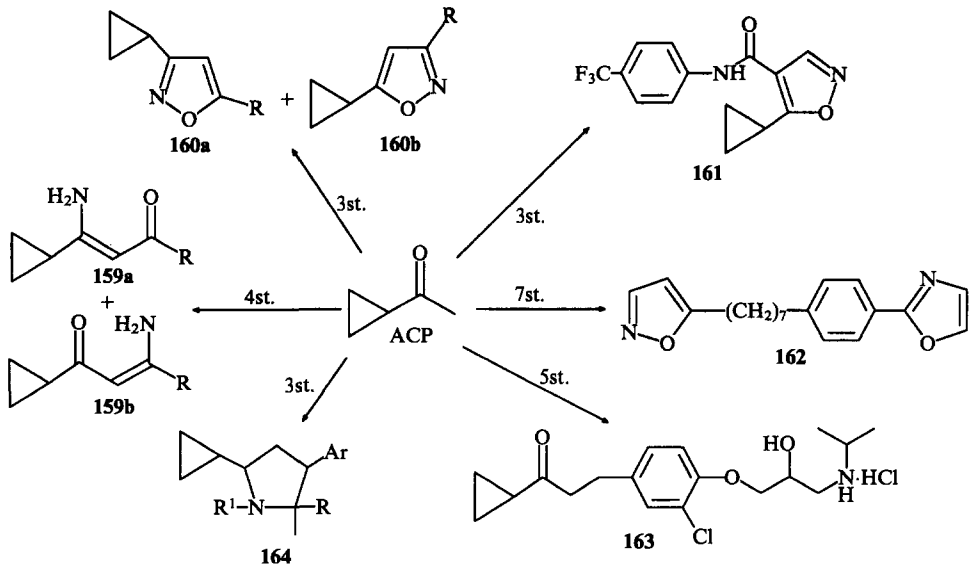
5. Synthesis of medicinal preparations and herbicides

A whole series of substances of practical importance have been synthesised from acetylcyclopropane (Schemes 37 and 38).



In the first stages of the syntheses of each of compounds **152–164**, the transformations of acetylcyclopropane discussed above were employed. The intermediates used in the syntheses were as follows: acetylcyclopropane hydrazone for the synthesis of compound **152**;[49] the aminonitrile **22** for the syntheses of compounds **153**[56] and **154**;[55] acetylcyclopropane oxime for the synthesis of compound **155**;[46] the vinylnitrile **44b** for the synthesis of compound **156**;[96] the bromoketone **70** for the syntheses of compounds **157**[224] and **158**;[185] the alkoxydiketones **86d, e** for the syntheses of compounds **159a, b**[208] and **160a, b**;[209] the ketoamide **87** for the synthesis of compound **161**;[212] the ketone **83e** for the syntheses of compounds **162**,[205,206] **163**,[203] and **164**.[199]

A high herbicidal activity was found in the polynitrogen heterocyclic representatives **152–154** while the ketoxime **155** was found to possess antiglaucoma activity. The diazepinone **156** exhibits pronounced antitumour properties,. while the azetidinone **157** has bactericidal properties. The thiazole derivatives **158** were found to have antiallergic activity, while the enaminoketones **159a, b** and the isoxazoles **160a, b** showed an analgesic activity. The fluorine-containing isoxazole **161** is recommended as a powerful antiarthritic drug, while the oxazole **162** is recommended as an antiviral agent. Finally, anti-inflammatory properties were found in a derivative of the aminoalcohol **163**, while the substituted pyrrolidines **164** were found to lead to the loss of appetite in dogs.



It is noteworthy that all the compounds examined above, with the exception of compound **162**, contain in their structure a three-membered ring, which is transferred from the initial acetylcyclopropane molecule.

The data described in this review illustrate the abundance of the chemical reactions of acetylcyclopropane, characteristic not only of methyl ketones but also of cyclopropylcarbinol derivatives. The possibilities in the selective transformations of acetylcyclopropane with participation of the methyl, carbonyl, or cyclopropyl groups serve as a basis for the extensive synthetic use of this commercially readily available C_5 building block. There is no doubt that this application will develop vigorously.
